A 55-year-old woman presents to the emergency department at 11:30 p.m. with hematemesis. She is otherwise healthy and has no risk factors for liver disease. Her only medication is aspirin (at a dose of 81 mg daily), which she started to take 6 months ago after reading that it reduces the risk of heart disease. The blood pressure is 94/60 mm Hg, and the heart rate is 108 beats per minute; the physical examination is otherwise normal. The hemoglobin level is 11.0 g per deciliter, platelet count 220,000 per cubic millimeter, international normalized ratio 1.0, and blood urea nitrogen level 20 mg per deciliter (7.1 mmol per liter). How should this case be further evaluated and managed?

**The Clinical Problem**

Gastrointestinal bleeding, the most common cause of hospitalization due to gastrointestinal disease in the United States, accounts for more than 507,000 hospitalizations and $4.85 billion in costs annually. Upper gastrointestinal bleeding, defined as bleeding from the esophagus, stomach, or duodenum, is responsible for 50% or more of these hospitalizations. The case fatality rate among hospitalized patients with upper gastrointestinal bleeding has decreased over the past 20 years and ranges from 2.1 to 2.5% in U.S. nationwide database studies to 10% in large, prospective European observational studies. The rate of death among patients who are already hospitalized for another condition when upper gastrointestinal bleeding develops is approximately 3 to 4 times as high as the rate among patients who are admitted to the hospital for upper gastrointestinal bleeding.

Peptic ulcers, which are primarily due to *Helicobacter pylori* infection or the use of nonsteroidal antiinflammatory drugs (NSAIDs), occur in the stomach or duodenum and are the most frequent cause of upper gastrointestinal bleeding. erosions in the esophagus (which are caused by gastroesophageal reflux disease) or in the stomach or duodenum (which are frequently due to NSAIDs) are also common sources of upper gastrointestinal bleeding. erosions are breaks confined to the mucosa (the most superficial layer of the gastrointestinal tract) and should not cause severe bleeding because veins and arteries are not normally present in the mucosa. Mallory–Weiss tears, linear tears that usually occur on the gastric side of the gastroesophageal junction, may cause severe bleeding and usually occur after retching or vomiting. Less common causes of nonvariceal upper gastrointestinal
bleeding include neoplasms, vascular ectasias (including gastric antral vascular ectasias), Dieulafoy’s lesions (aberrant vessels in the mucosa), bleeding from the bile duct or pancreatic duct, and aortoenteric fistulas. The proportion of upper gastrointestinal bleeding that is attributable to varices varies widely, from 1.9% to more than 30%, depending on the characteristics of the patient population (e.g., the prevalence of injection-drug or alcohol use and the country of origin).

This article, which considers only nonvariceal upper gastrointestinal bleeding, focuses on ulcer bleeding.

**Upper Gastrointestinal Bleeding**

- Gastrointestinal bleeding is the most common cause of hospitalization due to gastrointestinal disease in the United States.
- Peptic ulcers, primarily due to Helicobacter pylori infection and the use of nonsteroidal antiinflammatory drugs (NSAIDs), are the most common cause of upper gastrointestinal bleeding.
- In patients with upper gastrointestinal bleeding, tachycardia (heart rate ≥100 beats per minute), hypotension (systolic blood pressure ≤100 mm Hg), age older than 60 years, and major coexisting conditions are associated with increased risks of further bleeding and death.
- Patients with bleeding ulcers due to H. pylori infection should receive treatment for this infection and, after eradication is confirmed, discontinue antisecretory medications.
- Patients with bleeding ulcers due to NSAIDs other than low-dose aspirin should discontinue NSAIDs; if NSAIDs must be resumed, a cyclooxygenase-2 (COX-2)-selective NSAID plus a proton-pump inhibitor should be used.
- Patients with bleeding ulcers due to low-dose aspirin taken for secondary cardiovascular prevention should resume the use of aspirin within 1 to 7 days after bleeding stops.

