Pulmonary hypertension: diagnosis and management

David G Kiely,1 Charlie A Elliot,1 Ian Sabroe,1,2 Robin Condliffe1

Pulmonary hypertension was previously considered a rare untreatable condition. The past two decades have seen major changes in our understanding of the spectrum of disease affecting the pulmonary circulation. More than 30 randomised controlled trials (RCTs) of treatments have been performed, and surgery for patients with chronic thromboembolic pulmonary hypertension has been developed. Advances in imaging have enabled more detailed patient assessment, but pulmonary hypertension continues to be a life-shortening condition, and there is often a delay of around two years from onset of symptoms to diagnosis.1 This article focuses on adult pulmonary hypertension in primary and secondary care, its diagnosis, and management.

What is pulmonary hypertension and how common is it?
Pulmonary hypertension is defined at cardiac catheterisation as a mean pulmonary artery pressure of 25 mm Hg or more. The initial clinical classification in 1973 arose from a World Health Organization sponsored international meeting after an epidemic related to use of the appetite suppressant, amphetamine.2 It defined primary pulmonary hypertension (now termed idiopathic pulmonary arterial hypertension) as being characterised by vasculopathy of the pulmonary arteries. Better understanding of disease mechanisms led to subsequent classification of conditions with shared clinical and pathophysiological characteristics:

Group 1: Pulmonary arterial hypertension (PAH), which can be idiopathic (IPAH) or associated with other conditions, notably systemic sclerosis and congenital heart disease
Group 2: Pulmonary hypertension owing to left heart disease (PH-LHD)
Group 3: Pulmonary hypertension owing to lung disease or hypoxia (PH-Lung), or both

Group 4: Chronic thromboembolic pulmonary hypertension (CTEPH)
Group 5: Unclear or multifactorial mechanisms (fig 1).

Many mechanisms can lead to elevation of pulmonary pressures. In PAH, progressive narrowing of the pulmonary arterial bed results from an imbalance of vasoactive mediators, including prostacyclin, nitric oxide, and endothelin-1. This leads to an increased right ventricular afterload, right heart failure, and premature death. Between 11% and 40% of patients with IPAH and 70% of patients with a family history of PAH carry a mutation in the gene encoding bone morphogenetic receptor-2 (BMPR2); however, penetrance is low—carriers have a 20% lifetime risk of developing pulmonary hypertension.4,5 Therefore, “multiple hits” are probably needed for the development of PAH. In PH-LHD, raised left atrial pressures result in secondary elevation of pulmonary pressure. In PH-Lung, raised pulmonary arterial pressures result from mechanisms such as vascular destruction and hypoxic vasoconstriction. In CTEPH, mechanical obstruction of the pulmonary vascular bed is the primary process.

Incidences are estimated to be 1-3.3 per million per year for IPAH and 1.75-3.7 per million per year for CTEPH; the prevalence of PAH is estimated at 15-52 per million.1-10 Pulmonary hypertension is more common in severe respiratory and cardiac disease, occurring in 18-50% of patients assessed for transplantation or lung volume reduction surgery, and in 7-83% of those with diastolic heart failure.11-14

Who gets pulmonary hypertension and why is classification important?
IPAH is rare and primary care doctors may never encounter a case. By contrast, the prevalence of PAH is high in certain patient groups, such as those with systemic sclerosis (9%), portal hypertension (2-6%), congenital heart disease (5-10%), and HIV (0.5%).15-20 Between 0.5% and 4% of patients develop CTEPH after acute pulmonary embolism; patients at increased risk include those presenting with large, recurrent, or unprovoked clots.21,22 Classification is crucial in determining treatment and prognosis.1 Specific treatments exist for PAH and CTEPH. By contrast, in PH-LHD and PH-Lung, treatment is best directed at the underlying

SUMMARY POINTS
Pulmonary hypertension has many causes so prognoses and treatments vary
The condition is diagnosed by systematically evaluating the breathless patient and screening patients at high risk
Patients at high risk of severe and treatable pulmonary hypertension include those with systemic sclerosis, portal hypertension, congenital heart disease, and previous pulmonary embolism
Specialist centres provide access to tailored investigative and treatment pathways and support networks for patients
Patients with severe pulmonary hypertension can deteriorate rapidly—do not delay referral to perform specialist investigations
Only selected patients with pulmonary arterial hypertension and chronic thromboembolic pulmonary hypertension benefit from interventions directed at pulmonary vasculature; for most patients treatment is aimed at the underlying condition

condition, and currently PAH specific treatments are not recommended. Distinguishing between IPAH and PH-LHD due to diastolic dysfunction in the setting of normal left ventricular systolic function may be challenging (table 1).

