**CLINICAL REVIEW**

Cauda equina syndrome

Chris Lavy, Andrew James, James Wilson-MacDonald, Jeremy Fairbank

An understanding of cauda equina syndrome is important not only to orthopaedic surgeons and neurosurgeons but also to general practitioners, emergency department staff, and other specialists to whom these patients present. Recognition of the syndrome by all groups of clinicians is often delayed as it presents with bladder, bowel, and sexual problems, which are common complaints and have a variety of causes. Patients may not mention such symptoms because of embarrassment or because the onset is slow and insidious.

Cauda equina syndrome is a clinical area that attracts a high risk of litigation. Although symptoms have poor predictive value on their own for the syndrome, it is important to document the nature and timing of bladder, bowel, and sexual symptoms (along with any associated clinical findings), particularly if they are new, especially in those with a history of back pain and associated leg pain, and to make a timely referral for appropriate investigation and expert treatment.

This review aims to highlight cauda equina syndrome as a possible clinical diagnosis, review the evidence for an emergency surgical approach, and maintain an awareness of the medicolegal issues that surround the condition.

**What is cauda equina syndrome and how common is it?**

Cauda equina syndrome results from the dysfunction of multiple sacral and lumbar nerve roots in the lumbar vertebral canal. Such root dysfunction can cause a combination of clinical features, but the term cauda equina syndrome is used only when these include impairment of bladder, bowel, or sexual function, and perianal or “saddle” numbness.1 2 (box)

A retrospective review in Slovenia found an annual incidence of cauda equina syndrome resulting from intervertebral disc herniation of 1.8 per million population.3 Using US data on annual incidence of symptomatic disc herniation (1500 per million population), the author estimates that each year 0.12% of herniated discs are likely to cause cauda equina syndrome. We suspect this is an underestimate and are conducting our own review in the United Kingdom, but if these figures are even approximately correct then most UK general practitioners are unlikely to see even one true case caused by intervertebral disc herniation in their career.

**How does cauda equina syndrome present and what symptoms suggest it?**

A history of perianal sensory loss and sphincter disturbance, with or without urinary retention, suggests the presence of cauda equina syndrome (figure 1 illustrates the anatomy of the lower lumbar and sacral spine showing the cauda equina). Three classic patterns of presentation have been described.4 It can present acutely as the first symptom of lumbar disc herniation (type 1); as the endpoint of a long history of chronic back pain with or without sciatica (type 2); or insidiously in a more chronic way with slow progression to numbness and urinary symptoms (type 3). Most clinicians now divide cauda equina syndrome into two clinical categories5: cauda equina syndrome with retention, in which there is established urinary retention; and incomplete cauda equina syndrome, in which there is reduced urinary sensation, loss of desire to void, or a poor stream, but no established retention or overflow.6 Often the slower the presentation, the better tolerated the symptoms are and the less likely the patient is to be alarmed. Patients with pre-existing bladder and incontinence problems resulting from other disease may also present late.

**What causes cauda equina syndrome?**

The commonest cause of cauda equina syndrome in our practice and the focal causative condition in the literature7 is compression arising from large central lumbar disc herniation at the L4/5 and L5/S1 level. Parke and colleagues suggest that there is an area of relative hypovascularity at the proximal portion of the cauda equina.8 Blood supply alterations resulting from nerve root pressure may therefore be of greater importance in this region of the cauda equina than elsewhere, with rapid changes allowing less adaptation than those of a slower onset.

**SOURCES AND SELECTION CRITERIA**

We searched Medline using the search term "cauda equina syndrome". In addition, we used our personal reference archives and consulted other experts.

---

**Clinical diagnosis of cauda equina syndrome**

- Dysfunction of bladder, bowel, or sexual function
- Sensory changes in saddle or perianal area

**Other possible symptoms**

- Back pain (with or without sciatic-type pains)
- Sensory changes or numbness in the lower limbs
- Lower limb weakness
- Reduction or loss of reflexes in the lower limbs
- Unilateral or bilateral symptoms
Patients may be predisposed to cauda equina syndrome if they have a congenitally narrow spinal canal or have acquired spinal stenosis arising from a combination of degenerative changes of the disc and the segmental posterior joints with consequent thickening of the ligamentum flavum and narrowing of the available canal cross section.

Numerous other less common causes of cauda equina syndrome have been reported—for example, spinal injury with fractures or subluxation. Spinal neoplasms of metastatic or primary origin can cause compression, usually accompanied by marked pain and often as part of a chronic condition. Infective causes with abscess formation or bony involvement, either within the spinal canal or impinging on it, may also cause cauda equina syndrome.8 The spine is the most commonly affected skeletal site for tuberculosis, and Pott’s paralysis is well documented.9 A wide range of iatrogenic causes are reported, including manipulation,10 spinal anaesthesia,11 postoperative complications such as haematoma12 or gelfoam implanted to protect the dura. Other space-occupying lesions, such as nerve derived tumours, schwannomas, ependymomas, facet joint cysts,13 perineural Tarlov cysts, haemangiomas,14 vena varix,15 and hydatid cysts16 are also recognised.