**Strategies and Evidence**

**Initial Assessment**

At the initial encounter with a patient, risk assessment is performed to determine the severity of upper gastrointestinal bleeding according to vital signs and patient factors. Tachycardia (heart rate ≥100 beats per minute), hypotension (systolic blood pressure ≤100 mm Hg), age older than 60 years, and major coexisting conditions are associated with an increased risk of further bleeding and death.7

Risk-assessment tools are available and are useful in identifying patients at very low risk. For example, discharge from the emergency department followed by outpatient care has been suggested for patients with a Glasgow–Blatchford score of 0, 0 to 1, or, in patients who are younger than 70 years of age, 0 to 2 (on a scale of 0 to 23, with higher scores indicating higher risk) (Table 1).8-11 A prospective study showed that when hospitalized, less than 1% of such patients require intervention and less than 0.5% die.10

Hemoglobin levels should be monitored; however, unlike blood pressure and heart rate, they are a poor initial indicator of the severity of upper gastrointestinal bleeding. Because patients bleed whole blood, the hemoglobin level does not drop immediately but takes hours to equilibrate as the intravascular volume is replenished with intravenous and interstitial fluid.

**Initial Therapy before Endoscopy**

Transfusion of red cells is generally recommended when the hemoglobin level decreases below 7 g per deciliter. A randomized trial showed lower rates of death (the primary outcome), rebleeding, and adverse events with a transfusion threshold of 7 g per deciliter than with a transfusion threshold of 9 g per deciliter.12 For patients in hemodynamically stable condition who have pre-existing cardiovascular disease, guidelines recommend transfusion at a hemoglobin level of less than 8 g per deciliter or in patients with symptoms. These guidelines are based on randomized trials that primarily involved patients without gastrointestinal bleeding who had undergone surgery.15 In patients with hypotension due to severe upper gastrointestinal bleeding, transfusion before the hemoglobin level decreases below 7 g per deciliter is reasonable to prevent the decreases to levels well below 7 g per deciliter that will occur with fluid resuscitation alone.

A meta-analysis of six randomized trials showed that a proton-pump inhibitor administered to patients with upper gastrointestinal
bleeding soon after presentation did not significantly reduce the risks of further bleeding, surgery, or death. The use of this therapy was associated with a decrease in the frequency of high-risk endoscopic findings (active bleeding, a nonbleeding visible vessel, or an adherent clot) and the need for endoscopic therapy. Although they are based on the same data, guidelines vary substantially regarding the use of proton-pump inhibitors before endoscopy. Some recommend high-dose intravenous proton-pump inhibitors, and still others recommend that clinicians not administer proton-pump inhibitors.

Erythromycin (at a dose of 250 mg intravenously 30 minutes before endoscopy) increases gastric motility and improves visualization of the gastric mucosa at endoscopy. A meta-analysis of four randomized trials showed that the use of erythromycin decreased the need for blood transfusion and repeat endoscopy.

**USE OF A NASOGASTRIC TUBE**

A nasogastric tube is not required in patients with upper gastrointestinal bleeding. Observational evidence does not suggest a clinical benefit. Standard-bore nasogastric tubes probably do not allow sufficient clearance of clots to substantially improve visualization of the gastric mucosa at endoscopy.

**ENDOSCOPY**

Most patients who are hospitalized with upper gastrointestinal bleeding should undergo endoscopy within 24 hours, after appropriate resuscitation and transfusion, as needed, to a hemoglobin level greater than 7 g per deciliter. In some observational studies, prompt endoscopy, as compared with endoscopy after 24 hours, has been associated with reductions in the need for surgery, length of hospitalization, and mortality.

Most patients with a low clinical risk (normal blood pressure and heart rate and no major co-existing conditions) should undergo endoscopy as soon as possible during routine clinical hours. Approximately 40 to 45% of patients who undergo endoscopy within 2 to 6 hours have low-risk endoscopic findings that allow discharge, thereby reducing costs. An observational study and a subgroup analysis of a randomized trial suggest that endoscopy within 12 to 13 hours in patients with high clinical risk (Glasgow–Blatchford score ≥12, bloody nasogastric aspirate, hypotension, and tachycardia) may be associated with improved outcomes.