Median survival in untreated IPAH is 2.8 years, but more recent registries have observed overall median survival of at least five years. In the past, the mean age at diagnosis in IPAH was 35 years; current five year survival in this younger age group is now about 75%. PAH associated with systemic sclerosis carries a worse prognosis than IPAH, whereas the opposite is true for congenital heart disease. The development of pulmonary hypertension in cardiac and respiratory disease has a negative impact on prognosis, which depends on the underlying cause and severity of pulmonary hypertension.

| Table 1 | Pulmonary hypertension in patients with normal left ventricular systolic function: features useful in discriminating between idiopathic pulmonary arterial hypertension and pulmonary hypertension caused by left ventricular diastolic dysfunction |
| Factor | Idiopathic pulmonary arterial hypertension | Diastolic dysfunction |
| Age | Younger | Older |
| Comorbidities | None | Essential hypertension, atrial fibrillation, diabetes |
| Echocardiography | Right axis deviation, right ventricular hypertrophy, ST depression inferiorly and anteriorly | Left axis deviation, left ventricular hypertrophy, ST depression laterally |
| Mitral flow and tissue Doppler | E/E’>15** | |
| Cardiac magnetic resonance imaging | Morphology | Ventricular mass index often raised | Ventricular mass index often normal |
| Septal position | Systolic eccentricity index often raised | Systolic eccentricity index often normal |
| Function | Right ventricular function often moderately or severely impaired | Right ventricular function often normal or mildly impaired |
| Right heart catheter | Pulmonary arterial wedge pressure normal | Pulmonary arterial wedge pressure raised |

*Ratio of mitral peak velocity of early filling (E) to early diastolic mitral annular velocity (E’). †Ratio of right ventricular mass to left ventricular mass. ‡Ratio of maximal short axis left ventricular diameters parallel and perpendicular to interventricular septum.

What are the symptoms and signs of pulmonary hypertension?
Pulmonary hypertension is diagnosed by systematically evaluating the breathless patient and screening high risk groups. Unexplained progressive exertional breathlessness in the absence of symptoms or signs of respiratory or left heart disease is suggestive. Screening protocols exist for high risk groups. Rheumatology centres screen patients with systemic sclerosis annually, and potential liver transplant recipients are routinely investigated for portopulmonary hypertension. Persistent breathlessness after pulmonary embolism should alert the doctor to the possibility of CTEPH.

When should I suspect pulmonary hypertension?
Pulmonary hypertension is a chronic progressive condition requiring prompt diagnosis and treatment. A high index of suspicion is required. Symptoms and signs may be subtle or absent in early disease. Look for signs of associated conditions (such as connective tissue disease or liver disease).
Leukaemia update.

Achilles tendon disorders (BM 2013;346:f1485)

Postpartum management of hypertension (BM 2013;346:f894)

breathlessness (fig 2, see bmj.com). Evidence of right heart strain on electrocardiography and prominent pulmonary arteries or cardiomegaly on chest radiography were seen in 80-90% of cases in a large IPAH registry.\(^a\) In clinical practice, however, a normal electrocardiograph and chest radiograph cannot exclude the diagnosis. A reduction in gas transfer (lung capacity to “transfer” an inhaled gas into the blood) and mildly deranged spirometry both occur in IPAH.\(^b\) If pulmonary hypertension is still suspected, echocardiography should be performed.\(^c\) Figure 3 describes the estimation and interpretation of systolic pulmonary artery pressure, together with other echocardiographic features suggesting the presence of pulmonary hypertension. Importantly, pulmonary hypertension is defined by mean pulmonary artery pressure (measured at right heart catheterisation) not systolic pulmonary artery pressure (estimated by echocardiography). In addition, systolic estimates are less accurate in respiratory disease and during intercurrent illness.\(^d\)

**How is pulmonary hypertension assessed in a specialist unit?**

If initial investigations suggest that pulmonary hypertension is possible, further tests are needed to confirm the diagnosis and to establish cause and severity. In the United Kingdom, a network of specialist centres was commissioned in 2001 to standardise and improve care (box 1, see bmj.com). If severe disease is suspected, do not delay referral to a specialist centre, although imaging to exclude thromboembolic disease may be considered. If the degree of pulmonary hypertension seems to be disproportionate to the underlying cardiorespiratory disease, or if diagnostic doubt exists, discussion with a specialist centre is recommended. In these groups it is also important to exclude coexisting thromboembolic disease as a cause of pulmonary hypertension. Accurate classification and assessment of disease severity (fig 2, see bmj.com) requires integration of clinical, physiological, and radiological data. This is central to further management (fig 4, see bmj.com).

**Blood, exercise testing, and overnight oximetry**

Immunological and HIV testing may identify a cause of pulmonary hypertension. Brain natriuretic peptide (BNP) and N-terminal-pro-BNP have prognostic importance. Lower levels at baseline and improvement during follow-up are associated with better outcomes.\(^e\) The six minute walk test has been extensively evaluated. It provides functional and prognostic information and can be used to monitor treatment response.\(^f\) Cardio pulmonary exercise testing in selected patients gives more detailed physiological and prognostic information.\(^g\) Overnight oximetry is performed if sleep disordered breathing is a suspected cause.