**What features on examination suggest cauda equina syndrome?**

When cauda equina syndrome is suspected a neurological examination of the legs should be performed, including perianal sensation and an assessment of anal tone (table). This is easily done in the lateral position: perineal sensation can be tested from the outside in towards the skin using a gentle gloved finger stroke and, if there is any uncertainty, a folded tissue and an unfolded paper clip. After this, a rectal examination can be performed. Loss or diminution of the bulbocavernosus reflex (whereby stimulation of the glans, penis, or clitoris causes reflex contraction of the anal sphincter) is suggestive of cauda equina syndrome as the reflex is mediated through the sacral roots.

**How should suspected cauda equina syndrome be investigated?**

Recently published guidelines for the management of patients with back pain and neurological signs recommend urgent surgical referral for suspected cauda equina syndrome.17 Clinical diagnosis of cauda equina syndrome even by resident neurosurgeons has a 43% false positive rate,18 so accurate confirmatory imaging is important. In the United Kingdom magnetic resonance imaging (MRI) is the imaging modality of choice. It does not define bone as clearly as computed tomography (CT) but is better at showing soft tissues such as intervertebral disc, ligamentum flavum, dural sac, and nerve roots. In resource poor settings where neither MRI nor CT is available myelography can be useful in showing the presence and site of compression of the cauda equina.19 Figures 2 and 3 show examples of cauda equina on MRI scans.

**How is cauda equina syndrome treated?**

When a patient has clinical features of cauda equina syndrome and an MRI scan shows a potentially reversible cause of pressure on the cauda equina then current consensus recommends surgical decompression.6 This article will not review management of all the conditions leading to cauda equina syndrome, and some causes such as tumour clearly require detailed assessment of the nature and extent of the pathology. However, most cases of cauda equina syndrome are caused by herniation of the lumbar disc, for which the surgery indicated is...
decompression at the level of the herniation, usually involving discectomy. The operation can be very demanding technically, and great care is needed to avoid causing further damage to nerve roots or tearing tightly compressed dura.

**Is surgery for cauda equina syndrome urgent?**

The urgency of surgery remains controversial. When there is pressure on the cauda equina causing loss of sphincter control it would be understandable to think that the ideal treatment would be to remove the pressure as soon as possible with surgery. Ethical considerations will not allow this hypothesis to be tested by a randomised study, and it is very difficult to prove by literature review of retrospective and cohort studies (level 3 evidence) for two reasons. Firstly, the time of onset of symptoms is difficult to specify. Thus it is difficult to define the delay between symptoms and surgery. Secondly, any discussion is muddied by many published (mainly retrospective) series containing a mix of patients with both incomplete cauda equina syndrome and cauda equina syndrome with retention.

The authors of two recent reviews argue that only incomplete cauda equina syndrome requires emergency surgery to try to stem the deterioration in bladder function. They conclude that in patients with cauda equina syndrome with retention the clinical outcome is poor anyway and bears no relation to timing of surgery. Thus these patients can wait until an elective surgical list the next morning rather than having a potentially difficult operation in the middle of the night, when circumstances are less than optimal.

Two other recently published UK series have found that outcome is independent of the timing of surgery. Incontinence at presentation is a poor prognostic feature in the largest prospective series.

A review that is widely quoted suggests that intervention less than 48 hours after the onset of symptoms will produce a better outcome than intervention delayed for longer than this. These data have been selectively reanalysed and suggest that the outcome for both types of cauda equina syndrome (with retention, or incomplete) is better with interventions within rather than after 24 hours. In a further analysis of the selected retrospective series, the authors noted that of 47 patients having surgery within 24 hours, 41 (87%) recovered normal bladder function, whereas of 46 patients having surgery later than 24 hours, only 20 (43%) recovered normal bladder function.

A recent meta-analysis supports the view that early surgery is related to better results with incomplete cauda equina syndrome, but the case for cauda equina syndrome with retention is less certain. We urge the establishment of a multicentre outcome study with clear clinical entry points and clear separation of incomplete cases and those with retention.

**What are the medicolegal implications of cauda equina syndrome?**

Persisting cauda equina syndrome has a devastating effect on personal and social life, and its
Litigation is common when the patient has residual symptoms. Good retrospective evidence supports urgent surgery especially in early cases, once urinary retention has occurred, the prognosis is worse. Cauda equina syndrome is rare, but devastating if symptoms persist.

**SUMMARY POINTS**

- All these websites are free and do not need registration.
- Cauda Equina Syndrome Resource Center (www.caudaequina.org) - Support group for people with cauda equina syndrome to share information about the condition.
- BackPainExpert (www.backpainexpert.co.uk/CaudaEquinaSyndrome.html) - Patient information site with articles written by invited experts.
- Wikipedia (http://en.wikipedia.org/wiki/Cauda_equina) - Part of the online editable encyclopedia wikipedia; anyone may post comments or make changes
- Cauda Equina (http://orthoinfo.aaos.org/topic.cfm?topic=A00362) - Information on the website of the American Academy of Orthopaedic surgeons