Endoscopic features of ulcers are key in predicting risk and determining management strategies (Fig. 1). Rates of further bleeding are highest among patients with active bleeding and nonbleeding visible vessels. If endoscopic treatment is not provided, serious further bleeding

*Glasgow–Blatchford scores range from 0 to 23, with higher scores indicating higher risk. Positive predictive values were calculated in a study by Laursen et al. Among 2305 patients presenting to a hospital with upper gastrointestinal bleeding, 313 (14%) had a score of 0 (positive predictive value, 99.0%), 562 (24%) had a score of 0 or 1 (positive predictive value, 98.8%), and 588 (26%) had a score of 0 to 2 and were younger than 70 years of age (positive predictive value, 99.0%). To convert the values for blood urea nitrogen to millimoles per liter, multiply by 0.357.
occurs in approximately 25% of patients with actively oozing hemorrhage, approximately 35% with nonbleeding visible vessels, and more than 60% with actively spurting hemorrhage.\(^8,25\) An adherent clot is also a high-risk endoscopic finding, although randomized trials show that rates of rebleeding without endoscopic therapy vary widely, from 0 to 35%.\(^26\) Flat, pigmented spots and clean-base ulcers, which are detected at endoscopy in approximately 70% of patients with ulcer bleeding,\(^27\) are associated with low rates of serious rebleeding (5.6% and 0.5%, respectively, in a pooled analysis).\(^25\)

Endoscopic therapy with injection (e.g., of epinephrine or alcohol), thermal devices (such as bipolar electrocoagulation probes or heater probes), or clips (Fig. 2) is performed in patients who have ulcers with active bleeding or a non-bleeding visible vessel. A meta-analysis of randomized trials revealed absolute risk reductions in further bleeding of 58 percentage points among patients with active bleeding and 20 percentage points among patients with nonbleeding visible vessels.\(^26\) Endoscopic therapy may be considered for ulcers with adherent clots, for which randomized trials show heterogeneous results.\(^26\)

If bleeding recurs, endoscopic therapy should be repeated. A randomized trial involving patients with rebleeding after endoscopic therapy showed that surgery was avoided in 73% of cases and adverse events were significantly less common with endoscopic therapy than with surgical therapy.\(^28\) Transcatheter arterial embolization or surgery is performed if repeat endoscopic therapy fails. Complications of bleeding or perforation occur in approximately 0.5% of patients who undergo endoscopic therapy.\(^26\) Endoscopic therapy also may be used for vascular ectasias, Dieulafoy’s lesions, neoplasms, and actively bleeding Mallory–Weiss tears.\(^11\)

In patients with ulcers or erosions, biopsy specimens should be obtained from lesion-free areas of the gastric body and antral mucosa for assessment of *H. pylori* infection.\(^5,11\) A pooled analysis indicated that such testing has 83% sensitivity and 100% specificity for *H. pylori*.\(^29\) If this testing is negative for *H. pylori*, subsequent retesting (e.g., with a stool test or breath test)

---

**Figure 1.** Initial Treatment of Patients with Ulcer Bleeding, According to the Endoscopic Features of the Ulcer.

Intensive proton-pump inhibitor (PPI) therapy is an intravenous bolus (80 mg) followed by an infusion (8 mg per hour) for 72 hours or an oral or intravenous bolus (e.g., 80 mg) followed by intermittent high-dose PPI therapy (e.g., 40 to 80 mg twice daily) for 3 days.\(^11\) The diets shown are diets after endoscopy in patients who do not have nausea or vomiting. The duration of hospital stay after endoscopy is shown in patients who are in stable condition and do not have further bleeding or concurrent medical conditions requiring hospitalization.
has been recommended because some observational studies suggest decreased sensitivity of testing during acute upper gastrointestinal bleeding.11,16,29

