Assessing Risk of Future Suicidality in Emergency Department Patients

Krista Brucker, MD, MS, Carter Duggan, MD, Joseph Niezer, MD, Kyle Roseberry, MD, Helen Le-Niculescu, PhD, Alexander B. Niculescu, MD, PhD, and Jeffrey A. Kline, MD

ABSTRACT

Background: Emergency departments (ED) are the first line of evaluation for patients at risk and in crisis, with or without overt suicidality (ideation, attempts). Currently employed triage and assessments methods miss some of the individuals who subsequently become suicidal. The Convergent Functional Information for Suicidality (CFI-S) 22-item checklist of risk factors, which does not ask directly about suicidal ideation, has demonstrated good predictive ability for suicidality in previous studies in psychiatric patients but has not been tested in the real-world setting of EDs.

Methods: We administered CFI-S prospectively to a convenience sample of consecutive ED patients. Patients were also asked at triage about suicidal thoughts or intentions per standard ED suicide clinical screening (SCS), and the treating ED physician was asked to fill a physician gestalt visual analog scale (VAS) for likelihood of future suicidality spectrum events (SSE; ideation, preparatory acts, attempts, completed suicide). We performed structured chart review and telephone follow-up at 6 months post-index visit.

Results: The median time to complete the CFI-S was 3 minutes (first to third quartile = 3–6 minutes). Of the 338 patients enrolled, 45 (13.3%) were positive on the initial SCS, and 32 (9.5%) experienced a SSE in the 6 months of follow-up. Overall, SCS had modest diagnostic accuracy sensitivity 14/32 = 44%, (95% CI: 26–62%) and specificity 275/306 = 90%, (86–93%). The physician VAS also had moderate overall diagnostic accuracy (AUC 0.75, confidence interval [CI] = 0.66–0.85), and the CFI-S was best (AUC = 0.81, CI = 0.76–0.87). The top CFI-S differentiating items were psychiatric illness, perceived uselessness, and social isolation.

Conclusions: Using CFI-S, or some of its items, in busy EDs may help improve the detection of patients at high risk for future suicidality.

With more than 4 million visits to the ED annually in the United States for mental disorders, the ED is considered by many to be the first line of evaluation for patients at risk and in crisis, with or without overt suicidality (ideation, attempts). The weighted national estimate of patients with a diagnosis of “suicide or intentional self-harm” in the National Emergency Department Sample for 2013 was 1,411,770, patients, with 98.8% of those with suicidality as a first diagnosis discharged from the ED. In 2013, visits for suicidal ideation accounted for nearly 1% of all adult ED visits (108.3 million visits).
To better predict and prevent suicides, emergency care providers need improved risk stratification tools for patients with overt or covert mental health crisis. Several tools—PHQ9, the ED-Safe Patient Safety Screener4 and the Suicide Behaviors Questionnaire—Revised (SBQ-R)5—have been created and validated for suicide screening. All of these include direct questioning about current or recent suicidal thoughts. None of these tools has been compared to physician gestalt or evaluated for their ability to predict rates of adverse suicide-related events in patients who screen negative using the tool. There are yet no widespread clinically used simple objective tools to assess and track changes in suicidal risk without asking the individuals directly, although others in the field besides us are actively working on this problem and progress is being made (for example Nock and colleagues,6,7 Bouvard and colleagues8,9). Such tools are desperately needed, as individuals at risk may choose not to share their ideation or intent with others, for fear of stigma or hospitalization or that in fact their plans may be thwarted.

The Convergent Functional Information for Suicidality (CFI-S) is a novel suicide risk instrument that comprises 22 questions and has shown good to excellent predictive value for suicidality in settings other than the emergency department (ED).11–13 The CFI-S is a checklist of risk factors for suicidality from a variety of domains including life satisfaction, mental health, physical health, environmental stress, addictions, cultural factors, and demographic information and assigns a numeric point value for each response. Each answer of yes resulted in one point. The total CFI-S score is calculated by dividing the total number of affirmative answers by the total number of questions answered.

METHODS

This study received approval from the Indiana University School of Medicine Institutional Review Board and all patients completed a written informed consent process before participation. Patients were eligible for inclusion if they were over 18 and were able to participate in the survey. Exclusion criteria included age less than 18, severe trauma or illness requiring emergent intervention, or acute intoxication as reported by the clinical staff or patient. Patients were enrolled in the ED of the Sydney and Lois Eskenazi Hospital, an urban safety net hospital that has an annual volume of 95,000 visits. Between March 2016 and April 2017 the CFI-S was prospectively administered to a sample of 338 ED patients. The patients were consecutive and nonselected, meaning the research staff enrolled patients one after the other without interruption and without regard to the chief complaint. Research staff approached patients after their initial nursing and physician assessments were complete. They administered the CFI-S asking subjects for yes or no answers to all questions, documenting start and end times of the survey. Questions were asked exactly as written and requests for clarification from patients responded to with “please answer the question as you understand it.” Each answer of yes resulted in one point. The final CFI-S score is calculated by dividing the total number of affirmative answers by the total number of questions answered.