**Imaging**

Isotope perfusion lung scanning has high sensitivity for CTEPH and a normal scan excludes the diagnosis, whereas increased renal isotope uptake may identify right to left shunts and explain hypoxaemia.\(^h\) High resolution computed tomography and computed tomography pulmonary angiography visualise the pulmonary arterial tree and provide a wealth of additional diagnostic information (fig 5). Direct features of chronic thromboembolic disease include occlusions, stenoses, and intraluminal webs (fig 1), whereas indirect signs include a mosaic perfusion pattern. These signs can be subtle and may be missed by a non-specialist radiologist. Magnetic resonance imaging provides a radiation-free method of quantitatively assessing cardiac structure and function, prognosis, and response to treatment.\(^i\) Magnetic resonance pulmonary angiography can supplement computed tomography pulmonary angiography in the assessment of CTEPH operability, and magnetic resonance perfusion imaging is as sensitive as isotope perfusion lung scanning.\(^j\) Pulmonary angiography is not commonly used in the UK to select CTEPH patients for pulmonary endarterectomy, but is used widely in other centres throughout the world to assess for surgical accessibility.

**Right heart catheterisation**

If non-invasive investigations support a diagnosis of pulmonary hypertension, right heart catheterisation is needed to confirm the diagnosis by directly measuring pulmonary pressure. It also allows measurement of cardiac output and estimation of left atrial pressure using pulmonary arterial wedge pressure. Haemodynamic parameters (such as right atrial pressure, cardiac index, and pulmonary vascular resistance) and pulmonary artery saturations have important prognostic value. Raised pulmonary arterial wedge pressure is suggestive of PH-LHD. Changes in oxygen saturations between right sided cardiac chambers may suggest an intracardiac shunt. Vasoreactivity testing, usually using inhaled nitric oxide, can

---

**Estimation of systolic pulmonary arterial pressure (sPAP)**

Maximal tricuspid regurgitant jet velocity (V) measured using continuous wave Doppler

RV systolic pressure (RVSP) calculated using equation:

\[
RVSP = 4V^2
\]

sPAP = RVSP + right atrial pressure (RAP)

RAP estimated at 5 mm Hg unless size of interventricular septum suggests higher

In this example sPAP = 4 x (4.8)^2 + RAP = 92 mm Hg + RAP

**Other features suggestive of pulmonary hypertension**

- Dilated right sided chambers
- Reduced RV function
- RV hypertrophy
- Enlarged pulmonary artery
- Abnormal interventricular septal motion

**Likelihood of pulmonary hypertension**

- Pulmonary hypertension unlikely sPAP ≤ 36 mm Hg\(^*\) with no other features of pulmonary hypertension
- Pulmonary hypertension possible sPAP 36-50 mm Hg\(^*\) + other features of pulmonary hypertension
- Pulmonary hypertension likely sPAP >50 mm Hg\(^*\)

*including 5 mm Hg RAP

PAH associated with other conditions is less clear. Diuretics are often needed to treat heart failure. Digoxin and long term oxygen therapy may be considered, but there is no evidence from RCTs on their use. Annual flu vaccination is recommended. Pregnancy is poorly tolerated despite changing practices, and a recent systematic review found that maternal mortality remains high (17-33%). Women are counselled about the high risks and are offered effective contraception; termination is recommended if pregnancy occurs. Progestosterone-only contraceptives—oral desogestrel, intramuscular medroxyprogesterone, and etonogestrel implants—avoid the prothrombotic effects of combined oral contraceptives. The levonorgestrel releasing coil is effective, but poor tolerance of potential vaginal episodes mandates insertion in hospital. Emergency hormonal contraception is safe after unprotected intercourse. Non-obstetric surgical intervention also poses risks and its indication requires careful evaluation.

Specific medical treatment (table 2)

High dose calcium channel blockade
About 10% of patients with IPAH have a positive response to vasoreactivity testing at right heart catheterisation. Observational studies suggest that half of these patients exhibit long term clinical responses to high dose calcium channel blockade (such as diltiazem titrated to 480-720 mg/day or nifedipine titrated to 60-120 mg/day), with near normalisation of prognosis. No evidence exists for this treatment in other forms of PAH, and because of the potential negative inotropic effect, treatment should not be started without a positive acute vasoreactive test.

Prostanoids
Prostacyclin is a vasodilator with antiproliferative effects. Infused continuously through an indwelling central line, it was the first PAH specific drug shown to be efficacious in a small RCT, demonstrating improvements in exercise capacity, haemodynamics, and, uniquely, survival. It has a half life of about six minutes, is unstable at room temperature, and intravenous administration has an associated risk of line infection. Alternative routes of administration also pose risks and its indication requires careful evaluation.