**Clinical Practice**

**CARE AFTER ENDOSCOPY**

Guidelines recommend that patients with ulcers and high-risk endoscopic findings receive an intravenous proton-pump inhibitor bolus (at a dose of 80 mg) followed by a continuous infusion (8 mg per hour) for 72 hours.8,11,16 A meta-analysis of randomized trials showed that this strategy, as compared with endoscopic therapy alone, significantly reduced risks of further bleeding, the need for surgery, and mortality.26 However, a recent meta-analysis showed that intermittent oral or intravenous proton-pump inhibitor therapy resulted in outcomes that were noninferior to those after continuous infusion30; this suggests that intermittent proton-pump inhibitor may be used in place of continuous infusion.24 The most appropriate intermittent dosing is not known, but an initial oral or intravenous bolus of 80 mg followed by 40 to 80 mg twice daily for 72 hours has been suggested.11

Early studies suggested that rebleeding was uncommon more than 3 days after endoscopy, so patients who present with ulcers and high-risk endoscopic findings typically are hospitalized for 3 days after endoscopy if they have no further bleeding and no other reasons for hospitalization. However, in a systematic review of five randomized trials in which patients received endoscopic therapy and infusion of high-dose proton-pump inhibitors, among patients who had rebleeding (overall rate, 11% over 30 days), rebleeding occurred after 3 days in 44% of patients and after 7 days in 24%.31 Nevertheless, anticipation that a small number of patients may have rebleeding in the coming weeks does not justify hospitalization for more than 3 days in patients who are in stable condition and do not have other medical problems. Patients should be informed about symptoms of recurrent upper gastrointestinal bleeding and the need to return to the emergency department if any occur.

After discharge, patients who presented with high-risk endoscopic findings and clinical factors (hemodynamic instability, older age, or a major coexisting condition) should receive twice-daily proton-pump inhibitor therapy for 2 weeks, followed by a proton-pump inhibitor once daily.

![Figure 2. Endoscopic Hemostatic Therapies.](image)
A trial compared once-daily with twice-daily proton-pump inhibitor dosing for 11 days (followed in both groups by 2 weeks of treatment with a proton-pump inhibitor once daily) in high-risk patients who had undergone infusion of a proton-pump inhibitor for 3 days. This trial showed a significantly lower rate of ulcer rebleeding with twice-daily therapy than with once-daily therapy (11% vs. 29%).

Patients with low-risk clinical features (a normal heart rate and blood pressure and no major coexisting conditions), low-risk endoscopic findings (clean-base ulcers, erosions, or nonbleeding Mallory–Weiss tears), and outpatient support can be discharged home after endoscopy, and a regular diet can be resumed. (Fig. 1). Once-daily proton-pump inhibitor therapy is recommended in patients with erosions or ulcers without high-risk endoscopic features.

**PREVENTION OF RECURRENT ULcer BLEEDING**

Rebleeding is common after ulcer healing if strategies to prevent recurrence are not used. For example, a systematic review of studies with a 12-month follow-up showed a 26% rebleeding rate among patients with *H. pylori*–associated bleeding ulcers who did not receive treatment for *H. pylori* infection.

Strategies to prevent recurrent ulcer bleeding depend on the cause of the ulcer. The three major causes are *H. pylori* infection, the use of NSAIDs (including aspirin), and an idiopathic cause (Fig. 3).

**H. pylORI INFECtION**

Patients with *H. pylori* infection should receive therapy to eradicate the bacteria. A meta-analysis of randomized trials of such therapy showed significantly less rebleeding in patients who received this therapy than in patients who did not receive treatment for *H. pylori* infection and in those who received maintenance antisecretory therapy.

Eradication of *H. pylori* should be confirmed after therapy with a breath test, a stool test, or, if repeat endoscopy is performed for another reason, gastric biopsy. Patients must not receive bismuth or antibiotics for at least 4 weeks and should not receive proton-pump inhibitors for at least 2 weeks before testing to avoid false negative results; histamine H₂-receptor antagonists are permissible. In a systematic review of studies with a mean follow-up of 11 to 53 months, the incidence of rebleeding was only 1.3% among patients with confirmed eradication of *H. pylori*.