After the CFI-S was completed, research staff also approached the patient’s ED physician (board-certified emergency physicians or emergency medicine residents in training) to obtain their physician clinical gestalt VAS regarding the patient’s risk of future suicide-related outcomes over the following 6 months. Physicians were asked to assess their numeric probability (0%–100%) that the patient would have a suicidality spectrum event (SSE), defined as repeat ED visit or admission for suicidal ideation, preparatory acts, suicide attempts, aborted or interrupted attempts, or completed suicide in the 6 months following the patient’s
index ED visit. This spectrum of severity approach is substantiated by our previous blood biomarker studies and is supportive of suicidality as its own free-standing diagnosis, per the proposal of Oquendo and colleagues. Physician gestalt VAS was obtained by clinicians making a vertical hash mark with a pen on a 10-cm horizontal line with 0 cm equaling 0% probability of suicide and 10 cm representing 100% probability. Research assistants also recorded subjects’ responses to the health system’s standard two-question universal screening tool. This screen includes the questions: “Do you have any thoughts of hurting yourself or anyone else?” and “Do you feel hopeless or helpless?” An affirmative response to either question is considered a positive screen in the health system but only those answering yes to the first question were coded as positive suicide screen for the purposes of our analysis. Patients were followed prospectively for SSEs. Members of the research team, who were trained by the principal investigators, performed structured telephone and chart review follow-up on all patients 6 months post–index visit. For follow-up, study personnel dialed the telephone number that patients directly stated as the best way to contact them. The number was dialed at least three times on different days at different times of day. After 6 months, we also queried the CareWeb electronic interface to the Indiana Network for Patient Care (INPC) system for a suicidal event. The INPC represents over 100 separate healthcare entities in Indiana providing data including hospitals, health networks, and insurance providers. Chart reviewers were trained study personnel who individually read and considered any documented medical encounter for specific words suggesting a suicidal event. Ambiguous cases were resolved by consensus between two authors.

We compared areas under the receiver operating characteristic curve (ROC AUC) for gestalt VAS versus the CFI-S using the method of Hanley and McNeil. The optimal cutoff was chosen as the point on the ROC curve that conferred the peak diagnostic odds ratio (OR), defined as the maximal likelihood ratio positive/likelihood ratio negative. Statistical analyses were performed with StatsDirect statistical software (v.3.0.187) and plots were made with as performed using GraphPad Prism version 7.00 for Windows.

RESULTS
As shown in Figure 1, we approached 367 patients, and 338 (92%) agreed to participate. Physician clinical gestalt VAS data were collected on 170 subjects.

Survey Characteristics
The median time to complete the CFI-S was 3 minutes (first to third quartile = 3–6 minutes). Two research personnel, blinded to each other’s results, administered the CFI-S twice to 10 patients approximately 1 hour apart and found that the repeated values were within 10% of the first value in eight of 10 retests. The internal consistency of the CFI-S was good, as reflected by the Cronbach’s alpha of reliability of 0.84 (95% lower confidence limit = 0.81). Data were missing for one or more questions in 56 (16%) of the surveys.

Patient Outcomes and Predictive Characteristics
Of the 338 patients, 32 (9.5%) experienced a SSE in the 6 months of follow-up. Table 1 outlines the

**Figure 1.** Flow diagram of research subjects. Number of patients approached and enrolled and with completed follow-up.
Of the 32 subjects who experienced a suicide-related outcome, 18 (56.3%) were not suicidal at first presentation as measured by the health system’s standard two-question universal screening tool. This screen includes the questions “Do you have any thoughts of hurting yourself or anyone else?” and “Do you feel hopeless or helpless?” For study purposes a positive screen required the first question to be answered affirmatively although anyone answering the second question affirmatively did have additional ED assessment for thoughts of self-harm per screening hospital protocol.

Figures 2–4 examine predictive ability of VAS, and CFI-S for future SSEs. Figure 2 shows box plots with 1st-3rd quartiles and visually highlights the expected finding that VAS and CFI-S values tended to be higher in patients identified as having SI by standard clinical screening (SCS). Figure 3 compares the ROC for the CFI-S with the VAS. Physician VAS shows a higher ability to discriminate with an AUC of 0.75 ($p = 1.27 \times 10^{-4}$). CFI-S had the highest numeric AUC of 0.81 ($p = 5.11 \times 10^{-9}$). The optimal cutoff for physician VAS was 1.2 and for the CFI-S was 0.65. Figure 4 plots the first order regression between the CFI-S and VAS and shows moderate correlation (Pearson’s $r = 0.42$). Comparing the AUCs for physician VAS versus the CFI-S using the method of Hanley and McNeil first required restriction of data to patients with both values recorded, yielding 20 patients with SSE positive and 150 patients with SSE negative. The AUCs for this restricted data set were 0.77 (SEM = 0.04) for the CFI-S and 0.75 (SEM = 0.05) for the physician VAS yielding $Z = 0.585$ and $P = 0.558$.