What treatments are available for pulmonary hypertension?

Supportive treatment
Patients with CTEPH require anticoagulants because of the central role of thromboembolic disease. Although anticoagulation is recommended in IPAH, its role in identifying patients with IPAH who may respond to long term high dose calcium channel blockers. A positive response is defined as a reduction in mean pulmonary artery pressure of at least 10 mm Hg, to less than 40 mm Hg, without a fall in cardiac output.

Table 2 | Licensed drugs for treating pulmonary hypertension

Fig 5 | Computed tomography assessment of pulmonary hypertension. RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; IVS, interventricular septum; PA, pulmonary artery; Ao, aorta; CTEPH=chronic thromboembolic pulmonary hypertension
times a day. Because of its superior stability, iloprost is also given intravenously in some centres. Treprostinil (half life about four hours) was shown, in a very large RCT, to significantly improve exercise capacity when given by continuous subcutaneous infusion. Further RCTs also showed significant improvements in exercise capacity when it was given by nebulised and intravenous routes. Oral prostanoids have also been assessed with large RCTs, but results have generally been disappointing, and studies are ongoing.

Endothelin receptor antagonists
Endothelin is a potent vasoconstrictor of vascular smooth muscle. Two oral endothelin receptor antagonists are currently licensed, bosentan and ambrisentan, on the basis of well conducted RCTs showing improved exercise capacity and time to clinical worsening. Bosentan causes reversible abnormalities in liver function tests in 5–10% of patients, so monthly monitoring is needed.

Phosphodiesterase-5 inhibitors
Nitric oxide acts via cyclic GMP to increase pulmonary vascular relaxation and reduce cellular proliferation and is degraded by phosphodiesterase-5. Two oral phosphodiesterase-5 inhibitors (sildenafil and tadalafil) improved exercise and functional capacity in large well conducted RCTs. These drugs have important interactions with nitrates, so concomitant use is contraindicated.

Treatment approach
Guidelines suggest starting oral treatment for patients with PAH in WHO functional classes II and III, and considering parenteral prostanoids in suitable patients in class IV or those with poor prognostic markers in class III (box 2). If response to treatment is suboptimal, switching or adding further drugs is suggested. Sequential addition of drugs to achieve predefined treatment goals in six minute walk distance, maximal oxygen capacity, and peak systolic blood pressure was associated with improved outcome compared with patients whose treatment had been escalated in a non-standardised manner. Several RCTs of combination therapy are ongoing. Assessment of the patient’s ability to use complex prostanoid therapy and adherence to treatment require the support of experienced healthcare professionals.

Box 2 | WHO functional classes

Class I: Patients with pulmonary hypertension but in whom ordinary physical activity does not cause undue symptoms

Class II: Patients with pulmonary hypertension resulting in slight limitation of physical activity. They are comfortable at rest but ordinary physical activity causes undue dyspnoea or fatigue, chest pain, or near syncope

Class III: Patients with pulmonary hypertension resulting in marked limitation of physical activity. They are comfortable at rest but less than ordinary activity causes undue dyspnoea or fatigue, chest pain, or near syncope

Class IV: Patients with pulmonary hypertension who cannot carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnoea or fatigue may be present at rest. Discomfort is increased by any physical activity

Chronic thromboembolic pulmonary hypertension
About two thirds of patients with CTEPH are candidates for pulmonary endarterectomy. This operation offers the best prospect of substantial improvement in symptoms, haemodynamics, and long term survival, as shown by a recent UK observational study. Surgical eligibility criteria are not clearly established, and suitable candidates are identified after assessment at specialist surgical centres (Papworth Hospital in the UK). Perioperative mortality in large volume centres is now less than 5%. In inoperable cases PAH specific drugs are often used, although evidence is suboptimal. Do not delay referral for surgery for trials of medical therapy, although such treatment can be used to support patients with severe CTEPH as a “bridge” to surgery.

What challenges are on the horizon?
Despite progress in the management of PAH, it remains a life shortening condition. Understanding disease mechanisms and developing new treatments is a focus of international collaboration. Recent data have shown efficacy for a range of drugs. Studies with stem cell therapy are ongoing. The role of mechanical treatments, such as cardiac resynchronisation and right ventricular assist devices, in PAH are of interest. The optimal treatment of PH-LHD and PH-Lung is unclear and drugs are being studied in phase III trials. Pulmonary artery balloon angioplasty is being investigated in patients with CTEPH who are not amenable to pulmonary endarterectomy. Future availability of generic oral drugs for pulmonary hypertension may lead to inappropriate prescribing in PH-LHD and PH-Lung. It may also increase late referral to specialist centres and delays in escalation of treatment.