**NSAIDs OTHER THAN LOW-DOSE ASPIRIN**

Patients who have bleeding ulcers while taking NSAIDs should discontinue NSAIDs permanently if possible. If NSAIDs must be resumed, a combination of a cyclooxygenase-2 (COX-2)–selective NSAID and a proton-pump inhibitor is recommended. Studies have shown rates of rebleeding of 4 to 6% within 6 months among patients who had a bleeding ulcer and were subsequently treated with COX-2–selective NSAIDs alone or traditional NSAIDs plus a proton-pump inhibitor. A 12-month double-blind trial showed significantly less ulcer rebleeding with a COX2–selective NSAID plus a proton-pump inhibitor than with a COX-2–selective NSAID alone (0 vs. 9%).

**LOW-DOSE ASPIRIN**

Decisions regarding continuation of low-dose aspirin (50 to 325 mg daily) for prevention of cardiovascular events should be based on whether the therapy is for primary or secondary prevention. When used for primary prevention, aspirin has been shown to result in significant but small reductions in the absolute risk of cardiovascular events; the estimated number needed to treat to prevent one myocardial infarction, stroke, or vascular death is 1745. The risk of recurrent upper gastrointestinal bleeding probably outweighs the potential benefit of resuming primary prevention in most patients.

In contrast, the absolute reduction in cardiovascular events is much greater when aspirin is used for secondary prevention (estimated number needed to treat, 67). A randomized trial involving patients with bleeding ulcers and high-risk endoscopic features who were taking low-dose aspirin for secondary prevention compared resumption of aspirin use within 24 hours versus withholding aspirin for 8 weeks. Patients assigned to prompt resumption of aspirin, as compared with those in whom aspirin was withheld, had no significant increase in the risk of rebleeding and had significantly lower mortality at 30 days (1% vs. 9%) and 8 weeks (1% vs. 13%). The risk of cardiovascular events may increase within 1 to 2 weeks after discontinuing aspirin.
used for secondary prevention 43,44; thus, aspirin should be resumed 1 to 7 days after bleeding stops.8,11,45 Cotherapy with a proton-pump inhibitor also should be administered to reduce rebleeding.8,45,46

**Combined H. pylori Infection and NSAID Use**

In patients who have received NSAIDs and who are found to have *H. pylori* infection, both eradication of *H. pylori* infection and discontinuation of NSAIDs are recommended. Randomized trials have compared outcomes of treatment for *H. pylori* infection if local patterns of clarithromycin resistance or eradication rates with triple therapy are not known: bismuth-containing quadruple therapy and concomitant (non-bismuth-containing quadruple) therapy.35 Bismuth-containing quadruple therapy is a PPI at a dose of 20 to 40 mg twice daily, bismuth (bismuth subnitrate at a dose of 262 mg, 2 tablets four times a day; colloidal bismuth subcitrate at a dose of 120 mg, 2 tablets twice daily or 1 tablet four times a day; bismuth biskalcitrate at a dose of 140 mg, 3 tablets four times a day; or bismuth subcitrate potassium at a dose of 140 mg as part of combination tablets, 3 tablets four times a day), metronidazole at a dose of 500 mg three times a day or 400 mg four times a day, and tetracycline 500 mg four times a day. Concomitant (non–bismuth-containing quadruple) therapy is a PPI at a dose of 20 to 40 mg twice daily, amoxicillin at a dose of 1 g twice daily, clarithromycin at a dose of 500 mg twice daily, and metronidazole at a dose of 500 mg twice daily. Triple therapy (e.g., a PPI at a dose of 20 to 40 mg twice daily, amoxicillin 1 g twice daily, and clarithromycin at a dose of 500 mg twice daily, all administered for 14 days) should only be used in geographic areas where the prevalence of clarithromycin-resistant *H. pylori* is known to be less than 15% or the eradication rate is known to be greater than 85%.
However, treatment with a proton-pump inhibitor is still recommended if aspirin is continued. A 12-month randomized trial involving *H. pylori*-positive patients with ulcer complications who were receiving low-dose aspirin showed that even after eradication of *H. pylori* infection, ulcer rebleeding was significantly less frequent with a proton-pump inhibitor than with a placebo (2% vs. 15%).46

