RSV is an RNA virus that belongs to the *Paramyxoviridae* family. RSV causes significant morbidity in children. It is an important cause of death in young children in the low- and middle-income countries. In the United States, RSV is associated with approximately 20% of hospitalizations and 18% of ED visits in children younger than 5 years old. RSV is also a significant cause of respiratory illness in older patients, affecting 3% to 10% of the population over age 65 each year. RSV is spread via contact with infected individuals, by exposure to respiratory secretions and fomites.

Clinical Features

RSV causes a range of respiratory disease. The illness is most severe in infants, causing pneumonia and bronchiolitis. Newborns with RSV can present with apnea. Symptoms usually begin with nasal congestion, rhinorrhea, low-grade fever, and cough. Then 1 to 2 days after symptom onset, patients develop wheezing and increased respiratory effort. Symptoms can last up to 2 weeks. In adults and older children, RSV usually causes a benign URI typically lasting less than 5 days. Geriatric patients, immunosuppressed patients, and adults with chronic medical problems can develop severe lower respiratory tract disease.

Differential Diagnosis

The clinical presentation caused by RSV infections is similar to other upper and lower respiratory tract pathogens, including rhinovirus, parainfluenza, influenza, enteroviruses, coronaviruses, and bacterial causes of pneumonia. It is important to consider noninfectious causes of hypoxemia in infants, such as foreign body aspiration and asthma.

Diagnostic Testing

The common methods of diagnosis include viral culture, molecular assays, and rapid antigen detection tests. Specimens are typically obtained from nasopharyngeal swabs or washings. Other routine diagnostic testing is generally unnecessary and should be symptom targeted.

Management

The mainstay of treatment is supportive care. Beta-agonist bronchodilators are not recommended by the most recent guidelines published

by the AAP.[30] The authors agree that routine inhaled bronchodilators should not be used for RSV bronchiolitis given the lack of evidence of improved outcomes. However, it is reasonable to administer a trial of inhaled albuterol for severe disease, because most of these patients were excluded from studies and some of the patients may actually have viral-induced asthma exacerbation. Corticosteroids have not been shown to provide any benefit. Supplemental oxygen should be provided for pulse oximetry less than 90%. Nebulized hypertonic saline can be used as an inpatient, but currently data do not support use in the ED. For severe cases, nasal continuous positive airway pressure (CPAP) can be trialed to avoid intubation. It is also important to treat dehydration associated with the disease with IV or nasogastric fluids if the patient cannot maintain oral intake. For prevention of RSV infection in high-risk patients, the AAP recommends the use of palivizumab, a monoclonal anti-RSV antibody preparation, during the first year of life for infants with hemodynamically significant heart disease or chronic lung disease of prematurity defined as preterm infants younger than 32 weeks' gestation who require more than 21% oxygen for at least the first 28 days of life.

Disposition

Healthy adults and older children have a short disease course that is mild and can be treated at home. The majority of infants with RSV may also be treated at home but may have prolonged illness. Infants younger than 1 year old that visit the ED for bronchiolitis have a median duration of symptoms of 15 days, and over one-third of them have a subsequent unscheduled medical visit. Approximately 1% to 3% of infants with RSV require hospitalization for hypoxemia, respiratory distress, or dehydration. Approximately 15% of geriatric patients requiring ICU care with an acute cardiopulmonary diagnosis are diagnosed with RSV infection.

VIRUSES ASSOCIATED WITH DIARRHEAL ILLNESS

Norovirus and Rotavirus

Norovirus is a member of the *Caliciviridae* family and is the most common cause of nonbacterial gastroenteritis. It is highly infectious because only a few particles are necessary to transmit the disease. Norovirus is spread through direct transmission from person to person via the fecal-oral route. Transmission can also occur through contaminated water, food, and surfaces. Because of its structure as a nonenveloped RNA virus, norovirus is very stable in the environment and is resistant to most disinfectants, including alcohol hand wash. Outbreaks of norovirus occur in areas where people are in proximity, including long-term care facilities, restaurants, hospitals, schools, and cruise ships. ED visits for norovirus peak in the winter months.

Rotaviruses are double-stranded RNA viruses that belong to the *Reoviridae* family. These viruses are ubiquitous, and by 5 years old most children have been exposed to them. They are the leading cause of severe gastroenteritis in children. The introduction of rotavirus vaccine in industrialized countries has dramatically decreased encounters for this disease.[31,32]

Clinical Features

Norovirus. The disease causes a severe gastroenteritis, with vomiting, diarrhea, and abdominal cramping. In infants and children, vomiting is the primary symptom, whereas adults more commonly have diarrhea. The gastrointestinal symptoms can be accompanied by fever, headache, and myalgias as well. The diarrhea is typically nonbloody, watery, and profuse. The acute illness usually lasts for half a day to 3 days.

Rotavirus. The illness manifests as sudden onset of nausea, vomiting, and profuse watery diarrhea, with fever, headache, and myalgias. The disease course is usually 3 to 7 days. The spectrum of disease can range from asymptomatic to severe and fatal dehydration.

Differential Diagnosis

Other causes of viral gastroenteritis include adenovirus, enterovirus, and certain coronaviruses. *Clostridioides difficile* infection and some bacterial gastroenteritis can present similarly.

Diagnostic Testing

Norovirus diagnosis can be confirmed by PCR of stool or vomit specimen. Rapid antigen detection test, enzyme-linked immunosorbent assay (ELISA), and PCR of stool specimen are the methods of diagnosis for rotavirus.

Management

There is no specific treatment for these viral gastrointestinal infections. Management centers on ensuring that patients are adequately hydrated and correcting significant electrolyte derangements. Most patients can be treated with oral rehydration alone. Patients with severe dehydration warrant IV rehydration. Meticulous attention to standard precautions and hand hygiene is important to prevent spread of these diseases.

Disposition

The majority of patients can be managed at home with oral therapy. Very young patients or patients with chronic illness may be at risk for more severe disease and benefit from IV therapy and monitoring. Depending on the severity of illness, these patients could be managed in an observation unit or may require inpatient admission.

VIRAL INFECTIONS WITH NEUROLOGIC MANIFESTATIONS

Rabies

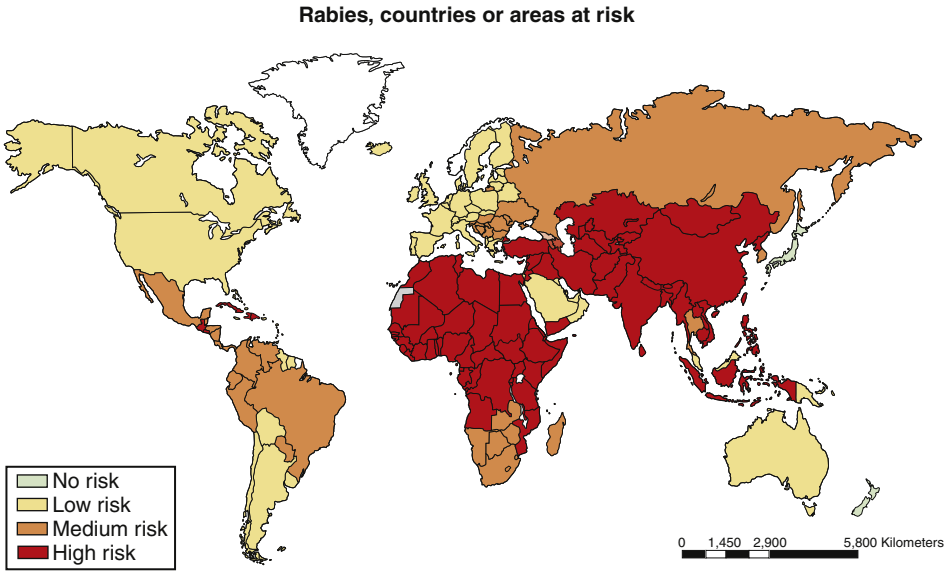
The natural history and clinical course of rabies disease is complex. After a bite from a rabid animal, the risk of developing clinical disease is unknown and depends on viral inoculation or migration into nerve tissue. The risk of death following untreated clinical disease, however, is almost 100%, and the risk of developing clinical disease following proper treatment approaches 0%.[33] Rabies remains a huge public health problem worldwide, particularly affecting vulnerable populations in poor and rural areas (Fig. 119.10). Human rabies disproportionately affects children, with an estimated 40% of rabid bites occurring in those 15 years of age and younger.[34]

Emergency medicine clinicians should be prepared to evaluate bites and other exposures for the risk of rabies inoculation as well as diagnose or rule out rabies disease in patients presenting with neurologic symptoms. The diagnosis of rabies requires a thorough medical history, noting the course of illness, and multiple laboratory tests. Likewise, the management of animal bites requires appropriate wound care, risk analysis in conjunction with local or state public health authorities, patient and physician decision making regarding the need for and timing of postexposure treatment, and appropriate bite reporting to animal control or public health authorities.[35]

The signs of rabies in all species of animals are extremely variable and cannot be used alone to determine the likelihood of rabies. Additionally, the incubation period for rabies (i.e., the time between when a human or animal is bitten by a rabid animal and the development of clinical signs) is highly variable, ranging from days to months or rarely years in both humans and animals.[36] For these reasons, thorough risk assessment based on environmental, historical, and clinical conditions is essential for every animal bite and exposure.

Epidemiology

All mammals are physiologically capable of becoming infected with rabies and transmitting the virus to humans, but globally the domestic



In countries of categories 1, 2 and 3, contacts with suspect rabid animals including bats should be followed by rabies post-exposure prophylaxis.

No risk: no risk at all.
Low risk: pre-exposure immunization recommended for people likely to have contact with bats.
Medium risk: pre-exposure immunization recommended for travellers and other people for whom contact with bats and other wildlife is likely.
High risk: pre-exposure immunization recommended for travellers and other people for whom contact with domestic animals particularly dogs and other rabies vectors is likely.

Fig. 119.10 Rabies—countries or areas at risk. (Courtesy of World Health Organization (WHO).)

dog is the highest-risk species for rabies exposure.[37] In many countries, endemic dog rabies still occurs, and the cycle of dog-to-dog transmission spills into the human population. The global burden of human rabies from dogs is high, with an estimated 59,000 deaths and the equivalent of over $8.5 billion (US) in economic losses from premature death and postexposure treatment.[38] Although the United States was declared free of endemic canine rabies in 2007, travelers to countries where canine rabies is endemic can be exposed to rabies and subsequently express symptoms after returning to the United States. Since 2003, all fatal cases of canine-attributed human rabies in the United States have been acquired outside the continental United States.[39]

In the United States, certain wildlife species are high-risk for human exposure. This risk is due to shared habitats, interactions between humans and wildlife, and human proximity to locations of endemic rabies in certain species, including the bat, raccoon, skunk, and fox. Small rodents such as squirrels, hamsters, guinea pigs, chipmunks, rats, and rabbits are almost never found to be infected and have not been known to transmit rabies to humans.[39]

Other modes of transmission are rare but exist. Human rabies disease has been caused via organ transplantation and aerosolization (in laboratories or high-concentration environments such as caves).[40,41] Other than through organ transplantation, person-to-person transmission of rabies has not been reported.

Pathophysiology

Rabies is caused by an RNA virus from the genus lyssavirus, in the family Rhabdoviridae. The rabies virus (RABV) is responsible for most human and animal rabies cases worldwide, but other lyssavirus have been implicated. RABV is found extensively throughout the world in terrestrial carnivores, but non-RABV lyssavirus is rarely encountered in nonflying carnivores.[37,42]

Bites through the dermis allow the virus to enter tissues and initiate infection. The virus spreads from muscle tissue to the peripheral nervous system via the neuromuscular junction and then travels to the spinal cord and brain. Host cell machinery is usurped, and rapid replication occurs, resulting in clinically apparent disease. Infection of the brain is followed quickly by peripheral viral dissemination. For the reservoir species, transmission to the salivary glands proceeds through the parasympathetic and sympathetic nervous systems. The associated aggressive behavior and hypersalivation promotes transmission to new hosts.[43,44]

Clinical Features

Two forms of clinical rabies are described, encephalitic and paralytic. The encephalitic form predominates and represents approximately 80% of all human rabies presentations.[45] It is believed that the burden of infection is in the brain in the encephalitic form, whereas the burden is in the spinal cord in the paralytic form. The initial symptoms of rabies infection are vague and may be confused with other flu-like illnesses. Presenting symptoms of rabies include headache, malaise, pharyngitis, and weakness which are followed by or concomitant with pruritus and paresthesia at the site of inoculation. Fever, tachycardia, and tachypnea foretell the acute behavioral changes characteristic of rabies: agitation, aerophagia, hydrophobia, seizures, and coma.[36] The image of a patient in the final stages of rabies delirium with agitation and foaming of the mouth is aptly described by the genus name lyssavirus, named for Lyssa, a Greek goddess of rage, fury, madness, and frenzy (Fig. 119.11). Infection in the central and peripheral nervous systems leads to multiorgan failure.

Encephalitic Rabies. Encephalitic rabies progresses rapidly over days, and the presenting signs and symptoms are supplanted rapidly by diffuse neurologic involvement. A brief period of anxiety, confusion, insomnia, and cerebellar dysfunction are soon replaced by frank delirium, hallucinations, and the clinically defining behavioral changes: hydrophobia, aerophobia, aggressive behavior, and seizures. These are the clinical symptoms most associated with rabies infection,

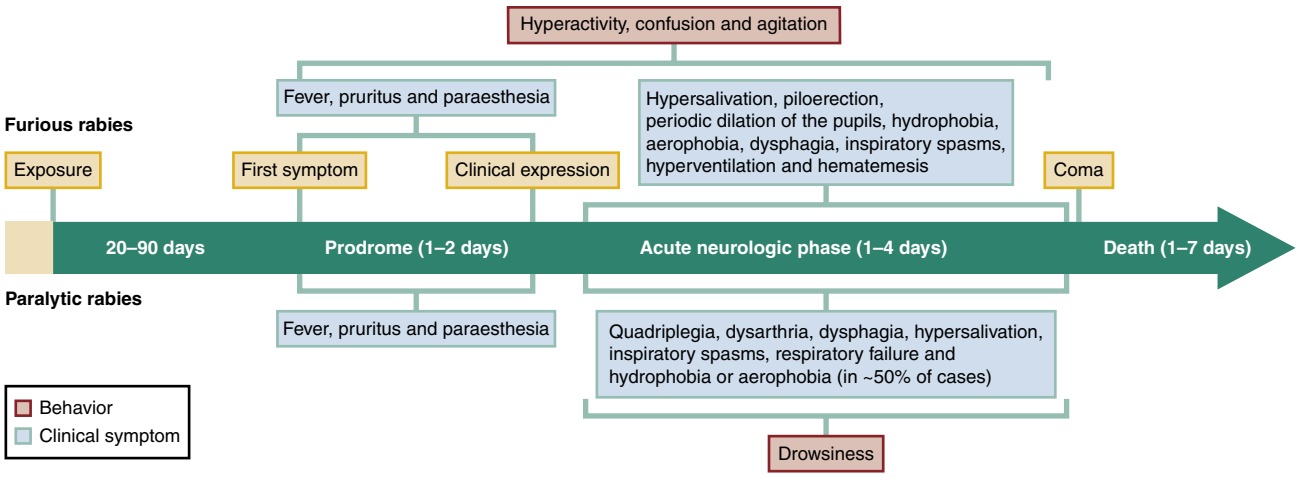


Fig. 119.11 Spectrum of clinical rabies. (From: Fooks AR, Cliquet F, Finke S, et al. Rabies. *Nat Rev Dis Primers.* 2017;3:17091.)

and these portend death.[45] In the final stage of encephalitic rabies, the patient has difficulty swallowing from involuntary muscle spasms of the pharynx, and hypersalivation occurs. If offered water, the patient may develop pharyngeal spasm with resultant gagging. Patients are unable to handle salivary secretions, leading to characteristic drooling and foaming of the mouth. The findings of hydrophobia with resultant gagging and hypersalivation are so characteristic of rabies infection that in many developing countries, water is offered to the patient as a diagnostic test. Coma and death follow rapidly, usually within 5 days of presentation.[36]

Paralytic Rabies. Paralytic rabies accounts for approximately 20% of human rabies infections. The presenting symptoms are similar to encephalitic rabies and include headache, weakness, and malaise. Muscle weakness and paresthesia occur at the site of the bite and, over days to weeks, an acute flaccid paralysis ensues. Unlike the encephalitic form, the patient does not develop agitation, hypersalivation, or hydrophobia. Rather, muscle weakness occurs over days to weeks, and the progression to coma and death takes longer than in the encephalitic form.[45] The paralytic form develops more often in patients who have been bitten by rabid bats than dogs and those who have had incomplete PEP, without a clear explanation. Exposed patients receiving the nerve cell–derived vaccine that is still used in a few countries are also at greater risk of developing the paralytic form.

Differential Diagnoses

The prodromal phase of rabies presents similarly to many common infections including mononucleosis, bacteremia, and meningitis. In its early stages, rabies may appear similar to other infectious encephalitis including herpes simplex, cerebral malaria, and West Nile infections. Noninfectious toxic or metabolic encephalopathies, including serotonin syndrome, alcohol withdrawal, organophosphate poisoning, elapid or scorpion envenomation, may mimic early rabies. On rare occasion, psychiatric disease, such as schizophrenia and conversion disorders, may resemble rabies.[46,47] Tetanus, dystonia, and strychnine poisoning all present with muscular rigidity which may appear similar to rabies. Once aerophagia, hydrophobia, or dysphagia appear, however, the diagnosis of rabies becomes clear.

The early presentation of paralytic rabies may mimic Guillain-Barré syndrome, but is distinguished by the onset of encephalitis, asymmetry of limb involvement, persistent fever, bladder incontinence, and intact sensory function. Percussion myoedema is the mounding of muscle at the site of percussion and is characteristic of rabies.[33] It is best elicited on the chest, deltoid, and thigh (Box 119.2).

BOX 119.2 Rabies Rigidity/Paralysis: Differential Diagnosis

Muscular Rigidity
Tetanus
Dystonia
Strychnine poisoning

Paralysis
Guillain-Barré
Acute flaccid paralysis
Envenomation
Hypokalemia

In atypical presentations of encephalitic rabies or paralytic rabies, the diagnosis may not be clear and may delay institution of appropriate public health and infection control measures. As improved antemortem techniques arise, more timely diagnosis will provide more opportunity for appropriate prophylaxis to family members, and more timely discussions with patient and family regarding prognosis.[42]

Diagnostic Evaluation and Testing

The diagnosis of human rabies requires clinical acumen, understanding of local capabilities of treatment, and public health issues in the community.[36] The emergency clinician must consider rabies in two scenarios: possible exposure to rabies and the diagnosis of clinical rabies. The decision to initiate postexposure prophylaxis requires understanding of the type of exposure and the local vector demographics. Because the risk assessment of the exposure is intricately tied to its management, this topic is addressed in the management section.

Clinical cases of human rabies are categorized as suspected, probable, or confirmed. A suspected case is one that is compatible with clinical findings, probable cases have a reliable history of contact suspected, probably or confirmed rabid animal as well as suspected clinical findings, and confirmed case definition indicates laboratory confirmation.[36] The WHO definition of confirmed rabies requires at least one of the laboratory criteria in Box 119.3.

Typical laboratory tests are rarely helpful in the diagnosis of rabies. Complete blood count often demonstrates a leukocytosis, and cerebrospinal fluid findings include lymphocytic pleocytosis with elevated protein and normal glucose. Neither of these studies and their findings are specific for rabies. MRI imaging may demonstrate T2 signals

BOX 119.3 Laboratory Criteria Used to Confirm Rabies

- Presence of viral antigens in samples (e.g., brain tissue, skin);
- Isolation of virus from samples in cell culture or in laboratory animals;
- Presence of viral-specific antibodies in the cerebrospinal fluid or serum of an unvaccinated person; and/or
- Presence of viral nucleic acids in samples (e.g., brain tissue, skin, saliva, concentrated urine).

The WHO definition of rabies requires at least one of the criteria to be met.[35]

in the hippocampus, hypothalamus, and brainstem, but is not clearly diagnostic.[33]

Effective antemortem testing remains elusive, particularly in endemic regions with limited laboratory capability. Patients with suspected rabies who have not been vaccinated may not have rabies antibodies in serum or CSF until obvious clinical signs are apparent, but positive titers are then diagnostic. Patients who have received rabies vaccine or rabies immunoglobulin (RIG) have serum titers of rabies antibody but require subsequent testing in 7 days to assess if titers are rising. Various forms of molecular methods-reverse transcription (RT) and polymerase chain reaction (PCR) assays have demonstrated high sensitivity for RABV in dog brain tissue. In humans, real-time PCR testing of cerebral spinal fluid, nuchal skin, and saliva using the TaqMan probes has demonstrated excellent sensitivity and specificity.[48] Consultation with local public health authorities to determine which tissues should be sampled and how to obtain and transport safely is paramount.[35]

Postmortem testing of fresh brain samples remains the gold standard for the diagnosis of rabies in all animal species. The WHO and World Organization for Animal Health (OIE) recommend fluorescent antibody testing (FAT) of brain smears or touch impressions.[49] FAT provides sensitive and specific results within a few hours. The best results are obtained with fresh brain tissue, but saline-washed tissue preserved in 50% glycerol saline also works well.

The direct rapid immunohistochemical test (dRIT) was developed in 2006 at the CDC. The dRIT assay is an immunohistochemical diagnostic assay that utilizes polyclonal or monoclonal antibody that is directly labeled, and is performed after a touch impression of brain tissues. A streptavidin reagent catalyzes the formation of a colored precipitate when bound to the rabies virus, making it visible with simple light microscopy. dRIT provides results in 1 hour, does not require expensive fluorescent-labeled antibodies, and has been field-tested in endemic areas with 100% sensitivity and specificity when compared to FAT.[50] The use of dRIT allows regions with limited resources to obtain important incidence data, as well as the possibility of carrying out more informed postexposure prophylaxis. However, one significant drawback of dRIT is that the reagents used for the test are only available through the CDC.

Management

The treatment of rabies exposure and rabies disease is divided into preexposure (PreP) recommendations in high-risk groups, animal bite or exposure assessment, wound care, postexposure prophylaxis, and treatment of human rabies (Fig. 119.12).

Preexposure Prophylaxis. Pasteur described the first rabies vaccine in 1885.[51,52] Nerve tissue–derived vaccines similar to Pasteur's were used worldwide until the 1940s, when they were replaced by cell culture–derived vaccines (CCVs) that were safer and more immunogenic. The nerve cell–derived vaccines contain myelin basic protein, which may cause a severe immune response resulting in devastating neurologic adverse reactions. Despite warnings from WHO, some countries continue to manufacture and use nerve tissue–derived vaccines.[36]

All US-licensed rabies vaccines are inactivated cell culture vaccines that can be administered to immunocompromised individuals. Patients with immunosuppressive disorders and those taking corticosteroids, immunosuppressive agents, or antimalarials may have a reduced response to the vaccine, necessitating a 5-dose regimen. In this setting, serologic testing for neutralizing rabies antibody may be considered 4 weeks after the last vaccine dose to determine if a booster is necessary.[36]

Adverse reactions to rabies vaccines include local reactions, mild systemic reactions, and immediate hypersensitivity reactions. Typical local reactions include pain, swelling, redness, and induration at the injection site.[52] These symptoms are reported by 60% to 85% of recipients of the human diploid cell vaccine (HDCV) and by 11% to 57% of recipients of the purified chick embryo vaccine (PCEV). From 6.8% to 55.6% and up to 31% of recipients of HDCV and PCEV, respectively, have reported systemic reactions, including gastrointestinal symptoms, headache, dizziness, and fever. Immediate hypersensitivity occurs in 1.2% of previously unimmunized HDCV recipients and in up to 6% of those previously immunized receiving HDCV as a booster. No deaths have been reported from recipients of the human diploid cell vaccine or purified chick embryo cell vaccine.[53]

Preexposure vaccine (PrEP) is recommended for travelers to endemic areas and those in high-risk professions (e.g., veterinarians, laboratory staff handling the virus). The PrEP regimen recommended by the WHO and CDC are not currently aligned, with WHO recommending a 2-dose strategy and CDC recommending a 3-dose regimen.[36,52]

Intramuscular or intradermal administration of vaccine is recommended.[36,52] In the United States, the CDC recommends the intramuscular route only. The intradermal method, common in many countries, uses less total vaccine in multidose vials and is thus less expensive while still being highly efficacious.[54] While some recommend preexposure prophylaxis for children younger than 15 years old in endemic areas, due to this group being responsible for approximately 50% of rabies deaths,[33,55] the current 3-dose PrEP regimen is cost-prohibitive in endemic areas, even with the lower-cost intradermal method. A PrEP regimen that induces immunity with a single injection is needed.[36]

Numerous serologic studies have provided evidence of robust production of neutralizing antibody in response to cell culture–derived vaccines. Following the use of WHO-approved vaccines, 100% of healthy individuals were found to have a significant antibody response. No individuals with circulating neutralizing antibody levels above 0.5 IU/mL have ever contracted rabies.

Animal Bite Risk Assessment. An animal bite or potential rabies exposure is a medical urgency, not an emergency. In the emergency department, PEP is either administered at the time of presentation after consultation with public health authorities or is postponed until the rabies risk of the biting animal is determined (Table 119.3). Discharge instructions for patients with postponed PEP should reflect the on-going nature of the risk assessment. Because of periodic national shortages of vaccine and immune globulin used in PEP, clinicians should consult with local or state public health authorities and complete a risk assessment before administering internal stocks of PEP supplies.

Bats are responsible for the greatest number of rabies exposures in the United States.[38] Because of the difficulty in identifying the very small bite wounds created by bats, the CDC classifies all bats found indoors with a person who was asleep or incapacitated, or a bat found near an unattended child or an adult who cannot reliably attest to their

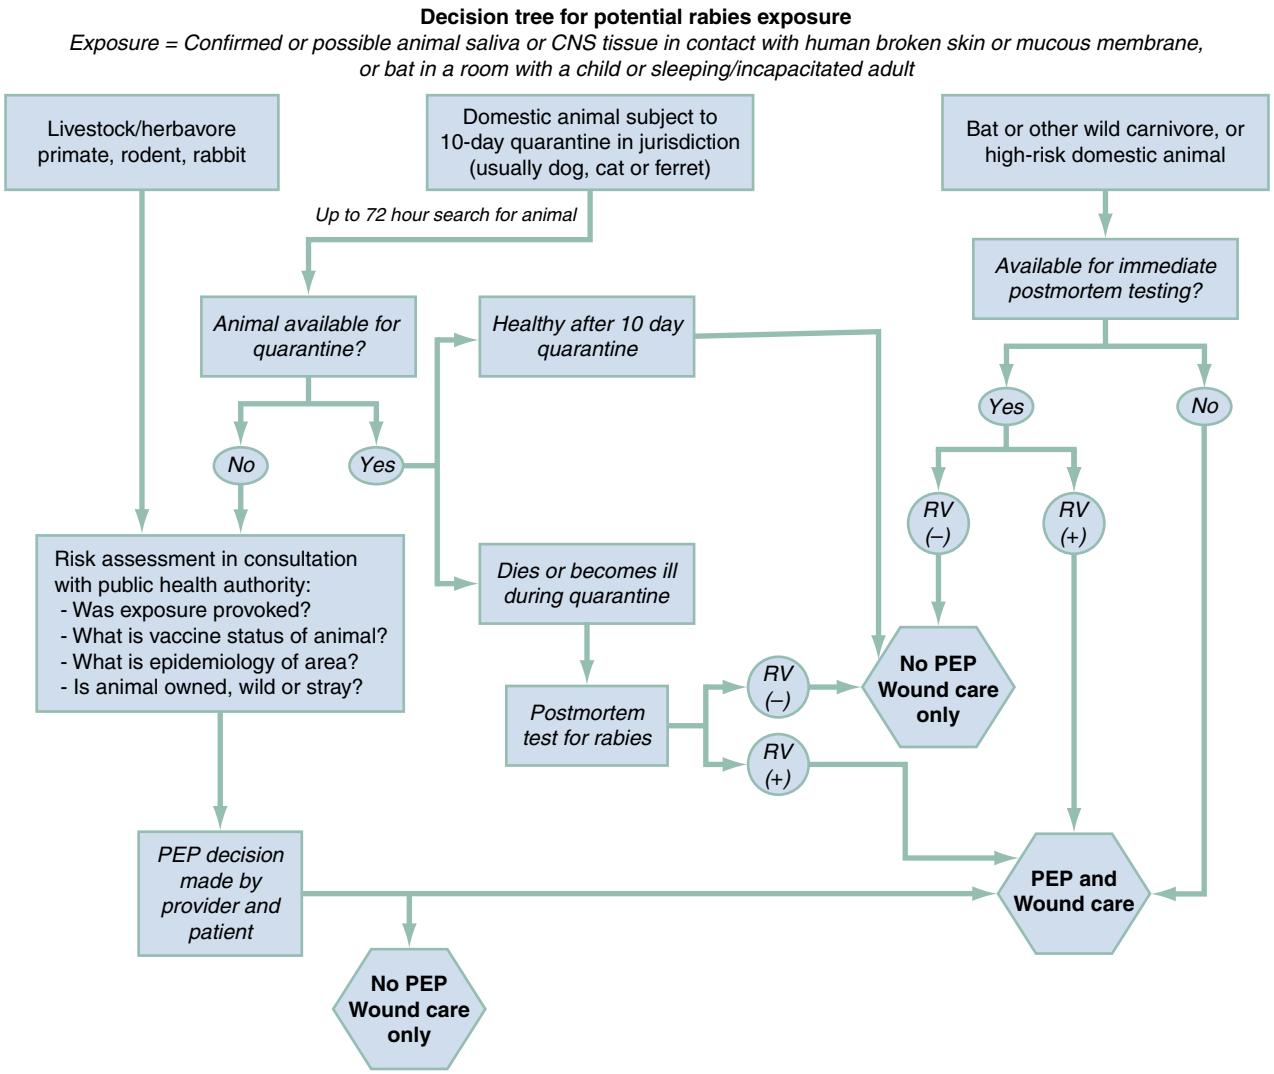

Fig. 119.12 Decision tree for potential rabies exposures.

physical contact with the bat, as an exposure. PEP is recommended under these conditions unless the bat is available for immediate testing and tests negative. In the United States, PEP always includes four doses of rabies vaccine and rabies immunoglobulin.[56]

Bites and exposure require a thorough history including geographic location where, when, and what type of exposure occurred (species, bite, scratch). Outside of the United States, WHO categorizes exposures in areas enzootic for rabies into three categories.[36] Category I includes touching or feeding animals, licks on intact skin, and contact of intact skin with secretions or excretions of a rabid animal or human. These are not regarded as significant exposures, and postexposure prophylaxis is not required. Category II includes nibbling of uncovered skin, minor scratches, or abrasions without bleeding. If these are caused by a bat, treat as category III. Vaccine should be injected as soon as possible, but RIG is not recommended for Category II. Category III includes single or multiple transdermal bites or scratches, licks on broken skin, contamination of mucous membrane with saliva from licks, and indoor exposure to bats. Category III contact requires full rabies prophylaxis including vaccine and rabies immunoglobulin.

Within the United States, most jurisdictions (state or local) require rabies vaccination of dogs and cats, and some require vaccination of pet ferrets. In addition, some livestock owners choose to vaccinate their animals against rabies. These variations in vaccination implementation result in different postexposure treatment recommendations among state public health officials for humans bitten by domestic animals. Each state and territory maintains a contact phone number for consultation for potential rabies exposure. The list of contacts is available from the U.S. Centers for Disease Control and Prevention at www.cdc.gov/rabies or by calling the CDC's information line, 877-554-4625 or 800-CDC-INFO, 24 hours/day, 7 days/week. In addition to seeking consultation for PEP, in some jurisdictions, emergency medicine clinicians must comply with mandated reporting of PEP administration to public health authorities. Clinicians should be familiar with their local regulations. Clinicians are also mandatory reporters of animal bites to animal control authorities in many states and local jurisdictions. This bite reporting initiates the process of animal location and testing or quarantine.[35,54] These PEP and bite reporting requirements are not generally waived for people bitten by their own animals.

The only species for which the shedding period has been scientifically determined are the domestic dog, cat, and ferret. A 10-day quarantine, based on the viral shedding period, is used in lieu of postmortem testing to determine the rabies risk of domestic animals in geographic areas with high rates of vaccination. Quarantine establishes that if a dog, cat, or ferret is alive on the tenth day after biting

TABLE 119.3 Assessment of Rabies Exposure

Exposure	Rationale	Action/Timing
Bite by a wild terrestrial mammal other than small rodent or lagomorph	Rabies is abundant in wildlife and cross-species transmission occurs. Many small rodents and lagomorphs paralyze and die before salivary excretion of virus occurs.	Animal will be sacrificed and submit head to public health authorities to test brain for rabies. Urgent PEP pending test results[a] If animal unavailable for testing, prepare for PEP and consult public health authorities for risk assessment.
Unprovoked bite by a pet (dog, cat, or ferret)	Pet vaccination is imperfect. Cross-species transmission occurs. Incubation periods are well-defined.	Report to animal control authorities as required. Observation for 10 d[b,c] Urgent PEP if animal is determined to have rabies
Unprovoked bite by a domestic mammal (horse, cow, or other pet)	Vaccinations exist for horses, cattle, and sheep, but efficacy and incubation period are poorly defined.	Report the incident to the local public health department. The animal may be sacrificed and the head submitted for testing.[b] Urgent PEP pending test results.
Dog or cat brings fresh prey to their master.	Without direct bite by the prey, there is no human exposure. The dog or cat is exposed.	Refer the pet to a veterinarian for assessment and treatment.
Dog or cat brings dead, desiccated prey to their master.	Virus is rapidly inactivated by desiccation or sunlight—no exposure.	No action
Physical contact with a bat	Bat bites are hard to appreciate or find by examination. Most American deaths from bat rabies have no known exposure, so known exposure confers very high odds for death from rabies.	Animal will be sacrificed and submit for testing. If positive or if animal cannot be tested, urgent PEP
Bat seen in the same room as a responsible child (>6 y) or adult	Physical contact can be reliably excluded—no exposure	No action
Bat seen in the same room as a young child (<7 y),[d] sleeping, intoxicated or cognitively impaired person	Eight percent of bats found indoors are rabid. Physical contact CANNOT be reliably excluded—exposure occurred	Animal will be sacrificed and submit for testing. If positive or if animal cannot be tested, urgent PEP
Bat found in a room that was previously occupied or seen in a hallway or room adjacent to persons who cannot report physical contact with a bat.	Risk of undetected contact is substantially lower—no exposure	No action

WHO Expert Consultation on Rabies, third report: WHO Technical Series Report No. 1012. Geneva; 2018. ISBN 978-92-4-121021-8.

a human, it did not have virus *in its saliva* on the day of the bite.[57] All other species that potentially expose a human to rabies, including domestic-wild animal hybrids, must be evaluated on a case-by-case basis without quarantine.

Wound Care. All mammal bites require meticulous wound care, and if rabies prophylaxis is considered the initial wound care is critical. Rabies virus is very sensitive to sunlight, soap, and drying. When performed within 3 hours of inoculation, scrubbing and flushing with benzalkonium chloride, 20% soap solution, or Ivory soap is nearly 100% protective. Wounds from high-risk animals should be scrubbed with soap, water, and a virucidal agent (e.g., povidone-iodine) and then flushed with saline or water.[33] As with other mammalian bites, bacterial infection, cosmetic results, and tetanus prophylaxis need to be considered, but any indicated wound closure should be sutured loosely with delayed scar revision as needed. The bite location is a significant determinant of disease potential. Wounds to the face are at highest risk, as well as other highly vascular areas, including the head, neck, genitals, and hands.

Postexposure Prophylaxis. PEP is almost 100% effective when administered according to CDC or WHO guidelines. Treatment failures usually occur when local wound care is not complete, immunoglobulin is not given, or nerve cell–derived vaccine is used. No postexposure prophylaxis failures have occurred in the United States, but scattered reports worldwide do occur. These are typically associated with variance from the WHO PEP protocol.

Once the decision to initiate PEP has been made, it should be started immediately. Currently, WHO describes 6 different protocols using 2 different routes for postexposure treatment of unimmunized individuals, 4 intradermal and 2 intramuscular to accommodate clinical care settings and preferences in different countries.[36] In the United States, the CDC recommends the intramuscular route only and 4 vaccinations over 14 days[56] (Table 119.4). Both the CDC and WHO recommend an intramuscular dose of 1.0 mL/injection, and an intradermal dose of 0.1 mL. Effective intradermal injections must form a bleb at the site. Two vaccines are currently available in the United States, RabAvert (Novartis, Chiron Behring GmbH) and Imovax (Sanofi Pasteur).

The CDC Advisory Committee on Immunization Practices (ACIP) recommends the 4-dose vaccine schedule for postexposure prophylaxis in previously unvaccinated individuals.[58] This regimen should start as soon as possible after the exposure, day 0, and should then be followed by repeated doses on days 3, 7, and 14. The dose is 1 mL of vaccine administered intramuscularly. The deltoid is the preferred site for adults; the anterolateral thigh is the preferred site in children. There is a diminished immunologic response to gluteal injection of vaccine, so this site should be avoided. The intradermal vaccination regimes recommended by the WHO are shorter in duration, but require may require two ID injections at each visit.[59]

In addition to vaccination, in the United States, once a decision to start PEP is made, rabies immunoglobulin (RIG) should be given promptly in patients not previously vaccinated. WHO only

TABLE 119.4 Postexposure Vaccination Comparison of WHO and CDC Protocols

Vaccine Regimen	Protocol Organization	Number of Vaccinations per Clinic Visit (Days 0, 3, 7, 14, 21, 28)	Route
If no previous rabies vaccinations:			
1 week, 2 sites	WHO	2-2-2-0-0	Intradermal
2 week, 1 site	WHO	1-1-1-1-0	Intramuscular
3 weeks, 1 site	WHO	2-0-1-0-1	Intramuscular
1 month, 2 sites	WHO	2-2-2-0-2	Alternative Intradermal
1 month, 4 sites	WHO	4-0-2-0-1	Alternative Intradermal
1 week, 4 sites	WHO	4-4-4-0-0	Alternative Intradermal
2 weeks, 1 site	CDC	1-1-1-1-0	Intramuscular
If previously vaccinated: 1 day, 4 sites	WHO	4-0-0-0-0	Intradermal
If previously vaccinated:3 day, 2 sites	CDC	1-1-0-0-0	Intramuscular

Center for Disease Control and Prevention: Rabies Post Exposure Prophylaxis https://www.cdc.gov/rabies/medical_care/index.html. O'Brien KL, Nolan T, on behalf of the SAGE WG on Rabies. The WHO position on rabies immunization—2018 updates. *Vaccine*. 2019;37(Suppl 1): A85-A87. PMC [article]PMCID:PMC6863036. PMID:30342901DOI:10.1016/j.vaccine.2018.10.014.

recommends RIG for Category III wounds, which differs from US practice. RIG may be derived from equine or human sources (human rabies immunoglobulin). RIG inhibits viral spread during the interval when antibodies are produced in response to the rabies vaccine.[33] Human rabies immunoglobulin produced by Grifols (HyperRAB) is available, but equine immunoglobulin[60] or monoclonal antibodies to rabies may be necessary for passive immunization if human RIG is not available.[36] Human rabies immunoglobulin, 20 IU/kg, should be administered soon after the bite occurs and not more than 7 days after the first dose of rabies vaccine. As much RIG is injected into and around the wound site as the patient will tolerate, with the remainder injected intramuscularly at a distance from the vaccine administration site.

Adverse reactions to human RIG are common, but these are primarily local reactions. Pain, induration, swelling, and erythema have been reported in 30% to 100% of injections. Headache is the most common systemic reaction to HRIG occurring in more than 50% of recipients. No deaths have been reported from human RIG.

Postexposure vaccination for previously vaccinated individuals requires wound care and a 2-dose intramuscular vaccination (days 0 and 3) or 4-dose intradermal vaccination (all on day 0). RIG is not needed in previously vaccinated individuals who have received ACIP- or WHO-approved PrEP or PEP or other vaccinations with documented rabies virus–neutralizing antibody response.[56]

Outside the United States, RIG is in short supply, and some countries do not use WHO-approved vaccines.[61] Exposed travelers from these areas may require further vaccination on return to their native country, and it is imperative that providers clarify what patients have actually received in the originating country.

Management

Reversal of the disease process in rabies remains elusive. RABVs ability to evade neuro and humoral immune responses and cross the blood-brain barrier without causing axonal apoptosis, is not completely understood, but it results in neuronal dysfunction rather than neuronal death. Without a clear understanding of the pathogenesis of this disease, targeting treatment is difficult.

Regardless of new developments, management remains focused on palliative care. Because the vast majority of human rabies occurs in low-income and rural areas, one must be cognizant of the local medical capabilities, and the local culture. Care focuses on comfort through sedation, analgesia, and rehydration in a calm, draft-free environment. The patient and family require support during the death process in a culturally sensitive manner. In resource-poor areas, the decision to initiate aggressive intensive care therapy should consider these factors: rabies vaccination prior to onset of disease, young age, rabies in previously healthy and immunocompetent individuals, initiation of treatment when neurologic signs are mild, New World bat variant rabies virus, and early detection of neutralizing anti–rabies virus antibodies in the serum and cerebrospinal fluid.[36]

Aggressive critical care management is rarely successful. In recent years, India reported survival in 6 individuals with aggressive therapy, but all suffered severe neurologic impairment.[62,63] Fifteen well-documented cases of survival with better cognitive outcomes were reported, but in all of these cases the patients had receive at least one preexposure vaccination.[45] The heralded Milwaukee Protocol, successful in treatment of a 15-year-old in Wisconsin in 2004, has not been replicated in spite of numerous attempts and should be abandoned.[64] Clinical trials for new protocols are limited. Thus, even in the ICU setting, sedation and analgesia with benzodiazepines, ketamine, haloperidol, and opiates remain the mainstay of therapy.

Disposition

Unfortunately, the survival of patients with rabies remains dismal and the disposition should focus on supportive therapy. Newer therapies may provide hope for patients in the future, but for now, prevention of canine rabies remains the single most important treatment for rabies and the best hope for eradication.

Arboviruses

Arboviruses are a group of viruses that are transmitted via arthropod vectors, generally mosquitoes and ticks. Encephalitis is a common manifestation of arboviral infection. Most of these viruses are primarily transmitted from the arthropod vector to another animal, and humans are only incidentally infected. The arboviral viruses that cause encephalitides belong to the following families: *Flaviviridae, Togaviridae, Bunyaviridae,* and *Reoviridae.*

St. Louis encephalitis virus, West Nile virus (WNV), Powassan virus, and Japanese encephalitis virus belong to the *Flaviviridae* family. Most of these viruses are maintained in a natural cycle of bird-mosquito-bird transmission. Given the mosquito vector, in North America and other temperate climates, these infections have a higher incidence in the summer months. WNV was popularized at the turn of the 20th century

because of its first-time appearance in the western hemisphere. WNV emerged in New York City in 1999 and since then has spread to the Pacific coast, as far south as Argentina, and as far north as Canada. Now WNV is the leading cause of domestically acquired arboviral infection in the United States.[65] Powassan virus is maintained in a natural cycle of ticks to rodents. In Asia, Japanese encephalitis virus is the most prevalent cause of viral encephalitis with the greatest morbidity as well.

La Crosse virus and California encephalitis virus belong to the *Bunyaviridae* family. According to reports from the CDC, La Crosse virus is the most common cause of encephalitis among children in the United States.[65] Eastern equine encephalitis (EEE) virus, Western equine encephalitis virus, and Venezuelan equine encephalitis virus belong to the *Togaviridae* family and cause infections in certain parts of North and South America.

Clinical Features

Arboviral infections cause a wide range of presentations, including subclinical disease, nonspecific febrile illness, hemorrhagic fever, meningitis, acute flaccid paralysis, and severe encephalitis. Typically encephalitis patients begin with a nonspecific febrile illness accompanied by malaise, sore throat, and respiratory symptoms. Headache, photophobia, meningismus, lethargy, somnolence, and altered mental status will then follow. Severe disease can manifest as paralysis, coma, and seizures. Depending on the virus, it can be common for patients that recover to have some neurologic sequelae.

West Nile Virus. The majority of people who become infected with WNV are asymptomatic. The most common presentation of symptomatic WNV is West Nile fever, a self-limiting illness characterized by fever, headache, malaise, and myalgias. Patients can also experience gastrointestinal symptoms. Between a quarter to half of the patients can also have an accompanying maculopapular rash on the chest, back, and arms. It is estimated that around 1% of WNV causes neuroinvasive disease. The neuroinvasive disease manifests as meningitis, encephalitis, or flaccid paralysis. WNV neuroinvasive disease carries with it a 10% mortality rate. Age and immunosuppression have been identified as a risk factor for more severe neuroinvasive disease and mortality for WNV infections.[66]

Eastern Equine Encephalitis Virus. EEE virus is the most dangerous of the viruses that cause equine encephalitides. It occurs along the Gulf and Atlantic coast with predominance in the late summer months. The usual manifestation is fever, chills, headache, and myalgias lasting 1 to 2 weeks, typically followed by resolution. A small portion of patients will go on to develop encephalitis with headache, nausea, vomiting, altered mental status, and focal neurologic deficits. Approximately 2% to 6% of infected patients develop rapidly deteriorating severe encephalitis that results in coma. EEE virus infection that results in encephalitis is associated with 30% mortality.

St. Louis Encephalitis Virus. The majority of infections are asymptomatic, but as patients get older the rate of symptomatic infections increases dramatically. The incubation period varies from 4 to 21 days. Symptomatic disease presents as fever, myalgias, and headaches. Patients older than 60 frequently present with encephalitis, with mental status ranging from lethargy to coma. Acute flaccid paralysis occurs in approximately 6% of patients with encephalitis.

Powasson Virus. The infection usually presents as fever with neurologic complaints including headache, confusion, weakness, paralysis, lethargy, or even seizures. The mortality rate is near 10%, and survivors are often left with long-term neurologic impairment.

Differential Diagnosis

The diagnosis of arboviral encephalitis is difficult based on clinical presentation alone. It shares many features with other arboviral infections, other viral causes of encephalitis, bacterial meningitis, HSV encephalitis, leptospirosis, Lyme disease, and brain abscess.

Diagnostic Testing

The primary method of diagnosis is CSF analysis for serologic markers or PCR. WNV encephalitis is diagnosed by detecting IgM antibody in CSF. Viral culture is not commonly used for these diagnoses. There is often a broad differential diagnosis when evaluating these patients, so it is crucial to elicit travel and potential exposure history to narrow the differential diagnosis. When performing a lumbar puncture, it can be helpful to obtain an extra tube or vial of CSF to put on hold. This extra CSF sample is useful because testing for arboviral infections is often sent after the initial evaluation, assessing for more common etiologies of neurologic infection, such as bacterial meningitis or HSV encephalitis, is completed. CSF demonstrates an elevated WBC count with lymphocyte predominance. Early during a WNV infection there may be a neutrophil predominance. Ancillary testing with CT or MRI may be indicated, depending on the severity of neurologic symptoms.

Management

The treatment for these entities remains largely symptomatic. There is no specific antiviral therapy or immunoglobulin treatment with proven benefit. In patients that develop cerebral edema, the therapies focus on preventing secondary brain injury and treatment of cerebral edema by maintaining adequate cerebral perfusion pressure, treating seizures, and avoiding hypoxemia, high fever, and hypoglycemia or hyperglycemia (see Chapter 4).

Disposition

Patients with neurologic symptoms should be admitted to the hospital. These patients often require neurology and infectious disease specialists to consult in their care. Arboviral infections are reportable diseases. Long-term outcomes for these patients can vary. Full recovery can usually be expected in patients with WNV meningitis. WNV encephalitis patients often have residual effects, with over half of them reporting some type of persistent symptoms (fatigue, muscle aches, decreased activity, memory difficulty, concentration difficulty) beyond 6 months.[67]

Other Arboviral Infections

Dengue Virus

Dengue is the most common virus in the *Flaviviridae* family to cause human infection. It can be found all over the world, with most infections occurring in Southeast Asia, the Western Pacific, and Central and South America. It is one of the most important causes of fever in the returned traveler. It is transmitted via the mosquito vector, *Aedes aegypti* and *Aedes albopictus,* and humans are the natural host.

Clinical Features. Dengue can cause a wide spectrum of disease. Many infected individuals with dengue are asymptomatic. Dengue fever is a self-limited illness characterized by fever, headache, retroorbital pain, severe myalgias, and arthralgias. Symptoms can last up to 1 week. Dengue hemorrhagic fever (DHF), a more severe syndrome, occurs when the following four criteria are present: (1) increased vascular permeability (pleural effusion, ascites, hemoconcentration), (2) thrombocytopenia, (3) fever lasting 2 to 7 days, and (4) hemorrhagic tendency or spontaneous bleeding. Dengue shock syndrome (DSS), the most severe presentation of dengue infection, is present when DHF occurs with circulatory shock.

Differential Diagnosis. Other diagnoses to consider in suspected dengue patients include Zika, malaria, chikungunya, rickettsial infections, leptospirosis, and other viral hemorrhagic fevers, including Ebola, Marburg, yellow fever, or bunyaviruses. It is also important to consider the diagnosis of measles in a returned febrile traveler with

a rash, because many countries that have endemic dengue also have endemic measles.

Diagnostic Testing. The diagnosis can be made via serologic testing with IgM assay, antigen testing of the viral antigen nonstructural protein 1 (NS1), or viral RNA detection with RT-PCR. Early in the course the IgM is often negative. Other laboratory findings that may be present with dengue infection include leukopenia, thrombocytopenia, elevated hematocrit (due to hemoconcentration from fluid loss), and abnormal liver function tests. In DHF, coagulopathy can be present.

Management. There are no specific antiviral agents that treat dengue. The treatment is mainly supportive. Dengue fever is usually a self-limited illness and can be treated with rest, antipyretics, analgesics, and fluid replacement therapy. Nonsteroidal antiinflammatory drugs and aspirin should be avoided given the bleeding tendencies associated with these medications. Patients with DHF and DSS require close monitoring, IV fluid replacement therapy, and organ support as indicated. Hemorrhagic sequelae are treated with blood product transfusions as needed. Steroid therapy for severe dengue has been evaluated in several low-quality studies, but the evidence to date is inconclusive, and steroid treatment cannot be recommended at this time. The control of epidemics revolves around reducing the mosquito vector population and preventing humans from being bitten by mosquitoes.

Disposition. Depending on the severity of illness, patients with dengue fever can be treated as outpatients, but some may require admission for rehydration therapy. Patients with DHF will require admission to the hospital for monitoring and IV fluid resuscitation, and patients with DSS will require admission to the ICU.

Zika Virus. Zika virus is an arbovirus in the *Flaviviridae* family that is transmitted to humans via the *Aedes* species mosquitos. Although transmission is predominantly from mosquitos, there have been reports of perinatal, in utero, sexual, and blood product transfusion–related transmission as well. In 2016 there was a large uptake in cases reported in the United States. Over 5000 cases of Zika virus were reported, with most travelers returning from Zika endemic regions.[68] Over 200 cases were reported from local transmission within the United States. Although the case fatality is low, Zika virus infection during pregnancy has been linked to severe congenital anomalies including microcephaly and other neurologic defects. This has led to the CDC issuing travel advisories to avoid Zika endemic regions for pregnant women, women planning on pregnancy, men with a pregnant partner, or men with a partner planning pregnancy.

Clinical Features. The majority of patients infected with Zika virus are asymptomatic. For those who do develop symptoms, the clinical manifestations include maculopapular rash, fever, nonpurulent conjunctivitis, headache, retro-orbital pain, myalgias, arthralgias, and vomiting. The most commonly reported symptom is an erythematous maculopapular rash (Fig. 119.13).[69] The course of the disease is typically mild with resolution within 2 weeks. Although rare, Zika infection has been associated with a variety of neurologic complications, including Guillain-Barré syndrome, meningoencephalitis, and myelitis.[70,71]

Differential Diagnosis. Other diseases with fever, rash, myalgias, and travel history should be considered, including dengue, chikungunya, malaria, rickettsial infections, leptospirosis, measles, rubella, and meningococcal disease.

Diagnostic Testing. The diagnosis of Zika virus infection can be made with RT-PCR or serology. In nonpregnant symptomatic patients with symptoms for less than 7 days, serum RT-PCR is the preferred method for diagnosis. If symptoms are present for more than 7 days, then serology is the preferred method. In pregnant symptomatic patients, RT-PCR and IgM antibody testing on a serum specimen and RT-PCR on a urine specimen are recommended.[72] It is important to test for dengue as well, as there is significant overlap in symptoms. Obtaining a CBC in severely symptomatic patients can be useful because significant thrombocytopenia has been reported in Zika infections.[73]

Fig. 119.13 Typical rash associated with Zika virus. (Courtesy of CDC website: https://phil.cdc.gov/Details.aspx?pid=21385)

Management and Disposition. Similar to other flavivirus infections, treatment largely consists of symptom management and supportive care. Antipyretics, analgesics, and hydration are the cornerstone of management. Acetaminophen is the agent of choice. If there is concern for severe thrombocytopenia or dengue infection, aspirin and NSAIDs should be avoided. Most of these patients can be discharged, and treatment can continue at home. Pregnant patients should have definite follow-up with their OB/GYN providers, given the risk of fetal anomalies. Typically, this follow-up will entail psychosocial support as well

Chikungunya Virus. Chikungunya is an arbovirus in the *Alphaviridae* family that was originally endemic to West Africa. Since early this millennium, the infection has spread broadly, responsible for multiple outbreaks in Asia, Europe, and the Indian subcontinent. In 2013, local transmission was identified in the Americas for the first time. The vectors are the same as dengue, the *Aedes aegypti* and *Aedes albopictus* mosquitoes.

Clinical Features. Chikungunya causes a self-limiting disease very similar to dengue. Fever, myalgias, and polyarthralgias are the hallmark of this disease. The joint pain can be so severe that ambulation is impaired. Symptoms typically last for 7 to 10 days. More than half of infected individuals develop a maculopapular rash several days after fever onset. Risk factors for severe disease with higher mortality include age older than 65, diabetes, and underlying cardiopulmonary disorders.

Differential Diagnosis. Other febrile illnesses with rash, myalgias, and arthralgias should be considered, including dengue, Zika, malaria, African tick bite fever, leptospirosis, measles, rubella, relapsing fever,

EBV, and meningococcal disease. Noninfectious disorders such as adult-onset Still disease and other rheumatologic disorders should also be considered.

Diagnostic Testing. The diagnosis can be confirmed via enzyme-linked immunosorbent assay (ELISA) testing for antibodies, RT-PCR for detecting viral RNA, or viral culture. Lab abnormalities associated with acute infection include abnormal liver function tests, thrombocytopenia, and lymphopenia.

Management and Disposition. Treatment is mainly supportive. Antipyretics, antiinflammatory agents, and analgesics play an important role in symptom control. IV fluids may be necessary, depending on disease severity. Prevention of disease centers on reducing mosquito exposure. Most patients can be treated at home. Patients that present with severe disease may require admission for IV hydration and observation until they are stable.

VIRAL HEMORRHAGIC FEVERS

Yellow Fever Virus

Yellow fever virus is an arbovirus in the *Flaviviridae* family that can cause a viral hemorrhagic fever. Prior to the discovery of its mosquito vector transmission, there were multiple yellow fever epidemics in Africa, Europe, and the Americas. The vector is the *Aedes* or *Haemagogus* mosquito. Vector control and development of a vaccine have significantly reduced the burden of this disease over the past several decades. Currently yellow fever occurs in tropical regions of Africa and South America.

Clinical Features

The incubation period is between 3 to 6 days. Patients present with an acute febrile illness accompanied by chills, malaise, headache, myalgias, nausea, and dizziness. Patients can have a much lower heart rate than expected in reference to the high fever that is present. This acute febrile phase of the illness can last between 3 to 6 days. Patients then experience a short period of remission, lasting up to 24 hours; some patients recover completely, whereas others go on to have a more severe recurrence of illness with fever, vomiting, jaundice, acute liver injury, acute renal failure, and hemorrhagic manifestations. The hallmark feature of yellow fever is jaundice with hemorrhagic fever. The mortality of patients with hepatorenal involvement ranges from 20 to 50%.

Differential Diagnosis

One must consider other febrile illnesses that occur in these endemic areas, including leptospirosis, relapsing fever, viral hepatitis, malaria, and other viral hemorrhagic fevers, including dengue.

Diagnostic Testing

Laboratory diagnosis is usually made by detecting IgM and neutralizing antibodies in the serum. There are a number of laboratory abnormalities that occur in this illness, including elevated aspartate transaminase (AST), alanine transaminase (ALT), and direct bilirubin. Patients with severe disease also have hematologic labs consistent with disseminated intravascular coagulation (DIC).

Management

There are no specific antiviral treatments for yellow fever. The treatment is supportive. Fluids, antipyretics, and analgesia are the main symptomatic treatments. Given the risk of hemorrhagic fever, aspirin and nonsteroidal antiinflammatory drugs should generally be avoided. If severe disease with shock develops, patients may require IV fluid resuscitation, blood product resuscitation, vasopressors, mechanical ventilation, and renal replacement therapy.

Because there is no specific treatment for yellow fever, much attention has been placed on prevention. Personal protection measures to avoid mosquito bites and vector control at the community level are important in preventing disease. The live-virus vaccine is recommended for individuals 9 months old and older who live in or are traveling to endemic areas. Many countries where yellow fever is endemic require a certificate of vaccination for entry.

Disposition

Depending on the severity of illness, patients can be treated at home or may require admission to the hospital. Severe illness may require ICU admission given the high mortality associated with severe forms of yellow fever.

Ebola

Ebola virus is an RNA virus that belongs to the *Filoviridae* family. Ebola virus disease (EVD) causes severe viral hemorrhagic fever. Ebola was first described in 1976 in Sudan and what is now the Democratic Republic of the Congo (Zaire at that time). Since then, there have been several outbreaks occurring in rural areas in Africa. The 2014 to 2016 Ebola outbreak in West Africa was the most severe in history. It began March 2014 in Guinea and then spread to Sierra Leone and Liberia. Nigeria, Senegal, and Mali have also been affected. At the close of this outbreak, 28,652 cases were identified, and 11,325 lives were claimed.[74] Prior to this outbreak, the largest recorded outbreak had resulted in fewer than 300 deaths. This outbreak also resulted in the first cases of Ebola acquired outside of Africa. A nurse assistant in Spain acquired the disease after caring for an Ebola patient transported from Sierra Leone to Spain. Subsequently, two nurses contracted Ebola in the United States after caring for an Ebola patient who contracted the virus in Liberia.[75]

The mortality rate for Ebola infections ranges from 25% to 90%. Transmission of the virus occurs by direct contact of infected tissue or infected bodily fluids, including blood, saliva, vomit, feces, or semen. Individuals are not contagious until they show symptoms. The usual incubation time is 5 to 7 days but can range from 2 to 21 days.

Clinical Features

The initial symptoms include high fever, headache, myalgias, malaise, sore throat, and profuse vomiting and diarrhea. After 5 to 7 days, patients can progress to develop the hemorrhagic manifestations, which include spontaneous bleeding, ecchymosis, and petechia. It is also common for patients to not develop any hemorrhagic complications.[76] An erythematous maculopapular rash can occur during that time that eventually desquamates. Patients can become hypovolemic and develop severe metabolic derangements secondary to fluid losses via the gastrointestinal tract. Eventually patients advance to shock and multiorgan failure.

Differential Diagnosis

The symptoms of Ebola are initially nonspecific and overlap with other diseases. Other more common infections from the endemic regions include malaria, typhoid fever, other viral hemorrhagic fevers (i.e., Marburg, bunyaviruses), meningococcemia, leptospirosis, or other bacterial illnesses.

Diagnostic Testing

Testing should only be conducted for patients that meet clinical criteria of having exposure history *and* signs or symptoms of EVD. The hospital should also have a protocol for handling lab specimens of potential EVD patients. The risk of acquiring EVD through lab testing is low but not zero. RT-PCR assay using a plasma specimen is currently the main

method of Ebola diagnosis. A rapid antigen point-of-care test with a turnaround time of 15 minutes has been developed with good sensitivity and specificity as compared to RT-PCR.[77] Laboratory findings that can accompany Ebola infection include thrombocytopenia, anemia, coagulopathy, transaminitis, elevated creatinine, hypocalcemia, and hypokalemia. All patients should have testing for malaria performed with thin and thick smear of the blood. Malaria is much more likely than Ebola in the endemic population and returned travelers. Coinfection is also common; in one study of Ebola patients in Guinea, 11% of the patients had concomitant malaria infection.[76]

Management

When managing a suspected EVD case, the important guiding principles are to treat the patient and prevent the spread of the infection. The CDC has developed practical algorithms for evaluating suspected EVD cases in United States EDs (www.cdc.gov/vhf/ebola/pdf/ed-algorithm-management-patients-possible-ebola.pdf). The basic tenets are to identify, isolate, and inform.

The main therapy for Ebola victims is supportive care. Patients are empirically managed with malaria treatment, broad-spectrum antibiotics, and antipyretics. They also require rehydration therapy, preferably with IV fluid and electrolyte repletion. Additionally, many EVD patients require support for organ failure, including renal replacement therapy, mechanical ventilation, vasopressors, or blood product administration.

Currently there are no clinically proven medical therapies against EVD. A number of therapies have been investigated, including monoclonal antibodies against Ebola viral antigens, convalescent plasma, and nucleotide analogue antiviral drugs. Unfortunately, many of these therapies have not shown clinical efficacy in studies.[78,79] The most promising therapies to date are a single monoclonal antibody, MAb114, and a triple monoclonal antibody, REGN-EB3.[80] Although specific therapies against Ebola are currently limited, a landmark breakthrough for the public health response was reached in 2019 when the FDA approved the first vaccine for prevention of EVD.[81]

Disposition

It is paramount that providers caring for potential EVD patients be familiar with proper isolation practices. The CDC stresses that health care providers should receive extensive training and demonstrate competency in Ebola-related infection control procedures, specifically in putting on and removing the PPE. Many hospitals have developed internal guidelines, but the CDC website is a useful resource and gives comprehensive guidance regarding how to deal with potential EVD patients in the United States health care setting (www.cdc.gov/vhf/ebola/healthcare-us/index.html).

The CDC has also developed a strategy to help hospitals prepare for suspected EVD cases (www.cdc.gov/vhf/ebola/pdf/preparing-hospitals-ebola.pdf). There is a tiered system categorized by frontline health care facilities, Ebola assessment hospitals, and then Ebola treatment centers. All hospitals should have and follow infection control protocols, ensure that staff is trained and competent in safe PPE practices, and have a system to manage waste disposal, cleaning, and disinfection. Patients with suspected EVD are admitted to hospital isolation rooms, and many of them will need ICU care. The mortality of EBV is high, but patients are likely to have much better outcomes than previously reported with access to medical facilities with ICUs. Of note, the Ebola patients treated in Europe and the United States had a mortality rate of 18.5%, much lower than reported in endemic regions.[82]

Marburg

Marburg virus is an RNA virus that belongs to the *Filoviridae* family. It is an important cause of viral hemorrhagic fever in central Africa. Marburg cases have occurred in Uganda, Zimbabwe, the Democratic Republic of the Congo, Kenya, and Angola. Cases have been reported outside Africa, including Germany, the former Yugoslavia, Netherlands, and the United States, all with confirmed exposure to an African source. The virus was described first in 1967 after an outbreak occurred in Marburg, Germany, when laboratory personnel working with African Green monkeys developed fever and hemorrhagic shock. Direct transmission occurs with contact with blood, secretions, or solid organs of infected individuals. It is currently thought that the natural host of the Marburg virus is the African fruit bat. The incubation period is 3 to 9 days. The disease carries a similar fatality rate to Ebola, with case fatality rate ranging from 24% to 88%.

Clinical Features

Marburg and Ebola virus cause a very similar clinical syndrome. Marburg virus illness initially causes fever, headache, malaise, and myalgias. After the third to fifth day, severe abdominal pain, cramping, vomiting, and diarrhea occurs. Around the same time, a maculopapular rash may develop. Half of the patients will also develop hemorrhagic manifestations during this time. Hematemesis, diarrhea, oropharyngeal bleeding, and bleeding from venipuncture sites can all occur. Death usually occurs because of acute blood loss and septic shock.

Differential Diagnosis

The differential diagnosis of Marburg infection is very similar to that of Ebola infection in that the symptoms are initially nonspecific and overlap with other diseases. Other more common infections from the endemic regions include malaria, typhoid fever, other viral hemorrhagic fevers (i.e., Marburg, bunyaviruses), meningococcemia, leptospirosis, or other bacterial illnesses.

Diagnostic Testing

Diagnosis requires laboratory testing, because the clinical features overlap with many other viral hemorrhagic fevers. Diagnosis can be made via RT-PCR, ELISA, antigen detection tests, serum neutralization tests, and viral culture.

Management

The priorities of managing a suspected Marburg hemorrhagic fever (MHF) case are similar to a suspected EVD case. Early recognition is key for controlling the spread of this infection. It is important to consider this disease in potential patients by assessing the patient for travel history to countries with endemic MHF or contact with someone who has had MHF within the past 3 weeks and then assessing if symptoms consistent with MHF are present. Patients identified at risk by the screening process should be isolated to a private room with private bathroom. Public health authorities and hospital infection control personnel should be immediately informed. Please refer to the Ebola section of this chapter for further details.

There is no specific treatment for MHF. The treatment is mainly supportive and directed at the patient's symptoms. Patients initially require large fluid volume resuscitation and antipyretics. Patients who develop end-organ failure need advanced therapies, such as vasopressors, mechanical ventilation, and renal replacement therapy. Patients with hemorrhagic manifestations also require blood product resuscitation with packed red blood cells (PRBCs) and fresh frozen plasma.

Disposition

Patients with MHF require hospital admission, and many will require ICU admission. It is important to observe strict isolation practices and ensure that staff use PPE when caring for the patient. When appropriate, patients should be transferred to specialized treatment centers that

are prepared for and designated to care for patients with viral hemorrhagic fevers.

Lassa Fever

Lassa virus is an *Arenavirus* that is endemic to West Africa. Its reservoir is the African rodent *Mastomys natalensis.* Humans contract the disease by exposure to urine or feces of *Mastomys natalensis.* Human-to-human transmission can occur via contact with blood or bodily secretions from infected humans. The incubation period is usually around 10 days, but can range from 3 to 21 days. Unlike Ebola and Marburg, the majority of Lassa infections are asymptomatic. The case fatality rate is less than 2%.

Clinical Features

When patients are symptomatic with Lassa fever, symptoms usually begin with gradual onset of fever and malaise. Headache, myalgias, sore throat, cough, chest pain, abdominal pain, nausea, vomiting, and diarrhea can all occur after a few days. Patients can also develop facial edema, pleural effusion, myocarditis, and encephalitis. Less than 20% of symptomatic patients progress to develop hemorrhagic manifestations. Patients that do go on to have full-blown hemorrhagic fever have a much higher mortality rate. Third-trimester pregnancy is associated with more severe disease with higher mortality as well.

Differential Diagnosis

The differential diagnosis is broad and includes that of other viral hemorrhagic fevers.

Diagnostic Testing

Diagnosis on clinical grounds alone is difficult, because Lassa fever shares features with many other diseases. Diagnosis can be made via RT-PCR, ELISA, antigen detection tests, and viral culture.

Management

Ribavirin has been shown to decrease overall mortality. The greatest effect occurs when treatment is initiated early within the first 6 days after fever onset. The remainder of treatment is supportive care with volume resuscitation, antipyretics, and blood product administration if hemorrhagic disease occurs. As with other viral hemorrhagic fevers, organ failure support with mechanical ventilation, vasopressors, and dialysis may also be needed. Although high-quality evidence does not exist, guidelines do recommend ribavirin as postexposure prophylaxis for definitive high-risk exposures.[83] Prevention of Lassa fever at the community level centers on good hygiene and rodent control.

Disposition

Symptomatic patients with Lassa fever require hospital admission. The same principles of the other viral hemorrhagic fevers of prompt recognition, identification, isolation, and informing authorities apply to Lassa fever as well. Please refer to the sections in this chapter on Ebola and Marburg for more details.

CHAPTER 119: QUESTIONS AND ANSWERS

1. In which of the following patients is antiviral treatment not recommended by the CDC for confirmed influenza infection?
   - **a.** 1-year-old male with 24 hours of symptoms
   - **b.** 22-year-old otherwise healthy female with symptoms for 3 days
   - **c.** 65-year-old male with history of asthma, coronary artery disease, and congestive heart failure with 2 days of mild symptoms
   - **d.** 35-year-old male with no significant past medical history with symptoms for 5 days, intubated with severe hypoxemic respiratory failure, admitted to the ICU

Answer: B. The 22-year-old female with no risk factors for influenza-related complications does not require antiviral treatment because her symptoms have been present for 3 days. The CDC recommends treating all patients as early as possible who are hospitalized, have severe illness, or are at risk for influenza-related complications. The greatest efficacy for antiviral treatment is within 48 hours of symptom onset, but admitted patients with severe disease should be treated regardless of symptom onset.

2. A 19-year-old female presents to the ED with fever, altered mental status, and seizures. She is a college student and lives in a dormitory. Her only past medical history is occasional cold sores. She had been in her usual state of health until 2 days ago when she developed fevers up to 38.5°C and headache. Today she became more lethargic and had two generalized seizures prior to ED arrival. What is the next best course of action?
   - **a.** Administer 1000 mg of intravenous acetaminophen, 2 liters of intravenous crystalloid fluids, and admit to the observation unit with the diagnosis of viral syndrome.
   - **b.** Prescribe 1 g valacyclovir twice daily for 10 days and 650 mg acetaminophen every 4 to 6 hours as needed and discharge home.
   - **c.** Administer 2 g intravenous ceftriaxone, 1 g intravenous vancomycin, intravenous acyclovir 10 mg/kg every 8 hours, order CT scan of head, and then perform lumbar puncture.
   - **d.** Order MRI of the brain, administer 1 g phenytoin, and consult neurology.

Answer: C. This patient has HSV encephalitis. Given the high mortality associated with this condition, antiviral therapy should be started as soon as the diagnosis is suspected. There is significant overlap in the clinical presentation of bacterial meningitis and HSV encephalitis, so patients should empirically be treated for both diagnoses while awaiting CSF results. HSV encephalitis cannot be treated as an outpatient and requires 14 to 21 days of treatment with intravenous acyclovir. An MRI may be necessary eventually to look for temporal lobe involvement but is not necessary at the time of ED presentation and can be negative early in the course of disease.

3. A 32-year-old emergency medicine intern crawls into bed after a 24-hour shift in the medical intensive care unit. Her 36-week pregnant spouse and 18-month-old daughter are asleep as she climbs into their bed. She is awakened from a dead sleep 3 hours later when her wife asks, "What is that brown thing on the ceiling?" Using a tennis racket, the bat is successfully encouraged out of the window. The intern calls you and asks if they need to be vaccinated. Your recommendations should include which of the following?
   - **a.** PEP (postexposure prophylaxis) is contraindicated in the pregnant spouse.
   - **b.** The 18-month-old and intern need PEP.
   - **c.** The spouse needs PEP.
   - **d.** They need better screens on their windows.

Answer: B. In spite of little evidence for a bite or scratch, the intern and 18-month-old fulfill requirements for PEP. Per CDC recommendations, based on developmental staging, the 18-month-old girl cannot know whether an exposure may have happened. The intern does not explicitly meet the requirements for PEP because she is not a child, developmentally challenged, or intoxicated but, after a 24-hour shift, she was likely in a state of deep sleep and would not have been aware of her surroundings. Initiating PEP for her should be seriously considered. Although there is no contraindication for PEP during pregnancy, at 36 weeks, her spouse probably was not sleeping well and was certainly more aware of her surroundings than the intern. PEP should be considered for her but, if she is adamant that no bite or scratch occurred, it may be held.

4. An 18-year-old male who arrived from Sierra Leone 2 weeks ago presents with fever, headache, vomiting, and rash. He has a temperature of 39.5°C and erythematous maculopapular rash over his trunk, back, and arms. He appears ill and severely dehydrated. Which of the following is immediately indicated?
   - **a.** Isolation and contact the public health department
   - **b.** Thin and thick smear to check for malaria
   - **c.** Ribavirin
   - **d.** Intravenous acyclovir for 10 days

Answer: A. This is a classic presentation for Ebola virus disease (EVD). The exposure history is important. Patients should be asked if they have lived or travelled to a country with Ebola or had contact with a confirmed EVD patient in the past 21 days. If the answer is yes, then the next task is to assess for any signs or symptoms compatible with Ebola, including fever, headache, weakness, myalgias, vomiting, diarrhea, abdominal pain or hemorrhage. Once a patient has been screened positive as a potential EVD patient, he or she should be immediately isolated and hospital infection control and the health department should be notified at once.

5. Which of the following viruses is not transmitted by a mosquito vector?
   - **a.** Dengue virus
   - **b.** Chikungunya virus
   - **c.** West Nile virus
   - **d.** Lassa fever virus

Answer: D. The reservoir for the Lassa virus is an African rodent, *Mastomys natalensis*. Humans contract the disease by exposure to urine or feces of *Mastomys natalensis*. Human-to-human transmission can occur via contact with blood or bodily secretions from infected humans. The other viruses are all arboviruses transmitted via a mosquito vector.

Coronaviruses

Raghu Seethala and Sukhjit S. Takhar

KEY CONCEPTS

- Coronaviruses infect humans and animals and have the ability for recombination, generating novel viruses.
- Most human coronaviruses cause mild disease. Three coronaviruses, severe acute respiratory syndrome (SARS) associated virus, Middle East respiratory syndrome (MERS), and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), have caused severe disease in humans.
- The hallmark presentation of severe disease in coronavirus patients is respiratory failure, usually manifesting as acute respiratory distress syndrome (ARDS).
- Public health measures, including social distancing, wearing face masks, limiting social gatherings, and vaccinations, remain integral to controlling the COVID-19 pandemic.
- The vast majority of children have a benign disease course. However, a small number may develop a severe hyperinflammatory illness called multisystem inflammatory syndrome in children (MIS-C).
- Treatment for COVID-19 is rapidly evolving with the available data. Management of nonsevere illness is largely supportive and can occur at home. Treatment of moderate to severe disease occurs in the hospital and focuses on supporting oxygenation and ventilation. These patients may benefit from antiviral and corticosteroid therapies. At this point, the remainder of therapeutics remain mostly investigational.

FOUNDATIONS

Coronaviruses (CoVs) are pathogens that cause a variety of human and veterinary diseases. Seven members of the coronavirus family infect humans, and three lethal CoVs have crossed species barriers over the last twenty years as the causative agents of severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS), and coronavirus disease 2019 (COVID-19). Two (SARS-CoV and MERS-CoV) have caused dangerous epidemics. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the cause of COVID-19, was identified as the causative pathogen in a cluster of unusual pneumonia cases in Wuhan, China, in late 2019, leading to a worldwide pandemic with profound social, economic, and political consequences.[1] As of late December 2020, it has infected over 77 million and killed over 1,700,000 people globally with continued rapid spread.[2] Advances in molecular biology have increased our knowledge of these infections and have contributed to the massive scale-up of testing, development, and distribution of vaccines at an unprecedented pace. At the time of this chapter's writing, several SARS-CoV-2 vaccines are being distributed in a massive worldwide campaign.

Severe acute respiratory syndrome–coronavirus (SARS-CoV), resulting in SARS, is a virulent coronavirus that first appeared in China in November 2002. SARS affected at least 8098 individuals in 29 countries across Asia, Europe, and North and South America. Most of the cases were from China and Hong Kong, with a mortality rate near 10%. As the last reported case of SARS occurred in 2003, SARS will be discussed only briefly in this chapter.

In 2012, another novel coronavirus, *Middle East respiratory syndrome–coronavirus (MERS-CoV),* emerged, causing international concern. The majority of cases have been reported from Saudi Arabia and the United Arab Emirates, but cases have been reported in the United States, Europe, and Asia. All reported cases have been associated with direct or indirect exposure to travel or residence in the following countries: Saudi Arabia, the United Arab Emirates, Qatar, Jordan, Oman, Kuwait, Yemen, Lebanon, and Iran. MERS is still circulating in the animal population in the Middle East, causing intermittent, sporadic cases and community clusters.[3]

Coronaviruses (CoVs) are large and spherical, enveloped positive-sense RNA viruses. The virus has four major structural proteins: membrane protein (M), envelope protein (E), nucleocapsid protein (N), and the spike protein (S) (Fig. 120.1). The spike protein gives the virus its characteristic look, binds with human cells, and is also the target of novel vaccines.

SARS-CoV-2, SARS-CoV, and MERS-CoV typically cause severe disease, whereas the other human coronaviruses (HCoVs)—HKU1, NL63, OC43, and 229E—are associated with mild illness. HCoVs cause about 15% of all colds (Table 120.1).

SARS-CoV-2 is under the genus beta-coronavirus, which includes a diverse group isolated from bats. Natural selection rather than laboratory manipulation is almost certainly the origin of SARS-CoV-2.[4] Potentially, this pathogen arose from genetic reassortment. The sizeable genetic composition, along with the possibility of reassortment, increases the probability of novel coronaviruses emerging.

Transmission

Knowledge of the transmission of SARS-CoV-2 continues to evolve. Person-to-person transmission occurs primarily during close contact with an individual infected with SARS-CoV-2 via respiratory droplets. These respiratory droplets, produced by sneezing, coughing, or even talking, can land on mucous membranes, starting the infective process. Transmission is much less likely to occur through contact with contaminated surfaces. The evidence that SARS-CoV-2 is spreading via aerosols in the community is mixed, and droplet transmission is likely much more important than the aerosol route. Transmission is highly overdispersed—80% of secondary infections arose from 8.9% of index cases.[5] Nasal viral concentration is usually highest in early and presymptomatic disease, and patients are most infectious during this time. Asymptomatic and presymptomatic spread of the virus has contributed to the difficulty in controlling outbreaks; asymptomatic or

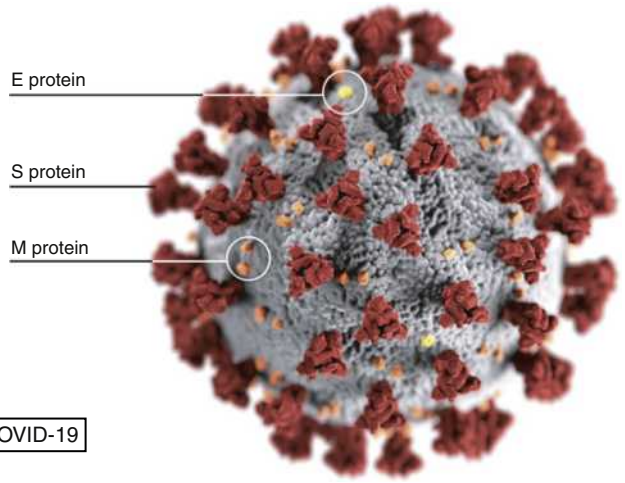

Fig. 120.1 Illustration of morphology exhibited by coronaviruses. Spikes are the S protein. (Courtesy of CDC website: https://phil.cdc.gov/Details.aspx?pid=23313.)

TABLE 120.1 Coronaviruses

Virus	Representative Disease	Clinical Features
SARS-CoV	SARS	Fevers, malaise, myalgias, chills, rigors, cough, dyspnea, tachypnea, pleuritic pain, ARDS
MERS-CoV	MERS	Fever, cough, dyspnea, sore throat, myalgias, GI symptoms, ARDS
SARS-CoV-2	COVID-19	Cough, fevers, chills, dyspnea, headaches, myalgias, diarrhea, nausea, anosmia, ageusia, ARDS
NL63, OC43, HKU1,229E	"Common cold"	Sore throat, rhinorrhea, nasal congestion, cough

presymptomatic individuals may cause as many as 50% of cases.[6-8] The duration of infectious viral shedding is unclear. Prolonged detection of viral RNA by PCR has been observed but does not necessarily mean that patients are infectious.[5] Patients are rarely contagious 10 days after symptom onset. However, those who are immune-compromised and those with severe disease can be contagious for much longer.[9] SARS-CoV-2 RNA has been detected in stool, blood, semen, and ocular secretions, but transmission via these routes is unlikely.

In health care settings, respiratory (either droplet or airborne) and contact precautions are recommended for COVID-19 patient contacts, with surgical or N95 mask, eye protection, gown, and gloves. Aerosolization can occur during certain procedures such as intubation or noninvasive ventilation. An N95 mask, powered air-purifying respirator (PAPR), or equivalent respirator, is recommended for aerosolizing procedures.

Emergency departments should screen patients with symptoms suggestive of COVID-19 so appropriate precautions can be quickly initiated. Because of the risk of asymptomatic spread during the pandemic, all persons entering medical facilities (both patients and visitors) should be masked. Persons in waiting areas and lines should be situated to maintain an adequate distance of 2 meters or more from each other. Health care workers should also be masked in the workplace to decrease the risk of asymptomatic spread to co-workers during the pandemic. In most health care settings, severe restrictions have been placed on patient visitors and accompanying family members.

MERS virus has a high mortality rate and shares many features with SARS-CoV. The mode of transmission has not been elucidated fully, but the most likely route is via direct droplet transmission. There have been case reports of transmission in the health care setting via a less than 10-minute encounter, maintaining 3 feet distance, but without any personal protective equipment (PPE). On the other hand, investigations have also revealed minimal transmission among close contacts at home, indicating that the viral load is higher in those who are more ill and in the hospital. In MERS and SARS, patients become more infectious as the illness progresses through the initial phase as viral replication increases. This contrasts with the early replication and infectivity of SARS-CoV-2, which makes the eradication of COVID-19 much more difficult.

CLINICAL FEATURES

Coronavirus Disease 2019

The incubation period for SARS-CoV-2 is up to 14 days from the time of exposure with a median of 4 to 5 days.[10] Patients present with a spectrum of illness, from minimally symptomatic, to a nonspecific influenza-like illness, with some developing a severe form requiring mechanical ventilation. Initial reports from China show 81% of individuals had mild or moderate disease, 14% had severe disease, and 5% were critical.[11] The most common presenting symptoms for patients who require medical care are cough, fevers or chills, and shortness of breath. Headaches, myalgias, diarrhea, and nausea also commonly occur. Anosmia and ageusia are also often reported.

Patients often worsen as the illness progresses, with a median time to dyspnea of 5 days after initial symptoms and acute respiratory distress syndrome (ARDS) occurring a few days after this.[12] Severe disease can occur in anyone, with the highest risk of fatal outcomes in people aged 65 years or older and those living in a nursing home or long-term care facility. Others at higher risk include those with comorbid conditions such as hypertension, cardiovascular disease, diabetes, chronic respiratory disease, cancers, renal disease, and obesity.[12] The COVID-19 pandemic has highlighted the disparities along several social determinants of health, including race, ethnicity, and socioeconomic status. Thrombotic complications are described in COVID-19 patients, leading to acute kidney injury, stroke, deep vein thrombosis, and pulmonary embolism.

Multisystem Inflammatory Syndrome in Children

Most children with COVID-19 infection have mild symptoms. Clinicians in the United Kingdom reported previously healthy children who presented with cardiovascular shock, fever, and hyper inflammation, which was later called multisystem inflammatory syndrome in children (MIS-C) (Box 120.1).[13] MIS-C has been reported to occur weeks after initial COVID-19 infection. MIS-C is also frequently associated with some degree of cardiac dysfunction. Cases of multisystem inflammatory syndromes have been reported in adults as well (MIS-A).[14] Features of MIS-C and MIS-A include cardiac dysfunction, abdominal pain, significantly elevated inflammatory markers, including C-reactive protein (CRP), D-dimer, ferritin, and interleukin-6. MIS-A is distinguished from severe COVID-19 by having minimal respiratory symptoms, hypoxemia, or radiographic abnormalities.

Severe Acute Respiratory Syndrome and Middle East Respiratory Syndrome

SARS and MERS both initially cause high fevers, malaise, myalgias, chills, and rigors. As with COVID-19, initial symptoms can be followed by cough, shortness of breath, tachypnea, and pleuritic pain. The reported incubation time for MERS-CoV is between 2 to 14 days, with a median incubation of 7 days.[3] MERS can rapidly deteriorate to acute respiratory

failure. Close to half of the patients evaluated in the hospital setting will require ICU admission. Similar to COVID-19, age, diabetes mellitus, and other chronic health problems are risk factors for poor prognosis.

Sore throat and fever were less commonly manifested in SARS, and diarrhea can occur later in the course of the disease. About one-third of patients will have improvement in symptoms after the initial febrile illness. Approximately 20% to 30% go on to require mechanical ventilation secondary to hypoxemia. Severe respiratory failure, sepsis, and multiorgan failure are the common causes of death in these patients. Risk factors for mortality include age older than 60 years old, the presence of diabetes mellitus, and heart disease.

DIFFERENTIAL DIAGNOSES

The less severe, more common coronaviruses have similar presentations to the other benign upper respiratory tract infections like rhinovirus, adenovirus, parainfluenza, and other viral causes of upper respiratory infection (URI). For SARS, MERS, and COVID-19, other diagnoses to consider include bacterial pneumonia, influenza, other viral pneumonias, or other causes of ARDS.

DIAGNOSTIC TESTING

Coronavirus Disease 2019

The most common test for the diagnosis of COVID-19 is the reverse transcriptase-polymerase chain reaction (RT-PCR) test of nasopharyngeal (NP), mid-turbinate, or anterior nasal swabs.[15] The true sensitivity and specificity of available tests is difficult to establish in the absence of an established gold standard. Testing of induced sputum samples may be more sensitive than NP swab, but collection carries risk of aerosolization.[16] RT-PCR tests can remain positive for weeks after infection but may not indicate an ongoing risk of transmission as it can detect noninfectious viral RNA fragments. Semi-quantitative methods in RT-PCR, which can identify the cycle threshold (CT), may prove useful in identifying who may be contagious, those with a low CT count being infectious. Antigen testing may be an alternative—though being less sensitive, it may be adequate in those who are contagious. Additionally, newer technology such as CRISPR may allow for widespread and cheaper testing.[17]

Serologic testing with IgM and IgG enzyme-linked immunosorbent assay (ELISA) can help determine community prevalence. (Refer to Table 120.2 to compare the various diagnostic tests.) IgM and IgG typically become detectable several days to a few weeks after symptom onset and are often negative when patients are evaluated during acute illness. Currently available tests have a range of sensitivity and specificity. There is a risk of a high proportion of false-positive tests when performed on a low-prevalence population. It is not known how long antibody levels remain detectable, and the level of immunity conferred by detectable antibodies is also unknown. The CDC does not recommend any change in personal protective equipment (PPE) use for health care workers who test positive for SARS-CoV-2 antibody.

Laboratory findings of hospitalized individuals commonly include lymphopenia, elevated levels of C-reactive protein, D-dimer, LDH, IL-6, and ferritin. There is a correlation between inflammatory marker elevation and progression to more serious illness, although the strength of associations and individual test thresholds are still being determined. Chest radiographs often show patchy bilateral infiltrates with a peripheral and basilar predominance (Figs. 120.2 and 120.3), and ground-glass opacifications in a peripheral and subpleural distribution are typically found on CT (Fig. 120.4). Lung point-of-care ultrasound has characteristic findings, including B-lines, pleural thickening, pleural irregularities, and focal consolidation (Fig. 120.5). Some early studies have demonstrated the ability of ultrasound in the ED to risk stratify the severity of illness for COVID-19 patients.[18]

Multisystem Inflammatory Syndrome in Children

As mentioned previously, patients with MIS-C have severely elevated inflammatory markers. Diagnostic testing involves measuring the degree of inflammation and assessing the severity of cardiac involvement. If MIS-C is suspected, clinicians should measure C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), fibrinogen, procalcitonin, D-dimer, ferritin, lactic acid dehydrogenase (LDH), and interleukin 6 (IL-6). Troponin, B-type natriuretic peptide (BNP) or NT-proBNP, electrocardiogram, and echocardiogram assess the severity of cardiac involvement.

BOX 120.1 Case Definition of Multisystem Inflammatory Syndrome in Children (MIS-C)

Age less than 21 years
Evidence of infection with SARS-CoV-2
Fever for at least 24 hours
Laboratory evidence of inflammation
Multisystem organ system inflammation or dysfunction
Serious illness requiring hospitalization
No alternative plausible diagnosis

From Centers for Disease Control and Prevention (CDC). MIS, multisystem inflammatory syndrome. "Information for Healthcare Providers about Multisystem Inflammatory Syndrome in Children (MIS-C)." 2020. https://www.cdc.gov/mis/mis-c/hcp/index.html?CDC_AA_refVal=https%3A%2F%2Fwww.cdc.gov%2Fmis%2Fhcp%2Findex.html. Accessed Sept 21, 2021.

TABLE 120.2 Diagnostic Testing for SARS-CoV-2

Test Type	Use	Type of Specimen	Comments
Nucleic acid amplification tests (NAATs) (including RT-PCR)	Diagnosis of current infection	Respiratory tract specimens (e.g., nasopharyngeal, oropharyngeal, nasal mid turbinate, anterior nasal, saliva)	Highly sensitive and specific. Often positive for weeks after initial diagnosis
Antigen tests	Diagnosis of current infection	Respiratory tract specimens	Less sensitive than NAAT. Potentially useful to identify those who are contagious.
Serology (antibody testing)	Diagnosis of prior infection	Blood	Potentially useful in the diagnosis of Multisystem inflammatory syndrome in children (MIS-C). Unclear if positive test means they are immune.

Fig. 120.2 Chest x-ray in mild disease demonstrating multifocal patchy bilateral airspace opacities.

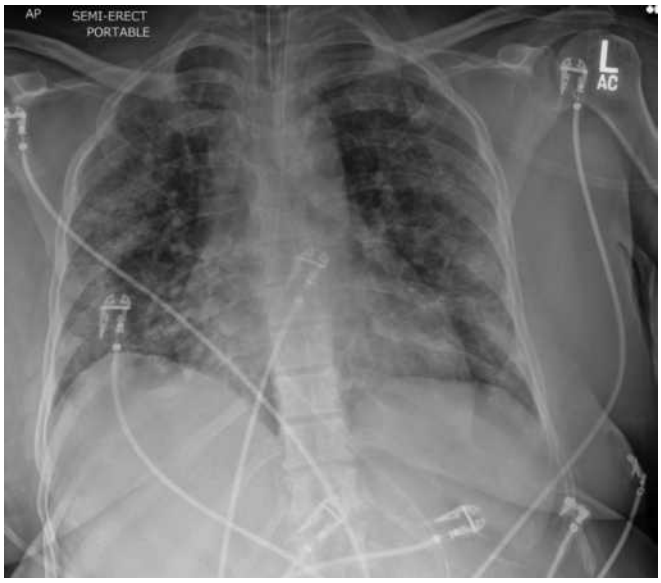

Fig. 120.3 Chest x-ray in severe disease demonstrating ground-glass opacities throughout the lungs, with the more coalescent opacities in the mid and lower zone subpleural regions.

Severe Acute Respiratory Syndrome and Middle East Respiratory Syndrome

The diagnosis of MERS can be also be confirmed by RT-PCR from upper or lower respiratory tract samples. MERS patients tend to have leukopenia, lymphocytopenia, and elevated transaminases as well. Over 80% of MERS patients have abnormalities on chest x-ray ranging from subtle findings to extensive bilateral infiltrates. SARS is thought to have been eradicated, but RT-PCR can be used to make the diagnosis.

MANAGEMENT

Coronavirus Disease 2019

Evidence on the management of COVID-19 is evolving, but treatment is largely supportive. The ED management of COVID-19 focuses on early identification, isolation, and risk stratification to decide which patients require further treatment and hospitalization. For patients that do not require hospitalization, management centers on symptom control and is similar to other nonspecific febrile viral illnesses (rest, hydration, antipyretics, and analgesics). The most important therapeutic interventions are supporting oxygenation and ventilation. At the time of this writing, only corticosteroids have been shown to decrease mortality. Some antiviral agents are thought to decrease hospital length of stay, although the data for this finding are mixed.

Oxygenation and Ventilation

Hypoxemia requiring supplemental oxygen or other ventilatory support is the most common reason for hospitalization. Patients should be given supplemental oxygen to target oxygen saturations of 92% to 96% as with other disease processes. There should be stepwise escalation to achieve this goal, starting with 1 to 6 L/min of oxygen via nasal cannula. If this support is not sufficient, oxygen therapy should be escalated to an Oxymizer or venturi mask. Patients with hypoxemic respiratory failure despite these measures should be tried on high-flow nasal cannula (HFNC).

Another therapeutic maneuver that has shown some promise is "awake proning" or "self-proning." This is the action of placing the nonintubated patient in the prone position. Proning increases oxygenation by improving ventilation-perfusion matching and increasing the recruitment of lung. This is typically done in moderate to severe ARDS patients who are intubated, but early on during the pandemic, multiple reports described an improvement in oxygenation with proning nonintubated patients with COVID-19 respiratory failure.[19] However, it is not clear that self-proning prevents the need for intubation.

Intubation and Mechanical Ventilation

Patients with COVID-19 may have rapid progression to respiratory failure, and these patients often meet criteria for ARDS. One study reported that approximately 12% of patients admitted to the hospital for COVID-19 required mechanical ventilation.[20] Intubation is an aerosol-generating procedure that can put the intubating clinician and other staff at increased risk. It is important to approach this procedure with caution. Guiding principles for intubation of a COVID-19 patient include reducing aerosolization of virus particles, maximizing the first attempt success rate, and reducing health care workers' exposure.[21] Intubations should be performed in a closed room, ideally a negative-pressure room, if available. All staff in the room should be protected with an N95 respirator, eye protection, gowns, and gloves. We recommend the use of high-dose neuromuscular blockade, with rocuronium 1.5 mg/kg or succinylcholine 2 mg/kg to reduce the risk of slow-onset or incomplete relaxation.[21] We also recommend videolaryngoscopy as a first-line approach to the airway, to maximize first-pass success and maintain distance between the intubating clinician and the patient.[21]

Because these patients typically meet moderate to severe ARDS criteria, postintubation management is similar to typical ARDS management. We recommend lung-protective ventilation with low tidal volumes (4–6 mL/kg/ideal body weight) targeting plateau pressures less than 30 cm H_2O (see Chapter 2). These patients usually require a moderate amount of PEEP. To tolerate these settings, these patients may need large doses of sedatives and analgesics.

Therapeutics

Medical treatments for COVID-19 are aimed at inhibiting viral replication, mitigating the inflammatory cascade, and augmenting immunity with antibodies to SARS-CoV-2. Patients may have sepsis, and treatment for bacterial pneumonia is also reasonable. Early optimism

about various treatments has typically faded once results from trials have become available; these include lopinavir/ritonavir, hydroxychloroquine, with or without azithromycin, and interferons.[22-24]

Fig. 120.4 CT scan demonstrating bilateral peripheral and peribronchovascular ground-glass opacities.

Most of the following treatments are primarily given to inpatients and are usually not administered in the ED. Symptoms can be treated with acetaminophen or NSAIDs as needed.

Antivirals. Remdesivir, an adenosine nucleotide analog active against a wide variety of RNA viruses including SARS-CoV-2, shows some promise in early studies and has gained FDA authorization for treatment of SARS-CoV-2. It may be more effective when started early in the course of infection.[25] The dose of remdesivir is 200 mg intravenously on day one and 100 mg a day for an additional 4 days days, depending on severity. The greatest benefits of remdesivir appear to be in hospitalized patients requiring low-flow supplemental oxygen and within 10 days of symptom onset.[25] A shorter course of 3-day remdesivir may be used for patients who are positive, largely symptomatic, but at high risk of developing severe disease. Results of ongoing trials continue to inform the role of remdesivir. However, due to the viral dynamics, we suspect that the benefit of remdesivir in hospitalized patients will be minimal, much like giving oseltamivir in those with later presentations of influenza.

Convalescent Serum and Monoclonal Antibodies. Convalescent serum has been used for over a century for viral infections and even bacterial infections. Studies are underway for pooled and concentrated antibodies specific for COVID-19, and for monoclonal antibodies that target SARS CoV-2. Serum obtained from people who have recovered from COVID-19 appears to be safe but likely will not prove to be effective. A monoclonal antibody targeting the spike protein recently obtained emergency use authorization for treatment of mild

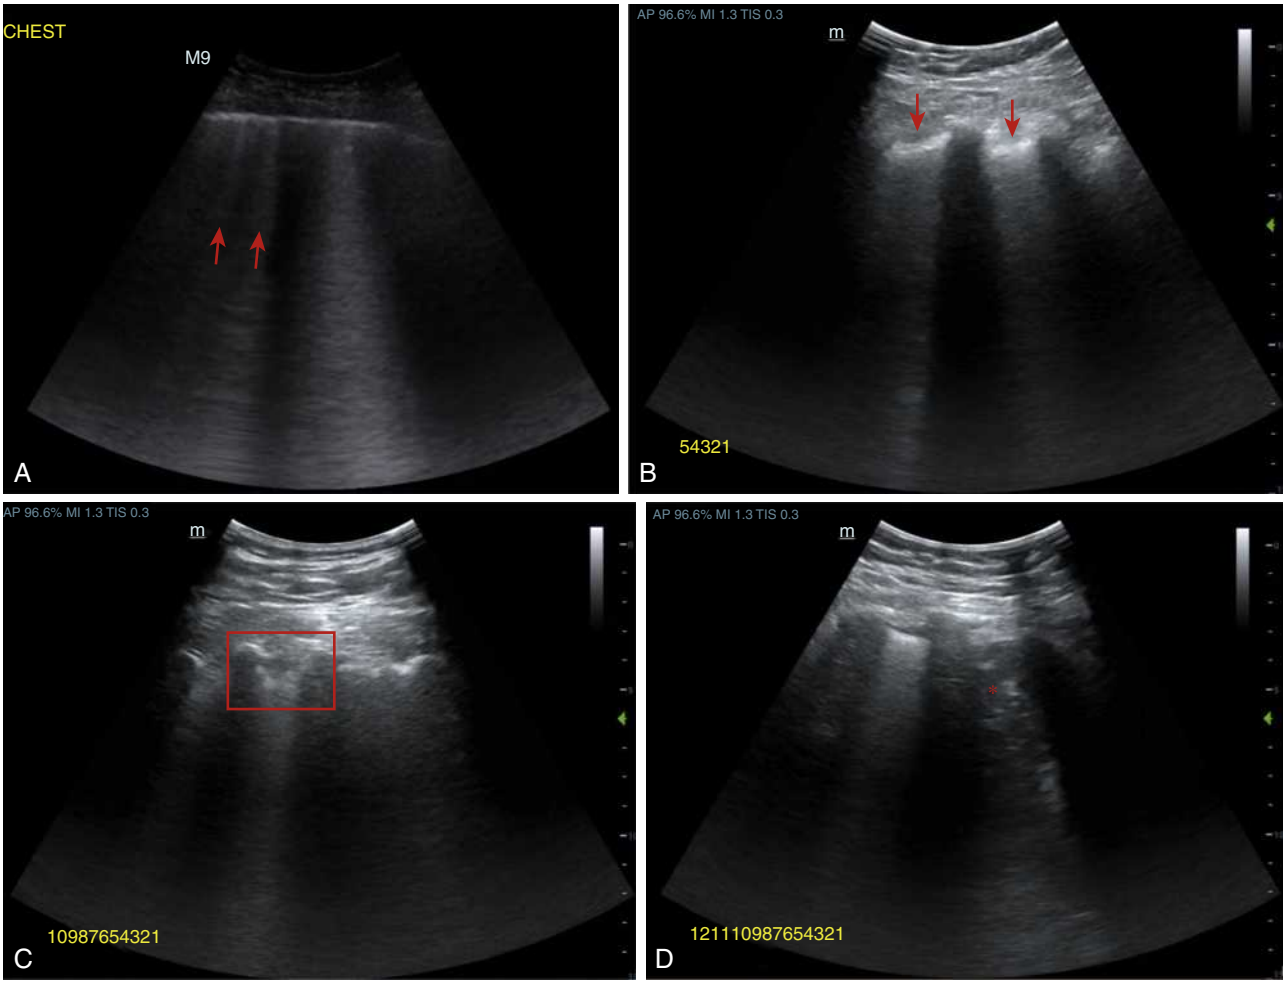

Fig. 120.5 Lung ultrasound demonstrating typical findings in COVID-19. (A) Isolated B-lines (*red arrow*). (B) Confluent B-lines (*red arrow*). (C) Irregular and thickened pleura (*red box*). (D) Subpleural consolidation (*red star*).

to moderate COVID-19.[26] Monoclonal antibodies are being evaluated for those early in their course and emergency departments may be a site where they are infused. We are hoping for a safe, oral medication for COVID-19, but at this time, there are no approved medications. Attempts at treatment with hydroxychloroquine, azithromycin, ivermectin, and zinc showed initial promise in small, uncontrolled studies but were found to be ineffective in more robust investigations.

Immunomodulatory Drugs Including Corticosteroids. Cytokine storm may trigger severe COVID-19 morbidity. Monoclonal antibodies targeting IL-6 and other components of the inflammatory cascade have been attempted as treatments, but preliminary data suggest they are not useful. In June 2020, data from the RECOVERY trial in England suggested that dexamethasone 6 mg daily orally or intravenously for up to 10 days is beneficial in patients with severe COVID-19, defined as those with oxygen saturations of less than 94% on room air and those who require supplemental oxygen, mechanical ventilation, or ECMO.[27-29] These data were the first to show any mortality benefit in treatments for patients hospitalized with COVID-19. Recently, hydrocortisone and other steroids have also been shown to improve mortality in critically ill patients, indicating a class effect.[30,31]

Several IL-6 pathway inhibitors are being studied in patients with severe COVID-19. Trials at this time have not shown a benefit of either tocilizumab, sarilumab, nor siltuximab, contrasting with observational studies.

Anticoagulation. Patients with COVID-19 are at risk for thrombotic complications, and those exhibiting evidence of thrombotic complications should undergo appropriate imaging and occasionally receive empirical anticoagulation. However, studies of empirical anticoagulation for COVID-19 patients without evidence of thrombosis have not shown better outcomes than DVT prophylaxis alone.[32] DVT prophylaxis with low-molecular-weight heparin does not have to be started in the ED, but should be initiated within 48 hours of admission. We do not recommend routine therapeutic anticoagulation in admitted patients without another indication. We also do not recommend anticoagulation in those who are discharged.

Prevention and Vaccination

Over one hundred first-generation COVID-19 vaccines are being developed, and several vaccines have been successfully brought to market, with aggressive roll out campaigns in the United States and Europe in December 2020. However, a SARS-CoV-2 vaccine is unlikely to lead to sterilizing immunity. The virus has a short incubation period and does not have a viremic phase, unlike measles. A variety of vaccine approaches are being used, either via a protein- or gene-based approach. The mRNA and DNA vaccines are not grown in cell cultures or eggs, which consumes time, making them theoretically easier to develop quickly. These genetic platforms have positive results but need to be refrigerated at −80°F.[33] This need for refrigeration presents a challenge to global scalability and a significant barrier to extending availability to low- and middle-income countries.

At this time, public health measures, such as physical distancing, wearing a mask, hand hygiene, and limiting gathering size, remain the most important factors in decreasing transmission. The best measures to control human coronaviruses rely on a strong public health system along with rapid diagnosis and isolating those who are infected.

Multisystem Inflammatory Syndrome in Children

The mainstay of treatment is supportive care and attenuating the inflammatory response. Patients typically require fluid therapy. More severe cases may require vasopressors, inotropes, mechanical ventilation, and in cases of refractory cardiogenic shock, ECMO. Patients are treated with immunomodulatory therapies such as IVIG, glucocorticoids, or interleukin antagonists.

Middle East Respiratory Syndrome

Obtaining an accurate travel history in febrile patients with an unknown respiratory illness, with a negative MERS-CoV-2 PCR, is key to early identification of MERS cases. Nosocomial outbreak was a critical component of the 2003 SARS outbreak as well as MERS outbreaks.

There is no specific antiviral treatment for MERS. The mainstay of treatment is supportive care. For the benign URI, nothing more than rest, antipyretics, and analgesics are needed. However, patients with MERS may require more invasive supportive measures. The diagnosis of MERS will not be immediately apparent, so patients should be treated initially with antibiotics covering community-acquired or health care–associated pneumonia. If mechanical ventilation is required, they should be ventilated with a lung-protective strategy with low tidal volumes to limit additional lung injury.

Prevention of transmission is an essential component of MERS management. This involves early identification of cases and prompt isolation of suspected cases. Obtaining an accurate travel history in all febrile patients with a respiratory illness is key to early identification of MERS cases. CDC guidelines on infection control measures for these infections can be found at www.cdc.gov/sars/infection/index.html and www.cdc.gov/coronavirus/mers/infection-prevention-control.html.

DISPOSITION

Most patients with coronaviruses can be treated at home. Those with moderate to severe COVID-19 will require hospitalization. Patients who have hypoxemia with an oxygen saturation of less than 94% on room air and those requiring oxygen or ventilatory support are classified as severe disease and require hospitalization. Children with suspected MIS-C should be admitted. All patients who are discharged should be counseled on infection control practices and self-isolation. Return precautions should be given. Patients should be counseled to return for dyspnea and confusion. If possible, we recommend providing patients who are discharged with a pulse-oximeter and clear instructions for use and interpretation.

Patients with MERS have a case fatality rate of 35% and will likely require admission to the hospital and ICU, depending on the severity of illness. Patients with suspected MERS should be isolated with contact precautions and airborne isolation, as are those with COVID-19. The hospital infection control team and department of public health should be notified immediately for patients under investigation for MERS.

CHAPTER 120: QUESTIONS AND ANSWERS

1. Which of the following viruses are not known to be currently circulating in the wild?

a. Middle East respiratory syndrome–related coronavirus (MERS-CoV)
b. Severe acute respiratory syndrome coronavirus (SARS-CoV)
c. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV2)
d. Measles

Answer: B. The last reported case of SARS was in 2003. There are still sporadic cases of MERS in the Middle East. Currently there is a global pandemic caused by SARS-CoV-2. SARS carried a high mortality and similarities of SARS-CoV-2 to SARS informed some of the original pandemic response to COVID-19.

2. What are classic CXR findings of SARS-CoV-2 (COVID-19)?

a. Patchy, ground-glass opacities
b. Pneumothorax
c. Lobar consolidation
d. Pleural effusion

Answer: A. Ground-glass opacities, particularly in the lower lobes, are the most common findings of COVID-19 on CXR and on CT scans. In fact, early diagnosis of COVID-19 in many areas relied on radiographs because the results of PCR testing were often delayed.

3. Which of the following medications has proven to reduce mortality in those with severe COVID-19?

a. Dexamethasone
b. Hydroxychloroquine
c. Lopinavir/ritonavir
d. Low-molecular-weight heparin

Answer: A. Dexamethasone was the first agent to show a mortality benefit in those who were hospitalized with COVID-19. Hydroxychloroquine and many other medications showed some in vitro activity against the virus, but well controlled studies did not show any benefit.

HIV

Bhakti Hansoti

KEY CONCEPTS

- HIV/AIDS can affect any organ system, and the nonspecific complaints seen with viral illness are common. Consider acute HIV infection in the evaluation of patients with mononucleosis-like syndromes in the presence of risk factors.
- The presenting illness may originate from acute HIV infection, opportunistic infections, medication side effects, inflammation, and immune reconstitution inflammatory syndrome (IRIS).
- Patients with CD4+ count above 500 cells/μL tend to have illnesses similar to those without HIV infection.
- Opportunistic infections are more frequent as the CD4+ count declines but can occur at any stage of HIV infection.
- The patient's immune status should guide formulation of the differential diagnosis, considering the CD4+ count, viral load, current medications, and prior opportunistic infections.
- The current medications used for the treatment of HIV infection (especially ART) can interact with many commonly prescribed drugs.
- The role of the emergency physician has expanded beyond the management of acute HIV-related presentations, but also the facilitation of PreP, PEP, ART initiation, and linkage to care.

FOUNDATIONS

Background and Importance

Acquired immunodeficiency syndrome (AIDS) is a pandemic caused by the human immunodeficiency virus (HIV). HIV has caused tremendous human suffering and has had an immeasurable impact on demographics, cultures, economics, and politics in most societies around the globe. There are an estimated 37.9 million people living with HIV infection worldwide, and approximately 770,000 deaths annually.[1] Significant strides have been made in areas of prevention and treatment. Since 2010 the number of new HIV infections has decreased by 16%, and the number of AIDS-related deaths by 33%.[1,2] Decline in the incidence of new cases of HIV infection and AIDS-related deaths is mostly due to the widespread use of highly active antiretroviral therapy (ART) and the treatment as prevention paradigm, resulting in a decline in the overall HIV incidence worldwide. Recent advances in HIV management have focused on the scale-up of preventative strategies such as preexposure prophylaxis (PreP), universal ART, and even same-day initiation (SDI). However, there is no cure for HIV and significant treatment gaps in at-risk populations have resulted in an increase in global HIV prevalence. Therefore, a significant number of patients in the ED may present with HIV coinfection, as well as ART-related or AIDS-related complications (Figs. 121.1 and 121.2).

Pathophysiology

HIV, a retrovirus from the lentivirus subfamily, is the cause of AIDS. There are two main subtypes of HIV, HIV-1 and HIV-2. Worldwide, the predominant virus is HIV-1. HIV-1 accounts for around 95% of all infections worldwide. HIV-2 is estimated to be more than 55% genetically distinct from HIV-1. The relatively uncommon HIV-2 virus is concentrated in West Africa but has been seen in other countries with links to West Africa. It is less infectious and progresses more slowly than HIV-1, resulting in fewer deaths. HIV-1 can be further divided into four groups; group M is the strain responsible for the global HIV epidemic and can be further divided into nine genetically distinct subtypes. The individual characteristics of each of the subtypes are beyond the scope of emergency medicine, but clinicians should be aware that most ART is largely tested on populations with subtype B, and tests used to diagnose HIV may not be sensitive to all subtypes. This is a concern in places where diverse subtypes are prevalent.

The mature HIV virion is a spherical structure with an outer envelope and inner core (Fig. 121.3). The core contains two copies of the RNA genome, enzymes (reverse transcriptase and integrase), and regulatory proteins. Surrounding the core is the viral membrane, containing the glycoproteins responsible for the attachment and entry of the virus into a CD4+ cell. In a multistep process, the HIV virion invades the host cell and integrates its genetic material into the host's chromosome (Fig. 121.4). The infection begins with the binding of the virus to the CD4+ host cell. The virus enters the cell by fusing its envelope with the target cell membrane. After internalization, reverse transcriptase forms viral DNA from the original RNA. The viral enzyme integrase then transports the newly formed viral DNA into the nucleus, where it integrates with human chromosomal DNA. Viral polyproteins and RNA are formed, and new infectious viral particles are created. This cycle continues with HIV infecting more CD4+ cells. Major targets of ART include reverse transcriptase, protease, integrase, and the CCR5 coreceptor.

The hallmark of HIV infection is CD4+ T cell destruction, leading to a deficient cell-mediated arm of the immune system. Humoral immunity is also impaired through B cell proliferation and the production of abnormal antibodies, making HIV-infected individuals more vulnerable to infections by encapsulated bacteria. HIV infection also leads to chronic immune activation. Ongoing viremia, along with pro-inflammatory cytokines, B cell proliferation, and hypergammaglobulinemia leads to a chronic inflammatory state that contributes to cardiovascular disease, cancer, and other chronic diseases in HIV-infected individuals.[2] Increased immune activation persists, even in patients with immune reconstitution on antiretroviral therapy.

HIV has been isolated from a wide range of body fluids, including semen, vaginal secretions, lymphocytes, cell-free plasma, cerebrospinal fluid (CSF), tears, saliva, urine, and breast milk.[3] However, only semen,

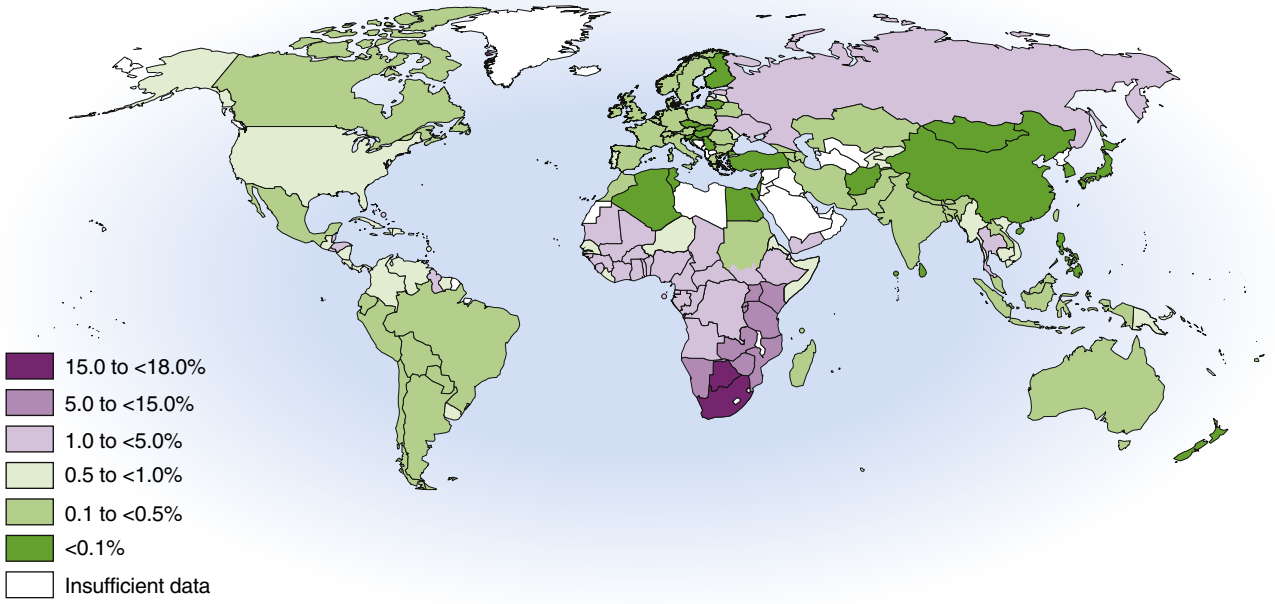

Fig. 121.1 Human immunodeficiency virus prevalence by country. (From Bennett JE, et al, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, ed 8. Philadelphia: Elsevier/Churchill Livingstone; 2015.)

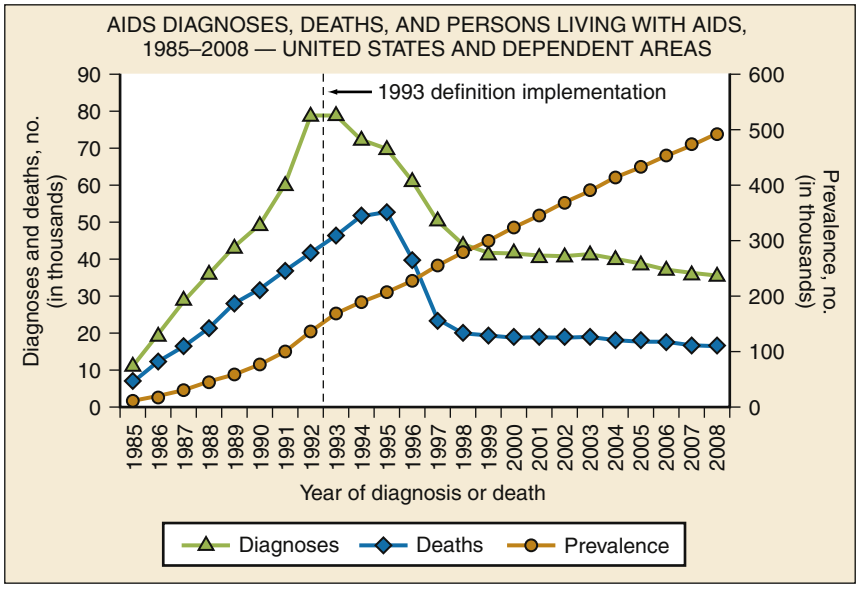

Fig. 121.2 AIDS diagnoses, deaths, and persons living with AIDS—United States. (From: Centers for Disease Control and Prevention. AIDS surveillance—trends [1985–2009]. www.cdc.gov/hiv/topics/surveillance/resources/slides/trends/index.htm.)

blood, vaginal secretions, and breast milk are significantly infectious. For transmission to occur, these fluids must come into contact with damaged tissue or with a mucous membrane or be directly injected into the bloodstream. After transmission, the virus replicates in the mucosal surface or lymphoid tissue at the site of entry in lymphocytes and macrophages. If enough cells are infected, the virus spreads to draining lymph nodes and infection is established, usually within 48 to 72 hours.

Means of transmission of HIV and the demographic distribution of the virus vary from country to country. Unprotected heterosexual intercourse with subsequent transmission of HIV to newborns and breast-fed babies (mother-to-child transmission) is the dominant mode of transmission worldwide, accounting for about 85% of all HIV infections. The main pattern of transmission in the higher-income countries of North America and western and central Europe is in men who have sex with men (MSM) and direct injection into the bloodstream in patients with intravenous drug use (IVDU).

The risk of transmission varies by modality. The average risk of HIV infection after a needlestick or cut exposure to HIV-infected blood is

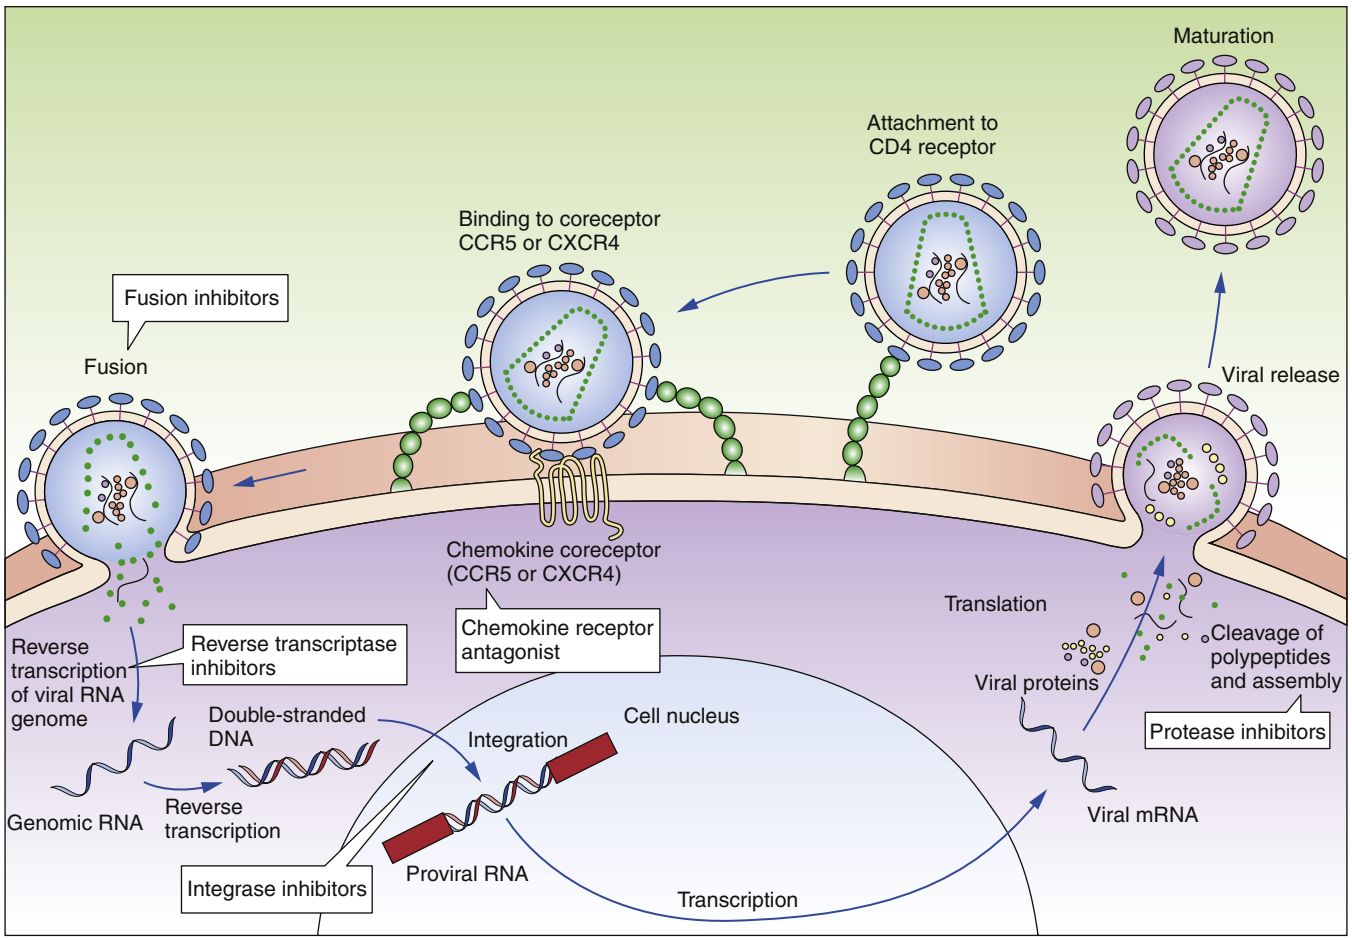

Fig. 121.3 Replicative cycle of the HIV virion. (Adapted from: Maartens G, et al. HIV infection: epidemiology, pathogenesis, treatment, and prevention. *Lancet.* 2014;384:258-271.)

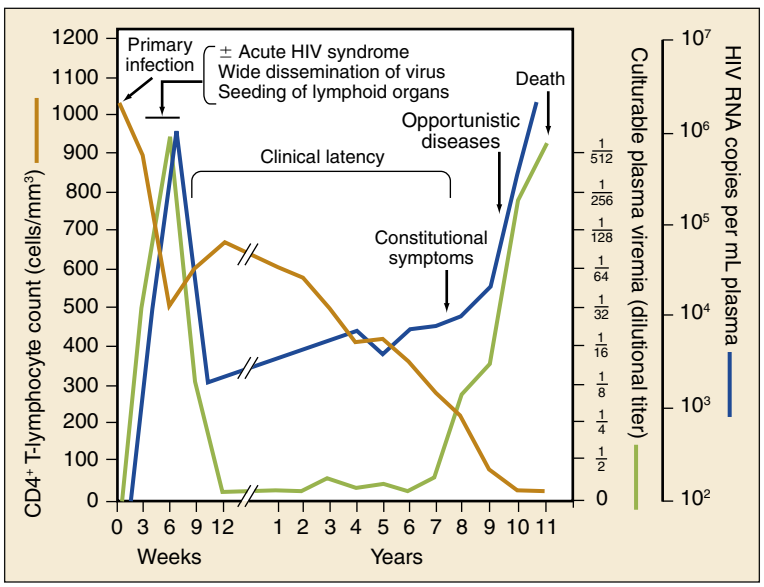

Fig. 121.4 Natural history of HIV infection in the absence of therapy in a hypothetical patient. (Adapted from: Fauci AS, et al. Immunopathogenic mechanisms of HIV infection. *Ann Intern Med.* 1996;124:654-663.)

0.3% while the risk after exposure of the eye, nose, or mouth to HIV-infected blood is estimated to be, on average, 0.1%. For people who inject drugs, the risk of transmission per injection from a contaminated needle has been estimated to be between 0.7% and 0.8%.[3] The risk estimates for the sexual transmission of HIV, per act, vary from 0.5% to 3.38% for receptive anal intercourse; 0.06% to 0.16% for insertive anal intercourse; 0.08% to 0.19% for male-to-female vaginal intercourse; and approximately 0.05% to 0.1% for female-to-male vaginal intercourse. Notably, the risk of HIV transmission is reduced by 99.2% with the combined use of condoms and antiretroviral treatment of the HIV-infected partner.

CLINICAL FEATURES

The clinical manifestations of HIV infection are varied. Patients may present to the emergency department (ED) with acute HIV infection, medication side effects, opportunistic infections, or other AIDS-related illnesses. The natural history of the disease has been altered significantly with the advent of ART. However, there still is no cure. In addition to causing progressive immune dysfunction, chronic HIV infection causes a constant inflammatory state, leading to the development of numerous manifestations that have not been classically thought of as HIV disease. These include malignant neoplasms, coronary artery disease, and neurocognitive disorders. The dramatic immune recovery seen with modern ART can also cause an inflammatory syndrome, immune reconstitution inflammatory syndrome (IRIS). IRIS can result in a paradoxical worsening of any preexisting infections. Overall, the spectrum of HIV infection is changing because of longer life expectancy and better treatment. However, many patients still have undiagnosed HIV infection and can present with acute HIV infection.

Acute HIV Infection

Acute HIV infection, also referred to as primary HIV infection, describes the earliest stage of infection with the HIV virus. Patients present with symptoms consistent with an acute, self-limited viral infection, including fever, fatigue, sore throat, pharyngitis, lymphadenopathy, muscle aches, diarrhea, and a rash. They can occur within a few days of exposure or up to 6 weeks after, and usually last about 14 days. Acute HIV infection can be complicated by encephalitis, Guillain-Barré syndrome, and mononeuritis. $CD4^+$ counts also transiently drop, occasionally to the level at which opportunistic infections can occur. Among others, *Pneumocystis jiroveci* pneumonia (PCP), toxoplasmosis, cytomegalovirus (CMV) infection, and thrush may occur in this stage.

During this time, the virus is actively replicating and antibodies to HIV have not been produced. The virus has many potential targets and viral loads are often enormous. The diagnosis of acute HIV infection has significant public health benefits. Patients with acute HIV infection transmit the infection disproportionately; these patients often do not know that they are infected, and their viral load may be in the range of millions of RNA copies per milliliter.

Diagnosis of acute HIV infection requires remembering the constellation of symptoms and understanding the pitfalls of laboratory testing for early infection. The results of routine HIV antibody testing may be negative for several weeks or even months after exposure. The diagnosis of acute HIV infection is confirmed with the presence of high titers of viral RNA and a negative antibody screen. Assay reactivity is dynamic; a plasma RNA test will detect HIV infection approximately one week before the ability to detect the p24 antigen and 12 days before antibodies to HIV develop (Table 121.1). A viral load test in the absence of symptoms of acute HIV infection is not recommended because false-positive results occur, and the test is costly.