Table 3 shows the individual items of the CFI-S that were most able to differentiate between SSE and non-SSE. The top items are history of psychiatric demographics of our sample. The median age of those who experienced an SSE outcome was 39 (interquartile range [IQR] = 30–51) versus 44 (IQR = 31–54) in those who did not. ED revisits and psychiatric hospitalizations were the most common outcomes. Completed suicides did not occur in our sample in the 6-month follow-up (Table 2).
illness, perceived uselessness, and social isolation. Pre-
diction results in all, by sex, and by items are summar-
ized in Supplementary Information Tables S1–S3.

**DISCUSSION**

In this sample of 338 consecutive ED patients, we
found the current two question universal screen for
suicidal intent failed to identify 18 (56.2%) patients
who went on to have a SSE within 180 days. Those
18 patients represent 5.3% of our overall sample of
unselected ED patients presenting for a wide variety of
chief complaints. While several studies have found a
high rate of undiagnosed depression in unselected
patients, to our knowledge, this is the first study to
use a tool to predict suicidality in an unselected ED
cohort. According to CDC data, an estimated 1.3 mil-
lion adults aged 18 or older (0.6%) attempted suicide
in the past year, and 43% of patients who complete
suicide visit an ED at least once in the year prior to
their death.

Given the increased risk of ED patients and the rel-
ative insensitivity of universal screening, we were inter-
ested if emergency physician clinical gestalt VAS
would be a better diagnostic tool to predict suicidal
events. To our knowledge, this is the first study to
assess the diagnostic properties of physicians’ clinical
gestalt VAS for suicide-related outcomes in the general
ED population. Unfortunately, physician gestalt for
adverse suicide-related outcomes as measured by VAS
shows only moderate diagnostic discrimination. In
our experience ED physicians rely heavily on their
clinical gestalt in combination with patients’ responses
to direct questioning about suicidal thoughts or plans. Given the limited diagnostic ability of both of these tools, data from Table 3 provide a preliminary inference that emergency physicians could use the three most sensitive questions from the CFI-S (prior mental illness/feelings of uselessness/social iso-
lation) to improve our ability to detect future risk of
suicidal behavior.

In addition to incorporating better risk assessments
into our clinical assessment of SCS-standard clinical
screening suicidal risk, making a significant impact on
morbidity and mortality related to undiagnosed suiici-
dality will require the development and broad imple-
mentation of brief, structured risk assessment tools
that obviate the need for patients’ to endorse directly
present or recent suicidal thoughts. We found that the
CFI-S can be given quickly and effectively, in the ED
setting, is an accurate predictor of adverse suicide-
related outcomes and avoids relying on patients’ self-
report of current or recent suicidal thoughts. The CFI-
S took 3 minutes to complete, which although longer

than it currently takes to complete our standard two question universal screening, is likely warranted given the potentially life-threatening consequences of a missed diagnosis.

Over half of patients who experienced suicide spectrum events in 180-day follow-up were not identified by standard screening. It is both striking and concerning that current screening methods missed more than half of patients who would go on to experience a suicide-related outcome. Given the weakness of current screening tools as well as of physician gestalt VAS, the CFI-S has the ability to more effectively screen for high risk of suicidal outcomes and could help identify patients missed by current screening tools.

Possible future implications of this work include incorporation of more robust but still relatively time efficient risk stratification tools for all patients presenting to the ED and other high-risk care settings. In a universal screening protocol, patients with a CFI-S > 0.65 should be referred for urgent outpatient mental health evaluation and could be targeted in active community-based ED follow-up programs focused on

decreasing social isolation and supporting linkage to follow-up care. The 0.65 was determined as the cutoff of the CFI from the ROC curve that produced the highest diagnostic OR (likelihood ratio positive/likelihood ratio negative).

LIMITATIONS

Our study sample was a convenience sample recruited from a single, urban safety net hospital, which may not represent a broad sample of patients in EDs across the United States. Our criterion standard relied on discovery from one or both of the following mechanisms: 1) patients had to be able to recall and volunteer to report suicidal events on telephone interview or 2) discovery of an accurate and clear description of a suicidal event documented by health care providers in medical records. It remains possible that these processes missed some suicidal events. Although all suicide spectrum events are important, those most dangerous (completed suicide) did not occur.

CONCLUSION

In this single-center study that enrolled a heterogeneous sample of ED patients, current screening methods for suicidality failed to identify over half of those who went on to have a suicidal spectrum event in the next 180 days. Physician gestalt had moderate predictive accuracy. The CFI-S has good accuracy for detection of those who would have future events, without directly questioning patients about suicidal thoughts. These data imply that the CFI-S or some of its component items notably related to mental health and stress, may be useful to improve detection of suicidality risk in emergency care, leading to targeted and personalized preventive strategies. The CFI-S was able to predict adverse suicide-related outcomes in some patients who screened negative for suicidal ideation at ED presentation and who were considered low risk by the physician evaluating them. We suggest that the broad implementation of CFI-S in ED settings may be complementary to current approaches and improve the detection of patients at high risk for future suicidal events.