**IDIOPATHIC ULCER**

An observational study47 showed a 42% incidence of rebleeding at 7 years among patients who did not have *H. pylori* infection, use NSAIDs, or have another uncommon identified cause of an ulcer (e.g., the Zollinger-Ellison syndrome or neoplasm) and who did not receive gastroprotective therapy. Thus, these patients should continue to receive once-daily maintenance therapy with a proton-pump inhibitor.8,16

**AREAS OF UNCERTAINTY**

Data from studies of new endoscopic tools such as Doppler ultrasonography (to assess bleeding risk and the adequacy of endoscopic therapy) and application of powders or cryotherapy (for hemostasis) are insufficient to establish the role of these tools in clinical practice. The appropriate dosing of proton-pump inhibitors to treat ulcers in patients with high-risk findings requires further study. In addition, more data are needed to guide the choice between interventional radiologic and surgical treatment in patients in whom endoscopic therapy has failed. Observational studies show associations between proton-pump inhibitors and adverse outcomes (e.g., dementia, chronic kidney disease, cardiovascular events, fractures, pneumonia, and enteric infections).48-50 The strengths of these associations are generally modest (odds ratios or hazard ratios <2 except for enteric infections), and it is not known whether they are causal.46-50 In patients with a prior bleeding ulcer, the documented benefit of proton-pump inhibitors outweighs the small and uncertain risks.

**GUIDELINES**

Guidelines for the management of upper gastrointestinal bleeding have been published by U.S. and international professional societies.8,11,15,17 The recommendations in this article are generally concordant with these guidelines. Only the European Society of Gastrointestinal Endoscopy guideline,11 which was published after the meta-analysis comparing intermittent with continuous proton-pump inhibitors30 became available, suggests consideration of intermittent rather than continuous proton-pump inhibitors for bleeding ulcers in patients with high-risk endoscopic findings.

**CONCLUSIONS AND RECOMMENDATIONS**

Ulcer bleeding is the most likely cause of upper gastrointestinal bleeding in the patient described in the vignette. Her aspirin use may have caused a new ulcer or may have induced bleeding from a preexisting lesion (e.g., an *H. pylori*-related ulcer).

I would initiate an intravenous normal saline infusion and recheck the patient’s hemoglobin level after volume resuscitation. I would perform endoscopy the next morning, within 12 hours after presentation because of the patient’s initial hypotension. If an ulcer is detected, I would perform endoscopic therapy for active bleeding or a nonbleeding visible vessel, perform biopsies of the gastric mucosa to detect *H. pylori*, initiate treatment with a proton-pump inhibitor, and discontinue aspirin given the patient’s low cardiovascular risk. If *H. pylori* was not present, I would prescribe a proton-pump inhibitor for 6 to 8 weeks. If *H. pylori* was detected, I would prescribe therapy for *H. pylori* infection for 2 weeks, followed by 2 to 4 weeks of a proton-pump inhibitor. I would confirm eradication of the infection by retesting for *H. pylori* after switching the patient’s treatment to a histamine H₂-receptor antagonist for 2 weeks. If *H. pylori* infection was eradicated (or was never present) and the patient agreed not to use aspirin and other NSAIDs, I would discontinue antisecretory medications.

Dr. Laine reports receiving fees for serving on data and safety monitoring boards from Bayer and Pharmaceutical Product Development (a contract research organization that oversaw trials sponsored by Eisai), and providing a review for a law firm representing Mylan in a patent-litigation case regarding formulation of a pill combining an NSAID and a proton-pump inhibitor.