Chronic HIV Infection

The second stage of HIV infection is chronic HIV infection (also known as asymptomatic HIV infection or clinical latency). Many patients have few or no clinical manifestations of HIV infection. There are several host and viral factors that are involved and affect the rate of progression. As a result, the asymptomatic period is variable; the average onset to AIDS from seroconversion is approximately 8 to 10 years. People who are taking ARTs may be in this stage for decades. Approximately 5% of patients are long-term nonprogressors (LTNP), sometimes also called elite noncontrollers; they are individuals who do not take ARTs and still maintain CD4 counts in the normal range indefinitely.

AIDS

AIDS is the final and most severe stage of HIV infection. Due to a severely immunocompromised state ($CD4^+$ count <200 cells/μL), the body is unable to fight off opportunistic infections, which for diagnostic purposes are reported as AIDS-defining conditions (Box 121.1). The types and frequency of opportunistic infections are more severe as the $CD4^+$ count continues to deteriorate. Some infections are so common in patients with AIDS that primary prophylaxis is indicated and is cost-effective.[4] Prophylaxis is started for PCP when $CD4^+$ counts are less than 200 cells/μL, for toxoplasmosis when $CD4^+$ counts are less than 100 cells/μL and, for *Mycobacterium avium* complex (MAC) infection when $CD4^+$ counts are less than 50 cells/μL (Table 121.2).

TABLE 121.1 HIV Testing by Laboratory Stage

	LABORATORY MARKER

BOX 121.1 AIDS-Defining Conditions

Bacterial infections, multiple or recurrent
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 mo duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 mo
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV related
Herpes simplex: chronic ulcers (>1 mo duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 mo)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 mo duration)
Lymphoma, Burkitt (or equivalent term)
Kaposi sarcoma
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii,* disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary, disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jiroveci pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 mo
Wasting syndrome attributed to HIV

Furthermore, isoniazid preventative therapy is given to all patients with a positive tuberculin skin test (TST) to prevent latent TB.

Clinical Manifestations by Organ System

Manifestations of HIV infection vary greatly, depending on the patient's immune status and whether the patient is receiving ART. Some of the clinical manifestations are secondary to severe immunocompromise state and secondary opportunistic infections, and others are due to the proinflammatory pathology of the disease process.

Cardiac Manifestations

Patients with advanced HIV infection can have a constellation of cardiac manifestations, including pericarditis, myocarditis, cardiomyopathy, pulmonary vascular disease, pulmonary hypertension, valvular disease, and neoplastic involvement of the heart. Purulent pericarditis and cardiac tamponade are potentially lethal clinical manifestations of cardiovascular disease in patients with AIDS; *Mycobacterium tuberculosis* is often the causative organism, especially in low-resource countries.

The success of ART has led to prolonged survival in patients with HIV. Cardiovascular disease is now the major cause of morbidity and mortality. HIV-infected patients have a 50% increased risk of acute coronary syndrome compared to the general population, after adjustment for risk factors. Patients receiving ART also suffer from a number of metabolic abnormalities (e.g., hyperglycemia, hyperlipidemia, lipodystrophy) and accelerated atherosclerosis, which increases their cardiovascular risk profile. Protease inhibitors, particularly ritonavir in higher doses, are strongly associated with dyslipidemia. Non-nucleoside reverse transcriptase inhibitors (NNRTIs) are associated with increases in low-density lipoprotein cholesterol and total cholesterol but also a significant increase in high-density lipoprotein cholesterol. Discontinuing ART has been shown to result in systemic inflammation, coagulation cascade activation, an increase in biomarkers associated with endothelial activation, and increased risk of major

TABLE 121.2 Prophylaxis to Prevent First Episode of Selected Opportunistic Infections

Pathogen	Indication	First-Choice Therapy	Alternative
Pneumocystis jiroveci pneumonia (PCP)	• $CD4^+ < 200$ cells/μL or oropharyngeal candidiasis • $CD4^+ < 14\%$ or history of AIDS-defining illness • $CD4^+ > 200$ cells/μL but <250 cells/μL if monitoring is not possible every 1–3 mo	TMP-SMZ	TMP-SMZ Dapsone Dapsone + pyrimethamine + leucovorin Aerosolized pentamidine Atovaquone Atovaquone + pyrimethamine + leucovorin
Toxoplasma gondii encephalitis	• *Toxoplasma* IgG–positive patients with $CD4^+$ count < 100 cells/μL • Seronegative patients receiving PCP prophylaxis not active against toxoplasmosis should have *Toxoplasma* serology retested if $CD4^+$ count declines to < 100 cells/μL • Initiate prophylaxis if seroconversion occurs.	TMP-SMZ	TMP-SMZ Dapsone + pyrimethamine + leucovorin Dapsone + pyrimethamine + leucovorin Atovaquone ± pyrimethamine + leucovorin
Disseminated *Mycobacterium avium* complex (MAC) disease	• $CD4^+$ count < 50 cells/μL (after active MAC infection is ruled out)	Azithromycin or Clarithromycin	Rifabutin (adjust dose on basis of ART interactions); rule out active TB before rifabutin is started.

ART, Antiretroviral therapy; *TB,* tuberculosis; *TMP-SMZ,* trimethoprim-sulfamethoxazole.

Guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm.

cardiovascular events. Studies have also shown that the virus alone is associated with dyslipidemia, endothelial damage, inflammation, and hypercoagulability.

Pulmonary Manifestations

Noninfectious and infectious pulmonary diseases are more common in those with HIV infection compared to uninfected individuals. Although the incidence is greatly reduced in the era of ART, pulmonary manifestations of Kaposi sarcoma and non-Hodgkin lymphoma can occur. HIV-infected patients also appear to be at increased risk for lung cancer, emphysema, cryptogenic organizing pneumonia, sarcoidosis, drug hypersensitivity, primary effusion lymphoma, foreign body granulomatosis, and lymphocytic interstitial pneumonitis.

The most frequent respiratory infections in people with HIV infection are upper respiratory tract infections and acute bronchitis. The incidence of lower respiratory tract infections increases as CD4⁺ counts decline. Potential causes of lower respiratory tract infections include viruses (influenza, respiratory syncytial, parainfluenza), bacteria, and fungi (*P. jiroveci*; Table 121.3). Bacterial pneumonia is more frequent in people infected with HIV than in uninfected persons (most commonly caused by *Streptococcus pneumoniae)*. In patients with a CD4⁺ count below 200 cells/μL, the prevalence of pneumocystis pneumonia (PCP) increases. The clinical presentation of PCP is characterized by the gradual onset of fever (79% to 100% of cases), cough (95%), and progressive dyspnea (95%). The cough is nonproductive, although sputum production does not exclude this diagnosis, and patients can be coinfected with bacterial pneumonia. Some patients, especially those taking nonsystemic prophylaxis (e.g., aerosolized pentamidine), may have extrapulmonary manifestations of PCP, such as hepatosplenomegaly, skin lesions, and ocular lesions. The most common associated laboratory abnormalities are a CD4⁺ count below 200 cells/μL and elevated lactate dehydrogenase level. Although chest radiographs can be normal, they usually show diffuse, bilateral, interstitial, or alveolar infiltrates (Fig. 121.5). High-resolution computed tomography (CT) has a high sensitivity for PCP and often reveals ground glass or cystic lesions (Fig. 121.6). The definitive diagnosis is made by isolation of the organism, commonly from respiratory specimens obtained by sputum induction, bronchoalveolar lavage, or endotracheal aspiration. Trimethoprim-sulfamethoxazole (TMP-SMZ) is also the preferred treatment of PCP; the route is dependent on the severity of the disease. There are a number of other possible regimens for those who are intolerant (Table 121.4). Patients with severe (partial pressure of oxygen 70 mm Hg or less or an alveolar-arterial oxygen gradient 35 mm Hg or

TABLE 121.3 Differential Diagnosis of Respiratory Infections in HIV-Infected Patients by CD4⁺ Count

CD4⁺ Count and Stage	Differential Diagnosis
Present at any stage	Acute bronchitis
	Bacterial pneumonia
	Tuberculosis
>500 cells/μL	Bacterial pneumonia[a]
Early HIV infection	PCP[a]
	HHV-8–related Kaposi sarcoma
200–500 cells/μL	Bacterial pneumonia[a]
	PCP[a]
<200 cells/μL	Bacterial pneumonia[a] (consider bacteremia)
AIDS	PCP[a]
	Histoplasma capsulatum or *Coccidioides immitis* pneumonia
	Cryptococcus neoformans pneumonia
	Extrapulmonary or disseminated tuberculosis[a]
≤50 cells/μL	Bacterial pneumonia[a]
Advanced HIV infection	PCP[a]

greater) PCP receive significant benefit from concurrent corticosteroid treatment and should receive a 21-day prednisone taper in addition to antibiotic therapy.

Pulmonary TB is so commonly found as a coinfection in HIV-positive patients that patients are recommended to take isoniazid preventative therapy (IPT). Patients with early HIV infection and TB have presentations similar to those of individuals without HIV infection; they often have classic symptoms of pulmonary TB, such as fever, cough, weight loss, malaise, and night sweats, with plain films showing upper lobe cavitations. In patients with advanced disease, atypical radiographic findings are more common, such as pulmonary infiltrates without preference for the upper lung fields. Patients with advanced HIV infection and severe immunosuppression may also present with extrapulmonary and disseminated TB. All patients with a clinical suspicion of TB should be placed in respiratory isolation. In addition to plain films and sputum samples, evaluation of extrapulmonary disease includes specimens of suspected areas of involvement (e.g., CSF, lymph nodes, pleural fluid, pericardial fluid, blood, urine). The treatment of TB in people with HIV infection is complicated, and drug interactions between ART and anti-TB therapy are severe and common. After initiation of anti-TB therapy, the patient requires close monitoring for assessment of adequate treatment response and for observation of signs of IRIS, a complication more common in patients with $CD4^+$ counts below 200 cells/μL.

Diagnostic evaluation of patients with HIV infection who present with respiratory complaints should be based on their HIV disease stage, as well as their clinical presentation (Table 121.5). Specific algorithms are difficult because of geographic differences in epidemiology. The evaluation includes pulse oximetry, chest radiography, and complete blood count. Additional tests may include arterial blood gas analysis to determine the need for corticosteroids in patients with PCP, levels of serum lactate dehydrogenase (elevated in PCP), 1,3-β-D-glucan (elevated in PCP), serum cryptococcal antigen, urine *Histoplasma capsulatum* antigen, and sputum studies (including Gram staining, acid-fast bacillus, and staining for *P. jiroveci*) if available. Blood cultures should be obtained before antibiotic therapy initiation. A thorough search for the pathogen is recommended in patients with HIV infection.

TABLE 121.4 Treatment of *Pneumocystis jiroveci* Pneumonia in Patients with HIV Infection

Severity of Illness	Preferred Therapy	Alternative Therapy
Moderate to severe	TMP-SMZ, IV; switch to oral administration after clinical improvement 21-day therapy	Pentamidine *or* Primaquine + clindamycin
Mild to moderate	TMP-SMZ	Dapsone + trimethoprim *or* Primaquine + clindamycin *or* Atovaquone

TMP-SMZ, Trimethoprim-sulfamethoxazole.

US Department of Health and Human Services. Guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. www.aidsinfo.nih.gov.

Oropharyngeal and Gastrointestinal Manifestations

HIV-infected patients with GI symptoms may present with common abdominal diseases or may have opportunistic infections, malignant neoplasms, or medication side effects. Patients receiving ART may suffer treatment-related adverse gastrointestinal events, including pancreatitis, hepatic steatosis, lactic acidosis, and drug-induced hepatotoxicity. Furthermore, a number of patients with HIV infection have concomitant hepatitis B virus (HBV) or hepatitis C virus (HCV) infection and may also have GI manifestations from these causes as well. Although improvements have been noted, end-stage liver disease remains a common cause of mortality in HIV-infected patients.

Patients with primary HIV infection often present with thrush (secondary to candida is most often the first manifestation of HIV

TABLE 121.5 Pulmonary Manifestations of Disease in HIV-Infected Patients

Disease	Presentation	Diagnostic Evaluation	Treatment
Bacterial pneumonia	Acute onset (<1 wk) Cough Purulent sputum Fevers, chills, rigors	Elevated white blood cell count Chest radiograph—unilateral focal consolidation $CD4^+$ count variable	Antibiotic therapy targeting *Streptococcus pneumoniae* and *Haemophilus influenzae* Also cover atypical bacterial pathogens
Pneumocystis jiroveci pneumonia (PCP)	Gradual onset (>2 wk) Nonproductive cough Dyspnea Fever	Exercise-induced hypoxia Elevated serum lactate dehydrogenase level Chest radiograph—bilateral reticular or interstitial pattern Computed tomography scan—ground glass opacity (56%) $CD4^+ < 200$ cells/μL	Trimethoprim-sulfamethoxazole for 21 days If $Pao_2 < 70$ mm Hg at room air or alveolar-arterial oxygen gradient > 35 mm Hg, give prednisone; taper over 21 days.
Mycobacterium tuberculosis infection (TB)	Gradual onset (>2 wk) Cough Fever Night sweats Weight loss Lymphadenopathy	Chest radiograph—alveolar pattern (±cavitation), miliary pattern, nodules, adenopathy, effusions $CD4^+$ count variable	Determine antituberculosis therapy with infectious disease consultant. Consider possibility of drug resistance. Multiple drug interactions exist between TB medications and antiretroviral therapy.
Kaposi sarcoma	Gradual onset (>2–4 wk) Cough Dyspnea Fever	Chest radiograph—bilateral perihilar nodules, opacities, effusions, adenopathy $CD4^+ < 200$ cells/μL	Cryotherapy, radiation therapy Infrared coagulation Sclerosing agents, intralesional vinblastine Systemic chemotherapy

infection), pharyngitis, and severe aphthous ulcers. Less commonly, oral hairy leukoplakia, caused by Epstein-Barr virus (EBV), is manifested as raised white lesions on the side of the tongue. Unlike in thrush, the lesions cannot be scraped off and are not responsive to topical antifungal agents. Kaposi sarcoma, which can occur in the mouth, is usually found on the palate.

Patients with $CD4^+$ counts below 100 cells/μl are particularly prone to esophagitis, presenting with dysphagia or odynophagia. The most common cause of esophagitis in patients with HIV infection is *Candida*, followed by herpes simplex virus, CMV, and deep aphthous ulcers. Diagnosis can be confirmed by endoscopic biopsy. Given the invasive nature of the testing, most patients are empirically treated by a 5- to 7-day course of fluconazole. However, the decision to start treatment is usually made in conjunction with the patient's infectious disease physician.

Gastroesophageal reflux is another common complaint, and treatment is with antacids. However, atazanavir requires an acidic environment to aid in absorption, and thus close monitoring is required post-treatment initiation.

Abdominal pain, diarrhea, cramping, and fever may be due to bacterial enteritis affecting the small or large bowel; causative organisms include *Clostridium difficile*, *Salmonella, Shigella, Campylobacter,* and *Yersinia* spp. Patients with advanced immunosuppression can have chronic diarrhea, often from opportunistic infections with *Cryptosporidium, Isospora,* and microsporidia. CMV is known to cause large bowel enteritis and generally occurs in severely immunosuppressed hosts with $CD4^+$ counts below 50 cells/μL. In developing countries, extrapulmonary TB should also be on the differential for abdominal disease in HIV-positive patients. The evaluation for diarrhea involves laboratory stool studies (ova and parasite, *C. difficile* toxin, bacterial culture, modified acid-fast staining) and, occasionally, colonoscopy. For patients with mild to moderate symptoms, this can be arranged as an outpatient. For patients with severe cases, dehydration, or electrolyte abnormalities, these should be performed as an inpatient. Treatment is often supportive, maintaining hydration; symptoms often persist until immune reconstitution.

Rarely, malignancies such as Kaposi sarcoma or lymphoma, have been known to result in massive GI bleeding and bowel obstruction. Disseminated opportunistic infections such as MAC and *Bartonella* may cause secondary liver failure. AIDS-related cholangiopathy, biliary obstruction from infection-associated strictures of the biliary tract, is seen with severe immunosuppression.

Central Nervous System Manifestations

Common neurologic complications of HIV infection include aseptic meningitis, cryptococcal meningitis, toxoplasmosis, primary central nervous system (CNS) lymphoma, and progressive multifocal leukoencephalopathy. Patients present with a constellation of findings, including headaches, possible focal neurologic deficits, altered mental status, and fever.

HIV itself is a neurotropic virus, and patients with an acute infection can present with aseptic meningitis with complaints of fever, headaches, and meningismus. There usually is lymphocyte-predominant, moderate pleocytosis in the CSF. *Cryptococcus neoformans* is the most common cause of meningitis in patients with AIDS. It usually affects patients who are profoundly immunosuppressed, with $CD4^+$ counts below 100 cells/μL. The disease is subacute, and patients present with fevers, malaise, and headache. Later in the course, because of increased intracranial pressure, patients experience vomiting and altered mental status. *Cryptococcus* often does not cause a significant inflammatory response, and meningeal signs are frequently absent. A lumbar puncture is diagnostic, demonstrating elevated opening pressures (70% with pressures > 200 mm Hg), presence of cryptococcal antigen (CRAG), and low white blood cell count in the CSF (typically, <50/μL). Serum CRAG testing is readily available, sensitive, and especially useful in resource-poor settings. If the serum CRAG is negative, it will not likely be positive in the CSF and not the cause of cryptococcal meningitis. Poor prognostic factors for cryptococcal meningitis are altered mental status, absence of CSF pleocytosis, CSF antigen titers greater than 1:1024, and a positive serum fungal culture. These signs are indicative of a high organism burden, elevated CSF pressure, and lack of an inflammatory response. If left untreated, cryptococcal meningoencephalitis is fatal. Therapy involves three phases: induction, consolidation, and maintenance. Two weeks of amphotericin B and flucytosine is the recommended initial treatment. Fluconazole is used for the consolidation phase and is continued until immune reconstitution ($CD4^+$ count > 100 cell/μL for more than one year). Elevated intracranial pressure is treated with repeated lumbar punctures; occasionally, a lumbar drain is needed. Cryptococcal meningitis immune reconstitution syndrome, a clinical deterioration in the setting of cryptococcal disease after the reversal of immune deficiency, can cause rapid clinical deterioration. A multicenter randomized trial has shown improved survival when ART is started five weeks after antifungal treatment compared to 1 to 2 weeks in those with risk factors.

Severely immunocompromised hosts ($CD4^+$ count < 200 cells/μL) are likely to have opportunistic infections or AIDS-associated tumors (Table 121.6). In developed countries, common causes of mass effect are toxoplasmosis and EBV-related primary CNS lymphoma; in developing countries, the cause is more likely to be tuberculomas. Toxoplasmosis is caused by reactivation of latent infection by the parasite *Toxoplasma gondii*. Most infected patients have a $CD4^+$ count below 100 cells/μL. Patients present with signs of increased intracranial pressure, such as headaches, confusion, lethargy, and seizures. Lesions are typically multiple and ring-enhancing on CT. Although the definitive diagnosis is made after a brain biopsy, patients who are serologically positive for toxoplasmosis are usually treated empirically with pyrimethamine and sulfadiazine, keeping in mind that toxoplasmosis is much less common in patients who have been receiving TMP-SMZ prophylaxis for PCP. Most patients will show radiographic improvement in 2 weeks; response to treatment obviates the need for a brain biopsy (Fig. 121.7).

Primary CNS lymphoma often looks identical to toxoplasmosis on magnetic resonance imaging (MRI) or CT scans. It also occurs with profound immunosuppression ($CD4^+$ count < 50 cells/μL). EBV is the cause of primary CNS lymphoma, and a polymerase chain reaction (PCR) analysis of the CSF, looking for the virus, has become an integral step in the evaluation of mass lesions. Treatment involves ART and chemotherapy.

Progressive multifocal leukoencephalopathy, caused by the JC virus, is characterized by demyelinating lesions in the CNS. The diagnosis is suggested by nonenhancing, hypodense lesions on CT or MRI, with a CSF PCR assay positive for the JC virus. Advanced imaging with positron emission tomography, MRI, and single-photon emission CT can help differentiate among toxoplasmosis, lymphoma, and progressive multifocal leukoencephalopathy.

The gold standard for the diagnosis of CNS mass lesions remains brain biopsy. Corticosteroid therapy can cause false-negative results on brain biopsies in patients with lymphoma, and therefore the use of corticosteroids should be limited to patients with life-threatening mass lesions.

Renal Manifestations

The two main categories of HIV-related kidney disease are HIV-associated nephropathy (HIVAN) and HIV immune complex kidney

TABLE 121.6 Differential of Focal Central Nervous System Lesions in Patients With HIV Infection

	Common Clinical Presentation	Imaging and Diagnostic Testing
Toxoplasma encephalitis	Fever Headache Altered mental status Focal neurologic findings Seizure Evolves during days to weeks	Ring enhancing (≈90% of the time) CNS lesions Frequent edema and mass effect Toxoplasma antibodies (reflects past exposure) CD4+ often <100 cells/μL PCR detection of *Toxoplasma gondii*
Primary CNS lymphoma (PCNSL)	Confusion Lethargy Memory loss Hemiparesis Aphasia Seizure Fever Night sweats Weight loss Evolves during months	CNS lesion or lesions (may have mass effect) Solitary lesions are often large (>4 cm) Some ring enhancement may occur but less regular PCR assay for Epstein-Barr virus (associated with PCNSL)
Progressive multifocal leukoencephalopathy (PML)	Progressive focal neurologic deficits (during months) Hemiparesis Visual field defects Ataxia Aphasia Cognitive impairment	Multifocal areas of demyelination primarily involving white matter Less frequent mass effect or ring-enhancing PCR assay for DNA of JC virus (causes PML)
HIV encephalopathy	Memory and psychomotor speed impairment Depressive symptoms Movement disorders	Multiple hyperintense signals in T2-weighted images Often symmetrical; not well demarcated
Cytomegalovirus encephalitis	Delirium Confusion Focal neurologic abnormalities	Magnetic resonance imaging shows multifocal scattered micronodules and ventriculoencephalitis. $CD4^+ < 50$ cells/μL
Brain abscess	Focal neurologic deficit Headache Bacteremia or craniofacial infection	Often concomitant evidence of disseminated infection
Tuberculoma	Focal neurologic deficit Headache Tuberculosis infection	Single or multiple mass lesions Can be manifested as focal lesion or meningeal infection

CNS, Central nervous system; *PCR,* polymerase chain reaction.

disease. HIVAN is a form of focal glomerulosclerosis that usually occurs in untreated individuals of African descent. Proteinuria, often severe, and an elevated creatinine concentration occur. Some patients recover renal function with ART, but many progress to end-stage renal disease and require dialysis. Transplantation is now widely accepted for patients with stable HIV infection.

ART can also affect the kidney. Indinavir, although less commonly used in industrialized countries, is associated with renal calculi. Tenofovir can cause acute renal failure, a Fanconi-like syndrome, and nephrogenic diabetes insipidus. Medications used to treat opportunistic infections can cause acute renal failure; amphotericin, pentamidine, and foscarnet are especially notorious.

Rheumatologic and Orthopedic Manifestations

HIV-infected patients are susceptible to the same types of orthopedic injuries and musculoskeletal disorders as patients without HIV infection. However, a few conditions specific to HIV infection are worth mentioning. Disseminated TB is more common in HIV-infected patients and can present with septic arthritis, spondylitis, osteomyelitis, and bursitis. Risk factors include injection drug use and hemophilia. The most common causative organism involved is *Staphylococcus aureus*. Disseminated gonococcus causing septic arthritis is another possibility, especially in sexually active individuals. In late-stage AIDS, bacillary angiomatosis secondary to *Bartonella henselae* and *Bartonella quintana* can cause disseminated disease affecting the skin, lymph nodes, liver, and CNS and can also cause long-bone osteomyelitis.

Fractures of the hip, spine, and wrist are more common in HIV-infected individuals because they have lower bone mineral density than that of age-matched controls. Osteonecrosis, especially of the femoral head, is common. Predisposing factors include corticosteroid use, ethanol abuse, and hypertriglyceridemia.

HIV-related polymyositis can occur at any stage of infection. These patients may have proximal muscle weakness, myalgias, and fatigue. Medications, especially nucleotide reverse transcriptase inhibitors (NRTIs), such as azidothymidine (AZT), can be toxic to the mitochondria and are common causes of polymyositis. Myopathies, spondylarthritis, pyomyositis, and HIV-associated arthritis are also common musculoskeletal problems. Reactive arthritis and other seronegative

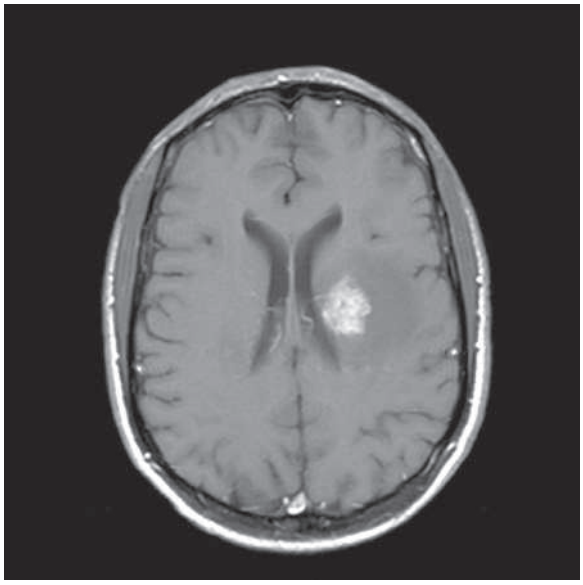

Fig. 121.7 Brain magnetic resonance image of a 38-year-old man with AIDS and *Toxoplasma* encephalitis. (From: Mandell GL, et al, ed. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, ed 7. Philadelphia: Elsevier/Churchill Livingstone; 2010.)

arthropathies are common, although it is unclear if these are because of sexual activity, generalized immune suppression, or the inflammatory response from the virus itself.

Hematologic Manifestations

HIV infection is known to cause anemia, thrombocytopenia, and leukopenia. While anemia and leukopenia occur in later stages of HIV infection, thrombocytopenia can occur at any stage. Anemia and leukopenia are often secondary to medication-associated (AZT, TMP-SMZ, and ganciclovir) bone marrow toxicity. Thrombocytopenia is often immune-related, presenting as a disease process similar to idiopathic thrombocytopenic purpura; the treatment is ART. Thrombotic thrombocytopenic purpura is also well described in HIV-infected patients and tends to occur at later stages of the disease. Lastly, systemic fungal infections and mycobacterial disease such as disseminated MAC disease can infect the bone marrow and decrease all three cell lines, as can nutritional deficiencies, such as folate and vitamin B_{12}, which are also common.

AIDS-related lymphoma (Hodgkin and non-Hodgkin) occurs more frequently in patients with advanced HIV infection. Most non-Hodgkin's lymphomas are of B cell origin and tend to be more aggressive in HIV-infected than in noninfected patients. CNS lymphomas and Burkitt's lymphoma are almost always associated with EBV, and primary effusion lymphoma is associated with human herpesvirus 8. The treatment involves standard chemotherapy and ART.

Cutaneous Manifestations

Dermatologic manifestations of HIV infection are extremely common, occurring throughout the course of HIV infection. Some skin findings are manifested early in the disease; others, found later, can be suggestive of profound immunosuppression (Box 121.2). Skin problems increase as HIV infection progresses. Recognition of HIV-related dermatologic conditions can lead to early diagnosis and can help the emergency clinician gauge the patient's immune status (Box 121.3).

Acute HIV infection often is manifested with a generalized maculopapular or morbilliform rash shortly after the onset of fevers. Oral ulcers, lesions on the palms and soles, and mucosal lesions can all be present. Aside from HIV itself, a variety of viruses can involve the skin.

BOX 121.2 Dermatologic and Mucocutaneous Manifestations of WHO Stage 4 HIV Disease

Chronic herpes simplex virus ulcers
Extrapulmonary tuberculosis
Kaposi sarcoma
Extrapulmonary cryptococcosis
Disseminated mycosis
Atypical disseminated leishmaniasis
Disseminated nontuberculous mycobacterial infection
Extrapulmonary cryptococcosis including meningitis

WHO, World Health Organization.

BOX 121.3 Cutaneous Findings Highly Suggestive of HIV Disease

Any WHO criteria for stage 4 HIV disease
Facial molluscum in an adult
Proximal subungual onychomycosis
Herpes zoster scarring
Oral hairy leukoplakia
Bacillary angiomatosis
Widespread dermatophytosis
Severe seborrheic dermatitis

WHO, World Health Organization.

Herpes simplex virus infections are often more severe and recur frequently. Chronic ulcerating herpes simplex occurs later in the disease course and is an AIDS-defining opportunistic infection. Other common viral diseases include molluscum contagiosum, human papillomavirus infection, and oral hairy leukoplakia.

Kaposi sarcoma, a vascular neoplasm, is the most common AIDS-related malignant disease in the United States, and the skin is the most commonly involved organ. Lesions are violaceous patches, nodules, or plaques (Fig. 121.8). Bacillary angiomatosis is manifested with lesions that resemble those of Kaposi sarcoma.

Disseminated fungal infections are often signs of severe immunosuppression, and patients can present with skin manifestations. Disseminated cryptococcosis can be manifested with centrally umbilicated skin lesions resembling those of molluscum contagiosum. Other fungi (e.g., *Histoplasma capsulatum*, *Coccidioides immitis, Blastomyces dermatitidis*, *Penicillium marneffei*) can cause cutaneous disease and are a significant cause of morbidity and mortality.

Noninfectious skin disorders are common. Seborrheic dermatitis, characterized by greasy, scaly patches that are often located on the nasolabial folds, eyebrows, and scalp, affects up to 80% of patients with AIDS. Cutaneous drug reactions occur with increased frequency and severity, such as toxic epidermal necrolysis. Often, the reaction is from sulfa-containing drugs. Abacavir can cause a hypersensitivity reaction that can be fatal if not recognized.

DIFFERENTIAL DIAGNOSES

Initial Evaluation

HIV-infected patients are at risk for some of the same infections and medical problems as noninfected patients, but they are more vulnerable to opportunistic and unusual infections. Knowledge of the $CD4^+$ count, along with the patient's clinical presentation, is critical in ED management. Before ART, patients were primarily hospitalized for

Fig. 121.8 Kaposi sarcoma lesions.

opportunistic infections. Patients with HIV infection are now dying of diseases that were not traditionally considered diseases of AIDS, such as heart disease, liver failure, and non–AIDS-related cancers.

The current $CD4^+$ count is a marker of the degree of immunosuppression and is critical background information for the interpretation of signs and symptoms. However, many ED patients have undiagnosed HIV infection or are medication noncompliant and may present with acute HIV infection, incidental HIV infection, or in later stages of the disease. Diagnostic clinical patterns are key to making an accurate diagnosis as to the stage of the disease. In lieu of a $CD4^+$ count, the total lymphocyte count may provide a rough approximation; a count between 1000 and 2000 cells/μL appears to be a reasonable surrogate of significant immunosuppression. Acute illness decreases peripheral lymphocyte counts and thus limits the value of the peripheral lymphocyte count as a diagnostic aid in an acute setting. However, an ED study has shown that patients with a peripheral lymphocyte count below 950 cells/μL are highly likely to have AIDS.

The possibility of HIV infection in patients presenting to the ED must be considered on a case by case basis. HIV infection should be considered in any patient who presents with unusual or recurrent serious infections without another explanation, especially patients with risk factors for HIV infection, such as IV drug users (IVDUs) and high-risk sexual practices. Although the opportunistic infections associated with AIDS can occur in the absence of HIV infection, they usually develop in patients with some form of immunosuppression. HIV infection should also be considered in younger patients who develop conditions that typically do not occur until later in life, such as herpes zoster.

Diagnostic Testing

HIV Testing

The diagnosis of HIV infection involves the detection of specific antibodies or viral antigens (see Table 121.1). Laboratory detection of HIV infection is a two-step process. The first step is a screening test; if the result is positive, a confirmatory test is performed.

The balance between public health and patient confidentiality has been an issue surrounding HIV testing and reporting. Most states and hospitals have developed policies related to these concerns. Regardless, testing should be done in a confidential manner, with appropriate follow-up and counseling.

With improved testing capabilities as well as efforts to diagnose existing cases of HIV infection in underserved populations, some experts have recommended routine screening tests. The advantages of testing in the ED include increased detection of HIV infection in difficult-to-reach populations and earlier diagnosis of HIV infection, allowing earlier ART implementation and therefore decreased viral transmission.

In 2006, the CDC published revised recommendations for HIV testing in health care settings, including hospital EDs.[5] This report recommended the use of diagnostic HIV testing and opt-out HIV screening in routine clinical care. Routine screening is recommended for 13- to 64-year-old patients, all patients who require TB treatment, those seeking treatment for sexually transmitted infections, and all pregnant women. Repeat annual screening is recommended for people at high risk. Recommendations specify that consent should be obtained for HIV testing, pretest information should be shared with patients, and those responsible for the patient's care should be notified verbally of the planned testing. The recommendations also call for reducing barriers to HIV testing. In April 2013, the U.S. Preventive Services Task Force issued similar recommendations.[3] Screening tests can include self-testing or provider-initiated testing. In emergency departments, given the resource constraints, there is a trend towards opt-out testing where the consent process is truncated and performed during triage. Testing can be in the form of a rapid point of care test, such as the INSTI©, or an oral test such as the Oraquick©. Local institutional availability and strategies for implementing testing in the ED will vary. Most rapid tests and self-tests are antibody tests; thus, it is recommended that patients with an initial negative test should retest at three months and, in the meantime, implement transmission reduction strategies such as condoms. The window period for a fourth-generation (antigen/antibody) test is still about four weeks.

MANAGEMENT

The care of the HIV-infected patient in the emergency department has evolved significantly, as has the management of HIV worldwide. In addition to the management of acute HIV infection, HIV-associated complications, and ART side effects, the modern ED physician may also be tasked with providing preexposure prophylaxis (PreP), postexposure prophylaxis, ART initiation, and linkage to care.

The clinical management of acute HIV infection is supportive. Management of opportunistic infections in the ED should be guided by the presumptive causative organism and may require consultation with Infectious Diseases.

Side effects of antiretroviral medications are extremely common. Protease inhibitors are notorious for GI side effects; most cause nausea and diarrhea. The NRTIs are mitochondrial toxic and can cause pancreatitis and hepatitis. Nevirapine, an NNRTI, can cause hepatic necrosis. Atazanavir causes Gilbert-like syndrome. Efavirenz is commonly associated with self-limited neuropsychiatric problems

Preexposure Prophylaxis

The CDC guidelines for preexposure for the prevention of HIV infection in the United States were updated in 2017. Daily oral PrEP with the fixed-dose combination of tenofovir disoproxil fumarate (TDF)

300 mg and emtricitabine (FTC) 200 mg is safe and effective in reducing the risk of sexual HIV acquisition in adults. It is recommended for patients with a substantial risk of HIV infection and for patients with HIV-positive partners. Currently, the data on the efficacy and safety of PrEP for adolescents are insufficient. Acute and chronic HIV infection must be excluded by symptom history and HIV testing immediately before PrEP is prescribed. Patients should be counseled that HIV infection should be assessed at least every three months, and renal function should be assessed at baseline and monitored every six months while on PrEP. Furthermore, when PrEP is prescribed, clinicians should provide access, directly or by facilitated referral, to proven effective risk-reduction services. Because high medication adherence is critical to PrEP efficacy but was not uniformly achieved by trial participants, patients should be encouraged and enabled to use PrEP in combination with other effective prevention methods.

Postexposure Prophylaxis

Postexposure prophylaxis (PEP) using ART significantly decreases the risk of transmission. Potentially infectious body fluids include CSF and synovial, pleural, peritoneal, pericardial, and amniotic fluids. Unless they contain blood, the following fluids are not considered infectious for HIV: vomitus, feces, nasal secretions, saliva, sputum, sweat, tears, and urine. Low-risk injuries are those involving solid needles (e.g., suture needles), those that are superficial, and those involving a low-risk source patient or body fluid. High-risk injuries include those involving hollow bore needles with visible blood and percutaneous injury from a needle that was in an artery or vein of the source patient. Unless a mucocutaneous exposure involves large volumes of blood from a source patient with a plasma HIV viral load more than 1500 copies/μL, mucocutaneous exposures are considered to be low risk.

The US Public Health Services updated guidelines on managing occupational exposures to HIV are as follows: (1) PEP is initiated when occupational exposures to HIV occur; (2) the HIV status of the exposure source patient should be determined, if possible, to guide need for HIV PEP; (3) PEP medication regimens should be started as soon as possible after occupational exposure to HIV, and they should be continued for a 4-week duration; (4) PEP medication regimens should contain 3 (or more) antiretroviral drugs for all occupational exposures to HIV; (5) expert consultation is recommended for occupational exposures to HIV, especially in cases of delayed exposure report, pregnancy or breastfeeding status of exposed individual, known or suspected resistance of source virus, underlying medical illness in the exposed individual, and unclear source (e.g., needle in sharps disposal container or laundry); (6) close follow-up for exposed personnel should be provided that includes counseling, baseline, and follow-up HIV testing, and monitoring for drug toxicity; follow-up appointments should begin within 72 hours of an HIV exposure.[6] Most institutions have specific guidelines that specify treatment regimens and follow-up plan through occupational health.

In addition to PEP, the initial response to exposure is immediate cleansing of the exposed or injured site; soap and water can be used for intact skin, and viricidal antiseptic agents, such as alcohol-based hand hygiene agents, can be used for small punctures and wounds. Mucosal surfaces and eyes should be flushed with copious amounts of water. Efforts should be made to document clinical information about the source patient, including risk factors and previous test results for HIV, HBV, and HCV, as well as to provide a description of the exposure and the time it occurred.

In situations where local expertise is unavailable, the Clinician Consultation Center (PEPline) can be contacted at 888-448-4911 for rapid, expert guidance in managing health care worker exposures to HIV and hepatitis B and C, including recommendations on when and how to initiate PEP through an online Quick Guide.[7]

Some patients may present after possible exposure to HIV/AIDS with concern about the potential of transmission. Possible means of exposure include sexual contact, injection drug use, and exposure to body fluids through broken skin or mucous membranes. The CDC recommends PEP for persons presenting within 72 hours after an exposure to a source known to be HIV-positive if contact of body fluid contaminated with blood (including semen, vaginal secretions, rectal secretions, and breast milk) was made with the vagina, rectum, eye, mouth or other mucous membranes, or nonintact skin or by percutaneous injection. Efforts should be made to determine the current HIV status of the source.

All persons offered PEP should be prescribed a 28-day course of a 3-drug antiretroviral regimen. The preferred regimen for otherwise healthy adults and adolescents is tenofovir disoproxil fumarate (tenofovir DF or TDF) (300 mg) with emtricitabine (200 mg) once daily plus raltegravir (RAL) 400 mg twice daily or dolutegravir (DTG) 50 mg daily.[4] RAL is preferred if the woman is pregnant. A modification of this regimen is recommended for children, persons with decreased renal function, and pregnant women.

Whereas most seroconversions will occur in the first three months after the exposure, these patients should be checked for HIV at six weeks, 12 weeks, and six months. The PEPline is also available to provide advice (see earlier). In addition, all persons evaluated for possible nPEP should be provided any indicated prevention, treatment, or supportive care for other exposure-associated health risks and conditions (e.g., bacterial sexually transmitted infections, traumatic injuries, hepatitis B virus, and hepatitis C virus infection, or pregnancy). Persons who report behaviors or situations that place them at risk for frequently recurring HIV exposures (e.g., injection drug use, or sex without condoms) or who report receipt of 1 course or less of nPEP in the past year should be provided risk-reduction counseling and intervention services, including consideration of preexposure prophylaxis

ART Initiation and Linkage to Care

Immediate antiretroviral therapy (ART) refers to starting HIV treatment as soon as possible after the diagnosis of HIV infection, preferably on the first clinic visit (and even on the same day the HIV diagnosis is made). This strategy also is known as "rapid ART," "same-day ART," and "treatment upon diagnosis." Immediate ART initiation may bring earlier benefits in personal health and reductions in the risk of further transmission of HIV. For persons with acute infection, immediate ART may limit the HIV viral reservoir. In pilot studies in the United States and in randomized controlled trials in resource-limited settings, rapid ART initiation has been shown to reduce time to linkage to care and viral load suppression.[8,9]

As such, same-day initiation (SDI), has not only been piloted but is the standard of care at numerous institutions in the United States. Local institutional guidelines must be followed. To support this practice, the ED clinician should identify patients suitable for ART initiation, provide counseling, complete baseline laboratory testing, and prescribe a blister pack with a locally recommended treatment regimen. ART is started before the results of baseline testing (including HIV RNA, CD4 count, genotype, HLA-B*5701, and creatinine) are available. Thus, the ART regimens must be potent and effective in the setting of high viral load and/or transmitted NRTI resistance. The preferred recommended regimens are dolutegravir (Tivicay) + TAF/FTC (Descovy) or darunavir (Prezista) + booster (ritonavir or cobicistat) + TAF/FTC.[10]

ART initiation will be successful only if closely tied to linkage to care. Patients will need additional HIV-related education, information regarding the importance of medication adherence, counseling about preventing HIV transmission, and encouragement about living healthy lives with HIV. Most institutions will have a partnership with their local infectious disease clinic. It is recommended that patients have a

phone call scheduled within 2 to 3 days of the index visit, and a clinic follow-up appointment at 1 to 2 weeks.

DISPOSITION

The widespread use of ART among HIV-positive individuals has dramatically changed the course of the disease; individuals often have sustained and lasting immune reconstitution and live relatively normal lives. Knowledge of their immune status is critical for disposition and treatment; patients with a normal or near-normal $CD4^+$ count should be treated like non–HIV-infected patients. Drug interactions are common. Patients with AIDS, unlike immunocompetent patients, often suffer from multiple, simultaneous underlying pathologic processes, making evaluation and treatment decisions even more difficult; a unifying diagnosis is not the norm. These patients are at greater risk of morbidity and mortality from common disease entities, as well as from complications of HIV/AIDS. Emergency clinicians who approach these patients with background knowledge of the potential manifestations of HIV/AIDS will be poised to deliver the best emergent care.

CHAPTER 121: QUESTIONS AND ANSWERS

1. A 52-year-old man with acquired immunodeficiency syndrome (AIDS) presents with dysphagia. The pain radiates to his chest. He does not appear toxic. There is white plaque on his tongue and oropharynx, which is easily scraped off. His $CD4^+$ count was 52 cells/μL. He was just recently started on highly active antiviral therapy (HAART) and is taking atazanavir-ritonavir, tenofovir, and emtricitabine. What is the most appropriate treatment?

a. Acyclovir
b. Fluconazole
c. Ganciclovir
d. Immediate endoscopy

Answer: C. Odynophagia with a $CD4^+$ count less than 100 cells/μL and oral thrush suggests esophageal candidiasis. If the patient can tolerate oral therapy, fluconazole is first-line treatment. Endoscopy is reserved for treatment failure or those with an atypical presentation. Cytomegalovirus and herpes simplex virus can cause esophagitis but are less common. They are diagnosed with endoscopy, often after treatment failure with fluconazole. Patients with HIV can have esophagitis due to reflux but, in this setting, empirical treatment for candidiasis is the most appropriate. Proton pump inhibitors can decrease the absorption of atazanavir and should not be prescribed without first discussing the case with the patient's human immunodeficiency (HIV) physician.

2. Which of the following is not an AIDS-defining condition?

a. Cellulitis
b. Extrapulmonary *Cryptococcus*
c. Invasive cervical cancer
d. Recurrent pneumonia

Answer: A. All the answers except A are AIDS-defining conditions.

3. A 52-year-old male patient presents with 3 days of confusion, fever, and headache. He was diagnosed with HIV 3 weeks ago and is not currently taking antiretroviral medications. His $CD4^+$ count at that time was 32 cells/μL. He has lived in the United States all his life. A head CT scan with contrast on this visit reveals multiple ring-enhancing lesions. Which of the following is the most likely cause of this central nervous system (CNS) lesion?

a. Cytomegalovirus encephalitis
b. HIV encephalopathy
c. *Mycobacterium* tuberculosis
d. *Toxoplasma gondii*

Answer: D. *Toxoplasma* encephalitis presents over days to weeks with fever, headache, altered mental status, focal neurologic findings, and/or seizures. In 90% of cases, there are ring-enhancing CNS lesions. the $CD4^+$ count is typically less than 100 cells/μL, and often the count is much lower. The main differential diagnosis in developed countries is CNS lymphoma. Patients with ring-enhancing CNS lesions are often empirically treated for *Toxoplasma,* and then a repeat CT scan is performed. A brain biopsy is diagnostic. Tuberculoma must be considered in patients with an exposure to tuberculosis and in those who live in areas highly endemic for tuberculosis.

4. A 36-year-old woman presents with a warm, red, painful lower leg. She has multiple other dermatologic concerns, including flesh-colored, dome-shaped lesions on her face, a new dark pigmented lesion on her arm, cold sores, and facial erythema. Which of her cutaneous findings suggests HIV disease?

a. Cellulitis
b. Facial molluscum
c. Melanoma
d. Oral herpes

Answer: B. HIV has many cutaneous manifestations. In this case, her facial molluscum is highly suggestive of HIV disease.

5. A 35-year-old man with AIDS presents with fever and a productive cough for 1 day. His last known $CD4^+$ count 1 month ago was 538 cells/μL. He has a lobar pneumonia in the left lower lobe on his chest radiograph. There is no evidence of lymphadenopathy. What is the most likely culprit pathogen in this case?

a. *Cryptococcus neoformans* pneumonia
b. *Pneumocystis jiroveci* pneumonia (PCP)
c. Pulmonary tuberculosis
d. *Streptococcus pneumoniae*

Answer: D. It is critical to have an understanding of diseases relative to the absolute $CD4^+$ T cell count. Patients with CD4 counts higher than 500 cells/μL typically develop illnesses similar to the general population. This patient presents with a lobar pneumonia, and *S. pneumoniae* is the most common cause. PCP is the most common opportunistic pathogen in AIDS patients, usually occurring in those with a $CD4^+$ T cell count lower than 200 cells/μL. It would be extremely unusual for PCP to cause a lobar pneumonia in someone who is immune-reconstituted. Tuberculosis can occur at any stage of HIV infection. However, the symptoms tend to be more gradual in onset, and a lobar pneumonia is unlikely.

122

Parasites

John D. Cahill and Bruce M.Becker

KEY CONCEPTS

- Parasitic diseases may manifest with almost any constellation of signs and symptoms.
- The combination of presenting signs and symptoms and a history of recent travel to specific geographic regions can lead to early diagnosis and the initiation of pharmacotherapy, decreasing morbidity and mortality and increasing the probability of eradication of the infection.
- Parasitic coinfections are particularly common in patients with HIV infection and AIDS. A travel history is essential because the clinical presentation may be atypical, morbidity and mortality are more severe, and treatment is often prolonged.
- Acute malaria should be suspected in patients with irregular high fevers associated with headache, abdominal pain, or respiratory symptoms. Falciparum malaria, which has a unique morphology easily identifiable on the peripheral blood smear, is the predominant species of malaria that causes coma and death. *P. falciparum* is the most highly resistant to chemotherapy, demanding close observation and clinical follow-up of patients. Patients who are clinically ill or who are suspected of having falciparum malaria should be hospitalized.
- Cysticercosis should be considered in the differential diagnosis of the patient with new-onset seizures, especially in patients who have been living in Central and South America.
- Giardiasis should be suspected in patients with diarrhea who have recently been camping or drinking unfiltered mountain spring water. Patients may have tolerated several weeks of severe bloating, flatulence, eructation, and weight loss without fever before seeking medical attention.
- *Trypanosoma cruzi* infection results in Chagas disease, most notable for the development of acute and chronic myocarditis. Cardiomyopathy can be severe, at times even necessitating heart transplant.

FOUNDATIONS

Parasitic infections are caused by a diverse group of eukaryotic organisms distributed across the globe, although the highest prevalence of these infections is found in tropical regions. Box 122.1 outlines the taxonomy of human parasites. Protozoal agents are unicellular, while the helminths are multicellular. These infectious organisms demonstrate complex life cycles that often include intermediate stages that target (human) hosts, along with stages of development in which they live freely in the environment. The modes of transmission to humans may include insect bites, the consumption of raw or undercooked and "infected" meat or seafood, the ingestion of water or food contaminated by human feces, or skin exposure to water or soil containing parasites at the infectious stage of development. The spectrum of clinical parasitic disease can vary from acute, life-threatening infection to chronic, progressive illness. Other infections may present with acute illness that can recover without sequalae and some cause asymptomatic infections that may manifest years later or never.

An understanding of parasitology has become increasingly crucial for emergency clinicians. In the last few decades, there has been a dramatic increase in immigration across the globe, including regions where parasitic infections are highly endemic. There has also been an increase in business and adventure travel to tropical regions, bringing immunologically naïve and vulnerable hosts to sites rich in parasitic disease. Patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who travel to or emigrate from countries where parasitic illnesses are endemic are at higher risk of infection with these illnesses. In addition, there continues to be an increase in the prevalence of endemic parasitic diseases in many rural areas of the southeastern and southwestern United States, and in some parts of Europe. Climate change has been extending the habitat of what were previously known as tropical parasites and vectors to previously temperate regions. Thus, a growing population of patients with parasitic illness now present to emergency departments, requiring the emergency clinician to consider these unusual but important diseases.

Many parasitic infections follow an indolent course or present with nonspecific symptoms, posing a challenge to diagnosis especially in the ED setting. While correct diagnosis and pharmacologic treatment of parasitic infections usually leads to a rapid and complete recovery, delayed treatment or mismanagement of parasitic diseases can have severe long-term consequences. To diagnose parasitic infection, the emergency clinician must obtain a thorough travel history, including questions summarized in Box 122.2, perform a detailed physical examination, and order appropriate laboratory studies. This information must be integrated with an understanding of the basic life cycles of parasites, incubation periods between inoculation and clinical presentation, and intersecting geography of the organism and host. Physicians must have the ability to recognize both the classical and atypical presentations of particular parasitic infections and institute appropriate therapy (Table 122.1).

Parasitic illness should be considered in the differential diagnosis of patients who have spent time in areas of the world with endemic parasitic illnesses (Table 122.2). For patients who have recently immigrated to the United States, the emergency clinician should elicit additional information specific to the country of origin, also summarized in Box 122.2. The incubation period for the development of symptoms for parasitic diseases ranges from days (falciparum malaria) to months (vivax malaria) to years (filariasis).

Parasite biochemical pathways are generally different from those of their human host, permitting selective metabolic interference by using relatively small doses of chemotherapeutic agents. New and more effective antiparasitic agents continue to be developed. The list of

BOX 122.1 List of Conditions and Taxonomy

Protozoa

Apicomplexan/Coccidia

- Malaria
- Babesia
- Cryptosporidia
- Cyclospora
- Cystoisospora
- Sarcocystis
- Toxoplasma

Amoebae

BOX 122.2 Comprehensive Travel History for Evaluation of Parasitic Disease in the Emergency Department

Questions for All Patients

- What were the exact dates of travel?
- What countries did the patient visit?
- How much time was spent in each country?
- What was the patient doing in the country, and where was he or she living?
- Was the patient a tourist, an adventure traveler, or a worker?
- Did the patient stay in cities or rural villages?
- Was the patient sleeping in hotels or tents?
- Did the patient engage in protected or unprotected sexual intercourse?
- What did the patient eat and drink?
- What were the patient's activities (e.g., swimming in fresh water leads to schistosomiasis)?
- Did the patient receive prophylactic immunizations before travel?
- Did the patient take malaria chemoprophylaxis and comply with the regimen?
- Did the patient use mosquito repellent and netting?
- Does the patient have underlying chronic medical problems?
- What medications does the patient take?
- When did symptoms start, and what has been the chronology of symptoms, particularly fever and diarrhea?

Questions for Patients Who Are Recent Immigrants to the United States

- When did the patient arrive, and from where?
- What acute and chronic illnesses did the patient have previously while living in the country of origin?
- What treatment did the patient receive there?
- If a refugee or immigrant, what countries did the patient pass through, and what were the living conditions (especially relevant for persons who have lived in numerous refugee camps)?
- What was the season during the patient's stay or travel in the countries (e.g., monsoon vs. dry)?
- What animal exposures and bites has the patient experienced?
- Has the patient had exposure to fresh water in work or recreational activities?

drugs used to treat parasitic infestations is long and varied. Table 122.3 includes recommended agents. The newer antiparasitic drugs tend to be less toxic and more efficacious. In many cases, single-dose treatment can eradicate an entire parasite burden, thus supporting effective public health initiatives that include mass treatment programs for populations with a large burden of infection in endemic areas.

MALARIA

Background and Importance

More than 41% of the world's population lives in malarial areas where plasmodia are endemic (e.g., parts of Africa, Asia, Oceania, Central America, and South America). The World Health Organization (WHO) has estimated that in 2013, malaria was responsible for 198 million clinical episodes and 500,000 deaths. Most of these deaths were the result of infection with *Plasmodium falciparum*.[1] Immigrants and returning travelers presenting with malarial symptoms warrant particular consideration as acute falciparum malaria, if left untreated, carries a high mortality. Although it is classically associated with cyclical fevers, malaria presents various symptoms, including headache and diarrhea. Fever is common but not universal at initial presentation. When fever is present, it is often continuous early in the course of illness. Some studies in low endemicity areas have suggested that the presence of fever or headache has a sensitivity greater than 95%. In recent years there has been an increase in the diagnosis of falciparum malaria in travelers returning to the United States; the most common region from which these travelers return is West Africa. Patients who have had a longer duration of travel and neglected to take prophylactic medications or who failed to adhere to prescribed regimens are at the greatest risk.

Most people contract malaria after being bitten by an infected vector mosquito in an endemic region. Other mechanisms of transmission have been reported, including blood transfusions, injection drug use with contaminated syringes, maternal-fetal perinatal transmission, transmission from infected organs after transplantation (worsened by immunosuppression), and what has been described as "airport malaria." This occurs when the infected mosquito is transported from the endemic region and released at the airport when the plane arrives, surviving long enough to transmit the parasite to a human host and then dying without establishing itself in its new location.

Pathophysiology

Malaria is caused by one of five species of the protozoan parasite *Plasmodium*: *P. falciparum, P. vivax, P. ovale, P. malariae*, and *P. knowlesi*. Of these species, *P. falciparum* poses the greatest risk of

TABLE 122.1 Drug Classes and Modes of Action of Agents Used for Treatment of Parasitic Diseases

Type of Drug	Examples[a]	Useful in the Treatment of:	Likely Target in the Parasite	Proposed Effects on Targets
Anthelmintic	Thiabendazole Mebendazole Albendazole	*Ascaris, Enterobius,* hookworm, *Strongyloides, Trichuris,* hydatid disease (long-term therapy)	Tubulin polymerization	Blocks cellular structural integrity and egg production; secondary effects on mitochondrial fumarate reductase and glucose uptake
	Ivermectin (Stromectol)	Many nematodes of humans (except hookworms) Filariasis Onchocerciasis	GABA-sensitive neuromuscular interface	Flaccidity or contraction (tight-binding drug effective at low dose)
Trematodicide	Praziquantel (Biltricide)	Schistosomes Most other flukes, such as *Clonorchis, Paragonimus, Fasciolopsis* (many tapeworms of humans)	Surface structure Carbohydrate metabolism	Vacuolization and surface disruption followed by immune attacks by the host; contraction of the muscles due to flooding of calcium through a permeable tegument; initial increase of glucose metabolism followed by shutdown
Antiprotozoal	Metronidazole (Flagyl) Tinidazole Niridazole	Amebiasis Balantidiasis Giardiasis *Schistosoma haematobium*	Molecular electron transport systems Acetylcholine recycling systems	Failure to sustain energy-producing systems Binds to acetylcholinesterase, inactivating normal neuromuscular function
Antimalarial	Chloroquine phosphate (Aralen)	Many species of susceptible malaria	Parasite digestive vacuole hemoglobinase	Local pH is changed so enzyme becomes inoperative
	Mefloquine	Many species of susceptible malaria		
	Proguanil-atovaquone	Many species of susceptible malaria	Mitochondrial electron transport prevents the normal function of the apicoplast	Works on erythrocytic and hepatic stages
	Doxycycline	Many species of susceptible malaria		Kills *Plasmodium falciparum*

GABA, γ-aminobutyric acid.

TABLE 122.2 Parasites Causing Human Disease: Geographic Location and Portal of Entry

Parasite	Geographic Distribution	Common Infective Stage and Portal of Entry
Protozoa Apicomplexan Amoeba Flagellate Ciliate		
Entamoeba histolytica	Especially prevalent in warm climates	Cyst via mouth
Balantidium coli	Warm climates	Cyst via mouth
Giardia lamblia	Found throughout temperate and warm climates	Cyst via mouth
Trichomonas vaginalis	United States	Trophozoite via vulva or urethra
Leishmania tropica	Mediterranean area to western India	Bite of sandfly introducing promastigote via skin, leading to visceral disease
Leishmania infantum	Southern Europe and Mediterranean	Bite of sandfly introducing promastigote via skin, leading to visceral disease
Leishmania donovani	China, India, Africa, Mediterranean area, continental Latin America	Bite of sandfly introducing promastigote via skin, leading to visceral disease
Leishmania chagasi	South America	Bite of sandfly introducing promastigote via skin, leading to visceral disease
Leishmania braziliensis	South America and Central America	Bite of sandfly introducing promastigote via skin, leading to cutaneous or mucocutaneous disease
Leishmania major, L. tropica	Africa and Asia	Bite of sandfly introducing promastigote via skin, leading to cutaneous disease

TABLE 122.2 Parasites Causing Human Disease: Geographic Location and Portal of Entry—cont'd.

Parasite	Geographic Distribution	Common Infective Stage and Portal of Entry
Leishmania mexicana, L. amazonensis, L. guyanensis, L. costaricensis	Central and South America	Bite of sandfly introducing promastigote via skin, leading to cutaneous disease
Trypanosoma brucei gambiense	West and Central Africa	Trypanosome via skin from bite of the tsetse fly
Trypanosoma brucei rhodesiense	Central and East Africa	Trypanosome via skin from bite of the tsetse fly
Trypanosoma cruzi	Continental Latin America	Trypanosome via skin from reduviid bug
Plasmodium vivax	Warm and cooler climates	Sporozoite via skin from *Anopheles* mosquito
Plasmodium ovale	Warm and cooler climates	Sporozoite via skin from *Anopheles* mosquito
Plasmodium malariae	Warm climates	Sporozoite via skin from *Anopheles* mosquito
Plasmodium knowlesi	Warm and cooler climates	Sporozoite via skin from *Anopheles* mosquito
Plasmodium falciparum *Babesia microti* *Cryptosporidium parvum* *Cyclospora cayetanensis* *Cystoisospora belli* *Toxoplasma gondii* *Sarcocystis hominis* *Naegleria fowleri* *Acanthamoeba* spp. *Balamuthia mandrillaris*	Warm climates	Sporozoite via skin from *Anopheles* mosquito
Nematodes		
Trichinella spiralis	Cooler and temperate climates	Encysted larva in pork or bear via mouth
Trichuris trichiura	Warm, moist climates	Embryonated egg via mouth
Strongyloides stercoralis	Warm, moist climates	Filariform larva via skin
Necator americanus	Common in warm climates	Filariform larva via skin
Ancylostoma duodenale	Common in warm climates	Filariform larva via skin
Enterobius vermicularis	Common in the United States	Embryonated egg via mouth
Ascaris lumbricoides	Global distribution; common in the United States	Embryonated egg via mouth
Wuchereria bancrofti	Prevalent in warm climates	Filariform larva via skin from bite of *Anopheles* or *Culex* mosquito
Brugia malayi	Asia	Filariform larva via skin from bite of *Anopheles* or *Culex* mosquito
Onchocerca volvulus	Tropical Africa, Mexico, Central America, and northern South America	Filariform larva via skin from bite of the blackfly
Loa loa	Tropical West Africa	Filariform larva via skin from bite of the *Chrysops* fly
Dracunculus medinensis *Capillaria philippinensis* *Anisakis simplex* *Baylisascaris procyonis* *Angiostrongylus cantonensis* *Gnathostoma spinigerum/binucleatum* *Toxocara canis* *Ancylostoma braziliense*	Increasingly rare	Ingestion of larva by copepod via mouth
Cestodes		
Taenia saginata	Global distribution; uncommon in the United States	Cysticercus in beef via mouth
Taenia solium	South America, Central America, Mexico, East Africa, India, China, Indonesia	
• Adult worm		Cysticercus in pork via mouth
• Cysticercus stage		Eggs in human infections via mouth
Echinococcus granulosus	Mediterranean, Russian Federation and neighboring countries, China, Central Asia, North and East Africa, and South America	Eggs from canines via fecal-oral transmission
Echinococcus multilocularis	Central Europe, northern Asia, Alaska	Eggs from foxes, dogs, and cats via fecal-oral transmission
Hymenolepis nana	Warm climates	Eggs in human infections via mouth

TABLE 122.2 Parasites Causing Human Disease: Geographic Location and Portal of Entry—cont'd.

Parasite	Geographic Distribution	Common Infective Stage and Portal of Entry
Hymenolepis diminuta	Warm climates	Larva in arthropod host via mouth
Diphyllobothrium latum *Diphyllobothrium pacificum* *Spirometra spp.* *Sparganum proliferum*	US Great Lakes region and Alaska, Scandinavia, Russia, Japan, Pacific Coast of South America, and Uganda	*Sparganum* larva in fish flesh via mouth
Trematodes		
Fasciola hepatica	Sheep-raising countries	Larva on vegetation via mouth
Fasciolopsis buski	Asia	Larva on water nuts
Clonorchis sinensis	Asia	Larva encysted in freshwater fish
Opisthorchis felineus	Europe, Asia	Larva encysted in freshwater fish
Opisthorchis viverrini	Thailand	Larva encysted in freshwater fish
Paragonimus westermani	Primarily Asia; also South America and Africa	Larva encysted in crabs or crayfish via mouth
Schistosoma japonicum	China, Southeast Asia, Philippines	Cercarial larva in water via skin
Schistosoma mansoni	Africa, Latin America, Middle East, Caribbean	Cercarial larva in water via skin
Schistosoma haematobium *Echinostoma hortense*	Africa, Middle East	Cercarial larva in water via skin

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections

		DOSAGE	
Infection	**Drug**[a]	**Adults**	**Children**
Amebiasis (*Entamoeba histolytica*)			
Asymptomatic			
	DRUG OF CHOICE	650 mg tid × 20 days	30 mg/kg/day in 3 doses × 20 days
	• Iodoquinol		
	ALTERNATIVES	500 mg tid × 10 days	25–35 mg/kg/day in 3 doses × 7 days
	• Diloxanide furoate *or*		
	• Paromomycin	25–30 mg/kg/day in 3 doses × 7 days	25–30 mg/kg/day in 3 doses × 7 days
Mild to Moderate Intestinal Disease			
	DRUG OF CHOICE	750 mg tid × 10 days	35–50 mg/kg/day in 3 doses × 10 days
	• Metronidazole *followed by* • Paromomycin or iodoquinol		
	ALTERNATIVES	2 g/day × 3 days	50 mg/kg (max, 2 g) qd × 3 days
	• Tinidazole *followed by* • Paromomycin or iodoquinol		
Severe Intestinal Disease, Hepatic Abscess			
Drainage of liver abscess	DRUG OF CHOICE	750 mg IV or PO tid × 10 days	35–50 mg/kg/day in 3 doses × 10 days
	• Metronidazole *followed by* • Paromomycin or iodoquinol		
	ALTERNATIVES		
	• Tinidazole *followed by* • Paromomycin or iodoquinol	2 g/day × 5 days	50 mg/kg or 60 mg/kg (max, 2 g) qd × 3 days
Amebic meningoencephalitis, primary (*Naegleria* spp.)	DRUG OF CHOICE • Amphotericin B	1 mg/kg/day IV, uncertain duration	1 mg/kg/day IV, uncertain duration
Anisakiasis (*Anisakis*)			
Treatment of choice	Surgical or endoscopic removal		

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections—cont'd.

Infection	Drug[a]	DOSAGE: Adults	DOSAGE: Children
Ascariasis (*Ascaris lumbricoides*)			
Roundworm	DRUGS OF CHOICE		
	• Mebendazole	100 mg bid × 3 days	100 mg bid × 3 days
	• Albendazole	400 mg × 1 dose	>6 yr, same dose as for adult
	• Nitazoxanide	500 mg bid × 3 days	200 mg bid × 3 days
	• Ivermectin	150–200 μg/kg for 1 dose; should be avoided in pregnant women	Should be avoided in young children
Balantidiasis (*Balantidium coli*)			
	DRUG OF CHOICE		
	• Tetracycline	500 mg qid × 10 days	40 mg/kg/day in 4 doses × 10 days (max, 2 g/day)
	ALTERNATIVES	650 mg tid × 20 days	40 mg/kg/day in 3 doses × 20 days
	• Iodoquinol		
	• Metronidazole	750 mg tid × 5 days	35–50 mg/kg/day in 3 doses × 5 days
Cutaneous Larva Migrans			
Creeping eruption	DRUG OF CHOICE		
	• Ivermectin	200 μg/kg once daily × 1 or 2 days	
Dracunculus medinensis			
Guinea worm; worm also needs to be extracted	DRUG OF CHOICE		
	• Metronidazole	750 mg tid × 5–10 days	25 mg/kg/day (max, 750 mg/day) in 2 doses × 10 days
	ALTERNATIVE		
	• Thiabendazole	50–75 mg/day bid × 3 days	50–75 mg/kg/day in 2 doses × 3 days
Enterobius vermicularis			
Pinworm	DRUGS OF CHOICE		
	• Albendazole	Single dose of 400 mg; repeat after 2 wk	11 mg/kg once (max, 1 g); repeat after 2 wk
	• Mebendazole	Single dose of 100 mg; repeat after 2 wk	Single dose of 100 mg; repeat after 2 wk
Filariasis (*Wuchereria bancrofti, Brugia malayi*)			
	DRUG OF CHOICE		
	• Diethylcarbamazine	Day 1: 50 mg PO Day 2: 50 mg tid Day 3: 100 mg tid Days 4–21: 6 mg/kg/day in 3 doses	Day 1: 1 mg/kg PO Day 2: 1 mg/kg tid Day 3: 1–2 mg/kg tid Days 4–21: 6 mg/kg/day in 3 doses
Loa loa	DRUG OF CHOICE		
	• Diethylcarbamazine	Day 1: 50 mg PO Day 2: 50 mg tid Day 3: 100 mg tid Days 4–21: 9 mg/kg/day in 3 doses	Day 1: 1 mg/kg PO Day 2: 1 mg/kg tid Day 3: 1–2 mg/kg tid Days 4–21: 6 mg/kg/day in 3 doses
Onchocerca volvulus	DRUG OF CHOICE		
	• Ivermectin	150 μg/kg PO once, repeated every 3–12 mo	150 μg/kg PO once, repeated every 3–12 mo
Hermaphroditic Fluke			
Clonorchis sinensis (Chinese liver fluke)	DRUG OF CHOICE		
	• Praziquantel	25 mg/kg/day in 4–6 doses × 1 day	25 mg/kg/day in 4–6 doses × 1 day
Fasciola hepatica (sheep liver fluke)	DRUG OF CHOICE	30–50 mg/kg on alternate days × 10–15 doses	30–50 mg/kg on alternate days × 10–15 doses
	• Bithionol		

Continued

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections—cont'd.

Infection	Drug[a]	DOSAGE: Adults	DOSAGE: Children
Fasciolopsis buski (intestinal fluke)	DRUG OF CHOICE		
	• Praziquantel	25 mg/kg/day in 4 to 6 doses × 1 day	25 mg/kg/day in 4 to 6 doses × 1 day
Opisthorchis felineu	DRUG OF CHOICE		
	• Praziquantel	25 mg/kg/day in 4 to 6 doses × 1 day	25 mg/kg/day in 4 to 6 doses × 1 day
Paragonimus westermani (lung fluke)	DRUG OF CHOICE		
	• Praziquantel	25 mg/kg/day in 4 to 6 doses × 2 days	25 mg/kg/day in 4 to 6 doses × 2 days
	ALTERNATIVE	30–50 mg/kg on alternate days × 10–15 doses	30–50 mg/kg on alternate days × 10–15 doses
	• Bithionol		
Giardiasis (*Giardia lamblia*)	DRUG OF CHOICE		
	• Metronidazole	250 mg tid × 5 to 7 days	15 mg/kg/day in 3 doses × 5 to 7 days
	ALTERNATIVES		
	• Nitazoxanide *or*	500 mg bid × 3 days	200 mg PO bid × 3 days (>4 yr)
	• Tinidazole	2 g as a single dose	50 mg/kg as a single dose
Hookworm Infection (*Ancylostoma duodenale, Necator americanus*)			
	DRUGS OF CHOICE		
	• Albendazole *or*	400 mg × one dose	
	• Mebendazole *or*	500 mg × one dose	500 mg × one dose
	• Pyrantel pamoate	11 mg/kg (max, 1 g) × 3 days	11 mg/kg (max, 1 g) × 3 days
LEISHMANIASIS			
Leishmania braziliensis, Leishmania mexicana, Leishmania tropica, Leishmania donovani (kala-azar, black fever)	DRUGS OF CHOICE		
	• Miltefosine *or*	Not indicated in those ≤12 yr	2.5 mg/kg/day PO × 28 days
	• Stibogluconate sodium	20 mg/kg/day IV or IM × 20–28 days	20 mg/kg/day IV or IM × 20–28 days
	ALTERNATIVE		
	• Amphotericin B	0.25–1 mg/kg by slow infusion daily or every 2 days for 8 wk	0.25–1 mg/kg by slow infusion daily or every 2 days for 8 wk
Malaria, Treatment of (*Plasmodium falciparum, P. ovale, P. vivax, P. malariae*) *All* Plasmodium *Species (Except Chloroquine-Resistant* P. falciparum*)*			
Oral	DRUG OF CHOICE		
	Chloroquine phosphate	600 mg base (1 g), then 300 mg base (500 mg) 6 hr later, then 300 mg base (500 mg) at 24 and 48 hr	10 mg base/kg (max, 600 mg base), then 5 mg base/kg 6 hr later, then 5 mg base/kg at 24 and 48 hr
Parenteral	DRUGS OF CHOICE		
	• Quinine dihydrochloride *or*	20 mg/kg loading dose in 10 mg/kg 5% dextrose during 4 hr, followed by 10 mg/kg during 2–4 hr q8h (max, 1800 mg/day) until oral therapy can be started	Same as adult dose
	• Quinidine gluconate *or*	10 mg/kg loading dose (max, 600 mg) in normal saline slowly during 1–2 hr, followed by continuous infusion of 0.02 mg/kg/min for 3 days max	Same as adult dose
	• Artesunate for treatment failure or adverse reactions from quinidine or quinine (available from the CDC)		
	ALTERNATIVE		
	• Chloroquine hydrochloride	200 mg base (250 mg) IM q6h if oral therapy cannot be started	0.83 mg base/kg/hr × 30 hr continuous infusion or 3.5 mg base/kg q6h IM or SC

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections—cont'd.

Infection	Drug[a]	DOSAGE: Adults	DOSAGE: Children
***Chloroquine-Resistant* P. falciparum**			
Oral	DRUGS OF CHOICE		
	• Quinine sulfate *plus*	650 mg tid × 3 days	25 mg/kg/day in 3 doses × 3–7 days
	• Doxycycline *or*	100 mg bid × 7 days	
	• Clindamycin	900 mg tid × 3–5 days	20–40 mg/kg/day in 3 doses × 3–5 days
	ALTERNATIVES		
	• Mefloquine	1250 mg once	25 mg/kg once (<45 kg)
	• Atovaquone-proguanil	1000/400 mg qd × 3 days	
	• Artemether-lumefantrine	4 tabs bid × 3 days	
Parenteral	DRUGS OF CHOICE		
	• Quinine dihydrochloride *or*	Same as above	Same as above
	• Quinidine gluconate *or*	Same as above	Same as above
	• Artesunate	Same as above	Same as above
Prevention of relapses—*P. vivax* and *P. ovale* only	DRUG OF CHOICE		
	• Primaquine phosphate	15 mg base (26.3 mg)/day × 14 days or 45 mg base (79 mg)/wk × 8 wk	0.3 mg base/kg/day × 14 days
Malaria, Prevention of			
	DRUG OF CHOICE		
	• Chloroquine phosphate	300 mg base (500 mg salt) PO, once/wk beginning 1 wk before and continuing for 4 wk after last exposure	5 mg/kg base (8.3 mg/kg salt) once/wk, up to adult dose of 300 mg base, same schedule as for adults
Chloroquine-resistant areas	DRUGS OF CHOICE		
	• Mefloquine *or*	250-mg tablet PO once/wk × 4 wk, then every other wk, continuing for 4 wk after last exposure	Same schedule as for adults with the following dosing guidelines: 15–19 kg, ¼ tablet; 20–30 kg, ½ tablet; 31–45 kg, ¾ tablet; >45 kg, 1 tablet
	• Atovaquone-proguanil *or*	250/100 mg qd 1 day before travel, each day in endemic region, and for 1 week afterward	
	• Doxycycline	100 mg daily during exposure and for 4 wk afterward	>8 yr: 2 mg/kg/day PO, up to 100 mg/day
Schistosomiasis			
Schistosoma haematobium	DRUG OF CHOICE		
	• Praziquantel	40 mg/kg/day in 4–6 doses × 1 day	20 mg/kg/day in 4–6 doses × 1 day
Schistosoma japonicum	DRUG OF CHOICE		
	• Praziquantel	40 mg/kg/day in 4–6 doses × 1 day	20 mg kg/day in 4–6 doses × 1 day
Schistosoma mansoni			
	DRUG OF CHOICE		
	• Praziquantel	60 mg/kg/day in 4–6 doses × 1 day	20 mg/kg/day in 4–6 doses × 1 day
	ALTERNATIVE		
	• Oxamniquine	15 mg/kg once	20 mg/kg/day in 2 doses × 1 day
Schistosoma mekongi	DRUG OF CHOICE		
	• Praziquantel	60 mg/kg/day in 4–6 doses × 1 day	20 mg/kg/day in 4–6 doses × 1 day
Strongyloidiasis (*Strongyloides stercoralis*)			
	DRUGS OF CHOICE		
	• Ivermectin *or*	200 μg/kg/day × 1–2 days	200 μg/kg/day × 1 or 2 days
	• Thiabendazole	50 mg/kg/day in 2 doses (max, 3 g/day) × 2 days	50 mg/kg/day in 2 doses (max, 3 g/day) × 2 days

Continued

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections—cont'd.

Infection	Drug[a]	DOSAGE: Adults	DOSAGE: Children
Tapeworm Infection			
Adult (Intestinal Stage)			
Diphyllobothrium latum (fish), *Taenia saginata* (beef), *Taenia solium* (pork), *Dipylidium caninum* (dog)	DRUG OF CHOICE Praziquantel	5–10 mg/kg once	5–10 mg/kg once
Hymenolepis nana (dwarf tapeworm)	DRUG OF CHOICE • Praziquantel	25 mg/kg once	25 mg/kg once
Tapeworm Infection, Larval (Tissue) Stage			
Echinococcus granulosus (hydatid cysts)	DRUG OF CHOICE • Albendazole	400 mg bid × 28 days, repeated as necessary	15 mg/kg/day × 28 days, repeated as necessary
Echinococcus multilocularis—treatment of choice	Surgical excision		
Cysticercus cellulosae (cysticercosis)	DRUG OF CHOICE • Praziquantel ALTERNATIVE • Surgery	50 mg/kg/day in 3 doses × 15 days	50 mg/kg/day in 3 doses × 15 days
Trichinosis (*Trichinella spiralis*)	DRUGS OF CHOICE • Steroids for severe symptoms *plus* • Mebendazole	200–400 mg tid × 3 days, then 400–500 mg tid × 10 days	Same as adult dose
Trichomoniasis (*Trichomonas vaginalis*)			
	DRUG OF CHOICE • Metronidazole	2 g once or 250 mg tid or 375 mg bid PO × 7 days	15 mg/kg/day PO in 3 doses × 7 days
Trichuriasis (*Trichuris trichiura*, Whipworm)			
	DRUGS OF CHOICE • Mebendazole *or* • Albendazole	100 mg bid × 3 days 400 mg once	100 mg bid × 3 days 400 mg once
Trypanosomiasis			
Trypanosoma cruzi (South American trypanosomiasis, Chagas disease)	DRUG OF CHOICE • Nifurtimox	10–15 mg/kg/day PO in 4 doses × 120 days	1–10 yr: 15–20 mg/kg/day in 4 doses × 90 days 11–16 yr: 12.5–15 mg/kg/day in 4 doses × 90 days
	Alternative • Benznidazole	5–7 mg/kg/day × 30–120 days	Same as adult dose
Trypanosoma brucei gambiense, Trypanosoma brucei rhodesiense (African trypanosomiasis, sleeping sickness), hemolymphatic stage	DRUG OF CHOICE • Suramin	100–200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14, and 21 Weight based: 2 mg/kg test dose followed by 10–15 mg/kg/day on days 1, 3, 7, 14, and 21	20 mg/kg on days 1, 3, 7, 14, and 21
	ALTERNATIVE • Pentamidine isethionate	4 mg/kg/day IM × 10 days	4 mg/kg/day IM × 10 days

TABLE 122.3 Drug Regimens for Treatment of Parasitic Infections—cont'd.

Infection	Drug[a]	DOSAGE: Adults	DOSAGE: Children
Late disease with central nervous system involvement	DRUG OF CHOICE		
	• Melarsoprol (Trypanosoma brucei rhodesiense)	2–3.6 mg/kg/day IV × 3 days; after 1 wk, 3.6 mg/kg/day IV × 3 days; repeat again after 10–21 days	18–25 mg/kg total during 1 mo; initial dose of 0.36 mg/kg IV, increasing gradually to max, 3.6 mg/kg at intervals of 1–5 days for total of 9 or 10 doses
	ALTERNATIVES (*T. b. gambiense* only)		
	• Tryparsamide	One injection of 30 mg/kg (max, 2 g) IV every 5 days to total of 12 injections; course may be repeated after 1 mo	Unknown
	• Eflornithine *plus*	400 mg/kg/day in 4 doses × 14 days injections; course may be repeated after 1 mo	Same as adult dose
	• Suramin	One injection of 10 mg/kg IV every 5 days to total of 12 injections; course may be repeated after 1 mo	Unknown
Visceral Larva Migrans			
Toxocariasis	DRUG OF CHOICE		
	• Diethylcarbamazine	6 mg/kg/day in 3 doses × 7–10 days	6 mg/kg/day in 3 doses × 7–10 days
	ALTERNATIVES		
	• Mebendazole *or*	100–200 mg bid × 5 days	Same as adult dose
	• Albendazole	400 mg bid × 3–5 days	400 mg bid × 3–5 days

[a]Some drugs may be available only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta; telephone, 404-639-3670 (nights, weekends, and holidays: 404-639-2888).

severe disease and death to the infected host. The female Anopheles mosquito is the arthropod vector that transmits malaria. The female ingests plasmodial gametocytes from ingesting a blood meal from an infected source. The gametocytes reproduce in the gut of the mosquito, transitioning to their sporozoite phase and migrating to the salivary glands in preparation for transmission. The plasmodia parasites enter the bloodstream of their next human host from the salivary glands of the female *Anopheles* mosquito during her blood meal. The sporozoites are trophic for human liver parenchymal cells; in hepatocytes, they undergo multiple replication rounds to form liver (extraerythrocytic) schizonts. The hepatocytes rupture, usually within 2 to 10 days after infection, releasing merozoites into the bloodstream. The merozoites invade red blood cells (RBCs), transforming into trophozoites and feeding on the hemoglobin in RBCs. Trophozoites mature into erythrocytic schizonts, which divide asexually into additional merozoites. Eventually, the erythrocyte undergoes lysis, releasing merozoites capable of infecting additional red blood cells. Although some merozoites are destroyed by the host's immune system, many enter new erythrocytes. As this cycle repeats itself, there is amplification of the number of infected erythrocytes. After several repetitions of the erythrocytic cycle, the process changes, and male or female macrogametocytes develop instead of merozoites. These gametes ingested by the mosquito, subsequently complete the reproductive cycle by fusion, which is accomplished sexually within the gut of a new female *Anopheles* mosquito after she feeds on the infected human.

Infection with *P. vivax* or *P. ovale* can manifest a dormant stage in human hepatocytes; this stage is known as the hypnozoite. Hypnozoites are metabolically inactive and thus less susceptible to standard pharmacologic therapies. Hypnozoites can eventually release merozoites into the blood stream weeks to months or even years after initial infection, initiating relapse in the host unless specific treatment for the hypnozoite stage was anticipated by the clinician treating the patient. Recrudescent infection occurs when primary blood stages of any species of *Plasmodium* are immunologically or pharmacologically controlled without being fully eradicated and the liver phase persists, thus leading to latent multiplication at a higher rate. This may occur later due to immune suppression or overlying acute illness. *P. malariae* can sometimes cause an initial asymptomatic infection, and clinical symptoms develop years or decades later.

Initial parasite replication cycles are asynchronous, as multiple liver schizonts may rupture and release merozoites into the bloodstream. The host immune response to these parasites can lead to cytokine production with fever and rigors, malaise, headache, and myalgia, in addition to a variety of other symptoms. Over time, cycles of parasite reproduction become synchronized, with 24-hour (*P. knowlesi),* 48-hour (*P. falciparum, P. vivax, P. ovale)*, or 72-hour (*P. malariae)* intervals of fever. Erythrocytes parasitized by *P. falciparum* express the parasitic protein PfEMP1, which binds to several host endothelial proteins, leading to cytoadhesion. RBC adherence to the endothelium leads to stasis of blood flow and microvascular occlusion, which can cause hypoperfusion of end organs. End-organ hypoperfusion in the brain can led to seizure, coma, and cerebral edema, which can be fatal. Hypoperfusion of other organs may lead to lactic acidosis or renal failure. Cytoadherence of parasitized RBCs may also result in low

measured levels of parasitemia or even false-negative blood smears due to sequestration of infected erythrocytes in capillary beds.

Clinical Features

Patients presenting with a fever or acute illness who have returned from travel in a region endemic for malaria should be evaluated for the possibility of malaria. Other signs and symptoms including anemia, headache, nausea, chills, lethargy, abdominal pain, and upper respiratory complaints should also be considered as manifestations of malaria.

P. falciparum is the malarial species most morbid to humans; it infects a larger percentage of the host's RBCs and is trophic for neural tissue leading to cerebral edema, seizures, encephalopathy, hypoglycemia (especially in children), metabolic acidosis, severe anemia, high-output cardiac failure, renal failure, pulmonary edema, disseminated intravascular coagulation, and death. In chronic malarial infection, increased cellularity from the host's exuberant immune response may lead to hepatosplenomegaly. Within the liver, parasites and malarial pigment distend the Kupffer cells. Parasitized RBCs also adhere to the sinusoidal system of the spleen, reducing its immunologic effectiveness. Anemia results from acute and chronic hemolysis. Hemoglobinuria caused by severe hemolysis leading to renal failure, known as blackwater fever, may occur in patients with chronic or acute falciparum malaria.

Signs of severe malaria requiring immediate IV antimalarial treatment include prostration, altered mental status (Glasgow coma scale <11), more than two generalized seizures, severe anemia (hemoglobin < 7 g/dL), acute renal failure (creatinine > 3 mg/dL or blood urea > 20 mmol/L), hyperbilirubinemia or clinical jaundice (total bilirubin > 3 mg/dL), respiratory distress or pulmonary edema, shock, hypoglycemia (glucose < 40 mg/dL), spontaneous bleeding or DIC, acidosis (bicarbonate < 15 mmol/L or lactate > 5 mmol/L), hemoglobinuria, and greater than 2% parasitemia on blood smear (i.e., more than 2% of the patient's RBCs contain malarial schizonts).

Cerebral malaria is a life-threatening complication of *P. falciparum* infection. Parasitized RBCs express malarial cell surface glycoproteins called knobs which adhere to capillary walls, resulting in sludging in the cerebral microvasculature. Impaired circulation leads to localized ischemia, capillary leakage, and petechial hemorrhages. Clinical manifestations of cerebral malaria include fever, altered mental status including obtundation and coma, and, not uncommonly, seizures. A careful history, rapid diagnosis, and immediate initiation of therapy are essential to prevent severe morbidity and death.

Differential Diagnosis

The emergency medicine clinician will most successfully diagnose parasitic infections by correlating historical features, such as exposure and travel history, with presenting symptoms that may be more nonspecific, including fever, anemia, peripheral edema, visual impairment, skin complaints, and symptoms related to the pulmonary, cardiovascular, and gastrointestinal (GI) systems. Other diagnostic considerations in at-risk travelers returning with febrile illness include more common conditions such as viral infections such as influenza or viral respiratory infections, and bacterial infections such as infectious diarrhea, urinary tract infections, and pneumonia. Cerebral malaria may manifest with confusion and mental status changes and should be differentiated from meningitis and encephalitis.

Malarial infection is often associated with anemia, particularly in children younger than 5 years. Anemia may develop quickly, from massive hemolysis in acute infection, or may have a more insidious onset, developing over months. Mature merozoites lyse parasitized RBCs. Uninfected RBCs undergo immune destruction from cell surface antibodies produced in response to parasite-associated changes in RBC surface proteins. This process of destruction is abetted by increased reticuloendothelial activity. The inhibition of erythropoietin secretion blunts the reticulocyte response in infected persons. Concomitant iron deficiency contributes to the severity of the anemia.

Diagnostic Testing

Microscopic examination of thick and thin blood films remains the gold standard for the diagnosis of malaria. Peripheral blood smears are stained with Giemsa or Wright stain and examined with ordinary light microscopy. The morphology of the intraerythrocytic schizonts allows the experienced clinician to determine the plasmodial species. In particular, *P. falciparum* has a very specific morphology, and the diagnosis can be made in a simply equipped laboratory. Even if the parasite is not visualized in the smear, treatment of malaria is indicated if the disease is suspected. The US Food and Drug Administration (FDA) has approved the use of an antigen-based rapid diagnostic test to screen patients. The Alere BinaxNOW kit provides qualitative testing for all four species and is available for approximately $5 per test. The test is not as sensitive as microscopy, which should still be performed for all patients with positive antigen test results to determine the species and severity of parasitemia.

Management

Untreated falciparum malaria can lead to coma and death; early treatment reduces morbidity and mortality. In the past, chloroquine phosphate was the treatment of choice for acute uncomplicated attacks of malaria. Resistance to chloroquine has been steadily increasing, and the drug is now recommended only in regions of known chloroquine sensitivity—Haiti, Dominican Republic, Central America north of the Panama Canal, and limited regions of the Middle East. For uncomplicated malarial infections in patients from chloroquine-resistant regions, oral quinine is given with doxycycline or clindamycin. Another suitable alternative combination is proguanil-atovaquone.

For severe *P. falciparum* infection or in patients unable to tolerate oral medication, intravenous (IV) artesunate is the recommended first-line treatment. It is available only as an expanded-access investigational new drug and must be obtained via request from the CDC (call CDC Malaria Hotline at 770-488-7788, Monday-Friday, 9 a.m. to 5 p.m. EST; at other hours call 770-488-7100). The artemisinin agents are excellent antimalarials and are available as enteral and parenteral preparations. They have a rapid onset of action and are well tolerated. An oral agent known as artemether-lumefantrine (Coartem) is now available for uncomplicated malaria, though other artemisinins are not approved for use in the United States.

Although not currently available in the United States, IV quinine or quinidine is another option for treatment of severe cases. Rapid infusion of IV quinine can cause profound hypoglycemia, as well as hyponatremia and coma vigil, a neurologic impairment due to high rates of parasite destruction. Patients should not receive IV quinine without cardiac monitoring.

Primaquine is used to eliminate the hepatic phases of *P. ovale* and *P. vivax* to prevent disease relapse. Primaquine therapy is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency because it can precipitate severe hemolysis.

Cerebral malaria is treated with IV quinine, quinidine, or artemisinin (as available), and supportive care, including mechanical ventilation for comatose patients and patients with noncardiogenic pulmonary edema, antiepileptics, and correction of acidosis and hypoglycemia. Hypoglycemia results from the high-grade falciparum parasitemia, as the protozoan is metabolically active, and the patient is often anorectic from the disease process or the quinine infusion and may be malnourished at baseline. The mortality rate is high, especially

in children, but neurologic sequelae are rare if the patient recovers. Corticosteroids, including dexamethasone, provide no benefit and can worsen outcomes. A second antimalarial, such as doxycycline or clindamycin, should always be administered in conjunction with artemisinin or quinine in these cases.

BABESIOSIS

Background and Importance

Babesiosis is a malaria-like illness that is becoming increasingly prevalent in the Northeastern United States (*Babesia microti*), northwestern United States (*Babesia gibsoni*), and Europe (*Babesia divergens*). Babesiosis is particularly endemic to Long Island, Cape Cod, Martha's Vineyard, Nantucket, and Block Island. Babesiosis must be suspected, along with ehrlichiosis/anaplasmosis and Lyme disease, in patients who live or have traveled in these regions who present with flu-like illness (see Chapter 123). *Babesia* is a protozoan, similar in structure and life cycle to plasmodia. It is transmitted by the deer tick *Ixodes dammini,* which also is the vector of Lyme disease, ehrlichiosis, and anaplasmosis. Several cases of babesiosis have been correlated with transfusions with infected blood.

Clinical Features

Patients with babesiosis experience fatigue, anorexia, malaise, and emotional lability, with myalgia, chills, high spiking fevers, sweats, headache, and dark urine. Other manifestations include hepatosplenomegaly, anemia, thrombocytopenia, leukopenia, elevated liver enzyme levels (particularly the transaminases), and signs of hemolysis, with hyperbilirubinemia and decreased haptoglobin. In an otherwise healthy person, the disease may remit spontaneously. In asplenic, older, and immunocompromised patients, especially patients with AIDS and those taking corticosteroids, up to 85% of RBCs may contain organisms and infections may be fatal with vascular collapse and a septic shock-like presentation due to massive hemolysis, jaundice, renal failure, disseminated intravascular coagulation, hypotension, and adult respiratory distress syndrome (ARDS).

Diagnostic Testing

Diagnosis is based on clinical suspicion, multiple thin and thick blood smears (*Babesia* organisms resemble plasmodia in blood smears), and serologic testing (convalescent titers may not be positive for several weeks after infection).

Management

The treatment of choice consists of atovaquone (750 mg BID orally) plus azithromycin (500–1000 mg once followed by 250 mg once daily orally) or, for severe illness, quinine (650 mg TID orally) plus clindamycin (1.2 g bid IV or 600 mg TID). Patients infected with *B. divergens* tend to be sicker and require more supportive care. Coinfection with *Borrelia burgdorferi,* the agent of Lyme disease, results in a more severe and prolonged illness.

SCHISTOSOMIASIS AND KATAYAMA FEVER

Background and Importance

The acute phase of schistosomiasis infection causes Katayama fever. Schistosomiasis is a trematode infection acquired through skin contact with freshwater habitats of snail species that are the intermediate host for the parasite. Motile cercariae are released from the snail and penetrate the skin of a person wading in the water. In the human host, the cercariae mature into schistosomulae, which migrate through the bloodstream to the host's lungs, and, subsequently, to the venous plexi of the gastrointestinal or genitourinary organs where they mature into adult worms and begin laying eggs. One to three months after the host is exposed to the parasite during the migration and early egg-production phases of infection, patients who have experienced prior infection develop nocturnal fever, diaphoresis, cough, wheezing, myalgia, headache, or abdominal pain. Infected patients may report brief exposures to fresh water in endemic areas.

Diagnostic Testing

Diagnosis depends upon positive schistosome serology and appropriate exposure history, correlated with the detection of eggs in urine or stool. Initial serology and egg examination may be falsely negative at the time of initial presentation and should be repeated at three-month intervals. Lab tests often reveal eosinophilia. Radiographs may reveal diffuse pulmonary infiltrates or nodules.

Management

Treatment should be initiated based on clinical suspicion because initial testing may provide false-positive results. In returning travelers with isolated exposure and low infectious burden, the most concerning result of untreated schistosomiasis is the embolization of schistosome eggs to small venules in the central nervous system creating intense inflammation, fibrosis, and tissue destruction manifesting as transverse myelitis or central nervous system lesions. Treatment consists of praziquantel in single dose or three-day course, as well as corticosteroids to reduce the severity of the inflammatory reaction.

CYSTICERCOSIS

Background and Importance

Cysticercosis is caused by the larval form of *Taenia solium,* a tapeworm, which is neurotrophic and endemic in many tropical areas. Ingestion of undercooked pork containing *T. solium* cysterici leads to tapeworm infection in the human intestine. Human cysticercosis is acquired via the fecal-oral route through accidental ingestion of stool containing eggs shed by the adult tapeworm. Autoinfection may occur when an individual unknowingly infected with a tapeworm fails to practice adequate hand hygiene, and household infection may occur through contamination of the environment, or of food and water sources. Once the egg is ingested, it hatches in the small intestine, releasing a larva that penetrates the gut wall and migrates throughout the host's body with particular trophism for the CNS, muscle, and soft tissue. The larvae encyst, and the ensuing local inflammation and fibrosis create a nidus for seizure activity in the brain. Neurocysticercosis is the leading cause of acquired epilepsy worldwide.

Clinical Features

In the brain, a *T. solium* larva forms an expanding cyst that induces an intense immunologic reaction, including inflammation, edema, fibrosis, and, ultimately, calcification. Cysts may be single or multiple. Neurologic abnormalities develop when neural tissue cannot accommodate the enlarging cyst. Seizure activity is often the first indication of cysticercosis, which should be considered in the differential diagnosis of new-onset seizures in adults. Racemose cysticercosis occurs when cysterici lodge in the cerebral ventricles or subarachnoid space, leading to hydrocephalus, cranial nerve deficits, vasculitis, and stroke.

Diagnostic Testing

The diagnosis of cysticercosis can be made by pairing the finding of characteristic cysts with scolices on noncontrast cranial computed tomography (CT) or magnetic resonance imaging (MRI) with positive serology for *T. solium*. Stool may reveal eggs of *T. solium* if the patient

has a living worm in their gut. Brain lesions can mimic a CNS abscess, metastatic malignant disease, or primary tumor such as glioblastoma multiforme.

Management

Treatment of neurocysticercosis consists of a 10- to 14-day course of albendazole 400 mg BID alone, or albendazole with praziquantel 50 to 100 mg/kg/day, divided q8hr, depending on the number of cysts present. Consultation with an infectious disease specialist is appropriate. Corticosteroids and antiepileptics are important adjunct medications during therapy, because CNS cysts can release highly antigenic inflammatory material as they die and necrose. We recommend dexamethasone 10 mg and levetiracetam 1000 mg for most adult patients. Neurosurgical consultation is warranted for ventricular or subarachnoid cysts, or in the presence of hydrocephalus, elevated ICP, or mass effect.

AFRICAN TRYPANOSOMIASIS

Background and Importance

African sleeping sickness is caused by *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*. This infection is endemic in limited areas of West and East Africa. Several recent cases have been reported in travelers who have returned from safari in East Africa. The motile organisms are transmitted by the bite of the *Glossina* (tsetse) fly, which introduces the infective form of the trypanosome into the host's blood. A small lesion or boil may develop and persist for several days. The flagellated organism travels throughout the bloodstream, invading the lymph nodes and spleen.

Clinical Features

The patient generally is febrile, and a maculopapular rash can often be seen. Once the parasite invades the CNS, cerebral inflammation causes severe headache. The Winterbottom sign, which is posterior cervical lymphadenopathy, usually is apparent at the time of initial presentation. Patients may display altered mental status, psychiatric symptoms, and eventually, extreme sleepiness and lethargy. Coma and death from starvation and trypanotoxins are inevitable in untreated patients.

Diagnostic Testing

An appropriate exposure history and characteristic symptoms should prompt the clinician to obtain diagnostic studies. The diagnosis is established when trypanosomes are found in peripheral blood, CSF, or lymph node and bone marrow aspirates. The presence of parasites in the CSF indicates advanced progression of the disease.

Management

Suramin sodium, given as 100 to 200 mg IV for a test dose, then 1 g IV on days 1, 3, 7, 14, 21, is the treatment of choice for early infection with *T. b. rhodesiense*. Pentamidine isethionate 4 mg/kg IM a day is the preferred treatment for early *T. b. gambiense* infection. Melarsoprol is used in CNS disease from *T. b. rhodesiense*; eflornithine is used in combination with nifurtimox in CNS disease from *T. b. gambiense* infection.

TOXOPLASMOSIS

Background and Importance

Toxoplasma gondii is a zoonotic protozoan that is estimated to infect one-third of the human population globally; however, clinically significant infection is rare, and is most often seen in congenitally acquired infection or in immunocompromised individuals, particularly those with HIV. CNS disease includes cerebral mass lesions, encephalitis, and chorioretinitis. Infections rarely occur in immunocompetent individuals.[3]

Clinical Features

Toxoplasma oocysts are infectious forms in the intestines of the usual host, members of the cat family. Oocysts shed in cat feces often contaminate food and water ingested by other mammals, leading to the formation of cysts in a variety of tissues. Humans generally become infected by one of two routes: ingestion of oocysts through environmental contamination in proximity to cats, or ingestion of raw or undercooked meat harboring tissue cysts. Upon ingestion of cysts, tachyzoites are released and disseminated through the blood or lymphatics, leading to an acute phase of infection. Acute infection manifests as fever, malaise, headache, myalgia, and lymphadenopathy, and can cause posterior uveitis in immunocompetent patients. Eventually, the host's immune system controls the acute infection, but cysts in tissues persist, supporting dormant infections. In immunocompromised hosts, the cysts release bradyzoites initiating reactivation. CNS toxoplasmosis has been a significant cause of morbidity and mortality in patients with advanced AIDS.

Diagnostic Testing

Serologic testing identifying IgM (acutely) or serially rising IgG levels support the diagnosis. The general population worldwide has a large prevalence of seropositivity with IgG titers, thus one positive titer does not suggest infection. PCR performed on body fluids or specific tissues is highly specific for infection and has a sensitivity of 70% to 95%. The classical finding in immunocompromised patients with CNS disease is a ring-enhancing lesion on contrast-enhanced CT.

Management

Therapeutic options include pyrimethamine 50 to 75 mg a day with sulfadiazine 1 to 1.5 gm QID or clindamycin 450 mg q6 to 8 hours. Pyrimethamine is a folate antagonist, so folic acid is often given with prolonged courses.

EOSINOPHILIC MENINGITIS

A number of helminths, including those that typically complete their life cycles in animal hosts, only infecting humans incidentally, can migrate to the brain and cause severe disease, including meningitis and intracerebral hemorrhage.

Angiostrongylus cantonensis, the rat lung worm, typically infects rats, and has snail species as intermediate hosts. Larvae may infect humans, either through ingestion of undercooked snail, which may be part of dietary practice in some cultures, or as has been reported in teens responding to a prank or dare, or through ingestion of vegetables that have been contaminated by snail slime. In infected humans, larvae migrate to the brain causing headaches, vomiting, and altered mental status. *Baylisascaris procyonis* is an intestinal roundworm found in racoons. Raccoon "latrines," sites of frequent raccoon urination and defecation, are often teeming with *B. procyonis* eggs. Geophagia or hand contamination and subsequent ingestion, especially among young children, can lead to significant human infection, with tropism for the brain and eye leading to severe neurologic sequelae and death.

Gnathostoma spinigerum is a roundworm that incidentally infects humans consuming raw or undercooked freshwater fish, including ceviche. Most cases occur in Southeast Asia and Latin America, initially manifesting as a migratory inflammatory swelling of the skin with subcutaneous hemorrhages. Migration to the brain and spinal cord causes eosinophilic meningitis, coma, cranial nerve deficit, and massive subarachnoid hemorrhage from erosion into cerebral arterioles. Cases of

CNS involvement with *Trichella spiralis* have been reported and are associated with cerebral edema and CNS vasculitis. *Toxocara canis* can also cause CNS disease. *Paragonimus westermani* occasionally causes eosinophilic meningitis or focal neurologic findings that demonstrate a classic cluster of ring-enhancing lesions on contrast-enhanced CT, with a "soap bubble" appearance.

Eosinophilic meningitis is diagnosed by CSF pleocytosis (>10 WBC/hpf) with at least 10% eosinophils, though up to 50% eosinophils may be seen. CT or MRI findings may suggest a particular helminthic infection, but serologic testing will be confirmatory. Treatment consists of appropriate antihelminthic therapy and corticosteroids. Albendazole is used for *Angiostrongylus, Baylisascaris, Gnathostoma,* and *Toxocara.* Ivermectin, in weight-based dosing, is an alternative for *Gnathostoma.* Praziquantel treats *Paragonimus* whereas mebendazole 100 mg PO q12hr or thiabendazole 500 mg PO are the drugs of choice for *Trichella.* The clinician should obtain neurosurgical consultation if there is evidence of mass or hemorrhage.

PARASITES ASSOCIATED WITH FEVER

Other parasitic illnesses that commonly present with fever include visceral leishmaniasis, and toxoplasmosis. Fascioliasis and amoebic liver abscess also generally present with fever.

Leishmaniasis

Leishmaniasis is spread to humans by the sandfly and is found in the Middle East, India, East Africa, Brazil, and along the Mediterranean coast. Although leishmaniasis can involve the skin (cutaneous) and mucosa (mucosal), fever is seen only in visceral leishmaniasis in immunocompetent persons. Patients present with massive hepatosplenomegaly, neutropenia, and weight loss.

Amebic Abscess

Amebic abscess of the brain or meningoencephalitis is a rare complication of infection with *E. histolytica* after ingestion of amebic cysts. Spread of amebae to the brain or meninges from the colonized large bowel wall is rare but should be considered in any patient with amebiasis and neurologic signs or symptoms. The diagnosis may be made by microscopic identification of trophozoites (motile amebae) in CSF; however, biopsy of affected tissue is more specific. CNS amebiasis is treated with IV metronidazole but may require neurosurgical intervention.

Naegleria fowleri, *Acanthamoeba* spp., and *Balamuthia mandrillaris* are free-living freshwater amoebae that infect patients swimming and diving in ponds and lakes. These organisms invade the CNS through the olfactory neuroepithelium or compromised corneal epithelium that has been violated by abrasion or contact lens wear, often resulting in devastating amebic meningoencephalitis. Cases of *Balamuthia* amoebic encephalitis are often preceded by skin lesions or rhinitis. Due to the rarity of the condition, there is little data on the efficacy of different therapeutic agents, but a pharmacologic regimen of five drugs is generally recommended. Therapeutic options include amphotericin B, miltefosine, fluconazole or miconazole, rifampin, azithromycin, flucytosine, and sulfadiazine. Treatment is initiated when motile amoebae are identified in CSF.

Strongyloides

Strongyloides stercoralis infection is a common disease in the tropics. The worm enters through the host's skin and migrates to their small bowel. Infection with *Strongyloides* is more clinically significant in immunosuppressed patients, particularly transplant patients or those with autoimmune disease who are treated with high-dose corticosteroids. Patients will manifest larval dissemination, with subsequent encephalitis and pyogenic meningitis. *Strongyloides* infection is treated with thiabendazole or albendazole. Ivermectin has recently been found to be as effective with fewer side effects, and we recommend this as a first-line agent.

WHIPWORM AND HOOKWORM

Infestation by the whipworm *Trichuris trichiura,* and especially by the two human hookworms *Necator americanus* and *Ancylostoma duodenale,* is a major cause of iron deficiency anemia worldwide. Adult worms penetrate intestinal mucosa and feed using mouthparts consisting of hooks or biting plates, causing significant luminal blood loss. Eggs are shed in the feces and mature in the soil, hatching to release a rhabditiform larva that subsequently develops into the infective filariform larva. These larvae penetrate the human skin, usually through the feet. In trichuriasis, anemia is seen only with massive parasite infestation. Ova from the whipworm are ingested through food and water contaminated with feces. Diagnosis of these infections requires identification of characteristic ova in the stool. As with most helminthic infections, peripheral eosinophilia is common. Mebendazole or albendazole effectively controls trichuriasis and hookworm infections in adults and children. Anemic patients should be further worked up and receive iron supplementation.

TAPEWORM

Infection with the fish tapeworm, *Diphyllobothrium latum,* is associated with pernicious anemia. This tapeworm competes with the human host, absorbing vitamin B_{12} from the host's intestine. Infection is acquired when the host ingests raw freshwater fish that contains the plerocercoid larvae in its muscle fiber. The larva develops in the human small intestine into an adult tapeworm that can grow to be longer than 15 meters and can live up to 20 years. The diagnosis is made by identification of the ova in the feces. Praziquantel is the drug of choice for adults and children.

PARASITES ASSOCIATED WITH CUTANEOUS MANIFESTATIONS

Elephantiasis

Elephantiasis, a manifestation of lymphatic filariasis, is the development of massive peripheral edema, with distention and thickening of the overlying epidermis, which acquires the appearance and texture of elephant skin. Elephantiasis is caused by infection with the filarial worm *Wuchereria bancrofti* or *Brugia malayi*. The infection is confined to humans and is widely distributed in the equatorial regions of the world, including Africa, Asia, South America, and Oceania. More than 90% of all infections are found in Asia, where the disease has reached epidemic proportions. Even in endemic regions in which most residents are infected, the disease is rare among travelers. Infected mosquitoes introduce larvae into the bloodstream of the human host during a blood meal. After infecting the host, the worms migrate into the lymphatic system and mature into coiled gravid adults. The adult worm triggers a robust inflammatory reaction in the lymphatic vessels, particularly in the lower extremities and genitalia. The macrophages, lymphocytes, plasma cells, giant cells, and eosinophils migrate to the inflamed and fibrotic lymphatic vessels, which becomes erythematous, edematous, and tender, suggesting the diagnosis of filariasis.

Chronic manifestations of filariasis include fibrosis of a lymphatic vessel containing a dead or calcified worm. Subsequent mechanical

blockage of the lymphatic system leads inevitably to severe lower extremity and genital edema accompanied by thickening of the skin. Recurrent cellulitis is common in these patients; prevention of superinfection requires meticulous skin care.

Diethylcarbamazine 50 mg orally rapidly clears the microfilariae from the peripheral blood and slowly sterilizes the gravid female nematode. Combined therapy with diethylcarbamazine and albendazole, or ivermectin and albendazole, may be more effective. Treatment with doxycycline eradicates *Wolbachia,* a symbiotic bacterium of the filarial parasite, increasing rates of eradication of the adult worm. Established elephantiasis of the scrotum can be successfully treated surgically. Chronic lymphatic obstruction of the limbs rarely responds to operative intervention.

Cutaneous Leishmaniasis

Cutaneous leishmaniasis is one of the most important causes of painless, chronic, ulcerating skin lesions globally. *Leishmania braziliensis* and *Leishmania mexicana* are responsible for New World leishmaniasis; *Leishmania tropica* and *Leishmania major* commonly cause Old World leishmaniasis. During a blood meal, a female sandfly of the species *Phlebotomus* or *Lutzomyia* transmits the promastigotes, which are then ingested by host macrophages and survive in their amastigote form in the skin.

Skin papules and nodules are seen early in the course of infection at the insect bite site. A raised lesion also can appear, which subsequently develops painless central ulceration and a raised border. Lymphocyte and macrophage invasions of the epidermis and dermis cause the induration that occurs at the ulcer border. Secondary bacterial infection of these ulcers increases the risk of associated scarring. *L. braziliensis braziliensis* (subspecies of *L. braziliensis*) can lead to spread of parasites from the primary lesion to the mucocutaneous skin borders (i.e., in tissues of the nose and mouth). Mutilation of the face occurs after massive tissue and nasal cartilage destruction. The soft palate, larynx, and trachea also can be involved, compromising the airway. Disseminated cutaneous leishmaniasis (*L. mexicana amazonensis* in South America and *L. tropica aethiopica* in Ethiopia) is characterized by diffuse nodules and papules resembling those of lepromatous leprosy (Fig. 122.1). Persons with this manifestation of leishmaniasis are thought to have a defect in their cell-mediated immune response.

Definitive diagnosis of leishmaniasis is made by direct visualization of the parasite with light microscopy. Diagnosis can also be made by an indirect fluorescent antibody test. Results of intradermal skin testing with parasite antigen often are negative during the acute stages of the disease.

Many forms of cutaneous leishmaniasis, especially *L. tropica* and *L. mexicana* infection, are self-limited and require no treatment unless the wounds become secondarily infected. Treatment options for advanced disease include sodium stibogluconate, meglumine antimonate, amphotericin B, miltefosine, fluconazole, and paromomycin. These treatments are rarely initiated in the ED setting.

Cutaneous Larva Migrans

Cutaneous larva migrans (CLM), the creeping eruption, occurs in the host's epidermis when the skin is penetrated by *Ancylostoma braziliense* (dog or cat hookworm) larvae. Exposure usually occurs after the host walks barefooted or lies directly on beaches or other warm soil contaminated by animal feces. The diagnosis is visual with a characteristic meandering erythematous track on the skin surface caused by larval migration. Visceral larva migrans occurs in young children after the ingestion of soil containing ova from the dog ascarid *Toxocara canis*. Thiabendazole, ivermectin, or albendazole may be used for treatment of cutaneous larva migrans, and antipruritics give symptomatic relief. Diethylcarbamazine treats visceral larva migrans. An alternative is thiabendazole.[2]

Fig. 122.1 Cutaneous leishmaniasis.

Swimmer's Itch (Cercarial Dermatitis)

Swimmer's itch is a dermatitis that occurs when skin is penetrated by a schistosome that is trophic for avians and nonhuman mammals while the patient usually was swimming in northern US freshwater lakes. The infection spontaneously resolves when the human host's immune system destroys the schistosome. A similar dermatitis also can occur after infection with schistosome species that are trophic for humans. Treatment is symptomatic.

Strongyloides

Strongyloides can cause a transient pruritic rash known as larva currens that may appear and then disappear within hours. *Taenia solium* can cause cysts in the soft tissues and muscles. These cysts often are an incidental finding. Onchocerciasis (from *Onchocerca volvulus*), common in West Africa and parts of South America, can cause severe pruritus and nodules overlying bony protuberances.

Dracunculus medinensis

Dracunculus medinensis, the fiery serpent, commonly referred to as Guinea-worm disease (GWD), is a parasite known since antiquity, which was once widely distributed in Africa and the Middle East. As the worm develops, it migrates to the subcutaneous tissues of the leg, where a painful blister forms; when the overlying skin is compromised, the worm emerges to release eggs into water. GWD has been eradicated and is currently primarily of interest for the success of this worldwide campaign, which has brought case numbers worldwide down from over 3 million in the 1980s to fewer than 100 per year over the last five years. While public health experts expect that GWD will be the first parasitic disease to be globally eradicated, COVID-19 has interrupted treatment programs and threatened years of progress.

PARASITES ASSOCIATED WITH OCULAR MANIFESTATIONS

Many different worms migrate to or through the eye, causing inflammation, tissue destruction, and blindness.

Onchocerciasis

Onchocerciasis is a major cause of blindness in the world; 95% of cases occur in Africa. The parasite is found only in humans and is transmitted by the bite of the *Simulium* fly. These flies live near rivers—hence, the common name of the disease, river blindness. Microfilariae of *O.*

Fig. 122.2 Patient with onchocerciasis (river blindness).

volvulus are released by adult nematodes, which coil in subcutaneous nodules in the infected host; the microfilariae then migrate through the dermis and epidermis. The presence of adult worms stimulates a brisk immune response, including the infiltration of lymphocytes, macrophages, plasma cells, and eosinophils.

The skin becomes chronically edematous and pruritic; it then atrophies, resulting in loose, thin folds of skin, known as lizard skin. River blindness is more likely to develop in patients with nodules close to the eyes. When the microfilaria dies during its migration in the eye, the immunologic response to parasitic antigens leads to sclerosing keratitis, which is the major cause of ocular destruction and subsequent blindness (Fig. 122.2). Posterior ocular disease can also occur, leading to subretinal fibrosis.

Onchocerciasis is diagnosed by identifying characteristic microfilariae in skin snipped from the patient. Ivermectin is the therapeutic drug of choice. Surgical excision of the subcutaneous nodules is recommended when they are located on the head.

Loiasis

Loiasis is confined to forest areas in West and Central Africa. Transmission of *Loa loa* occurs through the bite of flies of the genus *Chrysops*. The disease is caused by migration of the adult worm in the subcutaneous tissue. The edema initially associated with migration of the worm is called a Calabar swelling. The adult worm occasionally migrates through the subconjunctival tissues of the eye and can be surgically excised from the conjunctiva. Although it is upsetting to the patient, the disease is generally fairly benign. The adult worm releases sheathed microfilariae into the peripheral bloodstream during the daytime.

Microfilariae can be detected in a thick blood smear, securing the diagnosis of loiasis. The treatment of choice for *L. loa* infection is diethylcarbamazine. Albendazole is also effective. Corticosteroids or antihistamines should be used to supplement specific chemotherapy because of the intense allergic reaction when the dead adult worms and microfilariae disintegrate. Heavy infections require plasmapheresis before administering antihelminthic treatment to avoid encephalitis precipitated by dying microfilaria.

Toxocara canis (Dog Roundworm)

Toxocara canis (dog roundworm) has a trophism for the host's eyes. Toxocariasis is a roundworm infection found in urban dogs. Humans ingest eggs by the fecal-oral route. The larvae migrate and often enter the retina, where they become trapped. They stimulate an immune response that culminates in granuloma formation. These granulomas can impair vision and sometimes are mistaken for retinal tumors. There is no means of direct diagnosis except tissue biopsy. Although serologic tests are available, results may be unreliable. Infection is treated with albendazole and steroids; larvae visible in the retina can be destroyed with a laser.

PARASITES ASSOCIATED WITH PULMONARY MANIFESTATIONS

A number of parasitic infections may be associated with pulmonary symptoms, although the presence of pulmonary findings may not be sufficient to differentiate between various forms of parasitic diseases. Patients with *P. falciparum* malaria initially may seek treatment for fever and cough, further necessitating the consideration of malaria in travelers with apparent respiratory symptoms. Early in the course of treatment for severe malaria, noncardiogenic pulmonary edema or ARDS may develop, necessitating mechanical ventilation with positive end-expiratory pressure.

E. histolytica can cause sympathetic pleural effusions, pulmonary or pleural involvement by direct extension or rupture of an amebic liver abscess, or direct hematogenous seeding of the lungs, leading to considerable additional morbidity and mortality among patients with underlying amebic infection.

Löffler syndrome, characterized by persistent and nonproductive cough, substernal chest pain, wheezing, rales, pulmonary infiltrates on the chest radiograph, and marked eosinophilia, often is seen when larvae from the roundworm *Ascaris lumbricoides,* the hookworms *N. americanus* and *A. duodenale,* and the threadworm *Strongyloides stercoralis* transit the lungs as part of their developmental cycles. *Ascaris* larvae penetrate the small intestinal wall to gain entry into the small venules of the GI tract and then migrate to the lungs. *Strongyloides* and hookworm filariform larvae penetrate through the skin of the feet, entering small cutaneous venules before migrating to the lungs. The pulmonary infiltrates and symptoms are transient, resolving within 2 weeks. Diagnosis depends on the discovery of larvae in sputum or gastric aspirates. Negative stool examinations initially are nondiagnostic because eggs do not appear in the stool for at least one month after initial infection.

Tropical pulmonary eosinophilia is a syndrome that can result from the patient's immune response to the microfilariae of *W. bancrofti* and *B. malayi*. Affected patients present with malaise, weight loss, new-onset nocturnal wheezing and asthma, shortness of breath, and chest discomfort. Chest radiographs may show nodular or interstitial infiltrates, consolidations, or cavitation, but are sometimes normal. Untreated infection may result in obstructive or restrictive lung disease. Patients have marked eosinophilia and elevations of serum immunoglobulin E levels. Serologic testing demonstrates antibodies to filaria, and microfilaria can be seen on nocturnal blood smears. Young men are more commonly affected.

Paragonimus westermani and echinococcal species are trophic for the lungs in their human hosts. *P. westermani* eggs are shed in stool, hatch in fresh water, and, as miracidia, infect a snail intermediary. After further development, cercariae are released from the snail, penetrating and encysting in freshwater crabs or crayfish. If the human host consumes raw or undercooked shellfish, the metacercariae excyst within the host's duodenum, penetrating the duodenal wall into the abdominal cavity. The larvae migrate from the peritoneal cavity through the diaphragm into the pleural cavity, finally migrating to the lungs, where they cause hemorrhage, necrosis, and a granulomatous response. Early in the process, patients may have infiltrates and eosinophilia; later disease is marked by bronchiectasis, chronic bronchitis, fever, hemoptysis, and cachexia. Pulmonary nodules and cysts may cavitate. Many of these patients may have a positive result on purified protein derivative (PPD) testing, and their symptoms and chest radiographic findings may mimic those of tuberculosis. Sputum often is blood-streaked and

flecked with dark brown particles containing ova. Radiography, stool examination, and immune testing of sputum and blood are all helpful in making the diagnosis, and finding ova in sputum is diagnostic. Praziquantel is the therapeutic agent of choice.

E. granulosus causes pulmonary hydatid cyst disease; the host often remains asymptomatic until a cyst grows large enough to cause a mass effect or becomes superinfected. Pulmonary hydatid cysts also may be associated with cough, expectoration of cyst contents, chest pain, and/or hemoptysis. A thoracic CT scan may show a unilocular lung cyst; on a plain radiograph, a cyst with detached germinal membrane is said to resemble a water lily, a pathognomonic finding. Lung cysts can be treated with careful surgical excision or pharmacotherapy, depending on size.

PARASITIC DISEASES WITH CARDIOVASCULAR MANIFESTATIONS

Chagas Disease

Trypanosoma cruzi infection often leads to acute and chronic myocarditis. *T. cruzi* is endemic in South and Central America and causes Chagas disease. The vector is the reduviid bug (kissing bug) that inhabits the walls and roofs of thatched dwellings built adjacent to forests. Urban transmigration has expanded the epidemiologic scope of Chagas disease, which was previously a disease of rural populations. The disease is not seen commonly in travelers. The reduviid bug's bite is no longer the only source of *T. cruzi* infection; transfusion with blood containing live trypanosomes from infected hosts has been a growing source of infection. Oral transmission also has been reported through consumption of infected fruit.

The reduviid bug bites the patient, often around the eye, and excretes feces containing the trypomastigote of *T. cruzi*. The trypomastigote enters the inflamed bite wound or other mucosal or conjunctival surfaces, causing a local swelling called a chagoma. The Romaña sign (painless unilateral periorbital edema) is pathognomonic but rarely seen. The trypomastigote migrates to trophic tissues, including smooth muscle, cardiac muscle, and autonomic ganglia in the heart, esophagus, and colon, causing local inflammation and tissue destruction.

Acute infection is heralded by fever, facial and dependent extremity edema, hepatosplenomegaly, lymphadenopathy, malaise, lymphocytosis on peripheral blood smear, and elevated liver transaminase levels. At this stage, fatal left ventricular dysfunction and dysrhythmias are uncommon. Early illness lasts 1 to 2 months and resolves spontaneously, resulting in a latency known as the indeterminate phase, which can persist throughout the patient's lifetime.

In approximately 25% of cases, the infection progresses to chronic Chagas disease, principally with cardiomyopathy and GI pathology. Amastigotes invade cardiac muscle and the cardiac conduction system, causing chronic inflammation, mononuclear cell infiltration, and fibrosis. Involvement of the conduction system may lead to atrial bradydysrhythmias, right and left bundle branch blocks, complete heart block, and ventricular dysrhythmias, including ventricular fibrillation (see Chapter 65). Fibrosis and scarring from cardiac muscle infection leads to the development of right and left ventricular dysfunction and dilated cardiomyopathy. Mural thrombi are common, and the first indication of long-standing asymptomatic infection may be thromboembolic disease, such as stroke, pulmonary embolism, or peripheral arterial embolism. Heart failure is generally rapidly progressive and fatal within months unless treated with pharmacologic intervention and transplantation[4] (see Chapter 67).

Acute Chagas disease can be diagnosed by the presence of motile trypomastigotes in anticoagulated blood specimens. The organism also can be cultured in special liquid media. Chronic Chagas disease can be diagnosed by one of several serologic tests, including complement fixation, enzyme-linked immunosorbent assay (ELISA), and indirect immunofluorescence testing. The assays are nonspecific, and cross-reaction may occur in the presence of underlying malaria, syphilis, leishmaniasis, and some collagen vascular diseases. Polymerase chain reaction (PCR) is the gold standard for diagnosing acute or congenital infection, or immunosuppression-induced reactivation.

Nifurtimox 8 to 10 mg/kg/day orally divided every 6 to 8 hours and benznidazole 5 to 7 mg/kg/day orally every 12 hours are used for treatment of *T. cruzi* infection. Cure rates rarely exceed 50%. The duration of treatment with nifurtimox is prolonged, and the drug has many serious side effects. Benznidazole has fewer side effects, is FDA approved in children ages 2 to 12, and is now recommended for indeterminate-phase treatment. Nifurtimox is available under investigational protocols from the CDC. (It can be obtained by calling 404-639-2888).

Late complications of chronic diseases are modulated by autoimmune activity and do not respond to antiparasitic pharmacotherapy. Chronic Chagas disease of the heart, esophagus, or colon is treated symptomatically. Automated implantable cardioverter-defibrillators decrease the incidence of sudden death in infected patients. Patients receiving immunosuppressive therapy to prevent rejection after cardiac transplantation have developed recurrent disease in the transplanted myocardium.

PARASITIC DISEASES WITH GASTROINTESTINAL MANIFESTATIONS

Diarrhea

Diarrhea is one of the most common symptoms motivating travelers to seek medical attention. Diarrhea also is the leading cause of death in children younger than 5 years in developing countries and a major source of morbidity for older children and adults. Most diarrheal disease is viral or bacterial; however, some clinically significant diarrheal disease is caused by parasites.

Cryptosporidium and Cyclospora

Cryptosporidium parvum and *Cyclospora cayetanensis* are foodborne and waterborne coccidians that cause watery diarrhea. Both are particularly significant causes of morbidity in malnourished children and patients with AIDS. Cryptosporidial oocysts can be seen in stool when an acid-fast stain is used. ELISA and immunofluorescent assays of stool also are available for this organism. Paromomycin 25 to 30 mg/kg/day in 3 doses decreases diarrheal frequency in patients with AIDS with cryptosporidial infections; without treatment, patients have prolonged, disabling symptoms. Severe infections in immunocompetent patients can be treated with nitazoxanide 500 mg twice daily. *Cyclospora* oocysts can be detected in stool samples with a Ziehl-Neelsen stain. Trimethoprim-sulfamethoxazole treats this infection.

Entamoeba histolytica

E. histolytica causes an invasive or inflammatory diarrhea. Patients complain of fever, tenesmus, abdominal pain, and watery stool containing blood and mucus. Untreated disease can progress to widespread colitis and perforation of the bowel wall, with peritonitis and death. Stool examination reveals mobile trophozoites containing ingested RBCs. Cysts noted on stool studies do not necessarily reflect active infection because there are nonpathogenic ameba species occasionally found in the bowel of healthy adults. However, nonpathogenic entamoeba do not contain host RBCs. Immune assays of stool can now differentiate between *E. histolytica* and these nonpathogenic ameba

species. Serologic tests may be useful for an infected patient from a nonendemic region, but patients will not have a positive test result for one month after initial infection. Metronidazole 750 mg every 8 hours is the drug of choice for treatment of amebiasis.

Entamoeba histolytica can also cause hepatic abscesses. The patient presents with high fevers, elevated white blood cell counts, right upper quadrant pain, weight loss, anorexia, but no jaundice. Affected patients typically do not have amebic dysentery and do not shed *Entamoeba* in their stool, but results of serologic studies are almost always positive. These patients are treated with metronidazole or tinidazole 2 g/day and a luminal amebicide, such as iodoquinol 650 mg three times a day or paromomycin. Drainage of the abscess is not indicated but will yield a viscous liquid often described "anchovy paste."

Balantidium coli

Balantidium coli is another protozoan that can cause invasive diarrhea. The usual hosts are pigs. It has tropism for the terminal ileum, sometimes causing a clinical picture suggestive of appendicitis. It can also infect the colon, causing abdominal pain, fever, diarrhea, and occasionally colonic perforation. Tetracycline, metronidazole, and iodoquinol are active against *B. coli*.

Giardia lamblia

Giardia lamblia can cause persistent diarrhea, abdominal bloating, cramps, flatulence, and significant weight loss. The organism is ingested and reproduces exponentially in the small bowel. In severe infection, the entire jejunum becomes covered with organisms, and the patient has malabsorption with steatorrhea. The organisms are rarely seen in fresh stool preparations because they quickly break down and become indiscernible. Accordingly, an antigen test often is used to confirm the diagnosis. *Giardia* has many animal reservoirs, including the beaver—thus the lay term, "beaver fever." Campers who drink unfiltered, "pure" mountain spring water in the United States commonly contract *Giardia* infection. Men who have sex with men are also at high risk from a fecal-oral route of transmission. Metronidazole, tinidazole, or nitazoxanide treats the disease.

S. stercoralis, *Capillaria philippinensis*, *T. trichiura*, and *Schistosoma* infections can cause diarrhea. Hyperinfection or dissemination of *Strongyloides* can cause persistent diarrhea, weight loss, and abdominal pain. *Trichuris* causes diarrhea when the parasite load in the intestine is high. Schistosomiasis can cause a chronic granulomatous colitis, which may resemble inflammatory bowel disease, or an acute, bloody, febrile colitis associated with Katayama fever in the immunologically naïve patient.

In chronic schistosomiasis, worm pairs in patients' mesenteric and portal venous systems lay eggs that become ensnared in the liver, causing intense local inflammation, scarring, and classic "pipestem" cirrhosis, with periportal fibrosis. Clinical manifestations in these patients include portal hypertension, ascites, and esophageal varices (Figs. 122.3 and 122.4). Upper GI bleeding is not as common as in patients with alcoholic cirrhosis; however, many patients are infected with schistosomiasis in endemic regions, so variceal bleeding is an important cause of GI hemorrhage in these populations.

Fig. 122.3 Pipestem cirrhosis with extensive ascites in a patient with chronic schistosomiasis.

Fig. 122.4 Extensive ascites in a child, which may be from schistosomiasis or kala-azar (leishmaniasis).

Echinococcosis

Echinococcus granulosus is a tapeworm capable of causing disease in a number of organs, most commonly the liver, lung, bone, and CNS. The *Echinococcal* life cycle usually occurs outside of humans, with dogs and other canid species harboring the adult tapeworm in their intestinal tract. Sheep and other grazing animals ingest eggs shed in the stool of dogs in pastural areas. In the sheep, eggs hatch, penetrate the intestine, and migrate to other tissues where they form cysts. The life cycle is completed when infected viscera of sheep are consumed by dogs. This usually occurs when sheep are slaughtered for food, and the discarded offal is fed to dogs. Humans become incidental end hosts when they ingest eggs from an environment (often food or water) contaminated by the feces of infected dogs.

In humans, infection results in the liberation of the embryonic oncosphere into the small intestine. *Echinococcal* larva then penetrate the intestinal wall and migrate to many organs, where they form enlarging hydatid cysts. Hydatid cysts are loculated structures containing a germinal epithelium, which produces the multiple infectious protoscoleces (heads) of the adult worm, as well as daughter cysts. The liver is the target organ in more than two-thirds of cases, with 20% occurring in the lungs, 6% in the spleen, and 2% or fewer in the heart, kidney, and brain.[5] Hydatid cysts typically grow slowly at a rate of 1 to 10 mm per year. The host immune response leads to a fibrous capsule around the cyst.

Fig. 122.5 Hydatid cysts removed surgically.

Fig. 122.6 Additional hydatid cysts removed surgically.

Over time, the metabolically active germinal layer can separate from the acellular laminar layer leading to cessation of growth and eventual involution and calcification. Hydatid cysts, especially larger ones, can rupture spontaneously or from direct trauma spilling cyst contents and initiating the proliferation of daughter cysts. This spilling and proliferation can lead to a disastrous seeding of the peritoneum or pleural space with metastatic growth which is very difficult to treat (so-called "white cancer") as well as the possibility of secondary bacterial infection of the ruptured cyst cavity, bronchopleural fistula, and anaphylactoid reactions to parasite antigens. When a pulmonary cyst ruptures, it may lead to the expectoration of salty cyst fluid, a phenomenon known as "hydatid vomica." *Echinococcus multilocularis,* the cause of human alveolar echinococcosis, is a related parasite found in the northern hemisphere, with relatively high incidence in China, Siberia, and central Europe. Like hydatid echinococcosis, *E. multilocularis* has a canid definitive host (foxes, coyotes, domestic dogs). Its intermediate host is a number of rodent species. When humans are incidentally infected, they develop proliferative multiloculated liver cysts that can resemble hepatic neoplasms.

The diagnosis of hydatid cyst disease is suggested by the appearance and localization of the cyst on ultrasound examination or CT scan. The Gharbi classification scheme describes ultrasonographic stages of hydatid cyst development and involution, which is important for determining treatment modality. Serologic evaluation of serum or cerebrospinal fluid (CSF) may help confirm the diagnosis. Simple aspiration of the cyst should not be attempted because of the risk of seeding the host's body with metastatic cysts.

Treatment options include albendazole, praziquantel, and surgical resection. PAIR (puncture, aspiration, instillation, re-aspiration) is a procedure that can be used on larger hydatid liver cysts and uses instillation of 95% alcohol to inactivate the germinal layer of an active cyst. Resection of the cyst may cause an anaphylactoid reaction if there is spillage of hydatid sand, which contains parasite antigenic proteins (Figs. 122.5 and 122.6). Treatment of alveolar hydatid disease is primarily with albendazole.

Fascioliasis, caused by the liver fluke *Fasciola hepatica,* is endemic on all continents except Antarctica and has been found in over 50 countries, especially where sheep or cattle are reared. Infection begins with ingestion of the metacercariae often found in watercress. Within 6 weeks, patients exhibit right upper quadrant abdominal pain, fever, nausea and vomiting, jaundice, tender enlarged liver, and elevated transaminase levels. This syndrome can mimic viral hepatitis; however, eosinophilia and urticaria are often present. Imaging studies, including CT, show the tracks of burrowing flukes. Serologic testing establishes the diagnosis; the patient's stool may not contain eggs for several months after ingestion.

Several parasites have been identified in the pathologic examination of appendices of patients diagnosed with tropical appendicitis. These infections have included enterobiasis, amebiasis, ascariasis, trichuriasis, and taeniasis.

A. lumbricoides (roundworm) can cause significant persistent or recurrent abdominal pain in adults and partial intestinal obstruction in children with significant worm loads. Antihelminthics and conservative supportive therapy usually eliminate this infestation, thereby avoiding surgical intervention. Clinicians diagnose ascariasis by identifying eggs in the stool. Patients with large worm loads may excrete adult worms, especially after therapy is started. Severe intestinal amebiasis can be complicated by colonic perforation and peritonitis.

Angiostrongylus costaricensis, a species of rat lung worm, is common in Central America. Infected children may appear clinically to have Meckel diverticulum or acute appendicitis. Manifestations of the infection include nausea, vomiting, fever, abdominal pain localized to the right lower quadrant, and a tender mass. Surgical exploration may uncover abscesses, obstruction, or intestinal infarction. Anisakiasis is characterized by severe abdominal pain that occurs within hours of ingestion of raw fish (sushi and sashimi primarily). It is caused by *Anisakis simplex,* a nematode that burrows into the wall of the stomach or intestine. Treatment requires endoscopic removal of the worm.

Jaundice may result from hemolysis secondary to direct infection of RBCs with *Plasmodium* or *Babesia* or from biliary obstruction with pigmented stones. *Ascaris* can cause biliary colic, pyogenic cholangitis, pancreatitis, or liver abscess. Dead worms can be the nidus for gallstone formation. Biliary imaging and endoscopic retrograde cholangiopancreatography show worms in the biliary tree. Mechanical removal by endoscopy combined with antihelminthic therapy is curative. *Clonorchis sinensis* and *F. hepatica* are trophic for the biliary tree. Infection with these worms may be asymptomatic for years before eventually precipitating cholecystitis, cholangitis, or cholangiocarcinoma.

Enterobius vermicularis

Enterobius vermicularis, or pinworm, causes pruritus ani, a syndrome of intense perianal itching occurring primarily in children. Autoinfection is common, because children (and adults) scratch the pruritic anal area and then bite their nails or put their fingers in their mouth. The worm has a worldwide distribution. Diagnosis is clinical and is confirmed by finding the small adult worms wriggling the anal verge. Eggs are rarely seen in the stool but can be visualized by the tape test—transparent tape touched to the perianal region collects eggs, which can be seen with light microscopy. Albendazole or mebendazole is the drug of choice.

PARASITIC COINFECTIONS IN PATIENTS WITH HIV INFECTION AND AIDS

HIV infection is prevalent in developing countries. Heterosexual transmission and perinatal transmission are common; children and young adults of both sexes are primarily infected. Patients presenting to the ED may be coinfected with HIV and any other infectious agent, including all the parasites discussed in this chapter. HIV coinfection may worsen the symptoms and outcome, alter the presentation, increase the virulence, or assist the infective process.

AIDS causes abnormalities in almost every aspect of a host's immune response to infection; cell-mediated immunity, which is important in combating parasitic infection, is most affected. The diagnosis and response to therapy of many parasitic infections are monitored serologically. HIV infection interferes with this response, rendering many of these tests unreliable. Therapies that are extremely effective in the normal host may be ineffective in a patient with HIV infection. Pharmacologic agents may have to be given for long periods or the duration of the patient's life.

Specific Parasitic Coinfections

Malaria is not an opportunistic infection in patients with AIDS; however, many patients, especially children, with recurrent malaria and anemia from hemolysis have required transfusions from blood supplies not screened for HIV and have become infected. In regions where malaria is endemic, it is a common practice to treat most febrile patients with antimalarials. Some antimalarials are sulfonamides. Patients with AIDS have more severe allergic reactions to drugs, especially sulfonamides. Fever alone is not predictive of malaria in patients with AIDS; therefore, diagnosis should precede therapy.

Patients with HIV infection are at greater risk for severe clinical manifestations of babesiosis.

Visceral leishmaniasis is usually disseminated and often fatal in patients with AIDS. Latent leishmanial infections may be reactivated, and a prolonged febrile illness in an HIV-positive patient with a lifetime history of travel in leishmaniasis-endemic areas of the world should prompt consideration of this coinfection. Cutaneous infection also may become disseminated in these patients. Several clinical trials are examining the role of chemoprophylaxis for leishmaniasis in HIV-positive persons who live in endemic regions.

Chagas disease in the indeterminate phase can be reactivated in patients infected with HIV. These patients frequently have CNS involvement, with meningoencephalitis and severe myocarditis. Single-drug therapy may be insufficient because benznidazole penetration into the CSF is minimal. *T. gondii* infection is well recognized throughout the world as a common opportunistic infection for patients with AIDS, with a particular trophism for the CNS.

The coccidial organisms *Isospora belli, C. parvum,* and *C. cayetanensis* have been associated with prolonged diarrhea in patients with AIDS. These organisms cause difficult to treat infections and are almost impossible to eradicate in patients with AIDS. The diarrhea is extremely debilitating and can be as profuse as that seen in cholera. *E. histolytica* has a high prevalence among men who practice unprotected anal intercourse; however, invasive amebiasis is not an opportunistic infection associated with HIV infection.

Schistosomiasis may enhance the pathogenesis of HIV infection and is more difficult to treat and eradicate in patients who are HIV positive. Despite initial concerns, *S. stercoralis* infection does not appear to manifest more frequently as hyperinfection and disseminated disease in HIV-positive patients. In patients at risk for HIV infection and parasitic illness, it is essential to consider coinfection in the differential diagnosis. While many HIV-positive patients in industrialized countries are taking suppressive medication (HAART) and have fairly normal immune function, many patients who emigrate from developing countries may not have access to testing or HAART and thus may be HIV positive with active AIDS and parasitic coinfection.

CHAPTER 122: QUESTIONS AND ANSWERS

1. A 33-year-old man presents with irregular fevers, shaking chills, intermittent abdominal pain, and fatigue. The fever comes in cycles during approximately 2 or 3 days. He has no medical history and takes no medications. He works as a baggage handler in Miami, Florida. Physical examination reveals a low-grade fever and mildly tender hepatosplenomegaly. Laboratory evaluation is remarkable for hemoglobin 9.6 g/dL, leukocytosis, lactate dehydrogenase 1850 IU/dL, elevated bilirubin, and urine dipstick "blood positive" but no red blood cells or white blood cells. He has had no international travel. Peripheral smear reveals few possible parasites with fragmented red blood cells. What is this patient's most likely infection?

a. Babesiosis
b. Early sepsis
c. Leishmaniasis
d. Malaria

Answer: D. Airport malaria has been reported in people who have never been in endemic areas but who work in or live near an international airport. The infected mosquito is transported from the endemic region and released when the plane arrives. Babesiosis is a parasitic illness with a clinical picture like that of malaria. It is tickborne and is endemic in the northeastern United States.

2. Parasite-induced loss of vision would be suggested by which of the following?

a. Cardiomegaly
b. Edematous and pruritic skin
c. Fever
d. Hepatosplenomegaly
e. Iron deficiency anemia

Answer: B. Onchocerciasis is a major cause of blindness worldwide. Ninety-five percent of cases occur in Africa. The biting flies are found near rivers, and humans are the only host for the parasite. It occupies the skin, resulting in pruritus, edema, and later atrophy with redundant skin folds. The following are other causes of parasite-induced visual loss: *Toxoplasma* can cause retinal hemorrhages, *Toxocara* can cause inflammatory retinal granulomas, and *Acanthamoeba* may cause a keratitis in contact lens wearers.

3. A macrocytic anemia would suggest infection from which parasite?

a. Ancylostoma duodenale
b. Diphyllobothrium latum
c. Falciparum malaria
d. Necator americanus

Answer: B. The fish tapeworm is associated with pernicious anemia. Hookworm and whipworm are associated with gastrointestinal iron loss and microcytic anemia. Malaria causes hemolytic anemia.

4. A 42-year-old man from Ethiopia presents with complaints of skin nodules and skin ulcerations. He has no known past illnesses, exposures, medication use, or systemic symptoms. Examination is remarkable for four 2- or 3-cm cutaneous ulcers on the arms and legs and scattered 1-cm nodules. Vital signs are normal, and physical examination is otherwise unrevealing. Which of the following statements regarding this infection is TRUE?

a. Respiratory tract symptoms would suggest an alternative diagnosis.
b. The lesions always require treatment.
c. The lesions are likely painful to touch.
d. The skin pattern may be confused with leprosy.

Answer: D. Leishmaniasis is transmitted by the sandfly bite. Skin papules and macules develop at bite sites. These may ulcerate into painless ulcers. A microcutaneous variant may be seen, and the inflammatory process may involve the larynx and trachea. Disseminated cutaneous leishmaniasis may resemble lepromatous leprosy.

5. Which of the following is the correct association between the type of parasitic infection and pulmonary symptoms?

a. Hookworm—positive PPD response
b. Leishmaniasis—pulmonary nodules
c. Löffler syndrome—ascariasis
d. Pneumocystis—90% of opportunistic infections in Africa

Answer: C. Ascariasis and hookworm may cause Löffler syndrome of chest pain, fever, rales, wheezing, and eosinophilia. The following are the other correct associations:

- Pneumocystis—less than 10% of pulmonary opportunistic infections in Africa
- *Paragonimus westermani*—positive tuberculin skin test response and chest radiograph resembling tuberculosis
- Echinococcus—anaphylaxis from leakage of cystic contents
- Schistosomiasis—diffuse pulmonary nodules (Katayama fever)

123

Tickborne Illnesses

Edward B. Bolgiano and Joseph Sexton

KEY CONCEPTS

- Tickborne illnesses frequently are misdiagnosed as common viral or bacterial infections. Diagnosis can be facilitated by considering tickborne illnesses in patients who recently have been in endemic areas and routinely asking for a history of recent tick or insect bites in patients with febrile illnesses.
- Lyme disease should be suspected in patients who present with signs of a viral illness, monarticular arthritis, meningitis, multiple neurologic abnormalities, or heart block. Diagnosis can be confirmed with serologic testing of acute and convalescent serum samples.
- Normal physiologic changes from tick bites should not be confused with erythema migrans.
- Relapsing fever should be suspected in patients who present with recurrent viral-like illness associated with high fever. The diagnosis can be confirmed by identifying spirochetes on a blood smear obtained during a period of rising temperature.
- Ulceroglandular tularemia should be suspected in patients with slow-healing extremity ulcers associated with large lesions of regional adenopathy (buboes). The diagnosis can be confirmed with serologic testing.
- Rocky Mountain spotted fever should be considered in patients who present with an unexplained febrile illness, even in the absence of a rash or known tick exposure. Delayed diagnosis and late initiation of specific antirickettsial therapy may lead to a fatal outcome. Treatment never should be delayed pending laboratory diagnosis.

OVERVIEW

Ticks are hematophagous parasites of humans and animals, distributed worldwide. They transmit rickettsial, bacterial, spirochetal, viral, and protozoal diseases and cause disease employing their own toxins (Table 123.1). As vectors of human disease, ticks rank second in importance only to mosquitoes. Although it is generally understood that people who travel during the summer months may return from endemic areas with tickborne disease, increasing reports of infection acquired within urban areas emphasize the need to consider tickborne illness even in the absence of a history of travel to high-risk areas. In addition, tularemia and Q fever are now considered by the Centers for Disease Control and Prevention (CDC) to be significant threats during biologic warfare, adding to the importance of research on ticks and tickborne diseases.

Reports on ticks, their feeding habits, and their possible relation to disease can be found from early human history. Tickborne illness was first recognized on the North American continent by Native Americans. The causative association of the tick vector with Rocky Mountain spotted fever (RMSF) was noted by missionaries and early settlers, who named the affliction tick fever, and physicians in Idaho and Montana recorded the classic clinical descriptions of the disease in 1899.

The majority of tickborne diseases in the United States occur east of the Mississippi River (Fig. 123.1). The reported cases of these diseases have nearly doubled since 2008, led by Lyme disease, the ehrlichioses, and the Rocky Mountain or other spotted fever rickettsioses (Table 123.2).

Identification of Ticks

Ticks are arthropods but not insects. They have eight legs instead of six and generally two fusing body parts—a capitulum (head) and opisthosoma (abdomen)—instead of three. Identification of an arthropod as a tick is not difficult (Figs. 123.2 and 123.3), but speciation requires a trained acarologist. However, tick identification has limited importance in clinical decision making. Color, which varies seasonally, and size, which varies by amount of blood ingested at the time of presentation, are unreliable criteria for identification purposes.

Physiology of Tick Feeding

An understanding of the physiology of feeding in arthropods is helpful when assessing the risks of disease transmission. Blood-sucking (hematophagic) arthropods are divided into two groups according to their method of acquiring blood. The solenophagic feeders insert their mouthparts directly into capillaries to obtain blood. Telmophagic feeders insert their mouthparts indiscriminately, lyse tissue along with capillaries, and feed on the resultant pool of blood, extracellular fluid, and tissue. Ticks and deer flies, for example, are telmophagic feeders, whereas mosquitoes are mostly solenophagic.

Argasid ticks (soft-bodied ticks) are short, rapid feeders with preformed distensible endocuticles. They therefore need to feed for only minutes to hours to acquire a full meal. As a result, they tend to be found in nests and burrows where their hosts visit frequently. The soft tick genus *Ornithodoros* is the vector for relapsing fever. Ixodid ticks (hard-bodied ticks) include the genera *Ixodes, Dermacentor, Amblyomma,* and *Rhipicephalus,* which are those responsible for the remainder of human tickborne diseases in the United States discussed in this chapter.

Two mechanisms prevent many species of tick from being removed from the skin—the barbed hypostome, or a calcified mouth-piece that anchors the tick to the skin, and a cement-like salivary secretion from the base of the hypostome, composed of lipoproteins and glycoproteins. This allows ixodid ticks to remain attached for as long as 2 weeks. Because argasids are much faster feeders, they secrete no cement substance.

During a bite, trauma and salivary gland products can cause local inflammation, hyperemia, edema, hemorrhage, and skin thickening. Hard and soft ticks produce a histolytic secretion injected during feeding that liquefies tissue, which is then sucked into the gut. Eventually, the secretion breaks down the walls of the dermal blood vessels and the released blood is ingested. To prevent hemostasis, the saliva contains

TABLE 123.1 Tickborne Illnesses

Type	Disease	Pathogen	Arthropod Vector	Geographic Distribution
Bacterial (including spirochetal)	Lyme disease	*Borrelia burgdorferi*	*Ixodes scapularis*	Northeastern United States
			Ixodes pacificus	Upper Midwestern United States
			Ixodes ricinus	Pacific Coast Europe
	Tularemia	*Francisella tularensis*	*Ixodes scapularis*	Southwest central United States
			Amblyomma americanum	
			Dermacentor variabilis	
Rickettsial	Rocky Mountain spotted fever	*Rickettsia rickettsii*	*Dermacentor andersoni* *Dermacentor variabilis*	Predominantly southeastern United States
			Rhipicephalus sanguineus	Arizona
	Q fever	*Coxiella burnetii*	*Dermacentor andersoni*	Worldwide
	Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	*Amblyomma americanum*	South central and southeastern United States
	Human granulocytic anaplasmosis	*Anaplasma phagocytophilum*	*Ixodes scapularis*	New England and north central United States
			Ixodes pacificus	Northern California
Parasitic (protozoal)	Babesiosis	*Babesia microti*	*Ixodes scapularis*	Coastal New England
Viral[a]	Colorado tick fever	Orbivirus	*Dermacentor andersoni*	Mountain areas of western United States and Canada
Miscellaneous	Tick paralysis	Ixobotoxin	*Dermacentor andersoni* *Dermacentor variabilis* *Amblyomma americanum* *Ixodes scapularis* *Ixodes pacificus* *Ixodes holocyclus*	Worldwide

[a]Many other viruses are transmitted to humans by ticks. In the United States, only Colorado tick fever occurs with any significant frequency.

a thrombokinase inhibitor, apyrase, which prevents platelet aggregation by depleting adenosine diphosphate, prostaglandin E_2, and prostacyclin (prostaglandin I_2) to prevent vasoconstriction, and cytolysins. *Ixodes scapularis* also secretes a carboxypeptidase that destroys other inflammatory mediators, such as anaphylatoxins and bradykinin, as well as anti–complement C3 factor. These other mediators normally would cause further inflammation, which would enhance hemostasis. The neurotoxins responsible for tick paralysis also are found in tick saliva. All infectious agents and excretory liquids from some argasids are transmitted through this saliva. Transmission of a disease from *Ixodes* ticks is unlikely if the tick is not yet engorged with blood at the time of removal.

The local physiologic changes associated with tick feeding produce the characteristic 1- to 4-mm erythematous mark typically seen on the skin after a tick bite. This is a common finding from most blood-sucking arthropods. The mark should not be confused with certain rashes associated with disease progression—for example, erythema migrans. Informing patients of this difference may be reassuring.

LYME DISEASE

Lyme disease, the most common vector-borne disease in the United States, is a tickborne illness caused by six species in the spirochete family Borreliaceae. In North America, infection is caused primarily by *Borrelia burgdorferi*. The recognition of Lyme disease began in 1975, when health officials at the Connecticut State Department of Health and physicians at Yale University were alerted by two skeptical mothers to an unusually large number of cases of apparent juvenile rheumatoid arthritis occurring in their small coastal community of Old Lyme, Connecticut. Investigation led to the description of a new entity called Lyme arthritis. The causative agent of Lyme disease was isolated in 1982.

Lyme disease occurs worldwide and has been reported on every continent except Antarctica. It now accounts for more than 95% of all reported cases of US vector-borne illness. The incidence of Lyme disease is unknown because many cases go unreported. Lyme disease occurs in people of all ages but is more common in children younger than 15 years and in adults 30 to 60 years of age. Persons at greatest risk live or vacation in endemic areas. In the United States, three distinct endemic foci are recognized—the northeastern coastal, Mid-Atlantic, and north central states. Twelve states (Connecticut, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Washington, and Wisconsin) account for 92% of US cases reported (Fig. 123.4).[1]

The principal tick vectors are *I. scapularis* in the Northeast and Midwest and *Ixodes pacificus* in the West. The *I. scapularis* population density depends on that of its preferred hosts, the white-footed field mouse, *Peromyscus leucopus,* for the larval and nymphal forms, and the white-tailed deer, *Odocoileus virginianus,* for the adult form. The white-footed mouse readily becomes infected after being bitten by infected ticks and remains highly infectious for periods that approach its life span, thereby providing an important reservoir for *B. burgdorferi*. Adult *I. scapularis* ticks feed primarily on deer, which are key hosts in the tick life cycle and in whose fur the adult tick may survive the winter. The repopulation

of several areas in the United States by white-tailed deer preceded the recent emergence of Lyme disease in those regions.

Although all stages of the tick may feed on humans, the nymph is primarily responsible for transmitting Lyme disease. It is not surprising that more than two-thirds of patients with Lyme disease do not recall a tick bite, given the small size (1–2 mm) of nymphs (Fig. 123.5). The nymph feeds in the spring and summer, correlating with a peak incidence of early Lyme disease between May and August. In addition, recreational and occupational exposure is greatest during this time. Later manifestations of Lyme disease may appear throughout the year.

The spirochete *Borrelia burgdorferi* persists and multiplies in the midgut of its tick vector, *I. scapularis*. Transmission of the spirochete to humans occurs during feeding, generally about 2 days after attachment. The mechanism of transmission probably is inoculation with infectious saliva or with tick gut fluids periodically regurgitated during the feeding process.

After an incubation period that lasts several days to weeks, spirochetemia develops, and *Borrelia* organisms may migrate outward in the blood or lymph to virtually any site in the body. The spirochete appears to be tropic for synovial tissue, skin, and cells of the nervous system, but the mechanism of this tropism is not yet understood. Infection by the spirochete itself accounts for early clinical manifestations. It remains unclear whether late disease manifestations require the continued presence of viable spirochetes or whether an ongoing host immune response to initial infection is sufficient to cause some late disease effects, but persistent live spirochetes are likely responsible for most later manifestations of the disease. The variable severity of Lyme disease may in part result from genetic variations in the human immune system. For example, patients with chronic Lyme arthritis have an increased frequency of human leukocyte antigen (HLA) specificity, in particular for HLA-DR4 and, less often, for HLA-DR2.

Clinical Features

Lyme disease, a multisystem disorder, can be classified into three stages—early localized, early disseminated, and late disease. Virtually any clinical feature may occur alone or recur at intervals, and some patients who had no early symptoms may have late symptoms. The disorder usually begins with a rash and associated constitutional signs and symptoms, suggesting a viral syndrome (early Lyme disease). Neurologic, joint, or cardiac manifestations may emerge weeks to months later (early disseminated Lyme disease), and chronic arthritic and neurologic abnormalities may appear weeks to years later (late Lyme disease). The time course for the clinical features of untreated Lyme disease is illustrated in Fig. 123.6.

Early Lyme Disease

Ticks may attach to human hosts at the initial point of contact, generally around ankle level, or move about until they encounter an

obstruction. The groin, popliteal fossae, gluteal folds, axillary folds, and earlobes are common sites of attachment. With transmission of *B. burgdorferi* through a tick bite, the initial site of infection is the skin at the site of the bite. After an incubation period of approximately 1 week (range, 1–36 days), the spirochetes cause a gradually spreading localized infection in the skin and a resultant skin lesion, erythema migrans.

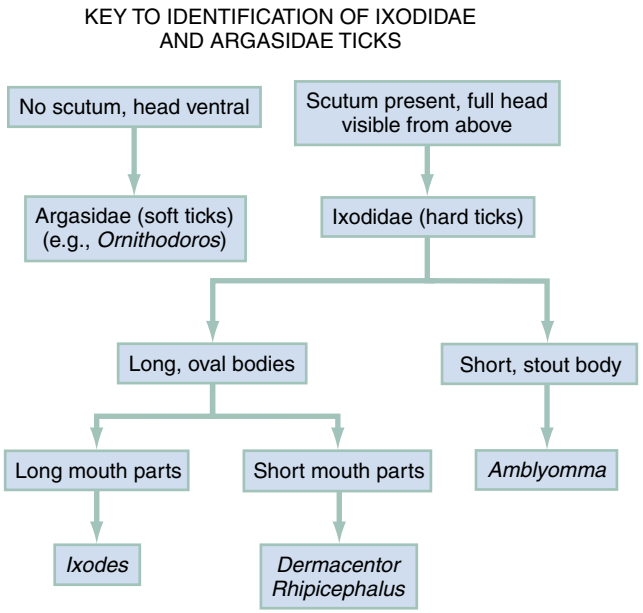

Fig. 123.3 Identification scheme for Ixodidae and Argasidae genera, the two primary disease-transmitting families of ticks.

Erythema migrans (EM) is the most characteristic clinical manifestation of Lyme disease and is recognized in 90% or more of patients. EM may go unnoticed if the entire skin surface is not examined. The characteristic rash begins at the site of the tick bite with an erythematous papule or macule. The lesion expands gradually (1–2 cm/day, a rate of expansion slower than cellulitis). The patch of erythema may be confluent or may have bands of normal-appearing skin. Central clearing may occur but is not an invariable feature. The lesion borders usually are flat but may be raised. The lesions generally are sharply demarcated and blanch with pressure. Most lesions are oval or round, but triangular and elongated patches may occur. In patients presenting 1 to 7 days after the appearance of lesions, the average lesion size is approximately 8 by 10 cm (range, 2 by 3 cm to 25 by 25 cm). In some cases, the center of some early lesions becomes red and indurated or vesicular and necrotic. The lesion is warm to the touch and may be described by the patient as nontender to minimally tender (Figs. 123.7 and 123.8).

Hematogenous spread of viable spirochetes (not additional tick bites) may result in one or more secondary lesions. These secondary lesions are smaller, migrate less, and typically spare the palms and soles. In all, 10% to 15% of patients have more than 20 such lesions; on rare occasions, they may number more than 100. Blistering and mucosal involvement do not occur. The primary and secondary skin lesions generally fade after approximately 28 days (range, 1 week to 14 months) without treatment and within several days of antibiotic therapy. Recurrent lesions may develop in patients who do not receive antibiotic therapy but not in those who receive appropriate antibiotics.

Constitutional signs and symptoms commonly appear in early Lyme disease (Table 123.3). Malaise, fatigue, and lethargy are most common (seen in ≈80% of patients) and may be severe. Fever typically is low grade and intermittent. Lymphadenopathy usually is regional in

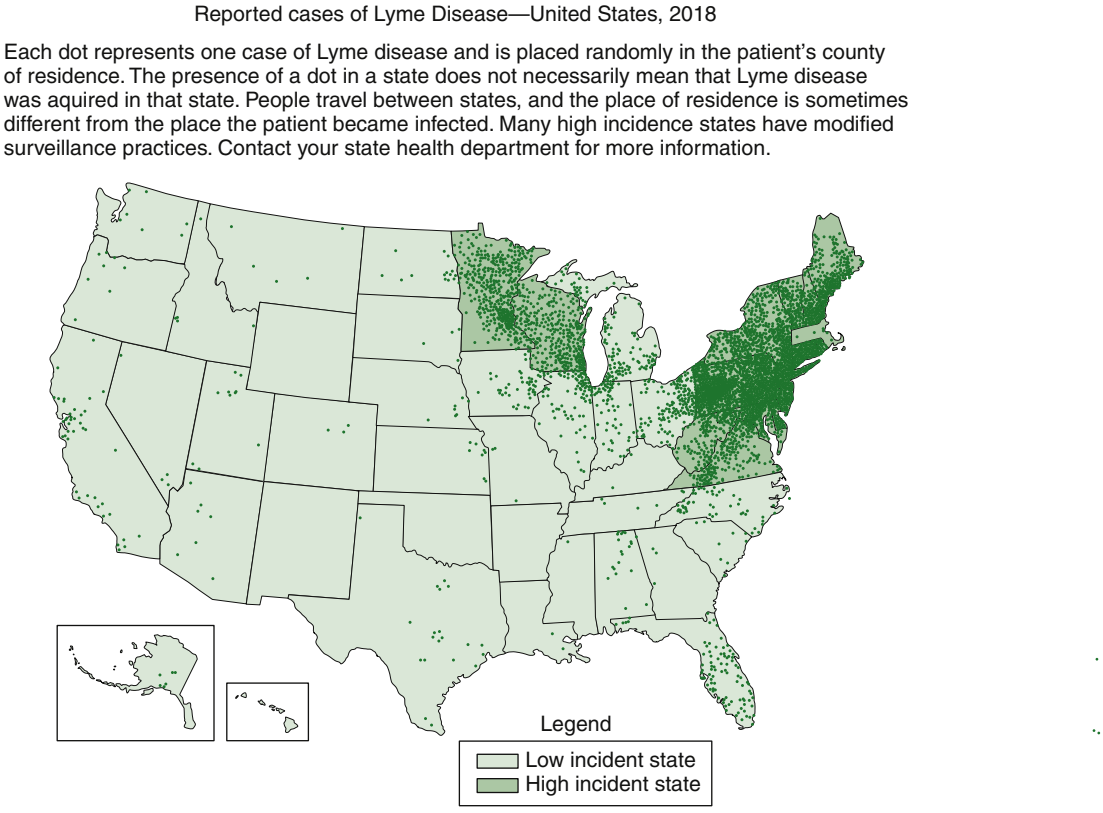

Fig. 123.4 Reported cases of Lyme disease cases by county in the United States in 2018. The number of confirmed cases totaled 23,558. (Adapted from: Centers for Disease Control and Prevention: Lyme disease maps. https://www.cdc.gov/lyme/stats/maps.html.)

the distribution of EM or may be generalized; splenomegaly may occur. Musculoskeletal complaints, such as arthralgias and myalgias, are common, and the discomfort typically is short-lived and migratory, sometimes lasting only hours in one location. Frank arthritis may occur at this stage but is rare.

Clinical manifestations of meningeal irritation are frequently seen. Headache, the most common symptom, usually is intermittent and localized. Nausea, vomiting, and photophobia occasionally accompany the headache. Kernig and Brudzinski signs typically are absent, and neck stiffness usually is noted only on extreme forward flexion. At this stage, the neurologic examination and cerebrospinal fluid (CSF) assessment usually yield normal findings.

Signs and symptoms of hepatitis, including anorexia, abdominal pain, right upper quadrant tenderness, nausea, and vomiting, may be present. Mild pharyngitis also may be present, but other upper respiratory symptoms, such as rhinorrhea, do not occur. Although the systemic symptoms of early Lyme disease often are described as flulike, that term can be misleading because clinically significant cough usually does not occur. Conjunctivitis develops in approximately 10% of patients.

The incidence of Lyme disease without EM appears to be approximately 10%. Because of the variety of nonspecific signs and symptoms at this stage, in the absence of the characteristic rash or history of tick bite, early Lyme disease may be easily confused with a viral or collagen vascular disease. The intermittent and rapidly changing nature of the early signs and symptoms of Lyme disease may be a helpful distinguishing feature, especially in a patient from an endemic area. In untreated disease, early symptoms usually last for several weeks but may persist for months.

Acute Disseminated Infection

Shortly after disease onset, hematogenous spread can cause various systemic signs and symptoms and result in secondary sites of infection. Organ systems commonly affected are the nervous system, heart, and joints. Less commonly, the eyes, liver, skeletal muscle, subcutaneous tissue, and spleen are infected.

Neurologic Manifestations. A relatively symptom-free interval usually occurs between early and disseminated infection; however, neurologic signs and symptoms may be the presenting manifestations of Lyme disease or may overlap with early or late manifestations. Beginning at an average of 4 weeks (range, 0–10 weeks) after the onset of erythema migrans, neurologic involvement occurs in approximately 15% of untreated patients.

The most common neurologic manifestation of Lyme disease is a fluctuating meningoencephalitis, with superimposed symptoms of cranial neuropathy, peripheral neuropathy, or radiculopathy. A triad of lymphocytic meningitis, cranial neuropathies (usually Bell palsy), and radiculoneuritis (motor or sensory or both) has been described, but each entity may occur alone. Headache of variable intensity usually is present; other signs and symptoms of a mild meningoencephalitis may be noted, including lethargy or irritability, sleep disturbances, poor concentration, and memory loss. At this point, the disease often is misdiagnosed as viral meningitis. As in early disease, Kernig and Brudzinski signs are absent and computed tomography (CT) findings are normal. Unlike in early disease, however, findings on CSF examination often are abnormal, with a lymphocytic pleocytosis and moderately elevated protein level. CSF glucose concentration usually is normal. Intrathecal *B. burgdorferi* antibody (usually immunoglobulin G [IgG] or IgA) is present in 80% to 90% of patients. CSF polymerase chain reaction (PCR) assay results are positive in less than 50% of patients, probably reflecting the low number of organisms usually present in spinal fluid. Routine testing of CSF by PCR assay is not recommended.

Cranial neuropathies are common, occurring in approximately 50% of patients with Lyme meningitis; the seventh nerve is usually involved. Other cranial nerves are affected less often. Bell palsy is bilateral in approximately one-third of patients. Its duration usually is weeks to months, and the condition generally resolves spontaneously without treatment.

Peripheral nervous system manifestations also may occur in early disseminated Lyme disease. The spinal root and plexus and peripheral nerves may be involved in the form of thoracic sensory radiculitis, brachial plexitis, mononeuritis, and motor and sensory radiculoneuritis in the extremities. Patients may complain of weakness, pain, or dysesthesia. Examination may reveal loss of reflexes. Involvement of the extremities usually is asymmetrical, but cervical and thoracic dermatomes may be affected. Radiculoneuritis can mimic a mechanical radiculopathy (such as sciatica) and should be considered in endemic areas in patients without an apparent mechanical cause. Other rare neurologic abnormalities described in association with Lyme disease include chorea, transverse myelitis, ataxia, and pseudotumor cerebri. Cerebral vasculitis associated with Lyme disease also has been reported.

Cardiac Manifestations. Cardiac involvement in Lyme disease is uncommon, with an estimated incidence in untreated patients ranging from 4% to 10%. Carditis occurs during the early disseminated phase of the disease. The average time from initial illness to the development of carditis typically is 3 to 5 weeks (range, 4 days to 7 months). Direct myocardial invasion has been demonstrated with endomyocardial biopsy. Electrophysiologic testing has demonstrated widespread involvement of the conduction system.

The most common cardiac manifestation of Lyme disease is atrioventricular (AV) block, although conduction defects may involve any level of the conducting system.[2] Myopericarditis, tachydysrhythmias including atrial fibrillation,[3] and ventricular impairment occur less often. In a review of 105 reported cases of Lyme carditis, 49% of cases were third-degree, 16% were second-degree, and 12% were first-degree AV block. The degree of AV block seen in a specific patient may fluctuate rapidly.

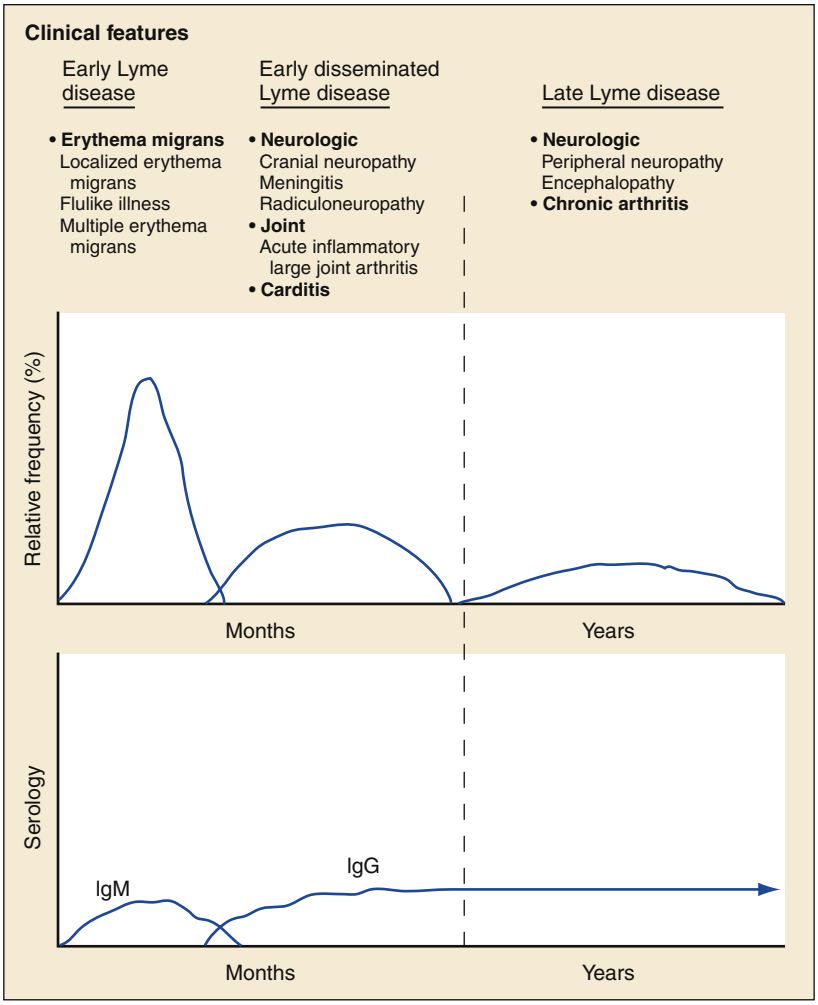

Fig. 123.6 Natural history of serologic response, with clinical features, in untreated Lyme disease. *IgG,* Immunoglobulin G; *IgM,* immunoglobulin M. (Adapted from: Rahn DW. Natural history of Lyme disease. In Rahn DW, Evans J, eds. *Lyme Disease*. Philadelphia: American College of Physicians; 1998, pp 35-48.)

Fig. 123.7 Lyme disease usually begins with a slowly expanding skin lesion, erythema migrans, which occurs at the site of the tick bite. The classic bull's-eye or target lesion has partial central clearing, a bright red outer border, and a target center. (From: Bhate C, Schwartz RA. Lyme disease. Part I. Advances and perspectives. *J Am Acad Dermatol*. 2011;64:619-636.)

A commonly observed feature of AV block in patients with Lyme carditis is its gradual resolution, resembling that occurring after an acute inferior wall myocardial infarction and presumably related to the resolution of inflammation. Assessment of the level of the AV block is important to determine the prognosis of a patient with Lyme carditis. In most cases, the block appears to be at or above the AV node; therefore, the prognosis is favorable. However, infranodal AV block does occur and may be characterized by slow escape rhythms of wide QRS pattern, asystole, or fluctuating left and right bundle branch block. Other electrocardiographic findings include nonspecific ST and T wave abnormalities and intraventricular conduction delay.

Patients with high-degree AV block usually are symptomatic. Symptoms include lightheadedness, palpitations, syncope, chest pain, and dyspnea on exertion. The physical examination may reveal flow murmurs and murmurs of mild mitral regurgitation, pericardial friction rub, or evidence of congestive heart failure. Associated left ventricular dysfunction may be present and has been documented by two-dimensional echocardiography and radionuclide studies; in most reported cases, it has been mild and transient. Sudden cardiac death attributable to Lyme disease has also been reported.

Fig. 123.8 Early erythema migrans on the lower leg. The erythematous nodular appearance could lead to misdiagnosis as a spider bite or MRSA cellulitis. (From: Bhate C, Schwartz RA. Lyme disease. Part I. Advances and perspectives. *J Am Acad Dermatol.* 2011;64:619-636.)

TABLE 123.3 Early Clinical Manifestations of Lyme Disease

Manifestation	No. of Patients (%)
Signs	
Erythema chronicum migrans[a]	314 (100)
Multiple annular lesions	150 (48)
Lymphadenopathy	
Regional	128 (41)
Generalized	63 (20)
Pain on neck flexion	52 (17)
Malar rash	41 (13)

Arthritis. Although it is generally considered a sign of late Lyme disease, acute arthritis may begin during the acute disseminated stage. Monarticular or oligoarticular arthritis, primarily affecting large joints, especially the knee, may develop weeks to months after the onset of initial illness. In an early study of the natural history of Lyme arthritis, approximately 50% of untreated patients experienced one episode or multiple intermittent attacks of arthritis. Acute arthritis typically is monarticular, with involvement of only one knee. The shoulder, elbow, temporomandibular joint, ankle, wrist, hip, and small joints of the hands and feet are involved less commonly. Episodes of arthritis typically are brief (lasting weeks to months) and are separated by variable periods of remission.

Arthrocentesis generally is nondiagnostic, yielding an inflammatory synovial fluid with a mean white blood cell count of approximately 25,000 cells/μL (75% polymorphonuclear leukocytes). Higher white blood cell counts have been reported, simulating septic arthritis. The synovial glucose concentration usually is normal, and protein levels are variable, ranging from 3 to 8 g/dL. Cultures of the fluid rarely identify the causative spirochete. The complement level generally is greater than one-third that of serum. Synovial biopsy reveals hypertrophy, vascular proliferation, and a mononuclear cell infiltrate. Findings, therefore, are similar to those in rheumatoid arthritis, except that rheumatoid factor and antinuclear antibody assays yield a negative result in Lyme arthritis. Radiography may reveal nonspecific abnormalities such as juxtaarticular osteoporosis, cartilage loss, cortical or marginal bone erosions, and joint effusions.

Ophthalmic Manifestations. Ocular involvement also may be seen in early disseminated disease; manifestations include conjunctivitis, keratitis, choroiditis, retinal detachment, optic neuritis, and blindness. These findings also may be seen in late disease.

Late Lyme Disease

The chronic phase of Lyme disease is characterized by arthritic and, less commonly, neurologic symptoms. Over time, the pattern of episodic inflammation in early disease transitions to a more indolent persistent inflammation. The term *chronic* (or *late*) *Lyme disease* describes continuous inflammation in an organ system for more than 1 year.

A pattern of exacerbation and remission of arthritis may extend for several years, with a gradual tendency toward less frequent and less severe occurrences. The spontaneous long-term remission rate approximates 10% to 20% annually in untreated patients. However, patients commonly have episodes of periarticular involvement, arthralgias, or fatigue interspersed between attacks of frank arthritis. During the second or third year of illness, attacks of joint swelling sometimes become longer in duration, lasting months rather than weeks. Chronic arthritis eventually develops in approximately 10% of patients.

Late neurologic complications include a wide variety of abnormalities of the central and peripheral nervous systems and fatigue syndromes. Diagnosis may be difficult because of the large number of other neurologic conditions that Lyme disease may imitate and because late neurologic symptoms may be the first symptoms of the disease. The manifestations of chronic neuroborreliosis (the neurologic manifestations of Lyme disease) usually appear months to years after the onset of infection.

The most common late neurologic manifestation of Lyme disease is a chronic encephalopathy manifested as a mild to moderately severe impairment of memory and learning. Hypersomnolence and mild psychiatric disturbances (depression, irritability, paranoia) also may develop.[4]

Peripheral nervous system manifestations often are seen in late disease, with involvement of cranial nerves, spinal roots, spinal plexuses, and peripheral nerves. A predominantly sensory

polyradiculoneuropathy that is manifested as radicular pain or distal paresthesia is common. Significant overlap occurs with early symptoms. Less commonly, a demyelinating condition resembling multiple sclerosis may appear in late disease. Symptoms are variable and, as in multiple sclerosis, may undergo exacerbations and remissions. CT and magnetic resonance imaging (MRI) may reveal multiple white matter lesions.

Chronic inflammation also may occur in the skin, causing a seldom-recognized late cutaneous manifestation of Lyme disease, acrodermatitis chronica atrophicans. This condition usually involves the skin of distal extremities at the site of a tick bite. It is characterized in its initial stages by an edematous infiltration, which progresses to an atrophic lesion resembling localized scleroderma in its more established form. *B. burgdorferi* has been demonstrated in the skin of patients with acrodermatitis chronica atrophicans and positive findings on serologic studies.

Differential Diagnoses

The diagnosis of Lyme disease should be considered based on clinical and epidemiologic features. Identification of the disorder often is difficult, however, especially in the early stage. Although Lyme disease manifests in many ways, each stage has characteristic clinical findings that narrow the differential diagnosis. Early Lyme disease (EM and associated constitutional symptoms) may be easily confused with various other diseases, especially if the characteristic rash of EM is absent. A common clinical presentation is an influenza-like illness with headache, nausea, fever, chills, myalgias, arthralgias, stiff neck, and anorexia, occurring during the summer months. Even in endemic areas during the summer months, most patients with such symptoms do not have Lyme disease. When headache and stiff neck are the predominant symptoms, the principal diagnostic distinction to be made is between Lyme disease and the enteroviral diseases (and other causes of aseptic meningitis). The enteroviral diseases also have their peak incidence during the summer months; however, diarrhea, commonly associated with enteroviral infection, is not a feature of Lyme disease. Abdominal pain, anorexia, and nausea suggest hepatitis, sore throat, adenopathy, and fatigue suggest mononucleosis, and myalgias and arthralgias suggest connective tissue diseases. In many areas where Lyme disease is endemic, *Ixodes* ticks can be infected simultaneously with *B. burgdorferi*, *Anaplasma phagocytophilum*, and *Babesia microti*. Coinfection with more than one of these agents can occur.[5]

The rash of EM is characteristic of but not pathognomonic for Lyme disease. Some patients are not aware of having had such a rash and, in others, its appearance is atypical. An EM skin lesion is frequently misdiagnosed as a spider bite or community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) cellulitis, resulting in treatment with ineffective antibiotics. Other cutaneous entities in the differential diagnosis for EM include fungal infection, plant dermatitis, and fixed drug eruptions. Secondary lesions may be confused with the target lesions of erythema multiforme, which generally are smaller and nonexpanding. Erythema multiforme also may involve the mucous membranes, palms, and soles; EM does not. The presence of a malar rash in association with Lyme disease suggests systemic lupus erythematosus. Erythema nodosum generally causes more painful induration than EM and has a predilection for the extensor surfaces of the legs. Erythema marginatum of acute rheumatic fever also is in the differential diagnosis for EM; the Lyme disease rash differs in comprising generally fewer, larger, less evanescent lesions that migrate more slowly. Atypical EM manifesting as an urticarial rash may suggest hepatitis B infection or serum sickness. Lyme disease should be considered in a patient with an atypical rash accompanied by a viral syndrome or meningitis-like illness, especially during the months of peak incidence.

Acute rheumatic fever, coronary artery disease, or viral myocarditis may be suggested by the cardiac manifestations of Lyme disease. The carditis of Lyme disease, like the carditis of rheumatic fever, may follow pharyngitis and migratory polyarthritis. Erythema marginatum usually occurs with the onset of arthritis, in contrast with EM, which usually precedes the carditis. Although some patients with Lyme disease may satisfy the clinical aspects of the Jones criteria for acute rheumatic fever, they lack evidence of a preceding streptococcal infection; in addition, valvular involvement is not a prominent feature of Lyme carditis.

The differential diagnosis of the neurologic manifestations caused by Lyme disease is extensive. Considerations include aseptic meningitis, herpes simplex encephalitis, Bell palsy of other causes, radiculopathy due to mechanical causes, multiple sclerosis, Guillain-Barré syndrome, dementia, primary psychosis, cerebral vasculitis, and brain tumor. Neurologic symptoms often occur in the absence of any epidemiologic clues or preceding clinical symptoms suggestive of Lyme disease, making the diagnosis particularly challenging.

Lyme arthritis may mimic other immune-mediated disorders. The arthritis of Lyme disease generally is asymmetric, oligoarticular, and episodic. In contrast to patients with rheumatoid arthritis, those with Lyme arthritis rarely have symmetric polyarthritis, morning stiffness, a positive result on rheumatoid factor assay, or subcutaneous nodules. Lyme arthritis is commonly mistaken for seronegative rheumatoid arthritis; however, Lyme arthritis is most similar to the spondyloarthropathies, particularly reactive arthritis. Lyme disease and reactive arthritis both commonly cause huge knee effusions but, in Lyme disease, absence of the extra-articular features of reactive arthritis (conjunctivitis, urethritis or cervicitis, balanitis, keratosis blennorrhagica) at the time of the onset of arthritis helps distinguish it from reactive arthritis. In children, Lyme arthritis may mimic juvenile rheumatoid arthritis, but joint involvement in Lyme disease usually occurs in short intermittent attacks, and iridocyclitis typically is absent. Rheumatoid factor titers will be negative in juvenile rheumatoid arthritis and Lyme disease. The diseases resemble one another closely enough to have been confused at the time of the initial description of Lyme disease. Other diseases in the differential diagnosis for Lyme arthritis include acute gouty arthritis, septic arthritis, gonococcal arthritis, rheumatic fever, polymyalgia rheumatica, and temporomandibular joint syndrome.

Diagnostic Testing

Results of routine laboratory studies are nonspecific, and such studies generally are not helpful in the diagnosis of Lyme disease. Abnormalities may include an elevated erythrocyte sedimentation rate, mild anemia, total white blood cell count in the normal range with a decreased absolute lymphocyte count, microhematuria, proteinuria, and mildly elevated hepatic transaminases. Cultures of blood, tissue, and body fluids (including CSF and synovial fluid) for *B. burgdorferi* and direct visualization techniques are difficult to perform properly and have such a low yield that they are not clinically useful.

Serologic testing measuring the host's antibody response (for IgG and IgM) to *B. burgdorferi* is the most useful means of confirming a clinical diagnosis of Lyme disease, but is not without limitations. Results of serologic tests should be interpreted within the context of symptoms, considering the presumed stage of Lyme disease. These tests should be regarded only as adjuncts in the diagnostic process. Limitations of the tests' performance and the interpretation of their findings often result in diagnostic confusion. False-negative and, especially, false-positive results are common. The antibody response to *B. burgdorferi* develops slowly. The peak of IgM titers appears between 3 and 6 weeks after the onset of illness. Earlier in the course of the illness, IgM titers may be negative. IgM antibody usually returns to nondiagnostic

levels 4 to 6 weeks after the peak, but elevations may persist. IgG antibody may be detectable 2 months after exposure and peaks at approximately 12 months. Early antibiotic therapy may blunt or even abolish the antibody response.

A two-tier strategy is recommended for serologic testing—a sensitive enzyme immunoassay (EIA) followed by a Western blot (immunoblot). Positive or equivocal EIA results should be followed by a Western blot. If the EIA is negative, no further testing is necessary. Several Lyme disease serologic assays have recently been cleared by the Food and Drug Administration (FDA) allowing use of an EIA rather than Western blot as the second test in a Lyme disease testing algorithm.[6] IgM and IgG immunoblots should be obtained if early disease is suspected. If late disease is suspected, IgG Western blot alone should be obtained. Criteria for positive Western immunoblotting (requiring the presence of bands at particular locations) have been adopted by the CDC.

About one-third of patients with early localized Lyme disease (erythema migrans) are seropositive at the time of presentation by the two-tier method. Patients with skin lesions typical of EM do not require confirmatory serologic testing, and the rash itself is sufficient for the diagnosis to be made. If the cause of the rash is uncertain, acute and convalescent phase serologic testing may be considered, with the convalescent sample drawn 2 to 4 weeks after the acute sample. In contrast to early localized disease, most patients with early disseminated Lyme disease or late Lyme disease are seropositive.

IgG (and occasionally IgM) antibody may persist for several years after adequate treatment and symptom resolution. Persistent seropositivity is not diagnostic of ongoing infection. Even an IgM response cannot be interpreted as a demonstration of recent infection or reinfection unless the appropriate clinical characteristics are present. IgG antibody that developed after natural infection does not always confer immunity against future infection by *B. burgdorferi*. Patients who are treated for EM may become reinfected; patients with Lyme arthritis, however, usually have high antibody titers to many spirochetal proteins and seem not to become reinfected. Thus, the expanded immune response of late disease appears to be protective against reinfection, at least in most patients, whereas the immature immune response of early disease does not.

False-positive enzyme-linked immunosorbent assay (ELISA) results are common. Serologic cross-reactivity can occur between *B. burgdorferi* and other spirochetes, most notably *Treponema pallidum*. False-positive results for Lyme disease also can occur with relapsing fever, gingivitis, leptospirosis, enteroviral and other viral illnesses, rickettsial diseases, autoimmune diseases, malaria, and subacute bacterial endocarditis. In addition, it is estimated that up to 5% of the normal population will test positive for Lyme disease by ELISA. Bayes theorem states that if the pretest likelihood of the disease is low, the positive predictive value is low: a positive test result is more likely to be a false-positive result. For this reason, screening serologic tests are not indicated in the absence of objective clinical evidence of Lyme disease.

Patients suspected of having acute Lyme neuroborreliosis should be evaluated with serologic tests and routine CSF examination, including cell counts and differential, protein, glucose, Gram stain, and culture. Most patients with neuroborreliosis have positive results on serum serologic testing, thereby making additional laboratory confirmation with CSF serology unnecessary. The PCR assay has low sensitivity when performed on CSF and is not routinely recommended. However, the PCR assay is superior to culture for detecting *B. burgdorferi* in synovial fluid and has a sensitivity of 73% and specificity of 99% in untreated Lyme arthritis.

Management

Prompt treatment of early disease can shorten the duration of symptoms and prevent progression to later stages of disease. Most manifestations of Lyme disease can be treated successfully with oral antibiotic therapy, with the exception of neurologic abnormalities, which usually require intravenous (IV) therapy. Treatment of Lyme disease is summarized in Table 123.4.

Early Disease

Prompt antibiotic therapy is essential in early Lyme disease because it generally shortens the duration of the rash and associated symptoms and, more importantly, prevents later illness in most patients. Some patients with severe early disease, however, progress to later stages, despite appropriate antibiotic regimens.

The drug of choice for men, nonpregnant and nonlactating women, and children older than 8 years is doxycycline, 100 mg bid for 3 weeks. An advantage of doxycycline is that it also is effective for the treatment of human granulocytic anaplasmosis, which is transmitted by the same tick that transmits Lyme disease. Pregnant or lactating women and children younger than 8 years should receive amoxicillin, 500 mg three times daily orally (20 to 40 mg/kg/day in three doses for children). Cefuroxime axetil has been shown to be as effective as doxycycline and may be used in children of any age, but cephalexin is ineffective in Lyme disease.

Macrolide antibiotics are not recommended as first-line agents for therapy for early Lyme disease. They should be reserved for patients who cannot tolerate doxycycline, amoxicillin, and cefuroxime axetil. Macrolide regimens for adults include azithromycin, 500 mg orally daily for 7 to 10 days, erythromycin, 500 mg orally qid for 14 to 21 days, and clarithromycin, 500 mg orally bid for 14 to 21 days.

A Jarisch-Herxheimer type of reaction may occur in the first 24 hours of antibiotic treatment, consisting of fever, chills, myalgias, headache, tachycardia, increased respiratory rate, and mild leukocytosis. Defervescence usually takes place within 12 to 24 hours. The pathogenesis of this reaction is controversial, but it probably is caused by the killing of spirochetes, with the release of pyrogens. The Jarisch-Herxheimer reaction occurs more commonly with penicillin and doxycycline than with erythromycin, probably because of their superior spirocheticidal activity.

Early Disseminated Infection

Neurologic Disease. For patients with relatively mild symptoms (e.g., solitary facial nerve palsy with normal findings on CSF examination), doxycycline or amoxicillin can be used in the same dosage as for early disease, but the duration of therapy should be extended to 28 days. The use of prednisone for facial nerve palsy from Lyme disease has been suggested but is not currently recommended.

Parenteral antibiotic therapy is required for patients with other objective neurologic abnormalities (e.g., meningitis or encephalitis, peripheral neuropathies, cranial neuritis other than facial nerve palsy) or evidence of the spirochete in the CSF. Ceftriaxone, 2 g/day IV for 14 days (75 to 100 mg/kg/day for pediatric patients), or penicillin G, 18 to 24 million units every 4 hours daily IV for 10 to 14 days, may be used. Ceftriaxone may be more effective than penicillin, and many experts recommend longer courses (e.g., up to 4 weeks). In cases of penicillin or cephalosporin allergy, oral doxycycline may be used for 28 days.

Cardiac Disease. Patients with mild cardiac conduction system involvement, such as a first-degree AV block with a PR interval less than 0.30 second, and no other significant symptoms usually can be treated safely on an outpatient basis with oral doxycycline or amoxicillin for 21 to 30 days.[7] Patients with higher degrees of AV block, including first-degree block with a PR interval of more than 0.30 second or evidence of global ventricular impairment, should be hospitalized for cardiac monitoring and treatment with parenteral antibiotics. Penicillin G, 18 to 24 million units IV in 4 divided doses, or ceftriaxone, 2 g daily for 21 days (50 to 80 mg/kg/day for children), may be used.

TABLE 123.4 Treatment of Lyme Disease

Syndrome and Manifestation	Drug	Adult Dosage	Pediatric Dosage[a]
Early Lyme disease	Doxycycline[b]	100 mg PO bid for 21 days	
	or		
	Amoxicillin	500 mg PO tid for 21 days	50 mg/kg/day tid
	ALTERNATIVE		
	Cefuroxime axetil	500 mg PO bid for 21 days	15 mg/kg/day bid (max dose of 250 mg bid)
	or		
	Erythromycin (less effective than doxycycline or amoxicillin)	500 mg PO qid for 14–21 days	
Neurologic disease			
• Facial nerve paralysis	With an isolated deficit, oral regimens for early disease, used for at least 28 days, may suffice. For a deficit associated with other neurologic manifestations, intravenous therapy is warranted (see below).		
• Lyme meningitis	Ceftriaxone	2 g IV by single dose for 14–28 days	75–100 mg/kg/day IV
	Penicillin G	20 million units daily in divided doses for 10–14 days	300,000 units/kg/day IV
	ALTERNATIVE		
	Chloramphenicol	1 g IV qid for 10–21 days	
Cardiac disease			
• Mild	Doxycycline[b]	100 mg PO bid	
	or		
	Amoxicillin	500 mg PO tid	50 mg/kg/day tid
• More severe	Ceftriaxone	2 g IV daily by single dose for 14–21 days	75–100 mg/kg/day IV
	or		
	Penicillin G	20 million units daily in divided doses every 4 hours for 14–21 days	300,000 units/kg/day IV
Arthritis	ORAL		
	Doxycycline[b]	100 mg PO bid for 30 days	
	or		
	Amoxicillin	500 mg PO tid for 30 days	50 mg/kg/day divided tid
	PARENTERAL		
	Ceftriaxone	2 g IV by single dose for 14–21 days	75–100 mg/kg/day IV
	or		
	Penicillin G	20 million units daily in divided doses for 14–21 days	300,000 units/kg/day IV

[a]Pediatric dosage should not exceed adult dosage.
[b]Tetracycline, 250 to 500 mg PO qid, may be substituted for doxycycline. Neither doxycycline nor any other tetracycline should be used for children younger than 8 years or for pregnant or lactating women.
[c]Regimens for radiculoneuropathy, peripheral neuropathy, and encephalitis are the same as those for meningitis.
[d]Oral regimens are reserved for mild cardiac involvement (see text).

The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2006;43:1089-1134.

The benefit of the adjuvant use of aspirin or prednisone in the treatment of Lyme carditis is uncertain and not currently recommended. Temporary cardiac pacing may be necessary in patients who have severe heart block with hemodynamic instability. The block generally resolves entirely with antibiotic treatment, so the recognition of Lyme carditis in young patients with unexplained heart block is critical for avoidance of unnecessary permanent pacemaker implantation.

Late Infection

Arthritis. In established Lyme arthritis, the response to antibiotic therapy may be delayed for several weeks or months. An oral regimen for 30 days, such as doxycycline, 100 mg orally bid, or amoxicillin, 500 mg tid, usually are effective and, for reasons of cost and convenience, may be selected as first-line therapy given on an outpatient basis before parenteral antibiotic therapy is considered. Persistent or recurrent joint swelling after recommended courses of antibiotic therapy can be treated with another 4-week course of oral antibiotics or with a 2- to 4-week course of IV ceftriaxone. A small percentage of patients with Lyme arthritis, particularly those with HLA-DR4 specificity or antibody reactivity with OspA, may have persistent joint inflammation, despite treatment with oral or IV antibiotics. Such patients often do not respond to any antibiotic therapy and may require arthroscopic synovectomy.

Neurologic Disease. Patients with late neurologic disease affecting the central or peripheral nervous system should be treated with ceftriaxone (2 g once daily IV for 2 to 4 weeks). Alternative parenteral therapy may include cefotaxime (2 g IV three times a day) or penicillin G (18–24 million units IV daily, given in divided doses every 4 hours). Response to treatment is usually slow and may be incomplete.

Lyme Disease and Pregnancy

Similar to the spirochetal agents of syphilis and relapsing fever, *B. burgdorferi* can be passed transplacentally. In rare cases, Lyme disease acquired during pregnancy may lead to infection of the fetus and possibly to stillbirth, but adverse effects on the fetus have not been documented conclusively. Counseling about the termination of a pregnancy because of maternal Lyme disease is unwarranted.

Lyme disease contracted during pregnancy can be treated and cured. Treatment of pregnant patients can be identical to that of nonpregnant patients with the same disease manifestations, except that doxycycline should be avoided. Most women give birth to normal infants despite documented Lyme borreliosis during their pregnancies.

Vaccination

No vaccine against Lyme disease is currently available in the United States. The LYMErix vaccine (SmithKline Pharmaceuticals, Philadelphia), initially licensed in 1999, was withdrawn from the market in 2002. The vaccine, directed against the outer surface protein A of *B. burgdorferi* (OspA), was apparently safe but required repeated doses for optimal protection. Ongoing questions about its safety and cost-effectiveness dampened demand for the vaccine.

A history of vaccination with the previously licensed vaccine should not change the approach to management. Because protective immunity produced by the vaccine is short-lived, it is unlikely that previous vaccination will provide any residual protective effect. Vaccination may cause a persistently positive ELISA result but a negative Western blot result.

Prophylaxis and Asymptomatic Tick Bites

A well-designed trial found that a dose of doxycycline given within 72 hours after a bite by a deer tick (*I. scapularis*) effectively prevented Lyme disease. A single 200-mg dose of doxycycline therefore should be considered for adult patients and children 8 years of age and older (4 mg/kg, up to a maximum dose of 200 mg) when all the following criteria are met: (1) the tick is an adult or nymphal *I. scapularis*; (2) the tick has been attached for 36 hours or more, as indicated by certainty of the time of exposure or degree of engorgement; (3) prophylaxis can be started within 72 hours after tick removal; (4) the local rate of infection of these ticks with *B. burgdorferi* is 20% or greater; and (5) doxycycline is not contraindicated. *B. burgdorferi* infects 20% or more of ticks in highly endemic areas such as New England, parts of the Mid-Atlantic region, and parts of Minnesota and Wisconsin. Most other areas of the United States do not have infection rates high enough to warrant prophylaxis.

The efficacy of single-dose doxycycline in patients who present more than 72 hours after removing a tick is unknown. In children, the dosing and efficacy of prophylactic treatment have not been evaluated. The effectiveness of doxycycline for preventing other infections transmitted by *I. scapularis* ticks (e.g., babesiosis, human granulocytic anaplasmosis) is unknown and should not be assumed. Other antimicrobial agents effective for treating Lyme disease (e.g., amoxicillin) and even other regimens of doxycycline (e.g., 100 mg bid) have unknown efficacy for Lyme disease prophylaxis. Anyone who has been bitten by a tick should be instructed to seek medical evaluation if symptoms of tickborne illness develop.

SOUTHERN TICK-ASSOCIATED RASH ILLNESS

A rash similar to erythema migrans (EM) has been described in humans following bites of the lone star tick, *Amblyomma americanum,* found from central Texas and Oklahoma eastward across the southern states and along the Atlantic coast as far north as Maine. The rash may be accompanied by fatigue, fever, headache, muscle and joint pains. This condition has been named southern tick-associated rash illness (STARI).[8] The cause of STARI is not known.

STARI is diagnosed based on symptoms, geographic location, and possibility of tick bite. Because the cause of STARI is unknown, no diagnostic blood tests are available.

It is not known whether antibiotic treatment is necessary or beneficial for patients with STARI. Because STARI resembles early Lyme disease, patients are often treated with oral antibiotics.

RELAPSING FEVER

Relapsing fever is caused by bacteria of the *Borrelia* species, order Spirochaetales. Human *Borrelia* infections occur worldwide, and all are associated with arthropod vectors. The epidemic (louseborne) form of relapsing fever is caused solely by *Borrelia recurrentis* and is found mostly in Africa, where mortality rates can reach 70% with outbreaks. The endemic form, tickborne relapsing fever (TBRF), is caused by a group of closely related *Borrelia* species, their names derived from the species names of *Ornithodoros* tick vectors that carry them. The more common species in North America are *Borrelia hermsii, Borrelia turicatae,* and *Borrelia parkeri*. *B. burgdorferi* has been recognized as the causative agent of the third and most recently described borrelial disease, Lyme disease.

TBRF is maintained in an animal reservoir consisting primarily of wild rodents, including squirrels, mice, rats, chipmunks, and rabbits. It is found predominantly at altitudes of 2000 to 7000 feet in coniferous forest habitats. The tick vectors are argasids (soft ticks) belonging to several species of the genus *Ornithodoros,* which routinely reside in the nests and burrows of their mammalian hosts. Ticks acquire the infection by feeding on a spirochetemic rodent. The borreliae remain viable in the ticks for several years and can be passed transovarially to the next generation. In addition, soft ticks—unlike hard ticks—can survive up to 10 years, making removal of all infested nests imperative.[9] Two unique characteristics make this genus a significant reservoir and vector. These soft ticks feed for brief periods (15–20 minutes), usually at night, and their painless bite generally is unnoticed by the sleeping victim. Transmission occurs by injection of infected saliva through the bite site or intact skin. Less common modes of transmission (e.g., venipuncture equipment in injection drug users) have been reported.

In the United States, TBRF occurs primarily in the western Mountain and Pacific states, including Montana, Wyoming, Nevada, Colorado, California, and Washington. Between 1990 and 2011, the CDC received 504 reports of TBRF. The groups most commonly affected were males and people between the ages of 10 to 14 and 40 to 44 years. Of all reported cases, 70% were collectively from California, Washington, and Colorado. Most cases involved visitors to those states. Although TBRF is not nationally reportable, it was reported in 12 states in 2011.[4] Outbreaks have been reported among groups of persons sleeping overnight in hunting cabins inhabited by wild rodents. In Texas, most cases were reported in the winter months among people who had been exploring caves.

Clinical Features

In TBRF, the initial febrile episode lasts 3 days. This is followed by an asymptomatic period of variable duration, usually, approximately 7 days. During this time, patients generally feel better and may return to their usual daily activity levels under the assumption that they have recovered from another viral illness. Relapse then occurs, with symptoms that mimic those of the original illness. With TBRF, this cycle repeats itself three to five times. Each successive relapse usually is less severe. Relapse is caused by the spirochete's unique ability to undergo

antigenic variation within the body of the infected host. Each successive antigenic variation is cleared from the bloodstream by specific host antibodies, and a characteristic relapsing febrile course results.

Clinical illness is manifested in two classic stages as each fever episode resolves. The first stage is called the chill phase (high fevers with reported temperatures of up to 106.7°F (41.5°C), mental status changes, tachycardia, and tachypnea), lasting approximately 30 minutes, followed by a flush phase (rapid temperature decrease, sweats, and hypotension), which can be confused with a Jarisch-Herxheimer reaction.[5]

After a postbite incubation period of 4 to 18 days, during which time the host concentration of spirochetes increases, fever of abrupt onset occurs, often accompanied by shaking chills, headache, arthralgias, myalgias, nausea, and vomiting. On occasion, a pruritic eschar may be noted at the site of the tick bite, but this usually is absent by the onset of clinical symptoms. Consequently, the nonspecific nature of the clinical presentation may lead to misdiagnosis of the disease as a viral illness. The patient's temperature is high, and generalized muscle weakness and lethargy are common. Hepatomegaly, splenomegaly, and jaundice are sometimes seen. Neurologic involvement is less common but can be manifested as delirium, nuchal rigidity, peripheral neuropathy, or pupillary abnormalities. Uveitis, iritis, and other cranial neuropathies can present acutely or, rarely, as long-term sequelae. A macular or petechial rash, more apparent on the trunk than on the extremities, may be present. There is evidence that febrile illness caused by relapsing fever might cause *Plasmodium vivax* malaria relapse.

Severe cases of TBRF resulting in acute respiratory distress syndrome (ARDS) in California and Nevada near the Lake Tahoe area and in the state of Washington prompted a comprehensive epidemiologic investigation of cases in those areas during a 10-year period. This study showed that ARDS may be more common than was previously suspected. Reported occurrence rates for Jarisch-Herxheimer reaction varied between 6% and 21%, 16% for hypoxia, 8% for elevated liver function test values, and 6% for ARDS; 46% of patients with TBRF required hospitalization.

Differential Diagnoses

On initial presentation, the differential diagnosis is extensive; however, it narrows with the occurrence of relapse. A history of possible soft tick exposure together with recurrent fever should suggest the diagnosis. Other conditions that initially may be considered include malaria, typhus, dengue, yellow fever, Colorado tick fever, and tularemia. Careful examination of blood smears, together with clinical data and other laboratory tests, aid in making the correct diagnosis.

A recently discovered Borrelia species, phylogenetically related to those responsible for relapsing fever, is now known to cause a new tickborne illness called Borrelia miyamotoi disease (BMD). It has been found in the Upper Midwest, mid-Atlantic, and Northeast states and tends to occur in late summer months as opposed to Lyme disease, which tends to occur in midsummer. Caused by the spirochete of the same name, BMD resembles Lyme disease and human granulocytic anaplasmosis (HGA), but the vectors consist of several species of the hard tick genus Ixodes. Headache, fever, and myalgias are the most common symptoms and tend to be more severe than those associated with Lyme or HGA. Diagnosis can be made using blood PCR samples and antibody titers. Giemsa-stained acute blood smears may reveal spirochetemia. Lab tests often show leukopenia, thrombocytopenia, and elevated liver enzymes. Both amoxicillin and doxycycline are effective treatments.[10,11]

Diagnostic Testing

In contrast to other spirochetal diseases, the definitive diagnosis of relapsing fever depends on the demonstration of spirochetes in peripheral blood smears during a febrile episode. In most cases, spirochetes are readily visible on a routine blood smear prepared with Wright or Giemsa stain. Thick or thin blood smears, such as those prepared for malaria evaluation, also are satisfactory. The organisms are seen within the plasma spaces between blood cells or may overlie the blood cells. Several organisms per high-power field typically are visible in smears from febrile patients with relapsing fever. Blood specimens for the smears should be obtained as the temperature curve increases. Repeated samples may be required before a positive result is observed because sensitivity approaches only 70%.

Spirochetes also may be visible in wet mounts with the use of phase contrast microscopy. Culture, although it is the most sensitive diagnostic method available, requires a special medium, does not yield rapid results, and therefore is not commonly performed. Genus-specific PCR testing has been used successfully and may be higher in sensitivity than serology or blood smear, especially in the acute phase of disease. Serologic testing is available through public and private health facilities but is not useful for immediate diagnosis. Nonspecific laboratory findings may include mildly increased bilirubin and liver function levels, thrombocytopenia, and an elevated erythrocyte sedimentation rate.[5]

Management

Relapsing fever is effectively treated with tetracycline or erythromycin. Tetracycline should be avoided in children younger than 8 years and in pregnant women. Tetracycline or erythromycin should be given in an oral dose of 500 mg four times daily for 10 days. Other treatment regimens have been recommended, including doxycycline and chloramphenicol. Treatment with penicillin G has been associated with an increased rate of relapse. Success with ceftriaxone has been reported in a patient with relapsing fever who did not respond to penicillin. Prophylaxis with doxycycline for TBRF in exposed subjects in high-risk infested areas is effective.

As many as one-third of patients experience a Jarisch-Herxheimer type of reaction during treatment with antibiotics. The reaction can be severe, especially with louseborne relapsing fever, and has been associated with high levels of cytokine intermediaries and endogenous opioids, and accelerated phagocytosis of spirochetes.[12] Approximately 4 hours after antibiotic treatment, and coinciding with the clearance of spirochetes from the blood, the patient usually experiences an increase in temperature and severe rigors, accompanied by a drop in the leukocyte and platelet counts and onset of hypotension. Anticipation of this reaction is crucial because volume expansion with saline solution may be required to maintain the blood pressure; the reaction can be more threatening than the disease itself.

The prognosis is good for treated patients with relapsing fever; approximately 95% achieve complete recovery. Poor prognostic signs include the presence of jaundice, high spirochete counts in the blood, and hypotension. Transplacental transmission can occur in infected pregnant women. Spontaneous abortions occur in nearly 50% of cases in pregnant women. Death is rare in TBRF and is limited to infants and older adults.

TULAREMIA

Tularemia was first characterized in 1837 by Soken, who described a febrile illness with generalized lymphadenopathy in people who had eaten infected rabbit meat. In 1912, McCoy first isolated *Bacterium tularense,* now known as *Francisella tularensis,* from rodents in Tulare County, California, giving rise to the name of the disease.

Tularemia occurs worldwide and is endemic between 30 and 71 degrees north latitude. The incidence of tularemia is low. There were between 180 and 314 yearly reported cases of tularemia in the United

States between 2014 and 2018, and it is a nationally notifiable disease.[13] Tularemia has been seen in every state except Hawaii but is most common in the southwest central region. During this period, most cases have come collectively from Missouri, Oklahoma, South Dakota, Colorado, Kansas, and Arkansas. It is more common in men than in women. Persons at increased risk for infection include hunters, trappers, butchers, agricultural workers, campers, sheep herders, mink farmers, and laboratory workers.

Ticks, lagomorphs (hares, rabbits), and rodents (mice, rats) are believed to be the most important sources of transmission to humans; however, the organism has been recovered from animals of more than 100 species. Significant epidemics have been linked to contact with a variety of them, including domestic cats. In 2002, a large number of commercially distributed prairie dogs from Texas died of tularemia.

The ticks most commonly involved in transmission of tularemia in the United States are from the hard tick family Ixodidae, specifically the Lone Star tick (*A. americanum*) and the dog tick (*D. variabilis*), both of which have been associated with other tickborne illnesses. Ticks were responsible for approximately half of tularemia cases in the United States between 2004 and 2014.[14] Whereas mosquitoes are major vectors in many European countries, horse fly and deer fly bites have been implicated in endemic situations in the United States. In 2007, an outbreak in Utah was associated with deer fly bites.

While transmission to humans most commonly occurs through tick bites or handling of infected animals, it also can occur with ingestion of infected food or water, inhalation of dust or water aerosol, and insect bites. Nonimmune laboratory workers who work with *F. tularensis* can acquire the disease. Person to person transmission is rare. Tularemia has a bimodal prevalence in the United States; an increased incidence in May to August is associated with tickborne transmission, and a December to January peak is associated with hunting and skinning of infected mammals (primarily rabbits). *F. tularensis* has been found to coexist in reservoir populations harboring the agent responsible for Lyme disease. Eleven cases of pneumonic tularemia, found to be from aerosolization of contaminated vegetation clippings, were discovered in Martha's Vineyard, Massachusetts. Outside the United States, tularemia has been confirmed in hundreds of cases in Kosovo through rodent contamination of food. Sweden has reported a high number of cases, usually associated with aquatic environments and mosquitoes.[15]

Tularemia is manifested in different ways, depending on the portal of entry of the organism. The primary route of infection by *F. tularensis* is through the skin. Entry can occur through hair follicles or small cuts and abrasions that may be contaminated by exposure to an infected animal; tick exposure can also introduce the bacteria. Because the bacterium has not been isolated from the salivary glands of ticks, it is thought that they transmit the organism through their feces. Scratching after a tick bite introduces the infected feces into the skin. Inhalation or ingestion of the organism or transmission through the conjunctivae also can cause infection. The incubation period is approximately 2 to 6 days, depending on the size of the inoculum.

After penetration of the skin or epithelial membrane, the organism usually spreads to the regional lymph nodes. An erythematous tender papule develops at the primary infection site, followed by inflammation and skin ulceration. The regional nodes enlarge, necrose, and may rupture. The necrotic, purulent, painful lymph node is termed a *bubo*. In the ulceroglandular form of the infection, the organism may not spread farther than the regional lymph nodes. If the inoculum is sufficiently large or host defenses are inadequate, bacteremia ensues, with dissemination to phagocytic cells of the reticuloendothelial system.

Pulmonary tularemia may result from inhalation of small-particle aerosols containing *F. tularensis* or from hematogenous dissemination. Small areas of localized pneumonitis are most commonly seen, although chest radiographic findings are nonspecific; lobar consolidation or abscess formation is rare. Oculoglandular tularemia occurs when the conjunctiva becomes infected from contact with material from an ulcer or contaminated finger. Typhoidal tularemia follows the systemic spread of *F. tularensis* from the oropharynx and probably the gastrointestinal tract when a large inoculum is swallowed.

Clinical Features

Presentations

Tularemia has six clinical presentations, depending on whether disease is localized to an entry site and its regional lymph nodes—ulceroglandular, glandular, oculoglandular, and oropharyngeal forms—or is more invasive and generalized—typhoidal and pulmonary forms. Ulceroglandular and glandular are the most common manifestations of tickborne tularemia.

Ulceroglandular Tularemia. This accounts for approximately 80% of cases. Typically, a skin lesion on an extremity at the site of primary inoculation begins as an erythematous papule, which then ulcerates 2 to 3 days later. The ulcer is slow to heal and often is still present when the subsequent regional lymphadenopathy and fever develop. The distribution of the regional adenopathy reflects the primary entry site; patients with tickborne tularemia usually have inguinal or femoral adenopathy, whereas those who acquire rabbit-associated tularemia have axillary or epitrochlear nodal involvement. Generalized lymphadenopathy also may be seen. On occasion, nodes suppurate and drain.

Glandular Tularemia. This is the second most common form. It is characterized by the development of lymphadenopathy (usually cervical) without an associated skin ulcer.

Oculoglandular Tularemia. This is seen in less than 2% of cases. It is characterized by unilateral conjunctivitis, with regional adenopathy involving preauricular lymph nodes.

Oropharyngeal Tularemia. This is manifested as severe exudative pharyngitis, with associated cervical lymphadenitis. It has been known to cause acute glaucoma.

Typhoidal Tularemia. This is a systemic form of the disease in which no obvious entry site can be found; it occurs in approximately 10% of cases. Only 10 to 50 organisms are required to induce disease; incubation time is 2 to 10 days. Symptoms and signs may include fever, chills, constipation or diarrhea, abdominal pain, and weight loss. A 30% to 60% case fatality rate is associated with untreated typhoidal tularemia.[16]

Pulmonary Tularemia. This has symptoms similar to those of other bacterial pneumonias—fever and chills, cough (usually nonproductive), substernal burning, dyspnea, malaise, and prostration. It may result from direct inhalation of aerosolized organisms or bacteremic spread from another site.

Other Considerations

Uncommon complications of tularemia include pericarditis, meningitis, endocarditis, peritonitis, appendicitis, perisplenitis, and osteomyelitis. Guillain-Barré syndrome associated with tularemia also has been reported.

Tularemia is one of the most widely studied diseases with respect to potential biologic warfare. The United States developed an aerosolized form in the 1950s, and the Japanese allegedly contaminated prisoners with the disease in the 1930s. It was removed from the national list of notifiable diseases in 1995 but then was reinstated in view of the heightened biologic weapons threat. It is classified by the CDC as one of the six category A critical biologic diseases.[7,13] An aerosolized form of the bacterium would be the most likely delivery mechanism used in biologic warfare. With the release of aerosolized particles, disease would

be manifested clinically as acute fever, progressive pneumonia, pleuritis, and hilar lymphadenopathy, beginning as early as 3 to 5 days after delivery. The mortality rate for untreated tularemia in general ranges from 5% to 30%, but the rate for the pulmonary form can reach 60%. With appropriate antibiotic treatment, death is rare (mortality rate < 1%). Only approximately 55% of emergency departments (EDs) have been adequately educated on the recognition of and preparedness for tularemia.

Diagnostic Testing

The diagnosis of tularemia is based on clinical findings and serologic testing. Antibody titers begin to rise approximately 7 to 10 days after exposure and peak in 3 to 4 weeks. In a patient with a clinical presentation suggesting tularemia, an antibody titer of 1:160 or higher in a single specimen is diagnostic. Confirmatory evidence is provided by a fourfold or greater rise in titer in a second sample obtained 2 weeks later. Unfortunately, titers of IgG and IgM can continue to be high for up to 10 years, and cell-mediated immunity can be maintained for up to 25 years. Rapid testing with PCR assay is available, and point of care analysis using an immunochromatographic approach has proven useful in testing water sources.

As for most infectious organisms, culture is the gold standard for diagnosis; however, aspiration of affected lymph nodes for culture is not routinely recommended because of the associated risk to laboratory personnel. If tularemia is suspected, the laboratory should be alerted so that appropriate precautions can be taken in specimen handling and enriched culture medium can be used. The risk of tularemia transmission lies in the danger of any handling that might produce aerosols or droplets.

Management

Isolation of patients with tularemia is not required because it is not transmitted from person to person. Streptomycin is the drug of choice for the treatment of all forms of tularemia but is not widely available. When given intramuscularly in a dose of 10 mg/kg (pediatric: 30 to 40 mg/kg/day) bid, streptomycin usually produces symptomatic improvement and resolution of fever in 1 to 2 days. After the third treatment day, half of the dose is given for a total course of 7 to 14 days. With this regimen, relapses are unusual.

Gentamicin is effective for treatment, especially in children (3 to 5 mg/kg/day for 10 to 14 days) and is more readily available than streptomycin. Tetracycline and chloramphenicol are also effective; however, the risk of relapse is greater than that associated with the aminoglycosides. Imipenem-cilastatin, an antibiotic without nephrotoxicity, has been used successfully to treat pulmonary tularemia in a patient with acute renal failure. Ceftriaxone is not effective against *F. tularensis* infections. Prophylaxis for possible exposure requires doxycycline, 100 mg bid for 14 days. Doxycycline or ciprofloxacin prophylaxis is recommended for a large biologic attack.

Ulcers and tender lymph nodes usually heal within 7 to 10 days; however, enlarged nodes occasionally develop into fluctuant sterile buboes, requiring incision and drainage after completion of the course of antibiotics. The unique ability of *F. tularensis* to attenuate host inflammatory responses has been emerging as a basis for research investigating the use of immunomodulatory agents or antibodies for adjunctive treatment. There continues to be no approved vaccine for tularemia. Because of recent interest in biologic warfare, however, research on tularemia vaccines has resurged.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is an acute, febrile, systemic tickborne illness caused by *Rickettsia rickettsii*. The genus *Rickettsia* is divided into the spotted fever group and typhus group. *R. rickettsii* is considered the typical representative of the spotted fever group. Twenty-six species have been described.

RMSF is found in North, South, and Central America and is a nationally reportable disease. All cases are to be registered with the respective state department. As of 2010, reported cases of RMSF are categorized in the broader name of spotted fever rickettsiosis (Box 123.1).[16] The number of reported cases in the United States more than tripled between 2000 and 2007, especially in suburban areas.[17] The increase during this period was thought to be due to more widespread use of ELISA. Use of the assay has also resulted in a significantly lower

BOX 123.1 Diagnostic Criteria for Spotted Fever Rickettsiosis (*Rickettsia* spp.)

- Clinical criteria
  - Any reported fever and one or more of the following: rash, eschar, headache, myalgia, anemia, thrombocytopenia, or hepatic transaminase level elevation
- Laboratory-confirmed
  - Serologic evidence of a fourfold change in immunoglobulin G (IgG)–specific antibody titer reactive with *Rickettsia rickettsii* or other spotted fever group antigen by indirect immunofluorescence assay (IFA) between paired serum specimens (one taken in the first week of illness and a second 2 to 4 weeks later) *or*
  - Detection of *R. rickettsii* or other spotted fever group DNA in a clinical specimen via amplification of a specific target by PCR assay, *or*
  - Demonstration of spotted fever group antigen in a biopsy or autopsy specimen by immunohistochemistry (IHC), *or*
  - Isolation of *R. rickettsii* or other spotted fever group *Rickettsia* from a clinical specimen in cell culture
- Laboratory-supportive
  - Has serologic evidence of elevated IgG or immunoglobulin M (IgM) antibody reactive with *R. rickettsii* or other spotted fever group antigen by IFA, enzyme-linked immunosorbent assay (ELISA),[a] dot ELISA, or latex agglutination
- Exposure
  - Exposure is defined as having been in a potential tick habitat within the 14 days preceding the onset of symptoms. The patient's occupation should be recorded if relevant to exposure. A history of a tick bite is not required.
- Case classification
  - Suspected: A case with laboratory evidence of past or present infection but no clinical information available (e.g., laboratory report)
  - Probable: A clinically compatible case (meets clinical evidence criteria) that has supportive laboratory results
  - Confirmed: A clinically compatible case (meets clinical evidence criteria) that is laboratory-confirmed

[a] NOTE: Current commercially available ELISA tests are not quantitative, cannot be used to evaluate changes in antibody titer, and hence are not useful for serologic confirmation. IgM tests are not strongly supported for use in the serodiagnosis of acute disease because the response might not be specific for the agent (resulting in false-positives) and the IgM response might be persistent. Complement fixation (CF) tests and older test methods are neither readily available nor commonly used. CDC uses in-house IFA IgG testing (cutoff ≥ 1:64), preferring simultaneous testing of paired specimens, and does not use IgM results for routine diagnostic testing.
From: Centers for Disease Control and Prevention. National Notifiable Diseases Surveillance System: Spotted fever rickettsiosis (*Rickettsia* spp.) 2010 case definition. www.cdc.gov/NNDSS/script/casedef.aspx?CondYrID=853&DatePub=2010-01-01.

case fatality rate, which could be related to the high cross-reactivity of serologic tests with more benign rickettsioses. Higher awareness and more aggressive empirical treatment of RMSF might also have contributed to the decreased fatality rate. In 2016, there were 4,269 reported spotted fever cases in the United States, which included all spotted fever rickettsioses, not just RMSF, in accordance with the surveillance changes mentioned.[18] Another rare rickettsiosis that emerged in North America in 2004 was caused by *Rickettsia parkeri*, transmitted through the Gulf Coast tick, *Amblyomma maculatum*. It is distinguished from RMSF by sometimes causing eschars or a vesicular rash.

RMSF ranges in clinical severity from mild or even subclinical illness to fulminant disease, with vascular collapse and death within several days of onset. It is the only rickettsiosis still associated with significant mortality, causing approximately 40 deaths in the United States each year, with a mortality rate ranging from 3% to 5%, despite appropriate treatment. Before tetracycline and chloramphenicol were available, death occurred in as many as 30% of cases in the 1930s. The highest mortality rates occur in patients between the ages 5 and 9 years or older than 70 years, among Native Americans, and among immunosuppressed patients. In the South Atlantic United States, mortality reaches 9% in patients older than 70 years. The median time between onset of illness and death is 9.5 days, whereas death occurs in hospitalized patients in a median time of 3 days.

The recorded history of RMSF suggests that the disease was present at least before the European settlement of western North America among inhabitants of wooded Rocky Mountain regions. Early terms used to name the disease included *tick fever* and *black measles*. In 1899, RMSF was described as "an acute, endemic, noncontagious but probably infectious, febrile disease, characterized by a continuous moderately high fever, severe arthritic and muscle pains, and a profuse petechial or purpuric eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body."

Although RMSF was first described in Montana and Idaho, it is now relatively rare in the Rocky Mountain states. Endemic in all 48 contiguous states except Maine, the disease continues to be most prevalent in the southeastern United States. RMSF has been reported in Canada, Central America, Mexico, and South America but never outside the Western Hemisphere. Recently, RMSF has become increasingly common in certain areas of Arizona, with 21 fatalities reported between 2003 and 2016. In 1987, four cases of RMSF were reported among residents of the Bronx in New York City; none of the affected persons had recently traveled to an area known for endemic disease, raising the possibility that other urban foci of RMSF may exist.

RMSF also tends to be focally endemic, with clustering of cases within a larger endemic area that may correspond to islands of infected ticks. These areas, ecologically distinct from surrounding areas, may be ideally suited to ticks; they usually consist of wild open fields, deciduous forests with thick ground cover and poor water drainage, or uncultivated areas. Geographic clusters of severe disease have been reported. In areas with frequent occurrence of RMSF (Oklahoma, North and South Carolina, Tennessee, Pennsylvania, Missouri, Arkansas, Arizona), an infectivity rate of 2% to 15% of the tick population has been reported. North Carolina and Oklahoma carry the highest incidence rates (35% of all cases) for RMSF.

R. rickettsii organisms are obligate intracellular bacteria with tropism for human endothelial cells. They often occur in pairs and possess a cell wall similar in structure and chemical composition to that of gram-negative bacteria. *R. rickettsii* contain RNA and DNA and, in contrast with other rickettsial organisms, can invade the nucleus as well as the cytoplasm.

The American dog tick, *Dermacentor variabilis,* and the Rocky Mountain wood tick, *Dermacentor andersoni,* have been the vectors responsible for human RMSF cases in the United States to date. However, the common brown dog tick, *Rhipicephalus sanguineus,* has emerged as a third vector. *R. sanguineus* has been the main RMSF vector in Mexico, Central America, and the southwestern United States. *Amblyomma imitator,* in the genus of the Lone Star tick, has been implicated as yet another vector because *R. rickettsii* has been found in its eggs.

Ticks feed on virtually any available warm-blooded animal and human; the occurrence of *R. rickettsii* in the United States does not depend on the presence of any given order of mammal. Domestic dogs infected with *R. rickettsii* can demonstrate clinical illness similar to that seen in humans. Although dogs do not play an important role in the amplification cycle of RMSF, they can serve as a conduit for infected ticks, carrying them into close contact with pet owners. Dogs may serve as sentinels for RMSF in humans. A high prevalence of rickettsial antibodies in stray dogs in Arizona was thought to be a major factor in the 70 cases and 8 deaths from RMSF reported there between 2003 and 2008. The deadliest spotted fever, Brazilian spotted fever, is also caused by *R. rickettsia*. The capybara, a common mammal in Brazil, appears to be the main reservoir through the vector tick *Amblyomma cajennense*.

Communication between physicians and veterinarians is important when cases of zoonotic diseases are detected. Humans serve only as accidental participants in the cycle of infection. A retrospective study has revealed that none of 10 recipients of blood products found to be from donors with confirmed or probable RMSF contracted the disease.[15]

Pathophysiology

After introduction of *R. rickettsii* into the host by the tick vector, the organisms invade and multiply in the vascular endothelial cells. They then enter deeper areas of the vessel walls and infect vascular smooth muscle. Rickettsial organisms move from cell to cell by actin-based motility. Damage to endothelial cells not only exposes subendothelium but also releases tissue plasminogen activator and von Willebrand factor, thereby causing microhemorrhage, microthrombus formation, and increased vascular permeability. In addition, antibody forms, with antigen activating the complement system (type III immune response), and a cellular response is recruited.

These widespread vascular lesions form the basis for most of the clinical features associated with RMSF. Hypotension, edema, and increased extravascular fluid space result from the increased small-vessel permeability. The early rash results from the vasculitis and associated changes in permeability; later petechial and hemorrhagic lesions are secondary to the vasculitis and thrombocytopenia. Microinfarcts and focal lesions develop in various organs, including the brain, heart, lungs, kidneys, adrenal glands, liver, and spleen. Rickettsial encephalitis and diffuse microinfarcts are usual features of central nervous system involvement. An interstitial pneumonitis caused by direct lung invasion by the organism may occur, and ARDS can ensue. Acute renal failure and hypovolemic shock, the primary causes of death, can occur as early as the second week of illness.

Clinical Features

Children from 5 to 9 years of age are the most common victims of RMSF. Two-thirds of all cases are in children younger than 15 years. More than 90% present with a fever and rash. A history of tick bite or presence in possible tick-infested areas is elicited in 60% to 70% of all patients with RMSF, although only 49% of the pediatric population reports a bite. The incubation period ranges from 2 to 14 days, with a mean of 7 days. A short incubation period may indicate a more severe infection. Factors that bring a higher risk of death include delayed onset of rash, glucose-6-phosphate dehydrogenase deficiency, hepatomegaly,

TABLE 123.5 Symptoms and Signs of Rocky Mountain Spotted Fever[a]

	FREQUENCY DURING ILLNESS (%)	
Symptom or Sign	**Any Time**	**First 3 Days**
Fever (temperature of 37.8°–38.9°C [100°–102°F])	99	73
Headache, mild to moderate	91	71
Fever (≥102°F [38.9°C])	90	63
Any rash	88	49
Myalgia, mild to moderate	83	57
Rash, maculopapular	82	46
Rash, palms and soles	74	28
Triad of fever, rash, history of tick exposure	67	3
Nausea and vomiting	60	38
Headache, severe	57	40
Abdominal pain	52	30
Rash, petechial and hemorrhagic	49	13
Myalgia, severe	47	25
Conjunctivitis	30	13
Lymphadenopathy	27	13
Stupor	26	6
Diarrhea	19	9
Edema	18	3
Ataxia	18	7
Meningismus	18	5

[a]In 262 patients.

neurologic deficits, renal insufficiency, increased period between symptoms and antibiotic treatment, and lack of tick bite history.

Onset of symptoms usually is abrupt but may be gradual in approximately one-third of patients. Early symptoms are nonspecific and similar to those of many acute infectious diseases, making early diagnosis difficult. Typical patients experience sudden onset of fever, severe headache, myalgias, prostration, nausea, and vomiting. Tenderness may be noted in large muscle groups (Table 123.5). As many as 80% of patients may have gastrointestinal symptoms secondary to myositis of the abdominal wall. Fever (temperature usually > 102°F [39°C]) is nearly always present during the first 2 to 3 days of illness and may precede other signs by 1 week or more. On occasion, the onset of illness is mild, with lethargy, headache, anorexia, and low-grade fever; these patients may remain ambulatory. Although the triad of fever, rash, and tick exposure traditionally was seen in only approximately 3% to 18% of cases, more recent data have shown that it is found in up to 45% of children with the disease. An extreme complication of RMSF is gangrene, which probably is induced by small-vessel occlusion.

Cutaneous Manifestations

Vasculitis secondary to rickettsial invasion of vascular endothelial cells causes the rash commonly associated with RMSF; however, the rash reportedly is absent in 4% to 16% of laboratory-confirmed cases, referred to as Rocky Mountain spotless fever. In addition, the rash may go unnoticed in dark-skinned patients. It usually appears on the third to fifth febrile day but can emerge as early as the second and as late as the sixth day. The initial lesions generally are restricted to the ankles and wrists, sometimes spreading to the palms and soles. The rash then spreads centripetally to the forearms, arms, legs, thighs, and trunk. The face can be involved, although it is usually spared. Despite the common belief that the palms and soles are critical for diagnosis, they are not consistently involved; rash on the palms and soles is reported in approximately 50% of cases. Involvement of the scrotum or vulva can be an evasive clue for RMSF. The rash of RMSF typically begins as 1- to 5-mm blanchable pink to bright red discrete macules that may be pruritic. At this initial stage, the lesions fade when pressure is applied and are not palpable. A warm compress applied to the area enhances the rash.

After 6 to 12 hours, the rash spreads centripetally. After 2 to 3 days, the rash becomes maculopapular and changes to a deeper red; at this stage, skin changes can be appreciated on light palpation. By approximately the fourth day, the rash becomes petechial and no longer fades with applied pressure. Applying tourniquets for several minutes or taking the blood pressure may cause additional petechiae to form distal to the site of occlusion (Rumpel-Leede phenomenon). The lesions occasionally coalesce to form large ecchymotic areas that may slough and form indolent ulcers (Fig. 123.9).

Prompt institution of specific therapy can cause the initial nonfixed lesions to disappear rapidly, unlike the later fixed lesions. Patients who have had the typical rash may exhibit brownish discolorations at the site during the convalescent period.

Cardiopulmonary Manifestations

Echocardiographic evidence of decreased left ventricular contractility secondary to myocarditis is commonly seen and often is detectable even before clinical signs of RMSF appear. Clinical manifestations of left ventricular dysfunction are uncommon, however, and hypotension and pulmonary edema, when present, usually have noncardiogenic causes. Chest radiographs may demonstrate cardiac enlargement. Electrocardiographic changes include low-voltage, nonspecific ST-T changes, first-degree AV block, dysrhythmias (e.g., sinus and nodal tachycardia, paroxysmal atrial tachycardia, atrial fibrillation), and left ventricular hypertrophy. Most cardiac abnormalities are transient, but persistent echocardiographic changes have been described. Decreased systolic function, elevated serum cardiac markers, no finding of vascular lesions, and a fourfold rise in antibody titers are consistent with myocarditis from RMSF.

Interstitial pneumonitis and increased pulmonary capillary permeability may result from infection of the pulmonary capillaries with rickettsiae. Nonproductive cough and dyspnea secondary to pneumonitis are sometimes seen on presentation. Chest radiographic abnormalities are identified in approximately 25% of patients. These abnormalities include interstitial infiltrates, patchy alveolar infiltrates, pleural effusions, and cardiomegaly with pulmonary edema. Pulmonary consolidation is rare. In severe cases, progression to noncardiogenic pulmonary edema and ARDS may occur.

Neurologic Manifestations

Neurologic manifestations of RMSF range from mild headache and lethargy to seizures and coma. Acute disseminated encephalomyelitis has been described. Headache, generally severe, is common, occurring in 50% to 90% of cases. Meningismus is present in 16% to 29% of patients. The CSF may be normal or show a slight protein elevation and pleocytosis of lymphocytes and polymorphonuclear cells (usually 8 to 35 cells/mL). The CSF glucose level and opening pressure usually are normal. Resolution of eosinophilic meningitis during RMSF after appropriate antibiotic treatment has been reported. Less than 40% of patients have a positive CSF finding.

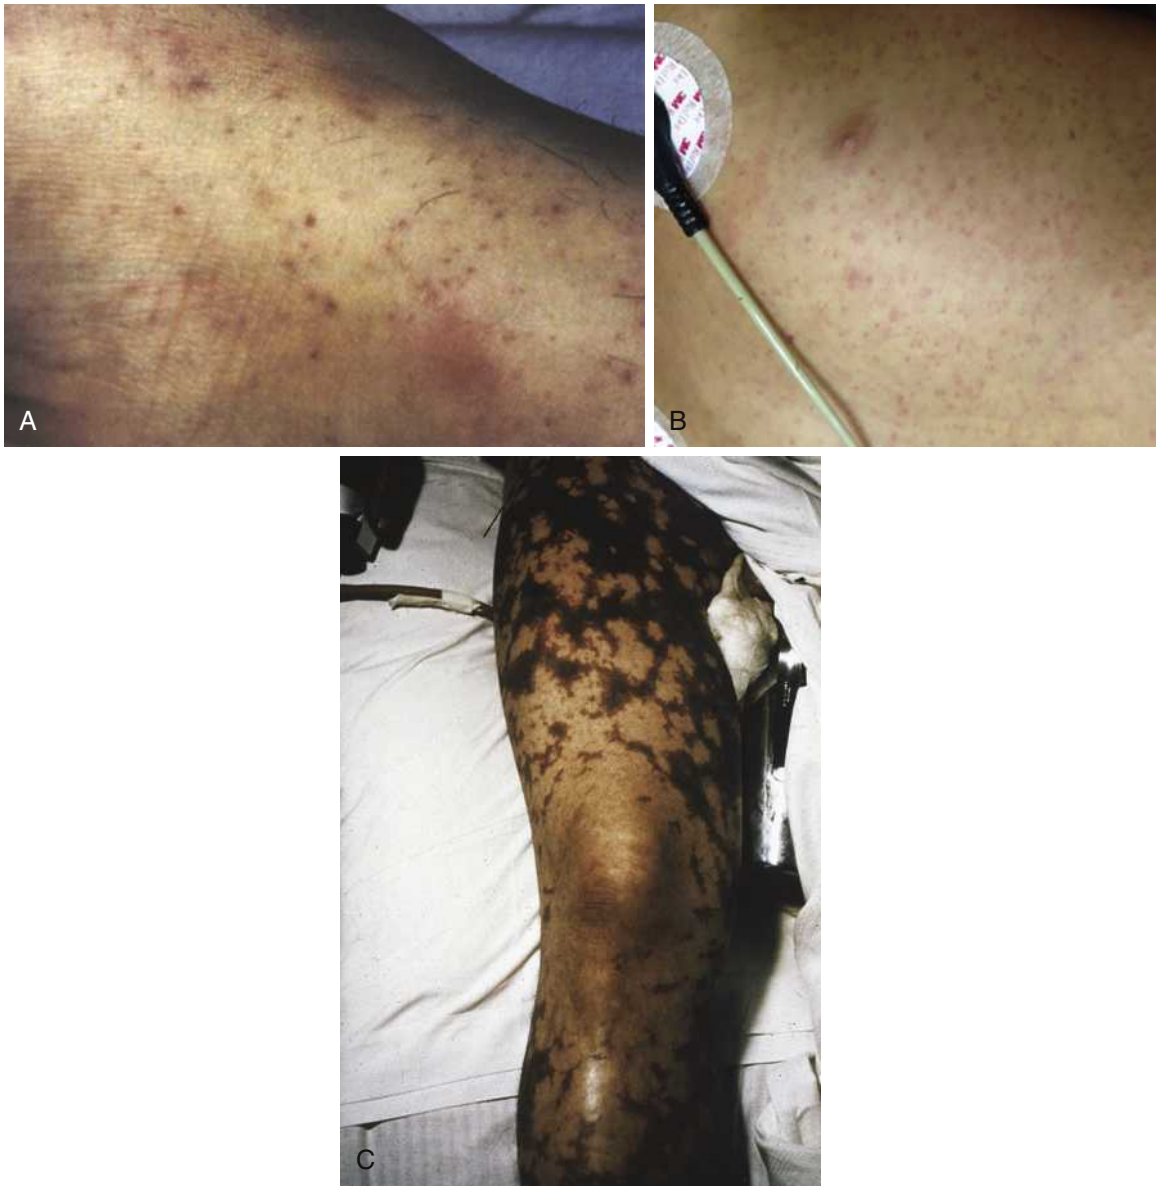

Fig. 123.9 Progression of rash of Rocky Mountain spotted fever. (A) Early, 2–4 days : Macular, maculopapular; small, flat, pink or red macules, usually on the wrists, forearms, and ankles. (B) Mid-stage, 5–7 days: Maculopapular, early petechia; progresses to maculopapular with petechiae, spreading centripetally to trunk. May involve palms and soles. (C) Late-stage, 7–9 days: Petechial, purpuric, necrosis; larger red to purple spots (petechiae) are considered a sign of progression to severe disease. These become diffuse, coalescing to form purpura. Areas of necrosis may occur. (A, From McGinley-Smith DE, Tsao SS. Dermatoses from ticks. *J Am Acad Dermatol*. 2003;49:363-392; B, From Centers for Disease Control and Prevention. RMSF training module: clinical diagnosis and treatment for healthcare providers [continuing education]. Accessed at: https://www.cdc.gov/rmsf/resources/module.html; Courtesy of Gerardo Álvarez; C, Courtesy Dr. Theodore Woodward.)

Cerebral thrombovasculitis may cause focal neurologic deficits, which usually are transient. Seizures can occur, especially during the acute phase of the illness. Generalized cerebral dysfunction ranging from lethargy to coma can occur secondary to systemic toxicity (e.g., fever, hypotension, hyponatremia) or vasculitic lesions involving the central nervous system. Coma is a late finding in patients with severe disease and is seen in less than 10% of cases. Some reports have described patients who remain alert but are amnesic for their illness after recovery. Other reported neurologic manifestations include transient deafness, tremor, rigidity, athetoid movements, paralysis, ataxia, opisthotonos, aphasia, and blindness. In general, neurologic signs abate without residual deficits, and permanent neurologic deficits are rare. Behavioral disturbances and learning disabilities have been reported after recovery from RMSF-associated coma in children.

Differential Diagnoses

Delayed diagnosis or misdiagnosis is the principal reason for the historically significant mortality associated with RMSF. Clinical diagnosis is difficult, especially early in the course of the illness, because of its nonspecific presentation. For avoidable deaths to be prevented, a diagnosis of RMSF should be considered in any patient with an unexplained febrile illness, with or without a rash and headache, even in

the absence of a history of tick bite or travel to an area known to be endemic for the disease. The emergency clinician should remember to ask routinely about recent tick bites, especially when assessing children with unexplained febrile illness, because parents do not always spontaneously provide this important information. An atypical presentation or manifestation of RMSF also should be considered during the differential diagnosis, including the following: (1) absence of a rash (Rocky Mountain spotless fever) or late appearance of a rash; (2) predominant gastrointestinal features or abdominal pain suggestive of an acute condition in the abdomen; (3) cough and pulmonary congestion suggestive of pneumonitis; and (4) meningismus suggestive of viral meningitis. A presumptive diagnosis is advised, with the initiation of specific therapy, well before specific confirmatory laboratory values are available.

A wide variety of other infections with similar exanthems can be confused with RMSF.[19] The most common include meningococcal infection, measles (rubeola) and atypical measles, gonococcemia, infectious mononucleosis, toxic shock syndrome, and enteroviral infections. Less common diseases include dengue fever, leptospirosis, murine typhus, and epidemic typhus. *R. parkeri* rickettsiosis should be considered.

Diagnostic Testing

Most immediately available laboratory tests provide little help in the diagnosis of RMSF. Early in the course of the illness, the diagnosis is based primarily on the history and physical exam, so epidemiologic features should be correlated with clinical signs and symptoms. The initial presentation of RMSF is similar to that of many acute febrile infectious diseases, and almost invariably a therapeutic decision must be made on clinical grounds alone, without the luxury of confirmatory laboratory evidence. Abnormalities such as thrombocytopenia, hyponatremia, and acute renal failure may be detected by routine laboratory tests, but they are nonspecific and unhelpful diagnostically. Up to 30% of patients present with anemia. A definitive diagnosis of RMSF requires positive results on one or more of several tests—skin biopsy, serologic study, or direct isolation and identification of the organism (see Box 123.1).

Skin Biopsy

Identification by immunofluorescent assay (IFA) and immunoperoxidase staining of *R. rickettsii* in biopsy specimens of the rash from patients with suspected RMSF are the best rapid diagnostic tests currently available. In experienced laboratories, the diagnosis of RMSF can be confirmed as soon as 4 hours after the specimen is obtained. The organisms can be detected as early as day 3 of clinical illness and as late as day 10. Unfortunately, this technique can be used only when a rash is visible for accurate localization of the biopsy site. Biopsy specimens generally are obtained with a 3-mm punch in the center of the skin lesion. Immunofluorescent demonstration of rickettsiae in frozen sections of skin biopsy specimens has a sensitivity of 70%. Results of immunohistochemical staining of tissues at autopsy were positive in all fatal cases in one study, whereas IFA results were negative in most cases. Failure to obtain a biopsy specimen of a rickettsial cutaneous lesion or failure to obtain sections through its center is associated with false-negative results. Treatment with anti-rickettsial drugs for 24 hours does not appreciably alter the sensitivity of the test; however, after 48 hours, rickettsiae are substantially reduced in number. Detection of rickettsial DNA in a skin biopsy specimen by PCR assay is available through the CDC, some state health departments, and other clinical laboratories.

Serologic Studies

Rickettsial infection can be confirmed by demonstration of an antibody rise in paired sera. Even with the most sensitive serologic tests, however, elevations in antibody titers do not occur until approximately 5 to 7 days after the onset of initial symptoms. Especially given the need to start treatment when RMSF is suspected, serodiagnosis is retrospective. It is achieved by comparing acute serum, which typically yields negative findings, with convalescent serum, which yields positive results for antibodies. The indirect IFA generally is considered to be the reference standard for RMSF diagnosis and is the test currently used by the CDC and most state public health laboratories. It has a high specificity and sensitivity (94%). IFA can be used to detect IgG or IgM antibodies. An RMSF latex agglutination test with results in less than 24 hours is available in selected laboratories.[15]

A prior study has shown a 12% seroprevalence, with antibody titers of 1:64 or higher, in the pediatric population in the southeastern and south central regions of the United States. Accordingly, clinical correlation with titers in these regions is critical.

Convalescent-stage blood samples are best obtained 2 to 3 weeks after the onset of clinical illness. Antibiotic therapy does not affect the time of appearance of antibodies or titers if initiated several days after the onset of illness. However, if antibiotic therapy is started earlier in the course of the illness, the rise in titers can be delayed for 4 weeks or more. Under these circumstances, antibody titers should be tested again at 4 to 6 weeks after the onset of illness.

Nested PCR testing with a turnaround time between 1 and 2 days has been used but is not specific for individual rickettsial species. Real-time PCR assays that can be completed in 1 hour and are 100% specific for RMSF have been developed but are not readily available.

Isolation of Organism

For most pathogenic infections, the standard diagnostic criterion is isolation and identification of the causative organism from the patient's blood or tissues. This is seldom attempted in rickettsioses, however, because the isolation procedures are time-consuming, expensive, and hazardous to laboratory personnel. In addition, primary isolation of rickettsiae by inoculation in the yolk sac of a chick embryo usually fails because of the small number of organisms in the patient's blood.

Management

Treatment of RMSF consists of antibiotic therapy, supportive care, and possibly steroids. An understanding of the underlying pathophysiologic changes and appreciation of the systemic complications that can occur in the patient afflicted with RMSF are necessary for the formulation of a balanced therapeutic regimen. The course of the disease can be complicated by electrolyte imbalances, renal failure, circulatory collapse, and coma. Although these complications are often absent in the mildly ill patient, for whom antibiotic therapy alone usually suffices, they should be anticipated in the seriously ill patient, especially if the patient is first seen late in the disease course.

The most important factor contributing to the persistent case fatality rate of 5% is the delayed administration of specific antibiotic therapy. Without appropriate treatment, the fatality rate rises to 25%. For a select group of early-stage, mildly ill patients, outpatient therapy with oral antibiotics can be successful if the patient is reliable and close follow-up observation is arranged. More severely ill patients in whom the diagnosis is uncertain should be hospitalized for the administration of IV antibiotics.

As part of an effort to improve physician awareness and timely treatment for RMSF, the CDC offers a free online training module that includes a rash comparison tool and case-based exercises.[20]

Supportive Care

Major complications of RMSF, such as shock, congestive heart failure, disseminated intravascular coagulation, and ARDS, should be

TABLE 123.6 Antibiotic Therapy for Rocky Mountain Spotted Fever[a]

Patient	Doxycycline[b] (Oral or IV)	Chloramphenicol[c] (Oral or IV)
Adult	100 mg bid; consider initial loading dose of 200 mg IV for seriously ill patients	50–75 mg/kg/day, divided q6h
Child (<45 kg)	2.2 mg/kg PO q12h	50–75 mg/kg/day, divided q6h

[a]Continue treatment at least 3 days after fever subsides or until unequivocal clinical improvement is seen; minimum course, 7 to 14 days.
[b]Doxycycline should not be given to pregnant women.
[c]Chloramphenicol should not be given to patients with thrombocytopenia; maximum of 1 g/day for children.

Clinical features of Rocky Mountain spotted fever. *Lancet Infect Dis.* 2008;8:143-144.

anticipated and standard supportive measures instituted when appropriate. Circulatory collapse is common in patients with severe illness and is a major contributor to morbidity and mortality in RMSF. Hypotension unresponsive to fluid administration may require the use of vasopressors. In the critically ill patient with widespread vasculitis, however, a delicate balance exists between maintaining effective circulating volume and excessive leakage of fluids into the tissues, including the lungs and brain. Under these circumstances, the excessive administration of IV fluids can be deleterious. Isolation of the patient is unnecessary unless the diagnosis is still uncertain and other highly communicable illnesses, such as meningococcemia and measles, have not been excluded.

Antibiotics

Antibiotic therapy is most effective when initiated during the early stages of disease, coincident with the initial appearance of the rash. Although data from randomized clinical trials about antibiotic selection for RMSF are lacking, doxycycline is still widely regarded as the therapeutic agent of choice for most patients, including children.[21] Chloramphenicol should be considered only for patients in whom tetracyclines have caused significant adverse events and for pregnant women, except for those who are near term. The recommended doses of doxycycline and chloramphenicol are summarized in Table 123.6.

The American Academy of Pediatrics and CDC recommend doxycycline as the agent of choice for treatment of RMSF in children of all ages. The risk of cosmetically perceptible tooth staining appears to be minimal for a single course of treatment and is subordinate to the potential lethality of this illness.[22]

The effectiveness of therapy depends on the duration of therapy and interval between the onset of illness and the initiation of therapy. Treatment should begin as early as possible and continue for 7 to 10 days or until the patient is afebrile for 2 to 5 days. Response to treatment, as manifested by decreasing fever and subsiding rash, generally occurs 36 to 48 hours after antibiotic therapy is begun. Resistance to chloramphenicol or tetracyclines has not been reported. Penicillin, erythromycin, cephalosporins, aminoglycosides, clindamycin, and sulfonamides are ineffective against RMSF. In fact, empirical use of these agents for presumed bacterial infections could permit progression of the illness.

Symptom overlap between early meningococcal infection and RMSF frequently leads to both diagnoses being considered simultaneously. After blood and CSF culture specimens are obtained, empirical antibiotic coverage with ceftriaxone plus doxycycline should be administered.

On occasion, secondary bacterial infection from the RMSF rash may occur. Although sulfonamides have become a mainstay for the empirical treatment of MRSA skin infections, the use of these agents should be avoided in RMSF patients because their mechanism of inhibiting *p*-aminobenzoic acid may worsen the primary RMSF infection. The role of the new quinolones as potential replacements for doxycycline and chloramphenicol in the treatment of RMSF is as yet unproved. At present, no vaccine is available for RMSF.

Corticosteroids

The use of steroids in RMSF is controversial and is not routinely recommended. However, along with concomitant specific antibiotic therapy, short-term, high-dose steroid therapy should be considered for severe cases of RMSF complicated by extensive vasculitis, encephalitis, and cerebral edema, although there are no robust data to support this recommendation.

Q FEVER

Q fever, or "query fever," was first described in 1937 in Australia as an occupational disease of abattoir workers and dairy farmers. Cattle, sheep, goats, and ticks are the primary reservoirs of the causative rickettsiae, *Coxiella burnetii,* but many other species may be infected. The disease is now endemic worldwide, although it is rare in Scandinavian countries. The southern area of the Netherlands experienced a serious outbreak and reported more than 4000 cases since 2007 and 500 cases, with 11 deaths, in 2010 alone. France and Australia have significantly more cases than the United States. Africa presently is hyperendemic with Q fever. In the United States, the Midwest and California have had the highest incidences of Q fever. More than 30 cases have been seen in US military personnel deployed in Iraq and Afghanistan. Approximately 80% of cases of Q fever occur in males.[23]

Pathophysiology

C. burnetii is an obligate intracellular gram-negative coccobacillus bacterium, with multiple strains having been identified. Although most Q fever infections are transmitted by particle inhalation, tick transmission does occur. Besides being a vector of the disease, extremely high levels of *C. burnetii* in the feces of infected ticks are found on ruminant animals on which they feed. The Rocky Mountain wood tick, *D. andersoni*, is the main tick vector in the United States, although the bacterium has been isolated in more than 40 hard tick and 14 soft tick species.

Q fever historically has been characterized as either an acute or chronic presentation, although the exact definitions and criteria are controversial, with some authors suggesting phases of infection, akin to tuberculosis.[24] The most common foci of infection are endocarditis, vascular infections, osteoarticular infections, or lymphadenitis. Both the type of bacterial strain and patient risk factors play a role in the course of illness.[24] It is extremely infectious for humans and animals; a single inhaled organism is likely sufficient to initiate infection. The Q fever rickettsiae are extremely resistant to desiccation, physical and chemical agents, and can survive for long periods in an inanimate environment. Consequently, it is classified as a category B biologic warfare agent by the CDC and has been a nationally notifiable disease since 1999.[25] The organism's infectivity and estimated casualty rate have been judged to be comparable with those of anthrax. Humans most commonly are infected by inhalation of aerosolized particles from contaminated environments. Patients with Q fever rarely recall a history of tick bite.

Clinical Features

The incubation period of Q fever ranges from 14 to 39 days, with an average of 20 days. Up to 60% of initial infections are asymptomatic. The acute form of the disease includes clinical manifestations such as severe retrobulbar headache, fever with temperatures to 40°C (104°F) or higher, shaking chills, general malaise, myalgia, and chest pain. Although Q fever is widely regarded as primarily a respiratory disease, the reported incidence of pulmonary involvement varies, ranging from 0% to 90%. The reasons for this reported variation are unclear, but explanations include geographic strain variation, plasmids that may regulate virulence, and source, route, and dose of the agent. Mild hepatic involvement is common. Osteomyelitis in children, acute renal failure, and lymphocytic meningitis secondary to *C. burnetii* have been described.

Rarely, Q fever may present as a "chronic infection," occurring in less than 5% of cases, with or without an antecedent acute episode. Clinical syndromes that historically have been labeled as a chronic form of the disease include granulomatous hepatitis and culture-negative endocarditis. Endocarditis has been documented in up to 68% of patients with chronic Q fever; the mortality rate for this group approaches 25%. Most patients with Q fever in whom endocarditis develops have a history of valvular heart disease, particularly affecting the aortic valve. These patients should be especially cognizant of the potential hazards of Q fever infection and should be restricted from certain at-risk occupational settings. Patients with aneurysms and vascular grafts also are at risk.

Human fetal demise and deaths have been attributed to *C. burnetii* infection. Persons infected with human immunodeficiency virus (HIV) are at increased risk for Q fever.

Diagnostic Testing

The diagnosis of Q fever should be suspected in any patient with a severe febrile illness without an obvious cause, especially someone who has had recent contact with sheep, cattle, goats, or animal byproducts. Few patients with this disease recall a tick bite. Because of the laboratory hazards associated with the cultivation of Q fever rickettsiae, isolation of *C. burnetii* is not recommended for routine diagnosis. Rather, serologic studies such as IFA, PCR, and ELISA are the preferred diagnostic tests, but the results are not identifiable until 2 to 3 weeks after the onset of illness.

C. burnetii displays an antigenic phase variation. In patients with acute Q fever, phase II antibodies dominate the humoral immune response and are detectable by the second week of illness, whereas phase I antibodies are prominent only in patients with chronic (persistent) Q fever. Confirmation of a Q fever case requires (1) a fourfold increase in IgG titers between acute and convalescent samples or the presence of IgM phase II antibodies, (2) a positive PCR test result, (3) the culture of *C. burnetii* from a clinical specimen, or (4) the positive immunostaining of the organism in tissue. Measurement of IgA and IgG together has been useful in the diagnosis of endocarditis. The finding of granulomatous changes on bone marrow biopsy can be characteristic of Q fever in patients with osteomyelitis.

Management

Uncomplicated acute Q fever is treated with doxycycline (200 mg once daily for 2–3 weeks). Acute disease with concomitant valvular heart disease is treated with doxycycline (200 mg once daily) plus hydroxychloroquine (600 mg once daily) for 1 year. Fluoroquinolones have also been successful in this situation. Patients with persistent infections should be continued on the same regimen for 1.5 to 3 years. Combination therapy with doxycycline and hydroxychloroquine is effective for treatment of endocarditis in HIV-infected patients. Strong evidence has recommended combination therapy for endocarditis for 18 and 24 months in patients with native valves and prosthetic valves, respectively, with evidence of persistent infection. Cotrimoxazole is the recommended alternative treatment. Some macrolides and rifampin may also be effective. Treatment of pregnant women with Q fever with long-term cotrimoxazole, although not always curative, has been shown to decrease complications to the fetus.

In mass casualty situations, prophylaxis is recommended by treating with 5 to 7 days of doxycycline. Most acute Q fever infections resolve without treatment, but the risk of persistent infection makes treatment advisable. The mortality rate is less than 1% in untreated patients and lower still in those treated with antibiotics. The prognosis is worse in patients with protracted illness and hepatic involvement or endocarditis. Inactivated whole-cell vaccines for Q fever have proven to be effective for as long as 5 years. Vaccination can afford considerable protection to slaughterhouse and dairy workers and others at risk. Information on the handling of suspected or confirmed exposure to *C. burnetii* or bioterrorist threats can be found on the CDC website.

EHRLICHIOSES

There are currently two major forms of human ehrlichiosis in the United States—human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA), caused by the bacteria *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum,* respectively. In 2001, restructuring of the *Ehrlichia* phylogenetic branches placed the previously known bacteria of human granulocytic ehrlichiosis into the genus *Anaplasma*—hence, the revised name. Both genera, *Ehrlichia* and *Anaplasma,* are now considered to be in the tribe Ehrlichieae, family Anaplasmataceae, but are still collectively referred to as being in the group of diseases called ehrlichioses. A total of seven different species are now thought to be possible human pathogens.[26] HME was discovered in 1986 and HGA (previously human granulocytic ehrlichiosis) in 1994. Both have been identified as emerging diseases by the CDC and are nationally notifiable diseases, reportable through the appropriate state departments.

More than 1650 cases of *E. chaffeensis* were reported in the United States between 2016 and 2017 (Fig. 123.10).[27] Dramatic increases in seroprevalence rates in both diseases during the past decade suggest that these diseases have previously been highly underdiagnosed, underreported, or both. Misclassification from failure to confirm *Anaplasma* serologically likely has led to underreporting of this disease.

Both diseases peak around June through August. High-risk populations are similar to those at high risk for Lyme disease, including those living in endemic areas or having frequent contact with wildlife or rural wooded areas. HME has been reported predominantly in the south-central and southeastern United States; HGA mostly is found in the upper Midwest, New England, parts of the Mid-Atlantic states, northern California, and many parts of Europe.

Pathophysiology

The causative agents in the ehrlichioses are gram-negative, obligate, intracellular, rickettsia-like coccobacilli. Transmitted from the midgut and salivary glands of their tick vectors, these organisms reside in specific circulating leukocytes in human and other mammalian hosts. Reservoirs include the white-tailed deer and white-footed mouse. *Ehrlichia canis* is the common pathogenic species in dogs. The species *Ehrlichia equina* has been isolated in California elk. HME, transmitted by the Lone Star tick, *A. americanum,* is most often caused by the organism *E. chaffeensis* (named for Fort Chaffee, Arkansas), which invades monocytes. *Ehrlichia ewingii* and *Ehrlichia muris* are also now known to be definite causative organisms.[28] *E. chaffeensis* has been isolated

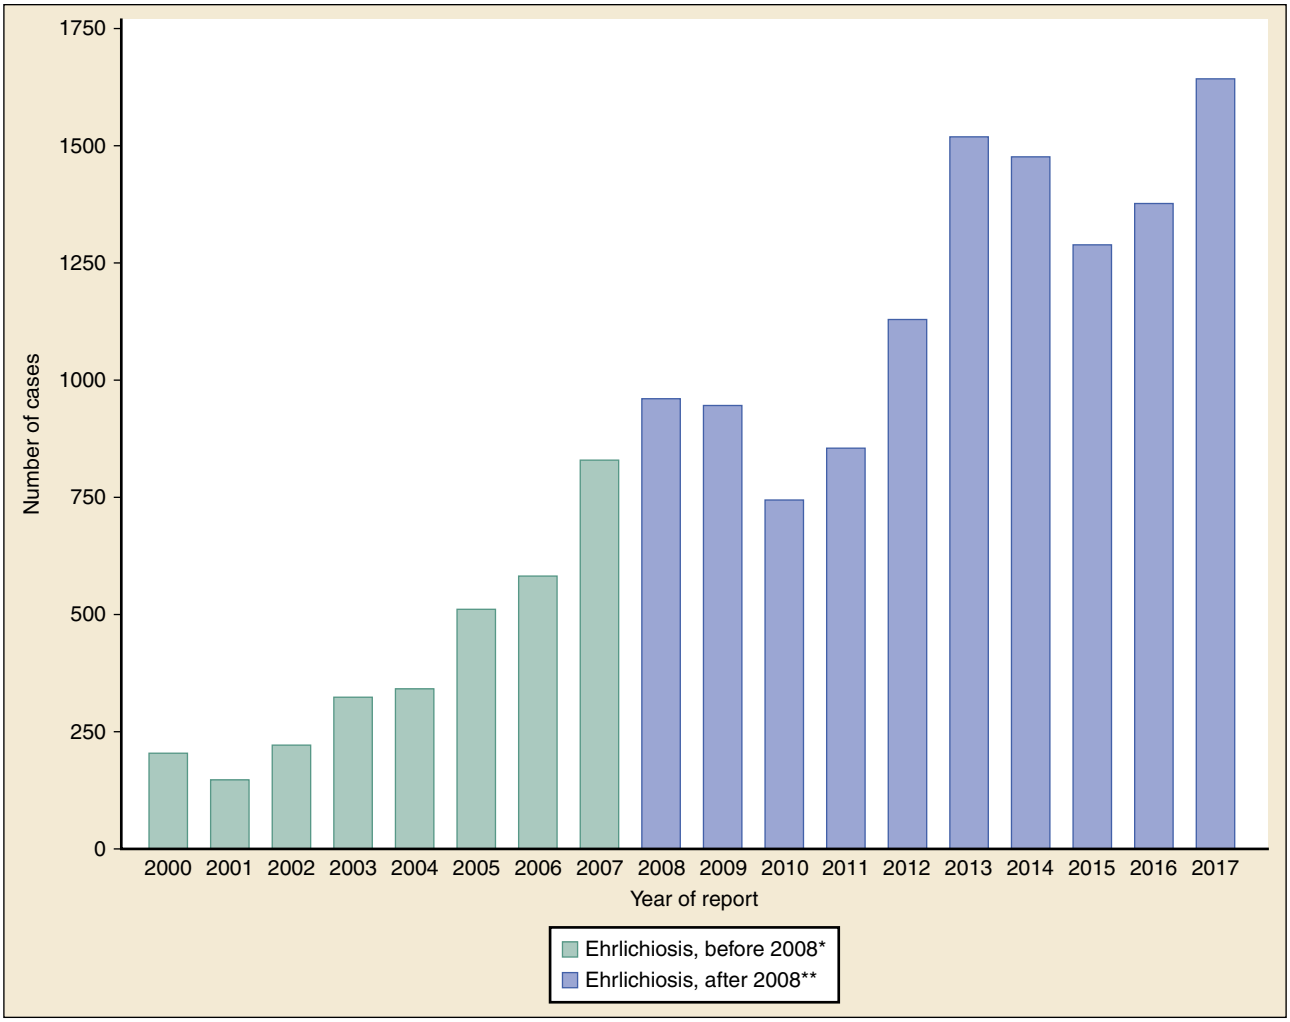

Fig. 123.10 More than 1650 cases of *Ehrlichia chaffeensis* were reported in the United States between 2016 and 2017.

from *I. pacificus* ticks in California. As of 2017, Missouri, Arkansas, New York, and Virginia are responsible for over half of reported HME cases.[27] *A. phagocytophilum* invades neutrophils (granulocytes), causing HGA and, in the United States, is transmitted by the black-legged tick, *I. scapularis*, and its West Coast counterpart, the western black-legged tick, *I. pacificus*. Deer, elk, and wild rodents are the main reservoirs for *Anaplasma*. Both ticks also are the vectors for Lyme disease. *A. phagocytophilum* has been detected in significant numbers in various *Ixodes* human tick species in mainland Portugal, Italy, and Japan.

Clinical Features

The clinical presentations of HME and HGA are similar and, for management, it is not necessary to differentiate between the two illnesses. The average time to onset of symptoms (for HME) from tick discovery is 9 days but ranges from 0 to 34 days. More than 90% of patients with HME report a history of tick bite or tick exposure. Ehrlichiosis characteristically is manifested with abrupt onset of fever, headache, myalgia, and shaking chills. Other, less frequent manifestations include nausea, vomiting, diarrhea, abdominal pain, cough, and confusion. Leukopenia, thrombocytopenia, and elevated liver function test values can be seen in 50% to 90% of patients.

Rashes occur in approximately one-third of patients with HME but in only 2% to 11% of those with HGA. In a small series of pediatric patients (average age, 7.4 years) with HME, a rash rate of 67% was found. Most of these patients suffered permanent cognitive or other neurologic damage.

Ehrlichiosis (HME) also has been associated with optic neuritis. ARDS, meningitis, pancarditis, renal failure, and disseminated intravascular coagulation have been associated with both ehrlichioses. Case fatality rates vary between studies but range from 0.5% to 3% for both diseases, with HGA usually reported as the lower of the two. Historically, data support only a 0.2% concurrence of lumbar puncture–proven meningitis or encephalitis with patients diagnosed with HGA who have a headache and/or stiff neck.[28] Approximately 45% of patients with HGA require hospitalization, although almost all recover without residual problems. HME has been associated with hemophagocytic lymphohistiocytosis.

Diagnostic Testing

For HME and HGA, the initial diagnosis is based largely on clinical presentation. With most tests, the diagnosis will be retrospective; results are rarely available immediately. The most common mode of diagnosis is confirmation of acute and convalescent antibodies with IFA. Enzyme immunoassay and confirmatory tests with Western blot have been developed but are not readily available. They provide only positive or negative results without titers. PCR testing for DNA fragments, although also not as readily available in most institutions, probably is most reliable in the acute phase of illness (at 1 week after onset of symptoms). Diagnostic serologic testing is available at the CDC through state health departments.

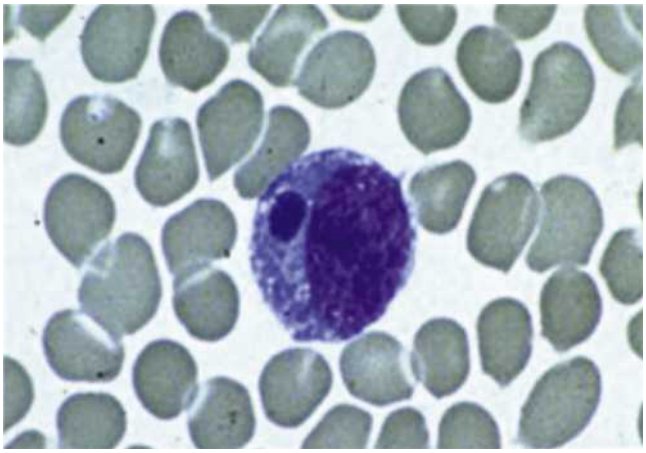

Fig. 123.11 Morulae detected in a monocyte on a peripheral blood smear associated with *Ehrlichia chaffeensis* infection (Wright stain; ×1000). (From: Centers for Disease Control and Prevention. Ehrlichiosis: symptoms, diagnosis, and treatment. www.cdc.gov/Ehrlichiosis/symptoms/index.html.)

Laboratory criteria required in the CDC's 2008 case definition to establish the presence of HME or HGA include detection of *E. chaffeensis* or *A. phagocytophilum,* respectively, through the use of the following diagnostic tests: (1) fourfold change in antibody titer to the organism antigen by IFA in paired serum samples; (2) positive result on PCR assay and confirmation of organism-specific DNA; (3) identification of morulae in leukocytes and a positive titer to the organism antigen; (4) immunostaining of the organism's antigen in a biopsy or autopsy specimen; or (5) culture of the organism from a clinical specimen. All tests require compatible clinical findings. Most patients with acute ehrlichiosis have antibody titers higher than 1 : 160.[29]

Cytopenia and abnormal liver function usually resolve after the acute phase of illness by 14 to 28 days. Microscopic identification of mulberry-like clusters (morulae) inside leukocytes on peripheral blood smears is helpful (Fig. 123.11). This finding, however, usually disappears after the first week of illness with HGA,[28] especially if the patient has been treated with doxycycline. Cultures take up to 2 weeks to grow the organisms.

Management

Doxycycline (100 mg bid; 2.2 mg/kg body weight bid for children weighing < 45 kg) and tetracycline regimens for 7 to 14 days are curative. Most patients respond rapidly after treatment is begun, and fever subsides within 24 to 48 hours. Tooth staining from doxycycline is no longer considered a concern for children and should not be a reason to withhold therapy. Rifampin is an effective alternative in children with human ehrlichiosis. Data supporting the use of chloramphenicol are inconclusive. The same ticks that transmit HGA (*Ixodes* spp.) also are responsible for Lyme disease and babesiosis. Each disease entity requires a full diagnostic evaluation because amoxicillin treats Lyme disease but not HGA or babesiosis, and doxycycline alone does not treat babesiosis. Failure of fever to resolve beyond 6 or 7 days of treatment of a suspected tickborne disease should heighten suspicion for another disease organism. There are no vaccines presently available for either of the ehrlichioses.

BABESIOSIS

Babesiosis is a tickborne, malaria-like, acute febrile illness caused by intraerythrocytic protozoal parasites of the genus *Babesia*. Babesiosis has long been recognized as an important veterinary disease and probably was known in ancient times; it has been proposed that the fifth plague described in the book of Exodus was likely babesiosis. The species almost solely causing the disease is the protozoan *Babesia microti,* which is transmitted via the tick *Ixodes scapularis. B. microti's* main reservoirs are the white-footed mouse, *Peromyscus leucopus*, and the white-tailed deer, *Odocoileus virginianus*.

The first human cases of babesiosis were reported in Montana in 1904. Investigators seeking the cause of RMSF examined blood smears from local inhabitants and described parasitic forms now known to be characteristic of *Babesia*. Since the late 1950s, several widely scattered cases (mostly in Europe) of human babesiosis have been reported in splenectomized persons. *Babesia divergens,* a species primarily infecting cattle, is the most common agent reported in Europe, but other species have been implicated as well, including *Babesia bovis, Babesia equi,* and a single case of *Babesia caucasia* infection. Two strains, WA1, related to a canine pathogen, *Babesia gibsoni,* and MO1, related to *B. divergens,* also have been found to cause disease in humans. In all these reported cases, the course was fulminant and the disease usually fatal.

In 2011, babesiosis became a nationally reportable condition. In 2013, 1762 cases of babesiosis were identified by the 27 states mandated to report. This count reached 2358 in 2017. Almost all these cases were caused by *Babesia microti,* a rodent parasite, and occurred in the coastal regions of southern New England, where *B. microti* is endemic. New Jersey and the eastern part of Long Island were found to be endemic with babesiosis. Ninety-five percent of cases came from seven states—Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin—and 85% of these patients presented with symptoms in June through August, coinciding with the nymphal feeding period and time of maximal human exposure in endemic areas.[30] The average age for cases reported was 62 and two-thirds were male.[31] This disease has been particularly on the rise within the last 8 years in the lower Hudson Valley in New York and in eastern Pennsylvania.[32]

These cases differ from the European cases in that most (≈80%) occurred in persons with intact spleens. Significant morbidity has been low in the United States, despite lack of specific therapy. Asplenic persons, older adults, and otherwise immunosuppressed patients usually have more severe disease.

Pathophysiology

B. microti is associated with mice and deer rather than with cattle. The ecology of *B. microti* is similar to that of *B. burgdorferi,* the causative agent of Lyme disease, with the same major vector, *I. scapularis,* and the same mammalian reservoirs—predominantly the white-footed mouse, which hosts the larval and nymphal stages of the tick, and the white-tailed deer, which hosts the adult ticks.

Human babesiosis results from accidental human intrusion on the natural cycle of infection. The nymphal form of the *Ixodes* tick most commonly transmits the disease to humans, although babesiosis also can be transmitted by the adult tick. *I. scapularis* nymphs measure only 1 to 2 mm long and thus are easily overlooked by the patient (see Fig. 123.5). In more than 50% of all cases of babesiosis, patients cannot recall tick exposure. Babesiosis acquired through blood transfusion has been well documented.

Clinical Features

Babesiosis has an incubation period of 1 to 4 weeks after tick exposure. A nonspecific influenza-like illness, with fever, chills, headache, fatigue, and anorexia, is characteristic. Less common manifestations are nausea, diaphoresis, depression, photophobia, myalgias, arthralgias, dark urine, emotional lability, and hyperesthesias. Unlike in Lyme disease, rash is not a feature of this illness; however, erythema figuratum, a

widespread exanthem with well-established annular lesions, has been associated with septic babesiosis. The physical examination usually reveals normal findings, except for fever, which typically is present, and splenomegaly, which occurs in some patients. Meningeal signs are absent. More severe disease occurs in splenectomized patients; hypotension, severe hemolytic anemia, hemoglobinuria, jaundice, renal insufficiency, ARDS, and disseminated intravascular coagulation can be seen in these cases. Some patients with babesiosis are only mildly ill, and asymptomatic infection also may occur, as demonstrated by serologic surveys in endemic areas. The diagnosis of babesiosis should be considered in any febrile patient from an endemic area during the tick season and should be part of the differential diagnosis for post-transfusion infections. Mortality rates for hospitalized patients historically range from 6% to 9%, and up to 21% in immunocompromised patients.

Diagnostic Testing

The diagnosis may be established through microscopy, antibody detection through IFA staining, or PCR assay. Microscopic examination is done with thick and thin Giemsa-stained blood smears. Characteristic intraerythrocytic forms (piriform, ring, tetrad) may be present. Babesiosis has been known to be misdiagnosed as malaria. Malaria may be excluded by the absence of intracellular pigment granules, schizonts, and gametocytes. The presence of parasites in budding tetrad formation, resembling a Maltese cross, is more suggestive of babesiosis. Contrary to what is commonly taught, this finding is uncommon. Because parasitemia may vary, serial smears over the course of several days may be necessary in suspected cases. An immunohistochemical assay has been developed that further allows easier microscopic differentiation between babesiosis and malarial organisms.

The diagnosis can be confirmed by serologic studies. IFA antibody to *B. microti* is available through the CDC, and titers usually rise to 1:1024 or greater within the first few weeks of illness. IgM–indirect IFA is sensitive and specific in acute babesiosis. Serologic tests for Lyme disease, which shares a common tick vector with babesiosis, also should be performed; concurrent Lyme disease has been reported in up to 50% of cases of babesiosis. ELISA and IFA sensitivities rise significantly after 5 days of illness, whereas PCR is more useful in the earlier days of sampling.

Parasitemia observed at 1 to 4 weeks after inoculation of blood from infected patients into gerbils or hamsters supports the diagnosis. Other nonspecific laboratory findings include mild to moderate hemolytic anemia, which is present in most patients, and resultant mild elevations in bilirubin and serum lactate dehydrogenase levels.

Management

Patients who have not undergone splenectomy generally recover without specific therapy, although prolonged malaise and fatigue are common. In patients with severe disease and those who have had splenectomies, the combination of clindamycin (1.2 g bid IV or 600 mg tid orally) plus quinine (650 mg tid orally) has been shown to be effective and is the treatment of choice. An alternative regimen that may be better tolerated, especially by children and infants, consists of atovaquone (750 mg bid orally) plus azithromycin (500–1000 mg once followed by 250 mg once daily orally); up to 25% of patients may have an adverse effect from quinine. Pediatric doses need to be adjusted accordingly. Therapy should be continued for a minimum of 7 to 10 days. Development of resistance during treatment with azithromycin-atovaquone in immunocompromised patients has been described.

Other antimalarial drugs, such as chloroquine and quinacrine, are not effective. Fulminantly ill patients with marked degrees of parasitemia and hemolysis have benefited from exchange transfusion or apheresis.[33] Effective live vaccines have been developed for bovine babesiosis but have not been developed yet for human disease.[34]

COLORADO TICK FEVER

Endemic to the Rocky Mountain area, Colorado tick fever is an acute, tickborne viral infection characterized by headache, back pain, biphasic febrile course, and leukopenia. The causative agent of Colorado tick fever is a small RNA virus of the genus *Coltivirus,* family Reoviridae. It is one of more than 500 viruses in the heterogeneous group of arthropod-borne viruses (arboviruses). Colorado tick fever has a sharply defined endemic zone encompassing mountainous and highland areas, from an altitude of approximately 4000 to more than 10,000 feet, in the Canadian provinces of British Columbia and Alberta and in at least 11 western states (California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, South Dakota, Utah, Washington, and Wyoming). The largest number of cases has been reported in Colorado. The distribution of the virus coincides with that of its principal tick vector, *D. andersoni,* the Rocky Mountain wood tick. Although RMSF is transmitted by the same vector, that disease is far less common in Colorado. The cases of RMSF are outnumbered at least 20-fold by cases of Colorado tick fever.

Pathophysiology

The Colorado tick fever virus has been isolated from at least eight species of ticks, but *D. andersoni* is the only proven vector for humans. The tick is a significant reservoir for the virus because trans-stadial transmission (from larva to nymph to adult) occurs, and the tick remains infected and infectious for life, up to 3 years. The primary vertebrate host species for Colorado tick fever virus maintenance are the chipmunk, *Tamias minimus,* and golden-mantled ground squirrel, *Spermophilus lateralis*; many other vertebrate hosts have been identified as well, including a species of porcupine in Colorado in Rocky Mountain National Park. Larval and nymphal stages of *D. andersoni* ticks are responsible for the transmission of Colorado tick fever virus among rodents, and overwintering of the virus is accomplished by nymphal and adult *D. andersoni*. Only adult ticks transmit Colorado tick fever virus to humans.

The CDC indicates that there were 83 cases reported between 2002 and 2012 in the United States. The actual incidence undoubtedly is much higher because many cases are diagnosed as nonspecific viral illness, and other cases may be mild or entirely subclinical. Human susceptibility to Colorado tick fever is universal, but it occurs most commonly in young men, reflecting greater occupational and recreational tick exposure. This disease is not notifiable nationally, but is in some states.

Clinical Features

After an incubation period of approximately 3 to 5 days (range, 0–14 days), a moderate to severe influenza-like illness occurs abruptly, with signs and symptoms similar to those in early-stage RMSF. Fever, chills, headache, retrobulbar pain, myalgia, lethargy, anorexia, and nausea are common; vomiting and abdominal pain are reported occasionally. Early physical findings are nonspecific. A macular or maculopapular rash has been reported in 5% to 12% of patients but, unlike the rash of RMSF, the rash of Colorado tick fever is not a prominent feature of the illness.

A distinct feature of the illness is a biphasic course that occurs in approximately 50% of patients, causing a characteristic saddleback fever curve. Initial symptoms resolve after 2 to 3 days, and the patient feels relatively well for 1 or 2 days, after which the fever, headache, and myalgias return. The second phase may be more intense than the first

phase and generally lasts 2 to 4 days. There may even be a third febrile period. Alternatively, a single prolonged febrile illness may occur. Recovery from Colorado tick fever usually occurs within 2 weeks, but convalescence can be prolonged, especially in patients older than 30 years.

Colorado tick fever is a self-limited disease, and virtually all patients recover without sequelae. Reports of severe complications, such as meningoencephalitis and hemorrhagic diathesis, have been limited to children. Only a few fatal cases have been recorded.

Diagnostic Testing

The peripheral leukocyte count often is depressed during the acute phase of illness to as low as 1000/μL, with a relative lymphocytosis. Transient thrombocytopenia can accompany the leukopenia and, less often, a mild anemia can occur. These hematologic abnormalities normalize during convalescence, but persistence of the virus in red blood cells causes a prolonged viremia, even when clinical recovery is complete. Transfusion-acquired infection has been reported and is caused by this persistent viremia in asymptomatic blood donors.

The diagnosis of Colorado tick fever can be confirmed by serologic testing (IFA, neutralizing antibody, complement fixation, enzyme immunoassay) of acute and convalescent samples, but serologic study is of little help early because of the slow rise of titers. The most rapid confirmation of Colorado tick fever, with corresponding elimination of concern about possible RMSF, is provided by direct immunofluorescent staining of virus in red blood cells in peripheral blood smears. RT-PCR testing is available for more rapid diagnosis. ELISA has shown promising sensitivity in detection of the Colorado tick fever virus.

Management

The treatment of Colorado tick fever is supportive only. Although not commonly a fatal disease, up to 30% of patients require hospitalization. If RMSF remains a diagnostic possibility, initial treatment with tetracycline or chloramphenicol and a period of observation are necessary until the diagnosis of RMSF can be ruled out.

OTHER TICKBORNE VIRUSES

In addition to the virus responsible for Colorado tick fever, at least 40 viral species have been transmitted to humans by ticks and caused illness, approximately 25 of them in the United States. Tickborne viruses are found predominantly in the RNA virus families. Historically, the most severe cases involved the tickborne encephalitis virus and Crimean-Congo hemorrhagic fever virus, but these have not been reported in the United States. A few tickborne viral illnesses have received notable press in the United States because of their mortality rates—the Heartland virus, a phlebovirus (family Bunyaviridae); the Bourbon virus, a thogotovirus (family Orthomyxoviridae); and Powassan virus (POWV). Recently, the exotic tick *Haemaphysalis longicornis* has been identified in several East Coast states in the United States. This tick is responsible for severe hemorrhagic fever in China and Japan and, so far, two cases in the United States have been confirmed.[35]

Eight cases of Heartland virus (RNA) disease were found among residents of Tennessee and Missouri as of March 2014. Four patients were hospitalized, and there was one death. All cases presented with leukopenia, thrombocytopenia, and fever. The Bourbon virus, named after the county of its discovery, caused the death of a man in Kansas. POWV, named after Powassan, Ontario, where a young boy died from this flavivirus, is transmitted by several *Ixodes* tick species, including *I. scapularis*. It can cause a severe encephalitis and up to 50% of subjects acquire permanent neurologic deficits.[36] Presentations and laboratory results of these new viral syndromes resembled those of other tickborne illnesses and were treated with antibiotics empirically and unsuccessfully. Other neurologic symptoms and encephalitis have been well-described with tickborne viral illnesses. As with most viral illnesses, treatment remains mostly supportive. The emergence and discovery of these newer tickborne diseases suggests that they have been underreported.[19,37]

TICK PARALYSIS

Tick paralysis occurs when an adult female tick attaches to a host and releases a neurotoxin that can produce cerebellar dysfunction or an ascending paralysis. Tick paralysis was recognized as early as the beginning of the 19th century. Hovell, while traveling through Australia, wrote in 1824 of "the small insect called the tick, which buries itself in the flesh, and would in the end destroy either human or beast if not removed in time."

Tick paralysis has been reported worldwide, but most cases occur in the southeastern and northwestern regions of the United States, western Canada, and Australia. Cases have been reported to occur in clusters; 43 species of ticks have been found to cause tick paralysis in humans, other mammals, or birds. Most cases in North America and Canada are caused by *D. andersoni* (Rocky Mountain wood tick) and *D. variabilis* (American dog tick). Species responsible for paralysis cases that also are associated with other tickborne diseases include *A. americanum* (Lone Star tick), *I. scapularis* (black-legged tick), and *I. pacificus* (western black-legged tick); in Australia, *Ixodes holocyclus* is primarily associated with this disorder. Family Argasidae ticks (soft ticks) also have been implicated. Tick paralysis usually occurs in the spring and summer months and most reported cases are in children, primarily girls, probably because ticks are more easily concealed in longer hair. Among adults, however, more men than women acquire the disease.

Pathophysiology

Tick paralysis is thought to be caused by a toxin secreted from the salivary glands of the tick during a blood meal. The toxin, ixobotoxin, affects sodium flux across axonal membranes without affecting the neuromuscular junction itself. The mechanism of action of the toxin is poorly understood, but it appears to produce a conduction block in the peripheral branches of motor fibers, resulting in a failure of release of acetylcholine at the neuromuscular junction. Electrophysiologic studies have confirmed a rapid reversal of significant impairment of motor nerve terminal function after tick removal, indicating that the disturbance is not a result of a neuromuscular junction defect. Possible central sites of action of the toxin have been postulated to explain cases in which the clinical picture is dominated by cerebellar dysfunction.

Clinical Features

The onset of symptoms usually occurs 4 to 7 days after the tick attaches. Initial manifestations include restlessness and irritability, followed by ascending flaccid paralysis, acute ataxia, or both. Deep tendon reflexes are almost invariably lost. These signs and symptoms can progress rapidly during a few days to bulbar involvement, respiratory paralysis, and ultimately death if the tick is not detected and removed.

The ascending nature of tick paralysis has been noted in most descriptions; however, ataxia and associated cerebellar abnormalities in the absence of muscle weakness may be seen. Thus, tick paralysis may sometimes be manifested as so-called tick ataxia. Isolated facial paralysis has been reported in patients with ticks embedded behind the ear. Fever, other systemic symptoms, and sensory deficits are unusual. Concomitant infection with Colorado tick fever has been reported.

Differential Diagnoses

Tick paralysis should be considered in the differential diagnosis for any patient thought to have Guillain-Barré syndrome, Eaton-Lambert syndrome, myasthenia gravis, poliomyelitis, botulism, diphtheritic polyneuropathy, or any disease with an acute onset of ascending flaccid paralysis or acute ataxia. Ocular findings, such as decreased convergence, unresponsive dilated pupils, and nystagmus (horizontal and vertical), seen early in tick paralysis can help distinguish this disease from Guillain-Barré syndrome.

Diagnostic Testing

No diagnostic tests to confirm tick paralysis are available other than the combination of the clinical scenario, presence of a tick, and improvement after its removal. The Tensilon test yields a negative result in patients with this condition, and CSF is normal.

Management

Treatment in the United States consists simply of removing the tick; improvement generally is seen within a few hours and complete recovery within 48 hours. Supportive care, including mechanical ventilation, may be necessary. The mortality rate is approximately 10%; nearly all patients who die are children. The recommended procedure for the removal of any tick, including ticks causing tick paralysis, is summarized in Box 123.2. Traditional methods, such as burning, forceful removal, and application of petroleum, viscous lidocaine, or gasoline, are not consistently successful and do not guarantee removal of mouthparts, where the salivary glands and toxin may remain. Retained mouthparts also may cause infection.

Tick paralysis in Australia is often more devastating than in the United States. Symptoms and signs of illness caused by the Australian tick, *I. holocyclus,* do not resolve and often worsen after tick removal. Hyperimmune serum is available in Australia and often is needed because symptoms may worsen up to 48 hours after removal.

TICK BITE PROPHYLAXIS WITH INSECT REPELLENTS

Insect repellents have long been used to prevent mosquito bites. With recent increased public awareness of and concern about tickborne illness, especially Lyme disease, skin and clothing repellents are now also being marketed for tick protection. Three active ingredients in repellents have been shown to be effective against blood-sucking arthropods, including ticks—*N,N*-diethyl-*m*-toluamide (DEET), picaridin in KBR 3023 (known as Bayrepel, Hepidanin, and Autan Repel outside the United States), and *p*-menthane-3,8-diol (PMD) in oil of lemon eucalyptus. The most effective and most studied is DEET. Formulation percentages of DEET vary widely, ranging from 4.75% to 23.8%, giving 1.5 to 5 hours of protection, respectively.[38] A long-acting 35% DEET formulation (US Army Extended Duration Topical Insect/Arthropod Repellent [EDTIAR]), available in the United States as Ultrathon (3M), provides protection for 6 to 12 hours. Picaridin is as effective as the 35% DEET formulation. Despite some earlier concerns, toxic and allergic reactions to DEET have been uncommon, and serious adverse effects are rare. Used as directed, concentrations up to 50% appear to be safe, even in young children, although toxic encephalopathy rarely can occur. Use for infants younger than 2 months is not recommended.

Permethrin is actually a contact insecticide rather than a repellent. It can be used as a clothing spray for protection against ticks. Applied to the clothing as an aerosol, it is nonstaining, nearly odorless, and resistant to degradation by light, heat, or immersion in water. Permethrin is toxic to the nervous system of insects, but in mammals it is poorly absorbed and rapidly inactivated. Reported adverse effects have been limited to the skin and are uncommon.

Topical DEET and clothing impregnated with permethrin are effective in field trials when each is used alone. Wearing protective clothing treated with permethrin in addition to the use of DEET on exposed skin provides the greatest degree of protection against tick bites.

BOX 123.2 Recommended Method for Tick Removal

1. Remove an embedded tick by grasping it with blunt forceps or tweezers as close to the point of attachment as possible.
2. Do not use bare fingers to remove ticks from animals or humans; when tweezers are unavailable, fingers should be shielded with a tissue, paper towel, or rubber glove.
3. Apply gentle, steady, upward traction with the forceps; do not twist or jerk the tick. Avoid squeezing or crushing the tick.
4. Do not handle the tick with bare hands. After removal of the tick, thoroughly disinfect the bite site and wash hands with soap and water.
5. Dispose of ticks by placing them in a container of alcohol or flushing them down the toilet.

CHAPTER 123: QUESTIONS AND ANSWERS

1. What is the most common vector-borne disease in the United States?
- **a.** Babesiosis
- **b.** Cysticercosis
- **c.** Lyme disease
- **d.** Malaria

Answer: c. Lyme disease accounts for 95% of cases.

2. Which of the following statements regarding erythema migrans (EM) is true?
- **a.** The incidence with Lyme disease is 70%.
- **b.** The lesion center may become necrotic.
- **c.** The lesion is tender and warm to touch.
- **d.** The rash does not begin at the tick bite site.

Answer: b. EM occurs in 90% of cases. It begins at the bite site and expands. There may be central clearing, skipped areas, central necrosis, vesicles, and marked erythema. It is warm but not tender. Satellite and secondary lesions may occur due to hematogenous seeding by spirochetes. They are smaller, nonmigratory, and spare the palms and soles. All lesions fade after approximately 1 month.

3. Which of the following clinical pictures is not seen with Lyme disease?
- **a.** Conjunctivitis
- **b.** Hepatitis
- **c.** Meningitis
- **d.** Pleuritis

Answer: e. Clinical pictures consistent with hepatitis, conjunctivitis, and meningitis may be seen with Lyme disease.

CHAPTER 123: QUESTIONS AND ANSWERS—cont'd

4. A 26-year-old woman presents complaining of muscle and joint aches. She has no past history and takes no medications except over-the-counter analgesics. She describes a pattern of migratory and intermittent muscle aches, which she reports as lasting only hours at any single location and then migrating. The physical examination reveals a mild pharyngitis and conjunctivitis and is otherwise normal. Which of the following statements is true?

a. A history of tick bite should be sought.
b. A rheumatoid factor (RF) level should be determined.
c. An erythrocyte sedimentation rate (ESR) would be confirmatory.
d. Creatine phosphokinase (CPK) levels are likely elevated.

Answer: a. The migratory, short-lived, and intermittent nature of the Lyme-related arthralgias is sometimes the best clue to the diagnosis. The ESR, RF, and CPK values will likely be normal. Both rheumatoid arthritis and fibromyalgia present with progressive and usually symmetrical symptoms. Conjunctivitis, pharyngitis, meningitis, and hepatitis pictures may be part of the Lyme presentation.

5. Which of the following statements regarding Lyme carditis is true?

a. Cardiac involvement is uncommon.
b. Electrocardiographic changes are stable and persistent.
c. Onset time from initial illness is 2 or 3 months.
d. The most common manifestation is bundle branch block.

Answer: a. Cardiac involvement is uncommon. The most common manifestation is atrioventricular block, which may fluctuate significantly but often resolves as the cardiac inflammation recedes. Onset time from illness is an average of 3 to 5 weeks.

Tuberculosis

Peter E. Sokolove and Robert W. Derlet

KEY CONCEPTS

- Early recognition of patients with risk for TB should begin at ED triage. Patients with possible active pulmonary TB should be placed in respiratory isolation promptly.
- TB should be considered in the differential diagnosis of patients who present with fever, cough, and weight loss.
- Risk factors for TB include HIV infection, immunosuppression, age older than 60 years, being from an endemic country, being undomiciled, and close contact with known cases.
- In addition to pulmonary manifestations, a variety of extrapulmonary manifestations may occur, including involvement of lymph nodes, pleura, bones, joints, genitourinary, gastrointestinal, and central nervous systems.
- Therapy should be determined based on consultation with infectious disease specialists. The most commonly used agents are isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB). Resistant strains, including multidrug-resistant TB (MDR-TB) and extensively drug-resistant TB (XDR), have been increasing in frequency.

FOUNDATIONS

Background and Importance

The emergency department (ED) serves as the front line of contact for many persons with untreated tuberculosis (TB) in the United States. Undiagnosed patients, incompletely treated patients, or those with active disease who develop complications may first seek medical care in EDs. For this reason, emergency clinicians must fully understand the complexities of the disease, including the multiple presentations of undiagnosed disease, complications, and initial therapeutic options.

TB is currently the world's second leading infectious cause of death, and one-third of the world's population has been infected by TB. Each year, more than 8 million people acquire active TB infection globally, and over 1.5 million die of the disease. In the United States, close to 10,000 new cases of TB are diagnosed each year, and 65% of these cases are in patients from endemic countries.[1] The largest numbers of people with TB originate from Eastern Europe, Africa, and Asia. Ongoing challenges of the 21st century include increasing occurrence of TB in institutional living settings, increasing rates of poverty, and substance use disorders. Being undomiciled and urban crowding also have contributed to the spread of TB in the United States and globally.

The HIV/AIDS epidemic has increased the incidence of TB in the United States. The pandemic of HIV-related TB also increased TB cases among non–HIV-infected people owing to the higher numbers of source cases in the community. The rate of clinical TB among patients who are HIV-infected and have a positive TB skin test is higher the cohort of non–HIV-infected patients.

Pathophysiology

One microorganism, *Mycobacterium tuberculosis* (MTB), causes human TB in nearly all cases. Humans constitute the sole known reservoir for MTB. Two other pathogenic mycobacteria, *Mycobacterium bovis* and *Mycobacterium africanum* have, on rare occasions, been implicated in causing TB. *M. bovis* is transmitted by drinking milk from diseased cows, which is rare in industrialized nations. *M. africanum* also is a rare cause of human TB in rural Africa.

MTB is an intracellular, aerobic, nonmotile, non–spore-forming bacillus with a waxy lipid coat. This coating makes MTB resistant to decolorization with acid alcohol after staining—hence, the term *acid-fast bacillus* (AFB). MTB grows slowly. Its generation time is 15 to 20 hours, compared with less than 1 hour for some common bacteria, and cultures take 4 to 6 weeks to grow on standard solid media. MTB produces neither endotoxins nor exotoxins. Its cell components are immunoreactive: some are immunosuppressive, and others are the agents of granuloma formation, macrophage activation, host toxicity, and modification of the immune response.

Transmission

TB is transmitted with rare exception by the respiratory route, including droplet spread and true aerosolization into microparticles. Patients with active disease expel MTB in liquid droplets during coughing, sneezing, and vocalizing. A single cough or 5 minutes of talking can produce 3000 infectious droplets, and sneezing can produce an even higher number. The droplets rapidly evaporate, and the desiccated bacilli circulate airborne for prolonged periods. These infective particles, or droplet nuclei, measure 1 to 5 μm in diameter, contain one to three tubercle bacilli and, when inhaled, can travel to the distal alveoli. Transmission by nonrespiratory routes, such as direct inoculation, occurs primarily among health care workers.

The susceptible host may become infected when only a few of the droplet nuclei are inhaled. Fomites are not important in the transmission of the disease, and patients' rooms, eating utensils, and bedding do not require special decontamination procedures. Because the infectious droplet nuclei are airborne, exchange of contaminated air is the most important environmental control. In addition, MTB is susceptible to ultraviolet radiation, so transmission rarely occurs outdoors because of the dilution of infectious particles and exposure to ultraviolet radiation.

The risk for TB transmission increases when source patients have airway and cavitary disease. Infectivity correlates with the number of organisms seen on sputum smear, extent of pulmonary disease, and frequency of coughing. Currently, there is no clear epidemiologic evidence to define a patient's contagiousness once they have started effective therapy. Most patients who initially had AFB-negative sputum smears are noncontagious after 2 weeks of chemotherapy. In contrast, patients who initially were smear-positive may still have viable

MTB detectable in their posttreatment sputum cultures after 2 weeks of treatment. Patients with extensive disease may still have AFB detectable on their post-treatment sputum smears; these two groups should be considered contagious. The Centers for Disease Control and Prevention (CDC) has published guidelines requiring the presence of three negative smears on different days as the criteria for removal of a patient from respiratory isolation, but debate about this recommendation is ongoing.

Extrapulmonary TB also may be infectious, but only if it is in the oral cavity or open skin lesion. Transmission of MTB to health care workers caring for patients with skin ulcers and draining tuberculous abscesses has been reported. Irrigation of the abscess may aerosolize the bacilli, forming infectious droplet nuclei.

Pathogenesis

When infectious droplet nuclei are inhaled, the airflow through the bronchial tree tends to deposit them in the midlung zone on the respiratory surface of the alveoli. The deposition launches a complex series of immunologic events. The pathogenesis of TB is divided into four stages.

Stage 1

The first stage begins when an alveolar macrophage phagocytoses the recently inhaled bacillus. A macrophage from a resistant host can immediately destroy a less virulent bacillus. In these cases, no tuberculous infection develops, and the process ends. If a virulent bacillus can overcome a macrophage's microbicidal capability, the infection may progress to the next stage.

Stage 2

When the alveolar macrophage is unable to destroy the inhaled tubercle bacilli, the bacilli replicate until the macrophage lyses. Circulating monocytes are attracted to the site of infection by the released bacilli, cellular debris, and various chemotactic factors. The monocytes differentiate into macrophages and ingest the free bacilli. Initially, these new macrophages are not activated and cannot destroy or inhibit the mycobacteria. The bacilli multiply logarithmically within macrophages and accumulate at the primary focus of infection, called a tubercle. The infected macrophages also may be transported through lymphatics to regional lymph nodes, from which they can reach the bloodstream, with subsequent spread. During this lymphohematogenous dissemination, the pathogens tend to distribute preferentially to lymph nodes, kidney, epiphyses of long bones, vertebral bodies, meningeal areas, and apical posterior areas of the lungs.

Stage 3

The third stage of TB begins 2 to 3 weeks after the initial infection, with development of the immune response that terminates the unimpeded growth of MTB. Cell-mediated immunity occurs through $CD4^+$ helper T cells. These T cells secrete cytokines that attract and activate monocyte-macrophages. Once activated, the macrophages, containing previously ingested mycobacteria and their progeny, kill the bacilli. Mild fever and malaise may develop in association with the immune response at 4 to 6 weeks, but the primary infection is generally insignificant clinically. Eventually, in the immunocompetent host with strong cell-mediated immunity, the caseous center inspissates (thickens) while the primary lesion is effectively walled off by epithelioid cells and is arrested. This sequence of events, from stage 1 to stage 3, represents the pathogenesis of primary TB in the immunocompetent patient. In most cases, primary TB is subclinical and self-limited. Clinically active TB develops in 8% to 10% of otherwise healthy persons. By contrast, in persons also infected with HIV, progression to acute primary TB occurs at a rate of 37% within 6 months.

Stage 4

The final stage usually occurs months to decades after an apparent recovery from the initial infection. TB may progress to stage 4 even in immunocompetent persons. Usually, host factors lead to decreased resistance and reactivation of dormant foci of MTB. Reactivation of dormant foci is responsible for the major clinical manifestations of TB. Exogenous reinfection of patients with well-documented previous TB infection causes clinical disease indistinguishable from that of reactivation TB. Because it may be incorrect to label all late-onset cases as reactivation disease, the preferred term is *postprimary TB*. Postprimary TB is active or chronic disease in a patient previously infected. In the United States and other developed countries, reactivation is thought to be the primary mechanism of postprimary TB. The primary walled-off tubercle eventually may erode through the bronchial wall and drains its contents, forming a cavity. The liquefied caseous material, teeming with mycobacteria, enters other parts of the lung and outside environment. The spilling of this liquefied material within the lung may produce a caseous bronchopneumonia.

CLINICAL FEATURES

Patients with TB may present with a primary infection or, more commonly, reactivation of an old infection. TB should be included in the differential diagnosis of common presenting complaints, such as isolated fever, chronic weakness, weight loss, failure to thrive, and night sweats.

Clinically significant pulmonary TB often is indolent, and signs and symptoms are absent or minimal until the disease advances. The constitutional symptoms of anorexia, weight loss, fatigue, irritability, malaise, weakness, headache, chills and, most commonly, fever can be caused by many other diseases. The fever usually develops in the afternoon; defervescence occurs during sleep, leading to the classic night sweats of TB.

Cough is the most common symptom of pulmonary TB patients presenting to the ED. It may initially be a dry nonproductive cough or, less commonly mucopurulent in nature. Hemoptysis, caused by caseous sloughing or endobronchial erosion, usually is minor but often indicates extensive lung involvement. Many otherwise asymptomatic MTB patients present for medical attention because they are alarmed by an episode of sudden hemoptysis. Patients also may complain of pleuritic chest pain, caused by parenchymal inflammation adjacent to the pleural surface. Dyspnea with chest pain may indicate a spontaneous pneumothorax. Shortness of breath from parenchymal lung involvement is unusual, however, and, if present, indicates extensive parenchymal disease or tracheobronchial obstruction.

The clinical manifestations of TB in patients presenting to the ED may be especially challenging. In one study, only one-third of ED patients with active pulmonary TB had pulmonary chief complaints. Any vague systemic disorder or fever of unknown cause may represent TB. Atypical presentations are particularly common in infants, older adults, and immunocompromised persons. In infants and young children, the development of large hilar lymph nodes is common. Pulmonary TB should be considered in older adults with chronic cough and failure to thrive. Young adults often show the adult pattern of apical pulmonary disease, including cavity formation, suggesting reactivation. Because of reduced immunocompetence, older adults typically have disease manifestations similar to those in young children.

Clinical manifestations of TB in patients coinfected with HIV are even more subtle and nonspecific, especially because these patients are vulnerable to opportunistic infections and neoplasms that can cause the same constitutional symptoms as TB. A synergy between MTB and HIV leads to a greatly increased viral load. Active TB with HIV

coinfection has been associated with an increased risk for opportunistic infections and death. Patients with advanced HIV infection commonly have extrapulmonary involvement (seen in 30%) as well as combined pulmonary and extrapulmonary TB (in 32%).

Risk Factors

All ED patients who have been coughing should be screened for the presence of TB risk factors (Box 124.1). Individuals from endemic countries and those living with persons who recently emigrated from endemic areas are at risk, as are patients with unexplained weight loss or cachexia. One of the most important risk factors is HIV/AIDS with $CD4^+$ levels below 500 cells/μL.[10] Overseas, coinfection with HIV and TB is common and results in an increased TB mortality rate. Risks for acquiring TB may also be stratified by age. Because infants and toddlers have poorly developed cell-mediated immunity, they have a much higher incidence of TB than adults. Patients on immunosuppressant medications such as steroids or antiarthritic immunosuppressant agents are at increased risk. Patients with a history of purified protein derivative (PPD) conversion should be asked about the presence of immunosuppressive medical conditions, which are associated with an increased risk for the development of active postprimary disease through reactivation. Household contacts also have increased risk of TB infection. Health care providers should ask patients with a history of active TB about all antituberculosis medications previously or currently taken and about compliance. Failure to improve after 2 months with an appropriate regimen may signal nonadherence to therapy or the presence of a resistant strain.

Physical Examination

A wasted patient with a cachexic appearance is a hallmark of advanced disease. The patient may show signs of dyspnea or tachypnea. The mental status examination may show subtle abnormalities. Examination of the chest can reveal abnormalities, but is unlikely to establish the extent of disease. Over areas of infiltration, rales may be heard when the patient breathes in after a short cough (posttussive rales), and bronchial breath sounds may be present over areas of lung consolidation. Distant, hollow breath sounds (amphoric breath sounds) may be heard over cavities. Most physical findings are a result of complications of TB or from the extrapulmonary forms of the disease (see section on "Extrapulmonary Tuberculosis").

Complications of Pulmonic Tuberculosis

Hemoptysis

Minor hemoptysis is a common complication of acute infection. The destruction of lung parenchyma leads to the rupture of blood vessels. TB also may cause massive hemoptysis. An uncommon complication is the erosion of a tuberculous lesion or cavity into a pulmonary artery, leading to pseudoaneurysm formation (Rasmussen aneurysm), with potentially fatal hemoptysis. Alternatively, superinfection of cavities by invasive organisms or tumor development in the scarred lung may cause erosion of bronchial or pulmonary vessels, with resultant major hemorrhage. Affected patients often require emergency surgical resection or selective embolization.

Pneumothorax

Spontaneous pneumothorax is uncommon (affecting <5% of patients with severe cavitary disease) but may occur when a tuberculous cavity ruptures and creates a bronchopleural fistula or when a bleb ruptures into the pleural space (Fig. 124.1). If treatment with tube thoracostomy and suction is delayed, progressive infection and fibrosis of the pleura can lead to air trapping in the pleural space.

Pleural Effusion

Pleural extrapulmonary TB may occur early after primary infection with MTB and is manifested as pleurisy with effusion. More rarely, it may occur late in postprimary cavitary disease and arise as an empyema. Tuberculous pleural involvement often causes no symptoms and resolves spontaneously; however, a 65% relapse rate has been reported in untreated patients, with development of active pulmonary or extrapulmonary TB within 5 years. The diagnosis usually is confirmed by microscopic and chemical examination of pleural fluid or pleural biopsy tissue. White blood cell counts usually range from 500 to 2500 cells/mL. The fluid is an exudate with protein usually exceeding 50% of the serum protein, and the glucose concentration may be normal to low. Because there are few bacilli, AFB smears rarely are positive, and cultures grow MTB for only 25% to 30% of patients known to have the disease. Pleural biopsy can confirm the diagnosis in most patients.

Empyema

An empyema, characterized by extensive, progressive parenchymal disease and cavitation, may develop in patients with TB. Although it is rare, empyema is more common late in the course of the disease in debilitated patients. Rupture of a cavity into the pleural space usually is catastrophic and often is associated with bronchopleural fistula

BOX 124.1 Population Groups with Increased Risk for Tuberculosis

- Close contacts of known case
- Persons with HIV infection
- From Eastern Europe, Asia, Africa, Latin America
- Medically underserved, low-income populations
- Older adults
- Residents of long-term care facilities (e.g., nursing homes, correctional facilities)
- Injection drug users
- Undomiciled
- Persons who have occupational exposure

HIV, Human immunodeficiency virus.

formation. An untreated empyema can result in spontaneous pleurocutaneous fistula formation, presence of a chest wall mass on the radiograph, or rib and vertebral destruction.

Airway Tuberculosis

When a cavity drains its highly infectious material into the bronchial tree, the airways not only spread the infection but also develop endobronchial TB. Bronchiectasis commonly complicates endobronchial TB. Bronchial stenosis may result from extensive damage caused by endobronchial TB or from direct extension of infection by tuberculous adenitis or lymphatic dissemination to the airway. Tuberculous bronchostenosis may appear radiographically as persistent segmental or lobar collapse, lobar hyperinflation, and obstructive pneumonia. Tracheal and laryngeal TB are less common than endobronchial TB. Laryngeal disease is the most infectious form; it results from the proximal extension of lower airway disease, pooling of infected secretions in the posterior larynx, or hematogenous dissemination to the anterior larynx. Patients with laryngeal TB also usually have active pulmonary disease.

Superinfection with Fungi

Extensive TB infection often heals with open cavities and areas of bronchiectasis. Superinfection may occur with a wide variety of organisms, including *Aspergillus fumigatus*. The characteristic finding on chest radiographs is the aspergilloma or so-called fungus ball (Fig. 124.2). Aspergillomas are of particular clinical significance because they may cause massive and fatal hemoptysis.

Primary Tuberculous Pericarditis

Primary tuberculous pericarditis usually results from direct extension of infection from the tracheobronchial tree, mediastinal or hilar lymph nodes, sternum, or spine. Pericardial involvement also may result from hematogenous spread secondary to acute miliary TB or from another focus elsewhere in the body. TB is the leading cause of pericarditis among HIV-infected patients in the United States. The predominant symptoms are cough, chest pain, and dyspnea, and the most common signs are cardiomegaly, audible rub, fever, and tachycardia. Complications of pericardial TB include pericardial effusion, constrictive pericarditis, myocarditis, and cardiac tamponade. Cardiac tamponade may result from the accumulation of pericardial fluid or rupture of enlarging lymph nodes into the pericardium. Emergency echocardiography reliably confirms the presence of pericardial fluid.

DIFFERENTIAL DIAGNOSES

Pulmonary Tuberculosis

Bacterial Pneumonia

Segmental or lobar infiltrates on chest radiographs in bacterial pneumonia may easily be confused with those seen in TB, especially primary disease. Compared with TB, however, bacterial pneumonias usually arise with more profound symptoms of systemic toxicity, more acute onset, and elevated white blood cell count. In pulmonary TB, there is no prompt response to antibiotics, as often seen in bacterial pneumonia.

Fungal and Nontuberculous Mycobacterial Infections

Histoplasmosis, coccidioidomycosis and blastomycosis, as well as nontuberculous mycobacterial infections—mainly with *Mycobacterium avium* complex and *Mycobacterium kansasii*—may be radiologically indistinguishable from TB. The incidence of these infections is influenced by geographic location; therefore the ED physician must take into account travel history and local epidemiologic risks. Nontuberculous mycobacterial infection usually involves chronic pulmonary infection in HIV-infected patients. Immunocompetent persons also may become infected with MTB, especially patients with chronic lung disease, such as cystic fibrosis. Other important risk factors include work in the mining industry, warm climate, advancing age, and male sex.

Pneumonias in Patients with HIV Infection

Bacterial pneumonias including upper lobe *Pneumocystis* pneumonia (due to *Pneumocystis jiroveci*) and, rarely, *Nocardia* and *Rhodococcus* infections may mimic TB in patients with HIV infection.

Cavitary Lesions

Lung abscess or cavitating pneumonia caused by *Klebsiella pneumoniae, Staphylococcus aureus,* or aspiration may appear similar to cavitary TB on chest radiographs. In older patients, especially smokers, bronchogenic carcinoma may mimic TB. This is particularly true of squamous cell carcinoma, which tends to cavitate. Because cancer may cause a focus of TB to spread, the two diseases may be present simultaneously. Other causes of nontuberculous cavitary lesions include *M. avium* complex infection in HIV-negative patients, pulmonary infarction secondary to pulmonary embolus, Wegener granulomatosis, and upper lobe bullous disease secondary to emphysema or neurofibromatosis.

Mediastinal Lymphadenopathy

The main considerations in the differential diagnosis for adenopathy include lymphoma and sarcoidosis. In sarcoidosis, lymphadenopathy usually is bilateral, symmetrical, and asymptomatic. Lymphadenopathy tends to be unilateral in TB; if it is bilateral, it is asymmetrical and associated with parenchymal lung disease. Lymphoma tends to involve bulky mediastinal lymphadenopathy.

Extrapulmonary Tuberculosis

Tuberculous infection involving multiple sites is usually seen in populations of patients less capable of containing MTB infection, such as infants, older adults, and immunocompromised persons.

Extrapulmonary TB may occur in multiple sites, with decreasing relative frequencies in lymphatic, pleural, bone or joint, genitourinary, meningeal, peritoneal, and other sites. The lymph nodes are the most common site of extrapulmonary TB for otherwise normal and HIV-infected patients. Involvement of the meninges is more common in young children than in other age groups (present in ≈4% of children with TB), and the incidence of TB in the remainder of the extrapulmonary sites increases with age. Less commonly involved locations for extrapulmonary TB include the skin, heart, pericardium, thyroid gland, mastoid cells, sclerae, and adrenal glands.

Lymphadenitis

Tuberculous lymphadenitis (scrofula) is the most common form of extrapulmonary TB. Scrofula is most commonly seen in young women but is also seen in children. The patient usually has an enlarging, painless, red, firm mass in the region of one or more lymph nodes, most commonly in the anterior or posterior cervical chain or supraclavicular fossa. Early on, the nodes are discrete rubbery masses that are freely mobile and the overlying skin is normal. Eventually, the nodes may become matted and harder and the overlying skin inflamed. Fluctuance as well as an abscess or sinus tract may be present if a node erodes through the skin. Systemic signs and symptoms are uncommon, except in HIV-positive patients, in whom lymphadenitis usually is generalized. Pulmonary infection is present in a minority of cases. Considerations in the differential diagnosis include lymphoma, metastatic cancer, fungal disease, cat-scratch disease, sarcoid, toxoplasmosis, reactive adenitis, and bacterial adenitis.

The diagnosis of scrofula usually is made by fine-needle aspiration of an affected lymph node. Although AFB smears are positive in only approximately 20% of cases, granulomatous inflammation may be obvious. Overall, fine-needle aspiration has a sensitivity of 77% and specificity of 93% for TB infection. First-line treatment of scrofula consists of antituberculosis drugs, but surgical excision may be performed when medical therapy has failed or if the diagnosis is unclear. Incision and drainage should not be done because permanent sinuses and prolonged drainage can result.

Bone and Joint Infection

Bone and joint TB remains a disease of older children and young adults in developing countries, and it is increasingly a disease of adults in developed countries. Skeletal TB presumably develops from reactivation of dormant tubercles originally seeded during stage 2 of the primary infection or, in the case of spinal TB, from contiguous spread from paravertebral lymph nodes to the vertebrae. In general, spinal TB (Pott disease) accounts for 50% to 70% of the reported cases; the hip or knee is involved in 15% to 20% of cases, and the ankle, elbow, wrists, shoulders, and other bones and joints account for 15% to 20% of cases. Approximately 50% of patients have a previous history or concurrent case of pulmonary TB, but the chest radiograph is normal in appearance in up to 50% of cases.

Patients with Pott disease may simply complain of back pain or stiffness. Early changes of spinal TB can be difficult to detect on plain radiographs and include loss of the so-called white stripe of the vertebral endplate subsequent to destruction of subchondral bone. Thus, computed tomography (CT) and magnetic resonance imaging (MRI) should be used when the disease is suspected. Paraspinal cold abscesses develop in 50% or more of cases, with occasional formation of sinus tracts. The abscess can spread the infection up and down the spine, sometimes sparing vertebral bodies along its course, forming the so-called skip lesions. These skip lesions can easily be missed in imaging of the spine for Pott disease. The main complication of Pott disease is spinal cord compression.

Renal Disease

The kidney is highly vascularized, and hematogenous dissemination to that organ can occur. After the typical tuberculous lesions develop within the parenchyma, infection can spread into the calyces, renal pelvis, ureters, and bladder. As a result, tuberculous granulomas, scarring, and obstruction can occur anywhere along the urinary tract. Advanced renal disease and destruction may occur before the diagnosis is made. The urinalysis often reveals pyuria, hematuria, and albuminuria. Sterile pyuria is a classic finding in renal TB but, in many cases with this finding, cultures will be positive for other urinary pathogens. The finding of pyuria in an acidic urine with no organisms isolated should increase clinical suspicion for TB. Complications of renal TB include nephrolithiasis, ureteral obstruction or reflux, recurrent bacterial infections, hypertension, papillary necrosis, renal insufficiency, autonephrectomy and, rarely, development of transitional cell cancer.

Genital Disease

Male genital TB is usually associated with coexistent renal TB. Spread of infection from the kidney may involve the prostate, seminal vesicles, epididymides, and testes. A painless or slightly painful scrotal mass is a typical finding, and the patient may have symptoms of prostatitis, epididymitis, or orchitis. Epididymal or prostatic calcifications may be clues to the diagnosis. TB involvement of the seminal vesicles may lead to infertility.

In women, genital TB disease usually begins with a hematogenous focus in the fallopian tubes. The infection then spreads to the endometrium (in 50% of cases), ovaries (30%), cervix (5%–15%), and vagina (1%). Clinical manifestations may include abdominal or pelvic pain, ascites, infertility, menstrual irregularities and, rarely, vaginal discharge. An ulcerating mass may be present on the cervix. Genital TB may be confused with ovarian or endometrial cancer, Meigs syndrome, vulvar or vaginal ulcer, pelvic abscess, cervicitis, or cervical carcinoma. Sexual transmission of TB by persons with active genital TB has been described.

Multisystem Disease

The term *acute disseminated tuberculosis* refers to active hematogenous spread of MTB to several organs in the body. The term *miliary tuberculosis* was first used to describe the pathologic lesions, which resemble small millet seeds. This is now used as a clinical term referring to the massive dissemination that leads to systemic illness. Miliary TB occurs when the host is unable to contain a recently acquired or dormant TB infection. In the past, miliary TB occurred mainly in young children after primary infection; today, it is more common in older adults and in persons infected with HIV. Miliary TB often is a subtle disease associated with alcohol use disorder, cirrhosis, neoplasm, pregnancy, collagen vascular disease, or use of corticosteroids or immunosuppressive medications. A presumptive diagnosis can be made rapidly if chest radiographs show a miliary infiltrate (Fig. 124.3). Unfortunately, the classic miliary pattern is absent on radiographs in approximately 50% of cases. Routine laboratory tests generally are not helpful. Hyponatremia from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is common and often is associated with meningitis. Cultures of sputum, urine, draining lesions, and blood should be sent to the infectious disease laboratory.

Mortality rates for miliary TB are higher than for the other forms of TB, with one case series reporting a rate of 21%. The high mortality rate often is caused by delay in treatment, which should be initiated immediately on the basis of clinical suspicion and not delayed until confirmation of the diagnosis. A fulminant form of miliary TB may cause acute respiratory distress syndrome (ARDS) and disseminated intravascular coagulation (DIC).

Central Nervous System Disease

Approximately 6% of all cases of extrapulmonary TB involve the central nervous system (CNS), and CNS involvement remains a grave consequence of tuberculous infection. The peak incidence of CNS TB occurs in newborns to 4-year-old children.

Tuberculous meningitis usually results from the rupture of a subependymal tubercle into the subarachnoid space rather than from direct hematogenous seeding of the CNS. When it is a complication of miliary TB, meningitis usually develops within several weeks of infection. In children, it is an early postprimary TB event, usually appearing within 6 months. Tuberculous cerebral involvement is most marked at the base of the brain, and vasculitis of local arteries and veins may lead to aneurysm formation, thrombosis, and focal hemorrhagic infarction. The vessels to the basal ganglia are usually involved, leading to formation of lacunar infarcts or deficits associated with movement disorders. Involvement of other vessels, such as the middle cerebral artery, may lead to hemiparesis or hemiplegia. Tuberculous meningitis begins with a prodrome of malaise, intermittent headache, and low-grade fever. In 2 to 3 weeks, a protracted headache develops. Vomiting, confusion, meningismus and focal neurologic signs, and coma may follow. Nuchal rigidity may be absent. Diplopia resulting from basilar exudate is present in up to 70% of patients. Hyponatremia may be present because SIADH is common. The cerebrospinal fluid (CSF) white blood cell count varies widely, from 0 to 1500 cells/mL, with a predominance of lymphocytes when WBCs are present; however, polymorphonuclear cells may predominate early in the course of the disease. The CSF protein concentration usually is elevated, and the CSF glucose concentration typically is low. The classic triad of neuroradiologic findings in patients with TB meningitis consists of basal meningeal enhancement, hydrocephalus, and cerebral or brainstem infarction. CT or MRI also may reveal rounded lesions typical of evolving parenchymal tuberculomas (Fig. 124.4).

Fig. 124.4 Head CT scan demonstrating tuberculomas in a patient with AIDS.

Gastrointestinal Disease

The most common clinical manifestations of gastrointestinal TB are abdominal pain, fever, weight loss, anorexia, nausea, vomiting, and diarrhea. Gastrointestinal TB infection usually is secondary to hematogenous or lymphatic spread but also may result from swallowed bronchial secretions or direct spread from local sites, such as lymph nodes or fallopian tubes. TB may occur in any gastrointestinal location from the mouth to the anus, but lesions proximal to the terminal ileum are rare. The ileocecal area is the most common site of involvement, producing signs and symptoms of pain, anorexia, diarrhea, obstruction, hemorrhage and, often, a palpable mass. The nonspecificity of these findings, as well as of those on the physical examination, may lead to the misdiagnosis of gastrointestinal TB as an acute abdomen, appendicitis, intestinal obstruction, or cancer. The clinical manifestations of anal TB include fissures, fistulae, and perirectal abscesses.

Tuberculous peritonitis may develop from local spread of MTB infection from a tuberculous lymph node, intestinal focus, or infected fallopian tube. In addition, peritonitis can develop from seeding of the peritoneum in miliary TB or from the reactivation of a latent focus. The patient with tuberculous peritonitis commonly has pain and abdominal swelling associated with fever, anorexia, and weight loss. Diagnosis may be confounded by the similarity of this disease to alcoholic hepatitis and by the fact that this disease often coexists with other disorders, especially cirrhosis with ascites. Paracentesis is thus essential. The peritoneal fluid is exudative, with a cell count of 500 to 2000 cells/mL. Lymphocytes usually predominate, with rare exceptions early in the process, when polymorphonuclear leukocytes may predominate. AFB smears of the fluid have a low diagnostic yield. Peritoneal biopsy often is necessary to confirm the diagnosis. Treatment is the same as for pulmonary TB, with a 6-month therapeutic regimen.

DIAGNOSTIC TESTING

Laboratory Tests

Routine laboratory studies generally are not useful in suggesting or establishing the diagnosis of TB in the ED. Normochromic normocytic anemia, elevated erythrocyte sedimentation rate, elevated C-reactive protein (CRP) and serum globulin levels, hyponatremia, and hypercalcemia can occur in active pulmonary TB, but these findings are nonspecific.

White Cell Stimulation Tests

The patient's blood can be tested for sensitivity of its T cells to tuberculin antigens. These tests are called interferon-gamma (IFN-γ) release assays (IGRAs). The QuantiFERON-TB Gold (Quest Diagnostics) and T-Spot (Oxford Immunotec) tests are the most widely available IGRAs. They use an enzyme-linked immunosorbent assay (ELISA) to measure the amount of IFN-γ released in response to PPD. IFN-γ is a cytokine associated with cell-mediated immunity. Determination of IFN-γ levels also can be used as a diagnostic test for tuberculous pleural effusions, ascites, and pericardial effusions. Clinical studies have reported sensitivity ranges from 90% to 100%. TB infection can be rapidly confirmed in an individual in 2 days, compared with several weeks for a traditional culture. However, a normal study does not completely exclude TB; therefore, cultures should be sent when a person thought to have TB has a negative QuantiFERON-TB Gold test result.

Serology

Although ELISAs have been developed for several MTB serum antigens, in practice no serodiagnostic approach to the diagnosis of TB currently is in widespread clinical use in the United States. Other countries have discouraged the use of serology. Limitations of the ELISA include inadequate accuracy and reproducibility, inability to distinguish active from latent infection, poor discrimination between MTB and other mycobacteria, and relative cost.

Diagnostic Imaging

Plain radiography of the chest is the most useful study for a presumptive diagnosis of pulmonary TB. The availability of chest CT scans in most EDs has enhanced the sensitivity of detecting classic TB in the ED. A normal appearance on the chest radiograph has a high negative predictive value and is therefore useful in screening ED patients for active pulmonary TB. However, the low false-negative rate among immunocompetent adults increases significantly in HIV-positive patients. Therefore, depending on the clinical circumstances, the absence of specific abnormalities on the chest radiograph does not always exclude active TB, especially in patients with concomitant endobronchial disease and HIV infection.

Primary Tuberculosis

Chest radiographic manifestations of primary disease in adults often are not recognized as TB. Primary tuberculous infiltrates can occur in any lobe. In any age group, a pneumonic infiltrate with enlarged hilar or mediastinal nodes should strongly suggest the diagnosis. The infiltrate usually is homogeneous and most commonly involves a single lobe. Thus, primary TB may appear radiographically identical to a bacterial pneumonia, with associated lymphadenopathy, if present, being the only distinguishing feature.

Lymphadenopathy is considered the radiologic hallmark of primary TB in children but is seen less commonly in adults. When present, adenopathy usually is unilateral and associated with parenchymal infiltrate (Fig. 124.5). It may occur bilaterally or, less commonly, may be an isolated finding on chest radiography. Other primary TB chest radiographic findings include a moderate to large pleural effusion, which often is an isolated finding whose prevalence increases with age, and miliary TB characterized by the presence of innumerable, 1- to 3-mm noncalcified nodules dispersed throughout both lungs with mild basilar predominance. When the healed primary focus is visible on the chest radiograph as a calcified scar, it is known as the Ghon focus. Calcified secondary foci of infection in the lung apex are known as Simon foci. A Ghon focus associated with calcified hilar nodes is called a Ranke complex. A right-sided predominance in the distribution of the Ghon foci and Ranke complexes is well recognized and probably reflects the likelihood that an airborne infection will affect the right lung. Calcification seen on the chest radiograph indicates healing, but viable bacilli may still exist in a partially calcified lesion.

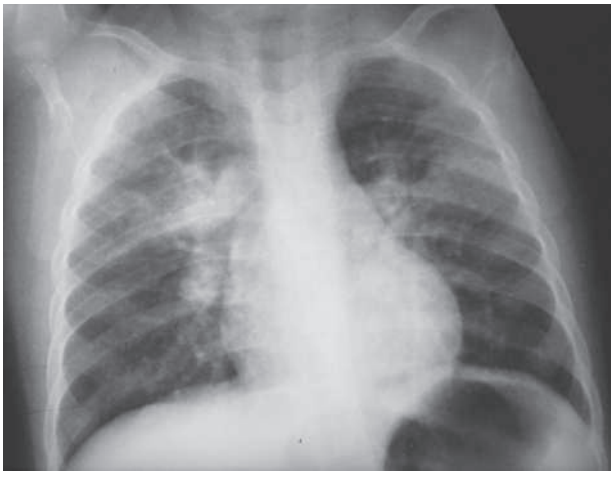

Fig. 124.5 Chest radiographic findings in a child with primary tuberculosis. Note the active Ghon focus, with associated hilar adenopathy and presence of bilateral infiltrates. (Courtesy Dr. John Pearce.)

Postprimary Tuberculosis

Postprimary TB typically appears as an upper lung infiltrate or consolidation, with or without cavitation. The lesion may be small or extensive and usually is located in the apical or posterior segment of the upper lobe but may appear in the superior segment of the lower lobe. Postprimary disease also occurs in the lower lung. In addition, bronchogenic spread can occur, leading to the involvement of multiple lobes (Fig. 124.6). Patients with bilateral upper lobe disease are extremely likely to have TB. The other important recognizable characteristics of postprimary disease are fibrosis and cavitation. These lesions are not purely exudative in that they are associated with a fibrotic pattern of nodules and a few fine, linear densities. Fibroproductive lesions often are irregular and angular in contour, have strands extending toward the hilum, and demonstrate calcification of one or more nodules and distortion of vascular and mediastinal structures. Severe fibrosis with upper lobe volume loss may eventually lead to retraction of the interlobar fissure and upward displacement of the hilum. The chest radiographic appearance at this stage has been variably referred to as "old scarring," "no active disease," or "fibrotic, apparently well-healed TB." Cavitation should alert one to the potential for high infectivity of the patient and associated complications, such as bronchogenic spread of TB (see Fig. 124.4). The walls of the cavities initially are thick and rough and become thinner and smoother with healing. Chest radiographs of patients with pulmonary TB and HIV infection may be atypical in approximately one-third of cases. Patients with late HIV infection more often demonstrate

Fig. 124.6 Chest radiograph showing evidence of right upper lobe cavitary disease. Also note the left-sided infiltrate, secondary to endobronchial spread.

mediastinal adenopathy or atypical infiltrates and less often have cavitation. Severe immunosuppression has been reported to be associated with a miliary pattern of disease on chest radiographs.

Microbiologic Testing

Sputum Studies

If the clinical or chest radiographic findings suggest the diagnosis of pulmonary TB, mycobacteriologic studies of the patient's sputum should be ordered. A positive smear supports a presumptive diagnosis, and the number of bacilli seen correlates with infectivity. For patients who are not producing sputum, nebulized induction of sputum is the method of choice for the collection of samples. Induction of sputum with nebulization may increase the risk of TB transmission to health care workers and should be performed only in specially ventilated rooms, preferably not in the ED. When the sputum is not diagnostic in adults, fiberoptic bronchoscopy with bronchial washings, bronchoalveolar lavage, brushings, or transbronchial biopsy may be necessary for the laboratory diagnosis of TB.

Direct Microscopy. Direct microscopic examination of a stained sputum specimen for AFB (i.e., an AFB smear) is the most rapid laboratory test widely available to support a presumptive diagnosis of TB and results usually are available from hospital laboratories within 24 hours. Negative findings on an AFB smear, however, do not rule out active pulmonary TB because microscopy is relatively insensitive when performed on samples with small numbers of bacilli. At least 5000 bacilli/mL of sputum must be present for a positive result by microscopy. Overall, AFB smears have a sensitivity of 20% to 80% and a specificity of 90% to 100%. Despite limitations, microscopy remains an essential diagnostic test because of its ease of performance, low cost, rapid turnaround time, and reasonable diagnostic yield.

Nucleic Acid Amplification Tests. Nucleic acid amplification (NAA) tests are performed on sputum and take only 24 to 48 hours to yield results. Their overall positive predictive value is about 95%. In some cases, patients with positive TB sputum smears have had negative NAA test results because of inhibitors that may prevent amplification. This has been a rapidly growing field in TB diagnostics, although most EDs do not yet have bedside capabilities. The best role of NAA is to aid emergency clinicians in decision making for patients thought to have active TB. It should not be ordered routinely when the clinical suspicion for TB is low.

Culture. Sputum culture is more sensitive than microscopy for the detection of MTB and is still considered the gold standard diagnostic modality. Liquid culture can detect 10 to 100 bacilli/mL, compared with 5000 to 10,000 bacilli/mL for an AFB smear. When the presence of mycobacteria is established, the specific identification of MTB may be accomplished by subjecting the initial mycobacteria to various isolation techniques. These include the detection of pigmentation on solid culture media, various biochemical tests, high-performance liquid chromatography, and nucleic acid probes. A presumptive diagnosis of TB based on a positive sputum smear usually is confirmed by isolation of MTB by culture. Traditional culture methods using solid media require 3 to 8 weeks for colony formation. The development of liquid culture systems has shortened the detection time to 7 to 14 days.

Tuberculin Skin Test

Although newer serologic diagnostic tests have become widely used in most US hospitals, the tuberculin skin test continues to be the diagnostic workhorse for the detection of exposure to MTB. The tuberculin test is based on the principle that MTB infection induces sensitivity to certain antigens of the bacillus. These antigens are contained in the tuberculin preparation called PPD. In a person infected with TB, the PPD test result usually turns positive 3 to 8 weeks after the infection, when the immune response is developed. The standard 0.1-mL dose used in skin testing contains 5 tuberculin units (TU). A properly placed needle should leave a blanched distinct wheal 6 to 10 mm in diameter. If the tuberculin dose is incorrectly administered, the test may be repeated immediately at a site several centimeters away. Test results are read 48 to 72 hours after administration of PPD. The largest diameter of palpable induration is measured and recorded in millimeters; erythema by itself is not measured. The precise measurement that denotes a positive test result depends on the patient's other clinical factors. The current CDC guidelines use 15 mm of induration as a positive test response for people without TB risk factors. Persons with previous TB immunization (see later, "Vaccines for *Mycobacterium tuberculosis*") may have a positive PPD result even though they are not infected with TB. However, a significant reaction to PPD and a long time interval between bacilli Calmette-Guérin (BCG) vaccination and the current skin test make it more likely that the reaction is due to MTB infection. Because the BCG vaccine is imperfect in protecting against MTB infection, and because most vaccinated persons come from areas of high TB prevalence, the CDC recommends that tuberculin skin test results be interpreted without regard to BCG vaccination status.

MANAGEMENT

Initial Management in the Emergency Department

Hemoptysis

The most emergent presentation of pulmonary TB is massive hemoptysis, defined as loss of at least 600 mL of blood in 24 hours. Exsanguination rarely occurs, and the major morbidity is due to asphyxiation from aspirated blood. Secure the airway with a large-diameter (8-mm) endotracheal tube that can accommodate a fiberoptic bronchoscope. The patient is positioned with the bleeding lung in a dependent position, and one should consider selective main bronchus intubation to allow ventilation of the unaffected lung and minimize the spread of blood from the affected lung. Emergency consultation for bronchoscopy,

surgical resection, or angiography with selective embolization is required. Patients thought to have active pulmonary TB should be immediately placed in respiratory isolation.

Fever or Wasting

Patients with fever and wasting generally should be admitted for an in-hospital evaluation. Patients should be placed in respiratory isolation until the diagnosis of TB has been excluded.

History of Tuberculosis, Therapy Discontinued

In patients with vague symptoms and a history of TB, consider reactivation. Given the numerous considerations in resuming therapy, we recommend consulting a local TB health officer or an infectious diseases specialist.

Antituberculosis Medications

Three basic therapeutic principles govern the treatment of TB: (1) any treatment regimen must contain multiple drugs to which the MTB organism is susceptible; (2) the therapeutic agents must be taken regularly; and (3) therapy must continue for a sufficient period. In clinical practice, the last principle is the most problematic. The most up-to-date recommendations for the treatment of TB are available from the CDC through online publications or at the CDC website. Medications used to treat MTB generally are divided into first-line and second-line agents. Of these, 10 have been approved by the US Food and Drug Administration (FDA) for the treatment of MTB. The most commonly used first-line agents are isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB).

First-Line Agents

INH demonstrates extremely potent early bactericidal activity and can rapidly decrease the patient's infectiousness. A small risk of hepatitis (<3%) occurs with long-term treatment. Supplemental pyridoxine is recommended for these patients. RIF also demonstrates strong early bactericidal activity. This agent causes orange discoloration of body fluids, including urine, tears, sweat, and sputum. PZA works against organisms contained in the acid environment of the macrophage. The chief side effect is hepatotoxicity, but this risk is very low at daily doses of 25 mg/kg or less. Polyarthralgias occur commonly (up to 40% of patients) but usually respond to nonsteroidal antiinflammatory drugs or aspirin. EMB is a first-line agent that helps prevent the emergence of RIF resistance during TB treatment. Retrobulbar neuritis can occur, resulting in decreased visual acuity to the point of blindness.

Second-Line Agents

Streptomycin must be given parenterally and has a peak of action 1 hour after the intramuscular dose is given. The chief side effects of this potentially teratogenic agent are ototoxicity and nephrotoxicity. Amikacin, kanamycin, and capreomycin also are injectable agents used for drug-resistant TB. As with streptomycin, ototoxicity and neurotoxicity are their major adverse effects. TB strains resistant to streptomycin usually are sensitive to amikacin and kanamycin, and resistance to these last two drugs usually is linked. Cycloserine, ethionamide, and *p*-aminosalicylic acid (PAS) are oral agents used for the treatment of patients with drug-resistant TB when the strain is presumed or known to be sensitive to these agents. The main adverse effect of cycloserine is psychosis or seizures, which occur in 3% to 16% of patients. Ethionamide is similar to INH in structure and toxicity. Major adverse effects of PAS include gastrointestinal distress (most common), hypothyroidism, and hepatitis. Fluoroquinolones have played a more recent role in the treatment of TB. They are less effective than the first-line agents and are used mainly in the treatment of drug-resistant disease.

Corticosteroids

Corticosteroids may prevent constriction in tuberculous pericarditis and decrease the neurologic sequelae in all stages of tuberculous meningitis, especially if they are given early in the disease. The CDC strongly recommends corticosteroids for MTB pericardial or CNS infections. Corticosteroids may provide some benefit to children with bronchial obstruction caused by enlarged lymph nodes. In addition, in patients with pulmonary TB, prednisone, 20 to 60 mg/day may benefit those who continue to experience temperature spiking and lose weight, despite a good bacteriologic response to appropriate antituberculosis therapy. In cases of miliary TB, 60 mg of prednisone should be added to the treatment regimen.

Initial Therapy

Emergency clinicians generally will not initiate treatment prior to consulting public health and infectious diseases specialists. To be successful, treatment must be continuous, ongoing, and monitored closely. A one-time dose of medications is fruitless in a patient who could be lost to follow-up. In some locations, this will require hospital admission with appropriate respiratory isolation.

Initial administration of anti-TB drugs in the ED is appropriate and necessary in certain circumstances, such as TB sepsis or miliary TB, critically ill HIV patients with TB, or life-threatening conditions. The CDC website should be reviewed for the most up-to-date treatment guidelines.[2,3] The goals of therapy are to rapidly kill large numbers of bacilli (bactericidal activity), prevent emergence of drug resistance, and prevent relapse by elimination of dormant or slowly dividing bacilli (sterilizing activity). In-person or telephone consultation with an infectious diseases specialist is critical, and they may recommend regimens that include INH, RIF, PZA, and/or EMB.[7]

Adequate treatment of active TB in patients coinfected with HIV is critical. It has been observed that immune activation from TB enhances systemic and local HIV replication and may accelerate the natural progression of HIV infection. Active TB in HIV-infected patients has been associated with increased risk for opportunistic infections and death. TB treatment alone leads to a reduction in viral load in these patients. Current recommendations for the initial treatment of MTB in HIV-infected patients are the same as those for patients who are not HIV-infected, with exceptions for complex drug interactions.[10] For example, significant drug interactions between rifamycins used for TB and antiretroviral drugs (protease inhibitors and nonnucleoside reverse transcriptase inhibitors [NNRTIs]) used for HIV infection complicate the treatment of patients with active TB who are coinfected with HIV. For treatment of MTB in patients who are taking protease inhibitors, rifabutin can be used instead of the other rifamycins. When TB treatment is initiated in HIV-positive patients, a paradoxical reaction to medical therapy may develop in some cases. The reaction is manifested with the development of fever, new or enlarging lymph nodes, or worsening of radiographic disease. Severe paradoxical reactions may be managed with a 2-week tapering course of prednisone or methylprednisolone.

Drug-Resistant Tuberculosis

Two types of drug-resistant MTB have emerged as a result of spontaneous mutations. Multidrug-resistant TB (MDR-TB) is defined as TB in which the mycobacteria are resistant to two or more first-line antituberculosis agents.[8] Extensively drug-resistant TB (XDR-TB) is TB characterized by resistance to first-line and at least three second-line drugs. Patients at high risk for MDR-TB and XDR-TB include those with HIV, those who have been treated in the past for TB, and those who live or lived in certain high-risk countries.

BOX 124.2 Risk Factors for Drug-Resistant *Mycobacterium tuberculosis* Infection

- Previous unsuccessful antituberculosis treatment
- Failure to respond or adhere to a treatment regimen
- Human immunodeficiency virus infection
- Injection drug abuse
- Close contact with source cases
- Recent immigration from area with a high prevalence of drug resistance
- Cavitary lung disease
- Undomiciled
- Imprisonment
- Drug malabsorption due to gastrectomy or ileal bypass surgery

Multidrug-Resistant Tuberculosis

The World Health Organization (WHO) has estimated the worldwide number of MDR-TB cases at close to one-half million persons. Airborne transmission of MDR-TB is a threat to those who come in contact with infected individuals, including family members, contacts in crowded living situations, and health care personnel. The spread of primary drug resistance is faster when HIV infection is highly prevalent in a population. Because initial TB infection in HIV-infected patients progresses rapidly to active disease, newly infected persons can quickly become source cases for further transmission of the resistant bacilli. In reports on hospital outbreaks of MDR-TB, more than 90% of patients had coinfection with HIV, and case fatality rates were as high as 70% to 90%. However, patients without HIV infection demonstrate excellent clinical responses when treated for MDR-TB.

For the identification of potential cases, health care workers should know the prevalence of drug resistance in their community and the risk factors for drug resistance (Box 124.2). Rapid identification and prompt isolation of these patients, along with other control measures, can reduce the nosocomial transmission of MDR-TB to patients and health care workers. Failure to control drug resistance may lead to wide dissemination of MDR-TB and to a public health crisis that physicians may confront without effective medications.

Treatment of drug-resistant TB can be challenging and requires familiarity with second-line agents. For MDR-TB, specialist consultation is essential. A general principle that applies in such cases is to use at least three drugs to which the organism is susceptible and that have not been used previously. In general, one of these medications should be an injectable agent. TB infection with strains that are resistant only to INH can be managed with shorter courses of RIF, PZA, and EMB.

Extensively Drug-Resistant Tuberculosis

XDR-TB was first recognized in patients coinfected with AIDS in South Africa in 2005 and is a major threat in Africa, Asia, and areas of the former Soviet Union. XDR-TB is found in 10% of patients presenting with MDR-TB. The strain has virulence similar to that of MTB, and disease does not progress faster in the absence of antibiotics. As resistance to so many antibiotics has developed, however, this strain has become a major threat, especially in patients with AIDS. Most alarming is a report that as many as 33% of patients with TB coinfected with HIV and MDR-TB had the XDR-TB strain. Mortality rates for this population of patients are high, because few alternative drugs exist. The CDC has reported cases in in the United States and has isolated patients as soon as they are identified. EDs could become a major focus for spread of this disease because of overcrowding, initial lack of recognition, and long wait times, exposing other patients to XDR-TB. Reports from Africa have shown that XDR-TB also can be transmitted directly to health care workers. Of great concern is the potential for transmission of the disease within the ED by a previously undiagnosed patient with XDR-TB, who presents for treatment of TB-related symptoms or an unrelated condition.

Vaccines for *Mycobacterium tuberculosis*

The BCG vaccine has been used since 1921, but its overall efficacy, duration of protective immunity, and optimal age for administration are debated. Nonetheless, 100 million children receive BCG vaccine each year outside the United States (US). In developing countries, BCG is credited with reducing the incidence of the most severe forms of pediatric TB and death, and some hospitals overseas require that staff have a BCG vaccination as a requirement for work. In the United States, BCG is rarely recommended because of the belief that it may undermine the epidemiologic and diagnostic value of PPD skin testing. BCG use in children is common in some countries. Tuberculin skin tests in patients given previous BCG vaccination usually demonstrate less than 10 mm of induration. Thus, previous BCG vaccination status should be ignored in the interpretation of skin test results. Institutional outbreaks of TB and the emergence of MDR-TB have been sparking reassessment of the BCG issue in the United States. Reports of BCG vaccine efficacy range from 0% to 80%. A meta-analysis of international data reported the efficacy of BCG vaccine to be approximately 50%. This is consistent with an American study conducted over 60 years in a Native American population which showed a 50% reduction in the development of TB in persons receiving BCG vaccine.

BCG vaccine is currently recommended in the United States only for tuberculin-negative infants and children who cannot take INH and have ongoing exposure to a persistently untreated or inadequately treated patient with active TB, who are continuously exposed to persons with INH- and RIF-resistant TB, or who belong to groups with rates of new MTB infection exceeding 1% per year. WHO recommends that all infants in developing countries receive the vaccine.[6]

BCG vaccine is strongly contraindicated in persons with HIV infection or another immunosuppressive disease.

New vaccines against MTB are being researched, including those using attenuated strains of the MTB complex, recombinant mycobacteria, subunit proteins, and DNA vaccines. Vaccines are also under development for treatment of occult TB. A recent trial tested an adjuvanted recombinant protein vaccine, M72/AS01, in adults with a positive interferon-gama release assay, but without evidence of clinical disease.[4] Conducted in 3 African countries, a nearly 50% reduction in progression to active clinical disease was found in those receiving the vaccine.

DISPOSITION

Acutely ill or older patients may require hospitalization during the first few days of treatment because adverse reactions to TB chemotherapy are common and may occasionally be life-threatening. In addition, severely ill patients may require parenteral drug administration. Patients with TB have a high rate of HIV coinfection, and the comorbid illnesses associated with HIV infection, complex synergy between MTB and HIV, and potentially harmful drug interactions between the antiretroviral agents and rifamycins may favor inpatient treatment for the initial management of these complicated cases.

Hospital admission also is indicated for patients with active or suspected MDR-TB. These patients commonly require observation during initiation of therapy because of the complexity of the treatment regimens, toxicity of the drugs, and need for close monitoring to ensure adherence to treatment and isolation measures. Finally, social issues such as being undomiciled, presence of infants or immunocompromised persons in the household, substance abuse, and inability for

self-care may necessitate hospitalization. The recalcitrant patient constitutes a potential threat to public health, and legal measures for involuntary hospitalization may be required.

Patients who are otherwise well but have suspected TB may be eligible for outpatient treatment in consultation with local county health officials, who agree to assume responsibility for ongoing care of the patient and investigate contacts for possible exposure to TB.

PREVENTION OF TRANSMISSION IN THE EMERGENCY DEPARTMENT

EDs often care for patients at increased risk for active pulmonary TB, such as those who are undomiciled, from endemic areas, recently incarcerated, or chronically ill. Accordingly, ED personnel can be at high risk for occupational TB infection. Increased hospital occupancy and ED crowding can lead to extended waiting periods for ED beds and hospital beds. Some EDs may lack an adequate number of TB isolation rooms.

Early Identification

For the most effective minimization of infectious exposures among health care workers and other patients, ideally, all patients with active pulmonary TB would be placed in respiratory isolation when they initially present. The CDC has recommended screening for TB at triage. Triage screening protocols can detect patients with more classic presentations of TB, but reported protocols are only moderately sensitive and somewhat cumbersome. Immediate respiratory isolation should be considered for patients with high-risk chief complaints, such as the HIV-positive patient with cough, the person with hemoptysis, or the patient with a history of TB presenting with cough or fever. The best guideline is to initiate respiratory isolation as soon as TB is considered a possible diagnosis. Masks should be placed on these patients before chest radiography is performed.

Isolation and Environmental Control

In addition to triage screening, the use of proper isolation facilities and environmental control measures can help prevent TB exposures. Airflow in the ED plays a central role, and inadequate ventilation has been a contributing factor in many nosocomial outbreaks of TB. Ideally, there should be single-pass airflow from waiting rooms to outside the facility. Within the ED, air should flow from clean areas to less clean areas, rather than vice versa. For EDs that frequently see patients with TB, at least one true respiratory isolation room should be available. The CDC recommends that respiratory isolation rooms have at least 12 air changes per hour and have negative pressure (air flows into the room from other ED areas). Other engineering approaches to TB infection control include the use of high-efficiency particulate air (HEPA) filters and upper room ultraviolet light irradiation.

Personal Respiratory Protection

ED personnel should be familiar with the appropriate use of respiratory protection against TB. Surgical masks (e.g., string tie masks) should be placed on potentially contagious patients to decrease the release of infectious droplets into the air. Air can leak around such masks, however, so they may not adequately prevent health care workers from inhaling infectious droplet nuclei. Thus, surgical masks are used only for source control, not for health care worker protection. More advanced personal respiratory protection devices include N95 particulate respirators. HEPA-filtered masks can also be used for health care worker respiratory protection; these masks were used more extensively before development of the N95 masks.

Preventive Therapy After Inadvertent Exposure

Health care workers who are exposed to patients with active pulmonary TB require referral to their primary care physicians or employee health services for follow-up testing and treatment. Tuberculin skin testing or IGRA blood testing usually is performed within days following exposure to establish whether the health care worker was previously infected with MTB. If the baseline test result is negative, a follow-up is performed 3 months later to determine whether conversion has occurred. The CDC has developed guidelines for the treatment of exposed personnel, which can be found on the CDC website.[9]

CHAPTER 124: QUESTIONS AND ANSWERS

1. Which of the following is not a typical vehicle for tuberculosis transmission?
- **a.** Coughing
- **b.** Eating utensils
- **c.** Parenteral transmission
- **d.** Sneezing

Answer: B. Bedclothes and eating utensils do not require special decontamination. Parenteral transmission is largely a risk of health care workers (e.g., skin ulcers, draining wounds). Talking, coughing, and sneezing all may produce significant droplet spread.

2. Which of the following anatomic areas is not a site of preferential organism spread during stage 2 spread of TB?
- **a.** Kidneys
- **b.** Long-bone epiphyses
- **c.** Lung bases
- **d.** Lymph nodes

Answer: C. Lung apices are favored rather than the bases. These sites are preferred, possibly because of high oxygen tension.

3. Clinically active TB develops in what percentage of immunocompetent purified protein derivative (PPD) converters?
- **a.** 5%
- **b.** 10%
- **c.** 15%
- **d.** 20%

Answer: B. TB develops in 10%: 3% to 5% in the first 2 years (acute primary) and 5% later in life (reactivation). Patients with HIV infection develop primary TB at a rate of 37% within 6 months and then develop active TB at a rate of 7% to 10%/year.

4. Which of the following statements regarding chest radiography findings in pulmonary tuberculosis is true?
- **a.** Adenopathy may distinguish TB from bacterial pneumonia.
- **b.** Primary TB typically appears as an upper lobe cavity lesion.
- **c.** The false-negative rate is 10% in immunocompetent patients.
- **d.** The false-negative rate is 40% in HIV-infected patients.

Answer: A. Hilar adenopathy may be the only way to suspect TB as opposed to a typical bacterial pneumonia. Primary TB is usually a single-lobe infiltrate with a homogenous appearance. It is postprimary TB that has a predilection for the upper lobes, with or without cavitation. The false-negative rate for chest radiography in immunocompetent patients is very low, 1%. The rate increases to 7% to 15% in HIV-infected patients and those with endobronchial disease.

5. Which of the following statements regarding the radiographic appearance of tuberculosis and infectivity is true?
- **a.** Chronic fibrotic changes are unlikely to be infective.
- **b.** Normal radiographs are uncommon with HIV infection.
- **c.** Only the presence of adenopathy can determine active disease.
- **d.** The presence of cavitation implies high infectivity.

Answer: D. Cavitation suggests high infectivity. Chronic fibrotic changes cannot differentiate old versus active disease, and many of these patients will have positive sputum. Active disease can only be determined radiographically by serial radiographs. Patients with late HIV infection are more likely to have mediastinal adenopathy and less likely to show cavitations. Normal radiographs are common with HIV infection.

Bone and Joint Infections

Neha P. Raukar and Brian J. Zink

KEY CONCEPTS

- Skeletal infection should be considered in the differential diagnosis of all patients who present with bone or joint pain.
- Laboratory evaluation is of little value in the diagnosis of bone and joint infections, with the exception of the ESR and CRP level, which are elevated in approximately 90% of cases of bone and joint infections.
- Joint aspiration is the definitive diagnostic procedure, and intraoperative synovial culture is the only reliable joint fluid test for establishing a diagnosis. When limited fluid is available, it should be sent for a cell count.
- With suspected septic arthritis, joint fluid and blood culture specimens are obtained before IV antibiotics are administered. With suspected osteomyelitis, blood culture specimens are obtained, and IV antibiotics are administered while plans are made for further imaging studies, surgical aspiration, or resection of bone.
- The most important aspect of antibiotic treatment of suspected bone and joint infections is to provide potent bactericidal activity against *S. aureus* with additional empirical antibiotic coverage aimed at suspected organisms on the basis of age, risk factors, and regional variability.

FOUNDATIONS

Background and Importance

Historically, bone and joint infections (BJIs) have been described in grim terms. *Aids to Surgery,* written in 1919, noted that "acute infective osteomyelitis … is a very fatal disease." With septic arthritis, "the patient becomes exhausted from toxaemia or pyemia," and "ankylosis is the usual most favourable termination." Advances in diagnostic methods, antibiotic therapy, and surgical techniques have resulted in better patient outcomes; however, new challenges are arising. The emergence of resistant bacteria endangers the efficacy of antibiotics, and antibiotic choices need to be informed by resistance patterns. Furthermore, there are increasing subsets of patients with reduced host immunity. This combination results in greater complexity in the management of BJIs than was previously encountered. The management focuses on prompt diagnosis, initiation of treatment, and avoidance of the complications and morbidity associated with bone or joint infections.

The overall occurrence of BJIs has remained constant during the past 4 decades.[1] In hospitalized patients in the United States, the incidence is approximately 1%. Osteomyelitis in children younger than 13 years occurs in 1 in 5000, whereas the incidence of septic arthritis ranges from 5.5 to 12/100,000 individuals.[1] In contrast to global patterns, socioeconomic factors or race do not affect the incidence of BJI in the United States. Both bone and joint infections show a bimodal age distribution, occurring most commonly in people younger than 20 years or older than 50 years. In children, BJIs usually occur in previously healthy individuals, with boys having a slightly increased susceptibility to bone infections. In adults, there are several known risk factors that lead to a higher risk of BJIs.

Orthopedic infections can be classified according to the site of involvement and include osseous (osteomyelitis), articular (septic, pyogenic, or suppurative arthritis), bursal (septic bursitis), subcutaneous (cellulitis or abscess), muscular (infectious myositis or abscess), and tendinous (infectious tendinitis or tenosynovitis) infections. The term *osteomyelitis* literally means inflammation of the marrow of the bone, but it is colloquially used to refer to infection in any part of the bone.

Infectious processes can also be categorized by their onset and are generally designated as acute, subacute, or chronic. An acute infection is one that is diagnosed within 2 weeks after disease onset, a subacute infection is one diagnosed after one to several months, and chronic infections after a few months. Periprosthetic infections follow a similar nomenclature, using time of onset after surgery. Chronic osteomyelitis is also used to define a bone infection that fails to respond to a normal course of antibiotic therapy.

For the emergency clinician, the most practical way to classify osteomyelitis is as hematogenous, which is more common, or contiguous, which is further subdivided based on the presence or absence of vascular insufficiency. This method of classification assists in the interpretation of diagnostic imaging examinations and helps guide management, including antibiotic therapy and surgical intervention.

Anatomy, Physiology, and Pathophysiology

Histologically, bone is composed of compact and trabecular tissue. Compact bone forms the shaft of long bones and also covers the epiphysis. Trabecular or spongy bone is found within the epiphysis and makes up irregular bones. Compact bone is dense and without cavities and consists of longitudinally running Haversian systems, which contain Haversian canals that house vasculature and nerves. Spongy bone, conversely, consists of a bony lattice, the trabeculae, which is located within the medullary cavity and contains marrow, making it more metabolically active. The central Haversian canals in spongy bone run parallel to the long axis of the bone and contain the blood supply and reticular connective tissue for the Haversian system.

The gross structure of long bones is divided into several sections. The diaphysis is the shaft of the bone and contains the compact cortical bone with an overlying periosteum and a medullary canal containing marrow. The metaphysis is the junctional region between the epiphysis and diaphysis. The metaphysis contains abundant trabecular bone, but the cortical bone thins here relative to the diaphysis. Finally, the epiphysis is the area at either end of a long bone and is made up of abundant trabecular bone and a thin shell of cortical bone (Fig. 125.1). In the skeletally mature individual, the epiphysis of most bones is involved in articulation and, instead of being covered by a periosteum, is covered with a thin layer of articulating cartilage. This cartilage is composed of a thin layer of secretory cells that sits on a loose fibrous stroma and allows frictionless movement of the bones.

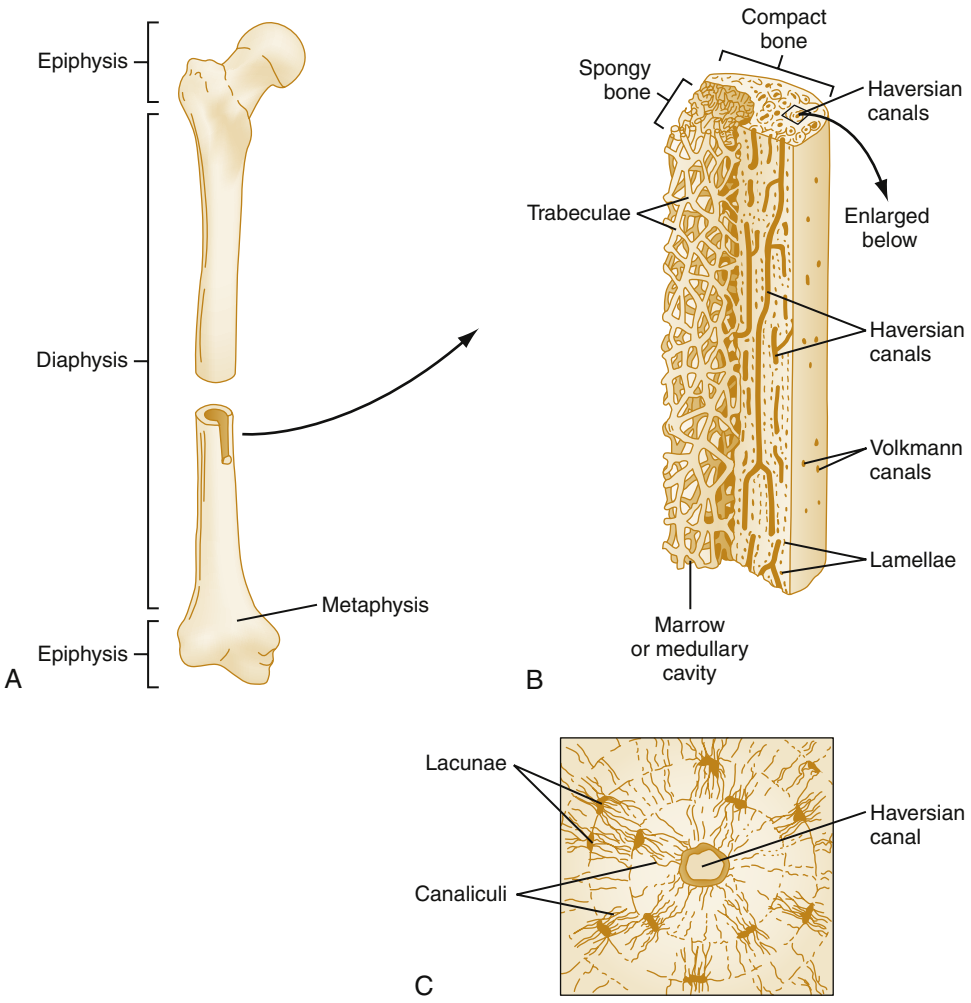

Fig. 125.1 Schematic drawing of long bone. (A) Regions of long bone. (B) Cross-sectional structure of long bone. (C) Microscopic structure.

Joints are enclosed by a synovial capsule. This layer of dense fibrous connective tissue offers structural integrity and is lined with synovial cells that secrete synovial fluid. This forms a sleeve around the articulating bones to which it is attached. The synovial membrane of the shoulder, hip, and knee joints extends beyond the epiphysis and attaches to the metaphysis allowing bacteria to spread directly from the metaphysis into the joint.

Osteomyelitis is an infection of the bone and medullary cavity. Bone is typically resistant to infection unless it is subjected to trauma, disruption of blood flow that deprives the bone of normal host immunity, a large inoculum of blood-borne or external microorganisms, or a foreign body. Hematogenous inoculation usually starts in the metaphysis, given the slow flow of blood in the sinusoidal blood vessels. Acute inflammatory cells migrate to the area, causing edema, vascular congestion, and small vessel thrombosis, which then leads to an increase in the intraosseous pressure compromising blood flow to the bone. The significantly reduced blood supply to this necrotic bone tissue makes bacterial infection difficult to eradicate with medication alone and, frequently, chronic osteomyelitis requires a combination of surgical debridement and antibiotic therapy. Eventually, lack of blood supply to the medullary canal and periosteum leads to areas of necrotic bone termed *sequestra*. Bony tissue attempts to compensate for the tensile stresses caused by infection by creating new bone around the areas of necrosis. This new bone deposition is called an involucrum.

The normal development of blood flow patterns at the metaphyseal-epiphyseal junction helps to explain the pathologic features of hematogenous osteomyelitis seen in the different age groups. In neonates and infants, osteomyelitis readily advances from the metaphysis to the epiphysis and adjacent joint space, leading to septic arthritis. After the first year of life, the infection usually spreads laterally through Volkmann canals, breaks through the cortex, and lifts the periosteum to form a subperiosteal abscess. In the adult, after the epiphyseal plate ossifies, anastomoses form between the metaphyseal and epiphyseal blood vessels and infection can once again spread from the metaphysis to the epiphysis and eventually into the synovium and joint space. In addition, because the periosteum becomes firmly attached to the underlying bone in adults, this limits subperiosteal abscess formation.

Bacteria congregate in a highly structured community, the biofilm, which plays an important role in the pathogenesis of septic arthritis and osteomyelitis. Within the biofilm, the bacteria are at varying stages of metabolism—some are active, some are slow-growing, and some are dormant. Antibiotics target metabolically active bacteria, such as those in the single cell state (planktonic state), and bacteria in other stages in the biofilm community are more resistant to the effects of antibiotics. Furthermore, Gram staining only identifies planktonic bacteria, which helps explain why Gram stains of aspirated synovial fluid in a suspected septic joint are often negative; therefore, a definitive diagnosis is made only by culture of the synovial fluid aspirate or synovial tissue. Biofilm

formation also explains why optimal treatment of a septic joint, especially of prosthetic joints, involves complete surgical débridement.

Hematogenous spread of bacteria causes almost all cases of osteomyelitis in children and in the subset of adults who have vertebral osteomyelitis. In the appendicular skeleton of adults, such as in the foot, hand, skull, maxilla, and mandible, osteomyelitis usually occurs by spread of the pathogens from a contiguous source of infection or direct implantation. Head and neck osteomyelitis is usually caused by sinus disease and odontogenic infection.

Infections from direct implantation of bacteria are caused by deep puncture wounds, such as by an animal bite, and tend to occur in the hands and feet. Although cats account for only 10% of animal bites, significant infection results from 20% to 50% of cat bites versus only 5% of dog bites because of the morphology of feline teeth. Most human bite injuries are related to fistfights and contamination of the metacarpophalangeal joints and metacarpals, with infection due to oral flora. Direct implantation of pathogens is also common with open fractures and surgical instrumentation.

Septic arthritis is usually a consequence of hematogenous spread unless there is direct injection of bacteria into the joint. The lack of a basement membrane makes the highly vascular synovium vulnerable to bacterial seeding. Infection occurs first in the synovium, spreads into joint fluid, and finally affects the articular cartilage. Bacterial enzymes and toxins directly damage cartilage. The synovial membrane responds to infection by increasing synovial fluid production, resulting in a large joint effusion. In response to infection, synovial cells and polymorphonuclear leukocytes release lysosomal enzymes, which irreversibly degrade articular cartilage, creating a painful joint with limited range of motion. This is amplified by the damage produced by bacterial enzymes and toxins. Even a small bacterial load in the joint space elicits profound and persistent inflammatory and immune responses. Bacteria can be cleared from the joint, resulting in a sterile-appearing inflammatory response. In addition, other structures that are enclosed within or adjacent to the synovium, such as bursae, tendons, and bone, may also become damaged in those with septic arthritis.[2]

Causes and Microbiology

Typically, hematogenous osteomyelitis or septic arthritis is caused by a single strain of bacterium, with gram-positive organisms being responsible for most infections. Even though gram-negative organisms account for 43% of cases of community-acquired bacteremia, they result in only about 10% of septic arthritis cases. Trauma predisposes patients to osteomyelitis by environmental pathogens. Patients who are wounded or sustain open fractures in fresh water are susceptible to infections with the gram-negative bacillus *Aeromonas hydrophila*. People who are bitten by animals, particularly dogs and cats, are at risk for the development of osteomyelitis from *Pasteurella multocida*. Osteomyelitis caused from human bites is most common in the hand and involves human oral flora, such as *Streptococcus anginosus, Fusobacterium nucleatum,* and *Eikenella* spp. In the population of injection drug users, *Staphylococcus aureus* is the most likely cause of infection, followed by *Pseudomonas* spp. *Pseudomonas aeruginosa* is also an important cause of osteomyelitis in puncture wounds, postsurgical wounds, and patients with sickle cell anemia.

Certain underlying disease states predispose a patient to BJI. These conditions include diabetes mellitus, sickle cell disease, HIV, alcohol use disorder, injection drug use, chronic corticosteroid use, preexisting joint disease (especially rheumatoid arthritis), and other immunosuppressed states. Postsurgical patients are also susceptible to BJIs, especially those who have implanted prosthetic devices.

Although most BJIs are bacterial, other pathogens include viruses, fungi, and parasites. The microbiology of osteomyelitis and septic arthritis is a function of several host and environmental factors. A patient's living environment also has some role in determining the incidence of BJIs. For example, people living in crowded conditions where tuberculosis is prevalent are at increased risk for tubercular BJIs, whereas older patients in hospitals and institutions may be more susceptible to infections with gram-negative bacteria. A summary of the organisms that cause osteomyelitis and septic arthritis is presented in Tables 125.1 and 125.2.

When considering the offending organism, *S. aureus* is the leading cause of osteomyelitis in all age groups except neonates. In neonates, group B streptococci, *Escherichia coli* and other gram-negative coliforms, and *Staphylococcus epidermidis* are the most common pathogens responsible for BJIs. Since the introduction of the vaccine, *Haemophilus influenzae* type b, once a common cause of septic arthritis and osteomyelitis in children younger than 2 years, has essentially disappeared as a pathogen in vaccinated children but cases of septic arthritis are being reported from other serotypes of *H. influenzae*. Another gram-negative coccobacillus in the Neisseriaceae family, *Kingella kingae* has been encountered with increasing frequency.[3] *K. kingae* can be part of the normal flora of the nasopharynx and can be spread hematogenously to bones and joints. It is a fastidious organism and may be mistaken for *Haemophilus* or *Neisseria* spp. and often requires PCR for diagnosis.[4] In older adults and patients with diabetes, gram-negative bacteria account for a higher percentage of cases of bone and joint infections.

P. aeruginosa has been reported as a cause of cervical spine osteomyelitis in injection drug users and lumbar spine osteomyelitis in patients

TABLE 125.1 Microbiology of Bacterial Septic Arthritis as Related to Age of the Patient

Organism	Child (%)[a]	Young Adult Engaging in High-Risk Sexual Behavior (%)	Adult (%)	Older Adult (%)
Staphylococcus aureus	10–20	15–20	60–0	45–65
Streptococcus species	5–10	1–5	15–20	10–15
Gram-negative bacterium	1–5	Rare	10–5	15–35
Haemophilus influenza	Rare[b]	Rare[b]	Rare[b]	Rare[b]
Neisseria gonorrhoeae	1–5	60–80	1–5	Rare

[a]Ages 6 months to 5 years.

Alt, Alternative antibiotics; *APAG,* antipseudomonal aminoglycoside; *AP Ceph,* antipseudomonal cephalosporin (ceftazidime or cefepime); *Ceph 3,* third-generation cephalosporin (e.g., ceftriaxone, cefotaxime, cefamandole, ceftizoxime, ceftazidime, cefazolin, moxalactam); *FLQ,* fluoroquinolone; *MRSA,* methicillin-resistant *S. aureus*; *PRP,* penicillinase-resistant penicillin (oxacillin, nafcillin, methicillin, amoxicillin-clavulanate [*AC*]); *TS,* trimethoprim-sulfamethoxazole.

[a]Concurrent treatment of *Chlamydia trachomatis* infection should be given to patients with suspected *N. gonorrhoeae* septic arthritis.

with chronic urinary catheters. *Pseudomonas* colonizes the rubber and plastic inserts in footwear and is therefore seen in soft tissue infections and osteomyelitis of the foot after a puncture wound through footwear.

Methicillin-resistant *S. aureus* (MRSA), methicillin-resistant *S. epidermidis,* and vancomycin-resistant enterococci (VRE) pose significant microbiologic problems. In fact, MRSA has become the most prevalent cause of acute hematogenous osteomyelitis in pediatric patients.[5] Traditional therapies, including vancomycin and clindamycin, remain effective for the treatment of much of pediatric AHO. Multiresistant enterococci pose the greatest potential danger in that bacteriocidal antibiotic regimens are limited.

The rise in injection opioid use in the United States since 2000 has also resulted in a rise in invasive bacterial infections, including osteomyelitis. One study found that those who inject heroin were 16 times more likely to develop MRSA than those who did not inject drugs.[6]

Diabetic foot osteomyelitis, posttraumatic osteomyelitis, and chronic septic arthritis or osteomyelitis are often polymicrobial. Anaerobic bacteria can complicate polymicrobial infections and may be present more often than is commonly identified because standard culture techniques may be inadequate to identify them. Anaerobic bacteria are reportedly discovered in up to 40% of cases of chronic osteomyelitis.

Mycobacterium tuberculosis may infect bones and joints, usually in the axial skeleton. The two most common forms of skeletal infection are vertebral osteomyelitis (Pott disease), in which the spine is affected in 50% of cases, and tubercular arthritis, which manifests as a chronic,

low-grade inflammatory process that resembles rheumatoid arthritis more than acute septic arthritis.

Patients with human immunodeficiency virus (HIV) infection and AIDS are predisposed to various common and opportunistic pathogens. Although *S. aureus* is still the most likely cause of bone and joint infections in patients with AIDS, fungal and other atypical organisms should be considered. One unusual but particularly characteristic form of osteomyelitis in HIV-positive patients is bacillary angiomatosis. This infection is caused by a gram-negative, rickettsia-like organism that frequently causes osteolytic bone lesions.

OSTEOMYELITIS

Clinical Features

History and Physical Examination

The symptoms and signs of osteomyelitis in adults vary. Patients with osteomyelitis often present with fever, rigors, and may even appear toxic. Systemic complaints of headache, fatigue, malaise, and anorexia are inconsistently reported and are less likely with chronic osteomyelitis. In children with lower extremity osteomyelitis, a sudden limp or inability to bear weight, localized warmth, swelling, and erythema may be reported. A careful review of the patient's past medical history should be performed to identify risk factors that may predispose to bone infection.

The predominant physical exam finding of osteomyelitis is point tenderness over the infected segment. Palpable warmth and soft tissue swelling with erythema may be present, but these findings are variable. In chronic osteomyelitis, the involucrum or sequestrum (fragments of necrotic bone separated from healthy bone) may be palpated, and sinus tracts that fistulize to the skin may be noted. A sympathetic effusion in the adjacent joint may develop in patients with osteomyelitis, even when the joint is not infected.

Complications

In addition to the development of chronic osteomyelitis, complications of acute osteomyelitis include bacteremia and sepsis. Depending on the location of osteomyelitis, local extension of an invasive suppurative process can lead to septic arthritis, brain abscess, meningitis, spinal cord compression, pneumonia, and empyema. In children, osteomyelitis damages the developing skeleton. If the infection involves the epiphysis, permanent growth alterations can occur, resulting in a shorter or deformed extremity on the affected side. Pathologic fractures may occur through sites of osteomyelitis.

Clinical Subsets of Osteomyelitis

Osteomyelitis in Children. Osteomyelitis in children tends to be acute, usually arising from hematogenous seeding of bone, and can often be treated with antibiotics alone. Acute hematogenous osteomyelitis (AHO) is seen in children as young as 3 months and as old as 16 years. *S. aureus* is the most common infecting organism in children of all ages, except neonates (see Tables 125.1 and 125.2) with MRSA being most common in AHO. As noted, *H. influenzae* is no longer a common cause of AHO.

AHO has a well-established male preponderance (male-female ratio of 2 : 1 to 3 : 1) and involves long bones approximately 80% of the time. The site of infection is usually the distal metaphysis because of its increased vascularity, but up to 30% of AHO occurs in other parts of the bone. Children with AHO may have fever, chills, vomiting, dehydration, and malaise, but they usually do not appear toxic. Most children have characteristic pain, limited use of the limb, and are point tender. The diagnostic evaluation for AHO is shown in Fig. 125.2. Blood cultures are positive for the bacterial cause of osteomyelitis in about 40%

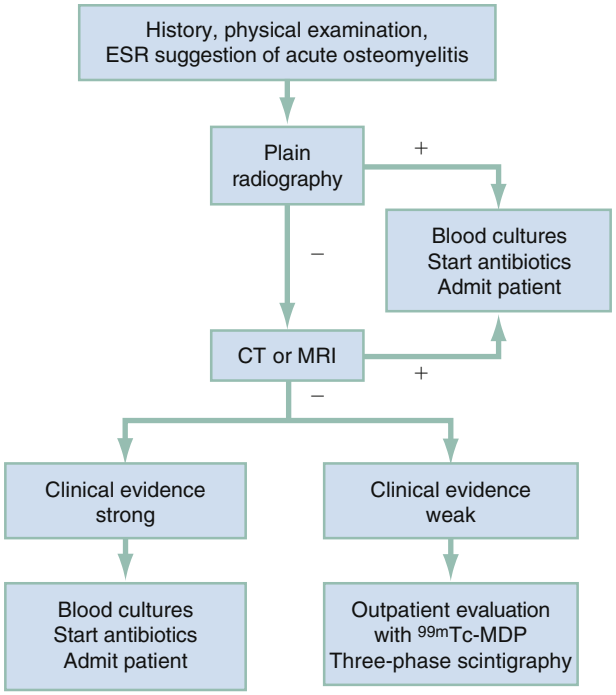

Fig. 125.2 Algorithm for the use of imaging studies in the emergency department diagnosis of osteomyelitis. *CT,* Computed tomography; *ESR,* erythrocyte sedimentation rate; *MRI,* magnetic resonance imaging; *^{99m}Tc-MDP,* technetium Tc-99m–labeled methylene diphosphonate.

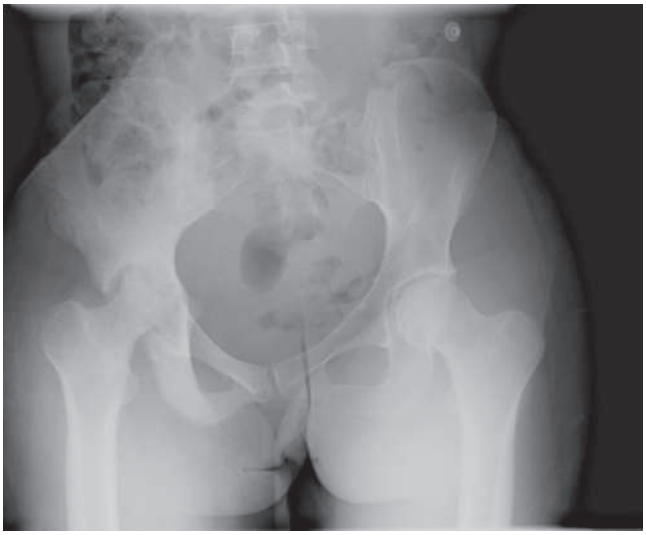

Fig. 125.3 Radiograph of chronic osteomyelitis. Diffuse sclerosis of the right hemipelvis includes the ischium and iliac bone, with extension to the right sacroiliac joint. The right acetabulum demonstrates whittling of the femoral head and neck, with marked loss of bone stock. Abutting the right symphysis pubis is increased cortical lucency suggestive of subchondral cystic changes. (Courtesy Dr. Peter Evangelista, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

of pediatric patients[7] with AHO while tissue cultures are positive 86% of the time. A positive blood culture and physical examination consistent with osteomyelitis may be sufficient to diagnose AHO. Figs. 125.3 and 125.4 show typical radiographs of AHO.

Neonatal osteomyelitis is more commonly seen after an abnormal pregnancy or delivery and often accompanies other acute illnesses

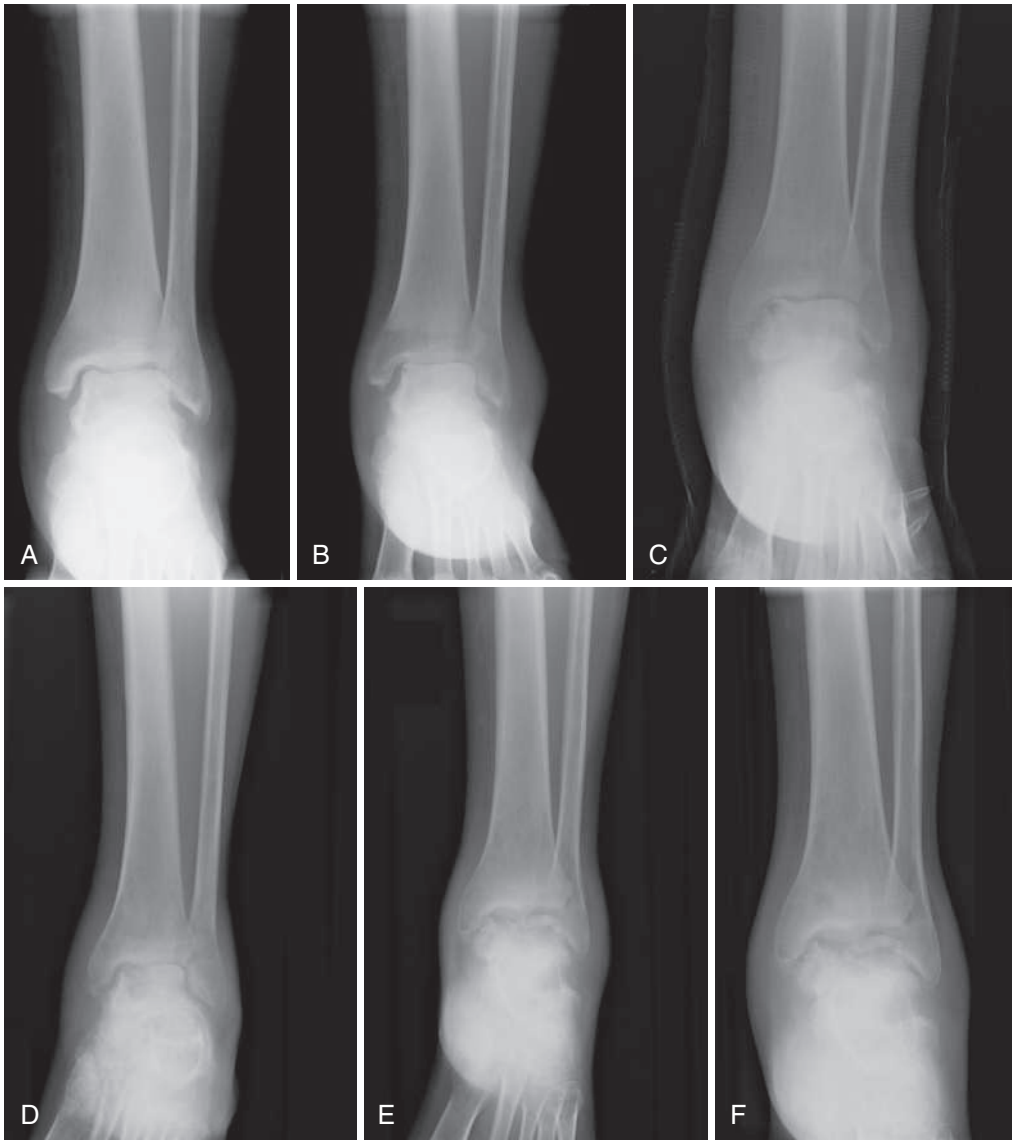

Fig. 125.4 Radiographic progression of acute osteomyelitis. (A) Soft tissue swelling at the medial and lateral aspects of the ankle, with a moderately sized effusion (August 2, 2006). (B) Large ankle effusion with extensive soft tissue swelling. There is complete loss of the tibiotalar joint space and widening of the medial joint space, suggesting chondrolysis. There are lucent areas in the distal tibia and fibula, suggestive of hyperemia, and the talus is diffusely sclerotic (September 11, 2006). (C) Increased erosion of the medial aspect of the talar dome, with increased joint effusion (October 12, 2006). (D) Talar bone destruction with demineralization involving all the osseous structures. There is also a small joint effusion (January 2, 2007). (E) Avascular necrosis of the talus and destruction of the articular surfaces of the tibia and talus is present, consistent with chronic osteomyelitis. There is diffuse osteopenia and loose bodies within the joint (April 19, 2007). (F) There is continued irregularity of the articular surface of the tibia and collapse of the talus. Loose bodies are still present within the joint, and there is a persistent joint effusion and soft tissue swelling (June 14, 2007). (Courtesy Dr. Thomas Egglin, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

but is difficult to diagnose because of a paucity of systemic findings. Multiple sites of bone involvement are found in approximately 50% of reported cases. Because of the unique vascular anatomy of the neonate, septic arthritis often accompanies osteomyelitis. Osteomyelitis of the flat bones, such as the facial bones, is more common among neonates than any other age group. Group B streptococcus is the leading causative bacterium in neonatal osteomyelitis, but staphylococcal species are still common. As with adults, plain radiographs are a good initial test because abnormalities are identified within days of development of neonatal osteomyelitis, and radiographs are usually abnormal when the disease is suspected. In the presence of a normal radiograph, the next step for the emergency clinician who suspects neonatal osteomyelitis is magnetic resonance imaging (MRI) in consultation with the orthopedic surgical service.

Two less common forms of osteomyelitis, subacute osteomyelitis and chronic recurrent multifocal osteomyelitis (CRMO), can occur in children, particularly older children (6–10 years) and adolescents. Subacute osteomyelitis refers to a form of the disease in which clinical symptoms and signs are slow to appear, and radiographs show small areas of osteomyelitis, usually in the metaphysis of long bones. Cultures

of blood and bone are negative more than 50% of the time but usually implicate staphylococcal species when they are positive.

CRMO is characterized by small foci of infection at various sites in the skeleton. The disease is defined by multiple episodes of indolent infection. Diagnosis is made by radiography because culture of the bone sites is almost always negative. This disease may be associated with certain psoriatic subtypes.

Vertebral Osteomyelitis. Vertebral osteomyelitis usually affects older adults and is increasing in frequency as the population ages and has more chronic medical diseases. Risk factors in older adults include intravenous (IV) access devices, indwelling lines, and asymptomatic urinary infections, whereas in younger individuals risk factors include injection drug abuse. The spine is particularly susceptible to bacterial infection because the venous system surrounding vertebral bodies is valveless, permitting two-way flow of blood, and has transverse and longitudinal anastomoses. This anatomy allows bacteria to readily spread to adjacent vertebral bodies. Vertebral osteomyelitis usually results from hematogenous seeding, direct inoculation at the time of spinal surgery, or contiguous spread from an adjacent infection. A clear source of bacterial hematogenous seeding with positive blood cultures occurs in approximately 40% of cases of vertebral osteomyelitis. *S. aureus* (including MRSA) is the most common offending agent, followed by aerobic gram-negative rods from urinary or gastrointestinal sources.

Vertebral infections occur in the lumbar (58%), thoracic (30%), and cervical (11%) spine. Only 10% of patients with vertebral osteomyelitis appear septic or toxic; most patients present with insidious symptoms, leading to delays in diagnosis of up to 4 months. Back pain, seen in roughly 90% of patients, is the most common presenting symptom, and physical examination often reveals tenderness over the spinous process. Neurologic deficits are reported in less than 40% of patients with vertebral osteomyelitis and often coincide with a concomitant epidural abscess. Up to 60% of patients with these abscesses present without fever or leukocytosis. On laboratory testing, the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level are elevated in 98% and 100% of cases, respectively. Blood culture specimens should be obtained before antibiotic treatment is initiated. Rapid diagnosis and treatment of this medical emergency start with the initiation of empiric antibiotics, immediate imaging, and early orthopedic (or spine service) involvement. Diagnostic delay is an independent risk factor for an unfavorable outcome.

Similar to osteomyelitis in other parts of the body, findings on plain radiographs are not seen until at least the second week of vertebral infection and are nonspecific. MRI has largely replaced bone scintigraphy for imaging in suspected vertebral osteomyelitis. Although computed tomography (CT) is good for defining bone destruction and is often used to assist needle aspiration of the lesion, MRI can identify an epidural abscess and rule out other noninfectious vertebral conditions. MRI has a sensitivity of 90% for vertebral osteomyelitis, with T2-weighted images most valuable in establishing the diagnosis. When suspected, an MRI of the complete spine, with and without contrast, is the imaging study of choice.

Cervical spine osteomyelitis can cause a retropharyngeal abscess, whereas lumbar spine osteomyelitis may be complicated by a psoas muscle abscess. Vertebral osteomyelitis can cause spinal cord ischemia if the vertebral infection causes septic thrombosis or compression of local blood vessels. When osteomyelitis affects the thoracic spine, infection can spread to the chest. Paraspinal abscesses, reactive pleural effusions, and empyema have been reported as complications of vertebral osteomyelitis and may mislead the emergency clinician. The most dreaded complication of vertebral osteomyelitis is the spread of infection into the spinal canal, development of an epidural abscess, and progression of the infection to cause spinal cord injury and permanent paralysis. Fortunately, this occurs in less than 15% of cases of vertebral osteomyelitis, and risk factors for this include older adults, those with cervical spine osteomyelitis, and those with serious underlying diseases (e.g., rheumatoid arthritis, diabetes mellitus).

Patients who present with a clinical picture consistent with vertebral osteomyelitis require rapid diagnostic confirmation to avoid progression and spinal cord compression. The diagnosis is suspected in patients who have recently undergone a spinal procedure or injection and have focal severe pain that is not relieved by rest. It can also result from hematogenous spread, making diagnosis elusive. The diagnostic procedure of choice for vertebral osteomyelitis is a spinal MRI with contrast, and needle biopsy may be indicated to identify the causative organism.

Patients with vertebral osteomyelitis initially require IV antibiotic therapy and can usually be successfully treated with antibiotics alone. Surgery may be required when there is spinal cord compression, for abscess drainage or débridement, for correction of the progressive anatomic deformity, and if the infection recurs after adequate treatment.

Diskitis is a variant of vertebral osteomyelitis. The disk is an avascular structure that depends on nutrient diffusion from adjacent blood vessels from the vertebral body and endplates. The avascular disk creates a rich environment for the bacteria to flourish. Due to the vascular anatomy, diskitis often coexists with vertebral osteomyelitis in adults while isolated diskitis is more common in children. The patient often complains of back pain and may refuse to walk. MRI demonstrates the anatomy of diskitis, whereas CT is used to guide aspiration. Cultures of the disk from needle aspiration are reported to be positive for bacteria 30% to 60% of the time, usually for *S. aureus*. The disease typically resolves with nonoperative treatment.

Posttraumatic Osteomyelitis. Posttraumatic osteomyelitis is a form of osteomyelitis that results from open fractures, burns, bites, puncture wounds, and surgery and invasive procedures. Open fractures are typically graded according to the Gustillo classification, which takes into account wound length and amount of soft tissue damage; this helps guide antibiotic treatment. Overall, the rate of osteomyelitis in open long-bone fractures is reported to be around 0.05%.[8] The fracture site may be contaminated directly from the environment or iatrogenically secondary to emergency procedures or surgery. When there is damage to soft tissues, a necrotic nidus of infection is created, and the bacteria can spread to bone. Polymicrobial infection is more common in this scenario. The imaging of posttraumatic osteomyelitis is complicated by changes induced by surgery and new bone formation in the fracture; therefore, the optimal imaging modalities are MRI and CT.

The intraoperative implantation of prosthetic devices increases the chance of infection. The rate of prosthetic joint infection is 0.5% to 1% for hips,[9] 0.5% to 2% for knees, and less than 1% for shoulder replacements. Osteomyelitis due to direct inoculation associated with joint arthroplasty and implantation of prosthetic devices typically becomes evident about 12 weeks after surgery. These patients generally do not report relief of their pain after surgery. Patients who have symptoms of infection more than 12 weeks after surgery and who have postoperative improvement of their pain are considered to have a hematogenous source of infection. Techniques to retain implanted prosthetic devices in the setting of an acute infection after total joint arthroplasty are evolving. Débridement and irrigation with prosthetic retention followed by antibiotic therapy is the treatment of choice in infections following total knee arthroplasty.[9,10] Postsurgical osteomyelitis should be considered in the postoperative patient with a painful joint. The prevalence of infection after total knee or hip arthroplasty is estimated to be approximately 1% to 2%, with infections within 3 months of injury likely the result of surgical contamination, and those that occur longer than 3 months postoperatively due to hematogenous seeding.

S. aureus and *S. epidermidis* account for 75% of postsurgical and prosthesis-related cases of osteomyelitis. Radiographs are often normal but may show subtle signs of bone resorption and loosening of the prosthetic components. It is difficult to distinguish mechanical from infectious loosening, so joint aspiration, synovial fluid analysis, and bone biopsy—all performed in a sterile operative setting—are undertaken to establish a diagnosis. Other imaging techniques such as CT and MRI are used but may be difficult to interpret because of scatter from the metallic components and postsurgical changes.

Puncture wounds to the feet have approximately a 2% incidence of development of osteomyelitis. The causative organism is usually *S. aureus* or beta-hemolytic streptococcus. *P. aeruginosa* is commonly associated with plantar wounds that occur while a person is wearing rubber-soled shoes. Invasive procedures that produce puncture wounds, such as venipuncture for central lines, intraosseous devices for intravascular access, and fetal scalp monitoring, may introduce infection that can lead to osteomyelitis. Proper antiseptic skin cleansing and avoiding punctures through infected skin will reduce the chance of contiguous bone infection.

Diabetic Foot Osteomyelitis. Diabetic foot infections lead to osteomyelitis 20% of the time, while diabetic ulcers have underlying osteomyelitis 15% of the time. This rate increases in ulcers greater in size than 2 cm^2. The pathologic changes induced by long-standing diabetes mellitus, such as compromised vascularity, encourage the development of osteomyelitis. Over 60% of patients report polyneuropathy, leading to repetitive trauma and subsequent foot ulcers. Once the skin has been violated and infected, the altered host defenses of diabetic patients make it easier for infection to occur and spread. Hyperglycemia resulting from the infection allows bacteria to proliferate, impairs leukocyte function, and results in defective chemotaxis, abnormal phagocytosis, decreased bactericidal function, defective antibody synthesis, and decreased complement levels, all of which impair healing and exacerbate osteomyelitis. The infection typically starts in the periosteum, spreads to the cortex, and eventually disrupts medullary bone.

Local findings in diabetic foot infections include swelling, erythema, and sometimes pain. Indolent ulcers and frank cellulitis are seen in more than 50% of cases. Laboratory testing cannot definitively diagnose osteomyelitis, though an ESR over 70 mm/h is associated with an 11-fold greater risk. Surgical biopsy of the bone is the only reliable way for the bacteriologic diagnosis to be made. The probe-to-bone (PTB) test can be performed by exploring the wound for palpable bone with a sterile blunt metal probe. The pretest probability plays a significant role in using PTB to diagnose osteomyelitis and the PTB result should be interpreted with the results of clinical, laboratory, and imaging findings.

Diabetic osteomyelitis is often chronic, so radiographic changes are often notable. Osteopenia, periosteal thickening, cortical erosions, new bone formation, and mottled lytic lesions are typical, and air may be present in the soft tissues. Bone biopsy for diabetic foot osteomyelitis has a reported sensitivity of 94%. Diabetic foot osteomyelitis is usually polymicrobial and often includes gram-negative bacteria. *S. aureus* is the most common pathogen; other organisms include streptococci, Enterobacteriaceae, and anaerobes. Surgical treatment with amputation had been the mainstay of treatment; however, a 10-week antibiotic treatment regimen, including IV administration followed by oral antibiotics, can be successful in select patients.[11]

Osteomyelitis in Sickle Cell Disease. Patients with sickle cell disease (SCD) are at increased risk for hematogenous infection, including osteomyelitis, often due to reduced or absent splenic function. In children, the difference in the vasculature of immature bone increases susceptibility to osteomyelitis. In contrast to AHO in non–sickle cell patients, AHO in children with sickle cell disease usually affects the diaphysis instead of the metaphysis. Also, although *S. aureus* is the most common bacterium in children without sickle cell disease, *Salmonella* spp. is the most common infecting organism in patients with SCD.[9,12] Reasons for this are not completely understood, although it has been postulated that microinfarcts in the bowel allow *Salmonella* bacteremia to seed the bloodstream and lead to hematogenous osteomyelitis.

The differentiation of bone infection from bone infarction and vaso-occlusive crisis in sickle cell patients is a challenge. Vaso-occlusive pain is typically consistent and far more common than either infarcts or infection. Fever, toxic appearance, and elevated ESR are more commonly associated with osteomyelitis than with bone infarction. Plain radiographs are not helpful in distinguishing between the entities, but MRI has been proving useful in differentiating between bone infarction and infection. Another approach is to note the response to conservative therapy; bone infarctions usually improve within 24 to 48 hours, whereas bone infections worsen. Empiric antibiotic treatment of osteomyelitis in the sickle cell patient should include coverage against *S. Aureus, Salmonella,* as well as other gram-negative bacteria with vancomycin and ciprofloxacin.

Chronic Osteomyelitis. Most chronic bone infections occur as a complication of posttraumatic infection, surgical procedures, or diabetic foot infections. The inflammatory response to infection triggers bone resorption and cartilage destruction and ultimately leads to bone death (see Fig. 125.3). The necrotic bone provides an inanimate surface to which microorganisms adhere. Clinical signs that the infection has become chronic include the formation of sequestra and presence of draining tracts or fistulas. Chronic infection is almost always polymicrobial and commonly involves anaerobes. Because sinus tract culture is not a reliable method to predict which bacteria are active in the underlying bone infection, direct biopsy of bone is the only option for the accurate diagnosis of most cases of chronic osteomyelitis. Chronically established infections can be remarkably persistent or evolve even in the face of prolonged antibiotic therapy; therefore, treatment commonly involves surgery.

Differential Diagnoses

Many processes involving bone may masquerade as osteomyelitis. Bone tumors, such as osteoid osteomas and chondroblastomas, metastatic bone tumors, and lymphoma may produce local pain and radiographic changes consistent with osteomyelitis, such as small, round, radiolucent lesions. Ewing sarcoma is a tumor of bone marrow in children that can be mistaken for osteomyelitis. Finally, occult fractures, such as buckle fractures in children, present with point tenderness that may be mistaken for osteomyelitis.

Diagnostic Testing

Laboratory Tests

Initial evaluation in the emergency department (ED) often involves laboratory and radiographic evaluation, but the gold standard to confirm diagnosis is bone biopsy and culture, which also helps guide treatment. Laboratory data are not specific and can only suggest the diagnosis of osteomyelitis. In acute osteomyelitis, the white blood cell (WBC) count can be elevated—typical values range from normal to 15,000/mm^3—whereas in chronic osteomyelitis the WBC count is often normal.

The ESR, a nonspecific measure of inflammation, is more helpful than the WBC count. The ESR is a relatively sensitive marker for infection, and many series have reported elevated ESR and CRP values in patients who have confirmed osteomyelitis. An elevated ESR in the presence of pertinent physical findings should lead one to suspect osteomyelitis, but a normal or slightly elevated ESR does not eliminate the diagnosis. Other inflammatory conditions, such as cellulitis, can

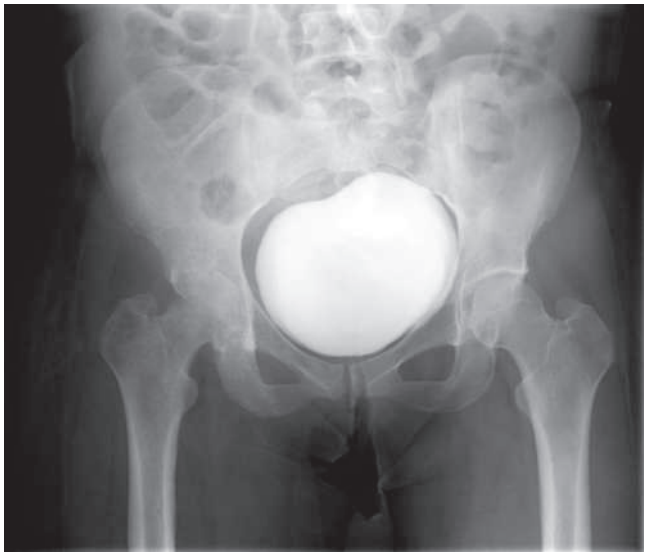

Fig. 125.5 Radiograph of right hemipelvis and proximal femur demonstrate permeative moth-eaten changes, with resultant femoroacetabular joint space narrowing consistent with osteomyelitis. (Courtesy Dr. Peter Evangelista, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

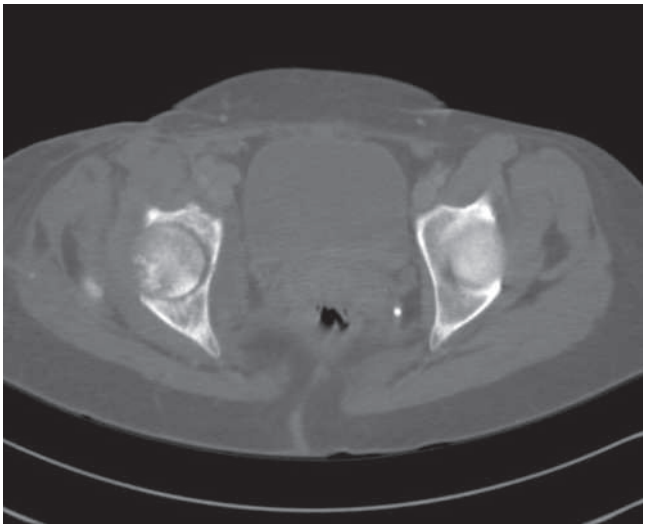

Fig. 125.6 CT scan of osteomyelitis. There is a diffuse moth-eaten appearance involving the right hemipelvis and right femoral head, with abundant periosteal reaction. (Courtesy Dr. Peter Evangelista, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

cause an elevated ESR, although the degree of elevation of the ESR is often higher with osteomyelitis. In evaluating a diabetic foot infection, an ESR greater than 70 mm/hr predicts the presence of an underlying bone infection.

The CRP level, another nonspecific marker of inflammation, increases within the first 24 hours of infection, peaks within approximately 48 hours, and is usually normal within 1 week of therapy. The CRP level may be a better early indicator of disease, but the ESR is most valuable in following response to treatment. Typically, the ESR falls steadily as osteomyelitis resolves and increases should it recur. However, it is common to see elevations in one and not the other parameter, especially when there is development of a concurrent illness or the infection has progressed so that the ESR rises and stays elevated while the CRP rises and falls. In children, an elevated ESR or CRP level is seen in all cases of osteoarticular infection; sensitivity of the use of both the ESR and CRP value is 98%, but a leukocytosis is reportedly seen in only 35% of cases.

Diagnostic Imaging

Conventional Radiography. Conventional radiography is the initial modality of choice to evaluate osseous changes and, in most cases, will be the only imaging technique used to aid in the diagnosis of osteomyelitis.

Conventional radiography is readily available, relatively inexpensive, and useful in the differentiation of infection from trauma and tumors. The characteristic findings of early osteomyelitis on the plain radiograph are lucent lytic areas of cortical bone destruction (see Fig. 125.4). However, lucency is not detected on radiographs until approximately 50% of bone mineral is lost, which often takes up to 2 weeks from the onset of infection. Although these findings are often difficult to identify on plain radiographs, soft tissue edema, distorted fascial planes, and altered fat interfaces may be present within 3 to 5 days from the onset of infection and can serve as a clue to osteomyelitis in the underlying bone. A periosteal reaction, hypertrophy or elevation of the periosteum, and presence of an involucrum can also be seen, especially in children, given their thinner periosteum (Fig. 125.5). In advanced disease, the lytic lesions are surrounded by dense sclerotic bone, and sequestra may be noted. By 28 days from the onset of osteomyelitis, 90% of the plain radiographs are abnormal.

Radionuclide Bone Scanning. Radionuclide skeletal scintigraphy (bone scanning) is more sensitive than plain radiography for the early diagnosis of osteomyelitis, and is especially useful in the presence of prosthetics or other hardware. Radionuclide scans can detect osteomyelitis within 48 to 72 hours after the onset of infection. A radioactive tracer is injected into the bloodstream and given time to bind or accumulate in body tissues, after which a camera is used to determine released radioactivity. An image is created that is evaluated for an increase or decrease in expected uptake of the radionuclide. Given the radiation burden associated with this modality, however, in the past 3 decades, there has been a movement away from skeletal scintigraphy to MRI to diagnose osteomyelitis. The amount of time this study requires makes this less than ideal in the emergency department.

Computed Tomography. Even though MRI is the best imaging modality to diagnose osteomyelitis because it can identify early changes in the bone, when it is not available, or is contraindicated, CT is a useful alternative. The bony cortex is seen particularly well on CT, and involucrum and sequestrum formation are easily identified. CT is generally used to detect and define areas of possible infection in bones that are difficult to visualize on plain radiographs, such as the sternum, vertebrae, pelvic bones, and calcaneus. On CT scan, osteomyelitis appears as lucent areas (Fig. 125.6), and gas may be seen in bony abscess cavities. The limitation of CT for the early diagnosis of osteomyelitis is the same as that for plain radiography, in that the disease must be present for more than 1 week for changes to be apparent. When required, the CT scan can guide the surgeon in débridement of infected bone and in choosing a site for diagnostic biopsy. However, the rate of a positive culture even with a CT guided bone biopsy is low and infrequently changes the course of the patient's care,[13] therefore, antibiotics should not be withheld while waiting for this procedure.

Magnetic Resonance Imaging. The use of bone scans and CT for the evaluation of osseous anatomy has been decreasing as the availability and image quality of MRI improves while its cost decreases. MRI findings are often evident before other modalities detect an abnormality with earlier detection of bone marrow involvement and medullary or cortical destruction, periosteal reaction, edema, soft tissue extension, joint

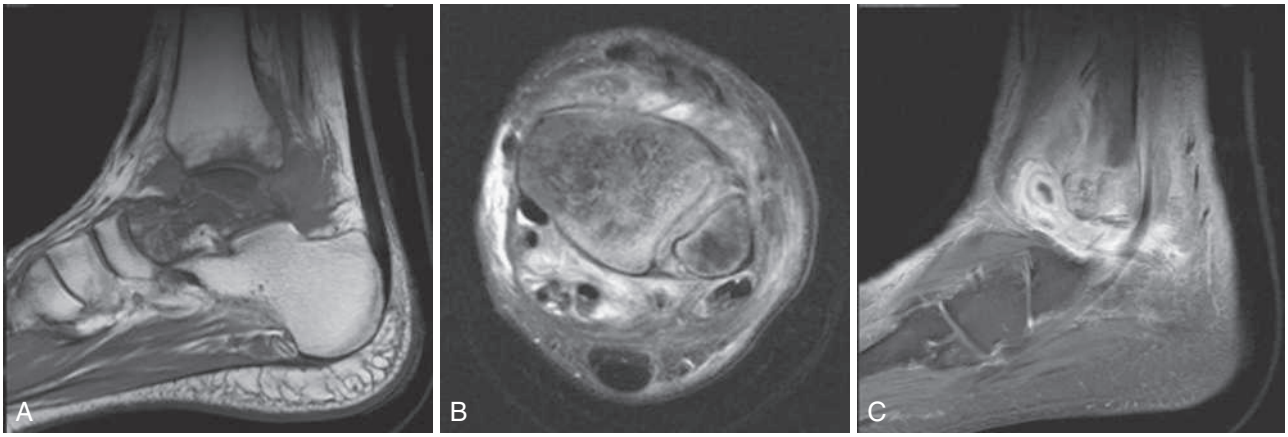

Fig. 125.7 MRI scan of osteomyelitis. (A) Sagittal T1 image shows decreased signal within the talus, suggesting osteomyelitis. (B) Axial T2 image demonstrating increased signal throughout the talus and distal fibula consistent with osteomyelitis (fat-suppressed image). (C) Sagittal T1 image after the administration of gadolinium demonstrates a small focus of nonenhancing fluid just anterior to the distal fibula, suggestive of an abscess. (Courtesy Dr. Thomas Egglin, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

effusion, articular damage, and complications of osteomyelitis, such as abscess formation. Whereas the presence of ferromagnetic material is a contraindication to the use of MRI, most materials used in orthopedic surgery, such as titanium and chrome cobalt, do not interfere with this imaging modality. Metal may cause distortion of the signal in the area adjacent to a joint prosthesis, but this does not exclude MRI in this group of patients. Osteomyelitis produces a diminished intensity of the normal marrow signal on T1-weighted images and a normal or increased signal on T2-weighted images (Fig. 125.7). These findings, however, are not specific to osteomyelitis; the differential diagnoses for the MRI findings in acute osteomyelitis are trauma, noninfectious inflammatory and metabolic lesions, and cancer. In cases in which a surgical procedure will be done to obtain a microbiologic diagnosis or is needed to treat osteomyelitis, MRI has obvious advantages over other modalities in detailing the anatomy for the surgeon.

The administration of gadolinium as a contrast agent enhances the interface between normal and abnormal marrow, helps distinguish devitalized bone from normally perfused bone, helps identify sinus tracts, and helps differentiate between an abscess and a phlegmon. Gadolinium becomes localized in areas of increased vascularity and blood flow and also helps distinguish soft tissue infections, such as abscesses and cellulitis from osteomyelitis (Fig. 125.8). Contrast improves the specificity of the images on MRI and if there are no contraindications, gadolinium should be used.

Microbiologic Diagnosis

The most definitive way to diagnose osteomyelitis is to obtain infected bone by needle aspiration or surgical resection. This also helps guide antimicrobial therapy. Cultures from draining fistulas or sinus tracts are not an acceptable substitute because these cultured organisms often differ from those in the underlying infected bone. Because osteomyelitis may be polymicrobial or due to unusual microorganisms, especially in immunocompromised patients, cultures for fungal and anaerobic organisms should be included.

Particularly in cases of hematogenous osteomyelitis, cultures of blood, urine, cerebrospinal fluid, when necessary, and pus from other sites of infection can help identify the infecting bacteria. Blood cultures in patients with acute untreated osteomyelitis are positive for the offending bacteria approximately 50% of the time, while in chronic osteomyelitis, blood cultures are almost always negative.

The emergency clinician's diagnostic approach in suspected osteomyelitis is presented as an algorithm in Fig. 125.2. A few key points should be considered with use of this algorithm:

- Radiographs lag behind the clinical picture.
- In infants and children, the amount of radiation exposure with imaging techniques must be considered.
- If the clinical presentation strongly suggests osteomyelitis, a lengthy diagnostic evaluation should not delay empirical treatment. Culture specimens of blood, urine, and other appropriate sites should be obtained and antibiotic treatment started.
- Early osteomyelitis is best identified on MRI with contrast. Other imaging modalities are useful later in the disease course and play an important role, especially when MRI is unavailable or contraindicated, and in concert with other clinical and laboratory findings.

Management

The goal of therapy is to contain the infection before bone necrosis occurs because cure rates fall dramatically once this happens. Medical management with antibiotics is usually sufficient for asymptomatic osteomyelitis that is coincidentally discovered during the evaluation of a patient with fever, weight loss, or bacteremia, hematogenous infection caused by sensitive microbacteria or fungi, or hematogenous vertebral osteomyelitis caused by sensitive pathogens.

For all other types of osteomyelitis, including contiguous focus osteomyelitis, diabetic foot infections, posttraumatic osteomyelitis, and implant-related infection, definitive care is frequently surgical. In these cases, a discussion with an infectious disease or orthopedic surgery specialist, depending on the scenario and available services, is appropriate to plan surgical and medical therapy.

The ideal antibiotic in the treatment of osteomyelitis should be able to penetrate through the bone or the synovial membrane. While most antibiotics fulfill these criteria, penicillin and metronidazole do not penetrate bone as well as other antibiotic classes.[14] Penicillin is reserved for bone contaminated with soil to cover *Corynebacterium* which causes gas gangrene, and penicillin with gentamycin and metronidazole is reserved for bone infections that are contaminated with fecal content. Effective antibiotics should also be bactericidal against the offending bacteria, such as beta-hemolytic streptococci and staphylococci (including MRSA), have low toxicity, be chemically stable at the site of infection, and be relatively inexpensive. The low pH of infected

Fig. 125.8 MRI scan of osteomyelitis. (A) There is diffuse, abnormal, decreased T1 signal increase. (B) There is an increased STIR signal through the T12 and L1 vertebral bodies, with loss of the normal disk space and enhancement of these vertebral bodies consistent with osteomyelitis and diskitis. (Courtesy Dr. Peter Evangelista, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.)

bone limits the bactericidal action of some antibiotics, particularly the aminoglycosides. Cephalosporins are stable in this environment.

In the ED, the first treatment priority is adequate coverage of *Staphylococcus* spp. with a penicillinase-resistant penicillin, such as oxacillin or nafcillin, or first-generation cephalosporin. In patients with a penicillin allergy, vancomycin is an acceptable alternative. Vancomycin is an often first-line antibiotic when MRSA is considered to be the causative organism. Retrospective studies have demonstrated higher relapse rates after vancomycin compared with those after a β-lactam for non-MRSA bone infections and in those with methicillin-sensitive *S. aureus* (MSSA), so vancomycin should be reserved for those patients with an actual type I penicillin allergy or in whom MRSA is strongly suggested.

Nonenterococcal streptococci are usually sensitive to antibiotics used to combat staphylococci. Gram-negative bacteria, including Enterobacteriaceae, *E. coli, Proteus mirabilis,* and *Serratia marcescens,* are rare causes of osteomyelitis. Third-generation cephalosporins, aminoglycosides, imipenem-cilastatin, and ampicillin are the usual choices for broad gram-negative coverage if this is identified on prior or current cultures. Beyond this initial broad-spectrum therapy, treatment for gram-negative anaerobic bacteria, *Pseudomonas,* and fungal organisms should be based on existing risk factors.

Antibiotics should be dosed to ensure a serum level eight times greater than its minimum inhibitory concentration. Table 125.2 lists common treatment regimens for the variety of bacteria that cause osteomyelitis. The standard recommendation is parenteral antibiotics for 4 to 6 weeks, then transition to an oral course of antibiotics.

Treatment of chronic osteomyelitis is a difficult surgical problem. A variety of adjunctive therapies have been investigated, such as installation of antibiotic-containing beads into infected bone and hyperbaric oxygen therapy.[15,16]

Prevention of posttraumatic osteomyelitis as can occur with an open fracture depends on reducing the concentration of bacteria on exposed bone. The proper management of open fractures in the field is to cut away surrounding clothing, pour sterile saline or water over the exposed bone, and cover the wound with moist sterile gauze bandages or a sterile sheet. Only in the case of severe vascular compromise to the distal limb should an open fracture site be manipulated or realigned because of the danger of introducing bacteria deeper into the wound. Wound surface cultures in the ED setting are not reliable in predicting future pathogens in bone infections and should not be performed. Even a single dose of antibiotics dramatically reduces the bacterial load and should be routinely administered in the emergency department.

Disposition

Patients with osteomyelitis are admitted for IV antibiotic treatment and some will also need operative débridement. After steady-state serum antibiotic levels have been achieved, patients can receive outpatient IV or oral antibiotic therapy.

SEPTIC ARTHRITIS

Foundations

Septic arthritis is an orthopedic emergency, and the incidence appears to be increasing. Even with prompt recognition and appropriate care, septic arthritis leads to a loss of function in 25% to 50% of patients. In the United States, the incidence of septic arthritis in native joints ranges from 2 to 10/100,000 and, in the subset of patients with rheumatoid arthritis, the incidence jumps to 30 to 70/100,000.

Septic arthritis usually results from hematogenous migration of bacteria into a joint and is often a monoarticular process. Like osteomyelitis, septic arthritis may also result from the spread from a contiguous focus of infection, direct inoculation from trauma, or iatrogenically after joint aspiration or injection. The synovial membrane extends beyond the epiphysis and attaches to the metaphysis in the knee, hip, and shoulder joints, allowing bacteria to spread easily from the metaphysis of the femur or humerus into the joint. This explains why septic arthritis may occur concomitantly with osteomyelitis, with infection spreading from bone to joint, and osteomyelitis may also be the result of septic arthritis with infection spreading from joint to bone. The most commonly isolated organism is *S. aureus.* Polyarticular involvement is present in less than 10% of pediatric cases and less than 20% of adult cases.[17] An adjacent infection, such as osteomyelitis and intramuscular

abscesses can also occur. A reactive arthritis, which is more common than bacterial arthritis, is a sterile secondary inflammation of a joint, with no identifiable infecting microorganisms in the synovial fluid. Commonly, reactive arthritis occurs after a systemic viral infection but can also develop after a group A streptococcal infection.

Clinical Features

History and Physical Examination

Septic arthritis is usually more acute in onset than osteomyelitis. The predominant symptom of septic arthritis is joint pain, exacerbated with range of motion. The lower extremity is more commonly affected in all populations. In adults, the knee is the site of septic arthritis 50% of the time, followed by the hip (25%) and shoulder (15%). Immunosuppressed patients, especially those receiving corticosteroids, may have septic arthritis with minimal joint pain. It is important in obtaining the patient's history to identify underlying joint disease, such as osteoarthritis, gout, rheumatoid arthritis, or joint surgery or a past medical history for chronic systemic disease, immunodeficiency, prolonged steroid use, or history of injection drug use. In these patients, a careful history may help differentiate chronic joint pain from the acute pain associated with septic arthritis.

On presentation, more than 80% of children and 40% of adults with septic arthritis have a fever; constitutional symptoms such as weakness, malaise, anorexia, nausea, and diffuse myalgias are inconsistently reported. If the hip is infected, the patient may present with referred pain to the thigh or knee. Many children who have septic arthritis will not use the involved limb.

On physical examination, tachycardia and hypotension may indicate a generalized septic process. In the neonate or infant, there may be a so-called pseudoparalysis of the affected limb. This can be mistaken for a neurologic problem; however, an isolated true paralysis is far less common than septic arthritis. The inability of a child to bear weight on a lower extremity or to move any joint spontaneously should be considered a sign of septic arthritis and should be investigated.

In the older child and adult, signs may be more localized. The extremity will usually be held in the position of greatest comfort, which is slight flexion. Palpation of the septic joint will cause exquisite pain, and any maneuver that stretches the synovium, such as flexion and extension, will cause severe pain. The cardinal signs of inflammation—swelling, erythema, and warmth—are commonly found in the infected joint. Joint pain is 80% to 100% sensitive for septic arthritis, and tenderness is 100% sensitive. Periarticular processes such as bursitis, tendinitis, and cellulitis may produce erythema, warmth, and tenderness, but a thorough physical exam can help differentiate from septic arthritis. Palpation of the joint line and maneuvers that stretch the synovium and joint are usually not painful in cellulitis. Periarticular processes also do not commonly produce an effusion. In general, the triad of fever (seen in 45% to 60% of cases), pain (seen in 75% of cases), and impaired range of motion suggests septic arthritis. One caveat with the physical examination is that an increasing number of patients have been receiving chronic immunosuppressive drugs; in these patients, the classic history and examination findings are significantly less dramatic than in their immunocompetent counterparts.

Complications

Septic arthritis leads to two types of serious complications, those involving the joint itself and those that are systemic. The introduction of bacteria into a joint triggers a profound immune response that leads to destruction of the articular cartilage. Bacteria, host synovial cells, chondrocytes, neutrophils, and macrophages all release enzymes and inflammatory chemicals such as collagenase, elastase, hyaluronidase, lipase, and lipoproteinase, which are destructive to the joint. Damaged articular cartilage has limited repair capacity, and a common result of articular cartilage destruction is arthritis or ankylosis, which results in a stiff and immobile joint.

Children are at great risk for epiphyseal damage if the infection extends through subchondral bone. This can progress to growth impairment and limb length discrepancy.

Other tissues adjacent to the joint can be invaded, leading to suppurative destruction of bursae, tendons, ligaments, or muscles. Sinus tracts may lead the infection out through the skin. In the hip, the pressure and edema of a septic synovial effusion can occlude the tenuous blood supply to the femoral head, resulting in avascular necrosis, especially in neonates.

The hematogenous spread of bacteria from an infected joint can produce sepsis, septic shock, and death. Seeding of other sites with bacteria is also a possibility, though less common, and this can produce endocarditis, pneumonia, and systemic sepsis.[18]

Clinical Subsets of Septic Arthritis

Bites. The human mouth is a polymicrobial environment comprised of aerobic organisms, such as *Staphylococcus*, oral gram-negative rods, such as *Eikenella corrodens*, and anaerobes, such as *Fusobacterium*, making bone and joint infections caused by human bites difficult to treat. Similarly, animal bites also lead to a polymicrobial infection, with *Pasteurella multocida* an important additional organism seen in cat bites. Antibiotics should be empirically started, but treatment may also require drainage and débridement.

Infants and Children. Septic arthritis is more common in children than in adults, and the incidence of septic arthritis is twice that of osteomyelitis in children. Two-thirds of pediatric cases occur in children younger than 2 years, and boys are affected twice as often as girls. The offending agent in septic arthritis varies with age. In the post–*H. influenzae* vaccine era, overall, *S. aureus* (methicillin-sensitive more than methicillin-resistant) is the most common infecting organism in all pediatric and adult age groups, followed by group A streptococci and *Streptococcus pneumoniae*. In neonates, group B streptococci, *S. aureus,* and gram-negative enteric bacilli are usual pathogens. *Candida albicans* should also be considered in neonates and premature infants. *K. kingae* has been emerging as an important cause of septic arthritis and osteomyelitis in children younger than 2 years and often appears concurrent or shortly after an oropharyngeal infection. Prior trauma or skin infection may be more common with staphylococcal septic arthritis.

In the pediatric population, the hip and knee have equal rates of infection, with each accounting for about one-third of infections. Patients may have concurrent osteomyelitis, and this diagnosis impacts management.[17,19,20]

Laboratory work, including complete blood count and determination of the ESR and CRP level, are part of the routine evaluation of the limping child but, individually, do not have adequate sensitivity or specificity to rule in or rule out the diagnosis. The Kocher criteria of fever (temperature ≥38.5°C [101°F]), non–weight-bearing on the affected side, ESR greater than 40 mm/hr, and peripheral blood WBC count more than 12,000 cells/mm^3 (Table 125.3), can be used to help identify children with septic arthritis of the hip and when combined with the CRP, can help determine which patients require arthrocentesis and orthopedic consultation. When all 5 markers are negative, patients were found to have less than a 1% chance of having septic arthritis.

A synovial fluid analysis should be performed if there is any suspicion for septic arthritis. Even when cultures of synovial fluid and blood are tested, a causative organism is not discovered in up to 30% of cases of septic arthritis in children. Prior antibiotic treatment in children decreases the yield on synovial fluid cultures from 80% to 38%.

TABLE 125.3 Kocher Criteria

No. of Kocher Criteria Met	Likelihood of Septic Arthritis of the Hip
1	3
2	40

4	99

Gonococcal Septic Arthritis. In the United States, *N. gonorrhoeae* is the most common cause of septic arthritis in sexually active patients. A person with gonorrhea of the urethra, cervix, rectum, or pharynx has a 1% to 3% chance to develop disseminated gonococcal infection (DGI). More than 75% of cases of DGI occur in women, possibly because of their increased risk of asymptomatic infection. DGI is common during pregnancy or after menstruation, when the alkaline vaginal environment makes the organism more resistant to host defenses in the bloodstream and therefore more likely to disseminate. Septic arthritis develops in approximately 40% of patients with DGI.

The classic triad of gonococcal bacteremia is migratory polyarthritis, tenosynovitis, and dermatitis. Asymmetric polyarthralgia, which may be migratory, is the most common presenting complaint, occurring in two-thirds of cases; 25% of patients have monoarthralgia. Polyarthralgia is usually asymmetric and most frequently involves the knee, although the elbow, wrist, metacarpophalangeal, and ankle joints are also affected. The sacroiliac and sternoclavicular joints may be involved, although these sites are far less common. The patient will present with classic signs of a septic joint, including a joint effusion, warmth, tenderness, decreased range of motion, and marked erythema. There is usually no clear progression of DGI and polyarthralgias to purulent monarticular arthritis, and many patients are afflicted with dermatitis and tenosynovitis without the development of true arthritis. Some strains of *N. gonorrhoeae* that produce DGI favor the development of tenosynovitis and dermatitis, whereas others favor the development of purulent arthritis.

Hemorrhagic pustules on the skin, scattered, painless, nonpruritic, small (0.5- to 0.75-cm) papules distributed below the neck that can involve the palms and the soles, are seen in 41% of cases. These papules can turn into pustules on a broad erythematous base with a necrotic or hemorrhagic center. There are usually fewer than 50 lesions, distinguishing DGI from the rash of meningococcus.

The diagnosis of gonococcal arthritis is difficult. In patients who present with localized purulent arthritis, *N. gonorrhoeae* will be isolated in only about 50% (range of 25% to 75%) of synovial fluid specimens.

In septic arthritis due to gonorrhea, the synovial fluid WBC count is often less than 50,000 cells/mm^3, Gram stains of aspirated joint fluid are positive for bacteria only 25% of the time, and cultures of the joint fluid are negative in approximately 50% of cases. This may be due to poor culture techniques or because a suppurative reactive process can occur in the joint in DGI, even when bacteria are no longer present. When gonococcal arthritis is suspected, cultures for *N. gonorrhoeae* should be obtained from mucosal surfaces, because these may be the only places where bacteria are readily recovered. Cultures of the genital tract, pharynx, or rectum will be positive in 80% of cases of gonococcal arthritis. Nucleic acid amplification testing of either urine specimens in both men and women or vaginal swabs in women is preferred, if available. This has a sensitivity over 75% and should be performed if gonococcal arthritis is considered.

Gonococcal septic arthritis responds rapidly to antibiotic treatment and, unlike other types of bacterial arthritis, rarely causes permanent damage to the joint. Patients with gonococcal septic arthritis require hospital admission, with antibiotic coverage against the likely pathogens until laboratory results are available. With the rise in fluoroquinolone-resistant gonorrhea, the recommended treatment of gonococcal arthritis is a third-generation cephalosporin, such as ceftriaxone, ceftizoxime, or cefotaxime. Patients are given the first dose via the IV route or intramuscularly in the ED and admitted until culture results are available. A presumptive diagnosis of gonococcal arthritis, or disseminated gonorrhea, is best treated with inpatient therapy involving intravenous administration of 1 gm of ceftriaxone every 24 hours.

Lyme Arthritis. Lyme disease, the most common tickborne disease in the United States, is caused by infection with a spirochete, *Borrelia burgdorferi*. Transmitted by the *Ixodes* tick, it is an important cause of arthritis in endemic areas, and its incidence has been increasing. Lyme disease has been reported in all 50 states, but endemic areas, including Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Wisconsin, Connecticut, Delaware, and Rhode Island, account for 93% of all cases annually. There is a bimodal age distribution in children aged 5 to 9 years and adults aged 55 to 59 years. Children infected by *B. burgdorferi* are more likely than adults to have arthritis as the initial manifestation of the disease. Although it is important to determine a history of a tick bite, up to 30% of people do not remember being bitten.

Arthritis, which is the most distinguishing feature of late-stage Lyme disease, develops in up to 60% of untreated Lyme patients and is manifested months after disease onset. After infection, spirochetes are disseminated and invade synovial joints, resulting in a profound immune response, similar to that seen in bacterial arthritis. Patients with Lyme arthritis present with migratory polyarthralgia that also involves bursae and tendons. This typically evolves into a monarticular process and usually involves single large joints. More than 90% of patients report knee inflammation, but other affected joints include the wrist, elbow, ankle, and hip.

The rash is often overlooked by patients and is generally not present in patients when they present with arthritis. However, fever is noted in up to 50% of all children who have Lyme arthritis. Clinically, the arthritis is similar to other inflammatory processes of the joint and includes warmth, erythema, swelling, and pain on motion of the joints; however, the effusion is usually large and out of proportion to the patient's complaints. The effusion also generally recurs after aspiration, even when the joint is appropriately treated.

The most widely used test for the diagnosis of Lyme disease is the serum antibody titer, including enzyme-linked immunosorbent assay (ELISA) and Western blot testing, but serum testing does not differentiate between acute and past infections. Synovial fluid analysis is not helpful in distinguishing Lyme arthritis and cultures are typically negative, but it usually reveals an inflammatory process with WBC counts that have been reported to have a very wide range, from 500 to 98,000 cells/μL. Arthrocentesis cannot differentiate between bacterial and Lyme arthritis because serologic analysis is similar. Testing of synovial fluid with ELISA or Western blot methods for Lyme disease is not recommended because no consensus exists on how to interpret these data. Lyme arthritis can be successfully treated with oral doxycycline, amoxicillin, or cefuroxime for 30 days. If this is unsuccessful, patients can be re-treated with the same oral regimen for another 30 days, or the antibiotic can be changed to IV ceftriaxone for 14 to 30 days.

Fortunately, Lyme arthritis has an excellent prognosis. Up to 95% of children remain asymptomatic after a single course of antibiotics; adults may show an increased incidence of persistent joint swelling months to years after the initial infection, even after appropriate antibiotics.

Periprosthetic Joint Infections. Infections occurring after joint replacement are a challenging and dangerous complication of arthroplasty, with rates reported to be 0.5 to 2% for knee replacements, 0.5 to 1% for hip replacements, and less than 1% for shoulder replacements. The prosthesis and cement are foreign bodies and are ideal sites for bacterial colonization. The most common infectious agents are *S. epidermidis* (40% of cases), *S. aureus,* methicillin-sensitive and methicillin-resistant (20%), and streptococcal species (20%). Risk factors for periprosthetic joint infections have been identified and include rheumatologic disease, preoperative anemia, coagulopathy, diabetes, depression, and low socioeconomic status. The American Academy of Orthopaedic Surgeons clinical practice guideline summary recommends that patients who present to the ED should initially be stratified to high or low probability for a periprosthetic joint infection. As with many diagnostic maneuvers performed in the ED, a pretest probability helps guide the evaluation.

On history and physical examination, the patient will complain of pain that is constant and present at rest, along with impaired function of the joint secondary to loosening of the hardware. Radiographs may also reveal movement of the prosthesis, bone erosion, new subperiosteal bone growth widening, or more than a 2-mm lucency at the bone-cement interface. The laboratory data should include an ESR and CRP level; if both test results are negative, a periprosthetic infection is unlikely (negative likelihood ratio, 0–0.06); when both test results are positive, a periprosthetic infection must be considered (likelihood ratio, 4.3–12.1). However, many inflammatory processes can result in an elevation of the ESR and CRP level, and these are not specific tests. The use of either test alone is less reliable, and no definitive conclusion can be drawn with just one result. In patients with an elevated ESR or CRP level in whom a prosthetic joint infection is suspected, consultation with the patient's orthopedic surgeon about the decision to perform joint aspiration in the ED and the selection and timing of antibiotics in suspected periprosthetic joint infection is advisable.

A synovial WBC count more than 1100 cells/mm^3 with more than 64% neutrophils is a sensitive and specific marker for periprosthetic joint infection in a patient with an elevated ESR (>30 mm/hr) and CRP level (>10 mg/L). Because of the difficulty in isolating infectious organisms from the prosthetic joint, even if done intraoperatively, in stable patients, antibiotics should not be started until after culture specimens are obtained.

Patients With Existing Joint Disease. Patients with underlying joint disease, especially rheumatoid arthritis or a crystal arthropathy, are at increased risk for septic arthritis. If septic arthritis is suspected, laboratory and radiographic evaluation are of lower yield in patients with these conditions compared to those without joint pathology. To reduce mortality, antibiotics are started immediately after synovial fluid is sent for testing. In patients with a crystal arthropathy, neutrophil invasion secondary to septic arthritis also leads to increased precipitation and release of crystals. Therefore, the emergency clinician who discovers crystals on joint fluid aspiration should not abandon the search for an infectious agent.

Atypical Joints. Septic arthritis can be particularly difficult to diagnose and treat if it occurs in fibrocartilaginous joints, such as the sternoclavicular, acromioclavicular, sacroiliac, or symphysis pubis. Septic arthritis of the axial skeleton, especially of the sternoclavicular joint, is commonly seen in injection drug users, with *Pseudomonas* a common infecting agent. In patients who are not injection drug users, the most common bacterial causes are *S. aureus* and *S. epidermidis*. The presentation is usually pain and point tenderness over the involved joint. Fever and an elevated ESR are commonly reported, although they are not always present because of the often suppressed immune status of the patient. As with other cases of septic arthritis and osteomyelitis, MRI with contrast is the preferred imaging modality and is helpful in the diagnosis of septic arthritis in the fibrocartilaginous joints.

Differential Diagnoses

Many disease processes can be confused with septic arthritis. Toxic or transient synovitis, an inflammatory process common in children, especially after an upper respiratory infection, can be confused with septic arthritis. It occurs in the 3-month to 6-year age range, usually affects the hip, and is a self-limited disease, with no long-term morbidity. Children with transient synovitis have less pain with passive joint motion than patients with septic arthritis; they do not usually have a fever or appear ill but tend to favor the unaffected leg, as in septic arthritis. The diagnostic evaluation typically reveals a normal WBC count and ESR and no radiographic abnormalities.

Metaphyseal osteomyelitis may mimic septic arthritis because the adjacent joint may develop an effusion, and the two infections can be concurrent. Juvenile rheumatoid arthritis is usually more gradual in onset and produces polyarticular arthritis in children younger than 16 years but may be manifested as a monoarticular process that mimics septic arthritis.

Other diseases of the hip in children that are included in the differential diagnoses are Legg-Calvé-Perthes disease (avascular necrosis of the femoral head) and slipped capital femoral epiphysis; however, these processes are not as acutely disabling as septic arthritis. Rheumatic fever commonly presents with a migrating polyarthritis and may mimic gonococcal bacteremia. Patients with Lyme arthritis are not as debilitated as those with septic arthritis. In endemic areas, serum antibody titers for Lyme should be obtained early in the evaluation of the patient with an effusion.

In the adult, osteoarthritis, gout, and pseudogout may produce findings on joint examination similar to the findings of septic arthritis. Other arthropathies, such as psoriatic arthritis, arthritis associated with inflammatory bowel disease, ankylosing spondylitis, crystal-induced arthritis, and drug-induced arthritis should also be considered in the differential diagnosis of septic arthritis. Collectively, these are known as the seronegative spondyloarthropathies. Trauma to the joint can produce synovitis and hemarthrosis, which may be mistaken for septic arthritis. In a patient with hemophilia, hemarthrosis causes joint inflammation and destruction, and there may be superimposed infection.

Reactive arthritis has traditionally been considered to be a sterile inflammatory response to a distant infection. However, antigens from the infectious trigger are often present in the joint. Several viral and bacterial microorganisms can produce reactive arthritis. The most recognized syndrome is poststreptococcal reactive arthritis. Some other common organisms that cause reactive arthritis are *Chlamydia, Salmonella, Shigella, B. burgdorferi* (Lyme disease), *Yersinia,* human T-lymphotropic virus type 1, rubella virus, hepatitis B virus, adenoviruses, parvovirus, and Epstein-Barr virus. Reactive arthritis can usually be distinguished from septic arthritis because it tends to involve multiple joints in a migratory pattern, the inflammatory process is less severe with reactive arthritis, there is less effusion, the joint is not as hot or tender as it is with septic arthritis, and joint fluid cell counts are usually below 50,000 cells/mm^3.

Diagnostic Testing

Serum and Urine Tests

Blood tests are not consistently helpful in making a diagnosis of septic arthritis. Serum leukocytosis is nonspecific and nonsensitive for diagnosis of septic arthritis. Traditionally, a serum WBC count more than 10,000 cells/mm^3 may suggest a systemic illness but is present in only 50% of patients with septic arthritis, and many sterile inflammatory

processes create a similar leukocytosis. The ESR is elevated in approximately 90% of cases and, along with the CRP level, can be used to help diagnose the infection and track resolution. When low thresholds are used in the ED, the sensitivity of ESR is reported to be 98%, with a cutoff of 10 mm/hr or more, and the sensitivity of CRP is 92%, with a threshold of 20 mg/L or more. A sensitivity of 96% for an ESR higher than 30 mm/hr has been demonstrated. A procalcitonin level more than 0.5 ng/mL is another possible serum marker for septic arthritis, but is also nonspecific and is often not readily available in the ED.[21] Synovial presepsin is another potential biomarker that seems to be both specific and sensitive in septic arthritis but needs to be tested further.[22]

Two sets of blood culture specimens should be obtained; however, blood cultures reveal the infecting organism in the minority of cases of both osteomyelitis and septic arthritis.[7,23] Cultures of infectious foci, such as the throat, cervix, and urine, may demonstrate the bacteria responsible for septic arthritis. Synovial leukocyte esterase has been studied as a possible new indicator for a septic arthritis; it is especially sensitive and specific in prosthetic joints, with initial studies showing a high sensitivity and specificity.[24]

Joint Fluid Analysis

The diagnosis of septic arthritis requires joint fluid for culture and analysis. The knee joint is the most likely to be infected and is the easiest to aspirate. Aspiration of other joints, such as the hip, often requires interventional radiology or orthopedic surgical consultation. When violating the joint capsule, aseptic technique should always be practiced. This has resulted in reducing the risk of introducing infection into a joint during intraarticular aspiration or injection, reported to be between 1 in 2000 to 1 in 15,000 injections,

Because joint fluid analysis is not performed as often as other diagnostic tests in the ED, a joint fluid protocol is useful to ensure that all necessary tests are prepared and ordered properly. To increase the bacterial yield from joint fluid, blood culture bottles should be inoculated with joint fluid immediately after joint aspiration. This allows some bacteria, which would normally die before being inoculated on culture media in the laboratory, to survive and grow in the blood culture bottle (brain-heart infusion broth). The sample should include special media to test for fastidious organisms such as *N. gonorrhoeae.* Anaerobic and fungal organisms should be cultured in patients with risk factors for these infections.

When only a small volume of synovial fluid is recovered from a joint aspiration, the single most important test is a cell count. If extra fluid is available after a cell count is obtained, other tests should be performed, including Gram stain and culture, crystal analysis, and joint fluid glucose level. The definitive test to determine bacterial arthritis is synovial culture. Tissue cultures from the operating room are more useful than fluid for identifying the offending organism and its susceptibility, but administration of antibiotics should not be delayed for these results.

Even with an adequate joint fluid sample, proper culture techniques, and the presence of fastidious organisms, synovial Gram staining results in clinically suspected septic arthritis are negative 45% to 71% of the time, likely due to the planktonic state of the bacteria in the joint. A positive result of Gram staining can be used to guide antibiotic treatment; however, empirical treatment should not be delayed if the result is negative.

Traditionally, a synovial fluid leukocyte count of more than 50,000 cells/mm^3 with a predominance of polymorphonuclear leukocytes was used to define septic arthritis, but other processes can produce similar cell counts. Up to 30% of patients with septic arthritis have been documented to have counts well below 50,000 cells/mm^3.

Many studies have not supported the idea that a specific range of elevation of the synovial fluid leukocyte count can be reliably used to diagnose septic arthritis. One large study found that a synovial fluid WBC count higher than 17,500 cells/mm^3 has a sensitivity of 83% and specificity of 67% for septic arthritis. The positive likelihood ratio at this level was 2.5, with a negative likelihood ratio of 0.25. A synovial fluid leukocyte differential count with at least 90% neutrophils suggests septic arthritis, with a likelihood ratio of 3.4; a count of less than 90% decreases the likelihood ratio. There is mounting evidence that one cannot rely solely on the synovial fluid leukocyte count to exclude or include the diagnosis of septic arthritis; this value should be used with the clinical, radiographic, and laboratory findings to help guide therapy as Gram staining and culture results become available.

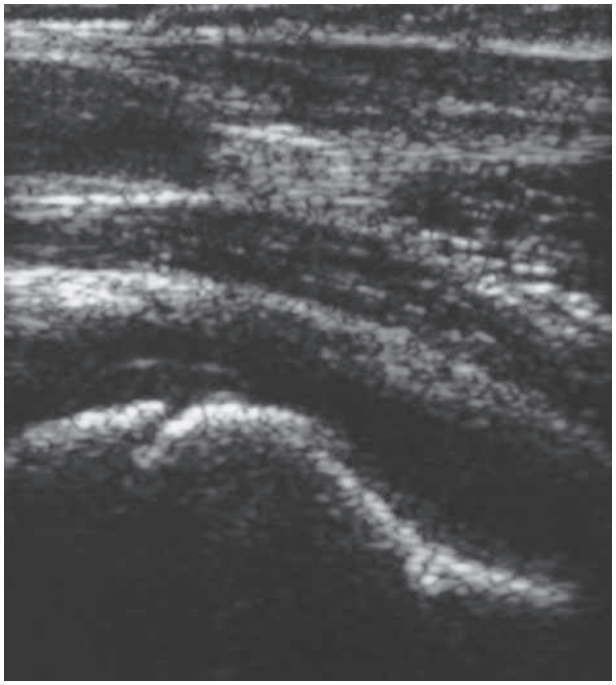

Fig. 125.9 Ultrasound image of the right hip in an 8-year-old girl with septic arthritis. A significant joint effusion can be seen just superior to the round contour of the femoral head. Joint aspiration revealed purulent fluid, with a white blood cell count of 71,000/mm^3.

The examination of synovial fluid under polarizing microscopy for the presence of crystals may be useful in the differentiation of inflammatory from noninflammatory joint disease but is not helpful in identifying infection in this population because the two often coexist. The identification of crystals does not rule out an infectious cause of the joint pain.

Imaging

Plain radiography is not an effective tool for the early evaluation of septic arthritis but may detect surrounding osteomyelitis. In most joints, the small areas of attachment of the synovial membrane to bone are devoid of cartilage. These so-called bare areas at the margins of the joint appear as lucencies or erosions early in the course of septic arthritis. Bone beneath the articular cartilage may start to erode 1 to 3 weeks into the disease. Air in the joint may be a sign of infection with gas-forming organisms but may be the result of a previous joint aspiration. In patients with existing joint disease, radiographs provide minimal assistance in the diagnosis of septic arthritis.

For joints that are not visualized, other than a physical examination, a variety of modalities are available to help detect a joint effusion, which under the right circumstances could suggest septic arthritis. Ultrasonography is a useful modality to help detect a joint effusion and assist in joint aspiration, particularly of the hip[25] (Fig. 125.9). CT and MRI provide detailed anatomic images of the joint, and MRI can also help

TABLE 125.4 Guidelines for Choice of Empirical Antibiotic Based on Gram Staining Results

Gram Stain or Clinical Condition	Probable Organism	Preferred Antibiotics	Alternative Antibiotics
Gram-positive cocci	*Staphylococcus aureus* Streptococci	Nafcillin or cefazolin	Clindamycin Trimethoprim-sulfamethoxazole Vancomycin
Gram-negative cocci or negative stain Healthy, sexually active patient	*Neisseria gonorrhoeae*	Ceftriaxone	Doxycycline
Gram-negative bacilli	*Pseudomonas aeruginosa* Enterobacteriaceae	Piperacillin ± gentamicin	Fourth-generation cephalosporin
Gram-positive bacilli	*Propionibacterium acnes*	Penicillin G	Nafcillin Vancomycin

Reprinted with permission from: Rao N, Esterhai JL Jr. Septic arthritis. In: Cierny G 3rd, McLaren AC, Wongworawat MD, eds. *Orthopaedic Knowledge Update: Musculoskeletal Infection*. Rosemont, IL: American Academy of Orthopaedic Surgeons; 2009.

determine if septic arthritis is complicated by concurrent osteomyelitis. CT and MRI can identify joint fluid but not necessarily an effusion, because a volumetric analysis cannot be done to assess the amount of fluid. In adult patients with an antalgic gait and painful internal and external rotation of the hip, MRI findings of bone marrow edema led to a diagnosis of septic arthritis only 6% of the time.

Skeletal scintigraphy (bone scanning) has been used in the diagnosis of septic arthritis, but its use has been decreasing. The main advantage of skeletal scintigraphy is for the detection of septic arthritis earlier than with other imaging techniques. In septic arthritis, scintigraphy shows symmetrical areas of increased uptake on both sides of the joint. In a three-phase ^{99m}Tc scan, all three phases will be hot with septic arthritis. In general, skeletal scintigraphy is used only when there is enough uncertainty about the diagnosis to warrant further investigation. However, in joints where aspiration is easier, skeletal scintigraphy has little role in diagnosis.

Management

Septic arthritis is an orthopedic emergency and, once synovial fluid is obtained, empirical antibiotics should be promptly administered based on Gram stain results, when possible (Table 125.4). Whereas many joint infections require surgical joint irrigation and débridement, there are a few cases in which medical management will suffice, such as gonococcal septic arthritis and Lyme arthritis.

Unlike most other infectious emergencies encountered in the ED, when time to antibiotic administration decreases morbidity and mortality, definitive management for most cases of septic arthritis requires surgical intervention and a prolonged course of antibiotics. Therefore, it is more important to obtain synovial fluid for Gram staining and culture than to start antibiotics, because this will guide appropriate long-term antibiotic treatment. In the hemodynamically stable patient in whom septic arthritis is a strong consideration, antibiotics should be held until blood and synovial fluid cultures are obtained.

The selection of antibiotics for the treatment of septic arthritis is outlined in Table 125.2. In most cases, because the emergency clinician does not know the identity of the causative organism, treatment should be tailored to the most likely causative agents based on the patient's age, history, and immune status, as well as results from the gram stain.

In general, if the initial Gram stain of synovial fluid demonstrates gram-positive cocci, empirical treatment starts with vancomycin whereas empirical treatment of gram-negative bacilli starts with a cephalosporin. In cases where pseudomonas is suspected, the antibiotic regimen should consist of two antipseudomonal agents such as ceftazidime with ciprofloxacin or gentamycin. Empirical antibiotic choices when the initial Gram stain is negative but there is still a high index of suspicion for a septic joint typically start with vancomycin.

S. aureus accounts for 44% of cases and remains the predominant pathogen for all age groups. Unless gonococcal arthritis, the most common cause of arthritis in young adults, is confirmed, the antibiotic selected should be bactericidal against *S. aureus*. Empirical antibiotics active against MRSA should be considered but should be based on the prevalence of this pathogen in the community. Group B streptococci have emerged as invasive pathogens in older adults, especially those with diabetes mellitus, cirrhosis, and neurologic disease. Penicillin- and fluoroquinolone-resistant strains of gonorrhea have become more prevalent, and a third-generation cephalosporin is the best choice for gonococcal arthritis. In older adults, gram-negative septic arthritis is more common, and agents such as the third-generation cephalosporins and aminoglycosides are added to the antistaphylococcal regimen. Establishment of good bactericidal serum levels of antibiotics will ensure that the levels in joint fluid are also bactericidal. In pediatrics, the use of dexamethasone to accelerate clinical improvement is no longer recommended.[26]

Disposition

Any patient thought to have septic arthritis requires joint aspiration. Patients for whom septic arthritis is considered to be the diagnosis should be given an initial parenteral dose of antibiotics after joint aspiration in the ED and admitted for culture results and continued management. If the joint fluid aspirate is not consistent with septic arthritis and clinical findings are equivocal, the patient can be discharged and reevaluated in 24 hours. In immunosuppressed patients, patients with preexisting joint disease, and patients with a joint replacement, septic arthritis can be difficult to detect. A conservative approach with in-hospital observation and treatment should be considered if there is any possibility of septic arthritis in these patients.

The prognosis for the patient with septic arthritis is favorable in most cases. From 50% to 75% of afflicted patients can expect to recover completely and achieve full painless range of motion of the joint. About one-third of patients have complications such as decreased mobility or ankylosis, pain on joint movement, chronic infection, or overwhelming sepsis and death. The patients most likely to do poorly include those who have had a delay in diagnosis and treatment, patients with underlying joint disease (especially rheumatoid arthritis), those with polyarticular septic arthritis, and those who have positive blood cultures. Despite many advances in diagnosis and treatment, the overall morbidity for patients with septic arthritis has not decreased in the last 3 decades. A general rule is that if the diagnosis of septic arthritis is made

and treatment is initiated within 1 week of the onset of symptoms, the outcome is almost always favorable. Diagnosis and rapid treatment of septic arthritis have proven to be most elusive in two groups of patients, infants and people with existing joint disease. In infants and children, early symptoms can be nonspecific and difficult to assess; consequently, children with septic arthritis, especially of the hip, who experience a delay in diagnosis and treatment have a disappointingly high rate of complications. In patients with existing joint disease, septic arthritis may be mistaken for an acute exacerbation of the underlying disease process, so emergency clinicians must remain vigilant in their pursuit of the correct diagnosis.

CHAPTER 125: QUESTIONS AND ANSWERS

1. Which of the following associations between osteomyelitis and pathogenic organism is true?

a. Dog bite—*Pasteurella*
b. Freshwater wounds—*Pseudomonas*
c. Human bite—*Aeromonas*
d. Intravenous drug use—*Fusobacterium*

Answer: A. The following are correct associations: freshwater—*Aeromonas hydrophila*; intravenous drug use (IVDU)—*Staphylococcus aureus*; sickle cell—*Pseudomonas* and *Salmonella*; cat or dog bite—*Pasteurella multocida*; human bite—mixed with *Fusobacterium*, *Eikenella*, and *Streptococcus anginosus*.

2. Which of the following statements regarding septic arthritis is true?

a. Despite vaccination, *Haemophilus influenzae* remains a frequent pathogen in children.
b. *Pseudomonas aeruginosa* is associated with IVDU-related osteomyelitis.
c. *Pseudomonas aeruginosa* is not associated with prosthetic device joint infection.
d. The most common organism in neonates is *Staphylococcus aureus*.

Answer: B. *Pseudomonas* is associated with IVDU-related cervical osteomyelitis and lumbar osteomyelitis in cases of prolonged urinary catheterization. *H. influenzae* has largely disappeared as a joint pathogen in vaccinated children. The most common neonatal joint pathogens are group B streptococci, *Escherichia coli,* and *Staphylococcus epidermidis*. The most common cause of septic arthritis in people younger than 30 years is gonococcal.

3. Which of the following statements regarding acute hematogenous osteomyelitis in children is ***not*** true?

a. Blood cultures are not usually positive.
b. Skeletal scintigraphy is indicated in neonates.
c. The child usually appears toxic.
d. The most common site is the long-bone epiphysis.

Answer: C. Children may be ill but not usually toxic. There is a 2:1 or 3:1 male predominance, with the most likely site being the distal metaphysis. Blood cultures are positive in 60% of cases. Scintigraphy is not useful in neonates due to a limited inflammatory response. Radiographs are more useful and sensitive early on than in adults.

CHAPTER 125: QUESTIONS AND ANSWERS—cont'd

4. Which of the following statements regarding vertebral osteomyelitis is true?
   - **a.** Children are less prone to isolated diskitis.
   - **b.** Of the cases of epidural abscesses, 30% are due to osteomyelitis.
   - **c.** The diagnostic procedure of choice is a magnetic resonance imaging scan.
   - **d.** The most common location is the lumbar spine.

Answer: D. The incidence of associated epidural abscess is 15%. The most common location of vertebral osteomyelitis is the thoracic, lumbar, and cervical spine. The diagnostic procedure of choice is needle biopsy. The disease usually involves two vertebrae and the disk in between. Children are more prone to isolated diskitis, although it may also occur in adults.

5. An 18-year-old woman with known sickle cell disease presents with leg pain of 2 days' duration. Her typical pain syndrome is lower extremity tibial and femur pain. Today's episode is primarily right tibial. She complains bitterly of pain, but there are no gross findings other than trace bilateral anterior tibial swelling, with no discernible warmth or erythema. Vital signs are remarkable for a low-grade fever and heart rate of 110 beats/min. Which of the following statements regarding this patient's condition is true?
   - **a.** Bony infection would be expected in the bony metaphysis.
   - **b.** Plain radiography can differentiate bony infarction from infection.
   - **d.** *Staphylococcus aureus* would be the most likely infectious cause.
   - **d.** MRI is not necessary as it will not differentiate infection from infarction.

Answer: A. Sickle cell osteomyelitis is more typically seen in the diaphysis than in non–sickle cell situations, which more often involve the metaphysis. Fever, toxicity, and an elevated ESR suggest infection. The most likely infectious cause is now *Salmonella*, followed by *Staphylococcus aureus*. Often, observation and response to therapy (e.g., analgesics, hydration) ultimately help differentiate the two. When in question, an MRI should be pursued.

Skin and Soft Tissue Infections

Michael Pulia and Larissa S. May

KEY CONCEPTS

- Bacterial skin infections such as cellulitis and abscess are common and are rarely life-threatening.
- Necrotizing infection is suggested by pain out of proportion to physical findings, crepitance, gas seen on imaging studies, or clinical instability. Suspected necrotizing infection should be managed with prompt broad-spectrum antibiotics and surgical consultation.
- Emergency clinicians should be familiar with toxic shock syndrome and Rocky Mountain spotted fever, which are rare, life-threatening, systemic infections with skin manifestations.
- Antibiotics reduce treatment failure after surgical drainage of uncomplicated abscesses.
- Current recommendations for the treatment of uncomplicated cellulitis suggest selection of an agent effective against streptococci and methicillin-sensitive *Staphylococcus aureus* (MSSA) (e.g., cephalexin at maximal doses). The addition of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) coverage does not improve outcomes for uncomplicated cellulitis.
- Clindamycin is no longer recommended for routine treatment of purulent SSTIs due to increasing rates of both MSSA and CA-MRSA resistance.
- White blood cell count should not be routinely measured in patients with uncomplicated skin infections.
- Blood cultures are not necessary to evaluate skin infections, except in cases of sepsis, necrotizing infections, immunocompromised hosts, and multifocal infections suggesting hematogenous seeding.
- Mimics such as venous stasis dermatitis are often misdiagnosed as cellulitis. These conditions are termed *pseudocellulitis* and novel tools are being developed that may assist clinicians improve diagnostic accuracy (e.g., ALT-70 and surface thermal imaging).

FOUNDATIONS

Background and Importance

Skin and soft tissue infections (SSTIs) exist on a clinical spectrum from common and typically mild bacterial infections, such as cellulitis and abscess, to relatively rare conditions with high mortality, such as necrotizing fasciitis and toxic shock syndrome. As a group, SSTIs are the third most common type of infection treated in the emergency department (ED), accounting for approximately 2.5% of all encounters.[1] The epidemiology of skin infections remained relatively stable over the past decade since the emergence of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) as the predominant cause of purulent SSTIs in the early 2000s.

Anatomy and Physiology

The skin is the largest organ in the body and accounts for about 15% of total body weight. It has three layers, the hypodermis, dermis, and epidermis (Fig. 126.1). Hair is present throughout the body except on glabrous skin, which is the heavily keratinized skin found on the palms, soles, and parts of the genitals.

The skin has a rich supply of blood vessels, lymphatics, and nerves, although the epidermis is entirely avascular and relies on the dermis for nourishment. The main cell type in the epidermis is the keratinocyte, which has a cytoskeleton composed of keratin filaments, which are proteins. Also living in the epidermis is the Langerhans cell, a motile, macrophage-like, antigen-presenting member of the immune system that originates in the bone marrow. Melanocytes in the epidermis produce melanin.

The epidermis contains the pilosebaceous follicles and sweat glands, known collectively as epidermal appendages. The combination of the hair apparatus and sebaceous gland is known as a pilosebaceous follicle. The epidermal appendages are important as sites of infection because they provide a break in the otherwise continuous protective layer of keratinocytes and create a potential space for bacterial replication. There are two types, sweat glands and follicles. Sweat glands take three forms—eccrine, apocrine, and apoeccrine.

The dermal-epidermal junction is a complex basement membrane whose disruption results in vesicles and bullae. The dermis consists of cells, fibers, and ground substance, which is an acellular material composed of glycoproteins and other macromolecules. The hypodermis, or subcutaneous tissue, is composed largely of adipocytes. The lymphatic system drains interstitial fluid, and its disruption leads to interstitial fluid accumulation and edema.

Pathophysiology

The source of a skin infection may not always be evident. Skin infections may arise from nonvisible breaks in the protective epidermal layer or more obvious portals of entry such as injections, abrasions or lacerations. Hematogenous seeding from another infected site is a less common source. Venous blood and lymph drain from the orbits and skin around them into the cavernous sinuses; thus, bacterial infections in this area can lead to central nervous system infection.

CLINICAL FEATURES

Overview

Most skin infections present with redness (erythema), warmth, and induration. Erythema, caused by microvascular dilation due to the immune response, can present differently depending upon the patient's pigmentation. Thus, emergency clinicians should familiarize themselves with pathology on different skin types. Confluent erythema is typical of most skin infections; discrete macules and morbilliform (measles-like) eruptions are not typical. Induration means hardening and is a common finding with many inflammatory lesions of the skin. Skin that is indurated from cellulitis may become engorged with interstitial fluid and

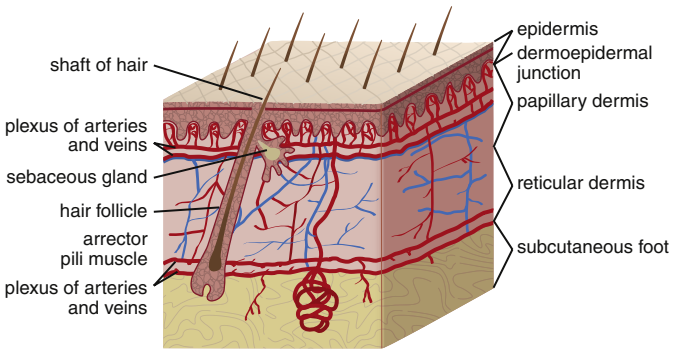

Fig. 126.1 Anatomy of the skin. (From Amirlak B: Skin anatomy. Available at http://emedicine.medscape.com/article/1294744-overview#a1.)

take on the texture of an orange peel due to dimpling where the skin is anchored by hair follicles. This classic finding is known by the French phrase *peau d'orange*. Fluctuance describes a fluid collection palpated on examination. "Pointing" or "coming to a head" conveys a sense of imminent rupture. Crepitance describes skin that feels crackly when palpated and suggests gas is present in the soft tissues.

Many skin infections have characteristic appearances. Well-demarcated erythema with a raised border, particularly on the face, is typical of erysipelas, a streptococcal cellulitis. Linear erythema tracking distally to proximally along a vascular pathway suggests lymphangitis or phlebitis. This usually represents the action of cytokines combating the infection, although proximal spread of the infection is a possibility. Vesicles suggest contact dermatitis, herpes simplex, varicella-zoster, or impetigo. Pruritic serpiginous (snakelike) lesions that are not particularly tender suggest an intracutaneous parasite, such as scabies (hands, intertriginous areas), hookworm larvae (feet or buttocks), or strongyloidiasis. Parasitic nematodes (e.g., Guinea worm) and insects (e.g., botfly) should be considered in the setting of a nodule after exposure to fresh water or insects in developing countries.

Other systemic infections may present with significant skin manifestations. Less common color changes associated with infection stem from small hemorrhages, vasculitis, or septic emboli. Janeway lesions are painless red, purple, or brown spots, usually seen on the hands or feet, due to septic emboli from infective endocarditis. Painless discolorations of the palms and soles may indicate secondary syphilis or Rocky Mountain spotted fever. Petechiae and purpura can indicate overwhelming bacterial infection, as with meningococcemia. When the diagnosis of infection is not clear, vasculitides such as Kawasaki syndrome in children and granulomatosis with polyangiitis should be considered. Intracutaneous pustules on the palms or soles of the feet are often due to a form of psoriasis called palmoplantar pustulosis, which can be uncomfortable for the patient, but is benign.

Fever is present in approximately 20% of patients with abscesses and 50% of patients with cellulitis presenting to the ED. Febrile skin infections are more common in children; in adults, fever may indicate a more serious infection. Skin infections can suggest underlying systemic illness. For example, a young man who presents with balanitis may have diabetes as the underlying problem. Disseminated varicella (other than the primary episode of chickenpox) suggests an immunocompromised state.

CELLULITIS

Clinical Features

Cellulitis is an inflammatory condition of skin and subcutaneous tissue caused by bacterial infection. Cellulitis may be purulent or nonpurulent and may occur in the setting of wounds, foreign bodies, or impaired perfusion. Purulent cellulitis drains freely, in contrast to abscesses, which are walled off by fibrous tissue and epidermis. CA-MRSA is the leading cause of purulent skin and soft tissue infections in ED patients but is not a common cause of nonpurulent cellulitis.

The cardinal feature of cellulitis is inflammation with increased local blood flow. Pain may be variable, but most patients without neuropathy have some degree of tenderness. The inflammation of cellulitis is typically confluent, although it may be patchy. The borders are typically poorly defined and irregular. Linear or circular lesions should prompt a search for other underlying causes, such as contact dermatitis or Lyme disease. In some cases of cellulitis, there are streaks of inflammation extending proximally from the main area of inflammation along vascular tracts. This finding is known as lymphangitis and is commonly seen with cellulitis due to streptococci and bite wound–associated *Pasteurella multocida*.

When localized edema becomes severe, epidermal layers can separate, leading to vesicles or bullae. This can make it challenging to distinguish cellulitis from other infectious and noninfectious causes of dermatitis. When the border of an area of cellulitis becomes well-demarcated, raised, and palpable, the term *erysipelas* is used. This form of cellulitis is most often caused by *Streptococcus pyogenes*. The bacterial causes of cellulitis vary according to body site, comorbidities, and environmental exposures (Table 126.1).

Diabetic Foot Infections

Diabetic foot infections are the most common cause of hospitalization for patients with diabetes, and an infected wound precedes two-thirds of lower extremity amputations in patients with diabetes. Neuropathy, vascular insufficiency, and hyperglycemia are important factors in the development of diabetic ulcers and foot infections. Although early antibiotic therapy is important in diabetic infections, to avoid antibiotic overuse, uninfected ulcers should not be treated with antibiotics. In addition to antibiotics, diabetic foot infections require careful wound care and, in some cases débridement, revascularization, or amputation.

The most likely organisms in an acute diabetic foot infection are *S. aureus* and streptococci. Chronic wounds are more likely to be polymicrobial with gram-positive and gram-negative organisms, as well as anaerobes. Chronic wounds that have previously been treated with antimicrobials are more likely to involve multidrug-resistant organisms. *Pseudomonas* is uncommon, although is more likely to occur in patients with diabetes than those without. Deep tissue specimens for aerobic and anaerobic culture or bone samples should be obtained at the time of débridement if deep tissue infection or osteomyelitis is suspected. Organisms cultured from superficial swabs are not reliable for identifying pathogens responsible for deeper infection. Osteomyelitis should be considered a potential complication of any deep or extensive ulcer, especially one that is chronic or overlies a bony prominence.

Bite Wounds

A high proportion of cat bites become infected and presumptive antibiotic treatment is appropriate in the absence of signs of infection. The typical agent is *Pasteurella multocida*. Human bites also become infected frequently (≈25%) with polymicrobial (mixed aerobic and anaerobic) being the predominant pattern. Typical pathogens included oral flora (e.g. *Eikenella, Fusobacterium*, group A *Streptococcus*) and skin flora (e.g., *S. aureus*). Dog bites become infected infrequently (≈16%) and do not require routine antibiotic prophylaxis.[2] However, certain circumstances warrant prophylaxis, including those on the hands, face, genitals, or areas with poor perfusion, or in immunocompromised patients.

TABLE 126.1 Skin Infections: Bacteriology and First-Line Antibiotic Therapy

Anatomic Variant or Predisposition	Likely Bacterial Cause	First-Line Therapy (Nontoxic and Immunocompetent)[a]
Uncomplicated cutaneous abscess	CA-MRSA	Incision and drainage, consider antibiotics
Nonpurulent bacterial skin infections	Various *Streptococcus* spp., *Staphylococcus aureus*	Cephalexin or clindamycin; adjunctive measures
Purulent cellulitis and wound infections	CA-MRSA, *Streptococcus* spp.	TMP-SMX or doxycycline monotherapy; adjunctive measures
Diabetic foot infection	Mixed gram-positive, gram-negative, and anaerobes	Amoxicillin–clavulanic acid plus trimethoprim-sulfamethoxazole; avoid antibiotics for uninfected ulcers.
Any cat bite or infected dog bite	*Pasteurella multocida*, others	Amoxicillin–clavulanic acid
Human bite (treat presumptively)	Oral anaerobes, others	Amoxicillin–clavulanic acid
Erythema migrans	*Borrelia burgdorferi* (Lyme disease)	Doxycycline
Puncture wound through sole of shoe (treat presumptively)	*Pseudomonas aeruginosa*	Levofloxacin
Buccal cellulitis	*Haemophilus influenzae* type b (vaccine serotype)	Ceftriaxone or ampicillin-sulbactam
Balanitis	*Candida albicans* or group A streptococcus	Fluconazole plus penicillin or amoxicillin; consider diabetes
Liposuction	*Peptostreptococcus* (anaerobe), group A streptococcus	Ampicillin–clavulanic acid ± trimethoprim-sulfamethoxazole
Saltwater exposure	*Vibrio vulnificus*	Doxycycline
Freshwater exposure	*Aeromonas* species	Ciprofloxacin
Butcher, clam handler, veterinarian	*Erysipelothrix rhusiopathiae*	Amoxicillin
Black necrotic eschar with raised border and severe surrounding edema	*Bacillus anthracis* (anthrax)	Ciprofloxacin

[a]For life- or limb-threatening infections, use IV equivalents and add vancomycin.
CA-MRSA, Community-associated methicillin-resistant Staphylococcus aureus.

Water-Borne Infections

Exposure and travel history are important considerations in the evaluation of skin and soft tissue infections. *Vibrio* spp., in particular *Vibrio vulnificus*, are associated with exposure to seawater and can cause severe soft tissue infections and sepsis. Patients with liver disease, such as cirrhosis, are particularly at risk. Infection occurs from contamination of open wounds by seawater or shellfish and rarely by hematogenous spread from the ingestion of contaminated seafood, such as raw oysters. *Edwardsiella tarda* is a rare cause of wound infection after seawater exposure; it has been implicated in serious soft tissue infections, including myonecrosis, particularly in patients with liver disease. *Erysipelothrix rhusiopathiae* is usually associated with a localized erysipeloid eruption with minor trauma, often on the hands of seafood workers.

Aeromonas myonecrosis is associated with exposure to fresh water by penetrating trauma or exposure to aquatic animals. It causes rapidly progressive suppurative infections that often require surgical drainage. *Mycobacterium marinum* causes so-called fish tank granuloma. It typically is manifested weeks after exposure as a papule or nodule that may ulcerate and drain serosanguineous fluid. Multiple nodular lesions may develop along the lymphatics.

Differential Diagnosis

Consideration of potential mimics (i.e., pseudocellulitis) is critical when assessing potential cellulitis because the misdiagnosis rate may be as high as 30% in the ED. Common examples of pseudocellulitis include venous stasis dermatitis, burns, viral infections, fixed drug eruptions, lymphedema, venous thrombosis, gout, and contact dermatitis.[3,4] Venous stasis dermatitis in particular may appear similar to cellulitis. It is typically located above the ankle and is often (but not always) circumferential. Persistent erythema despite elevating the affected limb suggests cellulitis. Cellulitis is rarely bilateral and alternative diagnosis should strongly be considered with this presentation. Symmetric venous stasis dermatitis in the afebrile patient should not be confused with cellulitis. The ALT-70 (asymmetry, leukocytosis, tachycardia, age ≥70 years) scoring system has recently been proposed to help differentiate cellulitis from pseudocellulitis but requires further validation before utilization in clinical practice.[5,6] When any dermatologic presentation is accompanied by fever or lymphangitis, co-occurring cellulitis should be considered. Cellulitis must always be distinguished from more severe necrotizing infections, as discussed later.

Lyme disease causes a rash known as erythema chronicum migrans which can mimic cellulitis. It a bright red, round lesion, usually larger than 5 cm, with central clearing that gives a targetoid appearance. It occurs in only 80% of cases of Lyme disease. When the rash is observed in an endemic area, Lyme disease can be diagnosed and treated without further testing. Lyme disease is transmitted by the deer tick, *Ixodes scapularis*, and attachment of the tick for at least 24 hours is necessary for infection. Noninfectious, localized bite reactions from insects, arthropods, and hymenoptera can be mistaken for cellulitis despite their rapid development. In contrast, cellulitis typically develops over a period of days. The time course should be considered before initiation of antibiotics.

Diagnostic Testing

Wound Cultures

For nonpurulent cellulitis, needle aspiration, superficial swabs, and skin biopsy are unlikely to reveal the cause and are not recommended for typical cases. These can be considered in complex cases involving purulent cellulitis, immunocompromised patients, immersion injuries, surgical wound infections, or animal bites.[2]

Blood Cultures

Blood cultures are not indicated in patients with uncomplicated cellulitis. They are recommended in cases involving immunocompromised patients or those with systemic infection (e.g., sepsis). In the past, blood cultures were recommended for facial cellulitis, due to concern over *Haemophilus influenzae* bacteremia. However, the relevant strain (type b) is now covered by childhood vaccination, leading to a revision of this recommendation.

Radiographic Studies

Radiographic studies are not part of the standard diagnostic process for cellulitis but should be utilized in certain clinical scenarios. When a foreign body is suspected, plain radiographs are obtained, although they occasionally miss small or radiolucent foreign bodies. Ultrasonography can detect many foreign bodies. The location and extraction of foreign bodies can be challenging, however, and emergency clinicians must use their judgment in deciding when to use plain films, ultrasound, or both.

If necrotizing infection is suspected, plain radiographs or computed tomography (CT) may reveal soft tissue gas or inflammation along fascial planes, but cannot rule out necrotizing infection. Ultrasound examination is useful for differentiating abscess from cellulitis, as discussed later.

Plain radiographs are used to evaluate for evidence of osteomyelitis for chronic skin infections, especially in patients with diabetes, peripheral vascular disease, and secondarily infected nonhealing ulcers. Plain films are not definitive, and magnetic resonance imaging (MRI) has higher sensitivity for detecting osteomyelitis. CT with intravenous contrast is helpful when there is concern that a skin infection is an extension of a deeper infection (e.g., post-surgery).

Surface Thermal Imaging

Specialized cameras capable of measuring skin surface temperature have been proposed as a means to help differentiate cellulitis from pseudocellulitis by replacing the subjective assessment of tissue temperature through touch with quantitative data. In a recent study, temperature gradients between affected and unaffected limbs were observed to be significantly greater for cellulitis cases as compared to pseudocellulitis.[7] The use of surface temperature gradients in the diagnosis of cellulitis will require further validation before use in routine practice.

Management

Fig. 126.2 is a universal treatment algorithm for skin and soft tissue infections. The algorithm assumes no prior treatment as previously treated infections failing therapy generally require broader spectrum antibiotic coverage and customized management decisions. Table 126.2 summarizes the most commonly used antibiotics for skin and soft tissue infections. As *Streptococcus* spp. and *Staphylococcus aureus* are the predominant organisms causing cellulitis, first-line therapy is cephalexin 500 mg, four times daily for at least 5 days, or an equivalent oral β-lactam (e.g., penicillin VK, dicloxacillin). Trials examining the addition of CA-MRSA coverage for uncomplicated, nonpurulent cellulitis found no reduction in treatment failure and is not recommended.[8,9] CA-MRSA coverage should be added for all cases of purulent cellulitis and cases of treatment failure. The most common strain of CA-MRSA is highly susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), making this the first-line empiric therapy. Critically ill patients (e.g., severe sepsis/shock) with suspected skin infection source should receive broad-spectrum empiric antibiotics, vancomycin plus piperacillin/tazobactam, and the emergency clinician should assess for a necrotizing soft tissue infection. Vancomycin is the recommended parenteral agent for MRSA.[2]

Two long-acting, broad-spectrum antibiotics, oritavancin and dalbavancin, recently have been approved for skin and soft tissue infections. These novel lipoglycopeptides cover all major cellulitis pathogens, including MRSA, and have extremely long half-lives. This results in oritavancin requiring only a single IV infusion for an entire treatment course and dalbavancin using a single IV infusion per week regimen. Clinical experience with these agents is limited but they have been proposed as a cost-effective alternative to hospital admission for complicated skin and soft tissue infections without an absolute need for admission (e.g., sepsis) or when concerns exist about medication compliance.[10-12] Due to the cost and logistical concerns (i.e., infusion time, follow-up plan) associated with these agents, we recommend using them only as part of an established ED pathway developed in partnership with pharmacy and infectious diseases.

We recommend amoxicillin–clavulanic acid for 3 to 5 days as a prophylactic regimen for high-risk bite wounds (i.e., cat or human source, puncture wound, immunocompromised patient, wounds to the hands/face, or penetrating the periosteum/joint capsule.) It is also the first-line agent for infected bite wounds. Doxycycline and moxifloxacin are second-line alternatives.[2] For severe infections, ampicillin-sulbactam is the first-line IV agent.

Patients allergic to penicillin may safely take cephalosporins in most cases due to limited cross-reactivity.[13] For patients with a cephalosporin or life-threatening penicillin allergy (e.g., anaphylaxis), clindamycin is the first-line alternative.

Although adjunctive measures are commonly recommended in the treatment of cellulitis. Extremity cellulitis responds dramatically to compression and elevation. Patients with cellulitis complicating venous stasis or lymphedema should be educated about the importance of compression with elastic socks, sleeves, or wraps. This is helpful for the acute infection and to prevent future episodes. Nonsteroidal antiinflammatory drugs (NSAIDs; e.g., ibuprofen) are helpful for pain control in the absence of contraindications.

Table. 126.1 summarizes the common skin and soft tissue infections, including causative organisms and first-line treatment. Recommendations in the table assume no treatment failure, necrotizing infection, or systemic illness. Cases involving these scenarios require broader-spectrum antibiotic coverage and customized management decisions.

Disposition

Immunocompetent patients with cellulitis who can take oral medications and adjunctive measures can be managed as outpatients. Hospitalization is generally required for patients with systemic symptoms (i.e., fever), immunosuppression, diabetic foot infections, infected lymphedema, or large, multifocal cellulitis. In severe cases, such as sepsis, broad-spectrum IV antibiotics are initiated in the ED prior to admission. ED infusion of novel lipoglycopeptides may represent an alternative option to admission for patients without an absolute indication for hospitalization.

ABSCESS

Clinical Features

An abscess begins when bacteria multiply beneath the epidermis. Neutrophils are drawn to the site of infection, and various cytokines combine with bacterial toxins to promote the development of purulence. A furuncle, or boil, is an abscess of the hair follicle. A carbuncle comprises multiple furuncles with loculations and connecting sinuses, often with multiple sites of drainage. Carbuncles are more likely to occur on the back of the neck and are more prevalent in diabetics.

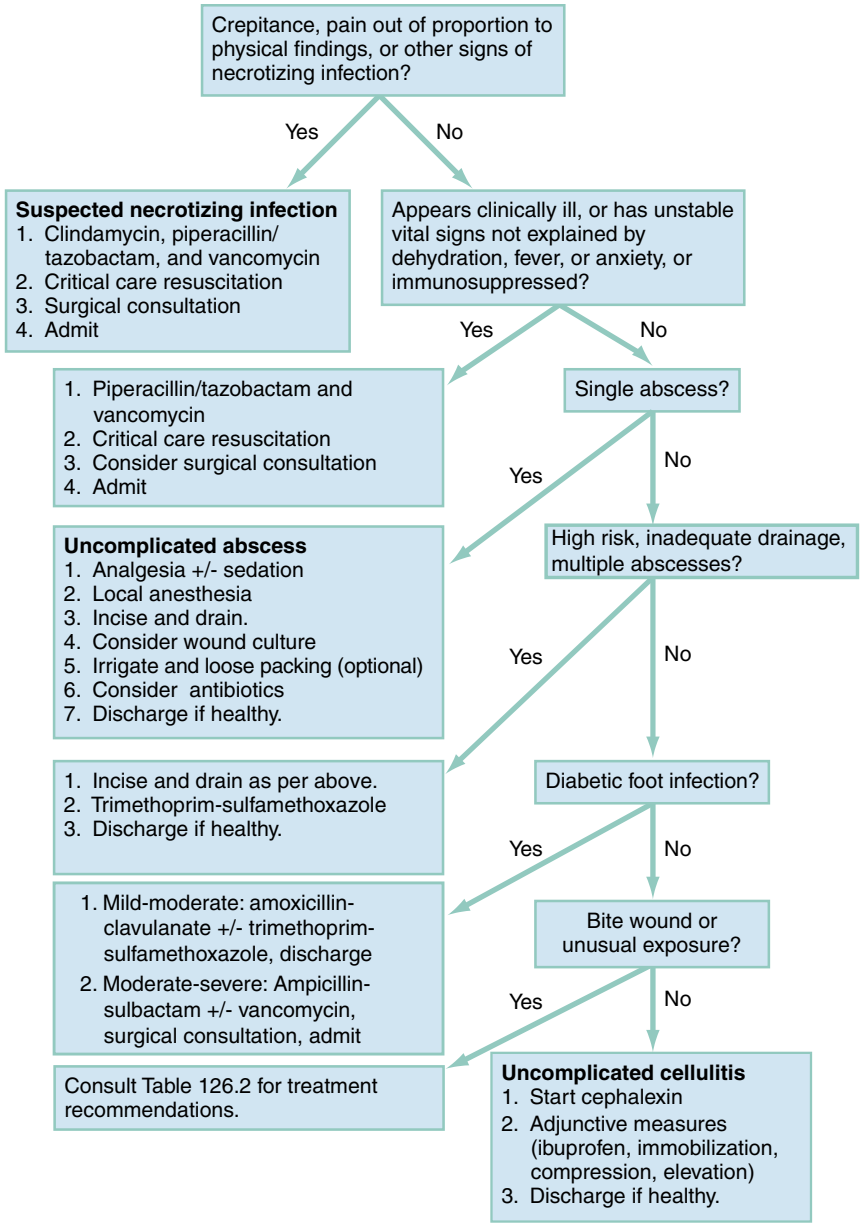

Fig. 126.2 Universal algorithm for skin and soft tissue infections, assuming no prior treatment.

In cutaneous abscesses, the overlying epidermis often prevents drainage and a painful, warm, and erythematous mass is usually seen. Skin abscesses rarely lead to systemic illness and most will eventually rupture through the epidermis and drain spontaneously. Historically, abscesses were caused by MSSA or mixed flora, but today CA-MRSA accounts for the majority of cases in the United States. Whirlpool baths at nail salons have been implicated in mycobacterial furunculosis.

Bartholin gland abscess is caused by an obstructed Bartholin duct. Bartholin gland is located at the upper part of the lower third of the labium majus, and its duct opens onto the mucosa in this area medially but externally to the labium minus. Bacteria cultured are usually a mixture of aerobic and anaerobic flora from the vagina. *Chlamydia trachomatis* or *Neisseria gonorrhoeae* is isolated approximately 10% of the time.

A pilonidal abscess is an abscess at the superior aspect of the gluteal cleft between the buttocks. Because they result from an infected pilonidal cyst, these abscesses are typically recurrent. Acute treatment is the same as for other cutaneous abscesses but patients should be referred for surgical excision of the cyst in recurrent cases.

A stitch abscess is a collection of pus around a suture. Stitch abscesses are generally caused by an inflammatory response in the suture tract and sterile. However, deeper wound infection can be confused with a stitch abscess.

Differential Diagnosis and Diagnostic Testing

The differentiation of abscess from cellulitis can be challenging. Bedside ultrasound examination with a high-frequency linear probe is the best option, improving diagnostic accuracy and management.[14] Abscesses are seen as hypoechoic areas with posterior acoustic enhancement. The hypoechoic areas are pus and may be heterogeneous, with some bright signals (Fig. 126.3A). Cellulitis is seen as a uniformly hyperechoic area or as hyperechoic areas separated by curvilinear hypoechoic areas (see Fig. 126.3B). This appearance is known as cobblestoning and results from interstitial edema.

TABLE 126.2 First-Line Oral Antibiotics for Skin and Soft Tissue Infection

Drug	Mechanism of Action	Pediatric Dose (Mg/Kg; Adult Dose Is Max)	Adult Dose (Mg)	Frequency (Doses/Day)	Special Instructions	Strep	MSSA	MRSA	Anaerobes
Cephalexin	Cell wall synthesis, bactericidal	12.5 qid	500 (max dose 2000 per day)	4		+	+	–	–
Dicloxacillin	Cell wall synthesis, bactericidal	10	250–500	4	Empty stomach	+	+	–	–
Amoxicillin	Cell wall synthesis, bactericidal	15	500	3		+	+	–	±
Amoxicillin–clavulanic acid	Cell wall synthesis, bactericidal	25 bid[a]	875 or 2000 for extended release formulation[a]	2		+	+	–	+
Clindamycin	Ribosome, bacteriostatic	10	300–450	3		+	+	±	±
Trimethoprim-sulfamethoxazole	DNA synthesis (folate metabolism), bacteriostatic	10[b]	160[b]	2	Warfarin interaction, avoid with glucose-6-phosphate dehydrogenase or folate deficiency	–	+	+	±
Doxycycline	Ribosome, bacteriostatic	2.2[c]	100	2	Empty stomach, sun sensitivity	±	+	+	–

[a]Dose by amoxicillin component.
[b]Dose by trimethoprim.
[c]Only for ≥ 8 years old.
MRSA, methicillin-resistant *S.* aureus; *MSSA*, methicillin-sensitive *S.* aureus.

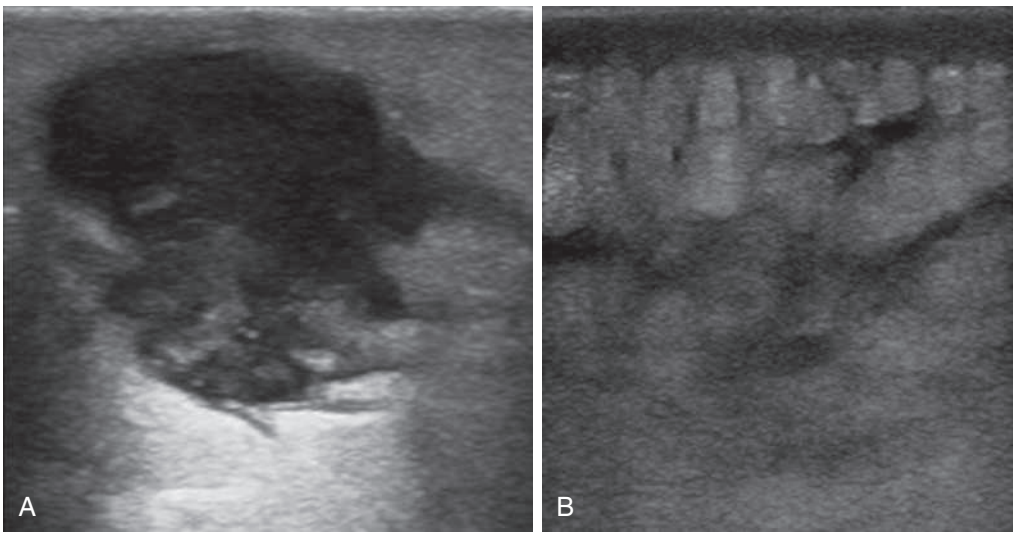

Fig. 126.3 Ultrasound examination to distinguish abscess from cellulitis. (A) Abscess visualized with 8-MHz linear probe demonstrating dark areas (pus) with posterior acoustic enhancement. (B) Cellulitis visualized with 8-MHz linear probe demonstrating cobblestoning. (Courtesy Dr. Mark W. Byrne, Department of Emergency Medicine, Brigham and Women's Hospital, Boston.)

Necrotizing fasciitis is always a consideration, although it is extremely rare relative to cellulitis. Fistula should be considered when perianal, perirectal, or perivaginal infections are evaluated, and the mucosa should be examined digitally. When perirectal abscess recurs, a deep abscess may be the source, and external examination may be unreliable. In this case, CT scanning should be performed.

The epidermoid cyst represents another diagnostic challenge. These lesions, formerly known as sebaceous cysts, are benign cystic tumors resulting from the pathologic accumulation of keratinaceous material. Patients report a long history of a cutaneous mass, often intermittently painful. These lesions become inflamed periodically and sometimes rupture spontaneously. With rupture, they drain a pearly white or yellowish, glistening, waxy material. Pus, which appears dull and viscous rather than waxy, may indicate an infected epidermoid cyst. Isolated mild inflammation of an epidermoid cyst does not contraindicate primary excision, although primary excision is more difficult during an

episode of inflammation. A brief course of antibiotics and NSAIDs with delayed excision is also an option.

Vascular aneurysms and enlarged lymph nodes can be misdiagnosed as abscesses. Ultrasound examination is helpful to distinguish the pathology, and a color Doppler study should be used to investigate perivascular abscesses. When there is doubt, needle aspiration should be used to confirm the presence of pus and absence of blood.

Inflamed cutaneous nodules and cystic masses in returning travelers and immigrants from developing countries present special diagnostic challenges. Typical staphylococcal abscesses are most common, but parasitic causes, such as dracunculiasis and myiasis, should be considered.

Management

The primary treatment of abscess is surgical drainage. Needle aspiration alone has not been found to be an adequate alternative to incision and blunt dissection.

Abscess incision and drainage is a nonsterile procedure, but the operator and all environmental fomites should be protected from contamination and transmission of infectious material. The main challenge is to attain adequate analgesia. Injection of local anesthetics into the skin overlying an abscess is difficult because the skin is usually edematous and tense. Also, superficial anesthesia is often inadequate for blunt dissection. An alternative is to administer procedural sedation. Another excellent option is regional anesthesia with a nerve block. Oral analgesia plus a ring block may also provide adequate anesthesia and analgesia. The following medications are safe together and have additive effects: ibuprofen, acetaminophen, oxycodone, and low-dose diazepam. The ring block is performed with a 25-gauge needle (3.5-inch spinal needle for large areas) to inject bupivacaine in a ring around the abscess, with as few punctures through the skin surface as possible and with care taken that the injection not spread bacteria from infected to healthy tissue. At least 20 minutes should be allowed for this to take effect.

Once anesthesia has been attained, incision and drainage of an abscess involves four steps—incision, blunt dissection to disrupt loculations, irrigation, and packing. The skin is prepared with povidone-iodine, although this is a nonsterile procedure and expensive sterile gloves are not needed. A single incision across the abscess is made, but there is little evidence to guide us in determining how large to make the incision. Incisions parallel to cutaneous tension lines will leave smaller scars. A small clamp is used to probe the cavity and disrupt loculations by opening the clamp through the loculations. Blunt dissection rarely risks injury to vessels and nerves, but the initial sharp incision should be made with such structures in mind. The drained cavity can be irrigated to break loculations further, although there is no evidence to support the practice. Traditionally, the abscess is then packed and left to heal without closure; however, packing may increase pain and the evidence to support this practice is lacking. The loop technique, which involves placing a tied sterile rubber tube through the central incision and a secondary lateral incision, allows continuous drainage and has been proposed as a less painful alternative to traditional packing.[15,16] There is insufficient evidence to institute routine use of loop drainage or primary closure of abscesses immediately after incision and drainage, although these can be considered on a case by case basis.

Bartholin abscesses are drained from the mucosal rather than from the cutaneous surface. The Word catheter is a device used to keep the surgical wound from closing (Fig. 126.4) because the abscess will recur if the wound is allowed to close. A very small incision (≈3 mm) is made, and the cavity is drained. The catheter is inserted and inflated with about 4 mL of water or saline. The catheter should be left in place for 4 to 6 weeks so that a sinus tract will have time to form. Sitz baths may help keep the area clean and draining. Marsupialization is used in recurrent cases to prevent further recurrences and is usually deferred

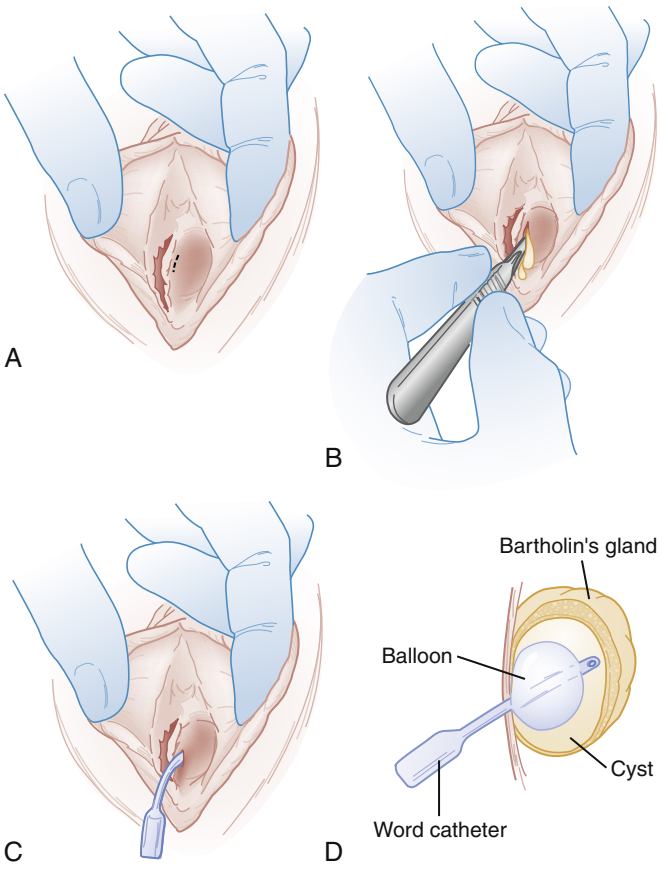

Fig. 126.4 (A–D) Drainage of Bartholin abscess and use of a Word catheter.

until the acute inflammation has subsided. A large incision is made, and the interior of the abscess is then sutured to the surrounding mucosa so that the abscess is sutured open.

The optimal approach to adjunct antibiotics following an adequate incision and drainage of abscesses is a matter of ongoing controversy.[17,18] Two recent, large randomized controlled trials focused on uncomplicated abscesses demonstrated a reduction in treatment failure (including recurrent abscesses) with antibiotic therapy. However, the numbers needed to treat ranged from 7 to 26 depending on how treatment failure was defined. A majority of patients in the control groups had clinical cure without antibiotics (70% to 90%).[19,20] Subgroup analysis of one trial demonstrated that patients with history of MRSA, MRSA as the causative organism, or fever derived the most benefit from antibiotic therapy.[21] Expert consensus suggests antibiotic decisions following incision and drainage for uncomplicated abscesses include an individualized patient risk/benefit assessment and shared decision making.[17,18] Routine antibiotics are recommended in patients with limited access to follow-up care and in severe or complicated cases, including: multiple sites of infection, associated cellulitis, systemic illness, associated comorbidities or immunosuppression, extremes of age, abscess in an area difficult to drain (e.g., face, hand, genitalia), septic phlebitis, and poor response to incision and drainage alone (see Fig. 126.2).

Universal wound cultures for uncomplicated abscesses are not recommended but they should be considered in cases of recurrent infections, treatment failure, or when considering treating with more than one antibiotic to facilitate tailoring of therapy. Although not widely implemented, rapid (≈90 minute) MSSA/MRSA polymerase chain reaction assays are available and can assist in tailoring of therapy to a single agent when providers are considering dual antibiotic coverage.[22]

Disposition

Patients can be discharged to home after incision and drainage of an uncomplicated abscess. It is traditional to schedule one or more visits for wound checks, but many patients can remove the packing themselves after 2 to 4 days and be instructed to return for reevaluation only in cases of persistent or worsening pain or other symptoms indicative of treatment failure. Admission can be considered for severe or complicated cases as defined previously.

IMPETIGO

Impetigo is a common superficial skin infection that is most prevalent in children aged 2 to 5 years, but it can occur at any age. It is communicable, spread by person to person transmission, autoinoculation, and fomites. It may be manifested as an infection of previously intact skin or may infect skin that has been damaged from minor trauma or atopic dermatitis.

Impetigo rarely progresses to systemic illness. However, most cases of poststreptococcal glomerulonephritis are believed to be caused by impetigo and not pharyngitis. Its onset is usually 10 days after the onset of impetigo but may occur up to 5 weeks later.

Clinical Features and Management

The two main forms of impetigo are nonbullous and bullous. Nonbullous impetigo, or impetigo contagiosa, is the most common. It was believed for many years that group A streptococci were the primary cause of this disorder, but studies have subsequently shown that most cases are due to *S. aureus*. Approximately one-third of cases have *S. pyogenes* isolated, usually in combination with *S. aureus*. The lesions begin as thin-walled vesicles that progress to pustules; subsequent rupture results in the characteristic so-called honey crusted lesions, typically found on the face or extremities. Associated lymphadenopathy is common.

Bullous impetigo is caused by *S. aureus,* including CA-MRSA. The bacteria produce an epidermolytic toxin that causes separation of the dermal-epidermal junction, resulting in bullae. The lesions in bullous impetigo are fewer and larger (0.5–3 cm) but rupture less readily than the vesicles of the nonbullous form. After rupture, the bullae leave a thin brown crust.

Ecthyma, or deep impetigo, is a less common ulcerative form of impetigo that extends through the epidermis into the dermis. It is manifested as ulcers with a punched-out appearance, with raised reddened margins covered with thick crust. It has a predilection for the lower extremities. Unlike impetigo, ecthyma can result in cutaneous scarring. Impetigo can be confused with contact dermatitis, varicella, herpes simplex, bullous pemphigoid, and Stevens-Johnson syndrome. It does not affect mucous membranes.

Nonbullous impetigo should be treated with topical mupirocin, which is active against most MRSA strains; however, extensive disease or multiple lesions should be treated with oral agents effective against MRSA. Bullous impetigo should be treated with systemic antibiotics active against MRSA and streptococcus (e.g., cephalexin plus trimethoprim-sulfamethoxazole). Ecthyma should also be treated with oral antibiotics, but it is rarely caused by CA-MRSA. Therefore, we recommend 7 days of either cephalexin or dicloxacillin as first-line treatment.

FOLLICULITIS

Folliculitis is a superficial inflammation of the hair follicle that is limited to the epidermis. It has many causes, including eosinophilic and drug-related factors, but it is usually an infection due to *S. aureus*.

Clinical Features and Management

Folliculitis is diagnosed clinically by its characteristic appearance of a small (2–5 mm), raised, erythematous, painful, tender lesion(s) that is typically pruritic. It can affect any hair-bearing area of the skin and is often associated with shaving. Folliculitis barbae involves the shaved beard area of the face or shaved scalp. Hot tub folliculitis is a pruritic condition caused by *Pseudomonas aeruginosa* that develops within 48 hours of bathing in a contaminated hot tub or swimming pool or from use of contaminated sponges. The rash consists of larger pustules and may have well-demarcated margins, typically involving the area of skin that was under the bathing suit. Candidal folliculitis occurs primarily in immunosuppressed patients and in individuals treated with broad-spectrum antibiotics. Eosinophilic folliculitis is a noninfectious recurrent disorder of unknown cause. It is more likely to occur in immunocompromised patients and is considered an AIDS-defining illness.

Folliculitis usually resolves on its own but can be treated with warm compresses or topical mupirocin. Multiple sites or a large cluster can warrant systemic antibiotics, although no randomized trials have been conducted on the efficacy of this treatment. Shaving of the involved area should be avoided. Hot tub folliculitis usually resolves on its own without specific treatment, but antihistamines and ciprofloxacin are treatment options. Fungal folliculitis is treated with topical antifungal agents. AIDS-associated folliculitis may be eosinophilic or fungal and may be treated with isotretinoin topically or systemic antifungals, respectively.

ACNE VULGARIS AND HIDRADENITIS SUPPURATIVA (ACNE INVERSA)

Acne vulgaris is a common cutaneous disorder involving the face, neck, or proximal upper extremities. It has an increased prevalence in adolescence with a male predominance. The exact pathogenic mechanism of acne is unknown but it is thought to originate in the sebaceous glands via androgen-mediated increased production of sebum and subsequent overgrowth of bacteria. An immune response then results in the formation of inflammatory papules, pustules, and nodules. Hidradenitis suppurativa (acne inversa) is an exquisitely painful condition usually seen in the axilla. It may also occur in other apocrine gland–bearing skin, including the perineum, breasts, and inner thighs. It is about three times more common in females than in males. There is some familial predisposition. The typical onset is between puberty and 40 years. It is currently believed to be an acneiform disorder that begins with follicular occlusion, rather than infection of the sweat glands. This has led to suggestions that the term *hidradenitis suppurativa,* which means suppurative inflammation of the sweat glands, be replaced with the term *acne inversa,* which implies an origin of follicular obstruction. The pathophysiologic mechanism remains incompletely understood and is likely to be a complex interaction of hormonal, environmental, and genetic factors.

Clinical Features and Management

Acne vulgaris manifests as papules, pustules, and nodules of varying severity. It is not typically associated with cellulitis or abscess formation. Acne fulminans is a rare complication involving large nodular lesions with associated ulcerations that can have systemic manifestations. Additional known complications include folliculitis, scarring, hyperpigmentation, and adverse psychosocial effects. The clinical course of hidradenitis varies from intermittent isolated inflamed nodules to recurrent draining cysts and sinuses that can progress to a chronic and debilitating condition that is difficult to treat. Recurrences can lead to scarring, sinus tract formation, and disfigurement. This is

a debilitating disease, and patients suffer not only from pain but also from social stigma due to the odor that may accompany the lesions and may suffer reactive depression.

Recommended therapies for acne vulgaris include oral doxycycline, topical clindamycin, or topical retinoids. Acne fulminans is managed with systemic steroids initially followed by isotretinoin, and dermatology consultation is recommended.

For hidradenitis, incision of painful nondraining lesions can be considered for symptomatic relief although it is uncertain whether this accelerates healing. Systemic antibiotics are usually prescribed for symptomatic lesions and should cover CA-MRSA. Perianal and vulvar manifestations of Crohn disease can mimic hidradenitis and should be considered as part of the differential for lesions in these areas. Perianal and vulvar hidradenitis lesions should be treated more broadly with agents active against CA-MRSA, gram-negative organisms, and anaerobes. Amoxicillin–clavulanic acid plus trimethoprim-sulfamethoxazole is recommended in this scenario.

The optimal approach to long-term management of hidradenitis is unclear. Options include immunomodulators (e.g., steroids, cyclosporine), hormones, and en bloc resection. All patients should be instructed to stop smoking and keep the affected area(s) clean and dry. Pain control is essential. Patients rarely show signs of systemic illness and thus can be discharged and referred to a plastic surgeon or dermatologist.

NECROTIZING SKIN AND SOFT TISSUE INFECTIONS

Clinical Features

Necrotizing infections progress rapidly, cause extensive tissue destruction, and can be fatal despite prompt treatment. Clinical manifestations that suggest a necrotizing infection are signs of systemic toxicity, including abnormal vital signs, severe pain or pain out of proportion to physical findings, altered mental status, rapidly advancing infection, crepitus, hemorrhage, sloughing, and blistering. Some patients appear well at presentation, and overlying skin may not be involved initially. Extensive tissue destruction occurs eventually; the mortality rate is 20%.

Risk factors include diabetes, vascular insufficiency, and immunosuppression, although healthy people are vulnerable. Inciting events include penetrating trauma, recent surgery, varicella infection, injection drug use, burns, and childbirth.

Typical bacterial isolates include group A beta-streptococci, *S. aureus*, including CA-MRSA, enterococci, Enterobacteriaceae, and the anaerobes *Bacteroides* and *Clostridium*. Most cases are polymicrobial. The classification schemes historically used for necrotizing infections are less important than optimizing early identification and pursuing prompt surgical treatment.

Necrotizing fasciitis is an aggressive infection of subcutaneous tissues that spreads rapidly along fascial planes. In the operating room, the fasciae are inflamed, and tissue layers separate friably. It is caused by direct extension from a skin lesion in 80% of cases. Two types are described. Type I is polymicrobial, with aerobes and anaerobes; it is more common in diabetics and immunocompromised individuals. Type II is caused by a single organism, and occurs in any age group and in patients who are not chronically ill. Group A streptococci are most common, and CA-MRSA is also a cause, although it appears to be less virulent. Initial symptoms may be vague (e.g., malaise, fever, body aches, nausea, diarrhea). There may initially be diffuse or fusiform swelling of an extremity, or it may appear to be a simple cellulitis or wound infection. Physical findings may not be obvious initially, and pain out of proportion to physical findings can be an early clinical indicator. Eventually, the skin turns violaceous or ecchymotic. Anesthesia may develop over the involved tissue because of infarction of superficial nerves. Subsequent inflammation may result in the classic sign of "woody" subcutaneous tissues.

Skin infections in the perineum warrant extra caution. *Fournier gangrene* is the term given to necrotizing polymicrobial infections of the perineum. Fournier gangrene progresses rapidly to extend to the entire perineum or abdominal wall. It can be recognized by severe pain, tenderness, and induration.

Myonecrosis, myositis, and pyomyositis refer to infections of muscle, which are rare. They may result from local spread of an adjacent infection, penetrating trauma, vascular insufficiency, or hematogenous spread. Clostridial myonecrosis, also known as gas gangrene, has two forms, a more common traumatic form and a rare spontaneous form. The traumatic form typically occurs from an injury that results in an interruption in the blood supply, and crush injuries are often implicated. The infection is most commonly due to *Clostridium perfringens,* a gram-positive spore-forming bacillus that is ubiquitous in nature, including the human body. Inoculation of the organism into tissue with low oxygen tension allows proliferation. Exotoxins destroy tissue, contribute to shock, and may cause intravascular hemolysis, with anemia and disseminated intravascular coagulation (DIC). Patients present with severe pain. The skin may initially be pale, then bronze, and eventually purplish red. Hemorrhagic bullae may develop. Soft tissue gas may not be present initially. Systemic toxicity and shock ensue when aggressive treatment is not initiated early and sometimes occur despite aggressive treatment. The spontaneous form of clostridial myonecrosis is very rare and occurs without any inciting wound. It is usually due to *Clostridium septicum* and occurs in patients with bowel disease, such as colon cancer. Synergistic nonclostridial myonecrosis is a related syndrome, usually seen in the immunocompromised.

Anaerobic streptococcal myositis usually results from trauma or is a postoperative complication. It resembles clostridial myonecrosis but has a more insidious course. It is caused by anaerobic streptococci, including *Peptostreptococcus,* but the infection may also include group A streptococci and *S. aureus*.

Spontaneous gangrenous myositis—also known as spontaneous streptococcal gangrenous myositis, group A streptococcal necrotizing myositis, or streptococcal myonecrosis—is rare but aggressive and fatal in most cases. It occurs spontaneously, without trauma, in immunocompetent hosts. Gangrenous necrosis of skeletal muscle then results in severe pain, with tense local swelling.

Pyomyositis is a deep abscess within striated muscle resulting from the hematogenous spread of bacteria in the setting of muscle injury. It is usually due to *S. aureus,* including CA-MRSA, and is more common in those who are immunocompromised. Mortality is less than 10%.

Differential Diagnosis and Diagnostic Testing

A necrotizing infection should be considered when a patient with a skin or soft tissue complaint presents with a rapidly progressing course or pain out of proportion to clinical findings. It should also be considered when the patient appears systemically ill (tachypnea, hypotension) or has tachycardia not explained by fever or dehydration. Crepitance or radiographic air is diagnostic of a necrotizing infection unless there is another explanation (e.g., recent surgery).

Phlegmasia cerulea dolens is iliofemoral vein thrombosis, which can be confused with necrotizing fasciitis. Arterial insufficiency causes gangrene, and it may be difficult to determine whether infection is present in severe or chronic cases. Similarly, compartment syndrome can be confused with necrotizing infection or coexist with it.

The diagnostic gold standard is the characteristic appearance of the tissue by direct visualization in the operating room. Some surgeons may elect to perform an exploration at the bedside.

The use of blood tests as part of scoring systems to help differentiate necrotizing infections from other skin infections has been proposed (e.g., Laboratory Risk Indicator for Necrotizing Fasciitis [LRINEC]). While laboratory values and scoring systems can assist in risk stratification, given the catastrophic consequences of delayed diagnosis and lack of validation, they should not be used alone to guide clinical decision making. The diagnosis of necrotizing infection remains clinical. Universal laboratory screening of well-appearing patients with uncomplicated skin and soft tissue infections is not recommended to evaluate for this rare condition.

Plain radiographs may show air in the soft tissues, but absence of this finding does not rule out necrotizing infection. Ultrasound examination can visualize the abscess of pyomyositis and evaluation for subcutaneous thickening, air, and fascial fluid (STAFF exam) has been proposed as a rapid modality for diagnosis, especially in unstable patients. CT and MRI may show compelling evidence of a necrotizing infection but can be time-consuming and delay definitive management. There is no established optimal use of imaging in these cases. The decision to pursue imaging depends on a patient's clinical status and the consistency of their presentation with a necrotizing soft tissue infection. If clinical suspicion is high, the diagnosis should not be ruled out solely based on any imaging modality.

Management and Disposition

Patients with suspected necrotizing infections should be treated for sepsis, with IV fluids as indicated by their hemodynamics and prompt administration of broad-spectrum antimicrobials. A good empiric regimen is clindamycin plus a broad-spectrum β-lactam such as piperacillin-tazobactam (gram negatives, anaerobes, *Streptococcus* spp., *Pseudomonas aeruginosa*) plus vancomycin (*S. aureus*, MRSA). Clindamycin, in addition to providing bacterial coverage, may reduce bacterial toxin (virulence proteins) synthesis and reduce disease severity.[23] Maximal doses of all antibiotics should be used.

When a necrotizing infection is suspected, a surgeon should be consulted in tandem with the diagnostic workup. The patient should be prepared for the operating room by being made NPO, ordering coagulation studies, and a type and screen. Repeated operative débridement is often needed. Fasciotomies are often necessary because these syndromes are associated with elevated compartment pressures, which contribute to myonecrosis. The efficacy of hyperbaric oxygen in the management of necrotizing infections is unproven, and treatment should not delay surgery.

TOXIC SHOCK SYNDROMES

Clinical Features

The main systemic, toxin-mediated, bacterial skin syndromes are streptococcal toxic shock syndrome, staphylococcal toxic shock syndrome, and staphylococcal scaled skin syndrome. These are caused by bacterial exotoxins known as superantigens because they cause a severe and pathologic host immune system response by stimulating T lymphocyte activation and functioning as mitogens in vitro. Systemic disease results from the immune system's response to the toxin, but may be accompanied by or simply resemble bacteremic septic shock (Table 126.3).

Streptococcal Toxic Shock Syndrome

Streptococcal toxic shock syndrome (TSS) is a severe, toxin-mediated syndrome that rapidly progresses to shock, with multiorgan failure and death. Identified in the mid-1980s, this syndrome is caused by group A streptococci, often in the setting of a severe soft tissue infection. Most victims were previously healthy. Rarely, TSS can occur as a complication of disseminated varicella (chickenpox).

Invasive group A streptococcal infections are often due to M-type isolates with potent exotoxins. Signs and symptoms are caused by pyrogenic exotoxins A and B. These act as superantigens and cause overactivation of T cells with a massive release of cytokines, including interleukins and tumor necrosis factor.

Patients may have an influenza-like prodrome with nausea, vomiting, diarrhea, myalgias, and chills. High fever, hypotension, and tachycardia are typical. Altered mental status with confusion is common. A diffuse rash is present in 10% of cases, which may make differentiation from staphylococcal TSS more difficult.

On presentation, the patient has a severe streptococcal infection; necrotizing fasciitis is present in 50% of cases. Pain is often out of proportion to physical findings. Most patients present with shock or develop it within 4 to 6 hours. Bacteremia is common, with positive blood cultures in about 60% of cases. Serious multisystem complications are common, including DIC, acute renal failure, and acute respiratory distress syndrome. In contrast to staphylococcal TSS, which is infrequently fatal, about 30% to 80% of patients diagnosed with streptococcal TSS die. Epidermolysis, typical of staphylococcal TSS, is not characteristic of the streptococcal variety.

TABLE 126.3 Comparison of Features of Streptococcal Toxic Shock Syndrome (TSS), Staphylococcal Toxic Shock Syndrome, and Staphylococcal Scalded Skin Syndrome (SSSS)

Parameter	Streptococcal TSS	Staphylococcal TSS	SSSS
Organism	*Streptococcus pyogenes*	*Staphylococcus aureus*	*Staphylococcus aureus*
Toxin	Pyrogenic exotoxins	TSS type 1; enterotoxins A, B, C	Epidermolytic toxin A or B
Patient	Previously healthy	Previously healthy	Infant
Source	Necrotizing infection	Nasal or wound packing, tampon; infection not obvious	Skin flora
Rash	Erythematous rash in only 10%; stigmata of necrotizing infection present; exfoliation weeks later	Initially diffuse erythroderma, with exfoliation after 1–2 wk; mucosal hyperemia	Tender erythematous rash, localized blisters, extensive exfoliation if no antibodies to toxin; mucosa spared
Systemic illness	Hypotension, shock, multiorgan failure likely	Hypotension, shock, sometimes multiorgan failure	Fever, irritability
Mortality	30%–80%	<5%	<5%
Treatment	Critical care resuscitation, operative debridement	Critical care resuscitation	Wound care, hydration

Staphylococcal Toxic Shock Syndrome

Although staphylococcal TSS is not as severe as the streptococcal variety, it remains a life-threatening systemic illness. The classic presentation is of fever, rash, and hypotension, often in previously healthy patients. It was first described in 1978 and, beginning in 1980, there was an epidemic of cases associated with the use of highly absorbent tampons. Menses-associated cases have since declined dramatically when these tampons were eliminated from the market, although tampon use remains a risk factor.

Nonmenstrual cases, which currently account for about 50% of cases, are associated with various conditions, including surgical procedures (e.g., rhinoplasty, abortion), nasal packing, burns, injection drug use, and the postpartum state. To the emergency clinician, menstrual and nonmenstrual staphylococcal TSS appear similar, and the source infection is often not readily apparent. Of note, prevention of TSS was a traditional indication for systemic antibiotic therapy after nasal packing for epistaxis, but recent evidence has suggested that this is not necessary, and topical antibiotics may be a preferred approach.

S. aureus exotoxins are superantigens that can activate large numbers of T lymphocytes, resulting in the massive release of inflammatory mediators, including interleukins, tumor necrosis factors, and interferon. Toxic shock syndrome toxin 1 (TSST-1) is associated with most menstrual cases. A lack of antibody against this toxin has been demonstrated in patients with menstrual staphylococcal TSS. Episodes of recurrent staphylococcal TSS have been reported in patients who do not mount a long-term antibody response, and it has been postulated that the toxin may interfere with antibody generation against itself.

Patients often have an acute onset of fever, chills, malaise, myalgia, muscle tenderness, and diffuse blanching macular rash that is not pruritic. There may be nausea, vomiting, or diarrhea. Patients may have fever and altered mental status.

Severe hypotension may ensue as a result of massive vasodilation and fluid shifts out of the intravascular space. Toxic cardiomyopathy may also contribute to low blood pressure. Hypotension or rhabdomyolysis may cause acute tubular necrosis. Anemia, thrombocytopenia, and leukocytosis are common, and DIC may develop. Desquamation of the skin, including the palms and soles, eventually occurs 7 to 14 days after onset. The overall mortality is below 5% with aggressive supportive care.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) is a desquamating skin disorder caused by exfoliating toxins produced by *S. aureus*. A disease of infants, it is rare in older children and adults. It can cause outbreaks in nurseries and daycare centers. SSSS was historically known as fourth disease and as Ritter's disease in newborns.

SSSS is caused by certain strains of *S. aureus,* including CA-MRSA, that produce epidermolytic toxin A or epidermolytic toxin B. These toxins probably act as proteases that target the protein desmoglein 1 on the stratum granulosum layer of the epidermis. Whether they meet the T lymphocyte mitogenic criterion for a superantigen has been a subject of debate.

The severity of the disease ranges from a few blisters at the site of infection to exfoliation of most of the body. People with preexisting toxin antibodies develop the localized form, in which toxin is found in the wound periphery; those without preexisting toxin antibodies develop the generalized form, in which toxin spreads through the bloodstream. Cultures of the bullae are negative unless they are contaminated or secondarily infected.

Typically, a young child presents with fever, irritability, and tender red rash. The erythema progresses to bullae formation and subsequent exfoliation of the affected skin. The skin exhibits the Nikolsky sign, which is separation of the epidermal layer of skin on gentle stroking. Desquamation may be patchy or sheet-like, leaving the skin denuded, with a red moist base and predisposing it to secondary infection. Perioral, perianal, and flexural skin may be affected more severely. Mucous membranes are spared. SSSS is not associated with multisystem illness and typically does not lead to shock. Mortality is usually a result of complications from comorbid conditions or superimposed infection.

Differential Diagnosis and Diagnostic Testing

Streptococcal TSS should be suspected in any patient presenting with shock, especially if the patient was previously healthy. Diagnostic criteria for streptococcal TSS include the presence of group A streptococcal infection, hypotension, and two of the following: renal impairment, liver abnormalities, acute respiratory distress syndrome, coagulopathy, necrotic soft tissue infection, and rash. These criteria were developed for epidemiologic purposes; failure to meet all criteria should not exclude the clinical diagnosis in suspicious cases.

Staphylococcal TSS should be considered in any patient presenting with diffuse rash and hypotension. The diagnosis is made on the basis of the clinical presentation. The characteristic rash often raises suspicion and ultimately aids in establishment of the diagnosis. Isolation of *S. aureus* is not necessary for the diagnosis to be made; in fact, blood cultures are positive in a small minority of cases. In severe cases, laboratory abnormalities are those resulting from shock and organ damage.

Early SSSS may be difficult to differentiate from bullous impetigo. The lack of mucosal involvement helps differentiate SSSS from toxic epidermal necrolysis and Stevens-Johnson syndrome. Other differential considerations include Kawasaki syndrome, Rocky Mountain spotted fever, meningococcemia, leptospirosis, and heatstroke.

Management

Streptococcal and staphylococcal TSS require critical care resuscitation. In streptococcal TSS, immediate surgical consultation for operative débridement of necrotizing infections is critical. In staphylococcal TSS, any potential source of infection should be removed, such as tampons or wound packing, and all postoperative wounds should be explored for infection. Clindamycin and vancomycin should be administered. Gram-negative coverage should be added when the diagnosis of TSS is uncertain because the clinical picture overlaps with that of septic shock.

IV immune globulin has theoretical benefit, but its efficacy has not been shown in clinical trials. It is a reasonable option in cases of presumed staphylococcal TSS unresponsive to IV fluids and vasopressors, but is not commonly employed in the ED setting. There has been conflicting evidence on its efficacy for the treatment of streptococcal TSS. SSSS is treated with antibiotics active against *S. aureus,* including MRSA. Wound care and hydration are important.

Disposition

Patients with suspected TSS should be admitted, usually to the intensive care unit, for IV fluids, antibiotics, and close monitoring due to the potential for decompensation. Patients with necrotizing soft tissue infections associated with streptococcal TSS usually require surgical débridement.

Children with mild SSSS may be considered for outpatient management with oral antibiotics and close follow-up. Those with more severe skin involvement often need admission for pain control, temperature regulation, and fluid and electrolyte management. Severely affected patients may need intensive or burn center care. With proper supportive care and antibiotic treatment, the prognosis is excellent, with an overall mortality of less than 5%. Scarring is rarely severe.

OTHER INFECTIONS WITH SKIN MANIFESTATIONS

Borrelia burgdorferi is the spirochete that causes Lyme disease, endemic in the United States, especially in New England. It produces a characteristic targetoid rash known as erythema migrans, which emerges one week on average after the infecting tick bite. The targetoid appearance results from central clearing of the erythema. However, 20% of Lyme disease patients do not report a rash, and the rash does not always have the characteristic round and targetoid appearance.

Another spirochete, *Treponema pallidum* (syphilis), is an increasingly rare cause of rash. The primary lesion of syphilis is a painless ulcer at the inoculation site, known as a chancre, with raised borders and regional lymphadenopathy. The chancre appears days to months after infection and resolves in approximately 1 month. Secondary syphilis develops weeks to months later in about 25% of infected patients. It involves a rash that can take any form other than vesicular and includes the palms and soles; there is usually diffuse lymphadenopathy. Syphilis is uncommon in the United States, although about 10,000 cases still occur annually.

Rocky Mountain spotted fever, caused by *Rickettsia rickettsii,* is even more uncommon, diagnosed only about 2000 times each year in the United States. A few days after a bite by a dog tick or wood tick, the characteristic rash begins on the wrists and spreads everywhere, including the palms and soles. It starts macular and becomes petechial and then dusky. Of those infected, 10% never develop a rash. The untreated mortality for Rocky Mountain spotted fever approaches 25%, but treated patients do well.

Cutaneous anthrax is transmitted from animal products of infected animals, such as wool or pelts, to exposed areas of veterinarians and farmers. A spore of the gram-positive anaerobe *Bacillus anthracis* enters a break in the skin and, after an incubation period of about 1 week, a vesicle forms. This ruptures, leaving a shallow-based ulcer with a raised border. The lesion progresses to painless necrosis and the characteristic eschar. Severe surrounding edema is due to bacterial toxins. The lesions may be confused with recluse spider bites. Unlike the case with inhalational anthrax, treated cases do well, and even untreated cases have a mortality rate of less than 20%.

Tularemia is a rare disease resulting from exposure to animals such as rodents, rabbits, and hares and is endemic in much of the United States, especially the south central states. The ulceroglandular form is most common and involves an influenza-like illness with a single raised ulcer that has a mild central eschar formation. The lesion itself is raised, rather than the border, which might suggest anthrax.

The floor of the mouth is a dangerous location for soft tissue infections. Severe infections may progress to Ludwig angina, in which the floor of the mouth becomes severely indurated. Ludwig angina can be fatal due to airway obstruction. Broad-spectrum antibiotics are indicated. Steroids may reduce swelling. Intubation should be considered and a difficult airway anticipated.

Scabies is a skin infestation of the parasitic mite *Sarcoptes scabiei*. It is endemic worldwide and can cause institutional outbreaks. Lesions are most prominent on the dorsal aspect of the hand and in intertriginous areas. It is diagnosed by visualization of characteristic burrows and, in ambiguous cases, by microscopy of skin scrapings. It is treated with topical permethrin or a single dose of oral ivermectin (200 μg/kg). Norwegian scabies, also known as crusted scabies, is an aggressive infestation in the immunocompromised; it is treated with permethrin and ivermectin.

Cat-scratch disease results from *Bartonella henselae* infection after a cat bite or scratch. Its hallmark is regional lymphadenopathy that appears weeks after a primary lesion at the site of inoculation. Treatment is with a standard 5-day course of azithromycin, with a double dose on day 1.

Strongyloidiasis is caused by infection with the parasitic helminth *Strongyloides stercoralis*. Skin lesions can appear years after infection and are urticarial or serpiginous. A rapidly extending burrow that is pruritic and erythematous is diagnostic; this finding, due to rapid migration of larvae in the skin, is known as larva currens (running larva). Such findings or unexplained eosinophilia in people who have lived in Southeast Asia or tropical Africa should prompt consideration of strongyloidiasis. Diagnosis is by an enzyme-linked immunosorbent assay performed on serum. Detection is important because, unlike other nematodes, strongyloides can complete its life cycle in the human host, leading to lifelong infection. When the infected patient becomes immunosuppressed by medications or illness, the strongyloides hyperinfection syndrome can result and is often fatal.

Cutaneous larva migrans is another serpiginous skin lesion caused by migrating larvae. In this case, the organism is hookworm, and the site is typically the foot or buttock; it is often seen after a vacation on the beach in Mexico. Treatment is with a single dose of ivermectin 200 mg/kg.

Cutaneous leishmaniasis is common in many parts of the world and is found on every continent except Australia and Antarctica. It is caused by protozoans of the genus *Leishmania* and is transmitted by sandflies. Lesions are most common on the face and are painless, ulcerative, and disfiguring. Papules in returning travelers and immigrants should raise suspicion of myiasis (botfly) and, rarely, dracunculiasis (Guinea worm).

CHAPTER 126: QUESTIONS AND ANSWERS

1. Which of the following statements regarding cellulitis is true?

- **a.** Bilateral cellulitis of the lower extremities is a common bacterial infection.
- **b.** Computed tomography (CT) can rule out necrotizing fasciitis.
- **c.** Fever and leukocytosis are key to the diagnosis.
- **d.** Needle aspiration of the uncomplicated cellulitis is unlikely to identify the causative organism.
- **e.** Ultrasound evaluation cannot rule out a large abscess.

Answer: D. Needle aspiration and even biopsy are rarely able to identify a causative organism in nonpurulent cellulitis. Necrotizing fasciitis is a clinical diagnosis and cannot be ruled out with a CT. Fever and leukocytosis are often absent, and measurement of the white blood cell count is not indicated. Ultrasound evaluation is sensitive and specific and can rule out a large abscess, although distinguishing small abscesses from the cobblestoning of cellulitis can be difficult. Bilateral lower extremity inflammation is usually venous stasis dermatitis, which can be confused with cellulitis. Bilateral cellulitis is rare and suggests hematogenous dissemination.

2. A 53-year-old woman presents with fever and painful swelling of the left side of her face. The physical examination is remarkable for a toxic-appearing woman with a sharply demarcated, raised, bright red, and extremely tender eruption involving the left side of her face. Which of the following statements regarding this patient's condition is true?

- **a.** Echocardiography is indicated.
- **b.** Fluoroquinolones are first-line antibiotics.
- **c.** Penicillin G monotherapy is the correct treatment.
- **d.** The face is the most commonly involved site.
- **e.** There is an association with glomerulonephritis.

Answer: E. Erysipelas is an acute cellulitis typically caused by group A streptococci. It presents with an angry red area of inflammation that is well-demarcated from the surrounding skin and has a raised border. Like other group A streptococcal skin infections, erysipelas can give rise to poststreptococcal glomerulonephritis. Penicillin G is probably the ideal therapy, but any toxic-appearing patient should be treated

more aggressively, with goal-directed therapy and broad-spectrum antibiotic coverage. *H. influenzae* is a classic cause of facial cellulitis but is more common in children, is rare in the era of HiB vaccination, and typically causes transdermal cellulitis, rather than the more superficial form of cellulitis known as erysipelas. The lower extremities are usually involved.

3. A 5-month-old girl presents with fever and a diffuse dermatitis characterized by bulla formation, with surrounding vesicles leading to the loss of large sheets of epidermis. She has no past medical history and has been on no medications. The areas of desquamation are tender and red. Which of the following statements regarding this patient's condition is true?
   - **a.** Antibiotics are not indicated.
   - **b.** Corticosteroids will help prevent progression.
   - **c.** Culture of the bullae is not indicated.
   - **d.** Mortality is greater than 30%.
   - **e.** Mucous membranes are likely affected.

Answer: C. Staphylococcal scalded skin syndrome is a toxin-mediated process occurring in the very young (6 months–6 years) and older adults. The cornerstone of treatment is resuscitation and prompt administration of antistaphylococcal antibiotics. Culture of bulla fluid is generally negative. Mucous membranes are spared. This condition is rarely fatal.

4. A 7-year-old boy presents with a left leg rash. The mother describes an initial sequence of a patch of small red papules that rapidly became vesicular, then pustular, and then crusted over. The emergency physician observes a 2- × 3-cm area on the left thigh with heavily crusted erythematous macules. There is moderate left inguinal lymphadenopathy. The lesions are not tender, and the child is not toxic-appearing. Which of the following statements regarding this patient's condition is true?
   - **a.** Acute rheumatic fever is a risk.
   - **b.** Corticosteroids are indicated.
   - **c.** Systemic antibiotics are necessary.
   - **d.** The streptozyme test is highly reliable.
   - **e.** Topical mupirocin is indicated.

Answer: E. Impetigo involves a blistering eruption with a honey-colored crust. It may be caused by streptococci or staphylococci. For limited disease, topical mupirocin is the treatment of choice. Oral or systemic antibiotics are only indicated for more severe cases. Corticosteroids are not indicated. No laboratory test is useful. Acute rheumatic fever does not occur after impetigo, but poststreptococcal glomerulonephritis may occur.

5. Which of the following statements about antibiotic therapy for skin infections is true?
   - **a.** Dual coverage of CA-MRSA and *Streptococcus* spp. reduces treatment failure for uncomplicated cellulitis.
   - **b.** Uncomplicated abscesses should always be treated with dual antibiotic therapy covering CA-MRSA and *Streptococcus* spp. after incision and drainage.
   - **c.** Single-dose intravenous antibiotics are recommended prior to discharge for uncomplicated cellulitis to reduce treatment failure.
   - **d.** Clindamycin should be included in the antibiotic regimen for necrotizing infections.
   - **e.** Mammalian bites should routinely receive CA-MRSA coverage.

Answer: D. Multiple trials suggest that dual antibiotic therapy does not improve outcomes for uncomplicated cellulitis. Recent data suggest a margin of benefit for systemic antibiotic after incision and drainage but there is no support for routine dual antibiotic therapy. Single intravenous doses prior to ED discharge have not been demonstrated to reduce outpatient treatment failure. Given its potential to mediate toxin production, clindamycin should be included in the initial antibiotic regimen for necrotizing infections, along with agents providing broad-spectrum gram-positive and gram-negative coverage. CA-MRSA is not considered a common pathogen in mammalian bites and amoxicillin–clavulanic acid is first-line therapy.

6. A young woman presents complaining of a painful itchy rash. She has just returned from a vacation in the Caribbean, where she was snorkeling. Examination reveals streaks of erythema with slight vesiculation along the lateral aspect of the right leg. The lesions are oriented diagonally, not along vascular lines, and are about 15 cm long. What is the most appropriate next step in this patient's management?
   - **a.** Obtain a CT scan to assess for necrotizing fasciitis.
   - **b.** Perform a Tzanck smear on an unroofed vesicle.
   - **c.** Treat with acyclovir.
   - **d.** Treat with corticosteroids.
   - **e.** Treat with trimethoprim-sulfamethoxazole.

Answer: D. This is an example of contact dermatitis, likely from seaweed or jellyfish stings. Nothing in the presentation is suggestive of an infection. Trimethoprim-sulfamethoxazole monotherapy is rarely appropriate because abscesses generally do not require antibiotics, and streptococci are thought to be covered poorly by this antibiotic. A Tzanck smear and acyclovir treatment would be appropriate if herpetic infection were suspected, but neither herpes simplex nor varicella zoster would present with 15-cm streaks.

Sepsis Syndrome

Nathan I. Shapiro and Alan E. Jones

KEY CONCEPTS

- Sepsis is a progressive disease due to a dysregulated inflammatory cascade, leading to organ dysfunction and circulatory compromise in severe cases.
- Older adults, immunocompromised and neutropenic patients, and patients with multiple comorbidities are at increased risk for the development of sepsis syndromes.
- A thorough history, physical examination, and laboratory testing should guide the diagnostic evaluation.
- Early treatment should focus on appropriate identification, improvement of tissue perfusion (through the administration of fluids and vasopressor medications), improvement of tissue oxygenation (through administration of oxygen and positive-pressure ventilation), administration of antibiotics, and early identification of infections requiring surgical management.
- Prompt administration of antibiotics is essential and should be based on the suspected source of infection.

FOUNDATIONS

Background

Sepsis syndrome represents the body's host response to an infection. The causative agent and host's activated inflammatory cascade overwhelm the body's defenses and regulatory systems, leading to disruption in homeostasis. Tachycardia, tachypnea, fever, and immune system activation are common manifestations. If the body is unable to overcome this insult, cellular injury, tissue damage, shock, multiorgan failure, or death may ensue.

In 1992, the American College of Chest Physicians and Society of Critical Care Medicine issued a consensus statement to establish uniform criteria defining the sepsis syndromes. The goal was to create a common nomenclature for disease classification and systematic comparisons across studies of septic patients. The term *systemic inflammatory response syndrome* (SIRS) is defined as two or more of the following: tachycardia, tachypnea, hyperthermia or hypothermia, high or low white blood cell count, or bandemia. Sepsis is the combination of infection plus SIRS, severe sepsis is sepsis plus organ dysfunction, and septic shock is sepsis plus hypotension, defined as a systolic blood pressure below 90 mm Hg, not responsive to a fluid challenge (Box 127.1). This nomenclature is intended to provide clinicians and researchers with a common classification. Efforts to validate this classification scheme in the emergency department (ED) population have demonstrated that the term *sepsis,* when characterized by fulfilling the SIRS criteria alone, is overly sensitive and nonspecific and does not convey an increased mortality risk. SIRS is not specific because it can be present in noninfectious inflammatory states and in localized infections that are not inclined to lead to sepsis, such as streptococcal pharyngitis or viral illnesses. However, organ dysfunction and shock have been shown to portend worse outcomes.

The Third International Consensus Definitions Task Force (SEP-3) is a group who revisited the sepsis definitions and published a set of revised definitions.[1] The quick SOFA (qSOFA) score emerged as a risk stratification tool for the Emergency Department (ED).[2] The qSOFA score uses three clinical criteria with each receiving one point if present: respiratory rate of 22 breaths or less per minute, altered mental status, and hypotension defined by a systolic blood pressure (SBP) 100 mm Hg or less. A qSOFA score of two or greater was associated with an increased risk of mortality. The definitions group proposed using a suspected infection plus a qSOFA of 2 or greater to help identify patients with potential sepsis in the non-ICU setting. Subsequent validation studies have called the accuracy into question; ultimately it appears that it is a reasonable tool that is less sensitive and more specific than the original sepsis criteria. However, consensus is lacking as to whether it should be used to define sepsis.[3]

Bacteremia may be present, but positive cultures are not obligatory in the diagnosis of sepsis. Culture-negative and culture-positive septic populations have similar outcomes in patients with similar illness severity. Pneumonia, abdominal abscess with viscus perforation, and pyelonephritis are common primary causes of sepsis. Gram-positive organisms account for 25% to 50% of infections, gram-negative organisms for 30% to 60%, and fungi for 2% to 10%. The distribution varies with the study and, more importantly, with host factors such as the status of the host immune system, age of the patient, recent hospitalizations, and presence of indwelling vascular catheters.

The health status of the host is an important risk factor in the development and progression of sepsis. Older adults and those with multiple comorbidities may be more susceptible to developing a systemic infection. Chemotherapy-induced neutropenia, acquired immunodeficiency syndrome, and steroid dependency increase susceptibility to sepsis. Increased use of indwelling devices such as intravascular catheters, prosthetic devices, and endotracheal tubes also contribute to the risk of systemic infection and sepsis.

Pathophysiology

Sepsis results from the complex interaction of detection molecules, signaling molecules, and numerous inflammatory and coagulation mediators in response to infection. Although our understanding of the pathophysiologic process of sepsis has evolved, it remains incomplete. The initial host response is to mobilize inflammatory cells, particularly neutrophils and macrophages, to the site of infection. These inflammatory cells then release circulating molecules, including cytokines, which trigger a cascade of other inflammatory mediators that result in a coordinated host response. Synthesis of the components of the cascade is increased at many steps along the pathway. If these mediators are not appropriately regulated, sepsis will occur. In the setting of

BOX 127.1 Definitions of Sepsis

- Bacteremia (fungemia)—presence of viable bacteria (fungi) in the blood, as evidenced by positive blood cultures
- Systemic inflammatory response syndrome (SIRS)—at least two of the following conditions: oral temperature > 38°C (100.4°F) or < 35°C (95°F); respiratory rate > 20 breaths/min or partial pressure of arterial carbon dioxide ($Paco_2$) < 32 mm Hg; heart rate > 90 beats/min; leukocyte count > 12,000/dL or < 4000/dL; or >10% bands
- Sepsis—systemic inflammatory response syndrome (SIRS) that has a proven or suspected microbial source
- Septic shock—sepsis with hypotension that is unresponsive to fluid resuscitation plus organ dysfunction or perfusion abnormalities, as listed for severe sepsis
- Multiple organ dysfunction syndrome (MODS)—dysfunction of more than one organ, requiring intervention homeostasis

Adapted from: Bone R, Balk RA, Cerra FB, et al. Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. The APP/SCCM Consensus Conference Committee. American College of Chest Physicians/Society of Critical Care Medicine. *Chest.* 1992;101:1644-1655.

ongoing toxin release, a persistent inflammatory response occurs, with ongoing mediator activation, cellular hypoxia, tissue injury, shock, multiorgan failure, and potentially death.

Mediators of Sepsis

Host response and pathogen characteristics are both important in the pathogenesis of sepsis. More than 100 discrete markers have been identified and attributed to the sepsis cascade, but the true culprits have not been clearly identified.[1] A pathogen is sensed by pattern recognition receptors, most notably Toll-like receptors, located on the surface of the white blood cell. The resulting host-pathogen interaction activates the inflammatory and coagulation cascades. The subsequent inflammatory signaling occurs through cytokines, chemokines, and other soluble mediators, including increased circulating levels of the interleukins IL-1, IL-6, and IL-8 and tumor necrosis factor alpha (TNF-α). Activation of the clotting cascade may result in increased D-dimer levels and decreased circulating levels of protein C.

In benign conditions, a self-limited response helps clear the pathogen. If the innate immune response is inadequate, mediators create a procoagulant state. Coagulation and fibrinolytic components are proinflammatory, precipitating a worsening cycle of procoagulant and proinflammatory mediators. Propagation of this cascade ultimately contributes to end-organ damage and often to disseminated intravascular coagulation (DIC). If it is not effectively reversed, the process leads to cellular hypoxia, organ dysfunction, shock, and death.

The primary mediators are cytokines that are primarily proinflammatory, antiinflammatory, or growth-promoting. The molecular mechanisms whereby they are regulated are not well understood. An initial cytokine, TNF-α, is found in serum approximately 90 minutes after the administration of endotoxin to healthy volunteers. IL-6 and IL-8 reach peak levels at approximately 120 minutes. The main proinflammatory cytokines include IL-1, TNF-α, and IL-8. The primary antiinflammatory cytokines are IL-10, IL-6, transforming growth factor-β, soluble receptors to TNF, and IL-1 receptor antagonist (IL-1RA). If the resultant inflammatory response is adequate, the infection is controlled and cleared. If the response is deficient or excessive, however, a persistent and worsening cascade is produced, ultimately leading to (once again) shock, organ failure, and potentially death.

Instability in vascular tone has become increasingly important in understanding the pathophysiologic mechanism of sepsis. Vasopressin, also known as antidiuretic hormone, is a naturally occurring hormone that is essential for cardiovascular stability. It is produced as a prohormone in the hypothalamus. The hormone is stored in the pituitary gland and released in response to stressors such as pain, hypoxia, hypovolemia, and hyperosmolality. In severe sepsis, there is a brief rise in circulating vasopressin levels followed by a prolonged and severe suppression. This pattern of secretion is different from other forms of shock, in which vasopressin levels remain elevated. Vasopressin has numerous physiologic effects, including vasoconstriction of the systemic vasculature, osmoregulation, and maintenance of normovolemia.

Nitric oxide (NO) is a gas that has an important role in septic shock, regulating vascular tone by an indirect effect on smooth muscle cells. NO also contributes to platelet adhesion, insulin secretion, neurotransmission, tissue injury, and inflammation and cytotoxicity. Its half-life is short (6–10 seconds), and it easily diffuses into cells. Although its mechanisms of action are not well understood, it seems to be a key mediator of sepsis. Animal data have shown that nitric oxide synthase, the enzyme that produces NO, is upregulated in cases of sepsis. Enhanced NO production is thought to contribute to the profound vasodilation found in patients in septic shock.

In the setting of ongoing inflammatory activation, the mediators of sepsis continue to be produced, and the cascade is perpetuated. Unless it is appropriately and rapidly controlled, the ultimate effect is a sequence of events starting with cellular dysfunction and ultimately leading to tissue damage, organ dysfunction, and death.

Organ System Dysfunction

The organ dysfunction that results from sepsis is central to the pathogenesis of the disease. The mortality of patients with sepsis increases as the number of failing organs increases (Fig. 127.1A). In one large study, the mortality rate was 1% for sepsis patients with no organ dysfunction, whereas the rates for patients with dysfunction of a single organ, two organs, three organs, and four or more organs were 6%, 13%, 26%, and 53%, respectively (see Fig. 127.1B).

Neurologic Impairment. Patients with sepsis may display neurologic impairment manifested by altered mental status and lethargy, commonly referred to as septic encephalopathy. The incidence has been reported as between 10% and 70%. The mortality rate in patients with septic encephalopathy is higher than that in septic patients without significant neurologic involvement. Although the pathophysiologic process has not been clearly defined, contributing factors may include direct bacterial invasion, endotoxemia, altered cerebral perfusion or metabolism, metabolic derangements, multiorgan system failure, and iatrogenic injury. In addition, impaired renal or hepatic function in the absence of overt organ failure has been shown to correlate with encephalopathy.

Cardiovascular Dysfunction. Cardiovascular dysfunction is common with sepsis. The cardiovascular dysfunction and failure arise from direct myocardial depression and distributive shock. Gram-negative, gram-positive, and killed organisms can cause myocardial depression. The direct insults of the toxic mediators as well as the mobilization of host mediators of sepsis produce a distributive shock. Early in sepsis, a hyperdynamic state develops, characterized by increased cardiac output and decreased systemic vascular resistance. Although the cardiac output is increased, it is at the expense of ventricular dilation and decreased ejection fraction (EF). Vigorous fluid resuscitation usually increases preload and, secondarily, EF, thereby improving the cardiac index. Much of the cardiovascular compromise from septic shock is reversible, and normal cardiovascular function usually returns within 10 days.

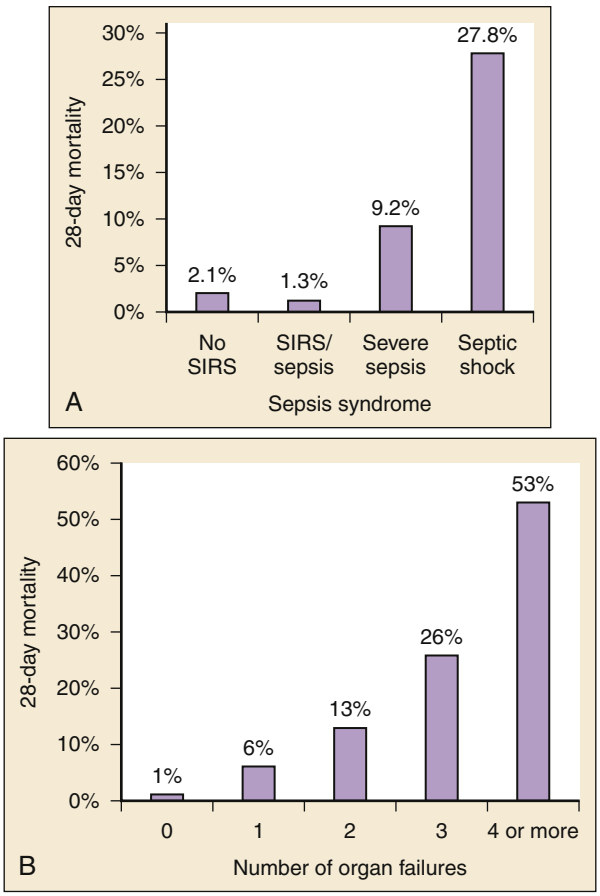

Fig. 127.1 Mortality rates by sepsis syndrome (A) and number of organ dysfunctions (B). *SIRS,* Systemic inflammatory response syndrome.

Pulmonary Involvement. Involvement of the lung is often seen in the inflammatory response to infection. These effects are apparent, irrespective of the primary infection that caused sepsis. Early infiltration with neutrophils, surfactant dysfunction, and edema gives way to monocyte infiltration and fibrosis. Significant right-to-left shunting, arterial hypoxemia, and intractable hypoxemia occur. The resulting morbidity is high and is a common endpoint to sepsis-related deaths.

Sepsis produces a highly catabolic state and places significant demands on the respiratory system to maintain the acid-base status. At the same time, airway resistance may be increased, and muscle function is impaired. Irrespective of whether pneumonia is the cause of sepsis, a common pulmonary endpoint is acute respiratory distress syndrome (ARDS). ARDS is defined clinically and correlates with the pathologic finding of diffuse alveolar damage (see Chapter 2). Because of alveolar-capillary membrane damage, fluid accumulates in the alveoli. Rather than being a diffuse disease, ARDS is a heterogeneous process that results in interspersed damaged and normal alveoli.

Gastrointestinal Effects. Splanchnic blood flow is dependent on mean arterial pressure because there is relatively little autoregulation. Therefore, hemodynamic dysfunction may have a profound effect on viscus metabolism. A shock state causes significant deleterious effects on a hollow viscus and its oxygen supply. A prolonged ileus may accompany hypoperfusion and persist beyond the perfusion deficit.

Solid organ involvement is also common. Even in the previously normal host, elevations in aminotransferases and bilirubin levels are common early in sepsis. The liver has also been implicated in the pathogenesis of sepsis; some of the mediators of sepsis are produced by the liver.

Endocrine Disorders. An absolute or relative adrenal insufficiency is common in sepsis. Depending on the balance of circulating cytokines, augmentation or suppression of the hypothalamic-pituitary axis is possible. IL-1 and IL-6 both activate the hypothalamic-pituitary-adrenal axis. TNF-α and cortistatin depress pituitary function. Other factors that may contribute to adrenal insufficiency in sepsis include decreased blood flow to the adrenal cortex, decreased pituitary function, and decreased pituitary secretion of adrenocorticotropic hormone due to severe stress. As a result of these interactions, the hypothalamic thermoregulatory mechanism may be reset, and temperature fluctuations may develop.

Hematologic Abnormalities. Sepsis causes abnormalities in many parts of the coagulation system. Endotoxin, TNF-α, and IL-1 are the key mediators. Pathologic activation of the extrinsic (tissue factor–dependent) pathway, protein C, protein S, and fibrinolysis lead to consumption of essential coagulation factors, causing DIC. The activation of the coagulation cascade produces fibrin deposition and microvascular thrombi. If these depositions are not corrected, they can compromise organ perfusion and contribute to organ failure. Tissue factor expression on monocytes is increased. This results in fibrin deposition and perhaps contributes to an increased incidence of multiorgan failure due to microvascular thrombi.

Protein C has been identified as an important modulator of inflammation and coagulation in patients with sepsis. Impairment of the protein C–dependent anticoagulation pathway is critical to the development of the thrombotic complications of sepsis. In healthy people, protein C is activated by a combination of thrombin and thrombomodulin. The activation of protein C results in the downregulation of many portions of the coagulation cascade, including release of tissue factor, inactivation of factors VIIIa and Va, and stimulation of fibrinolysis. It is possible that protein C activation in early sepsis is impaired because of an inflammatory cytokine–mediated downregulation of thrombomodulin. As a result, a consumptive coagulopathy ensues. This leads to increased fibrin deposition and a resulting upregulation of the fibrinolytic pathway, as identified by low plasma levels of the fibrinolytic proteins and increased fibrin split products. This sequence of events leads to consumption of coagulation factors and DIC. In late sepsis, the fibrinolytic system is suppressed.

Genetic Factors

There has been increasing evidence that genetics are a risk factor for the outcome of sepsis. An individual may contain a set of individual characteristics or polymorphisms that may affect the ways in which he or she responds to sepsis in general, or perhaps there may be differences in response to specific sepsis therapeutics. Identifying and understanding these differences in an individual's genetic makeup is likely to lead to tailored approaches to diagnosis and therapy. The impact of genetics on future treatment modalities for sepsis remains unclear, but the prospect of customized genetic therapy for sepsis is a promising early development.

CLINICAL FEATURES

Symptoms and Signs

The approach to a patient with sepsis relies on identification of the presence of a systemic infection and localization of the source of the initial infection. This allows appropriate treatment directed to the source of infection. Often, the source is not readily apparent, but early identification of the septic state allows implementation of broad-spectrum antibiotics.

The septic patient may manifest signs of systemic infection through tachycardia, tachypnea, hyperthermia or hypothermia and, if severe, hypotension. Very early in the patient's presentation, vital sign changes such as tachycardia and tachypnea may be first indicators of sepsis. If the patient is in shock, a rapid assessment that excludes other causes, such as hypovolemic or cardiogenic shock, is essential to the proper initial treatment. A septic patient will often have flushed skin with warm, well-perfused extremities secondary to the early vasodilation and hyperdynamic state. Alternatively, the severely hypoperfused patient with advanced shock may appear cyanotic. A complete detailed clinical examination will help the emergency clinician determine the cause of the shock state (see Chapter 3). These are classic signs; however, these findings may not be manifested in a septic patient, and signs and symptoms may be subtle or absent.

Both underlying comorbidities and the cause of sepsis should be considered. Risk factors such as immunocompromised states (e.g., acquired immunodeficiency syndrome, malignant disease, diabetes, splenectomy, concurrent chemotherapy), older age, debilitation, high-risk environments for iatrogenic infections (e.g., acute care hospitalizations, long-term care facilities), and multiple comorbidities should be considered.

The respiratory system is the most common source of infection in the septic patient (see Chapter 62). A history of a productive cough, fevers, chills, upper respiratory symptoms, sore throat, or ear pain should be sought. Physical examination should also include a detailed evaluation for focal infection, such as exudative tonsillitis, sinus tenderness, tympanic membrane injection, and crackles or dullness on lung auscultation. Also, pharyngeal thrush should be noted as a potential marker of an immunocompromised state.

The gastrointestinal system is the second or third (depending on the study) most common source of sepsis. A history of abdominal pain, including its description, location, timing, and modifying factors, should be sought. Further history, including the presence of nausea, vomiting, and diarrhea and time of the last bowel movement should be noted. A careful physical examination, looking for signs of peritoneal irritation, abdominal tenderness, and hyperactive or hypoactive bowel sounds, is critical in identifying the source of abdominal sepsis. Particular attention should be paid to physical findings suggestive of common sources of infection or disease—Murphy sign indicating cholecystitis, pain at McBurney point indicating appendicitis, left lower quadrant pain suggesting diverticulitis, or rectal examination revealing a rectal abscess or prostatitis.

The neurologic system should be evaluated for signs of meningitis, encephalitis, or epidural abscess, including nuchal rigidity, fevers, and change in consciousness (see Chapter 95). Lethargy or altered mentation may indicate primary neurologic disease or may be the result of decreased brain perfusion.

The genitourinary (GU) history includes queries about the presence of flank pain, dysuria, polyuria, discharge, Foley catheter placement, and genitourinary instrumentation. However, one must also remember that GU infection is a common source of infection in older patients and is a common offender in patients with nonspecific symptoms. Obstructed nephrolithiasis with associated urinary tract infection is a potentially lethal source of infection that can advance rapidly without decompression by nephrostomy.

Rarely, sexually transmitted infections may be the cause of sepsis. The genital examination could reveal ulcers, discharge, penile or vulvar lesions, or the woody induration of Fournier gangrene. Cervical motion tenderness indicates pelvic inflammatory disease, and adnexal tenderness in a toxic-appearing woman may represent a tubo-ovarian abscess. Tampons are rarely a cause of toxic shock syndrome, but when no other source of septic shock is found, a retained tampon should be considered.

The musculoskeletal history includes the presence of any localizing symptoms to a particular joint. Redness, swelling, and warmth over a joint, especially if there is a decreased range of motion in that joint, may be signs of septic arthritis and may mandate arthrocentesis. The skin should be examined for evidence of cellulitis, abscess, wound infection, or traumatic injury. Deep injuries, foreign bodies, and fasciitis may be difficult to identify clinically. The emergency clinician should look for crepitus, bullae, or skin edema extending beyond areas of erythema that may indicate the presence of an aggressive, gas-forming organism (see Chapter 126). Back pain and fever may be signs of an epidural abscess. Local lymphadenopathy, swelling, and streaking should also be noted as signs of an advancing infection. Petechiae and purpura may represent a *Neisseria meningitidis* infection or DIC. Generalized erythroderma and rash may represent an exotoxin from pathogens such as *Staphylococcus aureus* and *Streptococcus pyogenes*.

A history of fevers or chills in the setting of injection drug use, artificial heart valve, or mitral valve prolapse should increase the suspicion for endocarditis. The emergency clinician should suspect endocarditis in the presence of a murmur or other stigmata of endocarditis (e.g., splinter hemorrhages, Roth's spots, Janeway's lesions) (see Chapter 69).

Emergency clinicians must identify the severity of illness in patients with infection and initiate early resuscitation for those with the potential of becoming critically ill. Although a patient may meet SIRS criteria, this alone has little predictive value in determining the severity of illness and mortality. There are many scoring systems that have been developed to risk-stratify illness severity. Most scoring systems are not clinically relevant and not routinely used. The Mortality in Emergency Department Sepsis (MEDS) score is one proposed method to risk stratify ED patients with sepsis. The MEDS prediction rule assigns point values to specific clinical characteristics (Table 127.1). The total score can be used to assess risk of death. Thus, the greater the number of risk factors, the more likely a patient is to die during hospitalization. Although typically not calculated for all patients, the elements of the score may be identified and considered as a red flag when risk-stratifying a patient.

TABLE 127.1 Mortality in Emergency Department Sepsis (MEDS) Prediction Rule

Risk Factor	Odds Ratio for Death	Meds Score (Points)
Terminal illness (death within 30 days)	6.1	6
Tachypnea or hypoxia	2.7	3
Septic shock	2.7	3
Platelet count < 150,000/mm^3	2.5	3
Bands > 5%	2.3	3
Age > 65 yr	2.2	3
Pneumonia	1.9	2
Nursing home resident	1.9	2
Altered mental status	1.6	2

Risk of Death	Total Meds Score (% of Sepsis Deaths)
Very low	0–4 (1.1%)
Low	5–7 (4.4%)
Moderate	8–12 (9.3%)
High	13–15 (16.1%)
Very high	>15 (39%)

DIAGNOSTIC CONSIDERATIONS

Differential Diagnoses

The sepsis syndromes represent a spectrum of disease and clinical presentations. Often, noninfectious sources can cause a syndrome that mimics that of sepsis; thus, one must keep in mind a broad differential diagnosis when approaching these patients (Box 127.2). A detailed history and physical examination are the first steps in narrowing the differential diagnosis to identify the true source.

Diagnostic Testing

Diagnostic studies are used to identify the type and location of the infecting organisms and define the extent and severity of the infection to assist in focusing therapy. As a result, the diagnostic approach should be tailored to the particular patient.

BOX 127.2 Differential Diagnosis of Sepsis and Septic Shock

Sepsis

Dehydration
Acute respiratory distress syndrome
Anemia
Ischemia
Hypoxia
Congestive heart failure
Vasculitis
Toxicologic
- Poisonings
- Overdose
- Drug-induced
- Neuroleptic malignant syndrome

Pancreatitis
Hypothalamic injury
Disseminated intravascular coagulation
Anaphylaxis
Metabolic
Hyperthyroidism
Diabetic ketoacidosis
Adrenal dysfunction
- Environmental
- Burn
- Heat exhaustion or stroke

Trauma
Blood loss
Cardiac contusion

Septic Shock

Hypovolemic shock
Acute blood loss
Severe dehydration
Cardiogenic shock
Pulmonary embolus
Myocardial infarction
Pericardial tamponade
Tension pneumothorax
Vasogenic shock
Anaphylaxis
Paralysis

Laboratory Testing

Hematology. The white blood cell count can be an indicator of inflammation and activation of the inflammatory cascade. Leukocytosis is associated with infection and is incorporated in the consensus definition of sepsis; however, it is often insensitive and nonspecific, limiting its value in the ED. The febrile neutropenic patient has been shown to be at increased risk for severe infection. Thus, a neutrophil count of less than 500 cells/mm^3 should prompt consideration for admission, isolation, and empirical intravenous (IV) antibiotics in most chemotherapy patients. A bandemia (≥5%–10% bands on a peripheral smear) represents the release of immature cells from the bone marrow and may be a sign of infection and inflammation. Like the white blood cell count, it is an imperfect indicator of infection. The absence of leukocytosis or bandemia does not preclude the possibility of severe sepsis nor does their presence confirm it. The hemoglobin level should be determined to ensure adequate oxygen delivery in shock. Platelets are an acute-phase reactant and may be elevated in the presence of infection. Conversely, a low platelet count may be seen in patients with sepsis and septic shock. Thrombocytopenia, elevated prothrombin time, elevated activated partial thromboplastin time, decreased fibrinogen, and increased fibrin split products are associated with DIC and severe sepsis syndrome.

Blood Chemistry. Electrolyte abnormalities should be identified and corrected. A low bicarbonate level suggests acidosis and inadequate perfusion. An elevated anion gap acidosis in the setting of sepsis syndrome commonly represents lactic acidosis or diabetic ketoacidosis, but other causes need to be ruled out. An elevated serum creatinine concentration or decreased glomerular filtration rate signals renal dysfunction or failure, which, if due primarily to sepsis, indicates organ failure and a worse prognosis. Calcium, magnesium, and phosphorus levels should be checked.

An elevated lactate level is associated with inadequate perfusion, shock, and poorer prognosis. In one study, the mortality rate correlated with the venous lactate level—a lactate level of 0 to 2.5 mg/dL was associated with a 5% mortality rate, a lactate level of 2.5 to 4.0 mg/dL, 9% mortality, and a lactate level greater than 4 mg/dL, 28% mortality. A blood gas assessment is helpful in identifying and classifying acid-base disturbances, with metabolic acidosis suggesting inadequate tissue perfusion. Liver function tests can be used to identify liver failure or dysfunction. An elevated bilirubin level may suggest the gallbladder as a cause of sepsis. An elevated lipase level may represent pancreatitis as the cause of SIRS. Procalcitonin and C-reactive protein are biomarkers sometimes used in the diagnosis and prognosis of sepsis. The literature primarily supports procalcitonin in serial measurements and for antibiotic stewardship, but the role for procalcitonin in the ED has not been clearly delineated.

Urinalysis. Urinalysis is another essential laboratory test, especially in older patients with higher risk of urinary tract infection who may not manifest localizing symptoms of infection. Urinalysis is likewise important to rule out infection in patients with renal colic or ureteral obstruction.

Microbiology. Proper blood, urine, sputum, cerebrospinal fluid, and other tissue culture samples are important in guiding therapy. Although the results of culture are not helpful in the initial management, culture samples ideally should be obtained before the administration of antibiotics in the patient with sepsis. The initiation of antibiotic therapy should not be delayed significantly while waiting for culture samples to be obtained. Studies have suggested that the yield of initial blood cultures is low (5%–10%), but this is probably an artifact of the lack of reliable discriminatory guidelines for obtaining blood culture samples in the ED. Among patients with clinical sepsis, only 30% to 40% of patients will have positive cultures. The results of initial microbiologic

tests, including Gram staining whenever possible, will help guide subsequent antibiotic treatment. Initial empirical therapy should be broad spectrum to allow early treatment of all likely organisms.

Special Procedures

Historically, a central venous pressure (CVP) line was thought helpful in guiding fluid resuscitation in sepsis patients. We do not recommend the routine use of CVP to determine fluid responsiveness. When available, arterial lines can be useful for close monitoring of hypotensive patients, especially when one or more vasopressors are being titrated to maintain an adequate blood pressure. However, they are not routinely placed in the ED. The technology of noninvasive or minimally invasive cardiac output monitoring is evolving and, where available, may help guide fluid administration by evaluating cardiac output alone or in conjunction with a fluid challenge or passive leg raise approach. Cardiac ultrasound, while unproven, is also commonly used to assess volume status and cardiac function.

Radiology

Imaging studies are generally used to identify the source of infection. A chest radiograph should be considered in patients with suspected sepsis syndrome, looking not only for a focal infiltrate representing pneumonia but also for the bilateral infiltrates indicative of ARDS. An upright chest radiograph should be considered for suspected bowel perforation to detect free air under the diaphragm. The presence of pneumomediastinum is suggestive of esophageal perforation and current or impending mediastinitis.

Soft tissue plain radiographs of infected areas can be obtained, looking for air in the soft tissues associated with necrotizing or gas-forming infection, although plain x-rays are not sensitive for tissue infection. Periosteal thickening or bone erosion may be seen on plain radiographs of patients with osteomyelitis; a bone scan may be diagnostic. Computed tomography (CT) of superficial infections may be more helpful to quantify the extent of infection further and identify abscesses that are not readily evident on physical examination. A CT scan of the abdomen and pelvis may identify abdominal or pelvic pathologic lesions, provided there is no clear clinical indication for immediate operative intervention. Suspected disease, such as diverticulitis, appendicitis, necrotizing pancreatitis, microperforation of the stomach or bowel, or formation of an intra-abdominal abscess, may be best diagnosed by a CT scan. A head CT scan can identify septic emboli from endocarditis or increased intracranial pressure from a mass and should be considered before a lumbar puncture is performed. An abdominal ultrasound examination may be indicated for suspected cholecystitis, and a pelvic ultrasound examination may be indicated for tubo-ovarian abscess or endometritis. If endocarditis is suspected, a transesophageal cardiac ultrasound study may be performed for the detection of any valvular vegetations. Magnetic resonance imaging (MRI) can be useful to identify soft tissue infection, such as necrotizing fasciitis or epidural abscess.

MANAGEMENT

Early detection and appropriate treatment can reduce the mortality from sepsis. The primary goal is timely administration of appropriate antimicrobial therapy—or interventional source control as required—and maintenance of adequate tissue oxygenation and perfusion through titrated resuscitation. With early detection and early resuscitation there is increasing evidence that the natural history of sepsis can be altered. Initial resuscitation, including appropriate airway management, IV access, oxygen, early and appropriate antibiotics, fluid resuscitation, and vasopressor support, remains the foundation on which new efforts may be applied.

From a historical perspective, Rivers and associates[2a] provided compelling evidence supporting the importance of this concept when they published a protocol of standardized timely and titrated care being used to guide resuscitation in the ED. This randomized, double-blind, placebo-controlled study showed a 16% mortality reduction in patients with severe sepsis and septic shock. The protocol, termed *early goal-directed therapy* (EGDT), measures targeted goals and uses a resuscitation algorithm to guide the resuscitation. The theory behind the protocol was to normalize preload and blood pressure and prevent tissue hypoxia by matching oxygen delivery with consumption. Use of this protocol, which facilitated earlier and more aggressive fluid resuscitation through the use of increased fluids, increased blood products, increased use of dobutamine, and greater degree of normalization of tissue hypoxia, reduced mortality at their center. The interventions in combination were likely responsible for the better outcomes in the intervention group.

The principles of EGDT, as well as efforts such as the Surviving Sepsis Campaign, helped underscore the importance of early identification and timely resuscitation.[3] However, until 2014, the evidence in support of the formal EGDT protocol was only in the form of the original single- center trial and subsequent observational efforts. Subsequently, the ProCESS, ProMISE, and ARISE studies were large multicenter trials that sought to validate the value of EGDT.[4,5] Each of the trials showed no mortality benefit to EGDT as compared to usual resuscitation measures; thus, although EGDT is one strategy to consider, it is not a superior approach. It is important to underscore, however, that the usual care groups in these newer trials were all identified early, received antibiotics, and received generous amounts of fluids (on average, approximately 40–60 mL/kg in the first 6 hours across the trials), supporting the principle that early identification of sepsis, early antibiotics, and carefully titrated resuscitation should remain a core tenant.

Respiratory Support

Altered mental status is common in patients in septic shock, and patients may require rapid airway protection. Because patients with impending respiratory failure use a disproportionately large amount of energy for the muscles of respiration, improved oxygen delivery to other organs may be achieved by mechanical ventilation, sedation, and paralysis. Although there are no clear intubation guidelines, hypercapnia, persistent hypoxemia, airway compromise, and profound acidosis are valid indicators for intubation.

In addition to airway protection, intubation and mechanical ventilatory support provide positive-pressure ventilation. Pulmonary compliance is often low in ARDS, resulting in increased airway pressures to maintain oxygen delivery. The ARDSNet trial established the benefit of low tidal volumes (6 mL/kg) and plateau pressures of 30 cm H_2O or below in mechanically ventilated patients to prevent iatrogenic lung damage (see Chapter 2). Maintenance of a relatively low plateau pressure with higher positive end-expiratory pressure is an effective way to increase arterial oxygen delivery.

Cardiovascular Support

Fluid Resuscitation

Patients with sepsis are often administered IV fluid to maintain adequate perfusion. The primary reasons for this intravascular hypovolemia are venodilation and diffuse capillary leak. Initial therapy for adults with septic shock should generally be up to 30 mL/kg of isotonic crystalloid. Additional fluid replacement should be titrated to clinical parameters such as heart rate, blood pressure, change in mental status,

capillary refill, cool skin, and adequate urine output (0.5–1 mL/kg/hr). Colloids are as effective as crystalloids, but they are more expensive and less readily available. Balanced salt solutions (e.g., lactated Ringers) have been shown to have beneficial effects over normal saline, due primarily to adverse renal effects associated with normal saline. Evidence suggests that balanced solutions are likely as good or better than normal saline; thus, we recommend the use of balanced solutions for sepsis resuscitation.

Although one should be increasingly vigilant in watching for fluid overload in patients who are predisposed, such as older adults, those with congestive heart failure (CHF), or those with renal impairment, these patients are not precluded from volume resuscitation as described previously. Efforts to identify ways to measure regional perfusion more directly, such as direct measurement of splanchnic blood flow, have been proposed, but are not commonly used in clinical practice. Even in the absence of global hypoxia and impaired tissue perfusion, there is evidence that regional hypoperfusion and ischemia exist.

Vasoactive Drug Therapy

Use of mean arterial pressure alone as an indicator of overall efficacy of therapeutic intervention is not always sufficient. A mean arterial pressure of 65 mm Hg has been recommended in otherwise healthy, normovolemic adult patients but must be correlated with other indicators of adequate perfusion, such as mental status and urine output. Patients with previously uncontrolled hypertension may require a mean arterial pressure of 75 mm Hg or even higher. If appropriate fluid resuscitation has failed to maintain end-organ perfusion, vasopressor support may be required (Table 127.2).

The 2016 Surviving Sepsis Campaign guidelines provided consensus recommendations for treatment of septic shock.[6] Norepinephrine should be used as the initial vasopressor, with the addition of epinephrine or vasopressin to norepinephrine as adjuncts. Vasopressin has not been shown to improve outcomes when added to norepinephrine in refractory septic shock, but there is no evidence of harm. As such, the optimum role for vasopressin is unclear. Once the mean arterial pressure is adequately supported, dobutamine should be used as the primary inotropic agent if myocardial dysfunction is evident. Patients requiring vasopressors and inotropes require frequent reassessment and medication titration, as needs can change greatly during the first few hours of resuscitation.

Norepinephrine. Norepinephrine is predominantly α-agonist with some β_1-agonism with minimal β_2 activity and primarily functions to increase systemic vascular resistance and cardiac output. In a large study examining patients with varied causes of shock, norepinephrine was associated with fewer adverse events (particularly arrhythmias) compared with dopamine. Dopamine was also associated with a higher mortality rate in patients with cardiogenic shock. In another meta-analysis, norepinephrine was shown to be superior to dopamine in both in-hospital and 28-day mortality. Compared with dopamine in septic patients, norepinephrine increases glomerular filtration and urine output equally well. We recommend norepinephrine as the first-line vasopressor for septic shock, either as a sole vasopressor or in conjunction with other agents. Norepinephrine can be started at 3 to 5 μg/min and titrated to achieve the goal mean arterial pressure.

TABLE 127.2 Dosing of Vasoactive Therapy

Drug	Dosage
Dobutamine	2–15 μg/kg/min
Epinephrine	5–20 μg/min
Norepinephrine	3–30 μg/min
Phenylephrine	2–300 μg/min
Vasopressin	0.01–0.04 units/min

Dopamine. Dopamine is the immediate precursor of norepinephrine and epinephrine. It is primarily an α-, β_1-, and dopaminergic agonist. Dopamine was previously thought to improve renal outcomes, but it has not been shown to reduce mortality or decrease dialysis dependence, and should not be used for these indications. Persistent tachycardia, decreased partial pressure of arterial oxygen, and increased pulmonary artery occlusion pressure are common side effects of dopamine use. We do not recommend the routine use of dopamine if other vasopressors are available.

Vasopressin. Vasopressin is a naturally occurring peptide that is synthesized as a large prohormone in the hypothalamus. In states of septic shock, there is an early surge of vasopressin followed by a profound drop in circulating vasopressin levels. In a well-designed randomized trial, investigators demonstrated no change in mortality for patients with severe sepsis when vasopressin was added to catecholamine vasopressors. Vasopressin should not be used as the sole initial therapy for refractory septic shock. However, vasopressin does not increase pulmonary vascular resistance, making it a useful adjunct in patients with pulmonary hypertension, obstructive shock secondary to PE, or right ventricular dysfunction.

Epinephrine. Epinephrine is a potent mixed α- and β-agonist. Epinephrine infusion is also associated with increased oxygen consumption, increased systemic lactate concentrations, and decreased splanchnic blood flow. The rise in the lactate level is short term, and there is no evidence regarding its long-term effects. As a result of all the possible adverse effects of epinephrine, it is currently recommended only for those patients who are unresponsive to other vasopressors. Epinephrine can be a good adjunct for patients with combined septic and cardiogenic shock, given its vasopressor and inotropic activity.

Phenylephrine. Phenylephrine is a selective α_1-agonist, increasing systemic vascular resistance without significant changes in cardiac output. It can produce reflexive bradycardia or suppression in cardiac output. A single small study has shown that phenylephrine is effective in restoring perfusion in patients with septic shock refractory to dopamine or dobutamine. Another small study has demonstrated that phenylephrine is less effective than norepinephrine in the treatment of hypotension in septic patients; however, there was no difference in other measured hemodynamic parameters, including oxygen delivery. Phenylephrine does not impair cardiac and renal function and may be a good choice when significant tachyarrhythmia limits the use of other agents.

Dobutamine. Dobutamine is a mixed α- and β-agonist. In dosage ranges from 2 to 28 μg/kg/min, the cardiac index is increased at the expense of heart rate. In addition, decreased splanchnic blood flow is common. Dobutamine should be used in patients with depressed cardiac index and persistent hypoperfusion in spite of adequate volume expansion and the use of other vasopressor agents. Dobutamine decreases systemic vascular resistance, and therefore should not be used as the sole agent in a hypotensive patient. One study has suggested that survival in sepsis is associated with the patient's increase in stroke volume in response to dobutamine.

Bicarbonate

Bicarbonate supplementation was previously the standard treatment for patients with presumed lactic acidosis. Current consensus is that it should be reserved for severe acidemia (pH < 7.0–7.2) because there

TABLE 127.3 Suggested Initial Antibiotic Management[a]

Infection	Modifying Factors	Antibiotic
Sepsis, unknown source	Immunocompetent	Antipseudomonal cephalosporin *plus* aminoglycoside or fluoroquinolone, *or* antipseudomonal penicillin *plus* aminoglycoside or fluoroquinolone, *or* carbapenem *plus* aminoglycoside or fluoroquinolone
	Anaerobic infection	Add metronidazole or clindamycin to above regimen.
	Methicillin-resistant *Staphylococcus aureus* (MRSA)	Add vancomycin to above regimen.
	Neutropenia	Antipseudomonal penicillin *plus* aminoglycoside or fluoroquinolone, *or* carbapenem *plus* aminoglycoside or fluoroquinolone
	Splenectomy	Cefotaxime *or* ceftriaxone
Pneumonia	Immunocompetent	Second- or third-generation cephalosporin *plus* second-generation macrolide *or* fluoroquinolone
	Legionella suspected	Azithromycin, fluoroquinolone, or high-dose erythromycin
Abdominal infection	Immunocompetent	Ampicillin *plus* aminoglycoside *plus* metronidazole
	Multidrug-resistant organism suspected	Carbapenem, *or* piperacillin-tazobactam *plus* aminoglycoside
	Urinary tract source	Fluoroquinolone, *or* third-generation cephalosporin, *or* ampicillin *plus* aminoglycoside
Cellulitis	Nonnecrotizing fasciitis	Cefazolin *or* nafcillin
	MRSA possible	Vancomycin
	Necrotizing fasciitis (surgical drainage)	Ampicillin-sulbactam, piperacillin *plus* aminoglycoside *plus* clindamycin, *or* carbapenem
Intravenous catheter infection (remove catheter)	Outpatient-acquired	Third-generation cephalosporin
	MRSA suspected	Add vancomycin.
	Fungal infection	Amphotericin B
Cerebrospinal infection	Immunocompetent	Ceftriaxone *plus* vancomycin
	Older adult or immunocompromised patient	Add ampicillin.
Injection drug abuse	MRSA not suspected	Cefazolin *or* nafcillin *plus* aminoglycoside
	MRSA suspected	Vancomycin *plus* aminoglycoside

[a]Pending microbiologic identification of organism and sensitivity.

may be a paradoxical decrease in intracellular pH as a result of diffusion of soluble carbon dioxide across the cell membrane. Alternatively, hyperventilation has been suggested to help increase systemic pH.

Antibiotics

Early antibiotic therapy should target the nidus of infection if known. If the patient's condition permits, appropriate culture specimens should be obtained before the administration of broad-spectrum antibiotics (Table 127.3). Surgically correctable conditions, such as intra-abdominal abscesses, perforated viscus, retained products of conception, or retained foreign body (e.g., a tampon), should be treated concurrently. Antibiotics should be administered as soon as possible in patients with serious infections. Although some observational studies and national benchmarks have called for the administration of antibiotics within a predefined time period of 3 hours from ED presentation, a comprehensive meta-analysis failed to support an association between antibiotics administered after 3 hours and mortality.[7] Thus, early antibiotics are important, but their exact timing remains undefined.

In the absence of an obvious source of infection, the use of broad-spectrum antibiotics is recommended. The specific agent depends on many variables, including institutional preference and local resistance patterns. As results from cultures become available, therapy should be modified. There is no consensus about the need for double or triple antibiotic coverage for particular organisms, although it is common practice to double-cover virulent organisms, such as *Pseudomonas aeruginosa,* as well as areas commonly infected with multiple organisms, such as the peritoneum. With increasing rates of methicillin-resistant organisms, combinations that include nonpenicillin choices may be warranted.

Steroid Therapy

It has been nearly 40 years since the first treatment attempts to block inflammation in sepsis. Because sepsis involves a systemic inflammatory response, corticosteroids are a logical treatment modality as anti-inflammatory agents. Physicians have been working for decades to prove or disprove their value. Steroids appear to be more effective in reducing the amount of time patients spend in a hypotensive state, and moderate-quality evidence suggests a mortality benefit, especially in the most critically ill patients.[8-10] However, the optimum timing, dose, drug, and method of administration (continuous or bolus dosing) remains unknown. At this time, we believe that the role of steroid therapy in sepsis remains controversial and recommend their use when there is refractory cardiovascular insufficiency, despite fluid and vasopressor therapy.

DISPOSITION

Once ED management is complete, patients who are deemed at increased risk should be admitted to the hospital into a setting that is deemed appropriate for the severity of the patient's condition. For

example, in patients who remain hypotensive, are on vasopressors, or who are unstable and require more frequent monitoring, the intensive care unit may be appropriate. Other patients who are more stable but still require monitoring and perhaps IV therapy may be admitted to a hospital ward. Finally, in certain cases, patients initially meeting sepsis criteria but who are not severely ill (e.g., young patients with pharyngitis) may be appropriate for discharge.

CHAPTER 127: QUESTIONS AND ANSWERS

1. Which of the following patients meets the criteria for systemic inflammatory response syndrome (SIRS)?
- **a.** 6-year-old boy with pneumonia, temperature 39.0°C (102.2°F)
- **b.** 53-year-old man with respirations 30 breaths/min, white blood cell (WBC) count 16,000 cells/mm^3
- **c.** 74-year-old woman with chest pain, heart rate 130 beats/min
- **d.** 81-year-old man with WBC count, 2700 cells/mm^3, heart rate, 73 beats/min

Answer: B. SIRS is defined as two or more of the following—tachycardia, tachypnea, temperature higher than 38°C (100.4°F) or lower than 35°C (95°F), high or low WBC count, or bandemia. Sepsis is SIRS with infection. Severe sepsis includes organ dysfunction. Septic shock involves systolic blood pressure below 90 mm Hg.

2. Sepsis is characterized by which of the following?
- **a.** Depression of tumor necrosis factor levels
- **b.** Increased endogenous anticoagulant levels
- **c.** Prolonged suppression of nitric oxide levels
- **d.** Increased inflammatory cytokine levels

Answer: D. Clinical sepsis is induced by sustained levels of proinflammatory and procoagulant mediators. Cytokines (interleukin-1, interleukin-6, and tumor necrosis factor-α) and prostaglandins are primary mediators. Nitric oxide synthase is upregulated, resulting in sustained elevations of the serum nitric oxide level, with subsequent vasodilations. Sustained suppression of vasopressin adds to this sometimes refractory vasodilated state.

3. Which of the following statements regarding septic shock is true?
- **a.** Cardiac output is always decreased.
- **b.** Much of the cardiac decompensation is reversible.
- **c.** Systemic vascular resistance is high.
- **d.** The ejection fraction is always increased.

Answer: B. Sepsis affects myocardial function and peripheral vascular tone. The systemic vascular resistance is usually markedly depressed. Cardiac output is generally increased because of a compensatory tachycardia that can at least partially overcome the ventricular dilation and depressed ejection fraction. The myocardial effects are typically reversible.

4. What are the two most common sources of infection in cases of sepsis?
- **a.** Genitourinary > respiratory
- **b.** Musculoskeletal > genitourinary
- **c.** Respiratory > gastrointestinal
- **d.** Respiratory > genitourinary

Answer: C. Epidemiology studies show that pneumonia is the most common cause of sepsis, followed by an intra-abdominal source. However, a careful investigation to identify the source of infection should occur.

5. In most chemotherapy patients, which neutrophil count should prompt admission, isolation, and empirical antibiotics?
- **a.** <250 cells/mm^3
- **b.** <500 cells/mm^3
- **c.** <750 cells/mm^3
- **d.** <1000 cells/mm^3

Answer: B. Patients with an ANC <500 cells/mm^3 are at increased risk of infection; thus, a conservative approach should be taken in these patients.

6. Among patients with clinical septic shock, which percentage will have positive blood cultures?
- **a.** 0%–30%
- **b.** 30%–60%
- **c.** 60%–90%
- **d.** 90%–100%

Answer: B. Although blood cultures are perhaps a gold standard for identification and isolation of bacteria, they may be negative even when the etiology of illness is clearly infectious. Empirical antibiotic treatment in the ED remains a standard approach.

Hypothermia, Frostbite, and Nonfreezing Cold Injuries

Ken Zafren and Daniel F. Danzl

ACCIDENTAL HYPOTHERMIA

KEY CONCEPTS

- Patients with hypothermia should be actively rewarmed whenever possible. Specific indications for active rather than passive rewarming include trauma, cardiovascular instability, temperature below 32°C (89.6°F), poor rate of passive rewarming, and endocrine insufficiency.
- Rewarming methods should be chosen to minimize core temperature afterdrop.
- If tachycardia is out of proportion to core temperature then hypoglycemia, hypovolemia, or an overdose should be considered.
- The effects of most medications are temperature dependent. Overmedication to achieve an effect when the patient is cold could cause toxicity during rewarming.
- Laboratory coagulation tests are performed at 37°C (98.6°F). Despite clinically obvious coagulopathy, measures of coagulation will be deceptively normal. Treatment for coagulopathy is to rewarm the patient.
- There are no safe predictors of serum electrolyte levels. Hypothermia enhances the cardiac toxicity of hyperkalemia and obscures premonitory electrocardiographic changes.
- Failure to rewarm despite good technique should suggest infection, endocrine insufficiency, or a futile resuscitation.

Foundations

Background and Importance

Reported reanimations of profoundly cold victims in prolonged cardiac arrest and the emergence of targeted temperature management (formerly called "therapeutic hypothermia") after cardiac arrest have made hypothermia a compelling topic. The lowest recorded core temperature in accidental hypothermia with successful resuscitation in an adult is 13.7°C (56.7°F) in a 29-year-old Norwegian physician. Cardiopulmonary resuscitation was initiated at the scene. The 9-hour resuscitation included 179 minutes of cardiopulmonary bypass. The lowest recorded core temperature with successful resuscitation in a child is 11.8°C in a 2-year-old boy who had an unwitnessed cardiac arrest. CPR was administered for 135 minutes. He was weaned off ECMO after 22 hours.[1] Profoundly cold patients have been resuscitated with full neurologic recovery after CPR for as long as 9 hours.[2] The lowest possible temperature with neurologically intact survival in accidental hypothermia is not known. The lowest temperature in a survivor of induced hypothermia was long considered to be 9°C (48.2°F). Recently rediscovered journal articles from the early 1960s document survival after much lower induced core temperatures, as low as 4°C (39.2°F) measured using esophageal probes.

The treatment of accidental hypothermia has been controversial throughout history. The Bible recounts the truncal rewarming of King David by a damsel. Various remedies, including rubbing extremities with hot oil, were mentioned by Hippocrates, Aristotle, and Galen.

Cold weather has had a major impact on military history. Hannibal lost nearly half of his army of 46,000 while traversing the Alps in 218 BCE. The winter of 1777 took its toll on Washington's troops at Valley Forge. Napoleon's chief surgeon, Baron Larrey, reported that only 350 of the 12,000 men in the 12th division survived the cold during their retreat from Russia in 1812. Those soldiers who were rapidly rewarmed closest to the campfire died. Many lessons were relearned during World Wars I and II when pilots and U-boat crews perished in the cold waters of the North Atlantic.

Cold-related tragedies also affect civilians, including hunters, skiers, climbers, boaters, swimmers, and survivors of natural disasters. Hypothermia can occur in a wide range of climates and seasons. Large numbers of cases occur in urban settings. Indoor hypothermia in elderly patients is an increasing problem.[3] Primary hypothermia fatalities can be classified as accidental, homicidal, or suicidal. Death certificate data have underreported mortality from secondary hypothermia, in which cold complicates systemic diseases. As a result, the overall impact of cold on mortality from cardiovascular and neurologic disorders is greatly underestimated.

Anatomy, Physiology, and Pathophysiology

Hypothermia is defined as a core temperature below 35°C (95°F). Many variables contribute to the development of accidental hypothermia. Exposure, old age, poor health, inadequate nutrition, and various medications and intoxicants can decrease heat production, increase heat loss, or interfere with thermoregulation. Compensatory responses to heat loss through conduction, convection, radiation, and evaporation are often overwhelmed by exposure, even in healthy persons. Medications and central nervous system problems can also interfere with thermoregulation.

Temperature Regulation

Human basal heat production increases with ingestion of food or calorie containing fluids, muscle activity, fever, and acute cold exposure. Cold stress increases preshivering muscle tone, potentially doubling heat production. Maximal heat production, primarily due to shivering, lasts only a few hours because of fatigue and glycogen depletion.

Shivering thermogenesis increases the basal metabolic rate up to five times, markedly increasing oxygen consumption. Shivering begins at a normal core temperature when the skin is cooled. Shivering intensity is modulated by the posterior hypothalamus and the spinal cord. The preoptic anterior hypothalamus orchestrates nonshivering heat conservation and dissipation. Heat loss occurs by radiation, conduction, convection, respiration, and evaporation. The most common causes of accidental hypothermia are convective heat loss to cold air and conduction and convection in cold water. Heat loss increases up to five times in wet clothing. Conduction and convection in cold water can increase heat loss by a factor of 25.

Individuals with greater amounts of subcutaneous fat lose heat more slowly than thin people. Convective losses increase with shivering. Respiration and evaporation cause heat loss in the warming of inspired air and by insensible evaporation from the skin and lungs.

Cutaneous and respiratory heat losses are markedly influenced by the ambient temperature, air motion, and relative humidity. Greater losses occur in cool, dry, windy environments. When there is no sweating, most heat loss is through radiation and convection. Convective losses are significant in immersion-induced hypothermia. Children cool faster than adults because they have higher ratios of surface area to mass. Chronic cold exposure may result in thermal acclimatization (Fig. 128.1).

When the core temperature ranges from 37°C to 30°C (98.6°F to 86°F), vasoconstriction, shivering, and nonshivering basal and endocrine thermogenesis generate heat. From 30°C to 24°C (86°F to 75.2°F), the basal metabolic rate decreases, and shivering is absent. At temperatures below 24°C (75.2°F), autonomic and endocrine mechanisms for heat conservation become inactive. The pathophysiologic characteristics of hypothermia are described in Table 128.1.

Cardiovascular System

Initial tachycardia is followed by progressive bradycardia, although periods of tachycardia sometimes occur. The pulse decreases by 50% at 28°C (82.4°F). If the degree of tachycardia is inconsistent with the core temperature, consider associated conditions such as hypoglycemia, drug ingestion, and hypovolemia.

The bradycardia of hypothermia results from decreased spontaneous depolarization of cardiac pacemaker cells and is refractory to atropine. The electrocardiographic features of hypothermia include the

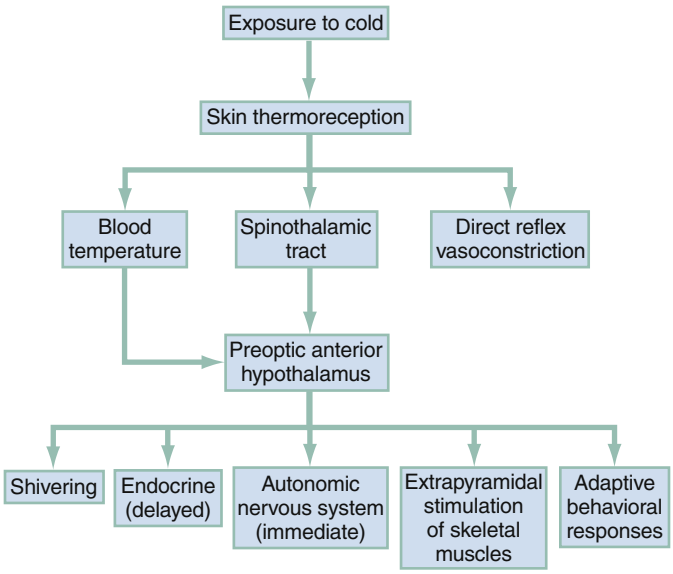

Fig. 128.1 Physiology of cold exposure.

TABLE 128.1 Physiologic Characteristics of the Four Zones of Hypothermia

State	Core Temperature °C (°F)	Characteristics
Cold-stressed	37–35 (98.6–95)	Shivering and increased metabolism
Mild	35 (95)	Increased shivering thermogenesis; increase in metabolic rate
	34 (93.2)	Normal blood pressure; maximum respiratory stimulation; ataxia, and apathy
	33 (91.4)	Amnesia
Moderate	32 (89.6)	Stupor; 25% decrease in oxygen consumption
	31 (87.8)	Increased shivering thermogenesis
	30 (86)	Atrial fibrillation and other dysrhythmias; poikilothermia; pulse and cardiac output two-thirds normal; insulin ineffective; Progressive decrease in level of consciousness; loss of consciousness can be seen
	29 (85.2)	Progressive decrease in pulse, and respiration; pupils dilated
Severe	28 (82.4)	Ventricular fibrillation susceptibility; 50% decrease in oxygen consumption and pulse
	27 (80.6)	Loss of reflexes
	26 (78.8)	Major acid-base disturbances; no reflexes or response to pain
	25 (77)	Cerebral blood flow one-third normal; cardiac output 45% normal; pulmonary edema may develop
	23 (73.4)	No corneal or oculocephalic reflexes
	22 (71.6)	Maximum risk of ventricular fibrillation; 75% decrease in oxygen consumption
	20 (68)	Lowest resumption of cardiac electromechanical activity; pulse 20% of normal
	19 (66.2)	Flat electroencephalogram
	13.7 (56.7)	Lowest accidental hypothermia survival in an adult
	11.8 (53.2)	Lowest accidental hypothermia survival in a child
	4.2 (39.6)	Lowest therapeutic hypothermia survivor

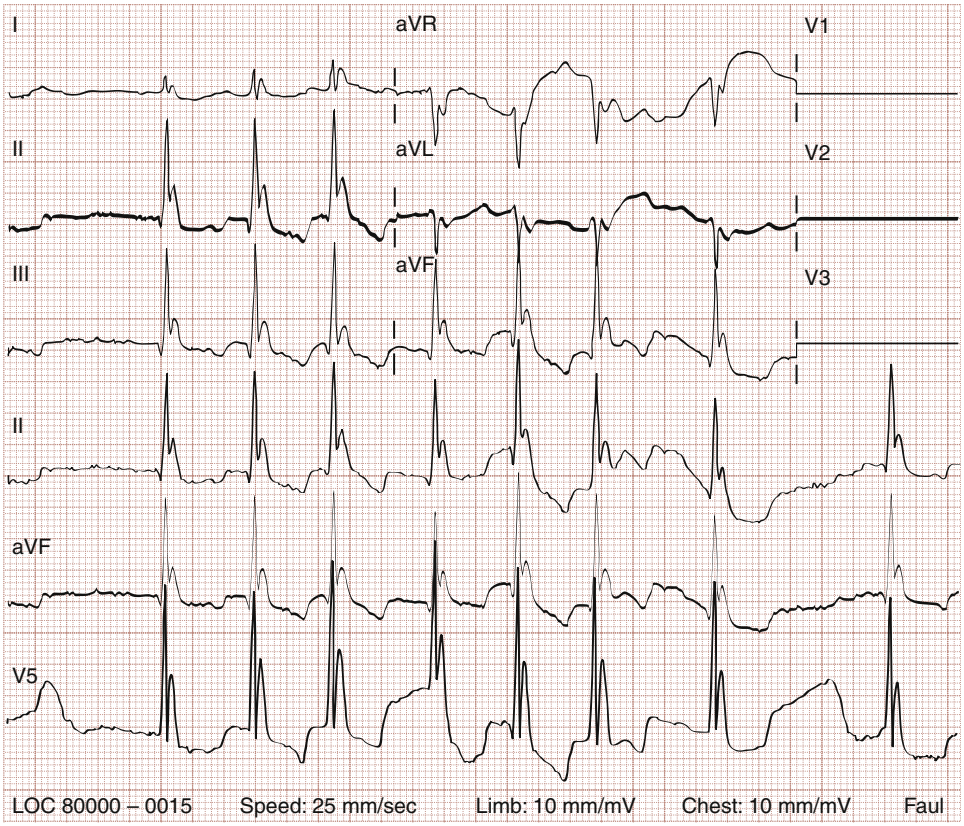

Fig. 128.2 Hypothermic J waves.

Osborn (J) wave seen at the junction of the QRS complex and ST segment with core temperatures below 32°C (89.6°F; Fig. 128.2). J waves are neither unique to hypothermia nor of any prognostic value. J waves are normally upright in aVL, aVF, and the left precordial leads. J waves can also be seen during local cardiac ischemia, with sepsis or CNS lesions, and hypercalcemia. J waves may resemble myocardial injury current and may not be recognized by ECG computer interpretations. This can result in misguided thrombolysis, which could exacerbate preexistent coagulopathies. Hypothermia can also cause electrocardiographic changes that mimic Brugada syndrome.

Atrial and ventricular dysrhythmias are common in moderate or severe hypothermia. Because the conduction system is more sensitive to the cold than the myocardium, cardiac cycle prolongation occurs. As hypothermia worsens, the PR interval, then the QRS interval, and finally the QTc interval become prolonged. Even in the absence of shivering, increased muscle tone may obscure P waves or produce artifacts. Atrial fibrillation is common when the core temperature is below 32°C (89.6°F). Sinus atrial or junctional rhythms also occur. Atrial fibrillation usually converts spontaneously during rewarming, but mesenteric embolization is a hazard. Ventricular fibrillation (VF) may be caused by tissue hypoxia, physical jostling, electrophysiologic or acid-base disturbances, or autonomic dysfunction. Asystole and VF can occur spontaneously when the core temperature falls below 25°C (77°F), but vital signs may persist well below 24°C (75.2°F).

The term *core temperature afterdrop* refers to a decrease in an individual's core temperature after removal from the cold. Temperature equilibration by conduction of heat from the core to the cooler peripheral tissue contributes to afterdrop, but countercurrent cooling of blood perfusing cold tissues in the periphery before returning to the warmer core results in a greater decrease in the core temperature. Active external rewarming of the extremities abolishes peripheral vasoconstriction and reverses arteriovenous shunting. In one human experiment, cooling followed by immersion in a warm bath produced a 30% fall in mean arterial pressure, with a 50% decrease in peripheral vascular resistance.

Core temperature afterdrop is clinically relevant in the treatment of patients with large temperature gradients between the core and periphery. Large afterdrops can occur in severely hypothermic patients if frostbitten extremities are thawed before the core is rewarmed.

Central Nervous System

Hypothermia progressively depresses the CNS. Significant alteration of brain electrical activity begins below about 33.5°C (92.3°F). The electroencephalogram becomes silent at about 19°C to 20°C (66.2°F to 68°F). Cerebral autoregulation is maintained with an increase in vascular resistance until about 25°C (77°F). In severe hypothermia, there is a redistribution of blood flow to the brain. Like the heart, the brain has a critical period of tolerance to hypothermia.

Renal System

Exposure to cold induces diuresis, regardless of the state of hydration. The kidneys excrete a large amount of dilute urine that is essentially glomerular filtrate and does not clear nitrogenous waste products. Severe hypothermia causes relative central hypervolemia due to peripheral vasoconstriction. Cold diuresis may act as a volume regulator to diminish the capacitance vessel overload. Cold water immersion can further increase urinary output by 3.5 times.

Respiratory System

Hypothermia initially stimulates respiration, followed by a progressive decrease in the respiratory minute volume. Carbon dioxide production decreases 50% with an 8°C (14.4°F) decrease in temperature. Stimuli for respiratory control are altered in severe hypothermia and carbon dioxide

BOX 128.1 Factors Predisposing to Hypothermia

Decreased Heat Production
Endocrine failure
Hypopituitarism
Hypothyroidism
Diabetes
Insufficient fuel
Hypoglycemia
Malnutrition
Marasmus
Kwashiorkor
Extreme exertion
Neuromuscular inefficiency
Age extremes
Impaired shivering
Inactivity
Lack of adaptation

Increased Heat Loss
Environmental
Immersion
Nonimmersion
Induced vasodilation
Pharmacologic
Toxicologic
Erythrodermas
Burns
Psoriasis
Ichthyosis
Exfoliative dermatitis
Iatrogenic
Emergency deliveries
Cold infusions
Heatstroke treatment

Impaired Thermoregulation
Peripheral failure
Neuropathy
Acute spinal cord transection
Diabetes
Central neurologic failure
Central nervous system trauma
Cerebrovascular accident
Toxicologic
Metabolic
Subarachnoid hemorrhage
Pharmacologic
Hypothalamic dysfunction
Parkinson disease
Anorexia nervosa
Cerebellar lesion
Neoplasm
Congenital intracranial anomalies
Multiple sclerosis

Miscellaneous Associated Clinical States
Recurrent hypothermia
Episodic hypothermia
Sepsis
Pancreatitis
Carcinomatosis
Cardiopulmonary disease
Vascular insufficiency
Uremia
Paget's disease
Giant cell arteritis
Sarcoidosis
Shaken baby syndrome
Multisystem trauma
Shapiro's syndrome
Wernicke-Korsakoff syndrome
Hodgkin disease

retention with respiratory acidosis can occur. Hypercapnia increases core temperature cooling during snow burial. Other pathophysiologic factors that adversely affect the respiratory system include viscous bronchorrhea, decreased ciliary motility, and noncardiogenic pulmonary edema.

Predisposing Factors

Factors that predispose to hypothermia include decreased heat production, increased heat loss, and impaired thermoregulation (Box 128.1). Hypothermia can occur even in warm conditions.

Decreased Heat Production. Decreased thermogenesis may be due to endocrine dysfunction, such as hypopituitarism, hypoadrenalism, or myxedema. Myxedema coma is several times more common in women and up to 80% of women with myxedema coma are hypothermic. Hypothyroidism is often occult, with no history of lassitude, dry skin, arthralgias, or cold intolerance. Hypoglycemia can predispose to hypothermia. Another cause of decreased heat production is malnutrition, with a decrease in subcutaneous fat. Severe malnutrition with wasting contributes to heat loss. Kwashiorkor is less of a risk due to the insulating effect of hypoproteinemic edema.

Neonates are at particular risk of hypothermia due to large surface area–to–mass ratio, relatively little subcutaneous tissue, and inefficient shivering. Additionally, neonates do not have behavioral defense mechanisms. Acute neonatal hypothermia is common after emergency delivery or resuscitation and has also been reported after abandonment of infants. Hypothermic neonates are lethargic, fail to thrive, and have a weak cry. Many have paradoxically rosy cheeks. Hypothermia that occurs after 72 hours of life is often due to septicemia. Hypothermia can occur in shaken baby syndrome and may be a factor in some cases of sudden infant death syndrome.

Most older adults are capable of normal thermoregulation, but conditions such as immobility and systemic disease may interfere with heat production and conservation. Geriatric autonomic dysfunction may cause an inability to sense cold, abnormal adaptive behavioral responses, and decreased peripheral blood flow.

Increased Heat Loss. Patients with erythrodermas, such as psoriasis, exfoliative dermatitis, ichthyosis, eczema, and burns, can have increased peripheral blood flow. Iatrogenic causes of heat loss include exposure during resuscitation, cold or room temperature

infusions, overcooling of patients with heatstroke, and overzealous burn treatment.

Ethanol is metabolized slowly in hypothermia and interacts with thermoregulatory neurotransmitters. Ethanol may directly suppress the activity of the posterior hypothalamus and mammillary bodies. Cutaneous heat loss increases through vasodilation and shivering thermogenesis is decreased. Ethanol is the most common cause of excessive heat loss in urban settings. Aging is associated with an increased sensitivity to the hypothermic actions of ethanol. Intoxicated persons may be incapable of adaptive behavior to avoid cold and can be impaired by hypothermic alcoholic ketoacidosis.

Impaired Thermoregulation. Thermoregulation can be impaired centrally, peripherally, or metabolically. Skull fractures, particularly basilar fractures, and chronic subdural hematomas are associated with central impairment. Other causes include strokes, neoplasms, anorexia nervosa, and Hodgkin and Parkinson diseases. The final common pathway in these disorders may be centrally mediated vasodilation. Cerebellar lesions can produce choreiform inefficient shivering.

In therapeutic or toxic doses, antidepressants, mood stabilizers, antipsychotics, anxiolytics, and general anesthetics interfere with thermoregulation by impairing centrally mediated vasoconstriction. Other overdoses, including by organophosphates, opioids, sedative hypnotics, barbiturates, and carbon monoxide, predispose to hypothermia.

Peripheral thermoregulatory failure occurs in neurogenic shock after acute spinal cord transection. In spinal cord injury, disruption of the autonomic nervous system eliminates vasoconstriction. The patient effectively becomes poikilothermic and can rapidly become hypothermic. Neuropathies and diabetes are also peripheral causes of heat loss. Abnormal plasma osmolality may cause hypothalamic dysfunction in uremia, lactic acidosis, diabetic ketoacidosis, and hypoglycemia.

Trauma

After trauma, hypotension, immobility in a cold environment, and hypovolemia predispose to hypothermia. In patients with major injuries, shivering is decreased or absent, causing skin and core temperatures to fall. Thermoregulation is impaired, and heat production decreases.

Hypothermia may exacerbate blood loss by inducing coagulopathy due to impaired activity of coagulation factors and enhanced plasma fibrinolytic activity, with decreased function and sequestration of platelets. Hypothermia in trauma is a risk factor for multiorgan dysfunction. Traumatic injuries may be missed if hypotension or neurologic findings such as areflexia or paralysis are misattributed to hypothermia. Major risk factors for hypothermia in trauma patients include extremes of age, severe injury, intoxication, large transfusion requirements, and prolonged field, emergency department (ED), and operating room times.

Hypothermia can protect the brain from ischemia only when induced before shock develops. This reduces adenosine triphosphate (ATP) use while ATP stores are nearly normal. In trauma patients, ATP stores are already depleted.

Clinical Features

Appreciation of subtle presentations facilitates the early diagnosis of mild to moderate hypothermia. Vague symptoms include hunger, nausea, confusion, dizziness, chills, pruritus, and dyspnea (Box 128.2). During outdoor activities, individuals may simply become uncooperative, uncoordinated, moody, or apathetic. Indoors, older patients may exhibit confusion or become less communicative and may display lassitude or a flat affect. Progression of mental deterioration or motor skill impairment may mimic dementia. Symptoms such as slurred speech and ataxia may resemble symptoms of stroke or intoxication. Some older adults have a decreased ability to sense cold and fail to take adaptive action.

Paradoxical undressing has been widely reported in hypothermic patients. This final preterminal effort may be related to peripheral vasoconstrictive changes of hypothermia. Hypothermic patients who have paradoxically undressed have been mistaken for victims of sexual assault or thought to have a psychiatric disorder. In urban settings, hypothermia is most commonly associated with alcohol consumption or underlying illness. Other causes include stroke, drug overdose, psychiatric emergency, and major trauma.

Neurologic manifestations vary widely. A progressive decrease in the level of consciousness is usually proportional to the degree of hypothermia. Some patients, however, continue to be verbally responsive and display intact reflexes at 27°C to 25°C (80.6°F to 77°F).

Eye movement abnormalities and extensor plantar responses do not correlate directly with the degree of hypothermia. Cranial nerve signs may be seen with bulbar damage from central pontine myelinolysis. Above 22°C (71.6°F), it should be assumed that nonreactive dilated pupils reflect inadequate tissue perfusion rather than hypothermia.

Neuromuscular examination may reveal stiff posture, pseudo–rigor mortis, or opisthotonos. Reflexes are usually hyperactive to 32°C (89.6°F) and then become hypoactive, disappearing around 26°C (78.8°F). Cremasteric reflexes are absent because the testicles are already retracted. The plantar response usually remains flexor until 26°C (78.8°F). The knee jerk reflex is the last reflex to disappear and the first to reappear with rewarming. Diagnosis of CNS disorders, including spinal cord lesions, may be obscured by hypothermia. From 30°C to 26°C (86°F to 78.8°F), both contraction and relaxation phases of the reflexes are equally prolonged. If intact, the ankle jerk is helpful to diagnose hypothermic myxedema. Myxedema characteristically prolongs the relaxation phase more than the contraction phase.

Psychiatric disorders do not improve when the patient is cold. Mental status alterations can include anxiety, perseveration, neurosis, and psychosis. Individuals who are functional in warm conditions may decompensate in cold weather. Hypothermia-induced psychiatric presentations and suicide attempts are commonly misdiagnosed.

Differential Diagnoses

The differential diagnosis of hypothermia is broad and includes hypothyroidism, hypopituitarism, diabetes, hypoglycemia, malnutrition, intracranial and spinal cord injuries, and sedative-hypnotic and alcohol intoxication (see Box 128.1). Hypothermia is also common in patients with Wernicke encephalopathy. Hypothermia can mask the usual clinical triad of ophthalmoplegia, confusion, and truncal ataxia. Intravenous thiamine can be diagnostic and therapeutic.

Hypothermia occurs in conjunction with infections, most commonly overwhelming gram-negative sepsis, pneumonia, meningitis, and encephalitis. Other infections that can lead to hypothermia include bacterial endocarditis, brucellosis, malaria, syphilis, typhoid, miliary tuberculosis, and trypanosomiasis.

Medical conditions associated with hypothermia include carcinoma, pancreatitis, peritonitis, and cerebrovascular disease. Low cardiac output resulting from myocardial infarction can induce hypothermia. Fetal and maternal bradycardia and hypothermia may result from magnesium sulfate infusion during preterm labor. Hypothermia can cause delayed recovery from neuromuscular blockade. Although many conditions can cause or be associated with accidental hypothermia, there is no true differential diagnosis of accidental hypothermia once the diagnosis has been established by core temperature measurement.

BOX 128.2 Presenting Signs of Hypothermia

Head, Eye, Ear, Nose, Throat
Mydriasis
Decreased corneal reflexes
Extraocular muscle abnormalities
Erythropsia (altered color perception)
Flushing
Facial edema
Epistaxis
Rhinorrhea
Strabismus

Cardiovascular
Initial tachycardia
Subsequent bradycardia
Dysrhythmias
Decreased heart tones
Hepatojugular reflux
Jugular venous distention

Ecchymosis
Necrosis
Edema
Gangrene

Diagnostic Testing

Except in mild cases of hypothermia, initial laboratory evaluation should include glucose level, complete blood cell count, comprehensive metabolic panel, serum lipase level, and coagulation studies. Blood urea nitrogen and creatinine levels should be checked because renal failure may occur after rewarming in patients with chronic hypothermia. Arterial or venous blood gases, if obtained, should not be temperature-corrected. A serum ethanol level and urine toxicology screen may be helpful based on history or when a depressed level of consciousness is inconsistent with the degree of hypothermia. Thyroid function studies, cardiac markers, and serum cortisol levels may also be indicated.

Acid-Base Balance. Blood gas analyzers warm blood to 37°C (98.6°F), increasing the partial pressure of dissolved gases. This results in arterial blood gases with higher oxygen and carbon dioxide and lower pH than in vivo values. Attempting to maintain a corrected pH at 7.4 and arterial partial pressure of carbon dioxide ($Paco_2$) at 40 mm Hg during hypothermia depresses cerebral and coronary blood flow and cardiac output and increases the incidence of VF. The ideal acid-base goal is an uncorrected pH of 7.4 and $Paco_2$ of 40 mm Hg.

Cold blood buffers poorly. In normothermia, pH decreases by 0.08 unit for every 10-mm Hg increase in $Paco_2$. At 28°C (82.4°F), the decrease in pH doubles. Because the neutral point of water at 37°C (98.6°F) is a pH of 6.8, the normal 0.6-unit pH offset between blood and intracellular water should be maintained at all temperatures (Fig. 128.3). Intracellular electrochemical neutrality ensures optimal

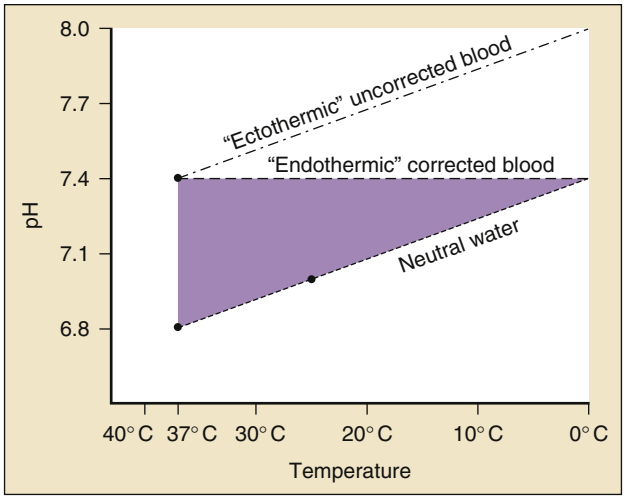

Fig. 128.3 Neutrality reflects the pH of water at any given temperature. The pH of water is 6.8 at 37°C (98.6°F) and 7.0 at 25°C (78.8°F). The physiologically ideal intracellular-to-extracellular, 0.6-unit pH offset will be maintained if the arterial pH is kept at 7.42, uncorrected for temperature.

enzymatic function at all temperatures. Relative alkalinity affords myocardial protection and improves the heart's electrical stability.

Hematologic Evaluation. The hematocrit can be deceptively high due to decreased plasma volume. The hematocrit increases 2% for every 1°C (1.8°F) fall in temperature. A low-normal hematocrit level in a moderately to severely hypothermic patient should suggest acute or chronic blood loss.

Splenic, hepatic, and splanchnic sequestration in hypothermia decreases leukocyte and platelet counts. As in normothermia, a normal white blood cell count does not exclude infection, especially if the patient is debilitated, alcoholic, myxedematous, or at either extreme of age.

Frequent evaluation of serum electrolyte levels during rewarming is essential. There are no safe predictors of values or trends. Changes occur in membrane permeability and in the sodium-potassium pump. The patient's preexisting physiologic status, severity and chronicity of hypothermia, and method of rewarming alter the serum electrolyte values.

The plasma potassium level is independent of hypothermia. Hyperkalemia can be associated with metabolic acidosis, rhabdomyolysis, or renal failure. Hypothermia enhances the cardiac toxicity of hyperkalemia and obscures premonitory electrocardiographic changes. Hypokalemia is most common with chronic hypothermia. It results from potassium entering muscle, rather than potassium diuresis. A decline in the serum potassium level despite a decreasing serum pH is caused by intracellular pH fluxes greater than extracellular pH fluxes.

Conditions associated with hypokalemia include preexisting diabetic ketoacidosis, hypopituitarism, inappropriate secretion of antidiuretic hormone, previous diuretic therapy, and alcoholism. If the serum potassium level is less than 3 mEq/L, provide supplementation during rewarming.

Blood urea nitrogen and creatinine levels are elevated with preexisting renal disease or decreased clearance. Because of hypothermic fluid shifts, hematocrit and blood urea nitrogen levels are poor indicators of actual fluid status.

The blood glucose level may provide a subtle clue to the chronicity of hypothermia. Acute hypothermia initially elevates the blood glucose level by catecholamine-induced glycogenolysis, diminished insulin release, and inhibition of cellular membrane glucose carrier systems. Subacute and chronic hypothermia produce glycogen depletion, leading to hypoglycemia. Hypoglycemia can also develop during rewarming in acute hypothermia. Symptoms of hypoglycemia can be masked by hypothermia. A cold-induced renal glycosuria neither implies hyperglycemia nor guarantees normoglycemia.

When hyperglycemia persists during rewarming, suspect hemorrhagic pancreatitis or diabetic ketoacidosis. Actively rewarm patients with diabetic ketoacidosis past 30°C (86°F) because insulin is ineffective below 30°C (86°F). Correction of hypoglycemia corrects the level of consciousness only to the level consistent with the degree of hypothermia.

Severe hypothermia also causes serum enzyme level elevation because of the ultrastructural cellular damage. Rhabdomyolysis is commonly associated with cold exposure. Ischemic pancreatitis may result from the microcirculatory shock of hypothermia. Decreased pancreatic blood flow then activates proteolytic enzymes, increasing the serum lipase level.

Hypothermic Coagulation. A physiologic hypercoagulable state can occur with hypothermia and can be associated with a disseminated intravascular coagulation (DIC)–type syndrome. The cause may be catecholamine or steroid release, circulatory collapse, or release of tissue thromboplastin from cold, ischemic tissue.

Coagulopathies also occur because the enzymatic activity of the activated clotting factors is depressed by the cold. Clotting prolongation is proportional to the number of steps in the cascade. Because kinetic tests of coagulation are performed in the laboratory at 37°C (98.6°F), there is a disparity between clinically evident coagulopathy in vivo and deceptively normal prothrombin times, partial thromboplastin times, and international normalized ratios reported by the laboratory. The only effective treatment is rewarming, not administration of clotting factors.

Leukopenia and thrombocytopenia usually reverse with rewarming. Clinically significant coagulopathies can still occur, particularly in association with trauma and volume resuscitation. Cold-induced thrombocytopenia may be from direct bone marrow suppression or from splenic and hepatic sequestration. Platelet thromboxane B2 production is also temperature dependent, which can result in decreased platelet function and adhesion.

Elevated blood viscosity seen in hypothermia may be exacerbated in patients with cryoglobulinemia or cryofibrinogenemia, especially in older patients. Cryofibrinogen, a cold-precipitated fibrinogen, is associated with collagen vascular diseases, carcinomas, and coliform sepsis. Cold hemagglutination from cold agglutinins produces hemolysis or agglutination with thrombosis, which might explain the increase in coronary and cerebral thromboses in winter.

Imaging

If the patient is not alert and there is suspicion of trauma, standard trauma imaging is indicated, including an extended focused assessment with sonography in trauma (eFAST) and computed tomography (CT) scan of the head. CT scanning of the abdomen and pelvis may show pancreatic calcifications, unsuspected pneumoperitoneum, small bowel dilation from hypothermia-induced mesenteric vascular occlusion, or colonic dilation associated with myxedema coma.

Management

General Measures

Patients who are cold, stiff, and cyanotic, with fixed pupils, inaudible heart tones, and no visible thoracic excursions, can still be successfully resuscitated. Unexpectedly, a few patients have revived in the morgue while awaiting autopsy.

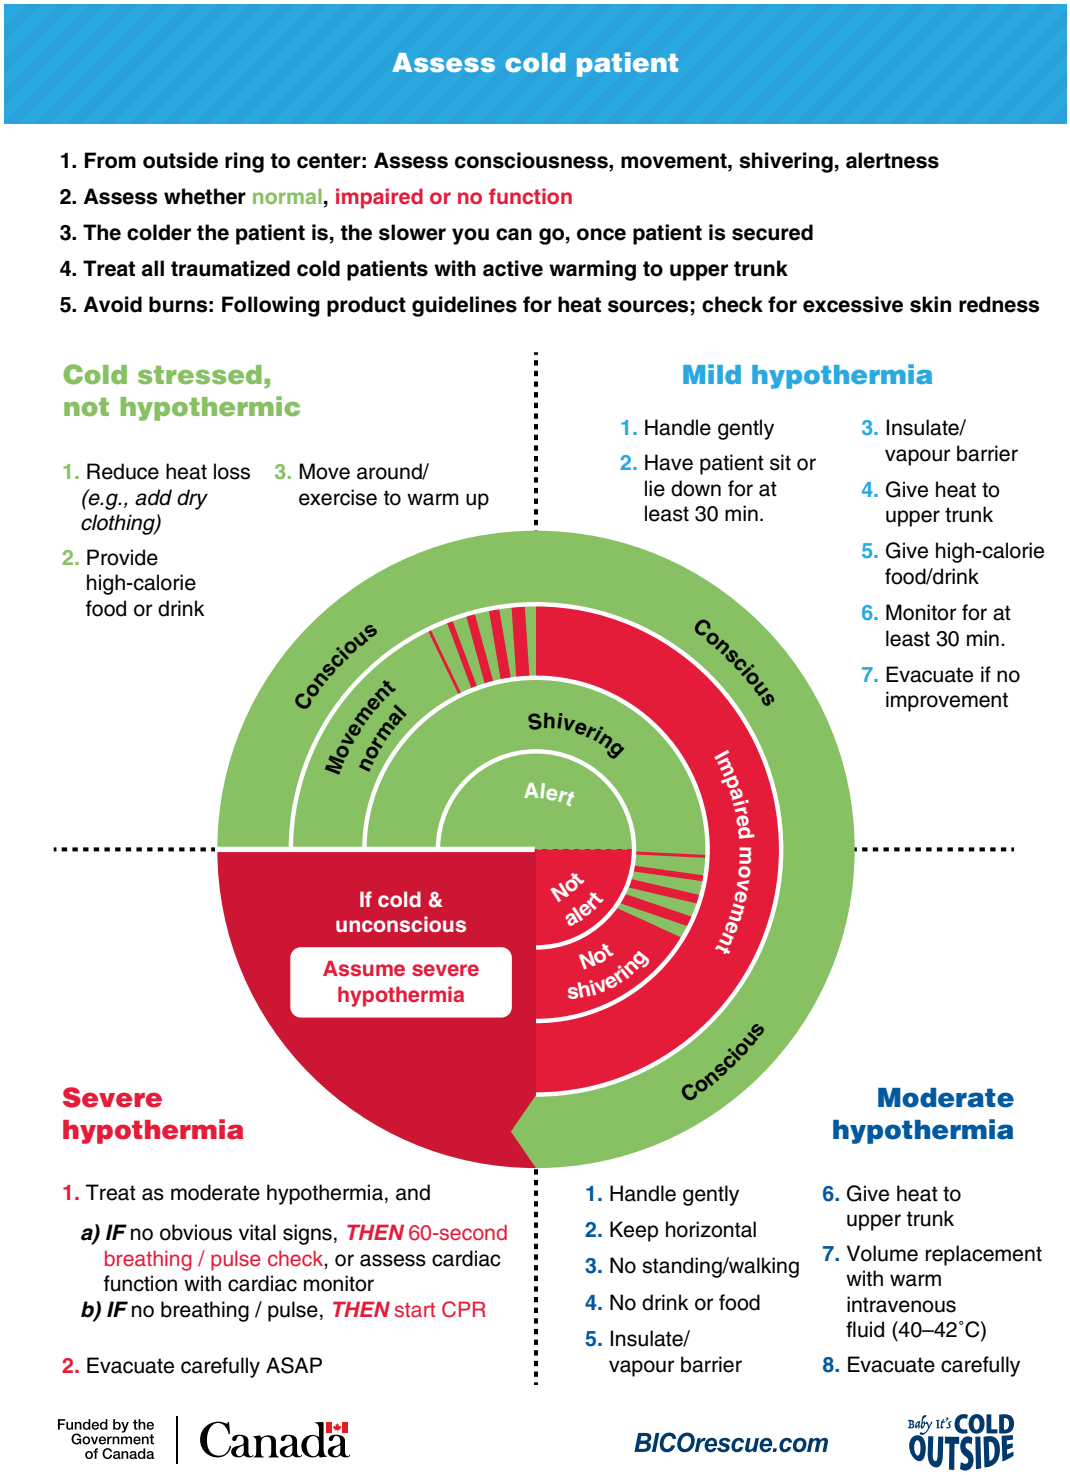

Fig. 128.4 "Cold card" for treatment of cold patients.

Pertinent history includes information about preexisting cardiac, pulmonary, neurologic, or endocrine disease. The duration of exposure, outdoor conditions, circumstances of discovery, associated injuries, and predisposing conditions should be documented. Initial management should emphasize prevention of further heat loss. Specific goals of prehospital care include adequate insulation, avoidance of core afterdrop, gentle handling, and transport in a horizontal position.[4] Hypothermic patients should be actively rewarmed in the field, if possible.[4] A graphic flowchart to assist with clinical staging of hypothermia and to guide treatment is available as a "cold card" (Figure 128.4).[5]

A patient who is unresponsive and not shivering should be treated for severe hypothermia. At core temperatures below 32°C (89.6°F), expect an irritable myocardium, a large temperature gradient between the core and periphery, and relative hypovolemia.

In the ED, hypothermia should be confirmed and monitored with continuous core temperature evaluation. Clinically, the rectal

temperature is most widely used. However, it lags behind core temperature changes and is influenced by lower extremity temperatures and probe placement. The probe should be inserted to 15 cm and not placed into cold feces. Epitympanic temperature equilibrates rapidly with core temperature and is closest to the hypothalamic temperature. Most epitympanic probes are not suitable for field use.[4] Infrared thermography (tympanic temperature) is too unreliable be used, except to exclude hypothermia. So-called temporal artery thermometers are often random number generators and unreliable for clinical use. If the airway is protected, an esophageal probe placed in the lower third of the esophagus, an average of 24 cm below the larynx in adults, is the ideal method for continuous core temperature monitoring. If the probe is placed higher, the reading can be falsely elevated by inhalation of heated oxygen. An esophageal probe without markings can have tape placed on the proximal part to mark the correct depth of insertion.

Hand-held Doppler may be useful to establish the presence of a spontaneous pulse. Bedside echocardiography should precede chest compressions. Pulse oximetry is usually unreliable in hypothermia with peripheral vasoconstriction. It is often not possible to obtain an accurate reading. End-tidal carbon dioxide measurements accurately assess tissue perfusion and tracheal tube placement, but only at normal temperatures. Commercially available devices do not function when humidified air is used for airway rewarming. Endotracheal intubation or placement of a supraglottic airway may be indicated unless the patient has intact protective airway reflexes. Cold depression of ciliary activity allows for the accumulation of secretions with frothy sputum and chest congestion. It may be hard to differentiate between bronchorrhea and pulmonary edema. Fiberoptic or blind nasotracheal intubation can be useful to avoid a surgical airway when cold-induced trismus is present.

Dysrhythmias during intubation are rare. These may be due to failure to preoxygenate, mechanical jostling, acid-base changes, and electrolyte level fluctuations. A nasogastric tube is indicated after endotracheal intubation because decreased gastric motility and gastric dilation are common. Physical examination of the abdomen is unreliable because cold can induce rectus muscle rigidity. Many moderately and severely hypothermic patients have decreased or absent bowel sounds. It is important to evaluate the patient for an associated ileus, pancreatitis, or occult trauma.

In moderate and severe hypothermia, indwelling urinary catheters are useful to monitor urine output and help determine the severity of vascular fluid shifts.

Cardiac monitoring should be continuous. If central venous access is required, avoid insertion of the catheter tip into the heart, which can irritate the myocardium and precipitate dysrhythmias. Arterial catheters for continuous monitoring of intra-arterial blood pressure may be helpful in profoundly hypothermic patients. Placement of a pulmonary artery catheter risks perforation of a cold, stiff, pulmonary artery and is not recommended in the emergency department.

Volume Resuscitation

Patients with moderate or severe hypothermia are usually volume depleted. They are prone to thromboembolism resulting from increased viscosity. During rewarming, the total plasma volume is usually high, but the circulatory plasma volume is usually low due to increased peripheral vascular resistance. Rapid volume expansion can be lifesaving, especially in hypothermic neonates. Adult patients with moderate or severe hypothermia should initially receive a 500-mL fluid challenge of warmed normal saline. Avoid lactated Ringers solution because the cold liver metabolizes lactate poorly. Fluids administered via the intravenous (IV) route should be warmed to 40°C to 42°C (104°F to 107.6°F). If a commercial fluid or blood warmer is not available, IV fluids can be heated in a standard microwave. Shake the fluid bag before administration to avoid hot spots. Avoid rapid central venous administration, which may produce myocardial thermal gradients. Another option in vasoconstricted patients is administration via the intraosseous route. Countercurrent heat exchangers effectively heat crystalloids and blood from 10°C to 35°C (50°F to 95°F). There can be significant conductive heat loss through IV tubing, especially with long lengths of tubing at slow flow rates. It is preferable to administer fluids as boluses to effect rather than as drips.

Normally, hypothermia increases natriuresis. Preexisting gastrointestinal losses or previous diuretic treatment can also contribute to sodium loss. Patients with a normal sodium level and osmolality may have preexisting sodium overload as a result of cirrhosis, nephrosis, or congestive heart failure. However, most patients will be free-water depleted, elevating the sodium level and osmolality. Hemoconcentration due to decreased plasma volume, fluid shifts, and increased vascular permeability usually is present. Hemodilution can occur from parenteral crystalloid administration, but a low hematocrit can also result from acute hemorrhage or preexisting anemia.

Advanced Life Support

During hypothermic cardiac arrest, cardiac output and cerebral and myocardial blood flows are much less than those during normothermic closed chest compressions. Metabolic demands, however, are also less during hypothermia.

Blood flow during cardiopulmonary resuscitation (CPR) in patients with hypothermia differs from flow during normothermia. In normothermia, some flow results from phasic alterations in the intrathoracic pressure rather than from direct cardiac compression. In hypothermia, the heart is a passive conduit, and phasic alterations in the intrathoracic pressure are exerted equally on all cardiac chambers. The mitral valve remains patent during systole, and blood continues to circulate through the left side of the heart. This explains an observation of a thoracotomy in a patient who ultimately survived severe hypothermia: "the heart was found to be hard as stone and it is hardly conceivable how effective external cardiac massage could have been." There have been many neurologically intact survivors after prolonged closed chest compressions.

Chest wall elasticity and pulmonary compliance are decreased with cold. More force is needed to depress the chest wall sufficiently to generate adequate intrathoracic pressure gradients. Powered thoracic compression devices are useful during prolonged resuscitations pending decisions about extracorporeal rewarming.

Apparent rigor mortis and fixed dilated pupils are not reliable criteria for withholding CPR in a hypothermic patient. Accurately diagnosed dependent lividity is a sign of death even in hypothermia, although previous guidelines have stated the contrary. Because intermittent flow may provide adequate support during evacuation, CPR should not be withheld just because continuous compressions cannot be ensured.[6]

Rescuers should initiate CPR in accidental hypothermia unless do-not-resuscitate status is known, obviously lethal injuries are present, chest wall depression is impossible, signs of life are present, or rescuers are endangered.[4] If possible, verify that there is no spontaneous mechanical cardiac activity with bedside ultrasonography before chest compressions are initiated.

Pharmacologic Treatment

The efficacy of most medications is temperature dependent. Protein binding increases during hypothermia. Liver metabolism is decreased. Large doses could be required to achieve a therapeutic response. Toxic levels could develop with rewarming. In severe hypothermia, withhold

medications until the patient is warmed, and then leave longer intervals between doses. No medication should be given orally because of the patient's decreased gastrointestinal motility. Intramuscular medications are also contraindicated because of poor absorption from vasoconstricted sites.

Cardiovascular Medications. The effects of hypothermia on the autonomic nervous system are variable. In primates, sympathetic response increases rapidly to cooling from 37°C to 31°C (98.6°F to 87.8°F) and then switches off at about 29°C (84.2°F). This suggests that modest catecholamine support might be useful below 29°C (84.2°F).

Pharmacologic manipulation of the pulse and blood pressure should be avoided. Epinephrine and other vasoconstrictors may be dysrhythmogenic and have a minimal effect on the maximally constricted peripheral vasculature. There are no clear indications for vasopressors although, in animal models, the return of spontaneous circulation after induced VF below 30°C (86°F) is higher after the administration of vasopressors.

Inotropes are usually not necessary to support blood pressure. Inotropic support may be considered in disproportionately hypotensive patients who do not maintain a mean arterial pressure of 60 mm Hg in response to volume replacement and rewarming.

Atrial dysrhythmias are common below 32°C (89.6°F), associated with a slow ventricular response. Atrial fibrillation is common but self-limited and typically converts spontaneously during rewarming. Beta blockers and calcium channel blockers are contraindicated unless there is a rapid ventricular response.

Preexisting, chronic, premature ventricular contractions can be suppressed during hypothermia and recur during rewarming. Most hypothermia-induced dysrhythmias convert spontaneously during rewarming. Asystole that develops during rewarming is not as ominous as asystole in normothermic patients. For VF, defibrillation should be attempted at the usual energy level. Successful defibrillation has been reported at 20°C (68°F) but attempted defibrillation is often unsuccessful until the core temperature is above 30°C (86°F). If a defibrillation attempt is unsuccessful, active rewarming should be initiated while continuing CPR. Defibrillation can be attempted occasionally during rewarming. Once the core temperature is above 30°C (86°F), further attempts can be made.[7]

The ideal approach to ventricular dysrhythmias in the hypothermic patient has not been well studied. Lidocaine and propranolol have minimal hemodynamic effects during hypothermia. Their efficacy in the treatment of ventricular dysrhythmias appears limited. In a canine model of severe hypothermic VF, neither amiodarone nor bretylium was effective. Human chemical defibrillations with bretylium tosylate in cases of severe hypothermia have been reported. Recurrent VF was controlled by isoproterenol in one reported case.[8] Amiodarone can cause torsades de pointes by QT prolongation and its safety during accidental and induced hypothermia is not known.

In hypothermia, at least one Group 1 antidysrhythmic agent, procainamide, increases the incidence of VF. Another drug in the same group, quinidine, can prevent VF during induced profound hypothermia and during cardiac manipulation at 25°C to 30°C (77°F to 86°F). Transvenous cardiac pacing is hazardous for bradydysrhythmias in hypothermia. External pacing may be worth trying in the rare setting of profoundly disproportionate bradycardia. Transcutaneous pacing has been used to facilitate continuous arteriovenous rewarming in perfusing patients by raising the systolic blood pressure above 60 mm Hg. Other active rewarming techniques do not require specific pressure gradients.

Antibiotics. Hypothermia compromises host defenses and predisposes to infection. In hypothermia, the usual signs of infection, including fever, are absent. Shaking chills from sepsis may be mistaken for shivering. Suspect CNS injury or infection if a patient's mental status remains altered, despite rewarming.

In hypothermic children younger than 3 months, empirical antibiotics are indicated after cultures have been obtained. There are no reliable clinical or laboratory indicators of infection, but bradycardia, anemia, uremia, and high serum glucose levels, as well as leukocyte abnormalities, are common clues. The role of empirical antibiotics in adults is less clear. Although gram-negative septicemia may cause hypothermia, coexistent infections from gram-positive cocci, Enterobacteriaceae, and oral anaerobes are common.

Older adults with thermoregulatory failure have a high risk of mortality and should be considered septic until proven otherwise. Routine empiric antibiotics are warranted in hypothermia only in geriatric patients. Administer antibiotics if the clinical picture is consistent with septic shock or if there is failure to rewarm. Cellulitis, myositis, bacteriuria, or infiltrate on chest x-ray warrants immediate antimicrobial therapy. In an urban setting, infection is the leading cause of failure to rewarm and subsequent mortality.

Failure to Rewarm. Cold abolishes adrenal responsiveness to adrenocorticotropic hormone (ACTH). A false diagnosis of decreased adrenal reserve is possible. The increase in ACTH level seen in hypothermic individuals may be a neurogenic or emotional response to the cold.

Acute cold stress initially stimulates cortisol secretion. There may already be a very high level as a result of underlying stress. In clinical series, total serum cortisol levels are commonly elevated; however, the active free fraction is decreased due to increased protein binding. Failure to rewarm may be due to adrenocortical insufficiency or steroid dependence. If either condition is suspected, administer 100 mg IV of hydrocortisone.

Empirical treatment with thyroxine is reserved for patients thought to have myxedema. Thyroid hormone should be replaced if there is a history of hypothyroidism, suggestive neck scar, or failure to rewarm. After thyroid function study samples have been drawn, levothyroxine, 250 to 500 µg IV, can be slowly administered over several minutes. Daily injections of 50 to 100 µg are necessary for 5 to 7 days. Hydrocortisone (100–200 mg) should be added to the first several liters of crystalloid fluid. The absorption of oral or intramuscular levothyroxine is variable. IV administration has a smooth effect after the onset of action at 6 to 12 hours. This will be manifested by improvement in vital signs and rewarming rate. Half the dose is converted by the peripheral tissues into L-triiodothyronine (T_3). An underlying infection can also compromise thermogenesis.

Rewarming

There are no published controlled studies comparing rewarming methods in hypothermia. Rigid treatment protocols are not evidence-based. The emergency clinician should choose specific methods on a case-by-case basis, taking into account availability, institutional resources, and clinical experience.

Passive External Rewarming. Spontaneous passive external rewarming is noninvasive. It is the treatment of choice for patients with mild hypothermia when active rewarming is not available. The patient should be able to generate sufficient metabolic heat to maintain an acceptable rate of spontaneous rewarming. Older adults are commonly glycogen-depleted, have central hypovolemia, and are not capable of normal cardiovascular or metabolic homeostasis.

The normal processes of heat dissipation are minimized by passive external rewarming. Cessation of evaporation and convection is coupled with insulation against further radiation of heat. This technique simply involves covering the patient with an insulating material in a favorable atmospheric condition. The ambient temperature should exceed 21°C (69.8°F). When the air is stationary, less heat is lost to conduction, convection, and radiation.

BOX 128.3 Indications for Active Rewarming

Cardiovascular instability
Mild to severe hypothermia
Inadequate rate of rewarming or failure to rewarm
Endocrine insufficiency
Trauma
Traumatic or toxicological peripheral vasodilation
Secondary hypothermia impairing thermoregulation

Shivering is the most effective thermoregulatory neuromuscular response to cold in humans. Without shivering, endogenously generated metabolic heat is insufficient to raise the core temperature. When the core temperature exceeds 32°C (89.6°F), unless complete glycogen depletion occurs, the major source of heat production is shivering thermogenesis.

Recommended rewarming rates vary between 0.5°C and 2.0°C/hr (0.9°F and 3.6°F/hr). The rewarming rate should be rapid enough to avoid prolonged exposure to dysrhythmias. Below 32°C (89.6°F), humans are functionally poikilothermic. Shivering is ineffective below 32°C (89.6°F) and absent below 30°C (86°F).

Active Rewarming. Active rewarming is the direct transfer of exogenous heat to the patient. It can be accomplished by external or internal techniques. Active rewarming is useful in mild hypothermia to decrease metabolic requirements of rewarming and improve thermal comfort.

In moderate to severe hypothermia, cardiovascular instability and decompensation require prompt elevation of the core temperature while minimizing afterdrop (Box 128.3). Defibrillation is rarely successful at temperatures below 28°C (82.46°F). Active rewarming is indicated with strokes and other conditions that impair CNS control of thermoregulation. Active rewarming is also indicated for patients when endogenous thermogenesis is insufficient or when glycogen depletion is present, usually from endocrine causes that include hypopituitarism, adrenal insufficiency, hypothyroidism, and Wernicke encephalopathy. Active rewarming is recommended in diabetic ketoacidosis because the core temperature must be elevated above 30°C (86°F) before insulin becomes effective.

Pharmacologically induced peripheral vasodilation or acute spinal cord transection prevents sufficient thermogenesis and requires active rewarming. Patients with severe hypothermia do not necessarily require invasive extracorporeal rewarming techniques, especially if they have a sustained perfusing rhythm.

Aggressive treatment of hypothermia is indicated in infants. Rapid rewarming is advantageous because it minimizes energy expenditures. Hypothermic neonates have been successfully rewarmed using minimally invasive methods. A neonate with a core temperature of 14.8°C (58.6°F) receiving CPR made a full neurologic recovery after being rewarmed by active external rewarming (AER), warmed IV fluids, and heated, humidified ventilator gases.

Active External Rewarming. Early concern with AER was sparked after a 1961 study, in which 20 of 23 patients died. Retrospective analysis of clinical series has shown widely varying mortality rates with AER. Various methods conduct heat directly to the skin. Rewarming options include plumbed garments that circulate warm fluids, hot water bottles, heating pads, forced air warming systems, and radiant sources. Thermal injury to vasoconstricted hypoperfused skin is a potential hazard with local heat application.

Forced air warming systems efficiently transfer heat. They can be used in field conditions or in the ED. These devices circulate hot air through a blanket. The air flows through apertures on the patient's side, allowing convective transfer of heat. Hypotension and core temperature afterdrop are not seen in forced air warming for accidental hypothermia in the ED. Like all active methods, forced air warming decreases shivering and is able to transfer large amounts of heat while minimizing afterdrop. Other options include thermoregulatory systems that circulate warm water through energy transfer pads.

Arteriovenous anastomosis (AVA) rewarming is a unique, noninvasive, AER technique. Exogenous heat is provided by immersion of distal extremities (upper extremities to the elbows and lower extremities to the knees) in hot (44°C to 45°C [111.2°F to 113.6°F]) water. The heat opens the AVAs, which are 1 mm below the epidermal surface in the digits. As a result, there is an increased flow of warmed venous subcutaneous blood returning directly to the heart. The forearms and calves must be included for this technique to be effective. The AVA technique was designed for use on ships and is not practical in most situations. In addition, many patients cannot tolerate the very hot water. Burns of vasoconstricted skin are a potential hazard.

Previously healthy patients with acute hypothermia are optimal candidates for AER. They have minimal dehydration and pathophysiologic circulatory changes. If AER is used, and the extremities are vasoconstricted, the heat source should be applied preferentially to the thorax rather than to the extremities. Application of heat to the extremities increases the cardiovascular load by increasing the metabolic requirements of the peripheral musculature. The depressed cardiovascular system may not be able to meet the demands, resulting in cardiovascular collapse.

Combining truncal AER with core rewarming can also be successful. The provision of heated humidified oxygen and warmed IV fluids, in addition to AER, may help prevent hypoxia, metabolic acidosis, core temperature afterdrop, and hypotension. If AER is used to treat moderate or severe hypothermia, it can be combined with one or more active core rewarming techniques.

Active Core Rewarming. Many methods achieve active rewarming of the core. These techniques minimize the risk of rewarming collapse in patients with core temperatures below 32°C (89.6°F).

Airway Rewarming. Airway rewarming with heated humidified oxygen is a simple and inexpensive method that can be used as an adjunct to other forms of active rewarming in moderate or severe hypothermia, although it is ineffective on its own. Airway rewarming improves oxygenation, helps avoid afterdrop, stimulates pulmonary cilia, decreases viscosity of pulmonary secretions, and reduces cold-induced bronchorrhea. Pulmonary absorption of moisture does not adversely affect surfactant or increase pulmonary congestion.

The respiratory tract is a limited site for heat exchange, but heated humidified oxygen increases blood oxygen content and temperature in the pulmonary circulation. The myocardium is perfused by warmer oxygenated blood, decreasing intermittent temperature gradients.

Sufficient minute volume and complete humidification are necessary for maximal heat delivery. Because dry air has low thermal conductivity, ventilation with warm dry air provides negligible heat. Increases in rewarming rates from 1°C to 4.5°C/hr (1.8°F to 8.1°F/hr) have been reported with heated humidified oxygen. The larger increases are unlikely to be true. Increases in warming rates with endotracheal intubation are higher than those with a mask. Positive-pressure ventilation with a mask can be used but has not been studied.

Maintenance of sufficient oxygenation is important in moderate to severe hypothermia. In patients on cardiopulmonary bypass cooled to 28°C to 30°C (82.4°F to 86°F), the capacity of hemoglobin to unload oxygen to the tissue is less than half that found in normothermic patients. Despite lower metabolic requirements, this decreased functional hemoglobin, combined with a depressed respiratory minute volume, results in minimal oxygen reserves. Some patients maintain a level of spontaneous respiration appropriate to depressed carbon

dioxide production. This may not be the case in patients with coexisting toxicologic, traumatic, or metabolic depression of the respiratory center.

Providing heated, humidified oxygen to a patient with spontaneous respiration requires a heated cascade nebulizer. An immersion heater can be connected to a hose with a warming wire. Because patients with a depressed level of consciousness do not complain of pain, it is essential to check the temperature of the inspired air frequently with an in-line temperature probe. The gas temperature should be maintained at 42°C to 45°C (107.6°F to 113°F). Most heater modules require modification to allow the temperature to reach 42°C to 45°C (107.6°F to 113°F). Modified heater modules should be labeled to avoid routine use. Most humidifiers will not exceed 41°C (105.8°F) close to the patient outlet with a 2-m tubing length. Strategies to circumvent the 41°C (105.8°F) ceiling include reduction of tubing length, addition of more heat sources, disabling of the humidifier safety system, and placement of the temperature probe outside the patient circuit. Because of the modest clinical benefit in stable patients, it is probably not worth the effort to circumvent the 41°C (105.8°F) ceiling. The only report of thermal airway injury was in a patient ventilated by endotracheal tube for 11 hours with 80°C (176°F) inhaled gas.

Peritoneal Dialysis. Peritoneal dialysis delivers dialysate at 40°C to 45°C (104°F to 113°F). Heat is conducted directly to intraperitoneal structures through the posterior parietal peritoneum and the solid viscera and through the hemidiaphragms to the heart and lungs. A double-catheter system with suction at the outflow can theoretically increase flow to about 6 L/hr. Two liters are infused, retained for 20 minutes, and then aspirated. In practice, it can be difficult to recover all of the infused fluid. This lowers the achievable flow rate. Rewarming rates average 1°C to 3°C/hr (1.8°F to 5.4°F/hr).

An additional benefit of peritoneal dialysis is hepatic rewarming, which reactivates detoxification and conversion enzymes. Serum electrolyte levels should be monitored because peritoneal dialysis can exacerbate preexisting hypokalemia. Peritoneal lavage is useful primarily in severe cases in combination with other rewarming techniques for patients without spontaneous perfusion but has also been used alone in patients undergoing CPR for whom extracorporeal circulation was thought to be contraindicated due to coagulopathy or was not available.

Heated Irrigation. Heat transfer from irrigation fluids is usually limited due to the minimal surface area available for heat exchange. Gastric or colonic irrigation can cause fluid and electrolyte level fluxes and are not recommended. An esophageal heat transfer device with closed circulation of heated water is practical and has been used successfully for rewarming in hypothermia.[9]

Closed thoracic lavage can be useful in severe hypothermia. Two large-bore thoracostomy tubes are inserted into one or both hemithoraces. One is inserted anteriorly in the second or third intercostal space at the midclavicular line, the historical classic site for needle thoracostomy. The other is inserted between the fifth and sixth intercostal spaces in the posterior axillary line, the usual site for tube thoracostomy. Normal saline heated to 40°C to 42°C (104°F to 107.6°F) is infused into the superior tube. The inferior tube is used for drainage. Left-sided tube insertion in perfusing patients risks causing VF. Efficiency of the heat transfer varies with flow rate and dwell times. Pleural adhesions can prevent adequate infusion and can result in a tension hydrothorax. Adequate drainage should be ensured to prevent intrathoracic hypertension.

Thoracic lavage is usually reserved for the severely hypothermic patient who does not respond to standard techniques or the patient with another indication for a chest tube. It should be combined with other rewarming modalities in potentially salvageable cardiac arrest patients. However, thoracic lavage has been used successfully in patients requiring CPR when extracorporeal circulation was not available. The rate of rewarming averages 3°C/hr (5.4°F/hr).

Mediastinal irrigation and direct myocardial lavage should be considered only in patients without spontaneous perfusion. The procedure requires a standard left lateral thoracotomy incision. The pericardium is not incised unless an effusion or tamponade is present. The heart is bathed in 1 to 2 L of an isotonic solution heated to 40°C (104°F) for several minutes. The fluid is removed and the lavage is repeated. Internal defibrillation is attempted at intervals of 2°C (3.6°F) after the myocardial temperature exceeds 26°C to 28°C (78.8°F to 82.4°F). When a perfusing rhythm is achieved, lavage is continued until the myocardial temperature exceeds 32°C (89.6°F). A median sternotomy approach allows ventricular decompression in addition to direct defibrillation. Open cardiac massage of a cold, rigid, and contracted heart may not generate flow.

Endovascular Rewarming. Another active core rewarming option uses endovascular warming devices that are intended for therapeutic cooling and subsequent rewarming of comatose, resuscitated, cardiac arrest patients.[10] These systems involve femoral vein catheterization with a closed-loop catheter that has a thermostat at the tip. If the core temperature is below 30°C (86°F), the fail-safe feature on the console must be circumvented to allow rewarming.

Diathermy. Truncal diathermy involves the conversion of energy waves into heat. Large amounts of heat can be delivered to deep tissues with ultrasonic and low-frequency microwave irradiation. Frostbite, burns, significant edema, and the presence of all types of metallic implants and pacemakers are contraindications. In spite of successes in piglets, infants, and a few adults, diathermy is still experimental.

Extracorporeal Blood Rewarming. The four common extracorporeal techniques to rewarm blood are venovenous rewarming, hemodialysis, continuous arteriovenous (AV) rewarming, and extracorporeal circulation–cardiopulmonary bypass (CPB and extracorporeal membrane oxygenation [ECMO]); Table 128.2).

In venovenous rewarming, blood is removed, ideally by a large peripheral venous catheter, heated to 40°C (104°F) and returned through a second venous catheter. Flow rates are 150 to 400 mL/min. The circuit is simple and efficient. There is no oxygenator, and the system does not provide circulatory support. Volume infusion is an option to augment inadequate cardiac output.

Standard hemodialysis is a widely available, practical rewarming technique. It is portable and efficient and can also be used to treat electrolyte abnormalities, renal failure, or intoxication with a dialyzable substance (e.g., ethylene glycol, methanol).

Continuous AV rewarming is an option if the blood pressure is at least 60 mm Hg, which may be maintained, if necessary, with CPR. AV rewarming involves the use of percutaneously inserted femoral arterial and contralateral femoral venous catheters. Heparin-bonded tubing circuits obviate the need for systemic anticoagulation. The blood pressure of a spontaneously perfusing, traumatized, hypothermic patient creates a functional arteriovenous fistula by diverting part of the cardiac output from the femoral artery through a commercially available countercurrent heat exchanger. The heated blood is then returned with admixed heated crystalloids through the femoral vein. Continuous AV rewarming avoids the need for specialized equipment and a perfusionist, which are necessary for cardiopulmonary bypass. The average rate of rewarming is 3°C to 4°C/hr (5.4°F to 7.2°F/hr). Because the catheters are 8.5 Fr, the patient should weigh at least 40 kg.

Extracorporeal circulation, also called *extracorporeal life support* or ECLS, refers to cardiopulmonary bypass or ECMO. In one review, the

TABLE 128.2 Extracorporeal Blood Rewarming Options

Options	Considerations
Venovenous circuit	Central venous catheter to central venous or peripheral catheter rewarming
	No oxygenator, circulatory support
	Flow rates, 150–400 mL/min
	Rate of rewarming 2°C–3°C/hr (3.6°F–4.5°F)
Hemodialysis circuit	Single- or dual-vessel cannulation; stabilizes electrolyte or toxicologic abnormalities
	Exchange cycle volumes 200–500 mL/min
	Rate of rewarming 2°C–3°C/hr (3.6°F–5.4°F/hr)
Continuous arteriovenous rewarming circuit	Percutaneous 8.5-Fr femoral catheters
	Requires blood pressure of 60 mm Hg systolic
	No perfusionist, pump, anticoagulation
	Flow rates, 225–375 mL/min
	Rate of rewarming, 3°C–4°C/hr (5.4°F–7.2°F/hr)
Cardiopulmonary bypass circuit	Full circulatory support with pump and oxygenator
	Perfusate-temperature gradient, 5°C–10°C/hr (9°F–18°F/hr)
	Flow rates, 2–7 L/min (average, 3–4 L/min)
	Rate of rewarming up to 9.5°C/hr (18.9°F/hr)

Adapted from: Danzl DF. Hypothermia and frostbite. In Kasper D, Fauci A, Hauser S, et al, eds. *Harrison's Principles of Internal Medicine*, ed 20. New York: McGraw-Hill; 2018.

mean temperature increase was 9.5°C/hr (17.1°F/hr) with CPB. ECMO appears to reduce the risk of intractable cardiorespiratory failure or severe pulmonary edema after rewarming.

The major advantage of extracorporeal circulation in perfusing patients is the preservation of flow if mechanical cardiac activity is lost during rewarming. Other candidates are patients who do not respond to less invasive rewarming techniques, those with completely frozen extremities, and those with rhabdomyolysis accompanied by major electrolyte disturbances. In some European centers, severely hypothermic patients without obvious trauma are admitted directly to the operating suite for extracorporeal circulation.

Very rapid rates of rewarming do not necessarily improve survival, but slow rewarming increases hospital mortality.[11] Complications of rapid rewarming include DIC, pulmonary edema, hemolysis, and acute tubular necrosis. Extracorporeal circulation can provide cardiovascular support in hemodynamically unstable patients.

Extracorporeal rewarming should be considered in hypothermic cardiac arrest patients if there are no contraindications to CPR.[12] A realistic assessment of the risk-benefit ratio for debilitated patients with secondary hypothermia should be made. Discontinue resuscitation if frozen or clotted intravascular contents are identified.

Disposition

Previously healthy patients who have mild primary accidental hypothermia (35°C to 32°C [95°F to 89.6°F) usually rewarm easily. They can be safely discharged if a warm environment is available. Patients with mild hypothermia associated with trauma are more difficult to rewarm and require admission.

Patients with severe hypothermia (<32°C [89.6°F]) generally require admission to an intensive care setting. These patients should be evaluated for the presence of underlying medical disorders (see Box 128.1). Cardiac monitoring should be considered for patients with persistent toxicologic or metabolic abnormalities and should be used for patients with cardiovascular instability or an inadequate rate of rewarming. Transfer of patients to tertiary care centers is generally not mandatory, but severely hypothermic patients may be most easily managed in facilities capable of extracorporeal circulation.

Because human physiologic responses are variable, it is difficult to predict outcomes. The type and severity of the underlying or precipitating disease process are major determinants.[13] The age of the patient is a weak predictor of mortality. Trauma, infection, and toxin ingestions unpredictably affect survival. Outcome prediction based on the Glasgow Coma Scale score is unreliable. Significant predictors of poor outcome include asphyxia, prehospital cardiac arrest, low or absent blood pressure, elevated blood urea nitrogen level, and need for endotracheal or nasogastric intubation in the ED. Patients with hypothermic cardiac arrest due to alcohol intoxication may have better neurologic outcomes than patients with hypothermic cardiac arrest from other causes.

In the past, the treatment dictum was that "*no one is dead until they are warm and dead.*" Now we realize that some patients are cold and dead. It would be useful and humane if they could be safely identified. The search for a valid triage marker of death continues. Grave prognostic indicators include evidence of intravascular thrombosis (fibrinogen < 50 mg/dL), ammonia levels greater than 250 mmol/L, and cell lysis (hyperkalemia > 10–12 mEq/L). In hypothermia with asphyxia in avalanche victims, hyperkalemia greater than 7 mEq/L is a reliable indicator of death.[14]

FROSTBITE AND NONFREEZING COLD INJURIES

KEY CONCEPTS

Frostbite

- Premature termination of thawing in 37°C to 39°C (98.6°F to 102.2°F) water is a common error. Reperfusion of completely frozen tissue may be painful, requiring parenteral analgesia.
- The early formation of clear blebs is more favorable than delayed formation of hemorrhagic blebs, which reflect damage to the subdermal vascular plexi.
- Advise patients that accurate prediction of eventual tissue loss is not always possible at presentation, despite imaging.
- Thrombolysis may salvage severely frostbitten tissue if given within 24 hours of thawing.

Nonfreezing Cold Injuries

- Immersion injuries should be rewarmed slowly and not above 30°C (86°F).
- Gentle cooling of nonfreezing cold injuries may be helpful to relieve pain and edema.
- Pernio can be treated by drying and gentle massage. The skin should not be warmed above 30°C (86°F).

FROSTBITE

Foundations

Background and Importance

Unlike other mammals that live outside the tropics, humans are susceptible to local cold injuries. Local cold injuries may occur in conjunction with systemic hypothermia. Frostbite involves tissue freezing with formation of ice crystals in the tissues. Immersion injury (trench foot) is a nonfreezing injury that results from exposure to wet cold.

Pernio (chilblains) is a nonfreezing injury that occurs in susceptible individuals, usually after repetitive exposure to dry or damp cold.

Historically, frostbite has been a disease of wars. Frostbite caused over 1 million casualties in World Wars I and II and the Korean War. Trench foot was common in the world wars and during the conflict in the Falkland Islands. Frostbite and immersion injuries are risks for anyone who ventures outdoors in severely cold conditions for recreation or work. Homeless or displaced people are also at risk, especially during cold winter months and disasters.

Anatomy, Physiology, and Pathophysiology

The human body attempts to maintain a core temperature of about 37°C (98.6°F). Skin cooling activates the anterior hypothalamus, causing catecholamine release, thyroid stimulation, shivering thermogenesis, and peripheral vasoconstriction. People are physiologically adapted to tropical conditions. In cold conditions, humans have a limited ability to protect themselves against decreased core temperature. Behavioral responses are far more effective if adequate clothing or shelter is available.

Cutaneous circulation is one of the keys to maintenance of a constant core temperature. Baseline cutaneous circulation greatly exceeds nutritional requirements. In warm conditions, the skin acts as a radiator to shed excess heat. Cold-induced vasoconstriction can reduce flow to as low as 10% of baseline without damage to the skin.

During cold stress, peripheral vasoconstriction limits radiant heat loss. Acral skin structures (including fingers, toes, ears, and nose) contain a plethora of arteriovenous anastomoses. These anastomoses shut down in the cold, causing drastic reductions in blood flow. This so-called life-versus-limb mechanism is a means of preventing systemic hypothermia.

Cooling of digits to about 15°C (59°F) results in maximal peripheral vasoconstriction, with minimal blood flow. Continued cooling to about 10°C (50°F) produces cold-induced vasodilation (CIVD, also called "the hunting response"), a counterbalance to cold-induced vasoconstriction. Vasodilation follows 5- to 10-minute cycles, interrupting vasoconstriction and protecting the extremity. Inuits, Lapps, and other northern peoples have stronger CIVD than do individuals from tropical regions. There is evidence of adaptation, with more robust CIVD in response to cold, in addition to genetic control.

Frostbite occurs only when the tissue is supercooled to well below 0°C (32°F). The required temperature is at least −4°C (24.8°F) and may be as low as −10°C (14°F) under some conditions. Tissue injury occurs due to structural damage to cells from ice crystal formation and due to microvascular thrombosis and stasis. In the prefreeze phase, tissue temperatures drop below 10°C (50°F), and cutaneous sensation is lost. Before ice crystals form, microvascular vasoconstriction can occur, with endothelial leakage of plasma into the interstitium. In the freeze-thaw phase, the timing, location, and rate of ice crystal formation depend on conditions. Wind and moisture increase the freezing rate. The phases vary with the extent and rapidity of the cold response and may overlap (Box 128.4).

Except in extremely cold conditions, ice crystal formation initially occurs extracellularly. Water then exits the cells to maintain osmotic equilibrium. Cellular dehydration increases the intracellular osmolarity and electrolyte concentrations. After approximately one-third of the cellular volume is lost, the cell collapses and dies, even if there was no direct structural damage from ice crystals. Extracellular crystallization increases the tissue pressure on cell membranes and vascular structures. Sludging, stasis, and cessation of flow occur at the capillary level.

A third phase, progressive microvascular collapse, first affects venules, then arterioles. Red blood cells sludge and form microthrombi during the first few hours after the tissues are thawed. Factors that decrease flow include hypoxic vasospasm, hyperviscosity, and direct endothelial cell damage. Ischemic conditions extend the surrounding injury. Plasma leakage and arteriovenous shunting result in thrombosis, increased tissue pressure, ischemia, and necrosis.

BOX 128.4 Freezing Injury Cascade

Prefreeze Phase
Superficial tissue cooling
Increased viscosity of vascular contents
Microvascular constriction
Endothelial plasma leakage

Freeze-Thaw Phase
Extracellular fluid ice crystal formation
Water movement across cell membrane
Intracellular dehydration and hyperosmolality
Cell membrane denaturation or disruption
Cell shrinkage and collapse

Vascular Stasis and Progressive Ischemia
Vasospasticity and stasis coagulation
Arteriovenous shunting
Vascular endothelial cell damage and prostanoid release
Interstitial leakage and tissue hypertension
Necrosis, demarcation, mummification, or slough

[a]Extremely rapid cooling produces more initial intracellular than extracellular ice crystallization.

Progressive dermal ischemia is partially mediated by thromboxane. Prostaglandins are found in clear vesicles. When subdermal vascular plexi are injured, hemorrhagic blisters develop, which also contain prostaglandins. Arachidonic acid breakdown products released from underlying damaged tissue into blister fluid include prostaglandins and thromboxane. These mediators produce platelet aggregation, vasoconstriction, and leukocyte immobilization.

Injury to the microvasculature is the ultimate determinant of progressive tissue damage. Endothelial cells are very susceptible to freezing injury. After thawing, the vasculature may be temporarily patent. Platelet and erythrocyte aggregates promptly clog and distort the vasculature. Intense vasoconstriction and arteriovenous shunting occur at the interface between normal and damaged tissue. Injured viable vasculature remains distorted. Local arteritis, medial degeneration, and intimal proliferative thickening occur. Nerve and muscle tissues are more susceptible than connective tissue to cold injury. Nonviable hands and feet can be moved after thawing if the tendons are intact.

Edema progresses for 48 to 72 hours after tissue is thawed. Necrosis becomes apparent as edema resolves. The dry gangrene carapace of frostbite is superficial in comparison to arteriosclerosis-induced, full-thickness gangrene. Although the historical surgical aphorism was "frostbite in January, amputate in July," advances in imaging modalities can accelerate the identification of the demarcation between viable and nonviable tissue.

The extent of peripheral cold injury is determined by the type and duration of cold contact with the skin (Box 128.5). Risk factors include physiologic, mechanical, psychological, environmental, and cardiovascular factors.

Any condition affecting judgment can jeopardize a physiologically tropical human. Cold injuries are often due to psychiatric impairment or intoxication, primarily ethanol intoxication. Ethanol also produces peripheral vasodilation, which increases heat loss. Blunting of self-protective instincts can cause people to put themselves at increased risk by not wearing appropriate clothing or finding shelter in cold conditions.

Although air is a poor thermal conductor, the combination of cold and wind (wind chill index) markedly increases heat loss. Direct skin contact with good thermal conductors such as metal, water, and volatile liquids

increases the rate and extent of tissue destruction. Commercial aerosol spray propellants, such as propane and butane, and carbon dioxide in fire extinguishers are potentially hazardous. Liquid oxygen and Freon can also cause frostbite. Overenthusiastic application of ice or frozen gel packs for soft tissue injuries can cause frostbite, with tissue loss. Contact with dry ice or vapor coolant sprays such as chloroethane can also cause frostbite.

Clinical Features

The term *frostnip* refers to a superficial freezing injury manifested by transient numbness and tingling that resolves after rewarming. No tissue destruction occurs. The most common, nearly universal, presenting symptom of frostbite is numbness. All patients have initial sensory deficits of light touch, pain, or temperature. Anesthesia is produced by intense vasoconstrictive ischemia and neurapraxia, usually in acral areas and distal extremities. Fingers, toes, nose, ears, and penis are the specific areas at the greatest risk. Patients often complain of clumsiness and report so-called "block of wood" sensations in the extremities. Complete anesthesia in a cold digit suggests a severe injury.

Initial presentation of frostbite is often deceptively benign. Most patients do not arrive in the emergency department (ED) with frozen insensate tissue. Frozen tissue feels hard and appears mottled or violaceous white, waxy, or pale yellow (Fig. 128.5). In severe cases, it is not possible to roll the dermis over bony prominences. Rapid thawing in warm water results in an initial hyperemia, even in severe cases (Fig. 128.6). After thawing, there is usually partial return of sensation until blebs form.

Favorable initial symptoms after rewarming include normal sensation, warmth, and color. Soft pliable subcutaneous tissue suggests a superficial injury. A residual violaceous hue after rewarming is ominous (Figs. 128.7 and 128.8). Early formation of large blebs with relatively clear fluid that extend to the tips of the digits (Fig. 128.9) is more favorable than a delayed appearance of smaller, more proximal hemorrhagic vesicles that are produced by damage to subdermal vascular plexi (Fig. 128.10). Bullae and vesicles usually form in 1 to 24 hours.

Fig. 128.5 Frostbite that is still frozen. The victim is thawing the foot using a car heater. This technique is not advisable due to a high likelihood of causing further damage. (Courtesy Dr. Nicholas Kanaan.)

Lack of edema formation suggests significant tissue damage. Post-thaw edema usually develops within 3 hours. In severe cases, frostbitten skin forms a black dry eschar that mummifies, with demarcation between living and dead tissue (Figs. 128.11 and 128.12). The appearance may be misleading as live tissue often extends distally deep to the eschar.

Historically, frostbite, like burns, was classified into degrees of injury. Anesthesia and erythema were considered to be first-degree frostbite. Superficial vesiculation surrounded by edema and erythema indicated second-degree frostbite. Third-degree frostbite produced deeper hemorrhagic vesicles. Fourth-degree injuries extended into subcutaneous tissues, including bones and muscles.

Fig. 128.12 Severe frostbite of the foot. Dry gangrene is clearly demarcated. There was significant tissue loss. (Courtesy Dr. Ken Zafren.)

Classification by degrees is a poor method of predicting the amount of tissue damage and is therapeutically misleading. A simpler, more useful classification divides frostbite into superficial (mild) frostbite, which does not result in tissue loss, and deep (severe) frostbite, which causes loss of tissue. It is difficult to predict the amount of tissue loss at the time of initial presentation. The best method is clinical staging using the extent of cyanosis immediately after rapid thawing in warm water (Table 128.3). In Grade 1 frostbite there is no cyanosis, predicting no amputation and no sequelae. In Grade 2, cyanosis limited to the distal phalanx predicts only soft tissue amputation and sequelae involving the nails. In Grade 3, cyanosis of the intermediate and proximal phalanges predicts bone amputation and functional sequelae. In Grade 4, cyanosis over the carpal or tarsal bones predicts limb amputation with severe functional sequelae.

Significant pain usually accompanies reestablishment of perfusion. A dull continuous ache evolves into a throbbing sensation in 48 to 72 hours. This may persist until tissue demarcation occurs weeks later. Short-term and long-term sequelae are common (Box 128.6).

Differential Diagnoses

The differential diagnosis of frostbite is limited. Burns, cellulitis, gangrene from causes other than freezing, vascular injuries, diabetic neuropathies, and pressure necrosis can resemble frostbite, but can usually be distinguished based on history. Severe, nonfreezing, cold injuries that have been complicated by pressure necrosis with or without infection, can also mimic frostbite. After spontaneous thawing, before edema develops, frostbitten areas may appear deceptively normal for a few hours.

Diagnostic Testing

Except in patients being considered for thrombolytic therapy, diagnostic imaging has a limited role in the emergency care of patients with frostbite. Ancillary diagnostic imaging techniques can be used to help grade the severity of injury, but no technique consistently predicts tissue loss at the time of initial examination.

Patients with frostbite should undergo laboratory testing and imaging, as indicated for coexisting conditions and injuries. Plain radiographs of frostbitten extremities can be used to diagnose fractures due to trauma. Follow-up radiographs may begin to demonstrate abnormalities due to frostbite 4 to 10 weeks after injury.

Patients being considered for thrombolytic therapy may undergo computed tomography angiography (CTA), magnetic resonance angiography (MRA) or Doppler ultrasound, for intra-arterial therapy or radionuclide scanning for intravenous (IV) therapy. Otherwise, angiography or scintigraphy should be delayed. In pediatric patients, magnetic resonance imaging (MRI) of developing hyaline cartilage can demonstrate physial injury, which has the largest impact on longitudinal growth.

Management

Prehospital

Napoleon's Surgeon General, Baron Larrey, first recorded the disastrous effects of the freeze-thaw-refreeze cycle. During the 1812 to 1813 Russian campaign, soldiers would thaw frozen extremities directly over open fires, only to burn them or have them refreeze, with resulting tissue destruction. Unfortunately, the formation of gangrene was misattributed to rapid thawing. Gradual thawing, often including friction massage with snow, became the standard treatment regimen until the 1950s. In 1961, William Mills, Jr., popularized rapid thawing in warm water after extensive research with severe Alaskan frostbite cases.

Field rewarming of frozen tissue is rarely practical. If possible, remove wet or constricting clothing and immobilize and insulate affected areas. Massage is not efficacious and increases tissue loss. Frozen parts should be kept away from dry heat sources, such as heated forced air during transport.

In general, the longer tissue has been frozen, the greater the extent of cellular damage. However, rewarming should not be initiated in the field if there is any possibility that thawing will be interrupted

TABLE 128.3 Frostbite Classification System

Frostbite injuries of the extremities	Grade 1	Grade 2	Grade 3	Grade 4
Extent of initial lesion at day 0 after rapid rewarming	Absence of initial lesion	Initial lesion on distal phalanx	Initial lesion on intermediary and proximal phalanx	Initial lesion on carpal/tarsal
Bone scanning at day 2	Useless	Hypofixation of radiotracer uptake area	Absence of radiotracer uptake area on the digit	Absence of radiotracer uptake area on the carpal/tarsal
Blisters at day 2	Absence of blisters	Clear blisters	Hemorrhagic blisters on the digit	Hemorrhagic blisters over carpal/tarsal
Prognosis at day 2	No amputation	Tissue amputation	Bone amputation of digit	Bone amputation of the limb ± systemic involvement ± sepsis
	No sequelae	Fingernail sequelae	Functional sequelae	Functional sequelae

or incomplete or that tissue will refreeze during evacuation. Tissue refreezing is disastrous. It is better to walk to safety on frozen feet if rescue will be delayed. When evacuation is not possible, rapid field rewarming, preferably in water at 37°C to 39°C (98.6°F to 102.2°F), may be the best option.

Emergency Department

Prethaw. Stabilize hypothermia and other life-threatening conditions before warming frostbitten extremities.[15] Do not delay treatment while waiting for the results of laboratory and radiographic studies. Most patients are volume-depleted, partly due to poor oral intake and hypothermia-induced cold diuresis, and volume replacement with crystalloid at 40°C (104°F) to decrease blood viscosity and sludging is indicated.

Thawing by Immersion in Warm Water

Rapidly rewarm completely frozen or partially thawed tissue by immersion in gently circulating water that is carefully maintained at a temperature of 37°C to 39°C (98.6°F to 102.2°F). A whirlpool is ideal, but any large container can be used for the hands or feet. Do not let frostbitten areas bump or rub against the side of the container. Water warmer than 39°C (102.2°F) does not thaw significantly faster but causes more pain. Tissue can suffer thermal injury when the water temperature exceeds 42°C (107.6°F). Rewarming should be continued until distal erythema is noted. The part should have return of color and feel pliable, which usually requires 15 to 30 minutes of submersion. Active gentle motion is encouraged during rewarming, but the tissue should not be massaged. Premature termination of rewarming results in a partial thaw, with increased tissue damage.

Parenteral analgesia is often indicated during rewarming. Reperfusion may be intensely painful, with throbbing, burning pain and tenderness. Sensation is usually diminished after thawing until it disappears with bleb formation.

Patients with completely frozen extremities are usually hypothermic and at risk for significant fluid and electrolyte fluxes during rewarming. The acute thawing of large amounts of distal musculature can extinguish peripheral vasoconstriction, resulting in a sudden return of cold, hyperkalemic, acidotic blood to the central circulation. This can produce core temperature afterdrop, with ventricular fibrillation. In the most severe cases, extracorporeal rewarming should be used (Box 128.7). Rewarm frostbitten extremities only after the hypothermic patient has been stabilized.

Postthaw. We elevate injured extremities to minimize edema formation, apply sterile dressings loosely, and handle frostbitten areas gently. Due to cold-induced anesthesia, soft tissue injuries are often not appreciated by the patient or emergency clinician. Persistent cyanosis in the extremities after a complete thaw may reflect increased compartment pressure. Tissue should be monitored carefully, although decompressive fasciotomies are usually not necessary during initial treatment.

Although there is no definitive supporting evidence, we recommend the use of topical aloe vera with oral aspirin or ibuprofen. Topical aloe vera every 6 hours inhibits thromboxane when applied directly to frostbitten areas. Aspirin and ibuprofen inhibit the arachidonic acid cascade, although there is no evidence of efficacy for either agent. Some experts prefer ibuprofen because it may also cause fibrinolysis. However, aspirin is also used widely. There is no convincing data showing improved tissue salvage with any of these agents.

Large clear blisters can be left intact, débrided or aspirated. We débride broken or intact nonhemorrhagic blisters. Hemorrhagic blisters are aspirated rather than débrided. When hemorrhagic blisters are débrided, secondary desiccation of deep dermal layers may extend the injury.

Although there is no demonstrated benefit of penicillin for streptococcal prophylaxis, it is used routinely in some centers. We recommend against prophylactic antibiotics for frostbite unless there is associated gross contamination or crush injury. Tetanus can occur after frostbite. Administer tetanus prophylaxis per usual wound care guidelines.

Thrombolytic therapy has been used to treat microvascular thrombosis in frostbite. In one retrospective study, IV tissue plasminogen activator (tPA) and heparin reduced predicted digit amputations in severe

BOX 128.7 Emergency Department Rewarming Protocol

Prethaw

Assess Doppler pulses and appearance.
- Protect part—no friction massage.
- Stabilize core temperature.
- Address medical and surgical conditions.
- Administer volume replacement as indicated.

Thaw

Provide parenteral opiate analgesia as needed.
- Administer ibuprofen 400–600 mg (or aspirin, 325 mg).
- Immerse part in circulating water at 37°C–39°C (98.6°F–102.2°F), monitored by thermometer.
- Encourage gentle motion, but do not massage.

Postthaw

Dry and elevate.
- Aspirate or débride clear vesicles.
- Débride broken vesicles and apply topical antibiotic or sterile aloe vera ointment every 6 hours.
- Leave hemorrhagic vesicles intact.
- Administer tetanus prophylaxis if indicated.
- Provide streptococcal prophylaxis if high risk.
- Consider phenoxybenzamine in severe cases.
- Perform imaging, including angiography, if thrombolysis may be indicated.
- Carry out thrombolysis, if indicated and available.
- Obtain admission photographs.

frostbite. In other studies, intra-arterial tPA decreased the incidence of amputations when administered within 24 hours of thawing.[16,17]

Thrombolysis should be reserved for patients with severe injuries (Grade 3 or 4) likely to produce significant tissue loss. Frostbite that has not undergone freeze-thaw-refreeze can be treated using tPA within 24 hours of thawing if there are no contraindications to thrombolysis. There is no standard dosing regimen. With intra-arterial tPA, angiography is performed with intra-arterial vasodilators, such as papaverine,[18] nitroglycerin,[17] and nicardipine.[19] If flow is not reestablished, intra-arterial, catheter-directed tPA can be infused with a bolus of 2 to 4 mg followed by an infusion of 0.5 to 1 mg/hr. Heparin is also given at 500 units/hour via the intra-arterial catheter. Angiograms are repeated every 8 to 12 hours. Treatment is stopped when perfusion is restored or up to 48 hours.

Intra-arterial thrombolysis should only be performed in centers that have intensive care capabilities and are familiar with the technique. An alternative approach that appears to have equal efficacy uses systemic IV thrombolytic therapy. After thawing, a technetium-99m triple phase bone scan can be performed. One regimen uses a loading dose of alteplase 0.15 mg/kg IV over 15 minutes followed by an infusion of 0.15 mg/kg/hour for 6 hours. If technetium scanning is available, a repeat technetium scan can be used to evaluate reperfusion. Treatment with alteplase is followed by enoxaparin 1 mg/kg subcutaneously twice daily for 14 days. Intravenous tPA for frostbite is an option at smaller hospitals where tPA is available for myocardial infarction or stroke.

Prostacyclin has vasodilatory properties that mimic a chemical sympathectomy. The risk of amputation was significantly lower in a controlled trial of patients with severe frostbite who received IV Iloprost (a prostacyclin analog not currently available in the United States) with aspirin after thawing. Selected patients with severe frostbite were also treated with recombinant tPA. We recommend treatment with Iloprost, if available for Grade 2 to 4 frostbite injury. It should be infused within 48 hours of thawing, combined with tPA in appropriate settings for Grade 3 to 4 frostbite injury in patients seen within 24 hours who meet the indications for tPA. Iloprost is safe enough that it can be used in prehospital settings if necessary.

There are many unproven therapies for frostbite, including low-molecular-weight dextran, vasodilator therapy, and phenoxybenzamine. Hyperbaric oxygen may accelerate demarcation but has not been shown to increase tissue salvage in severe frostbite.[20]

Chemical or surgical sympathectomies do not decrease tissue loss. Surgical sympathectomy produces a smoother initial clinical course but no long-term benefits, with the possible exception of decreased long-term pain. Forearm nerve blocks produce a chemical sympathectomy that increases finger skin temperature. Although prehospital wrist blocks may achieve rapid pain control with rewarming, there have been no systematic studies of outcomes.

Disposition

Patients with superficial frostbite can be safely discharged to a warm place unless there is another indication for admission. Consult social services if the patient is undomiciled. All other patients with significant frostbite are best admitted for further evaluation and treatment. Transfer or further consultation is indicated when the admitting service lacks experience in the care of frostbite. At hospitals not capable of giving intravenous tPA, patients who meet the criteria for thrombolysis should be transferred to a suitable facility if thrombolysis can be initiated after transfer within 24 hours of thawing.

NONFREEZING COLD INJURIES

Foundations

Background and Importance

Nonfreezing cold injury occurs when tissue fluids have not frozen. The most common nonfreezing cold injury is immersion injury, often referred to as *trench foot*, although the hands may also be affected. This is a significant threat during recreational activities and military expeditions in cold wet climates.

Anatomy, Physiology, and Pathophysiology

Trench foot is produced by prolonged exposure to wet cold at temperatures too high to cause frostbite. It usually develops slowly over several days and results in neurovascular damage. Immersion injury commonly develops while a person is wearing socks that are wet from immersion in water.

Immersion injury can also occur from sweat, especially with the use of neoprene socks, vapor barrier boots, or constrictive gaiters. People who soak their feet for hours in cool water for pain relief are also at risk. Bullae and tissue loss in immersion injury are due to pressure necrosis with or without infection rather than to cold injury. Most patients with severe immersion injury are military personnel who have worn boots continuously for days or weeks. Prevention of immersion injury may require frequent drying of feet and socks.

Pernio (chilblains) is a form of cold injury that often follows repetitive exposure to cold in susceptible individuals. Chilblains can also occur without exposure to cold in individuals who have underlying diseases, such as systemic lupus erythematosus (SLE).

Clinical Features

Immersion Injury

Immersion injury is classically described as progressing through four stages. In the first stage (during cold exposure), numbness is the most

Fig. 128.13 Nonfreezing cold injury (trench foot, immersion foot) in a homeless man in the emergency department, shortly after removal of wet socks and shoes. (Courtesy Dr. Ken Zafren.)

common symptom. The extremities may appear bright red, but soon become pale or white due to extreme vasoconstriction (Fig. 128.13). There is no pain or swelling at this stage.

In the second stage (following cold exposure) after removal from a cold environment and during rewarming, peripheral blood flow slowly returns, and the extremities become a mottled pale blue. This change may be subtle in highly pigmented skin. The extremities remain cold and numb, although pain and edema can result from active rewarming. This stage usually lasts for a few hours, but occasionally persists for several days.

In the third stage (hyperemia), blood flow increases markedly. The extremity suddenly becomes hot and red, with bounding pulses, while the microcirculation is sluggish, as evidenced by prolonged capillary refill. Dependent redness (rubor) with pallor on elevation may occur due to vasomotor paralysis. At the same time, numbness gives way to severe pain with hyperalgesia, even to light touch. Edema often develops. In severe cases associated with pressure necrosis, bullae, like those seen in frostbite, can form. In cases associated with tissue loss, necrosis becomes evident. The third stage may last weeks to months.

In the fourth stage (following hyperemia), the limb generally appears normal except in cases with tissue loss, but pain may persist. Tissue that was necrotic in the third stage becomes gangrenous and is lost. This stage can last from weeks to years or be permanent. Most cases of immersion injury present to the ED during the first or second stage, but pain that is often resistant to usual pain medications may be a presenting complaint during later stages.

Short- and long-term sequelae of cold immersion injury are similar to those of frostbite, although only the most severe immersion injuries are associated with tissue loss (see Box 128.6).

Pernio

Chilblains, or cold sores, appear within 24 hours of exposure and most often affect the face, dorsa of the hands and feet, and pretibial areas (Fig. 128.14). Young women with Raynaud phenomenon, SLE, or antiphospholipid antibodies are at increased risk. Persistent vasospasm and vasculitis result in burning, pruritus, erythema, and mild edema. Plaques, blue nodules, and ulcerations can develop. These painful lesions usually last 1 to 2 weeks but can persist much longer if there are repeated exposures to cold.

Fig. 128.14 Pernio in a woman who was working in an unheated high-altitude clinic. (Courtesy Dr. Alice Murray.)

Differential Diagnoses

Frostbite can mimic nonfreezing cold injury but can usually be diagnosed by history. Frostbite and nonfreezing cold injuries can also occur together. Warm immersion injuries, including jungle foot (paddy foot) or tropical immersion foot, may appear similar to immersion injuries due to wet cold, but resolve with drying and elevation within a few days.

Pernio has a wide differential diagnosis. The diagnosis is usually clear when pernio is associated with recent cold exposure. Cases of suspected pernio with uncertain cause should prompt a search for underlying conditions, such as SLE.

Diagnostic Testing

Intraepidermal nerve fiber density measurement can be used to assess the severity and guide management of immersion injury in patients with neuropathic symptoms. Diagnostic testing in patients with pernio is directed toward finding an underlying condition.

Management

Immersion Injury

Treat hypothermia, if present, before treating nonfreezing cold injuries. Provide volume replacement with warm IV fluids if the patient is clinically volume depleted. Immersion injuries should be allowed to rewarm slowly to room temperature. Rapid rewarming or rubbing may worsen the injury. No medications are known to be helpful. Local cooling, often in a cool room with a fan, lowers metabolic requirements and improves pain and edema. Cooling should be continued until hyperemia resolves. Pain after rewarming is common and usually responds poorly to most pain medications. Amitriptyline (50–100 mg orally at bedtime) is the treatment of choice.

Pernio

There is no standard treatment for pernio. We recommend drying the skin if it is damp and gentle massage if the patient can tolerate it. Avoid warming the skin above 30°C (86°F). Pernio is very painful and may require opioid analgesia. Nifedipine (20–60 mg daily) is the only

medication that has been shown to be potentially effective in the treatment of severe pernio.

Disposition

Many patients with significant immersion injury require admission for pain control, as well as social service assistance with activities of daily living. Patients with mild immersion injuries can be discharged if there are no other indications for admission and the patient can be released to a warm environment. Patients with pernio are usually managed as outpatients.

CHAPTER 128: QUESTIONS AND ANSWERS

1. Emergency medical services (EMS) notifies your emergency department (ED) that an unknown male who was "found down" is being transported. No history is available. Paramedics report that the patient's pulse is 42 beats/min and blood pressure is difficult to obtain. Spontaneous respirations are present at a rate of 10 breaths/min. The electrocardiogram (ECG) showing sinus bradycardia is faxed before the patient's arrival. What treatment should you administer when the patient arrives?
   a. Intravenous epinephrine
   b. Normal saline bolus
   c. Synchronized cardioversion
   d. Warm the patient

Answer: D. Warm the patient. When this hypothermic patient arrives in the ED, after assessment of the airway, the top priority is rapid rewarming. Patients with hypothermia should be actively rewarmed whenever possible. Specific indications for active rather than passive rewarming include trauma, cardiovascular instability, temperature below 32°C (89.6°F), poor rate of passive rewarming, and endocrine insufficiency.

2. Rapid rewarming is the mainstay of treatment for hypothermia. However, rewarming can cause complications. Which of the following complications should be anticipated and prevented when rewarming a hypothermic patient?
   a. Hyperkalemia
   b. Hyponatremia
   c. Hypotension
   d. Rhabdomyolysis

Answer C: Hypotension should be anticipated and prevented when rewarming a hypothermic patient. Patients with moderate or severe hypothermia are usually volume depleted. During rewarming, the total plasma volume is usually high, but the circulatory plasma volume is usually low due to increased peripheral vascular resistance. Rapid volume expansion can be lifesaving, especially in hypothermic neonates. Adult patients with moderate or severe hypothermia should initially receive a 500-mL fluid challenge of warmed normal saline. Avoid lactated Ringers solution because the cold liver metabolizes lactate poorly. Fluids administered via the intravenous (IV) route should be warmed to 40°C to 42°C (104°F to 107.6°F).

3. A 30-year-old woman in cardiac arrest is brought to the ED by emergency medical services. She was intubated in the field, and chest compressions have been continuously performed. Her temperature is 25°C (77°F). When placed on the cardiac monitor, she is noted to be in ventricular fibrillation. A defibrillation attempt is made at the appropriate setting, but she remains in ventricular fibrillation. A nurse resumes providing chest compressions and asks for further instructions. What should be done next?
   a. IV amiodarone
   b. IV lidocaine
   c. IV procainamide
   d. Warm the patient

Answer: D. Warm the patient. This severely hypothermic patient needs further rewarming before subsequent defibrillation attempts are made to treat her ventricular fibrillation. Most hypothermia-induced dysrhythmias convert spontaneously during rewarming. Asystole that

CHAPTER 128: QUESTIONS AND ANSWERS—Cont'd.

develops during rewarming is not as ominous as asystole in normothermic patients. For VF, defibrillation should be attempted at the usual energy level. Successful defibrillation has been reported at 20°C (68°F) but attempted defibrillation is often unsuccessful until the core temperature is above 30°C (86°F). If a defibrillation attempt is unsuccessful, active rewarming should be initiated while continuing CPR. Defibrillation can be attempted occasionally during rewarming. Once the core temperature is above 30°C (86°F), further attempts can be made.

4. A 27-year-old homeless man presents complaining of numb feet. He reports sleeping outdoors overnight. The temperature was consistently below −20°C (−4°F). The feet appear white and waxy. They are cold and hard to the touch. What is the best way to rewarm the feet?
   - **a.** Room temperature air convection
   - **b.** Room temperature water immersion
   - **c.** Warm air convection
   - **d.** Warm water immersion

Answer: D. This patient is suffering from frostbite of the feet. The treatment of choice in this scenario is rapid warm water immersion. Rapidly rewarm completely frozen or partially thawed tissue by immersion in gently circulating water that is carefully maintained at a temperature of 37°C to 39°C (98.6°F to 102.2°F). A whirlpool is ideal, but any large container can be used for the hands or feet. Water warmer than 39°C (102.2°F) does not thaw significantly faster but causes more pain. Tissue can suffer thermal injury when the water temperature exceeds 42°C (107.6°F). Rewarming should be continued until distal erythema is noted. The part should have return of color and feel pliable, which usually requires 15 to 30 minutes of submersion.

5. What is the most common error made when treating frostbite injury?
   - **a.** Débridement of broken blisters
   - **b.** Premature termination of thawing
   - **c.** Use of nonsteroidal antiinflammatory drugs (NSAIDs) for analgesia
   - **d.** Use of thrombolytic agents to restore blood flow

Answer: B. Premature termination of thawing in 37°C to 39°C (98.6°F to 102.2°F) water is a common error. Reperfusion of completely frozen tissue may be painful, requiring parenteral analgesia.

Heat Illness

Melissa A. Platt and Timothy G. Price

KEY CONCEPTS

- Classic heatstroke is generally diagnosed in older patients with comorbidities during heat waves, whereas exertional heatstroke is more common in young athletic patients or military personnel.
- Heat exhaustion and heatstroke are a continuum of the same pathophysiologic process. Neurologic dysfunction is a hallmark of heatstroke, and cerebral edema is common.
- In heat stroke, morbidity and mortality are directly related to the duration of core temperature elevation. Rapid cooling should be initiated without delay.
- The evaporative technique and ice water immersion are the 2 forms of primary cooling measures. Other cooling measures are secondary and considered adjunct therapy.
- Antipyretics are ineffective and should not be used to control environmental hyperthermia.
- Heatstroke can cause right-sided cardiac dilation and elevated central venous pressure and clinically resemble pulmonary edema but may still require crystalloid resuscitation.

FOUNDATIONS

Background and Importance

Humans have been plagued by heat illness throughout recorded history. Heat illness has the potential to affect all age groups and population types. Older adults and the poor (who often lack adequate air conditioning and nutrition) are susceptible to heat illness during environmental extremes and heat waves. Those with preexisting disease are also prone to heat illness. It is estimated that at least 10 times as many heat aggravated illnesses occur in patients with comorbid conditions such as coronary artery disease, cerebrovascular disease, and diabetes.[1] Children are also susceptible to heat stressors because of their higher surface area-to mass ratios. They also have lower sweat rates per gland. Military personnel, athletes, including American football players, and those who occupationally exert themselves in heat, are also at risk.

For an accurate heat illness diagnosis, information about living conditions, occupation, access to water, strenuous physical activity, acclimatization, and current environmental temperatures need to be ascertained. Heat illness is often associated with military exercises, athletic events, occupation, and recreational activities. A recognition of the microclimates conducive to heat illness including military tanks, tents in the sun, engine rooms, mines, hot tubs, saunas, and automobile interiors, is also important. In the United States, nearly 40 children die each year from hyperthermia after being left alone in a motor vehicle.[2]

Anatomy, Physiology, and Pathophysiology

Heat Production

Humans are essentially biochemical furnaces that burn food to fuel with a complex array of metabolic functions. These chemical reactions consume substrate, generate usable energy, and produce byproducts that must be eliminated for continued operation of the system. Water and carbon dioxide are produced and eliminated in large quantities, as well as urea, sulfates, phosphates, and other chemical byproducts. These reactions are exothermic and combine to produce a basal metabolic rate that amounts to approximately 100 kCal/h for a 70-kg person. In the absence of cooling mechanisms, this baseline metabolic activity would result in a 1.1°C (2°F) hourly rise in body temperature.

Heat production can be increased 20-fold by strenuous exertion. Rectal temperatures as high as 42°C (107.6°F) have been recorded in trained marathon runners, without ill effects. Metabolic factors (hyperthyroidism and sympathomimetic drug ingestion) can dramatically increase heat production. Environmental heat not only adds to the heat load but also interferes with its dissipation. The physics of heat transfer as it relates to human physiology involves four mechanisms—conduction, convection, radiation, and evaporation.[3]

Conduction. This is the transfer of heat energy from warmer to cooler objects by direct physical contact. Air is a good insulator; therefore, only approximately 2% of the body heat loss is by conduction. In contrast, the thermal conductivity of water is at least 25 times that of air.

Convection. This is heat loss to air and water vapor molecules circulating around the body. As the ambient temperature rises, the amount of heat dissipated by convection becomes minimal. Once the air temperature exceeds the mean skin temperature, heat is gained by the body. Convective heat loss varies directly with wind velocity. Loose-fitting clothing maximizes convective, and also evaporative, heat loss.

Radiation. This is heat transfer by electromagnetic waves. Although radiation accounts for approximately 65% of heat loss in cool environments, it is a major source of heat gain in hot climates. Up to 300 kCal/h can be gained from radiation when someone is directly exposed to the hot summer sun.

Evaporation. Evaporation is the conversion of a liquid to the gaseous phase. Evaporation of 1 mL of sweat from the skin cools the body by 0.58 kCal. In humans, heat loss through sweat evaporation is the principal means of heat loss during exercise and the dominant means of dissipating heat via the skin when ambient air temperatures exceed skin temperature. Panting mammals such as dogs have an oropharyngeal countercurrent flow mechanism *(carotid rete mirabile)* that results in selective cooling of the brain. In humans, respiratory and countercurrent mechanisms are minimal sources of heat loss.

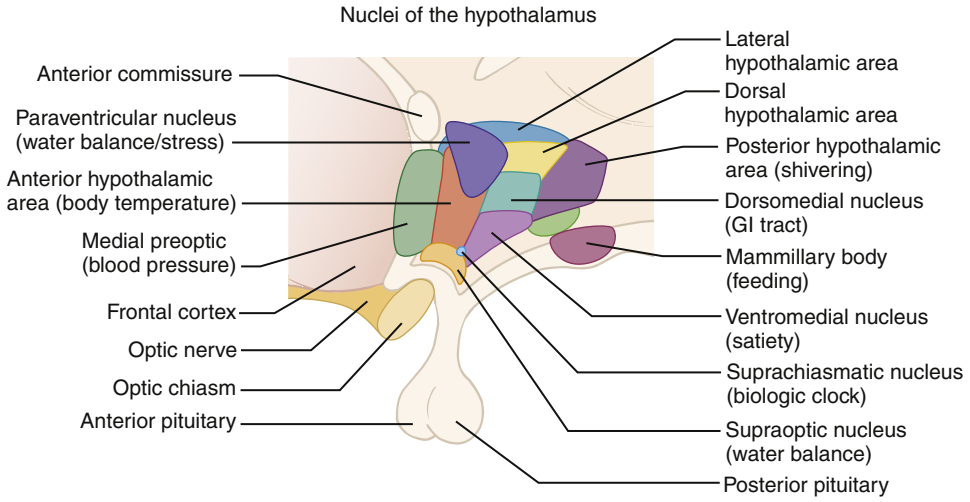

Fig. 129.1 Preoptic Anterior Hypothalamus. (Adapted from Nuclei of the hypothalamus. bhavanajagat.files.wordpress.com/2012/07/nuclei-of-hypothalamus.jpg.)

Heat Regulation

The regulation of body temperature involves three distinct functions—thermosensors, a central integrative area, and thermoregulatory effectors.

Thermosensors. Temperature-sensitive structures are located peripherally in the skin and centrally in the body. However, skin temperature changes correlate poorly with changes in the rate of heat loss. Thermosensitive neurons, located in the preoptic anterior hypothalamus, are activated when the temperature of the blood circulating through that area exceeds a set point (Fig. 129.1).

The skin temperature affects heat loss when a person resting in a warm environment initiates sweating, even though the core temperature remains constant. In contrast, changes in core temperature are more dominant than skin temperature changes in producing heat-dissipating responses.

Central integrative area. The central nervous system (CNS) interprets information received from the thermosensors to instruct thermoregulatory effectors properly. The concept of a central thermostat where an alteration shifts effector thresholds in the same direction fits a variety of clinical situations. For example, fever, the circadian rhythm of temperature variation, and the difference in rectal temperature after ovulation can be explained by variation of a thermal set point.

Thermoregulatory effectors. Sweating and peripheral vasodilation are the major mechanisms whereby heat loss can be accelerated. In a warm environment, evaporation of sweat from the skin is the most important mechanism of heat dissipation. Heat loss from the skin by convection and radiation is maximized by increased skin blood flow to facilitate sweating.

Humans possess apocrine and eccrine sweat glands. Apocrine glands are concentrated in the axillae and produce milky sweat, rich in carbohydrate and protein. They are adrenergically innervated and respond to emotional stress as well as to heat. Most glands producing so-called thermal sweat are eccrine glands. These are cholinergically innervated and distributed over the entire body, with the largest number on the palms and soles. Eccrine sweat is colorless, odorless, and devoid of protein. Individuals exercising in hot environments commonly lose 1 or 2 L/h of sweat. A loss of up to 4 L/h is possible with strenuous exercise.

Cooling is best achieved by evaporation from the body surface; sweat that drips from the skin does not cool the body. Each liter of completely evaporated sweat dissipates 580 kCal of heat. The ability of the environment to evaporate sweat is termed *atmospheric cooling power* and varies primarily with humidity, but also with wind velocity. As humidity approaches 100%, evaporative heat loss ceases.

The vascular response to heat stress is cutaneous vasodilation and compensatory vasoconstriction of the splanchnic and renal beds. These vascular changes are under neurogenic control and allow heat to be dissipated quickly and efficiently, but they place a tremendous burden on the cardiovascular system. To maintain blood pressure, cardiac output increases dramatically. For this reason, saunas and hot tubs may be dangerous for patients with cardiac disease. Cardiovascular and baroreceptor reflexes also affect skin blood flow. Reduced forearm sweating and vasodilation have been observed in severely dehydrated subjects exercising in a warm environment.

Acclimatization

Acclimatization is the constellation of physiologic adaptations that occur in a normal person as the result of repeated exposures to heat stress. Daily exposure to work and heat for 100 min/day results in near-maximal acclimatization within 7 to 14 days.[4] This is characterized by an earlier onset of sweating (at a lower core temperature), increased sweat volume, and lowered sweat sodium concentration. Acclimatization is hastened by modest salt deprivation and delayed by high dietary salt intake.

The cardiovascular system plays a major role in acclimatization and endurance training, largely resulting from an expansion of plasma volume. Heart rate is lower and associated with a higher stroke volume. Other physiologic changes include earlier release of aldosterone, although acclimatized individuals generate lower plasma levels of aldosterone during exercise heat stress. Total body potassium depletion of up to 20% (500 mEq) by the second week of acclimatization can occur as a result of sweat and urine losses, coupled with inadequate repletion.

Although many similarities exist among thermoregulatory responses to heat and exercise, the well-conditioned athlete is not necessarily heat-acclimatized. For heat and exercise-induced adaptive responses to be maintained, heat exposure needs to continue intermittently, at least on 4-day intervals. Plasma volume decreases considerably within 1 week in the absence of heat stress.

Predisposing Factors

Advanced age, psychiatric conditions, chronic disease, obesity, and certain medications increase the risk for classic heatstroke during periods of high heat and humidity. Adequate fluid intake is essential. Older adults often overdress during hot weather conditions. Heat loss is maximized by light, loose-fitting garments.

Exertional heatstroke is most likely to occur in young healthy people involved in strenuous physical activity, especially if they have not acclimatized to environmental factors that overwhelm heat-dissipating mechanisms. For example, wrestlers frequently fast, restrict food and fluid intake, and exercise vigorously wearing vapor-impermeable clothing in an effort to maintain or drop their current weight class. Pre-existing illness may not increase the risk of exertional heat stroke.[5] Fluid intake is the most critical variable. Dehydration can be minimized by education on work-rest cycles and fluid consumption, and through provision of cool flavored fluids.

The goal is to maximize voluntary fluid intake and gastric emptying so that fluid can rapidly enter the small intestine, where it is absorbed. Gastric emptying is accelerated to 25 mL/min by large fluid volumes (500 to 600 mL) and cool temperatures (10°C to 15.8°C [50°F to 60.4°F]). High osmolality inhibits gastric emptying; osmolality of less than 200 mOsm/L is optimal. Most commercially available electrolyte solutions contain excessive sugar. Hydration can be monitored by measurement of body weight before and after training or athletic competition. An athlete with a loss of 2% to 3% body weight (1.5 to 2 L in a 70-kg man) should drink extra fluid and be permitted to compete only when his or her body weight is within 0.5 to 1 kg (1 or 2 pounds) of the starting weight on the previous day. A weight loss of 5% or 6% represents a moderately severe deficit and usually is associated with intense thirst, scant dark-colored urine, tachycardia, and increase in rectal temperature of approximately 2°C (3.6°F). These athletes should be restricted to light workouts after hydration until they return to normal weight. A loss of 7% or more of body weight represents severe water depletion; participation in sports should not be permitted until the athlete is evaluated by a physician or sports trainer. The administration of salt tablets during strenuous exercise can cause delayed gastric emptying, osmotic fluid shifts into the gut, gastric mucosal damage, and hypernatremic dehydration. A 6-g sodium diet is sufficient for successful adaptation for work in the heat, with sweat losses averaging 7 L/day. Excessively high salt intake in relation to salt losses in sweat during initial heat exposure can impair acclimatization because of the inhibition of aldosterone secretion. Excessive salt ingestion can also exacerbate potassium depletion.

Evaporative cooling can be lost when clothing inhibits air convection and evaporation. Water evaporated from clothing is much less efficient for body cooling than water evaporated from the skin. Loose-fitting clothing or ventilated fishnet jerseys allow efficient evaporation. Light-colored clothing reflects rather than absorbs light.

The heat dissipation mechanisms of the body are analogous to the cooling system of an automobile (Fig. 129.2). Coolant (blood) is circulated by a pump (heart) from the hot inner core to a radiator (skin surface cooled by the evaporation of sweat). Temperature is sensed by a thermostat (CNS), which alters coolant flow by a system of pipes, valves, and reservoirs (vasculature). Failure of any of these components can result in overheating.

Effective circulation requires an intact pump and adequate coolant levels. β-adrenergic blocking agents or calcium channel blockers may prevent an increase in cardiac output sufficient to produce the necessary peripheral vasodilation to dissipate heat. Dehydration caused by gastroenteritis, diuretics, or inadequate fluid intake predisposes to heat illness. Individuals working in the heat seldom voluntarily drink as much fluid as they lose and replace only approximately two-thirds

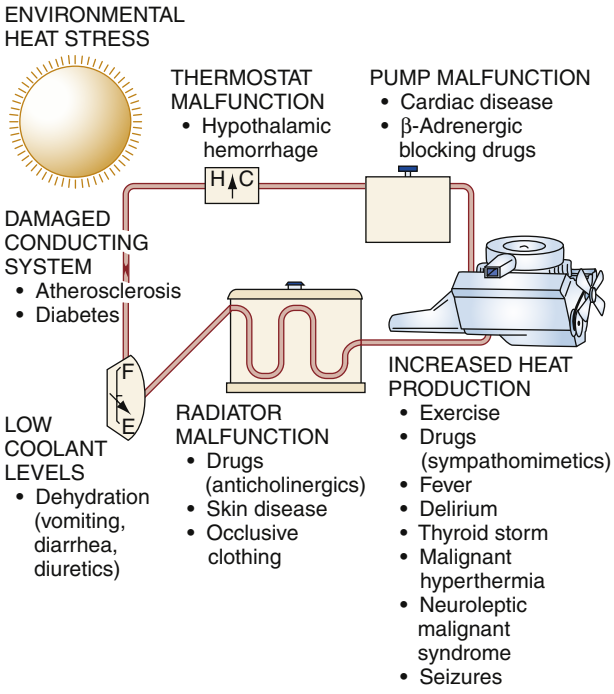

Fig. 129.2 Predisposing factors for heat illness, an automotive analogy.

of net water loss (so-called voluntary dehydration). Dehydration alone increases body temperature at rest by increasing the work of the sodium-potassium adenosine triphosphatase pump, which accounts for 25% to 45% of the basal metabolic rate. This is particularly true in cases of hypernatremic dehydration. The pipes and valves of the coolant system may be abnormal in diabetic or older patients with extensive atherosclerosis.

Radiator function depends on the skin and sweat glands. Occlusive, vapor-impermeable clothing hinders evaporative and convective cooling. Anticholinergic medications and stimulant drugs of abuse interfere with sweating and contribute to heat illness. Various skin diseases, including miliaria (prickly heat rash), extensive burns, scleroderma, ectodermal dysplasia, and cystic fibrosis, are risk factors. Anhidrosis can also be secondary to central or peripheral nervous system disorders.

Increased heat production causing heat illness most often accompanies exercise in a hot humid environment. When heat and humidity are extreme, exertion is not necessary to produce heat-related problems. Several indices help objectify heat strain. These indices can be divided into two categories, heat scales based on meteorologic parameters and those that combine environmental and physiologic parameters.

The wet bulb globe temperature heat index is an excellent meteorologic measure of environmental heat stress (Box 129.1). It measures the effects of temperature, humidity, and radiant thermal energy from the sun. When climatic conditions exceed 25°C (77°F) wet bulb, even healthy people are at high risk during exercise. Above 28°C (82.4°F), exercise and strenuous work should be avoided or limited to extremely short periods of time.

Fever Versus Hyperthermia

It is diagnostically and therapeutically important to identify patients suffering from a febrile response rather than heat illness. Fever does not cause primary pathologic or physiologic damage to humans and does not require primary emphasis in the therapeutic regimen, which is directed at the underlying disease state. If temperature-related physiologic changes such as febrile seizures and tachycardia compromise

BOX 129.1 Wet Bulb Globe Temperature

$$WBGT = 0.7\ T_n + 0.2\ T_g + T_a$$

T_n = "Natural" wet bulb temperature—the temperature achieved by a thermometer covered with a moistened white wick and left exposed to the ambient environment

T_g = Globe temperature—the temperature inside a blackened hollow copper sphere exposed to the ambient environment

T_a = Ambient temperature

These measurements can be done manually or calculated automatically with the help of computer algorithms.

a patient with marginal cardiac reserve, the temperature should be artificially regulated with antipyretics. In contrast, antipyretics are not effective against heat illness and are **not** recommended to control environmental hyperthermia.

MINOR HEAT ILLNESSES

Miliaria Rubra

Miliaria rubra, also known as prickly heat, lichen tropicus, and heat rash, is an acute inflammatory disorder of the skin that occurs in hot and humid climates. It is the result of the blockage of sweat gland pores by macerated stratum corneum and secondary staphylococcal infection. The acute phase is characterized by vesicles in the malpighian layer of the skin, caused by dilation and rupture of the obstructed sweat gland ducts.

Clinical Features

Miliaria produces intensely pruritic vesicles on an erythematous base. The rash is confined to clothed areas, and the affected area is often completely anhidrotic. During the next week, a keratin plug develops and fills these vesicles, causing a deeper obstruction of the sweat gland duct. The obstructed duct then ruptures a second time, producing a deeper vesicle within the dermis. This is known as the profunda stage, and it can persist for weeks. Profunda vesicles are not pruritic and closely resemble the white papules of piloerection. Chronic dermatitis is a common complication (Fig. 129.3).

Differential Diagnoses

Alternative diagnoses include contact dermatitis, cellulitis, and allergic reactions. A heat exposure history and distribution of the rash will solidify the diagnosis.

Diagnostic Testing

Laboratory data is not indicated with miliaria.

Management and Disposition

Miliaria rubra can be prevented by wearing light, loose-fitting, clean clothing and avoiding situations that produce continuous sweating. Avoid routine use of talcum or baby powder. Gentle exfoliation may help to remove debris that occlude the eccrine sweat ducts. However, soap may cause additional skin irritation. Topical corticosteroids, such as hydrocortisone 2.5% or triamcinolone 0.1% twice a day for one to two weeks, may decrease pruritus and inflammation but is not required for the resolution of miliaria. Patients can be discharged with dermatologic or primary care follow-up.

Heat Cramps

Heat cramps are brief, intermittent, and often severe muscle cramps occurring typically in muscles that are fatigued by heavy work or

Fig. 129.3 Prickly Heat. (From Habif TP. *Clinical Dermatology: A Color Guide to Diagnosis and Therapy*. 3rd ed. St. Louis: Mosby; 1996.)

BOX 129.2 Heat Cramps: Essentials of Diagnosis

Cramps of most worked muscles
Usually occur after exertion
Copious sweating during exertion
Copious hypotonic fluid replacement during exertion
Hyperventilation not present in cool environment

prolonged exercise. Heat cramps appear to be related to a salt deficiency. They usually occur during the first days of work in a hot environment and develop in persons who produce large amounts of thermal sweat and subsequently drink copious amounts of hypotonic fluid.

Clinical Features

Athletes, roofers, steelworkers, coal miners, field workers, and boiler operators are among the most common victims of heat cramps. Heat cramps tend to occur after exercise, when the victim stops working and is relaxing (Box 129.2). In this respect, they differ from the cramps experienced by athletes during exercise, which tend to last for several minutes, are relieved by massage, and resolve spontaneously.

Differential Diagnoses

Heat cramps are occasionally confused with hyperventilation tetany, which can occur during heat exhaustion. Hyperventilation tetany can be distinguished by the presence of carpopedal spasm and paresthesias in the distal extremities and perioral area.

Diagnostic Testing

Heat cramps accompanied by systemic symptoms may be part of salt depletion heat exhaustion. Check serum electrolyte levels as heat cramp victims often exhibit hyponatremia and hypochloremia.

Rhabdomyolysis or resultant renal damage is not present with isolated heat cramps.

Management and Disposition

Heat cramps are rapidly relieved by salt solutions. Many commercially available flavored electrolyte solutions are available. Mild cases without concurrent dehydration are treated orally with a 0.1% or 0.2% salt solution (two to four 10-grain salt tablets [56 to 112 mEq] or ¼ to ½ teaspoon of table salt dissolved in 1 quart of water), which is the general limit of palatability. Severe cases respond rapidly to an infusion of normal saline. Salt tablets are gastric irritants, delay gastric emptying, and are not recommended as treatment. Although most patients do not seek medical treatment, most patients with heat cramps may be safely discharged after the administration of balanced salt solutions and clinical improvement.

Heat Edema

It is presumed that hydrostatic pressure and vasodilation of cutaneous vessels, combined orthostatic pooling, lead to vascular leak and accumulation of interstitial fluid in the lower extremities. Simultaneously, the aldosterone level increases in response to the heat stress and perceived central volume deficit.

Clinical Features

Swollen feet and ankles are often reported by non-acclimatized individuals, especially older adults, who encounter climatic stresses of tropical and semitropical areas. They commonly have schedules that involve long periods of sitting or standing. The edema is usually minimal, is not accompanied by any significant impairment in function or ambulation, and often resolves after several days of acclimatization.

Differential Diagnoses

Differentiate heat edema from congestive heart failure, liver disease states, nephrosis, lower extremity infections, and deep venous thrombosis.

Diagnostic Testing

Awareness of this clinical presentation prevents overly vigorous diagnostic and therapeutic intervention. A brief diagnostic evaluation to rule out thrombophlebitis, lymphedema, or congestive heart failure may be appropriate, but invasive diagnostic techniques are not indicated.

Management and Disposition

Pharmacologic therapy is not indicated, and diuretic therapy is not effective. Simple leg elevation or thigh-high support hose should be used. In most individuals, the problem resolves through adequate acclimatization or with the individual's return to a temperate climate. Given its benign nature, patients with heat edema can be safely discharged with outpatient follow-up.

Heat Syncope

Individuals adapt to a hot, humid environment by dilation of cutaneous vessels to deliver heat to the body surface. Thus, an increased portion of the intravascular pool is located in the periphery at any given time. Increasing blood flow to compliant cutaneous veins raises skin vascular volume at the expense of thoracic blood volume. The combination of volume loss and peripheral vasodilation can result in inadequate central venous return, a concomitant drop in cardiac output, and cerebral perfusion inadequate to maintain consciousness.

Clinical Features

Heat syncope is a multifactorial disorder that results in a temporary loss of consciousness in the presence of heat exposure. Older adults have a special predilection for this disorder, due to reduced cardiovascular reserve and blunted baroreceptor reflexes.

Differential Diagnoses

The diagnosis of heat syncope requires the appropriate clinical setting and exclusion of other possible causes of syncope, given a patient's age and underlying medical disorders such as cardiovascular and neurological causes (see Chapter 11).

Diagnostic Testing

Heat syncope can be precipitated by an underlying metabolic or cardiac disorder, so cardiac monitoring, electrocardiography, and hemoglobin determination are warranted. Other tests are individualized based on clinical suspicion following a thorough history and physical examination (see Chapter 11).

Management and Disposition

This disorder is self-limited and placing the patient in a horizontal position is generally curative. Older patients with comorbidities may require admission to address cardiac or neurologic etiologies. These individuals are at risk for recurrent heat syncope and should be advised to move around often, flex leg muscles repeatedly when standing stationary, avoid protracted standing in hot environments, and assume a sitting or horizontal position when prodromal warning symptoms or signs occur.

MAJOR HEAT ILLNESSES

Heat Exhaustion

Foundations

Background and importance. Heat exhaustion (heat prostration) is a clinical syndrome characterized by volume depletion that occurs under conditions of heat stress. Two types of heat exhaustion are classically described, water depletion and salt depletion.

Anatomy, physiology and pathophysiology. Water depletion heat exhaustion results from inadequate fluid replacement by individuals working in a hot environment and incapacitated individuals without free access to water. Those working in the heat seldom drink as much as they lose, and this voluntary dehydration results in progressive hypovolemia. Left untreated, heat exhaustion caused water depletion will progress to heatstroke because they are a continuum of the same disease.

Salt depletion heat exhaustion takes longer to develop than the water depletion form. It occurs when large volumes of thermal sweat are replaced by water with too little salt. It differs from heat cramps in that systemic symptoms occur. Symptoms are similar to those seen in water depletion heat exhaustion; the body temperature usually remains normal or minimally elevated.

Clinical Features

The symptoms and signs associated with both types of heat exhaustion are variable and include weakness, fatigue, frontal headache, impaired judgment, vertigo, nausea and vomiting and, occasionally, muscle cramps (Box 129.3). Orthostatic dizziness and syncope can occur. Sweating persists and may be profuse. The core temperature is only moderately elevated, usually below 40°C (104°F). Signs of severe CNS dysfunction (e.g., altered mental status) are not present.

Differential Diagnoses

Mild heat exhaustion and full-blown heatstroke represent extremes of the spectrum of heat illness, and intermediate cases may prove difficult to differentiate. Heat exhaustion should not be diagnosed in the

BOX 129.3 Heat Exhaustion: Diagnosis

- Vague malaise, fatigue, headache
- Core temperature often normal; if elevated, <40°C (104°F)
- Mental function essentially intact; no coma or seizures
- Tachycardia, orthostatic hypotension, clinical dehydration (may occur)
- Other major illness ruled out
- If in doubt, treat as heatstroke.

BOX 129.4 Heat Exhaustion: Management

Rest

Cool environment

Assessment of volume status—orthostatic changes, blood urea nitrogen level, hematocrit, serum sodium concentration

Fluid replacement—normal saline to replete volume if the patient is orthostatic; replace free water deficits slowly to avoid cerebral edema.

Healthy young patients are usually treated as outpatients; consider admission if the patient is older, has significant electrolyte abnormalities, or would be at risk for recurrence if discharged.

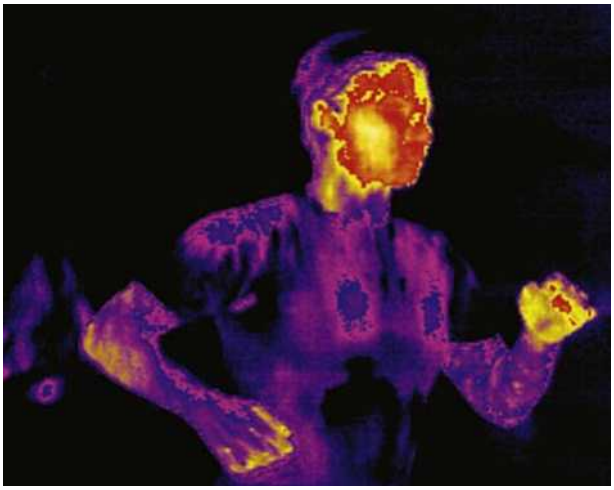

Fig. 129.4 Human Infrared Image. Note that the palms and face are substantially warmer than the rest of the body. (From Auerbach PS. *Wilderness Medicine.* 6th ed. Philadelphia: Mosby/Elsevier; 2012.)

presence of major CNS dysfunction (e.g., seizures, coma) or severe hyperthermia (40.5°C [105°F]).

Diagnostic Testing

This syndrome is characterized by hyponatremia, hypochloremia, and low urinary sodium and chloride concentrations. Determine a serum creatine kinase (CK) level and renal function. Measurement of hepatic transaminase levels may prove helpful. Elevations to several thousand units can be seen in patients with heat exhaustion or in healthy runners after a marathon.

Management

Pure forms of either type of heat exhaustion are rare, and most cases of heat exhaustion involve mixed salt and water depletion. Heat exhaustion is primarily a volume depletion problem, and rapid recovery follows fluid administration. Decisions regarding the type of fluid and electrolyte replacements should be based on serum electrolyte level measurements and the estimation of hydration status by clinical and laboratory parameters.

Patients with significant volume depletion or electrolyte abnormalities require IV fluids. If the patient is orthostatic, normal saline should be administered until vital signs normalize. Free water deficits should be replaced slowly over 48 hours to avoid a decrease of serum osmolality of more than 2 mOsm/h. Overly rapid correction of hyponatremia can result in cerebral edema and seizures.

Disposition

Young, otherwise healthy patients who do not have significant laboratory abnormalities and who respond rapidly to hydration do not require hospitalization. These patients should be instructed to drink plenty of fluids and avoid heat stress for 24 to 48 hours. Older patients, particularly those with cardiovascular disease or other chronic diseases, may benefit from more cautious inpatient fluid and electrolyte replacement and frequent reassessment (Box 129.4).

Heatstroke

Foundations

Background and importance. In the previously discussed forms of heat illness, although the body temperature rises, homeostatic thermoregulatory mechanisms remain intact. Heatstroke is the catastrophic life-threatening emergency that occurs when these mechanisms fail. This results in the elevation of body temperature to extreme levels, usually higher than 40.5°C (105°F), producing multisystem tissue damage and organ dysfunction.

Anatomy, physiology and pathophysiology. As heatstroke develops, energy will be insufficient to sustain thermoregulatory mechanisms, resulting in dramatic increases in core temperature and the clinical manifestations of heatstroke. Tissue damage is a function of a complex interaction of body temperature, exposure time, workload, tissue perfusion, and individual factors. The exact temperature at which cellular damage begins to occur in an individual patient varies. With rapid intervention, full recovery is possible, despite rectal temperatures up to 46.5°C (115.7°F).

Neurologic dysfunction is a hallmark of heatstroke, and cerebral edema is common. Other pathologic changes include petechiae in the walls of the third and fourth ventricles and marked cerebellar Purkinje cell damage.[6,7] Interestingly, the hypothalamus, the predominant site of central thermoregulatory control, is usually not damaged. Long term neurological impairment, such as motor, cerebellar or cognitive, is common.[6,7]

Heat stress creates tremendous demands on the cardiovascular system, and patients who succumb to heatstroke show signs of circulatory failure. Although such pathologic changes are common, cardiac damage alone is not lethal.

Prolonged heat stress produces impressive increases in skin blood flow (peripheral vasodilation) and a reduction of the thermal gradient between the core and the skin (Fig. 129.4). Functional hypovolemia is avoided by compensatory vasoconstriction of the splanchnic and renal vasculatures. The resulting splanchnic and renal ischemia may explain the nausea, vomiting, and diarrhea observed in runners after a marathon. Hepatic damage is a consistent feature of heatstroke, and its absence should cast doubt on the diagnosis.

If severe heat stress continues, compensatory splanchnic vasoconstriction will eventually fail, resulting in reduced mean arterial pressure and a continued cascade of exaggerated systemic inflammatory responses. Failure to perfuse the skin with heated blood from the core results in a dramatically increased rate of heat storage. This produces elevated intracranial pressure, which, in combination with the reduction in mean arterial pressure caused by failure of compensatory

BOX 129.5 Heatstroke: Diagnosis

- Exposure to heat stress, endogenous or exogenous
- Signs of severe central nervous system dysfunction (coma, seizures, delirium)
- Core temperature usually >40.5°C (105°F), but may be lower
- Hot skin common, and sweating may persist
- Marked elevation of hepatic transaminase levels

TABLE 129.1 Characteristics of Classic Versus Exertional Heatstroke

Exertional	Classic
Healthy	Predisposing factors or medications
Younger	Older
Exercise	Sedentary
Sporadic	Heat wave occurrence
Diaphoresis	Anhidrosis
Hypoglycemia	Normoglycemia
DIC	Mild coagulopathy
Rhabdomyolysis	Mild CK level elevation
Acute renal failure	Oliguria
Marked lactic acidosis	Mild acidosis
Hypocalcemia	Normocalcemia

CK, Creatine kinase; *DIC,* disseminated intravascular coagulation.

TABLE 129.2 Medications Associated With Heat Stroke

Drug Class	Examples
Anticholinergics	Atropine
	Benztropine
	Oxybutynin
	Scopolamine
Antidepressants	Tricyclics
Antiemetics	Metaclopramide
	Prochlorperazine
	Promethazine
Antiepileptics	Topiramate
	Zonisamide
Antihistamines	All
Antihypertensives	Beta blockers
	Calcium channel blockers
Antipsychotics	All
Diuretics	Hydrochlorothiazide
	Furosemide
	Spironolactone
Ergogenic Aids	Anabolic steroids
	Creatine
	Ephedra
Sympathomimetics	Amphetamines
	Cocaine
	Methylphenidate

splanchnic vasoconstriction, conspires to produce a decrease in cerebral blood flow. This results in the major CNS dysfunction characteristic of heatstroke.

Clinical Features

The onset of heatstroke is sudden, and the patient's level of consciousness is altered. Prodromal symptoms lasting minutes to hours occur in approximately 20% of cases. These are non-specific and may include weakness, dizziness, nausea, vomiting, anorexia, frontal headache, confusion, drowsiness, disorientation, muscle twitching, ataxia and signs of cerebellar dysfunction, along with possible psychiatric symptoms, ranging from anxiety and irritability to psychosis. These prodromal symptoms are reminiscent of the description of heat exhaustion. Heat exhaustion, particularly the water depletion variety, can progress to heatstroke if untreated.

The usual manifestations of heatstroke include hyperpyrexia above 40.5°C (105°F), profound CNS dysfunction, and hot skin (Box 129.5). Persistent sweating can be observed in patients with rectal temperatures of 41.5°C to 42.4°C (106.7°F to 108.3°F). Importantly, the cessation of sweating is not the cause of heatstroke, and continued sweating does not preclude the diagnosis.

Although in heatstroke the core temperature is elevated above 40.5°C (105°F), significant cooling may occur in the out-of-hospital setting, and the first temperature obtained in the emergency department (ED) may not represent the original maximum core temperature.

Classic heatstroke versus exertional heatstroke. The two forms of heatstroke, classic (epidemic) heatstroke (CHS) and exertional heatstroke (EHS), may have significantly different presentations and manifestations (Table 129.1).

CHS occurs during periods of sustained high ambient temperatures and humidity, such as during summer heat waves. Victims are often fixed income older adults who live in underventilated dwellings without air conditioning. Debilitated patients who have limited access to oral fluids may develop heat exhaustion due to water depletion, which progresses to heatstroke if untreated. Victims of CHS commonly suffer from chronic diseases, substance abuse, or psychiatric conditions which predispose to heat illness. Such patients are often prescribed medications (diuretics, antihypertensives, neuroleptics, anticholinergics) that impair the ability to tolerate heat stress (Table 129.2). Sweating ceases in most CHS patients. The central venous pressure (CVP) is usually elevated. The combination of elevated CVP with right-sided cardiac dilation suggests high output cardiac failure. These changes are expected because skin blood vessels dilate to dissipate heat; however, this low peripheral vascular resistance can persist in patients after reduction of body temperature to nearly normal. Pulmonary edema may also be present. Factors such as advanced age, hypotension, altered coagulation status, lactic acidosis, and the necessity for endotracheal intubation on arrival at the ED predict a poor outcome, despite successful cooling measures.

In contrast, patients with EHS are usually young and healthy individuals whose heat-dispelling mechanisms are overwhelmed by endogenous heat production. Athletes and military recruits are typical victims. Rhabdomyolysis and acute renal failure, rarely seen in patients with CHS, are common in patients with EHS. Sweating is present in 50% of cases of EHS. Hypoglycemia may occur as the result of increased glucose metabolism and hepatic damage, resulting in impaired gluconeogenesis. Coagulopathy is common. Hyponatremia

with serum sodium levels of less than 130 mmol/L has been detected in summer hikers in the Grand Canyon; many were found to have neurologic symptoms or seizures.

Patients with heatstroke usually have hyperdynamic cardiovascular systems with low peripheral vascular resistance, tachycardia (up to 180 beats/min), and an elevated cardiac index. Elevation of cardiac troponin is not uncommon with CHS; however, it is rarer in EHS. Respiratory alkalosis is a physiologic response to active or passive heating and may be severe enough to produce tetany. Although most patients with CHS have respiratory alkalosis, those with EHS usually have a relatively pure lactic acidosis. Lactic acidosis is associated with a poor prognosis in cases of CHS but not necessarily with EHS.

Signs of profound CNS dysfunction dominate the early course of CHS and EHS. Delirium or coma is characteristic, but virtually any neurologic abnormality, including bizarre behavior, opisthotonos, hallucinations, decerebrate rigidity, oculogyric crisis, and cerebellar dysfunction, can be seen. Convulsions occur in up to 75% of patients and can be precipitated by therapeutic cooling maneuvers. Profound muscle rigidity with tonic contractions, coarse tremor, and dystonic movements can mimic seizures. Pupils may be fixed and dilated, and the electroencephalogram may be isoelectric. All of these changes are potentially reversible with rapid intervention, although permanent damage, including cerebellar deficits, hemiplegia, dementia, and personality changes, may still occur in severe cases.[6,7]

Both CHS and EHS cause the hemoglobin-oxygen dissociation curve to shift to the right. An increase in the temperature denatures the bond between oxygen and hemoglobin, decreasing the concentration of oxyhemoglobin. Aberrations in coagulation are common in patients with severe heatstroke, and their presence is a poor prognostic sign.[8] Abnormal hemostasis is manifested clinically by purpura, conjunctival hemorrhage, melena, bloody diarrhea, hemoptysis, hematuria, myocardial bleeding, or hemorrhage into the CNS. Pancreatitis is described, with elevated serum amylase and lipase levels. Diarrhea, probably caused by intense splanchnic vasoconstriction, is commonly seen. Cooling aggravates the diarrhea, creating an unpleasant treatment dilemma.

Differential Diagnoses

Heatstroke occurs when the thermoregulatory responses are overwhelmed and fail. If the patient is evaluated as this is occurring, differentiation between heat exhaustion and heatstroke is difficult. If heatstroke cannot be excluded, efforts to cool the patient should begin immediately. Only after the initial assessment and cooling are initiated is the differential diagnosis relevant. When a history of collapse under conditions of heat stress is present, rapid improvement in mental status and blood pressure with cooling essentially eliminates alternative diagnoses. Consider other causes of fever and coma such as infectious causes if the temperature does not respond, and the patient does not recover neurologically (Box 129.6).

Meningitis and encephalitis. These can masquerade as heatstroke. In patients with heatstroke, the spinal fluid should be clear, with occasional lymphocytic pleocytosis and elevated protein levels. Cerebral falciparum malaria, which has a clinical picture of high fever and encephalitis, is seen in tropical areas where heat illness can also occur.

Thyroid storm. In patients with thyroid storm, the clinical symptoms resemble those of heatstroke. It should be suspected if the thyroid gland is enlarged or nodular, but a normal thyroid gland does not exclude the diagnosis. Thyroid function test results are elevated, but these may not be available on an emergency basis. Fortunately, thyroid storm is rare, and some critical aspects of treatment, such as rapid cooling, coincide with those for heatstroke.

BOX 129.6 Differential Diagnoses of Heatstroke

- Central nervous system hemorrhage
- Toxins, drugs
- Seizures
- Malignant hyperthermia
- Exercise-induced hyponatremia
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Thyroid storm
- High fever, sepsis
- Encephalitis, meningitis

Drug-induced heat illness. This is an important consideration, particularly anticholinergic poisoning. Differentiation may be difficult because heatstroke and anticholinergic poisoning cause hyperpyrexia, hot and dry skin, tachycardia, and abnormal mental status. Constricted pupils are present in many heatstroke patients. Mydriasis should be present in patients with anticholinergic poisoning, and its absence argues strongly against this diagnosis. Typhoid fever, typhus, delirium tremens, and hypothalamic hemorrhage all produce a symptom complex similar to that of heatstroke.

Drug overdose of sympathomimetics or stimulants, such as amphetamines, cocaine, and phencyclidine, can cause fatal hyperpyrexia. A high ambient temperature is associated with a significant increase in mortality from cocaine overdose. Many younger patients who die of hyperthermia test positive for cocaine. Heatstroke can occur with delirium resulting from ethanol withdrawal. Aspirin and clopidogrel attenuate the skin vasodilatory response and shifts the onset of peripheral thermoeffector mechanisms toward a higher body temperature during exercise heat stress. Heatstroke occurs in well-trained military soldiers and athletes who ingest dietary supplements containing ephedra or the ergogenic aid creatine. Some antipsychotics also cause suppression of thirst recognition. Individuals with a history of heatstroke, with or without an inherent aberration that predisposed them to the initial episode, are at increased risk for a recurrence.

Exercised associated hyponatremia. Symptoms of hyponatremia, especially exercised associated hyponatremia, can be mistaken for heat exhaustion or heat stroke. Although not a true heat related illness, it may be difficult to differentiate from exertional heat illnesses due to overlapping symptoms of collapse, dizziness, weakness, and in severe cases, mental status changes. However, severe hyperthermia (40.5°C) should not be present.[9]

Neuroleptic malignant syndrome. This disorder is induced by antipsychotic medications and is characterized by muscle rigidity, severe dyskinesia or akinesia, hyperthermia, tachycardia, dyspnea, dysphagia, and urinary incontinence. Although the so-called "lead pipe rigidity" and hyperthermia are reminiscent of malignant hyperthermia, the putative mechanism is different. Dopamine receptor blockade in the corpus striatum caused by butyrophenones (e.g., haloperidol) and similar agents produces severe muscle spasticity and dystonia, leading to the overproduction of heat in patients with NMS (see Chapter 150).

Serotonin syndrome. This can also mimic heatstroke because of the elevated body temperature tremors, clonus, and CNS alterations that occur. Serotonin syndrome is classically a triad of mental status

changes, autonomic hyperactivity, and neuromuscular abnormalities (e.g., clonus) secondary to increased CNS serotonergic activity. A history of recent exposure to an illicit drug or interaction with a therapeutic medication is an important clue.

Diagnostic Testing

Most standard measurements of body temperature vary significantly from the actual core temperature. Oral thermometry is affected by mouth breathing and is a poor approximation of the body's core. Rectal thermometry is less variable but responds to changes in core temperature slowly. Thermistors that are inserted 15 cm into the rectum, and not within stool, offer continuous monitoring of temperature and have less variability. Although rectal measurements are slower to respond to changes in core temperature than tympanic temperature readings, rectal measurements are not biased by head skin temperature. An esophageal thermistor positioned adjacent to the heart is another option. Do not use alternative methods such as oral, aural canal, tympanic, or skin to measure body temperature in patients with heatstroke.

The hematologic evaluation should include arterial blood gas determination, complete blood cell and platelet counts, liver transaminases, electrolyte values (including calcium), glucose, blood urea nitrogen, and serum creatinine levels. Hypoglycemia with a serum glucose level less than 65 mg/dL is often found in cases of EHS. With the risk of acute rhabdomyolysis, serum creatine kinase and myoglobin levels should be measured, and urinalysis performed. Severe heatstroke can induce disseminated intravascular coagulation (DIC). Measure prothrombin and partial thromboplastin times, international normalized ratio, and fibrin degradation products. Obtain serum cardiac troponin levels. Metabolic acidosis is common, especially in patients with EHS. Serum lactate levels are usually elevated and may persist or even worsen with improved extremity perfusion.

Acute renal damage is common. The initial urine specimen, usually obtained by catheterization, is a scant, brownish, turbid fluid resembling machine oil. Microscopic examination reveals proteinuria, with abundant granular casts and red blood cells. Acute oliguric renal failure complicates 25% to 30% of EHS cases and 5% of CHS cases. The glomerular filtration rate, renal plasma flow, urine flow, and sodium excretion diminish markedly during exercise. Heavy physical exertion in hot climates produces acidic and maximally concentrated urine, which can result in acute oliguric renal failure in combination with hypotension and myoglobinuria.

Because heatstroke patients are prone to liver failure, aspartate transaminase (AST), alanine transaminase (ALT), lactate dehydrogenase (LDH), and liver other enzyme levels should be monitored. Elevation typically occurs within 24 hours. Hepatic transaminase level elevations may be diagnostically helpful. In most febrile states that include altered mental status or coma, these enzyme levels will be normal or minimally elevated, although they are usually dramatically elevated early in the course of heatstroke. Hepatic damage is consistently featured in heatstroke. Hepatic injury is evidenced by markedly elevated levels of hepatic aminotransferases (serum AST and ALT). Elevation can be into the tens of thousands. Early experimental models have shown that high-mobility group box 1 (HMGB1) as a mediator of systemic inflammation is elevated in heatstroke, and its inhibition may be liver-protective. Jaundice typically appears 24 to 72 hours after the onset of severe heatstroke and gradually precedes if the victim survives. Survivors generally have no permanent impairment of liver function.

Management

Cooling. Immediate cooling is the cornerstone of treatment. If heatstroke cannot be excluded, begin cooling immediately. In EHS, it is usually best to follow the "cool first, transport second" guideline.[10,11]

BOX 129.7 Cooling Modalities to Lower Body Temperature in Heatstroke

Preferred

Evaporative cooling with large circulating fans and skin wetting
Ice water immersion

Adjuncts

Ice packs to axillae and groin
Cooling blanket
Peritoneal lavage (unproven efficacy in humans)
Rectal lavage
Gastric lavage
Cardiopulmonary bypass

Cooling should not be delayed in order to remove all clothing; this can be done simultaneously with cooling efforts.[12] Patients who present to the hospital with heatstroke have high mortality rates ranging from 20% to 65%, and mortality increases significantly when cooling is delayed. Insert a rectal thermistor probe as soon as possible and monitor the patient's temperature continuously.

Immersion in ice water results in a rapid reduction of core temperature to below 39°C within 10 to 40 minutes. Vigorous skin massage to maintain cutaneous circulation has been advocated, but there is no evidence that this is clinically efficacious. Ice water immersion presents many logistical challenges and may hamper resuscitative efforts especially in the ED. The lack of adequate space or drainage, the need for monitoring, rapid facilitation of patient entry and exit from the immersion tank create unique challenges. Environmental safety concerns surrounding management of spilled ice and water in proximity to electrical equipment is an additional concern. For EHS, it is most beneficial when it is preplanned and available for mass participation events during the warm season such as in medical tents in close proximity to the participants.[13] The military has recognized the difficulties with ice water immersion in remote military exercises and have adapted to ice water sheets draped over the patient. It can be initiated at the scene using skin lavage with ice water slurry and chilled intravenous saline.[14]

Evaporative cooling is also recommended because it is effective, easy to perform, noninvasive, and less likely to interfere with other patient care activities than other cooling techniques. The patient is stripped of all clothing, and tepid tap water is sprayed while fans blow air continuously over the body, causing evaporative cooling. One reported method of evaporative cooling uses a body cooling unit on which the patient lies suspended on a net surface while being sprayed with atomized 15°C (59°F) water from above and below. Air warmed to 45°C to 48°C (113°F to 118.4°F) is blown over the skin surface at a rate of 3 m/min. This approach maximizes evaporative and convective cooling by maintaining cutaneous vasodilation and avoiding heat generation caused by shivering. Vasoconstriction from ice water immersion may be beneficial to hypotensive patients and may be better than evaporative cooling for victims in shock who have poor peripheral circulation. Discontinue cooling measures when the patient's body temperature reaches 39°C (102.2°F) to avoid "hypothermic overshoot."[15] Continuous monitoring is necessary to maintain the core temperature at 37°C to 38°C (98.6°F to 100.4°F).

Cooling modalities other than evaporation and immersion are considered adjunctive treatments (Box 129.7).[16] Application of ice packs to high heat transfer areas (e.g., neck, groin, axillae) is commonly used. Cooling blankets may be a useful adjunct but will not produce rapid cooling if used exclusively. Cold irrigant gastric or rectal lavage will not provide significant heat exchange if used as the primary cooling

modality. Antipyretics have no role in the treatment of heat-related illness. The clinical efficacy of dantrolene has not been established in the setting of heat stroke.

Resuscitation. Mortality correlates with the elevated temperature duration and number of dysfunctional organ systems, with an increased risk of death if patients present with anuria, coma, or cardiovascular failure. Aspiration and seizures are common in patients with heatstroke, and airway control is indicated. Hypoxemia may occur because of aspiration, pneumonitis and pulmonary infarction, hemorrhage, or edema. Metabolic demands are high, and normal pulmonary ventilation may be inadequate in this setting.

Crystalloid fluid resuscitation is essential. Circulatory fluid requirements are modest in some cases, averaging 1200 mL of isotonic crystalloid solution in the first 4 hours. Pulmonary edema occurs in patients with heatstroke and can be exacerbated by overzealous fluid administration. The use of a CVP catheter to monitor fluid resuscitation may be deceptive. Most patients have a hyperdynamic circulation with a high cardiac index, low peripheral vascular resistance, and elevated CVP as a result of high output cardiac failure. These patients may require only modest IV fluids because cooling produces vasoconstriction and increases blood pressure. Hypotension is common in patients with heatstroke and is usually caused by peripheral vasodilation resulting in high-output cardiac failure in addition to dehydration. Blood pressure usually rises with cooling. If this does not occur, or if the invasively monitored patient has a low CVP, a fluid challenge of 250 to 500 mL of isotonic intravenous fluid should be given rapidly while blood pressure, pulse, and urine output are monitored. Fluid replacement is continued until the blood pressure reaches 90/60 mm Hg or the CVP exceeds 12 mL H_2O. On occasion, patients exhibit hypodynamic responses with a low cardiac index, elevated CVP, and hypotension. These patients may be cyanotic, whereas patients with hyperdynamic circulation are initially pink. This clinical observation can be helpful in identifying patients who may respond to catecholamines.

A variety of tachyarrhythmias commonly occur during heatstroke. These usually resolve with cooling, and electrical cardioversion should be avoided until the myocardium is adequately cooled. The use of α-adrenergic agents such as norepinephrine is not recommended because they promote vasoconstriction without improving cardiac output or perfusion, decrease cutaneous heat exchange, and may exacerbate ischemic renal and hepatic damage. Atropine and other anticholinergic drugs that inhibit sweating should be avoided.

The pathophysiologic processes of heatstroke and fever differ, so antipyretics are not indicated and may be harmful. Salicylates, particularly in large doses, may worsen hyperthermia by uncoupling oxidative phosphorylation and aggravating coagulopathies. Large doses of acetaminophen can result in further hepatic damage.

If rhabdomyolysis is present, maintenance of urinary output of at least 2 mL/kg/h is recommended. Consider urinary alkalinization (higher than a pH of 6.5) early in patients with acidemia, dehydration, or underlying renal disease. After volume repletion, administration of mannitol may be considered to increase intravascular volume and increase the glomerular filtration rate. Mannitol, however, should not be used in an oliguric patient. Persistent anuria, uremia, or hyperkalemia is an indication for consideration of hemodialysis.

Cooling modalities that drastically lower skin temperature may induce violent shivering; this increases metabolic heat production and may impede cooling. Intravenous benzodiazepines are the treatment of choice for shivering. The administration of neuroleptics, like chlorpromazine, should be avoided. These agents have anticholinergic properties that can interfere with sweating and cause hypotension or precipitate seizures. Many patients are extremely agitated during the initial cooling period. Short-acting benzodiazepines can be used for sedation and to control seizures. Barbiturates are less desirable as their metabolism is altered by hepatic dysfunction and they may exacerbate hypotension.

Coagulopathies can occur during the first day of illness but are more common on the second and third days. Initial treatment after cooling should include replacement therapy with fresh- frozen plasma and platelets while monitoring for laboratory signs of DIC (hypofibrinogenemia, elevated fibrin split products, prolonged prothrombin time, and thrombocytopenia). The bleeding diathesis seen in patients with heatstroke may be the result of fibrinolysis. Although α-aminocaproic acid can impede fibrinolysis, administration of this compound is associated with rhabdomyolysis, and its use is not recommended.

Disposition

Admission to an intensive care setting may be necessary. Heat stroke victims can have long term sequela from heat stroke that may not be readily apparent in the initial stages. Follow-up after hospitalization is needed. Patients with more complex end-organ damage (e.g., renal failure requiring dialysis) will require transfer to a center with more comprehensive tertiary care capabilities.

CHAPTER 129: QUESTIONS AND ANSWERS

1. An 18-year-old female marathon runner presents to the medical aid station during a hot summer race. She is extremely irritable and diaphoretic. She is complaining of generalized weakness, dizziness, nausea, and headache. The physical examination reveals an oral temperature of 40.5°C (105°F), heart rate of 120 beats/min, muscle twitching, and ataxia. What is the most appropriate management?

a. Assess her volume status and immediately start normal saline to replete volume loss before transfer to a hospital.
b. Encourage her to drink cold water to replace her free water deficit rapidly.
c. Immediately remove her from the hot environment and begin cooling before transfer to a hospital.
d. Prescribe immediate rest, after which she may be allowed to finish the race.

Answer: c. The onset of heatstroke is sudden. Prodromal symptoms lasting minutes to hours can occur that are nonspecific and similar to those of heat exhaustion. Signs and symptoms may include weakness, dizziness, nausea, frontal headaches, confusion, muscle twitching, ataxia and signs of cerebellar dysfunction, and psychiatric symptoms, ranging from anxiety and irritability to psychosis. Heat exhaustion can progress to heatstroke if it is untreated. If the patient is evaluated as this is occurring, differentiation between heat exhaustion and heatstroke is difficult. If heatstroke cannot be excluded, begin cooling the patient immediately.

Whereas rest is part of the treatment for heat exhaustion, it is not the only treatment. She must be removed from the hot environment, not be allowed to finish the race, and assessed for her volume status. Normal saline is used to replete volume if the patient is orthostatic; free water deficits are replaced slowly to avoid cerebral edema.

2. Which of the following statements regarding heat exhaustion is true?

a. It causes body temperatures that often exceed 40.5°C (105°F).
b. It only exists in two discrete forms, either salt depletion or water depletion.
c. It is associated with systemic symptoms.
d. It is characterized by hyponatremia and hyperchloremia.
e. It occurs when muscles are fatigued by heavy work.

Answer: c. Heat exhaustion is a clinical syndrome. Whereas there are typically two types of heat exhaustion, water depletion and salt depletion, pure forms of either type are rare. Most cases of heat exhaustion involve mixed salt and water depletion. In salt depletion heat exhaustion, the syndrome is characterized by hyponatremia, hypochloremia, and low urinary sodium and chloride concentrations. The symptoms and signs associated are variable and nonspecific but usually systemic, such as weakness, fatigue, frontal headache, vertigo, nausea, and vomiting. The body temperature usually remains nearly normal.

3. Despite cooling measures, poor outcomes are seen in heatstroke patients with which of the following?

a. Altered coagulation status
b. History of schizophrenia
c. Need for supplemental oxygen
d. Presentation with acute renal failure
e. Presentation with acute rhabdomyolysis

Answer: a. Factors such as advanced age, hypotension, altered coagulation status, and the necessity for endotracheal intubation on arrival at the emergency department predict a poor outcome, despite successful cooling measures.

CHAPTER 129: QUESTIONS AND ANSWERS—cont'd.

4. The usual characteristics of classic heatstroke include which of the following?
   - **a.** Diaphoresis
   - **b.** Disseminated intravascular coagulation
   - **c.** Hypoglycemia
   - **d.** Marked lactic acidosis
   - **e.** Usual occurrence during heat waves

Answer: e. Usual characteristics of classic heatstroke include predisposing factors or medication, older population, sedentary lifestyle, anhidrosis, normoglycemia, mild coagulopathy, mild elevation in creatine kinase level, oliguria, mild acidosis, and occurrence during heat waves. Diaphoresis, hypoglycemia, disseminated intravascular coagulation, and marked lactic acidosis are characteristics of exertional heatstroke.

5. Which of the following is associated with heat cramps?
   - **a.** Excessive salt intake
   - **b.** Drinking copious amounts of hypertonic fluids
   - **c.** Carpopedal spasms with distal extremity paresthesias
   - **d.** Hyponatremia and hypochloremia
   - **e.** Rhabdomyolysis

Answer: d. Heat cramps are brief, intermittent, and often severe muscle cramps occurring typically in muscles that are fatigued by heavy work. Heat cramps appear to be related to a salt deficiency. Heat cramps are occasionally confused with hyperventilation tetany. Hyperventilation tetany can be distinguished by the presence of carpopedal spasm and paresthesias in the distal extremities and perioral area. Heat cramps accompanied by systemic symptoms may be part of salt depletion heat exhaustion. Heat cramp victims exhibit hyponatremia and hypochloremia, so serum electrolyte levels should be measured. Rhabdomyolysis or resultant renal damage is not present with isolated heat cramps.

Electrical and Lightning Injuries

Paul Chen and Alice Kidder Bukhman

KEY CONCEPTS

- Electrical current follows the path of least resistance, which is often along neurovascular bundles. Deep tissue injuries and organ damage are often more extensive than indicated by examination of the overlying skin.
- Testing is not indicated for victims of low-voltage electrical injuries who are asymptomatic or have minimal local symptoms and physical evidence of burn injury. These patients may be discharged home after emergency department (ED) evaluation.
- Patients exposed to high-voltage sources or lightning strikes who present with syncope, altered mentation, focal neurologic abnormality, significant burns, entry and exit wounds, or persistent symptoms should have testing including electrocardiography, complete blood count, basic chemistry panel, myoglobin and troponin level determination, and urinalysis. Additional testing is directed at suspected areas of injuries.
- Patients with electrocardiographic signs of cardiac injury or dysrhythmias, or with evidence of significant local injury, should be monitored for 12 to 24 hours in the ED, observation unit, or inpatient setting.
- The enormous current of a lightning strike may cause critical injury or death, or the current may be directed superficially over the patient to the ground, resulting in no injury and minor burns.
- Electrocardiography is indicated for all patients evaluated for lightning strike. Additional testing should be based on specific signs and symptoms.
- Lightning strike patients who present without symptoms or signs of injury, or with only minor first-degree burns, and with a normal ECG can be discharged home from the ED after evaluation.
- Lightning strike can cause fixed, dilated pupils in the absence of irreversible brain injury.

FOUNDATIONS

Background and Importance

Electrical injuries are uncommon but can cause significant morbidity and mortality. Toddlers and younger children experience low-voltage injuries in the household as the result of contact with electric sockets and cords. Adolescents and young adults more frequently experience high-voltage injury from contact with electric lines outside of houses. Another peak occurs in the third to fourth decade of life, almost exclusively in men with occupational injuries due to high-voltage encounters with power lines and, to a lesser extent, from electric tools. Worldwide, electrical injuries comprise less than 5% of admissions to burn units, but in developing countries this proportion is much higher at 25%.[1] Forensic reports of deaths caused by electrical injury show that the overwhelming majority of victims are men and most deaths are accidental, with a minority attributed to suicide or homicide.[2]

Anatomy, Physiology, and Pathophysiology

Electrical Injury

Current and Voltage. *Joule's law*, which describes the amount of thermal energy applied to tissues from electricity, is described by the formula

$$P = I^2RT$$

where P is thermal energy, I the current, R the resistance, and T is the duration (time) that the electricity is applied. Current is the flow of electrons down an electrical gradient and is measured in units of amperage. Current is the most important factor in determining the degree of energy transmitted, but it is rarely known in a given exposure. Instead, voltage is used as a proxy for current. According to *Ohm's law*, current (I) is directly proportional to the voltage (V) of the source and inversely proportional to the resistance (R) of the material through which it flows (I = V/R).

Injuries are conventionally classified as being caused by high- or low-voltage sources, with 1000 V as the dividing line. In North America, household sources are low voltage, typically 120 or 240 V. High-voltage injuries, such as those caused by electrical power lines or occupational accidents, are characterized by partial to full-thickness skin burns, deep tissue destruction, and potential cardiac or respiratory arrest. High-voltage injuries are associated with higher rates of death, and more associated traumatic injuries, such as extremity fractures, blunt head injuries, and spinal cord injuries.[1,2] Low-voltage exposure causes less surface damage, but may be equally lethal, particularly in cases in which skin resistance is low, such as when immersed or exposed to water.

Current Type. Electrical sources create current that flows in one direction (*direct current, DC*) or alternates direction cyclically at varying frequencies (*alternating current, AC*). The few systems in the United States that use DC include batteries, automobile electronics, and railroad tracks. Exposure to DC most frequently causes a single, strong, muscular contraction. This may throw the victim back from the source in a way that limits duration of exposure but can result in other traumatic injuries. AC is more commonly used (e.g., household currents) because it conveniently allows for an increase or decrease of power at transformers. It is more dangerous than DC of similar voltage because amperage above the so-called "let-go" current will cause muscular tetanic contractions. Because the flexor muscles of the upper extremities are stronger than extensor muscles, these contractions pull the victim closer to the source resulting in prolonged exposure. Box 130.1 shows the physical effects of different amperage levels at a common 60-Hz AC exposure.

Capacitors store electric charge in circuits, and discharge from these devices may result in sudden bursts of very large amounts of electrical

BOX 130.1 Physical Effects of Different Amperage Levels[a]

1 mA—barely perceptible
6–9 mA—usual range of let-go current
16 mA—maximum current that an average person can grasp and let go
20 mA—paralysis of respiratory muscles
100 mA—ventricular fibrillation threshold
2 A—cardiac standstill and internal organ damage

energy. Injury from a capacitor may occur even when the electrical device is not energized or plugged in into an electrical source.

Resistance of Tissue Affected. Resistance is the degree to which a substance resists the flow of current; when resistance goes down, current increases. Resistance varies among body tissues. Neurovascular tissues are good conductors of electricity, whereas skin, tendons, fat, and bone are relatively poor conductors (Box 130.2). Current that is initially unable to pass through skin will create thermal energy and cause significant burns. As the skin blisters and deteriorates, its resistance decreases. Once current is through the skin, it can pass easily along lower resistance structures, causing deep tissue injury which may not be immediately evident. As a result, the degree of burns seen on the surface of the skin typically underestimates the damage occurring below the surface. As current strength increases, the relative resistance of tissues ceases to determine the pathway of current, and the entire body functions as a conductor. Current may also jump across skin surfaces in a behavior termed *arcing*, resulting in prominent burns across flexor surfaces.

Within a given tissue, resistance differs based on the fluid and electrolyte content of cells. Dry skin offers the largest resistance, up to 100,000 ohm (Ω) in thick, calloused skin, but dermal resistance decreases to as little as 1000 Ω when wet. This explains why electrical injuries are generally worse in the setting of water.

Path Taken by Current Through the Body. The pathway followed by electrical current determines morbidity and mortality. The entrance and exit sites of the electrical current typically demonstrate greater evidence of skin damage, with full-thickness burns commonly encountered. These sites are properly referred to as the *source and ground contact points*. A patient may have one or multiple source and ground contact points. The most common points of source contact are the hands, wrists, and arms, but children also present with burns from oral contact with electric cords or sockets. The most common ground contact points are the heels of the feet.

Electrical current passing through a limb causes greater local tissue damage than current passing through the trunk because the smaller cross-sectional area limits the ability to dissipate heat. However, current passing through the trunk results in greater mortality due to the involvement of more vital cardiothoracic organs. Transthoracic pathways (arm to arm) are more likely to generate dysrhythmias and have higher mortality rates than vertical currents (leg to arm) or straddle pathways (leg to leg).

Duration of Contact. The degree of tissue damage is directly proportional to the duration of exposure for all voltage levels. Exposure times greater than the length of one cardiac cycle tend to generate dysrhythmias, likely in a manner analogous to the R-on-T phenomenon.

Lightning Injury

Although the same basic scientific principles of electricity apply to lightning, there are several major differences. Lightning strikes involve hundreds of millions of volts, significantly more than those from electrical sources. In contrast, the duration of contact is drastically shorter, averaging 30 microseconds. As a result, current flow is altered, with most of the energy passing over rather than through a victim (termed the "flashover effect"). This reduction in penetration explains why lightning strikes paradoxically result in less destruction to tissues compared with lower-voltage electrical injuries.

Lightning takes various forms, described as streaked, forked, ribbon, sheet, or beaded. The most unusual form is ball lightning, which appears as a globe, rolls along structures, and may even pass through open doors or windows. Strikes occur from cloud to cloud, cloud to ground, and less commonly, ground to cloud.

Lightning may strike a person directly or indirectly. A person's chances of being struck are increased by wearing or carrying metal objects (such as golf clubs or umbrellas) or other conductors. Current from lightning may reach the body indirectly by traveling through a tree or other object (contact voltage), through the ground or even through the air from a struck object (side flash, or splash injury). Side flashes may travel as far as 30 meters.

The risk of injury from a ground strike is increased when one contact point on the victim (e.g., the right foot) is closer to the strike than a second contact point (e.g., the left foot), thus creating a potential difference. This is referred to as the "stride voltage" and is likely responsible for cattle deaths in a pasture after a thunderstorm. Hence, when out in the open during a storm, risk of a lightning strike can be reduced by placing an insulating material, such as a raincoat, between the ground and the body and assuming the lightning position, a squatting configuration with the feet together, or by curling up in a ball on the ground to reduce the number of contact points. Box 130.3 lists safety tips for avoiding lightning strikes.

Injury occurs from the force of a strike, blunt trauma when the victim is thrown, the superheating of metallic objects in contact with the patient, barotrauma, or penetrating trauma from shrapnel.

Conducted Energy Weapons

Conducted energy weapons (CEW), commonly known as Tasers or stun guns, are now widely used in law enforcement. These weapons deliver brief bursts of high-voltage, low-amperage direct current. Although CEWs have been associated with several high-profile police-involved fatalities, a clear causal link between their use and a death has not been established.

The most commonly known CEWs are the Taser (Axon Enterprise, Inc.) (Fig. 130.1). These weapons consist of a hand-held unit with two barbs (Fig. 130.2) with connecting cables that are deployed by the user at distances of up to 25 feet. The units typically lodge in the skin or

BOX 130.3 Tips to Avoid Lightning Strike

- Seek shelter inside an enclosed building or metal-topped automobile.
- Avoid large flat, open areas or hilltops.
- Avoid contact with metal objects and remove metal objects, such as jewelry or hairpins.
- Avoid trees, boats, and open water.
- If caught on open ground, curl up on your side with hands and feet close together to reduce contact points, or squat with feet together. If possible, place a rubber raincoat under your body or feet to reduce ground current effects.
- If in a forest, seek shelter under a thick growth of shorter trees.
- If indoors, avoid the use of wired phones and contact with plumbing or electrical appliances.

Fig. 130.1 Commonly used conducted energy weapon—Taser X26.

Fig. 130.2 Taser barbs that deliver electrical burst, causing neuromuscular incapacitation.

clothing and then automatically deliver a 5-second burst of energy. Further energy bursts can be delivered at the user's discretion. When these barbs lodge in the person at a distance from one another, they cause an energy arc that results in general muscle contraction and neuromuscular incapacitation (NMI). Newer devices have been developed to create a larger barb spread at close range to maximize the arc distance and more readily induce NMI.

BOX 130.4 Types of Burns Associated With Electrical Injury

Entrance and exit site burns
Arc burns, kissing burns
Thermal burns
Flash burns

CEWs may also include a touch-stun mode, in which direct contact of the weapon to the person is required to deliver an electrical energy pulse. In these cases, the barbs are not deployed, and the subject experiences localized pain but will not undergo NMI.

CLINICAL FEATURES

Electrical Injury

At the cellular level, current causes damage to cell membranes and alters membrane solubility, leading to electrolyte abnormalities and cellular edema. This process, termed *electroporation*, eventually leads to irreversible cell damage and death. At the tissue and organ levels, electrical current produces damage when electrical energy is converted to thermal energy. Electrical injury rarely causes immediate death, but when it does, it is often due to current-induced cardiac arrest (ventricular fibrillation or asystole), respiratory arrest due to respiratory muscle paralysis, or brainstem injury. Commonly reported delayed complications of electrical injuries include sepsis, acute renal failure, wound infections, and amputations.[3]

Lightning Injury

In contrast to electrical injury, lightning injuries involve very brief exposure to high-voltage energy. General effects are thus quite different than electrical injury, with deep muscle injury being much less common. Instead, lightning more commonly causes blunt traumatic injuries or cardiopulmonary arrest from transient stunning and disruption of the pacemaker cells and brainstem.

Skin

Electrical Injury. Most electrical injuries result in skin burns, which fall into one or more of four patterns (as described in Box 130.4). The relatively high resistance of skin in many cases leads to significant partial- or full-thickness burns at entrance and exit sites, most commonly seen over the upper extremities, particularly at the hand and wrist. The skull is another common source contact point. Visible burns may be insignificant in comparison to the damage that occurs beneath the surface and, as a result, are associated with significantly greater morbidity than simple thermal burns involving a similar surface area. Because of this, use of the Parkland formula or other fluid resuscitation equations tend to under-resuscitate these patients. Burns at entrance and exit sites will typically have a punctate appearance, with central depression and necrosis surrounded by a hyperemic border.

Arc burns, or so-called "kissing burns" (Fig. 130.3), occur when electricity jumps from skin surface to skin surface, typically across flexed areas of the body. Temperatures may reach 3500°C (6332°F) and cause severe damage. Arc burns are usually noted across the volar forearm and elbow and along the inner arm and axilla.

In cases in which clothing ignites and catches fire, patients also experience thermal burns. Flash burns are skin burns caused by brief, intense flashes of light, electrical current, or thermal radiation. Cutaneous burns across the chest and upper abdomen indicate a transthoracic current and portend a worse prognosis.

Fig. 130.3 Kissing burn. (Courtesy Dr. Mary Ann Cooper.)

Fig. 130.4 Lightning burn. (Courtesy Dr. Mary Ann Cooper.)

Lightning Injury. Roughly 90% of lightning strike victims suffer skin burns, but less than 5% are deep burns. Although the voltages involved in a strike are substantial, most of the voltage will pass over rather than through the body in what is called a flashover effect. Moreover, the duration of contact is so brief that significant damage does not usually occur. Skin resistance is typically lessened by rain or perspiration, contributing to the flashover effect, where current preferentially flows over the integument rather than through it (i.e., following the path of least resistance). The result is the arborescent or fernlike patterns of erythematous streaks (typically first-degree burns) that have been termed *Lichtenberg figures* (Fig. 130.4). Deeper burns may occur at the direct point of contact or wherever metal is involved (due to superheating), such as with a belt buckle or jewelry. Clothing may catch on fire, resulting in thermal burns. Unlike conventional high-voltage electrical exposures, exit wounds are generally not seen, and the overall effects are much less severe.

Cardiovascular

Electrical Injury. Cardiac or respiratory arrest is the most common cause of death immediately following electrical injury. High-voltage exposures are associated with higher rates of cardiac complications, although low-voltage exposures can also cause cardiac arrest.[2] Traditionally, it is believed that AC causes ventricular fibrillation and DC causes asystole. In reality, exposure to either type of circuit is associated with both dysrhythmias, especially at higher voltages. Respiratory arrest may occur as a result of tetanic paralysis of the thoracic respiratory muscles and diaphragm or as a result of damage to the brainstem respiratory centers. Prolonged apnea in these situations can lead to hypoxic cardiac arrest.

Most dysrhythmias are seen immediately following electrocution. These include life-threatening dysrhythmias, but more frequently involve sinus tachycardia or bradycardia, atrial fibrillation, and ectopic beats. A variety of electrocardiographic abnormalities may be present, including transient ST elevation or depression that does not correlate with myocardial ischemia or infarction. Injury to coronary arteries or directly to the myocardium may result in infarction, but this is rare. Nonspecific cardiac biomarker levels (e.g., creatine kinase) are frequently elevated in the period following electrical injury, but this is usually due to skeletal muscle injury and is only rarely related to cardiac damage. Dysrhythmias may also appear in a delayed fashion, with case reports of fatal dysrhythmias, although the limited available studies suggest the risk is very low.[4,5,6]

Lightning Injury. The most severe effects of lightning strike are cardiac and respiratory arrest. The massive surge is analogous to defibrillation and can result in asystole or nonperfusing ventricular rhythms, with the latter likely more common than previously thought.[7] The actual pacemaker cells are typically not permanently damaged. Thus, with recovery, the intrinsic pacemaker activity of the heart brings about a resumption of cardiac activity. However, a lightning strike can result in stunning of the respiratory center of the medulla and brainstem, causing central apnea. This respiratory arrest is thought to often last longer than the cardiac standstill itself, which may lead to hypoxic cardiac arrest. Research into the actual effects of lightning on humans is limited but it has been hypothesized that the strike leads to a state of suspended animation and cessation of metabolism in all cells, including the brain. This may explain reports of successful resuscitation and full recovery of lightning strike victims after being apneic and pulseless for up to 15 minutes and following resuscitations lasting up to 8 hours. This observation has led to the practice of treating the "apparent dead" first at the scene of a multiple-victim lightning strike because early resuscitative efforts may prevent death.

Lightning has also been linked to a variety of less ominous dysrhythmias, such as atrial fibrillation, most of which resolve with time. Lightning strikes can also cause QT prolongation which can persist for weeks after the incident.[7] A lightning strike in close proximity to a patient with an automatic implantable cardioverter defibrillator can cause firing of the device. The longer-term effect of a strike on the integrity of the device is not clear.[7]

A number of electrocardiographic changes, usually with gradual resolution, have been reported (Box 130.5). ST segment elevation and depression and T wave inversions suggestive of myocardial ischemia have been widely reported, and may be the result of cardiac contusion, hypoxia-induced infarction, transient coronary vasospasm or actual coronary thrombosis. Given this wide differential diagnosis, the role of immediate coronary interventions is not yet established.[7]

Head and Neck

Electrical Injury. Ocular involvement is common following exposure to electrical current, with cataracts being the most frequent manifestation. Other forms of injury include vitreous and anterior chamber hemorrhages, retinal detachment, macular lacerations, ocular foreign bodies, and corneal or conjunctival burns. Injury to structures of the ear is less common, but sensorineural deafness can be seen as a result of nerve damage. Patients frequently develop vertigo, which may be transient or persistent. Toddlers and young children sustain orofacial injuries after chewing or sucking on electrical cords or from lingual contact with sockets. Full-thickness burns may be sustained on the mucous membranes and lips, with destruction to the tongue and teeth as well. Injuries to the oral commissure produce cosmetic

BOX 130.5 Electrocardiographic Changes Seen with Lightning Strike

ST segment elevation
QT interval prolongation
Atrial fibrillation
Inverted or flattened T waves
Myocardial infarction pattern without cardiac sequelae

difficulties and, more significantly, delayed labial artery bleeding which typically occurs 2 to 3 days after injury when the resultant eschar separates from the wound.

Lightning Injury. The most common ocular event after lightning strike is the development of cataracts, occurring immediately or in a delayed fashion. Damage to almost every part of the eye has been described. Fixed and dilated or asymmetrical pupils due to autonomic dysfunction may accompany a strike, a finding that by itself should not obviate the need for resuscitative efforts.

The tympanic membranes of patients involved in lightning events are commonly ruptured due to the shock wave and blast effect produced by the rapid expansion of the air as lightning passes through it. Bleeding and cerebrospinal fluid leaks may accompany this injury. Other effects include hearing loss, tinnitus, vertigo, and nystagmus. Specific injuries include avulsion of the mastoid process, ossicle damage, rupture of the Meissner membrane, and strial degeneration.

Extremities

Electrical Injury. Neurovascular bundles have low resistance and are particularly prone to damage from electrical current. Muscle necrosis occurs primarily or is secondary to compromise of the blood supply. Vascular injury is most prominent at the intimal and medial layers. Involvement of the intima results in immediate coagulative necrosis and thrombosis. Injury to the media causes aneurysmal dilation, and occasionally artery rupture and hemorrhage, and may occur months after the injury. Decreases in tissue perfusion lead to edema and tissue death. Areas of infarction may be distributed sporadically throughout the injured region, with areas of surviving tissue adjacent to necrotic tissue.

Muscle that initially appears viable may deteriorate over days and weeks, especially in the periosteal regions. Rhabdomyolysis may occur from muscle breakdown and patients should be aggressively hydrated to prevent acute kidney injury (see "Management" section). Endothelial and smooth muscle function are depressed for many weeks following the initial injury, contributing to a hypercoagulable state that increases the risk of delayed deep venous thrombosis. The combination of tissue edema and perfusion defects makes compartment syndrome likely, necessitating emergent fasciotomy or possible amputation. Compartment syndrome and rhabdomyolysis are risk factors for late arterial rupture.[8] Cyanosis or pulselessness may be transient or may indicate permanent damage; in a similar fashion, limbs that appear initially well perfused may later necrose. Bony injury is common because bone is highly resistant to electrical current flow. This generates large amounts of heat resulting in periosteal burns and osteonecrosis. Fractures and dislocations often occur as a result of the patient being thrown or propelled (particularly with DC current) or from the strength of muscular contractions (AC current).

Nervous System

Electrical Injury. Electrical injury damages the central and peripheral nervous systems. The most common immediate central symptoms are altered mentation, seizure, or coma. Seizures may occur as an isolated event or as a chronic seizure disorder. Vascular injury may cause cerebral infarction, and secondary trauma may result in intracranial hemorrhage. Cerebral venous sinus thrombosis has been reported.

Patients may experience transient spastic paralysis with accompanying sensory deficits immediately following electrical injury. Delayed and chronic manifestations include ascending paralysis, transverse myelitis, and amyotrophic lateral sclerosis (ALS). Peripheral neuropathies are a common result, most often involving the median and ulnar nerves.

Unlike other complications, rates of neuropsychological sequelae are equal in low- and high-voltage injuries. Immediately after injury, sleep disturbances and anxiety are particularly common. Other short-term complications include depressed mood, flashbacks, dizziness, nightmares, and memory and concentration impairments. Longer-term neuropsychiatric sequelae include posttraumatic stress disorder and major depressive disorder.[9] A post–electrical and lighting injury syndrome has been described and features both prominent memory and executive function deficits as well as other miscellaneous features such as depression and social withdrawal.[10]

Lightning Injury. A wide variety of very serious neurologic effects follow lightning strike. Apnea, due to effects on the medullary respiratory center, may persist for several hours. Direct trauma may result in skull fractures, intracerebral and extracerebral hematomas and hemorrhages, cerebral edema, and elevated intracranial pressure. More common findings include transient loss of consciousness, amnesia of the event, and transient paresthesias and paralysis of the extremities. This later phenomenon, called *keraunoparalysis* is characterized as a flaccid paralysis, usually accompanied by marked vasomotor changes that result in extremities that appear cyanotic, mottled, and pulseless. The lower extremities are more commonly involved, and the typical prognosis is recovery within minutes to days.

Prolonged loss of consciousness may be related to trauma or hypoxia. "Miracle" recoveries have been documented, despite prolonged cardiac arrest and apnea. Conversely, death may occur rapidly from massive brain edema and herniation. Permanent peripheral nerve damage can occur. Other neurologic sequelae include seizures, cerebellar ataxia, Horner syndrome, cognitive dysfunction, facial nerve palsy, neuritis, and neuralgia.

Some psychiatric effects are predictable, usually anxiety and a logical fear of thunderstorms. Other negative effects are similar to those experienced with electrical injury, including memory loss and concentration deficits, prolonged depression, sleep disturbances, nightmares, nocturnal enuresis, and separation anxiety. Hysterical blindness, deafness, and muteness have been described.

Other Viscera

Electrical Injury. Extensive muscle damage may result in significant myoglobinuria, subsequent renal failure, and life-threatening hyperkalemia. These complications are more likely in patients who are hypotensive or volume-depleted. Stress ulcers are a common gastrointestinal complication. Uncommon but severe intra-abdominal injuries include a ruptured hollow viscus and necrosis of the pancreas or gallbladder. Pulmonary edema is rare. Although early fatalities are due to respiratory and cardiac arrest, delayed deaths occur from sepsis, pneumonia, and renal failure. For obstetric patients, the overall risk to the fetus is low, but a spontaneous abortion can occur. Secondary trauma may lead to placental abruption.

Lightning Injury. The lungs, gastrointestinal tract, and other internal organs may suffer injury from blunt trauma or a blast effect. Strikes to the face may produce damage to the tongue and oral structures, esophagus, and trachea. Various fractures, dislocations, and soft tissue

injuries occur. Myoglobinuria is relatively unusual due to the brief duration of contact.

Vasomotor changes may occur at the time of the strike and can last for variable periods. Mottling or cyanosis appears, and pulses may be absent. Although dramatic in appearance, these typically resolve without intervention. Vascular changes mimic those seen in compartment syndromes, but fasciotomy is generally not indicated. When pregnant women are struck by lightning, the effects on the fetus are not predictable therefore, depending on the dates of gestation, maternal-fetal monitoring is generally recommended.

Conducted Electrical Weapon. Patients who present after receiving a CEW barb discharge may have local injury to the skin and nearby superficial structures, such as vessels, nerves, and bones. Most barbs penetrate the chest or back, but barbs may also lodge in the face, eyes, or genitals. These patients may also sustain injuries from muscle contraction or falls due to NMI. Traumatic brain injury and spinal compression fractures in osteopenic patients as a result of CEW discharge have been described. However, the overall occurrence of injuries due to this mechanism is rare, occurring in less than 0.5% of CEW deployment subjects.[11] Patients who have received CEW touch-stun exposure may develop skin irritation or minor contact burns.

Current literature indicates that there is no evidence of cardiac ischemia, dysrhythmias, or structural cardiac damage to patients who have received CEW exposure of less than 15 seconds, and who are otherwise asymptomatic, awake, and alert. Most CEW exposures from law enforcement are less than 15 seconds, suggesting that the risk of cardiac complications is very low.[11]

DIFFERENTIAL DIAGNOSES

Electrical Injury

Most electrical injuries are self-evident, except in unwitnessed water-related exposures where there may be no skin burns. In such cases, patients may present with cardiac arrest, dysrhythmias, or altered mentation. Victims of known electrical injury who present with altered mentation may be suffering from electrical injury of the central nervous system, associated traumatic brain injury, or underlying metabolic disease.

Lightning Injury

In cases in which lightning strikes are not witnessed, these injuries should be suspected in patients presenting from the outdoors with altered mentation or cardiac arrest in the setting of a recent thunderstorm. Other clues include the presence of typical skin burn patterns, clothing that has been blasted off, singed or has melting of metal pieces such as zippers or grommets. Other suggestive findings are listed in Box 130.6. Differential diagnoses of altered mentation in lightning strike victims are the same as with other high-voltage injuries.

BOX 130.6 Findings Suggestive of a Lightning Strike

- Clothing wet from rain
- Tears or disintegration of clothing
- Multiple victims
- Typical arborescent pattern of erythema or superficial linear or punctate burns
- Tympanic membrane injury
- Cataracts, especially in a younger patient
- Magnetization of metallic objects on the body or clothing
- Electrocardiographic changes

DIAGNOSTIC TESTING

Electrical Injury

No evidence-based guidelines direct the ancillary testing of electrical injury victims. Testing is not required for victims of low-voltage electrical injuries who are asymptomatic or have minimal localized symptoms. Evaluation for underlying injury should be undertaken in patients who have been exposed to high-voltage sources. In addition, those victims who have lost consciousness or present with altered mentation or neurologic deficits, have entrance and exit wounds or more than superficial partial-thickness burns, cardiac dysrhythmias or other significant symptoms should be fully evaluated, regardless of the source voltage. Because the location and extent of injury cannot be predicted clinically, we recommend electrocardiography, a complete blood count, basic serum electrolytes, serum myoglobin and troponin, blood urea nitrogen, serum creatinine levels, and urine analysis, testing for myoglobinuria. Patients with suspected intra-abdominal injury from electrical current or associated trauma should have hepatic transaminases and pancreatic enzyme levels (lipase) measured and coagulation studies performed. Radiographs of injured extremities are indicated if there is significant pain, deformity, swelling or bony tenderness following trauma. Computed tomography or magnetic resonance imaging should be used when intracranial, spinal, intra-abdominal or pelvic injuries are clinically suspected. There is little evidence to guide further workup of patients with significant troponin elevations, but we recommend 12 to 24 hours of telemetry monitoring and an echocardiogram for those with a troponin rise thought to signify myocardial damage.[5] The utility of prolonged cardiac monitoring in patients with an electrical exposure is unclear, as most studies show delayed cardiac dysrhythmias are rare.[4] However, we recommend a period of observation for 12 to 24 hours in any patient who sustained a high-voltage electrocution as well for those who suffered loss of consciousness, or have a dysrhythmia or abnormal ECG on arrival to the ED.

Lightning Injury

The Wilderness Medical Society has recommended that an electrocardiogram (ECG) be obtained on lightning strike victims with high-risk indicators, such as suspected direct strike, loss of consciousness, focal neurologic complaint, chest pain or dyspnea, associated traumatic injuries, pregnancy, or burns of the cranium or legs or on more than 10% of the total body surface area. Cardiac markers are often elevated in victims of lightning strikes, but they do not correlate with myocardial injury and are not prognostic. Patients will often have been thrown or propelled by the force of the lightning and a detailed examination looking for signs of secondary trauma is indicated. Compared to electrical injuries, lightning strikes are much less likely to result in compartment syndrome or rhabdomyolysis and when these occur, it is often a result of a traumatic injury rather than from the strike itself. A thorough eye and ear exam should be performed because lightning current can affect the lens as well as the tympanic membranes, which can often burst due to the acoustic blast wave.

Patients without any obvious sequalae should still receive follow-up care, as a large percentage of lightning survivors will experience some neurocognitive sequelae. Regional burn centers are often equipped to further evaluate and refer these patients.

Conducted Electrical Weapon

In patients who are awake and alert, asymptomatic, and have had CEW exposure of less than 15 seconds, no specific diagnostic testing is required to evaluate for cardiac injury, electrolyte imbalance, renal abnormalities, or acid-base disturbances. Similarly, evidence has not shown any clinically significant rise in lactate or CK levels, and we do not recommend testing in this patient population. Additionally, routine

EKG, cardiac monitoring, or echocardiography are not recommended in this patient population. However, patients may have underlying conditions that precipitated the use of the CEW, including but not limited to altered mental status, intoxication, or psychiatric conditions, and they should undergo diagnostic testing as guided by their presentation and past medical history. Additionally, patients should be evaluated for secondary traumatic injury and undergo appropriate trauma evaluation.

MANAGEMENT

Electrical Injury

Low-voltage electrical injuries associated with minimal signs and symptoms generally require only local wound treatment and patient reassurance. The treatment of other patients is directed at the organ systems involved.

Patients who present in cardiopulmonary arrest should be resuscitated, regardless of cardiac rhythm, because favorable outcomes have been documented even with patients presenting in asystole. Patients with electrocardiographic signs of cardiac injury or dysrhythmias and patients with more than minimal local signs and symptoms should be monitored in the emergency department (ED), observation unit, or inpatient setting, depending on the extent and severity of associated injuries. Dysrhythmias are treated according to advanced cardiovascular life support (ACLS) guidelines. Hypotensive patients should be evaluated for possible blood loss from associated traumatic injuries. Hypotension may also be caused by third spacing of intravascular volume secondary to electrical injury of deep tissues, so fluid management is similar to that of crush injuries, often requiring more fluid than typically recommended by thermal burn wound protocols. Intravenous crystalloid fluids are given to maintain adequate urine output (over 100 mL/hr in adults and 1.5 to 2 mL/kg/hr in young children). Serum potassium levels should be closely monitored in patients with acute renal injury or myoglobinuria.

Although AC causes thrombotic injury to blood vessels, DC can result in transient vasospasm that results in extremities that appear cyanotic, mottled, and pulseless. This should be kept in mind when deciding when vascular surgical intervention is indicated. Skin and vascular findings are likely to resolve with supportive care only but, if significant thrombosis (immediate or delayed) develops, amputation may be required. The presence of pulseless and mottled extremities may limit the ability to detect hypotension with standard devices, and central monitoring or arterial lines may be required to accurately assess volume status.

Patients with myoglobinuria should be monitored with determination of serial serum myoglobin levels and renal function studies. The management of rhabdomyolysis is discussed in Chapter 116. Injured extremities require burn wound management (see Chapter 54). These injuries should be monitored for the development of compartment syndromes (see Chapter 41).

Lightning Injury

Lightning strike victims who present without symptoms or signs of injury, including those with minor first-degree burns, do not require treatment in the ED unless their electrocardiograms show signs of ischemia or concerning dysrhythmias. Patients who present with altered mentation or significant symptoms are approached in a manner similar to that used for victims of high-voltage electrical injury. However, a few differences should be noted. Lightning strikes can result in a spectrum of peripheral and central neurologic injuries, including pupils that are fixed and dilated in the absence of irreversible brain injury. This factor should be kept in mind when deciding when to discontinue resuscitative efforts in patients who present in cardiac arrest. Lightning strikes can cause extensive catecholamine release or autonomic stimulation, resulting in transient hypertension and tachycardia that can be treated with β-adrenergic blockers and hydralazine or with alpha-2 adrenergic agonists such as clonidine, to reduce adrenergic excesses.

Conducted Electrical Weapon

Patients injured by CEWs rarely require intervention. Patients with barb injury should have evaluation of the barb penetration site, and most will not require additional treatment beyond removal and localized wound care. For those who sustain barbs to the face, eyes, or genitals, specialist consultation and operative removal may be required. In those patients with touch-stun exposure, local wound care is recommended.

DISPOSITION

Electrical Injury

Asymptomatic patients who present after low-voltage exposures may be safely discharged home. Other patients are monitored and treated in the ED, observation unit, or inpatient setting, depending on their clinical status and extent and severity of identified injuries. There is some debate around the need for prolonged cardiac monitoring of patients, with most studies showing that the risk of delayed dysrhythmia is very low. A reasonable approach is to observe patients with loss of consciousness, dysrhythmia, high-voltage exposure, ECG abnormality or significant troponin increase on telemetry for 12 to 24 hours. Patients with significant burns should be stabilized and transferred to a burn unit, if available.

Pediatric patients with oral electric injuries are usually hospitalized for hydration, wound and pain management, and plastic surgery consultation. Patients with minor burns confined to the oral commissure can be discharged with close follow-up but should be provided with information regarding the possibility of delayed labial artery bleeding, which can be managed by the parents with direct wound pressure and return visit instructions.

Pregnant patients should receive a period of fetal monitoring when gestational age–appropriate. Women who are subsequently discharged should be counselled regarding the remote risk of spontaneous abortion and referred for high-risk obstetric follow-up care.

Patients may experience delayed neuropsychiatric sequelae, so discharge instructions with a neurologic referral may be provided.

Lightning Injury

The Wilderness Medical Society has recommended that victims of direct lightning strikes and those with an abnormal ECG be monitored with telemetry for a minimum of 24 hours. Other patients can be discharged but should be counselled regarding the need to seek further care if they develop delayed-onset symptoms, which can be cardiopulmonary, neurologic, psychiatric, ophthalmologic, or otolaryngologic in nature.

Conducted Electrical Weapon

Unless there is a concomitant condition present that requires further care or admission, routine cardiac monitoring, ED observation, or hospitalization is not recommended for patients who are awake, alert, and asymptomatic who have had CEW exposure less than 15 seconds.

For patients who have had CEW exposure for greater than 15 seconds, there is limited experience and no clear guidelines exist, so an observation period of 6 to 8 hours is a reasonable approach.

ACKNOWLEGMENTS

The authors wish to acknowledge and thank Kelly P. O'Keefe and Rachel Semmons for their valuable contributions, expertise, and authorship of this chapter in previous editions.

CHAPTER 130: QUESTIONS AND ANSWERS

1. A 37-year-old woman presents with blurred vision. Her vision has been progressively worsening for approximately 2 months. She denies eye pain or direct eye trauma. She reports that approximately 2 months ago, just before the beginning of her vision problems, she was struck by lightning while playing golf. She states that she went to an emergency department (ED) at that time, had no major injuries, and seems to have recovered well. What is the most likely cause of her decreased vision?

a. Cataracts
b. Glaucoma
c. Iritis
d. Macular degeneration
e. Retinal detachment

Answer: A. Cataracts are a well-known complication of electrical injury, either from artificial electrical sources or from lightning. They may occur immediately or have a delayed presentation. Glaucoma is due to elevated intraocular pressure and is often painful. Iritis and retinal detachment can be caused by electrical injury but are manifested acutely. Macular degeneration is a chronic condition of older adults with central vision loss and is not associated with electrical injury. Macular holes may occur acutely with lightning injury.

2. Which of the following patients presenting to the emergency department should have consultation by the burn surgery service?

a. 22-year-old female who presents after receiving a taser shock who is awake and alert. She has barb wounds in her abdomen that were removed by law enforcement prior to arrival and has mild erythema at the barb sites, but no other injuries.
b. 47-year-old male who presents after a lightning strike, who complains of chest pain and EKG shows sinus tachycardia.
c. 34-year-old male who presents after an occupational accident, in which he received an electrical shock to the right hand from a high-voltage source. He is awake and alert, with normal vital signs and no complaints other than a small area of hyperemia to his right palm and pain to his right arm.
d. 3-year-old female, brought in by parents for concern that she put her finger into an electrical socket. On exam, she is awake and alert, has normal behavior, and has no skin or soft tissue findings.
e. 67-year-old female who presented unresponsive after a lightning strike, but is now awake and alert, but reports hearing difficulties.

Answer: C. Electrical injuries, especially high-voltage injuries, can cause deep tissue burns and damage that may not be readily apparent on the surface, due to decreased resistance of neurovascular bundles. In severe cases, tissue edema and decreased perfusion may require fasciotomy. Often, fluid resuscitation calculations using the Parkland formula are underestimated, as visible injury may be insignificant compared to damage beneath the surface. Patients who receive a taser shock do not require further management beyond local wound care. The victims of lightning strikes may require further evaluation for cardiac and HEENT abnormalities, but skin and soft tissue damage in these patients is less likely as the electrical energy often passes over rather than through them. The 3-year-old does not require further management beyond reassurance.

3. A 42-year-old man suffers an electrical injury while working on power transmission lines near your hospital. Paramedics report that he is unresponsive and initially in ventricular fibrillation but spontaneously converted to sinus tachycardia before treatment. His initial electrocardiogram (ECG) from the field shows ST segment elevation in the inferior leads. An ECG repeated in the ED shows continued inferior ST segment elevation but with decreased magnitude. Creatine kinase (CK) and CK-MB levels are markedly elevated and troponin levels are slightly above normal range. While he does have pulses, he continues to be unresponsive, has no spontaneous respirations, and has bilateral fixed and dilated pupils. What is the appropriate next action?

a. Brain death testing
b. Cardiac catheterization
c. Mannitol infusion
d. Intubation and supportive care
e. Thrombolytic administration

Answer: D. Electrical injury can cause a variety of cardiac manifestations, including multiple dysrhythmias, transient ST elevation, and conduction blocks. Myocardial infarction, although reported, is rare. Extensive skeletal muscle damage can be seen in electrical injuries and

CHAPTER 130: QUESTIONS AND ANSWERS—cont'd.

results in marked elevations of CK and CK-MB levels. Respiratory muscle paralysis and ocular injuries often occur. This patient is probably not brain-dead, nor has he suffered a myocardial infarction. Mannitol is used in cases of impending cerebral herniation, which is not expected in this patient. Supportive care, including mechanical ventilation and treatment of dysrhythmias per ACLS protocols as needed is most appropriate.

4. A 22-month-old female is brought to the emergency department by parents after she was found chewing on an electrical cord. She has minor burns to the lips and oral commissure. Upon discharge, what condition should the parents be warned about as a reason to return to the ED?
   - **a.** Facial compartment syndrome
   - **b.** Cardiac dysrhythmias
   - **c.** Delayed dental eruption
   - **d.** Rhabdomyolysis
   - **e.** Delayed labial artery bleeding

Answer: E. Delayed labial artery bleeding usually occurs two days after the initial injury, when the initial eschar separates. When this occurs, there can be significant bleeding from the labial artery. Traditionally, admission for observation has been advocated for these patients but, if there is good social support, discharge with specific return instructions and close follow-up are appropriate. These types of electrical injury have only local effects, so dysrhythmias, cataracts, and rhabdomyolysis are not complications. Contractures are common and may require reconstructive surgery, but this complication is not life-threatening.

5. A 53-year-old male is brought to the emergency department by law enforcement after they incapacitated him with a taser. There are no visible signs of traumatic injury, but he is not responsive. The most appropriate next step is:
   - **a.** Supportive care as most patients quickly arouse after a taser shock.
   - **b.** Evaluate for burns around the taser barb site.
   - **c.** Perform EKG to evaluate for STEMI.
   - **d.** Evaluate the patient for other etiologies of altered mental status.
   - **e.** Discharge the patient with law enforcement to be taken to jail.

Answer. D. There have been a number of high-profile deaths associated with taser shocks by law enforcement. However, the cause of these deaths has not been linked to the electrical effect of the taser shock itself, and patients who present after a taser shock with altered mental status should be evaluated for other etiologies, including but not limited to infection, toxic/metabolic etiologies, and traumatic injuries. Burns evaluation and EKG alone would not be sufficient evaluation for this patient.

Scuba Diving and Dysbarism

David A. Peak

KEY CONCEPTS

- The majority of dive injuries are diagnosed on the basis of the focused dive history and physical examination and are best differentiated into disorders of descent, disorders of depth, and disorders of ascent.
- The *U.S. Navy Diving Manual* and the Divers Alert Network (DAN) are valuable resources for the clinician presented with a diving emergency. DAN provides a 24-hour medical emergency hotline at 1-919-684-9111 (see Table 131.4).
- Treatment with 100% oxygen is the initial therapy for *all* diving emergencies until the diagnoses can be determined. It has been demonstrated to reduce the morbidity and mortality related to decompression illness and can be helpful in patients with pneumothorax.
- Diagnostic imaging and laboratory studies are generally not useful for ruling in or out decompression illness and should not delay transfer for recompression therapy.
- Recompression treatment is recommended for patients with decompression sickness (DCS) and arterial gas embolism (AGE).

FOUNDATIONS

Background and Importance

Underwater free diving has been practiced for more than 5000 years both commercially and for recreation. Diving bells physically provided access to air and protection from pressure at depths to divers and have been described as far back as the 4th century BCE. The earliest artificial underwater breathing devices were restrictive to shallow water because of pressure constraints. In the 1940s, Cousteau and Gagnan introduced a self-contained underwater apparatus (SCUBA) and buoyancy control device (BCD), which revolutionized the ability of divers to safely dive to moderate depths. Diving has increased exponentially since that time among commercial, military, and especially recreational activities which now account for approximately 9 million participants per year in the United States alone, with several hundred thousand new divers trained per year. As a result of its recreational popularity, injuries related to diving have also increased.[1,2] According to the Divers Alert Network (DAN), which is the diving industry's largest association dedicated to diving safety, there are approximately three injuries of any kind per 100 dives and up to 10% of these are fatal. This represents a small but clinically relevant subpopulation of dives.

The symptoms and signs of diving-related illness, also known as *dysbarisms,* began to be recognized as diving became increasingly accessible. The ailment became known as *caisson disease,* named after the large diving bell commonly used for submersion. Construction workers on the Brooklyn Bridge (constructed between 1870–1880) termed the disorder "the bends," because the symptoms often caused the victim to bend forward in pain. The first clinical description by Bert in 1878 correctly attributed the disease to nitrogen gas coming out of solution in the tissues during decompression, which led to the recommendation of slow ascents for pressurized workers and the development of the first recompression chambers.

Most divers use compressed air, open-circuit scuba equipment at depths of less than 130 feet of seawater (fsw). Systems with artificial mixtures of various gases, however, are used to extend the depths to which divers can descend or the duration that a diver may safely remain submerged. Other variations of supplying air for divers include closed-circuit and semiclosed-circuit diving apparatus (called "rebreathers") that use calcium hydroxide to absorb expired carbon dioxide and add oxygen to the decarboxylated gas before rebreathing and allow more efficient and safe diving.

Physiology and Pathophysiology

The leading cause of death among divers is from drowning accidents. Scuba divers may also encounter emergencies common to environmental exposures (e.g., hypothermia, sun exposure, motion sickness, bites, envenomation, and physical trauma). They are also subject to the unique injuries related to pressure at depth.[3] The pathophysiologic mechanism of diving or dysbarisms can be separated into two broad categories: (1) Barotrauma which is related to pressure and; (2) Decompression illness which is related to gas bubbles. Barotrauma can be related to the speed of descent and ascent but is almost completely independent of time of depth. Bubble formation (primarily nitrogen) during and immediately after ascent as well as nitrogen narcosis are both dependent on being at depth for an extended period of time. Therefore, it is useful when treating a patient with an acute diving injury to know the recent dive history because it can assist the clinician in narrowing down the differential diagnoses. For instance, a recreational diver who was at a moderate depth for only a few minutes can still have a major barotrauma-related dive injury but would not have had time to accumulate enough gas or nitrogen in their tissues to cause symptoms.

Familiarity with several of the laws of physics that define the properties of liquids and gases (Table 131.1; Figs. 131.1 to 131.5) is useful when discussing diving pathophysiology. Boyle's law explains diver-related barotrauma and states that at constant temperature, the absolute pressure, and the volume of gas are inversely proportional ($PV = k$). In other words, as pressure increases (with descent), the gas volume is reduced; as the pressure is reduced (with ascent), the gas volume increases. A diver needs to descend only 33 feet in seawater to double the atmospheric pressure, an increase of 23 mm Hg per foot of depth. Abrupt changes in the volume of air-containing parts of the body (e.g., ears, sinuses, and lungs) are at risk of barotrauma with the extreme pressure changes of the environment. These include barotrauma associated with an inability to equalize, mask squeeze, or

TABLE 131.1 Laws of Physics

Gas Law	Formula	Significance
Pascal's law: A pressure applied to any part of a liquid is transmitted equally throughout.	$\Delta P = \varrho g (\Delta h)$ ΔP is the hydrostatic pressure. ϱ is the fluid density. g is acceleration due to gravity. Δh is the height of fluid.	Pressure increases in a contained space are transmitted throughout; significant for IEBT and MEBT (see Fig. 131.1)
Boyle's law: At a constant temperature, the absolute pressure and the volume of gas are inversely proportional. As pressure increases, the gas volume is reduced; as the pressure is reduced, the gas volume increases.	P1 • V1 = P2 • V2	Relates to change in the volume of a gas caused by the change in pressure due to depth, which defines the relationship of pressure and volume in breathing gas supplies (see Fig. 131.2)
Charles' law: At a constant pressure, the volume of a gas is directly proportional to the change in the absolute temperature.	V1/T1 = V2/T2	Increasing pressure (filling a scuba tank) causes heat; cooling a tank decreases the pressure (see Fig. 131.3)
The general gas law combines these concepts to predict the behavior of a gas when the factors change.	P1 • V1/T1 = P2 • V2/T2 P1 is the initial pressure. V1 is the initial volume. T1 is the initial temperature. P2 is the final pressure. V2 is the final volume. T2 is the final temperature.	A means of relating pressure, volume, and temperature together in one equation when variables are not constant
Dalton's law: The total pressure exerted by a mixture of gases is equal to the sum of the pressures (partial pressures) of each of the different gases making up the mixture, with each gas acting as if it alone is present and occupies the total volume.	PTotal 3 P1 + P2 + P3 + … + Pn	Nitrogen under pressure acts as if other gases are not present (see Fig. 131.4)
Henry's law: The amount of a gas that will dissolve in a liquid at a given temperature is directly proportional to the partial pressure of that gas.	$e^p = e^{kc}$ *e* is approximately 2.7182818 (the base of the natural logarithm). *p* is the partial pressure of the solute above the solution. *c* is the concentration of the solute in the solution. *k* is the Henry's law constant.	More nitrogen is taken into solution (e.g., serum) at high pressures than comes out of solution at lower pressures (see Fig. 131.5)

IEBT, Inner ear barotrauma; *MEBT,* middle ear barotrauma.

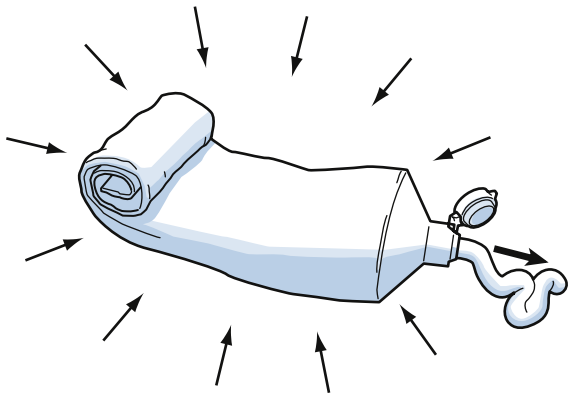

Fig. 131.1 Pascal's law. A pressure applied to any part of a liquid is transmitted equally throughout.

barotrauma to the ears and sinuses during descent, as well as barotrauma related to ascent (usually associated with breath-holding) including pneumomediastinum, pneumothorax, and arterial gas embolism. Fractional changes in volume are greater near where the proportional pressure changes are highest, which is generally in more shallow water.

Henry's law explains decompression illness and states that the amount of any gas that dissolves in a liquid at a given temperature is directly proportional to the partial pressure of that gas. At higher ambient pressures, an increasing concentration of each component gas of the inhaled air will dissolve in solution until a new steady-state concentration is achieved. Therefore, the length of time the diver is breathing the gas at the increased pressure and the inherent solubility of the gas also govern the quantity of a particular gas that dissolves. The dissolved gas remains in solution as long as the pressure is maintained. As the diver ascends, however, increasingly more of the dissolved gas comes out of solution. A rapid ascent may reduce the pressure at a rate higher than the body can accommodate, and the bubbles (particularly nitrogen) may accumulate and disrupt body tissues and systems, a phenomenon termed *decompression sickness* (DCS). This is similar to the rapid opening of a bottle of a carbonated beverage which allows bubbles of carbon dioxide to rapidly come out of solution.

Safe diving practice includes a controlled ascent rate (i.e., through the use of safe decompression tables or submersible dive computers), during which the gas is carried to the lung vascular bed and is exhaled before it accumulates to form significantly large or numerous bubbles in the tissues. This is similar to how opening of a soda bottle slowly reduces agitated bubbling of the contained carbonated liquid.

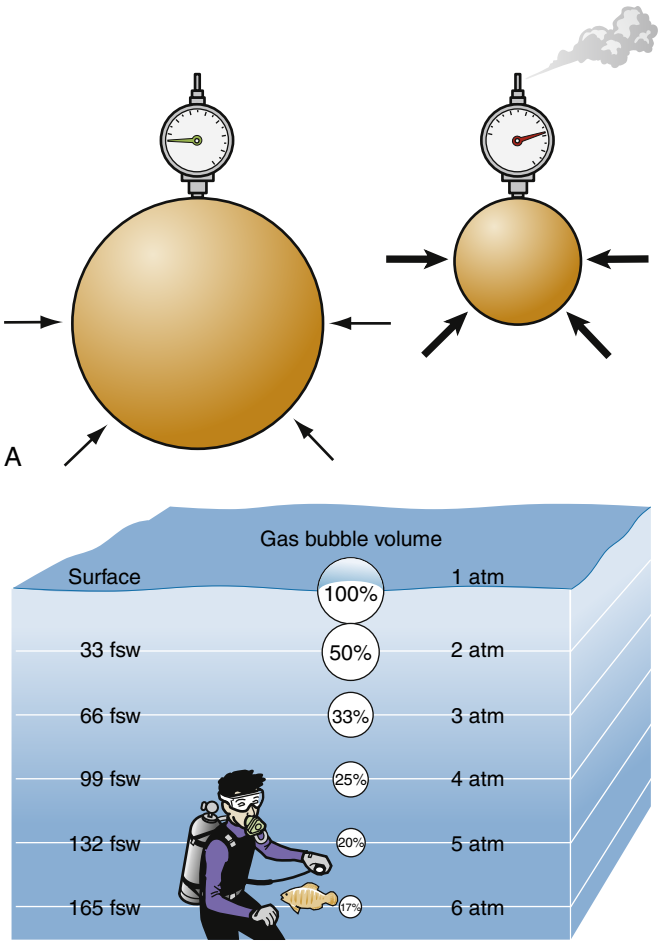

Fig. 131.2 Boyle's law. (A) At a constant temperature, the absolute pressure and the volume of gas are inversely proportional. (B) As pressure increases, the gas volume is reduced; as the pressure is reduced, the gas volume increases. *fsw,* Feet of seawater.

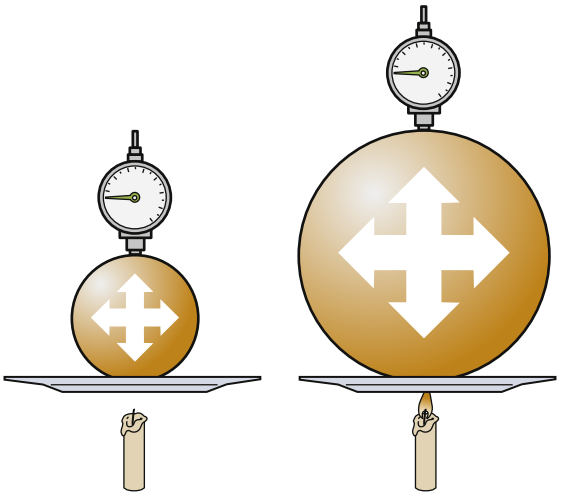

Fig. 131.3 Charles' law. At a constant pressure, the volume of a gas is directly proportional to the change in the absolute temperature.

CLINICAL FEATURES

The clinical features of the injuries and maladies related to diving will be presented in this section based on when the symptoms are likely to start during a dive, first those that occur on descent, then those that occur at depth, and finally those that occur upon surfacing. This organization is used to help the clinician stratify the likelihood of a specific disorder based on when the symptoms started during the dive. Box 131.1 lists the recommended components of a focused dive history.

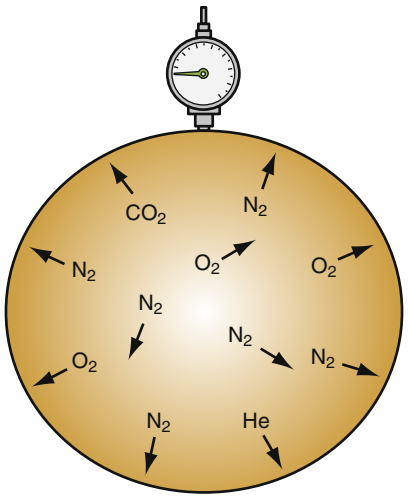

Fig. 131.4 Dalton's law. The total pressure exerted by a mixture of gases is equal to the sum of the pressures (partial pressures) of each of the different gases making up the mixture, with each gas acting as if it alone is present and occupies the total volume. *CO2,* Carbon dioxide; *He,* helium; *N2,* nitrogen; *O2,* oxygen.

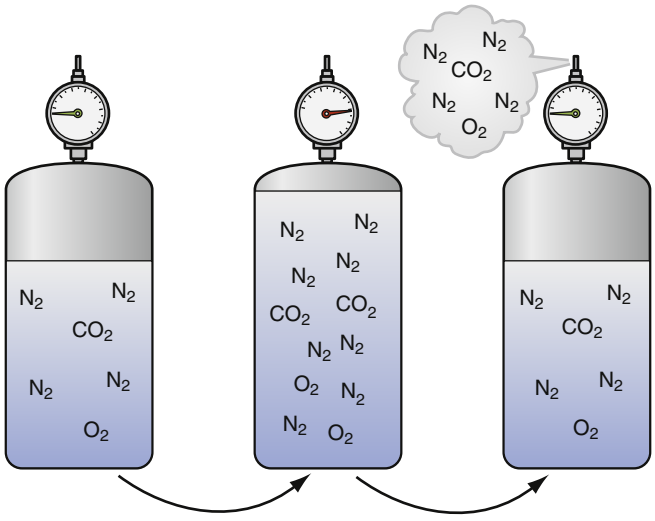

Fig. 131.5 Henry's law. The amount of a gas that will dissolve in a liquid at a given temperature is directly proportional to the partial pressure of that gas. *CO2,* Carbon dioxide; *N2,* nitrogen; *O2,* oxygen.

Disorders Related to Descent/Barotrauma

Middle Ear Barotrauma

Middle ear barotrauma (MEBT), also known as *barotitis or ear squeeze,* is the most common complaint of scuba divers. In a survey of over 750 recreational divers, over half experienced pain related to mild ear barotrauma multiple times during their dives. Most of these were minor pains associated with descent that resolve with equalization maneuvers with no long-term effects.[4-6]

The middle ear is an air-filled space with solid bone walls except for the tympanic membrane (Fig. 131.6). In the auditory system, the eustachian tube is the only anatomic passage to the external environment. During descent, there is an increase in external pressure that

BOX 131.1 Focused Dive History

When was the first onset of symptoms?
What type of equipment was used? Compressed air, mixed gas, enriched air, rebreather? What was the source of the gas?
Did the dive approach or exceed decompression limits? Was a dive computer used?
What were the number, depth, bottom time, total time, and surface intervals for all dives in the 72 hours preceding symptoms (the dive "profiles")?
Were decompression stops used? Was in-water decompression attempted?
What was the time delay from the last dive to air travel?
Did the diver experience difficulty with ear or sinus equilibration? Did the pain occur on descent or ascent?
Was the diver intoxicated? Dehydrated? Working strenuously?
How long after the dive did symptoms present? Were they present at surfacing? Delayed? Progressive?
Is a medical history of ear or sinus infections or abnormalities present? Emphysema or asthma? Coronary artery disease? Patent foramen ovale (PFO)? Neurologic illness?

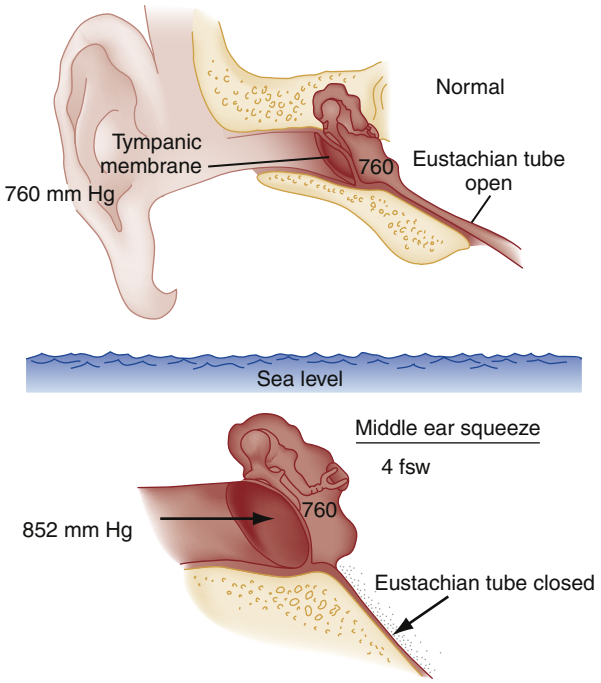

Fig. 131.6 Middle ear barotrauma symptoms include fullness and pain caused by stretching of the tympanic membrane. (From: Van Hoesen KB, Bird NH. Diving medicine. In Auerbach PS, ed. *Wilderness Medicine*, ed 6. Philadelphia: Elsevier; 2012: 1529.)

exerts inward pressure against the tympanic membrane (TM). This occurs when the eustachian tube (ET) does not effectively allow air to flow into the middle ear space to equalize pressure. The ET can become blocked and eventually locked in place by a combination of pressure differential and tissue inflammation or edema.

During a diving descent, there is increasing external and inward pressure against the tympanic membrane unless air enters the middle ear via the eustachian tube (ET) to maintain equal pressure across the tympanic membrane. Typically, a diver performs various equalization maneuvers to force air into the middle ear through the ET. The ET may become blocked or collapse related to the pressure differential or inflammation, making subsequent attempts at equalization virtually impossible. This is typically painful and may be associated with tinnitus; some patients develop transient vertigo. Further descent without successful equalization can cause the TM to collapse inward and rupture. The pain may or may not resolve as the TM ruptures. Rupture of TM can cause asymmetric caloric stimulation by exposure of the middle ear to cold water, inducing a transient nystagmus and vertigo. This can become life-threatening if the diver panics or becomes disoriented. The pressure of the water in the middle ear may also lead to a facial palsy in certain individuals where the seventh cranial nerve passes through this space.

External Ear Barotrauma

External ear barotrauma is less common than MEBT and can be caused by an obstruction of the external auditory canal (e.g., cerumen, ear plugs) which can trap air in the canal instead of filling with water. This may lead to localized pain or hemorrhages within the wall of the external auditory canal on examination. These symptoms are generally self-limited.

Inner Ear Barotrauma

IEBT is trauma occurring as a result of a pressure differential between the middle and inner ear spaces. Inner ear barotrauma (IEBT) results in damage to the cochleovestibular apparatus. It is less common than MEBT (reported as 0.5% lifetime incidence in divers) but is associated with greater morbidity. If the diver is unable to equalize the middle ear during descent, pressure is transmitted across the labyrinthine windows (oval and round) leading to inner ear hemorrhage. Intralabyrinthine membrane tears which effect the Reissner, tectorial or basilar membranes can also occur or cause a tear of the labyrinthine windows, leading to perilymphatic fistula formation (PLF). Fifty percent of these injuries are mixed cochlear and vestibular, 40% are isolated cochlear, and 10% isolated vestibular.

Symptoms associated with IEBT include variable hearing loss, severe vertigo, nausea, tinnitus, and fullness in the affected ear. Signs include severe nystagmus, positional vertigo, ataxia, and vomiting. The degree of sensorineural hearing loss is variable. Distinguishing IEBT from inner ear DCS can be challenging but should not delay recompression in a patient in whom the diagnosis is unclear.

Reverse Middle Ear Squeeze

Reverse middle ear squeeze is the opposite of middle squeeze and occurs during ascent. As the pressure lessens, a pressure gradient can cause the TM to bulge outward and even rupture causing pain. This is much less common than middle ear squeeze during descent.

Barosinusitis

After ear barotrauma, the second most common diving-related physical disturbance is sinus barotrauma. In a survey of over 750 recreational divers, 35% experienced sinus pain related to barotrauma on more than one occasion while diving. Most of these were minor pains associated with descent that resolve with equalization maneuvers and have no long-term effects. The air-filled maxillary, frontal, and ethmoidal sinuses are susceptible to volume-pressure changes on ascent or descent; the most commonly affected is the maxillary sinus, followed by the frontal. The most common symptoms are facial pain and epistaxis. Obstruction of the sinus ostia for any reason (e.g., mucosal thickening, polyps, pus, or deviated septum) predisposes to the inability to equalize and sinus barotrauma.[5-6]

Alternobaric Vertigo

Alternobaric vertigo is a common but usually transient, self-limited vertigo secondary to asymmetric ear pressure transmitting from the middle ear to the inner ear. It is not thought to have long-term effects.

Facial Barotrauma or Mask Squeeze

During descent, a negative pressure develops within the diving mask that may increase to the point of damaging surrounding tissues if the diver does not exhale into the mask in order to equalize the pressures within and outside the mask. "Mask squeeze" is a type of facial barotrauma injury that occurs more commonly in novice divers or in masks that cannot be exhaled into (e.g., free diving masks) The difference in pressure inside and outside the mask can lead to barotrauma to the contents inside the mask leading to injury of blood vessels and tissue of the eyes and face. This can lead to facial and conjunctival edema, diffuse petechial hemorrhages on the face, and subconjunctival hemorrhages which are generally self-limited. Rarely, optic nerve damage can result from severe facial barotrauma. Recent eye surgery or preexisting glaucoma may increase the risk of injury.

Disorders Arising at Depth

Nitrogen Narcosis

Nitrogen narcosis (known as *rapture of the deep*) is a phenomenon that occurs when exposed to the intoxicating increases of partial pressures of nitrogen and is considered a significant contributing factor in diving-related accidents. Narcosis is characterized by an impairment of psychomotor coordination and alterations in mood (such as euphoria or increased anxiety) and behavior (lowering of inhibitions and impairment in reasoning). Symptoms require time at depth and may become apparent at a depth of 100 ft (30 m) and increase with further increases in depth. Use of mixed gases with lower concentration of nitrogen is recommended for technical, military, commercial or sport diving to deeper depths. The effects of nitrogen narcosis resolve with gradual and controlled ascent to shallower depths.

Oxygen Toxicity

At elevated partial pressures for extended periods, oxygen can be toxic to the central nervous system (CNS) or lungs. Oxygen becomes toxic to the CNS when its partial pressure exceeds 1.6 atmosphere absolute (ata). Oxygen partial pressures below 1.4 ata are unlikely to produce CNS toxicity. A diver breathing compressed air would attain a partial pressure of 1.6 ata of oxygen at a depth of 218 fsw. This far exceeds the depth to which most recreational divers would dive. Most professional divers prevent oxygen toxicity by breathing mixed gases with decreased oxygen and nitrogen content to decrease the possibility of oxygen toxicity (and nitrogen narcosis). This requires special equipment and advanced training.

Pulmonary oxygen toxicity (low-pressure oxygen poisoning) can occur after 24 hours of exposure to partial pressures of oxygen in excess of 0.6 ata. The symptoms of pulmonary oxygen toxicity include a burning sensation or pain on inspiration and coughing. Pulmonary function gradually becomes normal after the exposure is terminated, but pneumonitis and permanent fibrosis are possible. CNS oxygen toxicity symptoms include headache, dizziness, irritability, anxiety, visual changes, extremity tingling or twitching, tinnitus and hearing abnormalities, nausea, and seizures. It can cause drowning and death. It is extremely unlikely that a sport diver would ever be exposed for the duration that is required to produce toxicity; however, long exposures to higher levels of oxygen, such as those administered for certain recompression protocols, may lead to oxygen toxicity. In a 20-year single hyperbaric center study of over 18,000 patients, only 0.02% of patients experienced seizure activity.[5] Most hyperbaric centers use intermittent "air breaks" during hyperbaric treatment sessions in which the patients breath air with a normal Pao_2 to give their bodies a break from high oxygen levels and prevent toxicity.

Contaminated Air

Rarely, other gases, such as carbon monoxide and carbon dioxide, can contaminate the air that is compressed into a tank. This can happen if the compressor intake is placed too close to the compressor's engine exhaust. As in the case of oxygen and nitrogen, the partial pressure of these contaminants in the tissues increases dramatically with depth, potentiating their clinical effects. The symptoms of hypercarbia or carbon monoxide poisoning are thus more severe at elevated partial pressures. Hypercarbia will also increase a diver's susceptibility to CNS oxygen toxicity.

Rebreathers are used by recreational divers to recirculate the gas used by the diver after replacing oxygen and removing carbon dioxide. The major advantages are extended dive times and diminished accumulation of bubbles. Rebreathers use absorbent material to remove carbon dioxide from the circuit. A hose rupture allowing seawater contamination of the circuit may create a caustic alkaline-based liquid containing calcium or sodium hydroxide, which can cause burns to the mouth, throat, and airways.

Disorders Arising on Ascent

Alternobaric Vertigo

Alternobaric vertigo (ABV) results from an inability to equalize pressure within the middle ear during ascent and affects up to 25% of divers. ABV is based on asymmetrical pressure changes in the middle ear that are transmitted through the oval and round window to the vestibular system, resulting in a sensation of spinning and loss of orientation. This profound but transient sense of vertigo during ascent may be associated with nausea and vomiting but is not thought to lead to major morbidity or mortality. Unlike those of IEBT, the symptoms are self-limited.

Barodontalgia

On occasion, air that is trapped beneath a poorly filled dental cavity or within a dental abscess and expands on ascent, leading to dental pain. This condition affects up to 10% of divers but is relatively benign and self-limited.

Gastrointestinal Barotrauma

Serious gastrointestinal barotrauma is a rare condition in scuba divers. It results from the expansion of bowel gas in the small intestine and colon on ascent after diving. Predisposing factors include consumption of carbonated beverages, large meals, or gas-producing foods before diving, as well as performance of the Valsalva maneuver in the head-down position. Symptoms include eructation, flatulence, bloating, and crampy abdominal pain. In divers with inguinal or other abdominal hernias, the potential for expansion of trapped gas within the hernia exists, and expansion may result in incarceration or strangulation. Gastric rupture has been reported. Although gastrointestinal barotrauma is a rare entity, it should be suspected in the diver-patient with a provocative history and acute abdominal pain.

Pulmonary Barotrauma

Without continuously expiring on ascent, the lungs of a scuba diver who takes a full breath at 33 fsw would have to expand to double their volume by the time they reached the surface (based on Boyle's law). However, expansion of the alveoli is limited. Breath-holding during ascent with resultant expansion of lung volumes and pressure can force gas bubbles across the alveolar-capillary membrane and cause the wall of the alveoli to rupture. This can occur with as little a change in depth from 3 to 4 feet (or pressure difference of 80 mm Hg) and *does not* require being at depth for a prolonged time period.

BOX 131.2 Factors That Increase Pulmonary Barotrauma Risk in Asthmatics

1. Bronchospasm and mucus plugging predispose local regions of lung to injury.
2. When air is compressed, it becomes denser. This may contribute to greater turbulent flow through narrow airways.
3. During scuba diving, there is a reduction in breathing capacity related to the effects of immersion. At 33 feet underwater, the maximum breathing capacity of a normal scuba diver is only 70% of the surface value. At 100 feet underwater, the reduction is approximately 50%.
4. When compressed air (from the scuba tank) expands in the regulator before delivery to the lungs, it cools (Charles' law). Breathing of chilled air may trigger bronchospasm in asthmatics who have a cold-induced component of their disease.
5. Scuba diving takes some effort; asthmatics who have an exercise-induced component of their disease may experience bronchospasm.
6. Compressed air may be contaminated by pollen and other allergens.

BOX 131.3 Recommendations for Asthmatic Patients

A thorough history and physical by a trained physician
The patient's asthma should be well controlled
Normal spirometry: FEV_1 ≥80%, FEV_1/FVC ≥75%
Successful completion of a bronchial provocation challenge
Cold-, exercise-, or emotion-induced asthmatics should not dive
Asthmatics requiring rescue medication with 48 hours should not dive

FEV1, Forced expiratory volume in 1 second; *FVC,* forced vital capacity. Adapted from: Coop CA, Adams KE, Webb CN. SCUBA diving and asthma: clinical recommendations and safety. *Clin Rev Allergy Immunol.* 2016;50(1):18-22.

In fact, the greatest risk for pulmonary barotrauma occurs in less than 10 feet of water. Therefore, it is important for the clinician to consider this disease entity in patients with symptoms even after exposure to shallow depths for a short period. Pulmonary barotrauma can result in the following four conditions: pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage. Risk factors elicited from the dive and medical history may suggest the diagnosis of pulmonary barotrauma. In most cases, fast ascent, panic, problems in regulating proper buoyancy, or running out of air precipitates an uncontrolled ascent with breath-holding.

Patients with restrictive and obstructive lung diseases are at increased risk. Asthmatics have a twofold-increased risk for pulmonary barotrauma compared with the general diver population. Box 131.2 lists six mechanisms that contribute to the increased risk in asthmatics,[8] who should be instructed not to dive unless they are completely free of symptoms. Box 131.3 summarizes the recommendations from the multiple national scuba governing agencies, as well as expert consensus.[6]

Pneumomediastinum and subcutaneous emphysema result when air crosses the alveolar endothelium and dissects into the pulmonary interstitium. Most commonly, air travels into the neck, mediastinum, or pericardium. The manifestations of pneumomediastinum may include fullness or pain in the neck, palpable subcutaneous crepitance, and a change in voice quality. Unless evidence of either hemodynamic instability or airway compromise exists, interstitial air or subcutaneous emphysema is not a life-threatening condition.

Pulmonary barotrauma-induced pneumothorax occurs when air from alveoli crosses the visceral pleura. A tension pneumothorax is a rare complication. The symptoms and signs of a pneumothorax secondary to pulmonary barotrauma are similar to a pneumothorax of any other cause.

Pulmonary barotrauma can also cause alveolar hemorrhage. Patients may present with hemoptysis coincident with chest pain and dyspnea. Chest radiography may reveal an interstitial infiltrate. If alveolar gas invades the pulmonary veins and enters the systemic circulation it can cause arterial gas embolism (AGE) which is discussed later.

Decompression Sickness

The term *decompression sickness (DCS)* refers to a spectrum of clinical illnesses resulting from the formation of small bubbles of nitrogen gas in the blood and tissues on ascent. The clinical expression of DCS depends on the location, destination, and degree of nitrogen bubble formation in blood and tissues. Small, usually asymptomatic venous gas emboli are common in the ascending diver after ascent and for the first several hours after ascent and are usually filtered by the lungs without apparent permanent damage. Persistent intravascular bubbles, however, may elicit inflammatory cascades, cytokines, the complement system, platelet aggregation, and thrombosis. They can also induce mechanical obstruction leading to ischemia and hypoxia resulting in major pathology and even death. Nitrogen is highly fat soluble, and the heavily myelinated white matter of the CNS is at particular risk for DCS.

The incidence of DCS ranges from 1 per 1000 dives to 1 in 20,000 dives based on previous studies, but may be underreported because some divers may not present to a health care professional. The potential for development of DCS increases with the length and depth of diving. Other risk factors may include age, obesity, fatigue, heavy exertion, dehydration, fever, cold ambient temperatures after diving, diving at high altitude or flying soon after diving. The risk of DCS is 2.5 times greater for men than for women, possibly due to risk-taking behaviors. A patent foramen ovale (PFO) or other left-to-right shunt (e.g., atrial septal defect) is a risk factor for increased susceptibility to DCS and larger defects are likely to be more relevant.[7,8,9] Sixty-five percent of divers who present with serious DCS have a PFO. Most sport divers do not undergo screening for PFO with echocardiographic bubble studies.

The United States Navy dive tables estimate the amount of nitrogen that accumulates in the body during a dive to a particular depth and duration. The tables calculate a maximal dive time, called the *no-decompression limit.* If the no-decompression limits are exceeded, underwater decompression stops are recommended. Many sport scuba divers use submersible dive computers to calculate maximum dive times in lieu of the tables. These tables and computers are meant to reduce the likelihood of exceeding the solubility of nitrogen at sea level to produce DCS. The diver still must ascend in a slow, controlled manner to allow the gradual release of nitrogen. Off-gassing continues after the diver has surfaced. Repetitive dives within several hours result in accumulation of tissue nitrogen and shorter no-decompression limits. Because dive tables are based on several assumptions about nitrogen elimination, even strict adherence to these tables does not guarantee that DCS will not occur. It is important for emergency clinicians to realize that divers can develop DCS even when they are within these calculated no-decompression limits.

DCS typically is manifested within hours after surfacing. Approximately 40% of symptoms occur within 1 hour after diving, 60% within 3 hours, 80% within 8 hours, and 98% within 24 hours. Flying shortly after diving or ascending to altitude, however, may cause symptoms in patients later than expected, and some patients may present days after diving with DCS.

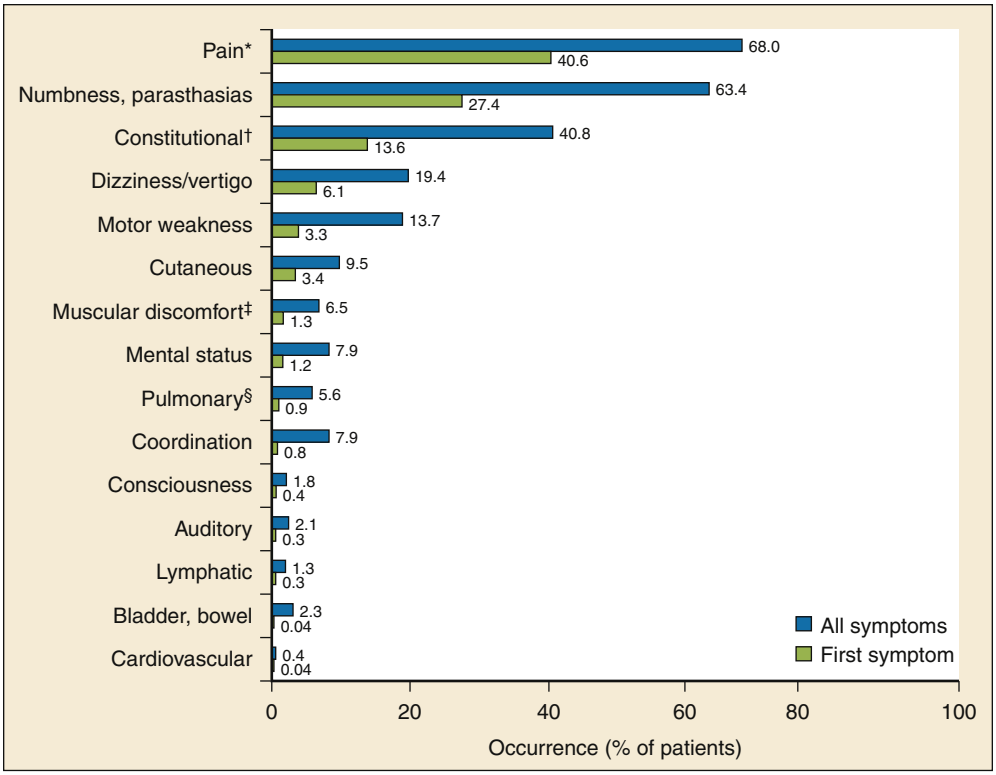

Fig. 131.7 Classification of initial and of all eventual manifestations of decompression illness in 2346 recreational diving accidents reported to the Divers Alert Network (DAN) from 1998 to 2004. *For all instances of pain, 58% consisted of joint pain, 35% muscle pain, and 7% girdle pain. Girdle pain often portends spinal cord involvement. †Constitutional symptoms included headache, lightheadedness, inappropriate fatigue, malaise, nausea or vomiting, and anorexia. ‡Muscular discomfort included stiffness, pressure, cramps, and spasm but excluded pain. §Pulmonary manifestations included dyspnea and cough. (From: Vann RD, Butler FK, Mitchell SJ, et al. Decompression illness. *Lancet*. 2011;377:153-164.)

Traditionally, DCS has been divided into two categories, type I and type II. Type I DCS is considered less severe and affects the musculoskeletal system, skin, and lymphatic vessels. Type II DCS involves any other organ system and typically involves neurologic, vestibular or pulmonary symptoms. The more inclusive decompression illness (DCI) or "decompression-related illness" is now also used to encompass DCS I, DCS II, and arterial gas embolism (AGE). This simplified DCI terminology can aid clinicians to more rapidly select the necessary intervention since all types of decompression illness require recompression. DCS I, DCS II, and AGE can also coexist. The symptoms of DCS may be subtle and resolve by the time of evaluation. A distribution of the initial most common symptoms is presented in Figure 131.7.

Divers experiencing more minor type I DCS generally experience joint pains. The elbow and shoulder joints are most commonly affected. Local tenderness and erythema are uncommon. The placement of a blood pressure cuff inflated to 150 to 200 mm Hg on an affected joint produces relief of pain and helps confirm the diagnosis; however, the sensitivity of this maneuver has been reported to be as low as 60%. Mild skin irritation or pruritus may also be consistent with more minor type I DCS. Lymphatic obstruction by air bubbles can also occur, causing extremity edema, but is still considered type I DCS. (Fig. 131.8).

Patchy cyanotic marbling of the skin, known as *cutis marmorata* was previously considered as part of type I DCS, but more recent literature suggests that this reticular rash may be related to CNS-related changes in vasomotor regulation and may be more closely related to type II DCS.[10] This update has been reflected in the Divers Alert Network website information as well. Cutis marmorata may begin as

Fig. 131.8 Marbling of the thigh in cutaneous decompression sickness (DCS). (From: Maeyens E. Aquatic skin disorders. In: Auerbach PS, ed. *Wilderness Medicine*. ed 6. Philadelphia: Elsevier; 2012: 1665.)

severe pruritus and progress into an erythematous rash and then skin mottling which commonly involves the trunk and torso but does not follow a dermatomal distribution. Type II DCS includes symptoms that can involve the CNS, the inner ear, and the lungs. The CNS is particularly susceptible to decompression illness because of its high lipid content. The spinal cord, especially the upper lumbar area, is more often involved than cerebral tissue. Symptoms of spinal DCS include limb weakness or paralysis, paresthesias, numbness, with low back and abdominal pain. Limb symptoms often begin as a distal prickly

sensation that advances proximally, followed by progressive sensory or motor loss. Urinary retention, bladder and fecal incontinence, and priapism may also occur. Unlike patients with spinal cord trauma, patients experiencing DCS may have patchy or unequally distributed sensory and motor findings.

Spinal DCS can occur alone or in combination with cerebral, inner ear, or pulmonary symptoms. Cerebral symptoms include mild to moderate headache, blurred vision, diplopia, dysarthria, unusual fatigue, inappropriate behavior, dizziness and a sense of detachment. Loss of consciousness in CNS DCS is rare (in marked contrast to AGE).

Inner ear DCS is commonly called *the staggers*. Approximately one-third of patients that present with DCS report cochlear vestibular symptoms. The symptoms of inner ear DCS are the same as those of IEBT and include nausea, dizziness, vertigo, nystagmus, and hearing loss. Vestibular symptoms predominate with only about a quarter of patients experience hearing loss or tinnitus. This can usually be distinguished from IEBT because the onset occurs during ascent or after surfacing.

Pulmonary DCS is commonly called *the chokes*. All divers are exposed to some degree of microbubble emboli to the lungs on ascent. The progression to symptoms depends on the number and volume of bubbles. The deposition of venous gas emboli in the pulmonary arterial circulation produces progressive dyspnea, cough, and chest pain. The cough may progress to paroxysmal fits with worsening pain. This is usually a progressive process after ascent as opposed to pulmonary barotrauma-related pathology which generally occurs immediately after ascent.

The physical examination of patients suffering from pulmonary DCS may reveal cyanosis and hypotension in association with increased central venous pressure and pulmonary arterial pressure. The condition may progress to respiratory arrest.

DCS may be particularly dangerous to a developing fetus of a scuba diving mother because the majority of the fetal circulation bypasses the pulmonary bed through the foramen ovale and the ductus arteriosus. This bypass prevents the fetal lungs from acting as a filter for microbubbles. In addition, venous gas emboli may appear in the fetal circulation before they are apparent in the maternal circulation. Data on the effects of diving on pregnant women suggest a higher incidence of low-birth-weight infants, prematurity, congenital malformations, stillbirths, and spontaneous abortions. There are no safe-diving tables that would protect a fetus from DCS; therefore, pregnant women should be advised to refrain from scuba diving.

Arterial Gas Embolism

AGE can be caused by barotrauma with air forced across the alveolar-capillary membrane through the pulmonary venous circulation into the arterial system. Alternatively, venous bubbles can cross into the arterial circulation from a left-to-right shunt. Barotrauma-related AGE from air bubbles forced across the alveolar-capillary membrane into the pulmonary venous circulation through the left atrium and ventricle and then into the arterial circulation can be immediately life-threatening. It is one of the most common causes of death in divers and is usually related to an uncontrolled ascent with breath-holding and does not require a significant time at depth. Even at a relatively shallow depth, a diver can elicit significant barotrauma with rapid surfacing, especially with breath-holding. Clinical symptoms and signs are the result of mechanical obstruction by gas bubbles. AGE can also result from a right-to-left shunt of venous bubbles, such as in a diver with a PFO, and often presents with symptoms consistent with type II DCS. AGE may occur alone or in conjunction with DCS.

Although air bubbles may embolize to any organ, the coronary and cerebral arteries are associated with the most serious consequences. Emboli to the coronary arteries may cause cardiac ischemia, myocardial infarction, dysrhythmias, or cardiac arrest. Dysrhythmias may also be indirectly caused by centrally mediated autonomic dysfunction from cerebral emboli. Mechanical occlusion of the cerebral vasculature from emboli, most commonly to the anterior and middle cerebral arteries, causes a variety of symptoms and signs similar in appearance to an acute stroke. Large volumes of intracardiac bubbles can mechanically displace blood in the ventricles, leading to a precipitous fall in cardiac output with resultant hypotension and cardiac arrest.

The clinical manifestations of AGE may be sudden, dramatic, and life-threatening. Any diver breathing compressed air at any depth underwater and who surfaces unconscious or who loses consciousness within 10 minutes of reaching the surface should be assumed to be suffering from AGE. The most common presentation of AGE includes a global alteration of consciousness, headache, dizziness, convulsions, and visual changes. Other common presenting symptoms and signs include cranial nerve symptoms, unilateral weakness, unilateral or bilateral sensory loss, ataxia, and speech changes. Pulmonary symptoms, including dyspnea, pleuritic chest pain, and hemoptysis, occur in up to a quarter to half of cases.

Pulmonary Edema

Pulmonary edema while scuba diving was first reported in the 1980s. An increase in afterload (from vascular hyper-reactivity, possibly triggered by cold water) combined with an increase in preload (from the hyperbaric underwater environment) are likely causes.

DIFFERENTIAL DIAGNOSES

Most diving injuries have limited differential diagnoses that include medical disorders and trauma unrelated to dysbarism. The differential diagnoses of IEBT include inner ear DCS, ABV, and isolated MEBT with a rupture of the tympanic membrane. It is relatively easy to distinguish IEBT from MEBT and ABV because the vestibular symptoms associated with the last two entities are transient and self-limited (Table 131.2). When IEBT occurs simultaneously with MEBT, the presence of both may be documented by an audiogram, which demonstrates both a conductive and a sensorineural hearing loss.

The differentiation of IEBT from inner ear neurologic DCS is crucial because the treatments differ. IEBT is considered classic when symptoms begin during descent or the diver relates a history of difficulty equilibrating or performing a vigorous Valsalva maneuver. Inner ear DCS usually presents within 15 minutes to 2 hours after ascent, and usually includes a dive profile which approached no-decompression limits. A trial of recompression therapy is prudent if concerns for DCS exist.

Differential diagnoses of pulmonary DCS include AGE. Table 131.3 provides factors that differentiate the two conditions. Although the treatment of both requires recompression therapy, they can be differentiated by the timing of the onset of symptoms. Almost all cases of AGE present within the first 10 minutes of surfacing, whereas DCS presents more typically well after 10 minutes upon surfacing: 40% of pulmonary DCS symptoms begin within 1 hour of surfacing, 60% within 3 hours, 80% within 8 hours, and almost all within 24 hours.

Diagnostic Testing

Most diagnostic imaging and laboratory studies are not useful in diving- and dysbarism-related injuries and should not delay transfer for definitive recompression therapy. Focused history concerning the dive profile, including the depth and length of the dive and other details of the dive profile (including rapid ascent) and a careful assessment of when the symptoms first occurred, may provide

TABLE 131.2 Middle Ear Barotrauma, Inner Ear Barotrauma, and Alternobaric Vertigo

	Middle Ear Barotrauma	Inner Ear Barotrauma	Alternobaric Vertigo
Symptoms	Ear pain during descent	Ear pain during descent	Ear pain during ascent
	Hearing loss	Hearing loss	Transient hearing loss
	Possible transient vertigo	Severe vertigo and nausea	Nausea
Signs	Conductive hearing loss	Nystagmus	Nystagmus
	TM injury	Emesis	Emesis
	Unilateral face paralysis	Ataxia	TM injury
		Romberg sign	
		Neural hearing loss	

TM, Tympanic membrane.

TABLE 131.3 Decompression Sickness Versus Arterial Gas Embolism

Decompression Sickness	Arterial Gas Embolism
Dive History	
Depth and length dependent	Independent of dive profile
Decompression limits approached	Rapid ascent
Flying after diving	Inexperience
Diving at altitude	Out of air
Risk Factors	
Fatigue	Obstructive lung disease
Dehydration	Emphysema
Fever, hypothermia	Mucus plugging
Obesity	Patent foramen ovale (PFO)
Strenuous activity	
Symptoms and Signs	
Progressive onset	Rapid onset
Spinal symptoms predominate	Cerebral symptoms predominate
Headache	Headache
Unusual fatigue	Loss of consciousness
Limb weakness or paralysis	Confusion
Paresthesias	Convulsions
Abdominal pain	Motor or sensory loss
Urinary retention	Cardiac dysrhythmias or arrest
Fecal incontinence	
Periarticular joint pain	
Skin marbling	
Vertigo or nystagmus	
Treatment	
Recompression	Recompression

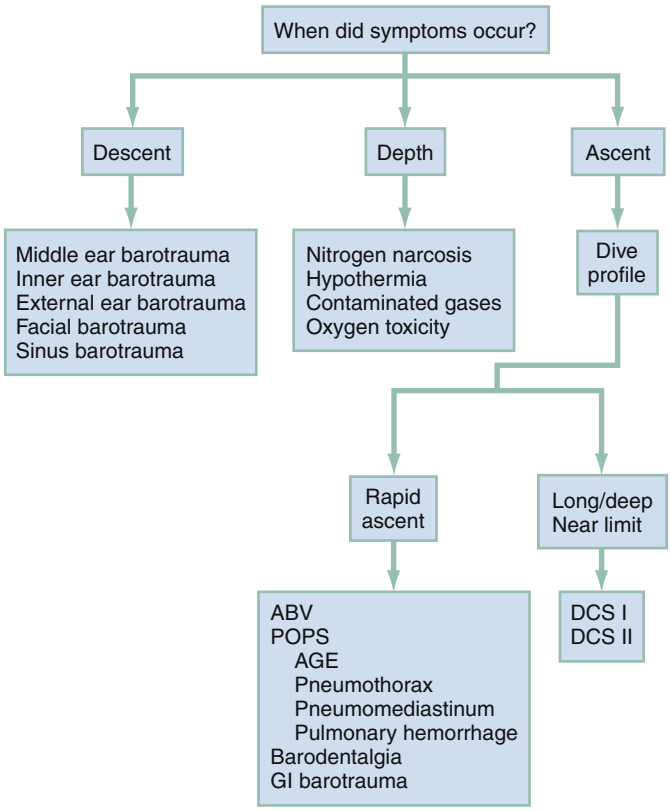

Fig. 131.9 The approach to the injured diver. *ABV,* Alternobaric vertigo; *AGE,* arterial gas embolism; *DCS,* decompression sickness; *GI,* gastrointestinal; *POPS,* pulmonary overpressure syndrome.

important diagnostic clues (see Box 131.3). In making the diagnosis of a dive injury, it is helpful to think of the injuries in terms of occurring during descent, while at depth, or during ascent (Fig. 131.9). Because recompression therapy is time sensitive, it is more important to concentrate on treatment decisions rather than on securing a definitive diagnosis.

Pulmonary barotrauma can also cause alveolar hemorrhage. Patients may present with hemoptysis coincident with chest pain and dyspnea. Chest radiography may reveal an interstitial infiltrate or pneumothorax. An untreated pneumothorax is considered an absolute contraindication for recompression therapy and will need to be managed prior to treatment. Magnetic resonance imaging (MRI), computed tomography (CT), and single-photon emission CT with technetium (Tc-99m)–labeled hexamethyl propylene amine can identify the bubbles of CNS DCS. However, *no* imaging studies are sensitive enough to exclude DCS, and normal imaging results should not delay transfer for definitive therapy. DCS can cause right-sided strain on an electrocardiogram and decreased end-tidal carbon dioxide level. Even after ascent from very shallow saturation dives, microbubbles in the venous circulation can be routinely detected by M-mode ultrasonography; however, their presence does not necessarily correlate with symptoms.

DAN, Divers Alert Network.

MANAGEMENT

Patients with stable vital signs and suspected dive injuries should receive 100% oxygen until the clinician can exclude pulmonary barotrauma or decompression illness. Normobaric 100% oxygen can improve outcomes and should be provided until the patient can be treated definitively. Patients with unstable vital signs or in cardiac arrest should be treated according to advanced cardiac life support (ACLS) guidelines. The clinician should conduct a focused history, including elements summarized in Box 131.1, and then perform a thorough physical examination.

Diving-related illnesses are diagnosed and treated on the basis of the history and physical examination, with several resources available for emergent advice. The Divers Alert Network (DAN), located at Duke University in Durham, North Carolina, is a membership association that provides courses on diving-related emergencies and publishes data on diving accidents and fatalities. DAN provides a 24-hour medical emergency hotline at 1-919-684-9111 (collect calls are accepted) and a nonemergency advisory line Monday through Friday, 8:30 a.m. to 5 p.m. Eastern time, at 1-919-684-2948 or 1-800-446-2671 (Table 131.4). In addition, DAN international contacts are in Europe, Brazil, Japan, Asia Pacific, and southern Africa. DAN maintains a website with links to key information at www.diversalertnetwork.org. DAN uses a telephone intake form, the DAN On-Site Neurological Assessment for Diver's History (Fig. 131.10).

The United States Navy has its current diving manual (6th edition) available at its website, www.usu.edu/scuba/navy_manual6.pdf. This manual contains readily accessible information describing diving principles, equipment, operations, and recompression.

Diving Disorders Requiring Recompression Therapy

Diving disorders that require recompression therapy are listed in Box 131.4. Early consultation with a hyperbaric specialist is recommended. Treatment with 100% normobaric oxygen during recovery, assessment, and transfer is recommended. Treatment with 100% oxygen replaces inert gases in the lungs with oxygen by establishment of a large gradient from the tissues to the alveoli, removal of inert gases is enhanced, and bubble size is reduced. In addition, oxygen administration treats the tissue hypoxia created by the accumulation of gas bubbles.

Dehydration may increase the seriousness of DCS. Diving appears to be associated with dehydration and hemoconcentration in many studies. Intravenous fluids may be administered to divers suspected of having nonpulmonary ("chokes") DCS. Overly aggressive hydration in divers with pulmonary DCS may worsen pulmonary edema and is discouraged. Similarly, fluid overload should be avoided in patients with suspected cerebral or spinal cord edema or AGE. If given, fluids should be administered to ensure a urinary output of 0.5 mL/kg per hour.

The goals of recompression therapy are to reduce the mechanical obstruction of air bubbles, to facilitate the washout of nitrogen by increasing the tissue-blood nitrogen gradient, and to increase oxygen delivery to ischemic tissue. Recompression is the only definitive treatment of DCS and AGE and is most effective if administered early. Treatment of DCS or AGE should not be withheld even if a significant time delay in transferring a patient to a hyperbaric chamber is anticipated. Although delayed recompression is less effective than immediate recompression in serious cases, the time beyond which recompression offers no benefit is not well documented.

Hyperbaric therapy for AGE is also considered time sensitive. Patients with AGE who are recompressed within 5 hours of surfacing have a mortality rate of 5%, and there is an extremely low risk of morbidity among the survivors. If recompression is delayed by 5 hours or more, the mortality rate increases to 10%, with 50% morbidity. Although spontaneous resolution of symptoms may occur in patients with AGE, all patients should be recompressed. The rationale is that although microbubbles may clear from the cerebral circulation, secondary capillary edema and swelling may be further ameliorated by recompression.

Similarly, the prognosis for DCS when it is treated with recompression is generally good but depends on the severity of symptoms at onset, and the delay to recompression. A delay to definitive recompression treatment is associated with a worse outcome in cases of severe DCS. Patients can obtain some benefit from recompression, however, even if treatment is initiated more than 24 hours after the dive. Recompression therapy for DCS initiated as late as 10 to 14 days after exposure has been associated with improved outcomes.

Recompression for DCS and AGE may be performed in a multiplace chamber with one or more in-chamber attendants or within a monoplace chamber. Monoplace chambers are compact, lightweight, and more widely available than multiplace chambers, but most monoplace chambers cannot be pressurized beyond 3 ata (100 fsw) or deliver air-oxygen mixtures. The most common recompression schedule is the United States Navy treatment (or an equivalent procedure). With this protocol, the diver is compressed to 2.8 bar (60 fsw pressure) while breathing 100% oxygen. The time to complete treatment is 4 hours 45 minutes, not including descent and ascent time.

Ground transport to a hyperbaric facility is preferred to air transportation, if feasible, because an increase in altitude lowers the ambient pressure and allows microbubbles to expand. If air transportation must be used, it is recommended maintain cabin pressure at less than 1000 feet. Commercial aircraft are typically pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight (30,000 feet). Many of these aircraft are capable of near–sea level cabin pressures if flying no higher than 15,000 to 20,000 feet. Because helicopters are not pressurized, it is recommended that they maintain an altitude of no more than 500 feet during transport of a diving accident victim.

DAN On-Site Neurological Assessment for Diver's History

Last Name: _____ **First Name:** _____ **MI:** _____

Date: (mm/dd/yy): _____ **Time: (hh:mm)** _____

COMPLETED BY: _____

How do you feel? _____

Symptoms? _____

Did symptoms start during descent, on bottom, during ascent, or after surfacing? _____

_____

Dive profile, breathing gas, ascent and time of surfacing, recent dive history _____

_____

_____

_____

Unusual features of dive (eg, out of air, rapid ascent) _____

Decompression computer, table _____

Difficulty with middle ear equalization? _____

Numbness, tingling? Where? _____

Pain? Where? What makes it better or worse? _____

Rate the pain on a scale of 0 (no pain) to 10 (the worst pain imaginable) _____

Shortness of breath? _____

Ringing or buzzing in ear? _____ Decreased hearing? _____

Dizziness? Vertigo? _____

"Vertigo" implies a sensation of the world spinning around. Vague "dizziness" is not vertigo.

Weakness? _____

Difficulty walking? If so, is this due to difficulty with balance or leg weakness? _____

Nausea, vomiting? _____ Able to urinate? _____

From "observer" (eg, dive buddy, companion) _____

Confirm dive profile _____

His/her version of events _____

_____

_____

Did the diver breach safe procedures (eg, ascent rate, out of air, was he/she breathing during ascent)?

_____

Has the diver been acting inappropriately? _____

Was there loss of consciousness, seizure? _____

Fig. 131.10 The Divers Alert Network (DAN) On-Site Neurological Assessment for Diver's History.

BOX 131.4 Diving Disorders That Require Recompression Therapy

Decompression sickness type I
Decompression sickness type II
Arterial gas embolism (AGE)
Contaminated air (carbon monoxide poisoning)

In addition to recompression therapy, several adjunctive treatments are proposed in the treatment of DCS and AGE. The treatment or prevention of hypothermia may increase tissue perfusion and prevent off-gassing. Anticoagulants to prevent deep venous thromboembolism may be considered in patients with paralysis with long transport times. Intermittent pneumatic compression devices are alternative therapeutic measures. Seizures may be managed with standard doses of benzodiazepines; however, mannitol should be avoided. Spinal DCS patients often develop urinary retention requiring bladder catheterization.

BOX 131.5 Diving Disorders That Do Not Require Recompression Therapy

Middle ear barotrauma (MEBT)
External ear barotrauma
Inner ear barotrauma (IEBT)
Barosinusitis
Facial barotrauma
Nitrogen narcosis
Oxygen toxicity
Pneumothorax
Pneumomediastinum
Subcutaneous emphysema
Alveolar hemorrhage
Alternobaric vertigo (ABV)
Barodontalgia
Gastrointestinal barotrauma
Avascular osteonecrosis

Urinary catheter (and endotracheal tube) balloons should be inflated with saline (not air) before recompression therapy is initiated.

The head-down position (Trendelenburg) has traditionally been advocated to prevent migration of intra-arterial bubbles to the brain, however, it may actually result in worsening cerebral edema and intracranial pressure and is no longer recommended. Transport of the patient with AGE in a flat supine position is recommended to maximize arterial-venous flow.

Suspected carbon monoxide poisoning from contaminated air supplies in a diving environment should be treated immediately with high-flow normobaric 100% oxygen and may require hyperbaric oxygen therapy if neurologic symptoms are present. Consultation with a hyperbaric specialist or medical toxicologist is recommended.

Diving Disorders Not Requiring Recompression Therapy

Diving disorders that do not require recompression therapy are summarized in Box 131.5.

External Ear Barotrauma

Treatment of external ear barotrauma includes cleaning of the external canal and removal of foreign bodies. Earplugs should not be worn when diving.

Middle Ear Barotrauma

Prevention of MEBT requires that the diver equalize the pressure in both middle ears. Any diver who cannot clear both ears on the surface should not dive. The diver should not perform a forceful Valsalva maneuver during descent or ascent to clear the ears because of the risk of ABV, round or oval window rupture (descent), or pulmonary barotrauma (ascent). The prophylactic use of pseudoephedrine (60 mg taken orally 30 minutes before diving) or oxymetazoline nasal spray may reduce the incidence and severity of MEBT. The use of these medications to facilitate diving with symptoms of an upper respiratory infection, however, is not recommended. Antihistamines should be avoided before diving because these agents induce dry mouth when breathing compressed air and drowsiness. Sinusitis and upper respiratory infections increase the likelihood of suffering barotitis. Diving should be avoided during and for 2 weeks after the resolution of an upper respiratory infection. Persistent symptoms may require otolaryngology consultation.

Treatment of uncomplicated serous otitis from MEBT includes topical nasal vasoconstrictors, such as phenylephrine and oxymetazoline hydrochloride, and repeated Frenzel maneuvers to displace the fluid through the eustachian tube. The *Frenzel maneuver* is performed by pinching the nose, placing the tongue on the roof of the mouth, as far forward as possible, and gently moving the back of the tongue upward, as when starting to swallow. This is repeated as many times as necessary until equalization occurs. If the physical examination reveals a ruptured tympanic membrane, prophylactic treatment should also include an oral antibiotic. Oral steroids (prednisone) may speed recovery when a seventh nerve palsy is diagnosed in conjunction with a perforated tympanic membrane, although this disorder is typically self-limited. Diving must also be suspended until the tympanic membrane heals to prevent calorically induced vertigo. Outpatient follow-up with an otolaryngologist is recommended.

Internal Ear Barotrauma

A conservative treatment approach to IEBT includes bed rest for 5 to 7 days with the head elevated, avoidance of straining or the Valsalva maneuver, and decongestants to facilitate drainage of the middle ear. Early surgical intervention may benefit patients with total or near-total hearing loss but is not effective in isolated high-frequency hearing loss.[11] All patients with suspected IEBT should be referred to an otolaryngologist, because IEBT suggests significant injury to the cochleovestibular system.

Barosinusitis

Treatment of barosinusitis is typically conservative, including the use of decongestants and occasionally, antibiotics. If symptoms persist, referral to an otolaryngologist should be considered. The patient should be advised not to dive until any underlying respiratory infection or acute inflammatory process has resolved.

Facial Barotrauma

The victim of facial barotrauma may have a dramatic appearance, but the condition is usually benign and requires no specific treatment. The patient should be advised not to resume diving until facial edema resolves.

Nitrogen Narcosis

Nitrogen narcosis symptoms should resolve on ascending as the partial pressure of nitrogen decreases. Persistent symptoms should prompt a search for other causes, such as DCS, cerebral AGE, contaminated air, and near drowning.

Pulmonary Barotrauma

With the exception of AGE, none of the pulmonary barotrauma disorders (pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage) require recompression therapy. Treatment with 100% oxygen may aid in the resolution of these disorders. Tube thoracostomy may be required for divers undergoing recompression therapy to prevent a tension pneumothorax. Catheter aspiration of the pneumothorax may be an acceptable alternative to tube thoracostomy if the patient does not receive positive-pressure ventilation or recompression therapy.

The evaluation and management of pneumomediastinum includes observation, monitoring, and serial chest radiographs to ensure that no coexisting pneumothorax develops. One hundred percent oxygen therapy may hasten the resolution of symptoms.

Alternobaric Vertigo

Oral and intranasal decongestants may be indicated if symptoms persist. Myringotomy is occasionally required. Outpatient follow-up with otolaryngology is recommended for persistent symptoms.

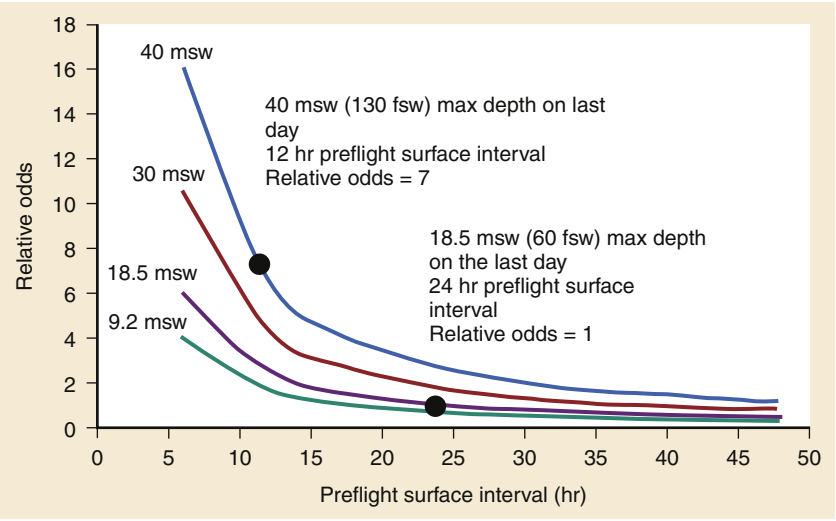

Fig. 131.11 The risk of decompression sickness (DCS) relative to flying. *fsw,* Feet of seawater; *msw,* meters of seawater. (From: Freiberger JJ, et al. The relative risk of decompression sickness during and after air travel following diving. *Aviat Space Environ Med.* 2002;73:983.)

DISPOSITION

Divers should be aware that commercial airliners may be pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight. Many cases of DCS have a delay in the onset of symptoms in divers who fly after diving even if they are symptom-free before departure. Divers who experience DCS symptoms before departure and still elect to fly, are more likely to have type II DCS, less likely to achieve complete relief after recompression, and more likely to have residual symptoms for at up to 3 months.

The relative risk for development of DCS increases with longer dive times at significant depth and shorter preflight surface intervals (Fig. 131.11). Flying should be delayed for at least 12 hours after diving if less than 2 hours of total dive time was accumulated in the preceding 48 hours. For multiple-day, unlimited diving, flying should be delayed for at least 24 hours. Patients recompressed after DCS or AGE should not fly for at least 72 hours.

United States Navy guidelines recommend that the patient not return to diving for 7 days after recompression for type I DCS and for 4 weeks after type II DCS. Divers who experiences DCS type II symptoms or AGE should be discouraged from future diving again and may referred to dive specialist for further recommendations.

After treatment for pulmonary barotrauma or DCS, divers should be referred to a dive specialist to consider if they require further evaluation to determine if there are any preexisting conditions (e.g., bullae, PFO or left-to-right shunts) prior to diving. A history of any major diving-related injury is a clear risk factor for future events.

The author wishes to thank Richard L. Byyny and Lee W. Shockley for their valuable contributions and expertise in previous chapter editions.

CHAPTER 131: QUESTIONS AND ANSWERS

1. When is a diver most likely to suffer barotrauma?

a. When the diver also suffers from decompression sickness (DCS)
b. When the diver is at extreme depth
c. When the diver is closest the surface
d. When the diver stays at depth for an extended period of time
e. When the diver uses specialized gas mixtures with decreased partial pressure of nitrogen

Answer: C. Barotrauma refers to injuries due to pressure changes. Boyle's law states that pressure and volume are inversely proportional ($P \times V = k$ or $P_1V_1 = P_2V_2$). As the pressure decreases, the volume of gas increases and can damage gas-filled structures (sinuses, inner/middle ears, lungs, and intestines). The incremental changes in pressure (and therefore volume) are greatest at the surface, so barotrauma most commonly occurs near the surface (either at the beginning or at the end of a dive). Long or deep dives are not required for barotrauma but predispose to decompression illness due to the build-up of tissue nitrogen which comes out of solution during ascent.

2. A 55-year-old man presents with the acute onset of left-sided weakness and confusion. Family members report that they are on vacation and had just finished scuba diving when the patient complained of chest pain, became confused, and stopped moving his left arm and leg. This happened 30 minutes ago. The patient has no known medical history and takes no medications. Physical examination reveals a drowsy and confused male who follows commands but does not move his left arm or leg. His blood pressure is 162/98 mm Hg, and his other vital signs are within normal limits. What is the appropriate treatment?

a. Computed tomography (CT) of the brain
b. Endotracheal intubation
c. Intravenous labetalol
d. Intravenous tissue plasminogen activator
e. Recompression in a dive chamber

Answer: E. This patient has suffered an arterial gas embolism (AGE). In AGE, air bubbles gain access to the arterial circulation and can cause mechanical obstruction of the artery. Symptoms can mirror an acute thrombotic or embolic event including myocardial infarction or stroke. Treatment with 100% oxygen should be instituted immediately, but the only definitive treatment is emergent recompression.

3. Which of the following individuals should be advised not to dive?

a. A 10-year-old boy with no known medical problems
b. A 19-year-old woman with no medical problems but who just landed from an intercontinental commercial flight
c. A 20-year-old man with well-controlled asthma
d. A 27-year-old woman who is 20 weeks pregnant
e. A 70-year-old man with asymptomatic coronary artery disease

Answer: D. Upon surfacing, small nitrogen bubbles form in the circulation of all divers. If proper technique is followed, these bubbles are small and asymptomatic. They form in the venous circulation and are eliminated in the lungs. However, if these bubbles are transmitted into the arterial system, embolization with serious consequences can occur. The fetus has a patent foramen ovale (PFO) and ductus arteriosus, both of which would allow air to bypass this filtering effect of the lungs and proceed into the systemic circulation. Asthmatics can dive as long as symptoms are well controlled. There are no definite age recommendations for diving. Flying immediately after diving should be avoided; flying prior to diving is of less concern.

4. A 24-year-old woman presents with complaints of severe chest pain and shortness of breath. The symptoms started approximately 1 hour ago while surfacing from a dive. She denies loss of consciousness or other symptoms. Physical examination reveals decreased breath sounds in the right chest and crepitus in her neck; otherwise, it is normal. Vital signs are normal except for a slight tachypnea. A chest radiograph shows a moderate right-sided pneumothorax and a pneumomediastinum. She has no other symptoms or signs. You place a chest tube on her right side. What is the next course of action?

a. Computed tomography (CT) of the brain
b. CT of the chest
c. Observation and supportive care
d. Pericardiocentesis
e. Recompression in a dive chamber

Answer: C. This patient has suffered from pulmonary barotrauma. Although this injury does predispose one to arterial gas embolism (AGE), the diagnosis of AGE is clinical. The treatment for a pneumothorax from pulmonary barotrauma is the same as for a pneumothorax from another cause—that is, aspiration, catheter insertion, or chest tube placement. Management of pneumomediastinum is supportive. Recompression is only necessary for decompression sickness (DCS) or AGE, not for barotrauma.

CHAPTER 131: QUESTIONS AND ANSWERS—cont'd.

5. A 32-year-old man presents with bilateral lower extremity numbness and weakness. The patient reports several days of scuba diving without incident until after his most recent dive, when the symptoms started. Physical examination reveals bilateral lower extremity weakness and decreased sensation to pinprick and light touch. Priapism is also noted. The remainder of the physical examination and all vital signs are within normal limits. You decide that recompression therapy is indicated, but your emergency department does not have a dive chamber and the nearest chamber is 50 miles away. The patient has been accepted in transfer. What is the most appropriate way to transfer this patient?

a. Air ambulance, lying flat
b. Air ambulance, Trendelenburg position
c. Ground ambulance, lying flat
d. Ground ambulance, Trendelenburg position
e. This patient has not yet been stabilized for transport; he should remain at the current hospital.

Answer: C. This patient is suffering from spinal decompression sickness (DCS II). Recompression therapy is the treatment of choice. Unless an inordinate delay to the recompression chamber would result, anything that further decreases ambient pressure should be avoided (e.g., flying). If a patient must be flown, the aircraft should fly at the lowest possible altitude or pressurize the cabin at the highest possible pressure. Traditionally, the Trendelenburg position was advocated because it was believed that it would decrease the incidence of AGE to the brain. This is not the case. In addition, the Trendelenburg position increases cerebral edema and the incidence of coronary artery air embolism. Therefore, the Trendelenburg position should not be used for patients with diving injuries.

6. You decide that a 27-year-old patient with an arterial gas embolism (AGE) following scuba diving requires recompression therapy. Which of the following treatments should be initiated before hyperbaric therapy?

a. Administer 40% oxygen.
b. Administer steroids.
c. Ensure that the endotracheal tube and urinary catheter balloons are filled with water, rather than air.
d. Place prophylactic thoracostomy tubes bilaterally.
e. Place the patient in the Trendelenburg position.

Answer: C. 100% normobaric oxygen is standard of care during evaluation, treatment and transport. Inflate endotracheal tube and urinary catheter balloons with sterile saline. There is no evidence that steroids are effective. The Trendelenburg position increases intracranial pressure and facilitates coronary gas embolization.

High-Altitude Medicine

N. Stuart Harris

KEY CONCEPTS

- All forms of altitude illness can be treated with oxygen and rapid descent.
- The diagnosis of acute mountain sickness requires the presence of headache in the setting of a recent elevation change to greater than 8,000 feet. Additional nonspecific symptoms may include nausea, anorexia, and fatigue. Those with significant symptoms should not ascend further until symptoms improve.
- Patients with mild high-altitude pulmonary edema may be treated in place if experienced providers and treatment options exist. Patients with moderate high-altitude pulmonary edema or high-altitude cerebral edema should descend immediately.
- Dyspnea at rest is an early symptom of high-altitude pulmonary edema. More advanced findings include rest tachypnea, cough productive of frothy sputum, and altered mentation. Treatment involves oxygen and descent.
- Altered consciousness and cerebellar ataxia are early signs of high-altitude cerebral edema. Failure to initiate immediate treatment with oxygen, descent, and dexamethasone can result in permanent disability or death.
- Acute mountain sickness may be prevented by using acetazolamide or dexamethasone. Symptoms can be controlled with analgesia and antiemetics. High-altitude pulmonary edema may be prevented using nifedipine. In patients unable to use nifedipine, consider inhaled salmeterol, and oral phosphodiesterase type 5 inhibitors (sildenafil [50 mg every 8 hours] and tadalafil [10 mg every 12 hours]). Temazepam (7.5 mg qhs) can safely improve sleep quality.

FOUNDATIONS

Background and Importance

Acute high-altitude illnesses result from exposure to low oxygen states caused by low atmospheric pressure (hypobaria). Syndromes of the brain and lung are the primary clinical manifestations of high-altitude illness. They result from ascent too rapid to allow for adequate acclimatization. Cerebral forms of altitude illness occur as a continuum, from common and benign acute mountain sickness (AMS), to rare, but potentially lethal high-altitude cerebral edema (HACE). High-altitude pulmonary edema (HAPE) is the primary lung syndrome. HAPE is the leading cause of death from altitude illness.

All forms of altitude illness have their origins in acute oxygen insufficiency due to hypobaria. All can be treated with oxygen and descent. Although the percentage of atmospheric oxygen is a constant 20.9%, as elevation increases, atmospheric pressure decreases and with it, oxygen availability. Human physiology is adaptable when given sufficient time to acclimatize by gradual ascent. Rapid ascent to elevations greater than 8,000 feet prevents adequate acclimatization and can lead to debilitating and deadly high-altitude illnesses. On the summit of Mt. Everest (8848 m), the partial pressure of inspired oxygen (Pio_2) is only 29% of the sea-level value. Although gradual ascents (over weeks) of Mt. Everest without oxygen are not uncommon, a rapid ascent to the same summit would result in loss of consciousness and death. Gradual ascent reduces symptoms and can save lives. Serious altitude illness typically follows from unheeded warning symptoms of mild altitude illness. The importance of patient and public education to reduce the morbidity and mortality of serious altitude illness cannot be overstated.[1]

Epidemiology

It is estimated that approximately 40 million individuals worldwide live above 8,000 feet. These individuals do not suffer acute altitude illness. Instead, it is the individual who rapidly travels to high altitude (whether for skiing, climbing, or travel) who is at the greatest risk. In the United States alone, approximately 35 million visitors travel to high-altitude recreation areas every year. Internationally, millions more travel to high mountain ranges in Europe, Asia, Africa, and South America, placing these transient sojourners at risk.[2]

The incidence and severity of altitude illness are directly related to elevation and rapidity of ascent. Other variables include prior acclimatization, individual genetic susceptibility, sleeping elevation, and duration of stay. Rapid ascent to 8000 feet is associated with an approximately 25% incidence of AMS, whereas a rapid ascent (1 or 2 days) to 14,410 feet on Mt. Rainier has rates as high as 67%. Rapidity and mode of ascent also matter; trekkers who fly into the Khumbu region to explore the Mt. Everest region are more likely to develop AMS (47%) than those who trek in from lower elevations (23%).

HACE is much less common than AMS, occurring in less than 1% of rapid ascents to more than 14,000 feet. Although rare, it carries a grave prognosis if not quickly recognized and treated. The incidence of HAPE varies from 0.01% to 2% but may be as high as 15.5% if flown directly to 14,500 feet without a chance to acclimatize at a lower altitude. Both HAPE and HACE are more common with a longer duration of visit (more than 2 days) and higher sleeping altitude.

Age may be a relative risk factor. Most studies of children suggest that they have the same incidence of AMS as adults. Younger individuals (younger than 20 years old) are more likely to have HAPE, although HAPE is extremely rare in children younger than 2 years old. Gender does not affect the incidence of AMS; however, women may have less risk for development of HAPE. No relationship appears to exist between AMS development and timing of the menstrual cycle.

The number of older travelers visiting mountain resorts is increasing. Many of these individuals have underlying health problems, including lung disease, heart disease, and hypertension. Despite these conditions, the risk for AMS in adults older than 50 years old may be less than in younger age groups. Nevertheless, there are indications that elders may not react well to acute high-altitude exposure. Pulmonary vital capacity decreases by one-third in elders ascending from sea level

to 14,000 feet for 1 week, producing a large decrease in both oxygen saturation and maximal oxygen uptake during altitude-related exercise.

Definitions

Moderate altitude is between 5000 and 8000 feet of elevation. Rapid ascent to this altitude may result in mild, transient symptoms, but severe altitude illness is uncommon. *High altitude* is between 8000 and 14,000 feet. Although most people do not experience significant arterial oxygen desaturation until they reach higher altitudes, high-altitude illness is common with rapid ascent above 8000 feet, and individuals with underlying medical problems may be predisposed to develop altitude illness at lower levels. The pathophysiologic effects of high altitude begin when the oxygen saturation of the arterial blood begins to fall below the 90% level. The sigmoidal shape of the oxyhemoglobin dissociation curve prevents a significant fall of arterial oxygen saturation (Sao_2) in most individuals until an altitude of approximately 12,000 feet. At this altitude, the steep portion of the curve is encountered, and marked oxygen desaturation may occur with relatively small increases in altitude (Fig. 132.1). Some predisposed individuals may desaturate to less than 90% at altitudes as low as 8000 feet. *Very high altitude* is between 14,000 to 18,000 feet. At this elevation, the likelihood of altitude illness is high, and the risk of serious altitude illness (HAPE and HACE) increases. *Extreme altitude* is above 18,000 feet. Although climbers using careful acclimatization schedules can transiently tolerate this elevation, complete acclimatization generally is not possible and long durations above this level result in progressive deterioration. Given limitations in physiologic reserves, climbers who become incapacitated at this elevation typically are dependent on others to survive.

Environmental Considerations

Barometric pressure decreases logarithmically as the altitude rises. The pernicious effects of altitude are due to hypobaric hypoxia; as atmospheric pressure decreases the partial pressure of oxygen (Po_2) decreases. Due to centrifugal forces, the earth is slightly flatter at the poles and bulging at the equator. The atmospheric envelope that surrounds the earth has a similar shape; therefore, at any one elevation the barometric pressure tends to be lower at higher latitudes than at the equator. Although subtle, the physiologic reserves are so limited at extreme elevations that it has been calculated that if Mt. Everest happened to be at a more northern latitude, it would be impossible to climb without supplemental oxygen.

The atmospheric envelope also undergoes seasonal variations in local thickness. In the winter, barometric pressures tend to be lower making "relative altitudes" physiologically higher. Local weather can also significantly affect the barometric pressure. A low-pressure front can reduce the barometric pressure 12 to 40 mm Hg and so increase the "relative altitude" by 500 to 2,500 feet. At extreme elevations these changes can be physiologically relevant. High-altitude illness can occur even where mountains appear distant. Although the South Pole is on a flat, barren plain, it rests at approximately 9300 ft and severe altitude illness caused by rapid transport from sea-level research facilities is not uncommon.[3]

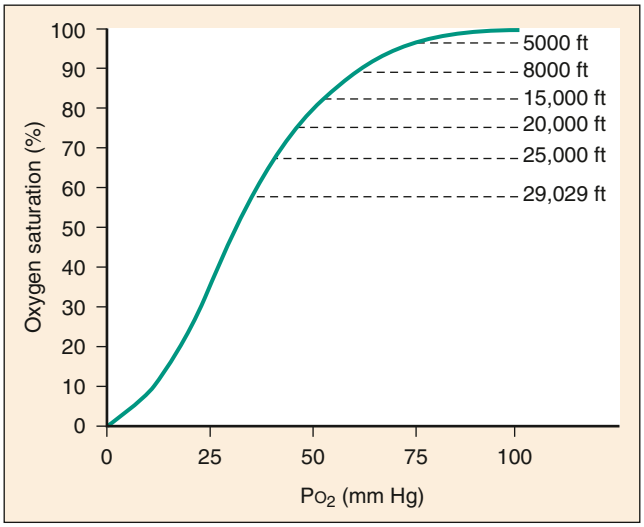

Fig. 132.1 Oxygen-hemoglobin dissociation curve. Approximate oxygen saturations are marked for several altitudes. Po_2, Partial pressure of oxygen. Anatomy, Physiology, and Pathophysiology

Acclimatization

Exposure to acute hypobaric hypoxia results in myriad physiologic responses that act to improve oxygenation. *Acclimatization* is both immediate (within minutes the carotid bodies sense hypoxemia) and continuous over months (hemoglobin increases may continue over more than 6 weeks). It involves multiple systems from mitochondrial function, protein synthesis to respiratory, cardiovascular, renal, and hematologic responses. Acclimatization begins as the oxygen saturation of arterial blood falls below sea-level values. The altitude at which this occurs depends on the rate of ascent, the duration of exposure, and the individual's physiology. Individuals with preexisting conditions that limit cellular oxygen delivery and pulmonary reserves may have a decreased altitude tolerance. Most healthy, unacclimatized visitors to high altitude will not desaturate significantly (to less than 90%) until they reach elevations higher than 8000 feet.

The risk of high-altitude illness depends, in part, on an individual's inherent ability to acclimatize. Some people acclimatize easily without having any clinical symptoms. Others may transiently have AMS during acclimatization and a few develop severe altitude illness. This variability involves many genetic and epigenetic factors that influence acclimatization. Previous successful acclimatization may be predictive of future responses for adults in similar conditions, but this may not be the case for children.

One of the most fundamental physiologic changes that occurs during acclimatization is an increase in minute ventilation. Within minutes of exposure to high altitude, the peripheral chemoreceptors in the carotid bodies sense hypoxemia resulting from the decrease in the partial pressure of oxygen in alveoli (P_{AO_2}) and signal the respiratory control center in the medulla to increase ventilation. Increased minute ventilation causes a decrease in the partial pressure of carbon dioxide in alveolus (P_{ACO_2}). As described by the alveolar gas equation, for any given inspired oxygen tension, the level of ventilation determines alveolar oxygen: as the P_{ACO_2} decreases, P_{AO_2} correspondingly increases (Box 132.1). This increased ventilation in response to hypoxic challenge is known as the *hypoxic ventilatory response (HVR)*. The magnitude of the HVR varies among individuals and may be genetically predetermined. HVR may also be inhibited or stimulated by numerous

BOX 132.1 Alveolar Gas Equation

R	Respiratory quotient

factors, including ethanol consumption, sleep medications, caffeine, cocoa, prochlorperazine, and progesterone.

As minute ventilation increases, carbon dioxide exhalation increases. Within minutes, a resulting respiratory alkalosis acts on the central respiratory center to limit further increases in ventilation. To compensate for this respiratory alkalosis, the kidneys begin to excrete bicarbonate. Acetazolamide enhances this excretion. Gradual, progressive renal excretion of bicarbonate allows ventilation to rise slowly, reaching a maximum after 6 to 8 days at a given altitude. An individual's HVR is related to their ability to acclimatize. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE. For the majority of people with intermediate HVRs, however, ventilatory drive appears to have no predictive value for AMS development.

The stress of acute hypoxia leads to rapid release of catecholamines. This results in increased cardiac output and elevations in heart rate, stroke volume, blood pressure, and venous tone. Except at extreme altitudes, acclimatization over weeks results in the gradual return of the resting heart rate to near sea-level values. Continued resting tachycardia is evidence of poor acclimatization. As the altitude increases, the maximal heart rate capacity decreases. At the limits of acclimatization, maximal and resting heart rates converge. Ultimately, for most individuals it is pulmonary, not cardiac reserves that limit high-altitude performance.

The hematopoietic response to high-altitude acclimatization includes an increase in both hemoglobin and the number of red blood cells. As a result of fluid shifts into the extravascular space, hemoglobin concentration increases up to 15% after rapid ascent to high altitude. Long-term acclimatization leads to an increase in plasma volume and total blood volume. Within hours of ascent, erythropoietin is secreted in response to hypoxemia which in turn stimulates the production of red blood cells, leading to new circulatory red blood cells in 4 or 5 days. During the next 2 months, red blood cell mass increases in proportion to the degree of hypoxemia.

Hypoxemia also results in an increase in 2,3-diphosphoglycerate, causing a rightward shift of the oxyhemoglobin dissociation curve, which favors a release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the oxyhemoglobin dissociation curve caused by the respiratory alkalosis from hyperventilation. The net result is a negligible change in the oxyhemoglobin curve. Some individuals with mutant hemoglobin and high oxygen-hemoglobin affinity are found to acclimatize more efficiently than their normal counterparts at moderate altitudes.

Physiologic Response to Hypobaric Hypoxia

Although acute hypoxia elicits a broad array of physiologic responses, the clinical syndromes of high-altitude illness predominantly affect the brain and lungs. Hypobaric hypoxia's effects on central nervous system homeostasis give rise to AMS and HACE. AMS is the common, benign form that unheeded, can develop into rare, but potentially lethal HACE. HAPE results from overly exuberant increases in pulmonary arterial pressures that lead to stress failures of the delicate pulmonary capillary beds.

Although discrete physiologic responses occur within minutes of exposure to acute hypoxia, the clinical syndromes of high altitude typically require hours to days to manifest themselves. AMS can develop within 4 to 8 hours of acute exposure to hypobaric hypoxia. HACE and HAPE typically occur 2 to 4 days after exposure to high altitude. Because hypobaric hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness. Instead, it appears to be the initiating factor for a complex pathologic process that leads to the development of the various clinical syndromes. The proposed mechanisms for the development of AMS, HAPE, and HACE are represented schematically in Figure 132.2.

HVR is the first response to insufficient oxygen, leading to increased minute ventilation. A robust HVR tends to be protective by encouraging compensatory ventilation. A limited HVR leads to relative hypoventilation and inadequate response to the hypoxemia of high altitude.

Centrally mediated periodic breathing associated with high-altitude exposure may result in periods of apnea during sleep, causing severe arterial oxygen desaturation, which further exacerbates hypoxemia. Significant hypoxemia initiates multiple systemic responses that involve the circulatory, pulmonary, endocrine, and central nervous systems.

Hypoxemia alters fluid homeostasis, resulting in generalized fluid retention followed by the shift of fluid into the intracellular spaces. This is manifested by peripheral edema, decreased urinary output, decreased central vascular volume, and increased body weight in patients with AMS. Several different mechanisms may account for these fluid shifts, including arginine vasopressin levels and centrally mediated sympathetic stimulation. Arginine vasopressin levels are elevated in some cases of AMS and HAPE and decreased in others. Aldosterone, plasma renin, and atrial natriuretic levels are higher in people with AMS.

HAPE results from hypoxia-induced acute pulmonary hypertension leading to stress failure of pulmonary capillaries with consequent alveolar and interstitial edema. Although exercise and cold stress at altitude may increase hypoxemia and exacerbate pulmonary hypertension, the hypoxic pulmonary vasoconstrictive response (HPVR) acts as the primary mediator. HPVR results in pulmonary arterial smooth muscle contraction within the typically low-pressure pulmonary arterial system, with consequent increases in pulmonary arterial pressures within minutes. The HPVR can vary widely between individuals and can even vary widely in different regions of the lungs of the same individual. This unevenness of pulmonary vasoconstriction within the lung is thought to contribute to the pathophysiology of HAPE. In patients with HAPE, exaggerated pulmonary arterial pressures (mean pressure 36 to 51 mm Hg) occur. Uneven vasoconstriction forces the pulmonary hypertension to be transmitted to delicate capillary vessels in an asymmetrical fashion, leading to the failure of capillary endothelium with resultant alveolar and interstitial edema. This uneven edema explains the patchy nature of the infiltrate seen on a chest radiograph with HAPE. Although elevated pulmonary arterial pressure is the sine qua non of HAPE, even marked acute pulmonary hypertension is not alone sufficient to cause HAPE.

The mechanism for the uneven vasoconstriction in HAPE may be due to decreased nitric oxide bioavailability at the pulmonary tissue level. That HAPE has its origins in acute pulmonary hypertension and resultant over-perfusion is supported by studies revealing that pharmacologic agents that limit excessive rises in pulmonary artery pressure prevent HAPE.

Once mechanical injury and pulmonary edema occur, other factors come into play. Acute inflammatory mediators appear and likely contribute to worsening lung function. As alveolar fluid accumulates, impairment in a patient's transepithelial sodium transport may decrease their ability to clear alveolar fluid worsening HAPE. Sodium channel–mediated alveolar fluid clearance is upregulated by inhaled beta-adrenergic agonists, which have been proven to decrease risk of HAPE.

Preexisting inflammation may also be a risk factor for HAPE. Particularly in children, preexisting respiratory infection during ascent to high altitude increases susceptibility to HAPE. Inflammation may "sensitize" the pulmonary endothelium to mechanical injury and increase susceptibility to alveolar fluid accumulation and HAPE during ascent.

The definitive etiology of the cerebral forms of altitude illness remains unclear. Evidence suggests that clinical manifestations of AMS

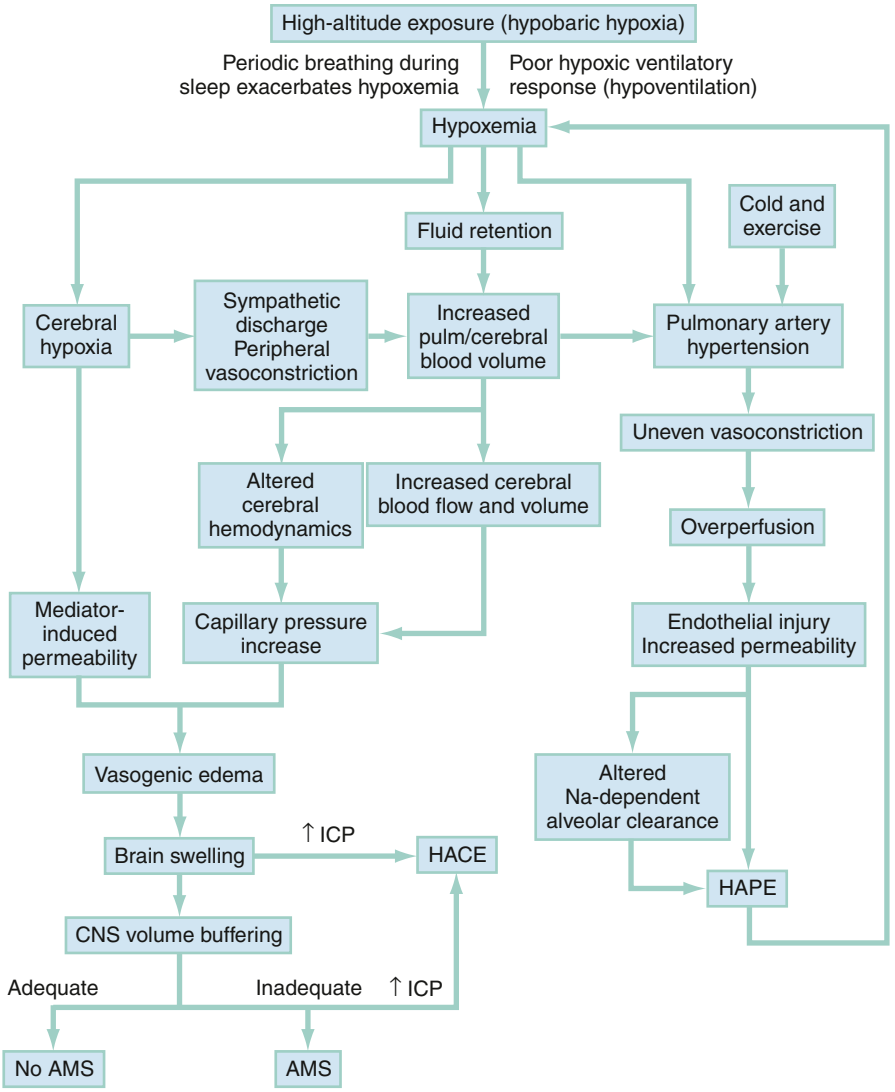

Fig. 132.2 Flowchart of proposed mechanisms for the development of acute mountain sickness *(AMS),* high-altitude pulmonary edema *(HAPE),* and high-altitude cerebral edema *(HACE). CNS,* Central nervous system; *ICP,* intracranial pressure.

and HACE result from the combined effects of altered cerebral hemodynamics and inflammatory mediators. Within minutes of exposure to hypoxia, cerebral vasodilation occurs with increased arterial blood velocity and volume. Hypocapnia (secondary to increased ventilation) creates a countervailing cerebral vasoconstriction, however, the overall effect is one of increased cerebral blood flow. Given the rigid confines of the skull, increases in intracranial blood volume require compensatory changes in the brain and cerebral spinal fluid or intracranial pressures will increase. CNS hypoxemia leads to impaired vascular autoregulation, causing increased pressures within the brain's capillary beds. In addition, systemic hypertension from strenuous exercise at high altitude may overwhelm the brain vasculature, resulting in transcapillary leakage and vasogenic edema. In susceptible individuals, these hemodynamic changes are likely to contribute to clinical manifestations of AMS and HACE.

Additional circumstances, however, may be necessary for the development of vasogenic edema and clinical symptoms. Inflammatory mediators may contribute to edema formation. Vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, mitochondrial dysfunction, and free radical formation may alter brain endothelial permeability. The roles that these play in the pathophysiologic process of altitude illness remain unclear.

The role of vasogenic edema in AMS is still under investigation. Magnetic resonance imaging (MRI) of subjects acutely exposed to hypoxia reveal similar signal changes in both subjects with and without clinical AMS. In patients with HACE, MRI studies reveal characteristic white matter changes consistent with vasogenic edema that correlate with symptoms. Although still an area of active research, AMS and HACE pathophysiology is likely due to disturbances in the blood-brain barrier through a combination of mechanical factors and biochemical mediation of permeability.

In severe AMS, MRI studies have revealed cytotoxic edema to present. Rather than being the primary mechanism of severe AMS or HACE, this cytotoxic edema is likely secondary to increased cell ischemia resulting from initial hemodynamic changes, vasogenic edema, biochemical mediators, and increased ratios of brain volume to intracranial space. Increasing data highlight the independent role of hypobaria in the development of AMS and on physiologic responses, including heart rate.[4] In experiments where subjects are exposed to identical levels of alveolar oxygen deprivation, subjects exposed to

normobaric hypoxia (by decreasing fraction of inspired oxygen [Fio_2]) alone have much lower AMS incidence than subjects exposed to a hypobaric hypoxia.

The "tight fit" hypothesis was proposed more than three decades ago to explain AMS development and its inherent individual susceptibility. This theory suggests that individuals are more susceptible to AMS and HACE as their ability to accommodate increased hypoxia-related intracranial blood volume and cerebral edema decrease. As brain volume increases from increased cerebral blood volume, the volume-buffering capacity of the central nervous system may prevent an immediate rise of intracranial pressure. As brain volume increases, the intracranial cerebrospinal fluid (CSF) is displaced through the foramen magnum into the spinal canal. Increased absorption of CSF by the arachnoid villi and decreased CSF production also occur. Individuals with less intracranial and intraspinal CSF buffering capacity have less compliance, and so experience larger increases in intracranial pressure, and become more symptomatic (i.e., manifested as AMS) from mild brain swelling. The tight fit hypothesis is supported by lumbar puncture, MRI, and computed tomography (CT) studies. More recently, optic nerve sheath ultrasonography has emerged as an early, noninvasive diagnostic tool to assess intracranial pressure. Increasing intracranial pressure correlates directly with optic nerve sheath diameter (ONSD). Studies have demonstrated that elevated intracranial pressure is associated with AMS and HACE.

ACUTE MOUNTAIN SICKNESS

Clinical Features

AMS is a clinical diagnosis. As defined by the Lake Louise Criteria, the diagnosis of AMS requires a patient to have recently ascended to an elevation to 8000 feet, with report of a headache *plus* at least one of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), general weakness or fatigue, or dizziness or lightheadedness (Box 132.2).[5] The headache may vary from mild to severe, is generally bitemporal and throbbing in nature, and is worse during the night and on awakening or when suddenly becoming upright. Anorexia and nausea, with or without vomiting, are common, and the other symptoms described can range in severity from mild to incapacitating. The disturbance of sleep caused by periodic breathing is common in all visitors to high altitudes but may be exacerbated in the setting of AMS. The symptoms of AMS develop within a few hours after arrival at high altitude and generally reach maximum severity between 24 and 48 hours, followed by a gradual resolution. Most individuals become symptom-free by the third or fourth day. Patients with continued symptoms should not ascend until symptoms abate, and descent and alternative diagnoses should also be considered.

BOX 132.2 Acute Mountain Sickness

Incidence: 12% to 67%, varies widely with elevation, rate of ascent, and individual susceptibility; rare below 8000 feet, most common with rapid ascent to altitudes above 10,000 feet.

Symptoms and signs: Headache, anorexia, nausea, fatigue, dizziness.

Treatment: Mild cases are usually self-limited and do not require treatment; discontinue ascent, rest. For moderate cases, administer acetazolamide; ibuprofen, aspirin, or acetaminophen for headache; Zofran or prochlorperazine for nausea; supplemental oxygen if available; descend if persistent or severe; add dexamethasone in severe cases.

Prevention: Gradual ascent to allow acclimatization; high-carbohydrate diet, avoidance of ethanol or smoking; acetazolamide if ascent is rapid or known history of recurrent acute mountain sickness (AMS).

Given its subjective nature, AMS is difficult to definitively diagnose in infants and pre-verbal children. AMS may be manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance. Although AMS, or a change in environment, sleeping accommodation, or eating habits may result in a fussy, unhappy child, the differential diagnosis for these nonspecific findings must remain broad. If occult bacteremia or another serious illness is suspected in a young child, descent to lower altitude for an appropriate diagnostic and treatment regimen is recommended.

Differential Diagnoses

AMS is a clinical diagnosis without objective diagnostic physical findings, therefore a broad differential diagnosis when treating these nonspecific symptoms is prudent (Box 132.3). Less common, but lethal etiologies of headache, nausea, and fatigue must be considered before the relatively benign diagnosis of AMS is made. Any evidence of ataxia or altered mentation suggests HACE or other malignant etiology and mandates immediate descent. Benign focal neurologic findings and transient global amnesia have been described at altitude but should be assumed to be malignant in etiology until proven otherwise. Acute carbon monoxide (CO) poisoning should also be considered in high-altitude settings and is most commonly detected in poorly ventilated shelters near campfires, stoves or gas-powered generators used for heat, cooking, and fuel. Physiologically, when coupled with hypobaric hypoxia, carbon monoxide exposure is more dangerous in cold high-altitude locations than in other environments. Although dyspnea on exertion is universal and expected at high altitudes, dyspnea at rest suggests HAPE and warrants a careful examination for pulmonary edema.

Diagnostic Testing

Serial measurement of ONSD using ultrasound has demonstrated that subjects with symptoms and signs of worsening AMS or HACE have enlarged ONSDs on serial measurements, which may prove a useful adjunct in the diagnosis and monitoring of AMS and HACE (Fig. 132.3). Given significant individual variability in ONSD, isolated ONSD ultrasonography at a single point in time has little utility in the diagnosis of AMS.

Management

Patients with AMS should not ascend to a higher sleeping altitude until symptoms resolve to allow acclimatization to occur. Continued ascent exacerbates the underlying pathologic processes and may lead to severe AMS or lethal HACE. If patients develop neurologic abnormalities

BOX 132.3 Acute Mountain Sickness Differential Diagnosis

- Tension headache
- Viral syndrome
- Alcohol intoxication/toxidrome
- Carbon monoxide (CO) poisoning
- Dehydration
- Caffeine withdrawal
- Migraine headache
- Infectious (meningitis, encephalitis/viral syndrome)
- Intracranial hemorrhage or mass
- Central nervous system aneurysm
- Venous sinus thrombosis
- Abdominal process (e.g., gastroenteritis)
- Acute angle closure glaucoma/ocular process

Fig. 132.3 Diagnostic image of optic nerve sheath ultrasonography. (A) Probe positioning: This study is typically performed with the subject supine and with eyes closed. The probe is placed on the closed lid, lateral of the center of the pupil, and adjusted until a longitudinal, cross-sectional image of the optic nerve (deep to the retina) is obtained. For clarity, this figure does not show the use of ultrasound gel, occlusive dressing, or a high-frequency (7- to 10-MHz) linear probe. (B) Optic nerve sheath ultrasonogram with measurements. (Courtesy N. Stuart Harris, MD.)

(e.g., ataxia or altered mentation) or evidence of severe pulmonary edema, immediate descent is indicated.[6]

Mild AMS may be treated by symptom management and cessation of ascent until acclimatization occurs. This may take 1 to 4 days. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention necessitates descent. A descent of as little as 500 feet may be sufficient. Descent of 1500 to 3000 feet effectively reverses high-altitude illness in most cases. Descent should be continued until symptom improvement is seen, and efforts to minimize exertion should be instituted during the descent.[7]

Oxygen Therapy

All forms of altitude illness, including AMS, are effectively treated with supplemental oxygen. In mild AMS, supplemental oxygen may be helpful but is not essential. For severe forms of altitude illness, oxygen can be lifesaving. In resort settings, oxygen can often be rented directly from the hotel or condominium. For AMS, low flow oxygen (1 to 2 L/min), including small amounts during sleep, is often sufficient. In the wilderness, oxygen tanks are cumbersome, heavy, and are usually unavailable in adequate quantities. To overcome this, remote clinics often use solar-powered oxygen generators. In resource-limited settings, oxygen therapy is reserved for the more serious manifestations of high-altitude illness. Hyperbaric therapy with a portable fabric chamber that simulates descent is also effective.

Analgesics and Antiemetics

Symptomatic treatment of headache and nausea can be beneficial during the course of mild AMS. Aspirin, ibuprofen, and acetaminophen are useful for the treatment of high-altitude headache. Narcotic analgesics should be avoided because of depression of the hypoventilation response (HVR) and respiratory drive during sleep. For nausea and vomiting, prochlorperazine, unlike other antiemetics, stimulates the HVR and is preferred.

Acetazolamide

Periodic breathing causes insomnia, which is best treated with the respiratory stimulant acetazolamide.[8] Doses of acetazolamide as low as 62.5 mg to 125 mg bid may prevent intermittent breathing and eradicate insomnia.[9] Most benzodiazepines and other sedative-hypnotics should be avoided because of their tendency to decrease ventilation during sleep. Even individuals who have previously used diazepam at lower altitudes without difficulty describe unusual reactions, including agitation, hallucinations, and disorientation when this agent is used at high altitude. Studies suggest that low doses of benzodiazepines in combination with acetazolamide are safe at high altitude and can improve sleep quality and reduce episodes of nocturia without increasing oxygen desaturation. Nonbenzodiazepine sleep agents (such as zolpidem and zaleplon) do not depress ventilation and may prove useful in AMS-related insomnia.

Acetazolamide accelerates acclimatization and, if given early in the development of AMS, may rapidly resolve symptoms. Although the optimal dose has not yet been definitively established, a dose of 250 mg of acetazolamide at the onset of symptoms and repeated twice daily is effective therapy for AMS. The treatment of AMS in children is not formally studied, but anecdotal experience supports the use of acetazolamide in children. The dose for children is 2.5 mg/kg/dose every 6 to 8 hours or 125 mg given twice daily to a maximum of 250 mg.

Acetazolamide has myriad beneficial effects. By acting as a carbonic anhydrase inhibitor, it enhances renal bicarbonate diuresis and so improves renal correction of the ventilation-related respiratory alkalosis by causing continued increased ventilation and arterial oxygenation. It improves sleep by decreasing nocturnal period breathing. Acetazolamide also acts as a diuretic and so attenuates fluid retention common in patients with AMS. It lowers CSF volume and pressure, which may play an additional role in its therapeutic effect. In addition, it has positive effects beyond its role as a carbonic anhydrase inhibitor, with beneficial chemoreceptor effects on ventilatory drive, alterations of cerebral blood flow, relaxation of smooth muscles, and upregulation of fluid resorption in the lungs.

The most common adverse reactions to acetazolamide are paresthesias and polyuria. Less common reactions include nausea, diarrhea, drowsiness, tinnitus, and transient myopia. Carbonic anhydrase inhibition at the tongue causes dysgeusia, altering the flavor of carbonated beverages, including carbonated beers (of note, nitrogenated beers are unaffected). Acetazolamide is a sulfa compound and carries a low risk of cross-reactivity for individuals with an allergy to sulfa antibiotics. Patients with known sulfonamide allergy may consider administration of a trial dose of acetazolamide in a controlled environment before ascent. Acetazolamide is contraindicated in patients with a history of anaphylaxis or severe skin reactions to any sulfa-containing medication, and it should be avoided in breast-feeding mothers and pregnant women.

Dexamethasone

Dexamethasone is an effective alternative treatment of moderate to severe AMS. An initial dose of 8 mg followed by 4 mg every 6 hours is recommended. As a treatment option, concurrent use with acetazolamide is advocated by some to promote acclimatization. Dexamethasone is known to have antiinflammatory properties. Additionally, it may reduce cerebral blood flow and block the action of vascular endothelial growth factor. Reduction of AMS symptoms with the use of dexamethasone may be the result of these or its euphoric effects. Prophylactic use of dexamethasone should generally be reserved for use in individuals forced to rapidly ascend (e.g., professional mountain search and rescue operations). Although dexamethasone effectively relieves the symptoms of AMS, unlike acetazolamide, it does not enhance acclimatization. If used as a prophylactic agent to allow ascent beyond physiologic acclimatization, acute cessation can result in rapid onset of severe altitude illness. For treatment, use should be limited to patients with acetazolamide intolerance or more advanced cases of AMS, especially to help facilitate descent. Common side effects of dexamethasone include gastrointestinal irritation, gastritis, esophagitis, altered mood, and gastroesophageal reflux disease (GERD). Dexamethasone should not be used for more than 3 days for this indication because more serious side effects such as GI bleed and altered mental status with aberrant behavior have been described.

Disposition

Individuals with AMS may resume their ascent after symptoms resolve. Consider prophylactic acetazolamide if they are to further ascend. Further elevation gain should be halted if symptoms recur.

Prevention

The symptoms of mild AMS are generally benign and well-tolerated. For some, however, they are unpleasant and debilitating to the point that travel, business, or vacation plans are interrupted. Up to 50% of individuals with AMS report a decrease in activity.

The best method of prevention is a gradual or staged ascent that allows adequate time for acclimatization; however, the time constraints of many vacationers and inexperienced guides often make such an ascent profile unrealistic. The 19th-century climbing adage, "Climb high, sleep low," is born of experience: during acclimatization, hypoxic nadirs encountered during sleep are much greater than those during waking hours. Decreased respiratory drive during sleep can lead to increasing symptoms of poor acclimatization. Ideally, the first night should not be spent at an altitude higher than 9200 feet, with a subsequent increase (to a new sleeping altitude) of not more than 1600 feet each night. One extra night of acclimatization (at the same sleeping altitude) should be added for every 3000 to 5000 feet of altitude gain above 10,000 feet. Excursions to higher altitudes during the day with a return to a lower sleeping altitude aid in successful acclimatization.

Pre-exposure to artificially hypoxic environments to prompt acclimatization and to decrease symptoms of high-altitude illness have been studied. Pre-exposure regimens (typically in normobaric, hypoxic tents) lasting less than 8 to 12 hours appear to offer limited protection from subsequent altitude exposure.

Mild to moderate exercise likely aids acclimatization; however, overexertion can contribute to the development of AMS. Maintaining adequate hydration—targeting relatively clear (dilute) urine and normal urine output—is also recommended. No data support recommendations for hyperhydration that is sometimes promoted in the lay literature. In fact, consumption of excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness. Balanced electrolyte solutions are recommended (premixed or prepared with purified water).

The elevation goal, rate of ascent, and prior history of altitude illness should be considered in the assessment of the risk for development of altitude illness and the choice of prevention strategies (eTable 132.1). Individuals in low-risk situations should not need medications for prophylaxis. Ascent should be gradual to prevent illness. In some cases, such as arrival at a high-altitude airport (e.g., Lhasa, Tibet, 11,995 ft) or the immediate dispatch of rescue personnel to high altitude, a slow or staged ascent is not possible. Mountain climbers commonly ascend at rates that are higher than recommended, and some individuals continue to suffer AMS symptoms despite gradual ascent. Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical fall into the moderate- and high-risk categories and should consider prophylactic medication in addition to gradual ascent.

Numerous studies demonstrate the effectiveness of acetazolamide in prevention of AMS in adults. Lower dosages provide prophylaxis similar to that of higher dosages with fewer adverse reactions. A dose of 125 mg twice daily starting 24 hours before ascent and continuing for the first 2 days at high altitude is effective. When compared with higher doses, this dose has a lower likelihood of noxious side effects. Although it is unstudied, the recommended dosage of acetazolamide for AMS prophylaxis for children is 2.5 mg/kg/dose up to 125 mg total given twice daily, and this weight-based approach may reduce side effects in smaller adults. Ibuprofen compared with acetazolamide is equally efficacious in preventing headache.

Dexamethasone also prevents AMS. The lowest effective prophylactic dosage is 2 mg every 6 hours or 4 mg every 12 hours. Some patients experience the rapid onset of AMS after dexamethasone is discontinued. Dexamethasone does not facilitate acclimatization but rather reduces nausea and enhances mood. In most cases, dexamethasone use should be reserved for treatment of AMS rather than for prophylaxis. Military or rescue personnel rapidly ascending to high altitude and individuals with acetazolamide intolerance are candidates for prophylaxis with dexamethasone. The combination of acetazolamide and dexamethasone may be more effective than either drug alone.

Oxygen is an effective prophylactic modality for rescue personnel. Adequate supplies should be available to ensure the safety of all team members for the entire duration of the rescue. Air drops of oxygen can be lifesaving when weather or terrain prevents the immediate arrival of rescue personnel.

HIGH-ALTITUDE PULMONARY EDEMA

Clinical Features

HAPE is the most common fatal manifestation of severe high-altitude illness (Box 132.4). Although HAPE is uncommon below 10,000 feet, it can occur and even be fatal at altitudes below 8000 feet. Episodes occurring between 8000 and 10,000 feet are usually related to heavy exercise or comorbidities; but at higher altitudes, pulmonary edema can also occur at rest or with light activity.

Some individuals are susceptible and experience HAPE with each ascent to altitude, but many patients have a single episode of HAPE and subsequently are able to return to high altitude without a recurrence. Less commonly, those with multiple previously uneventful high-altitude exposures may still develop HAPE. Individuals, especially children and young adults, who have been residents at high-altitude locations for extended periods may have pulmonary edema develop on re-ascent from a trip to low altitude. This phenomenon has been termed *reentry HAPE*.

The initial symptoms of HAPE typically begin insidiously 2 to 4 days after arrival at high altitude. Most cases occur during the second night, but HAPE may develop rapidly, with early symptoms apparent after

ETABLE 132.1 Risk Categories for Acute Mountain Sickness[a]

Risk Category	Description
Low	Individuals with no prior history of altitude illness and ascending to ≤9200 feet
	Individuals taking ≥2 days to arrive at 8200 to 9800 feet with subsequent increases in sleeping elevation <1600 feet per day
Moderate	Individuals with prior history of AMS and ascending to 8200 to 9200 feet in 1 day
	No history of AMS and ascending to >9200 feet in 1 day
	All individuals ascending >1600 feet per day (increase in sleeping elevation) at altitudes above 9800 feet
High	History of AMS and ascending to ≥9200 feet in 1 day
	All individuals with a prior history of HAPE or HACE
	All individuals ascending to >11,500 feet in 1 day
	All individuals ascending >1,600 feet per day (increase in sleeping elevation) above >11,500 feet
	Very rapid ascents

[a]Altitudes listed in the table refer to the altitude at which the person sleeps. Ascent is assumed to start from elevations <4000 feet. The risk categories described pertain to unacclimatized individuals.
AMS, Acute mountain sickness; *HACE,* high-altitude cerebral edema; *HAPE*, high-altitude pulmonary edema.
Modified from: Luks AM, et al. Wilderness Medical Society consensus guidelines for the prevention and treatment of acute altitude illness: 2019 update. *Wilderness Environ Med.* 2019;30(4S):S3eS18.

BOX 132.4 High-Altitude Pulmonary Edema

Incidence: 0.01% to 15%, varies with elevation and rate of ascent; rare below 8000 feet and more common above 14,500 feet; typically occurs 2 to 4 days after arrival at high altitude.

Symptoms and signs: Dyspnea at rest, cough, anorexia, cyanosis, rales, tachypnea, tachycardia.

Treatment: Patients with mild cases may recover with bed rest. Moderate cases can be treated with bed rest and supplemental oxygen if clinical monitoring is available. Severe cases require oxygen and descent; use hyperbaric therapy if available; if oxygen or descent is unavailable, then nifedipine 30 mg slow-release every 12 hours; consider acetazolamide (125–250 mg every 12 hours) and tadalafil 10 mg every 12 hours (limited data).

Prevention: Gradual ascent and recognition of early AMS symptoms so that ascent is stopped before HAPE develops; with previous HAPE history, use nifedipine 30 mg slow-release every 12 hours during ascent, then continue for 3 days (monitor for hypotension).

AMS, Acute mountain sickness; *HAPE,* high-altitude pulmonary edema.

just a few hours at high altitude. Marked dyspnea on exertion, fatigue with minimal-to-moderate effort, prolonged dyspneic recovery time, and dry cough are early manifestations of the disease. The symptoms of AMS usually occur concurrently with the development of HAPE.

As the HAPE patient deteriorates, usually through the night, the dyspnea intensifies with effort and is unrelieved by rest. Dyspnea at rest is a red flag warning. The cough may become productive of copious amounts of clear, watery sputum. Hemoptysis may be seen in severe cases. As the condition intensifies, cerebral edema or simply severe hypoxemia may cause central nervous system dysfunction, such as ataxia and altered mentation. Coma may follow and precede death in a few hours if immediate oxygen therapy and descent are not instituted.

The physical examination reveals a few rales in patients with mild HAPE, usually found in the region of the right middle lobe, progressing to unilateral or bilateral rales and then to diffuse bilateral rales, rhonchi, and gurgles audible without a stethoscope. Neck veins are not distended. Cyanosis of the nail beds alone may progress to severe central cyanosis. Tachypnea and tachycardia become more pronounced as severity increases. Elevated temperatures are common, and a concurrent respiratory tract infection is occasionally seen, especially in children.

Differential Diagnoses

It is prudent to maintain a wide differential diagnosis in assessing patients with acute dyspnea at high altitude (Box 132.5). Although HAPE occurs at high altitude, so does acute coronary syndrome, pulmonary embolism (PE), congestive heart failure (CHF), and pneumonia.

Pneumonia can be misdiagnosed in the setting of HAPE because the symptoms and signs of pneumonia are similar to those of HAPE. The incidence of pneumonia and the common organisms responsible for pneumonia at high altitude are understudied, but visitors to high altitudes may be predisposed to acquire bacterial infections because of impaired T-lymphocyte function. Treat patients for HAPE who present with symptoms compatible with pneumonia at high altitude. Initiate antibiotics if there is doubt about the diagnosis of HAPE versus pneumonia. Because of decreased respiratory reserves and mild immunosuppression coincident with high-altitude exposure, the treatment of any serious pulmonary infection at high altitude requires oxygen, descent, and antibiotics.

BOX 132.5 High-Altitude Pulmonary Edema Differential Diagnoses

- Carbon monoxide (CO) poisoning
- Pneumonia
- Pneumothorax
- Pleural effusion
- Pulmonary embolism (PE)
- Acute coronary syndrome
- Acute congestive heart failure (CHF)
- Acute exacerbation of preexisting pulmonary hypertension
- Acute flare of chronic obstructive pulmonary disease (COPD)
- Acute asthma flare
- Acute exacerbations of valvular disease (insufficiency and stenosis)

High-altitude bronchitis ("Khumbu cough") and pharyngitis are common problems among climbers. They may result from the increased ventilation of cold, dry air across the upper airway mucosa, causing mucosal inflammation. Copious sputum production is sometimes seen, and antibiotic therapy is rarely helpful. Coughing spasms may be severe and require treatment with antitussives. Other therapeutic measures include hydration, lozenges, and steam inhalation.

Death from PE at high altitude is described. Given frequent travel involving long plane flights prior to many vacations at high altitude, patients may often have increased risk of deep vein thrombus (DVT) and PE. Additional predisposing factors for DVT include acute hyperviscosity due to increased hematocrit, dehydration, and forced stasis due to sleeping and sheltering in confined spaces, particularly during inclement weather conditions. The symptoms and signs of PE can mimic those of HAPE; however, embolic disease tends to have a more rapid onset, and pleuritic chest pain is a more prominent feature.

Diagnostic Testing

Ultrasonography

Ultrasound machines are portable, require limited training for effective use in this setting, and use non-ionizing radiation. As a result, serial assessments can easily be performed to gauge response to treatment. Given their portability, limited power requirements, and instant access to diagnostic data, they are the preferred modality for many remote clinical settings.

Thoracic ultrasonography allows rapid, accurate assessment for acute pulmonary edema at the bedside (Fig. 132.4). The presence of "lung comet tails" (also called *B-lines*) on thoracic ultrasound indicates extravascular water, is reproducible, quantifiable, and has been inversely correlated with oxygen saturation and clinical status in HAPE patients. The use of ultrasonography to estimate pulmonary artery pressure is an established modality for early detection and diagnosis of HAPE. Demonstration of high pulmonary artery pressures with normal left ventricular function is associated with HAPE and HAPE susceptibility.

Chest Radiographs

In HAPE patients, chest films reveal patchy alveolar infiltrates with areas of clearing between the patches. Unilateral infiltrates may be present in mild cases; however, bilateral infiltrates are seen in more advanced cases, most commonly involving the right mid-lung fields (Fig. 132.5). Pleural effusion is rare but may be present in severe cases. The extent of the edema on the chest radiograph roughly parallels the clinical severity. Of note, the radiographic findings of cardiomegaly, bat-wing distribution of infiltrates, and Kerley B-lines, which are typical of cardiogenic pulmonary edema, are generally absent in cases of HAPE.

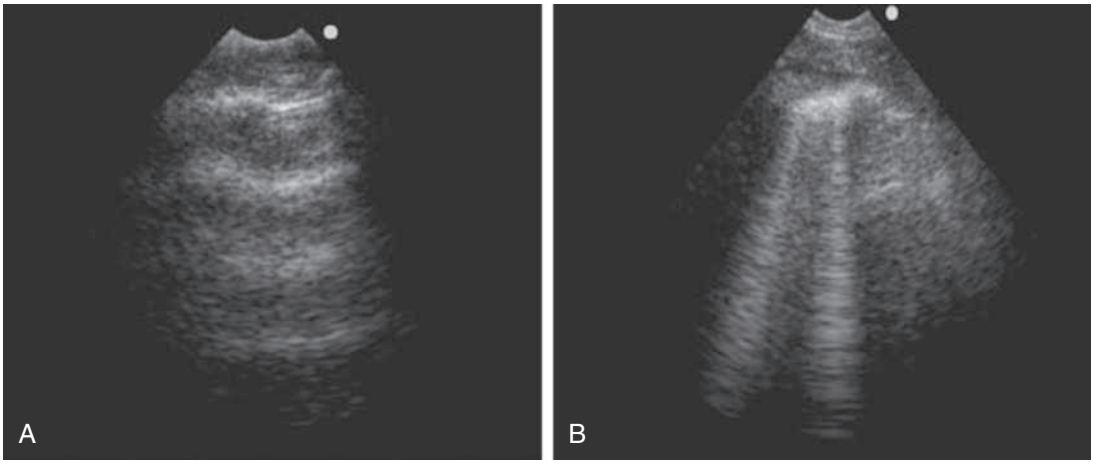

Fig. 132.4 Diagnostic image of thoracic ultrasound of lung with high-altitude pulmonary edema (HAPE). (A) Normal lung tissue is uniform "snowstorm." (B) B-lines, also known as "comet tails," are present in this patient with HAPE. They are defined as echogenic, coherent, wedge-shaped signals with a narrow origin in the near field of the image, arising from the pleural line and extending to the edge of the screen. B-lines indicate pulmonary interstitial fluid (edema). Views obtained using *low* frequency, curved probe and B-mode imaging. (Courtesy American College of Chest Physicians.)

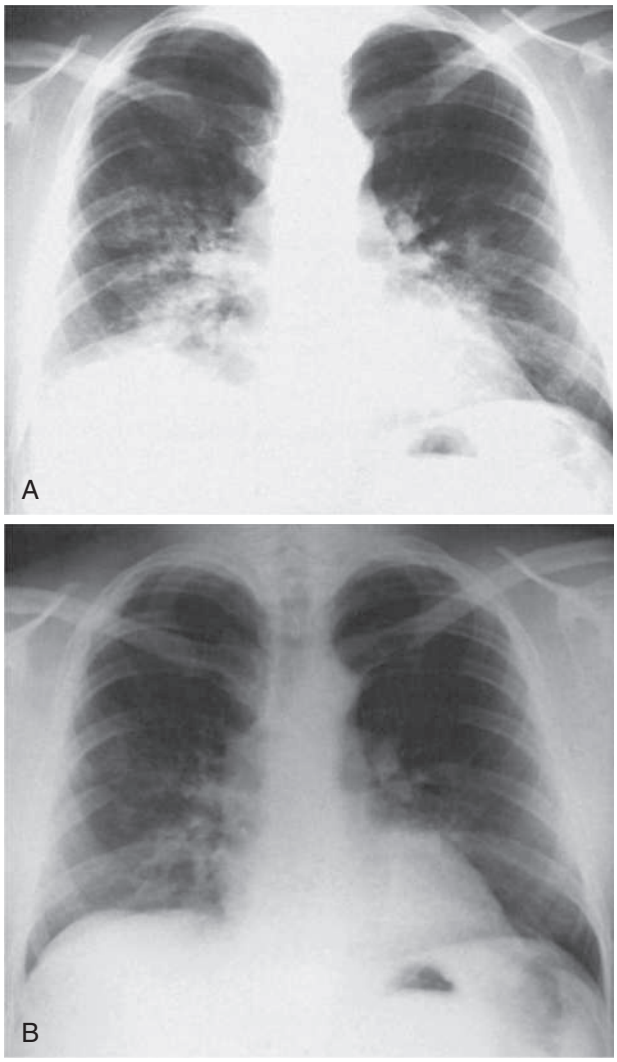

Fig. 132.5 Diagnostic image of chest radiograph of a patient with high-altitude pulmonary edema (HAPE). (A) Before treatment. (B) After treatment. (Courtesy Richard Nicholas, MD.)

Radiographic evidence of HAPE clears rapidly after initiation of treatment; some mild cases may clear in 4 to 6 hours, and most clear by 24 hours. Radiographs of patients with severe HAPE may reveal infiltrates that persist for as long as 2 weeks, even though the clinical symptoms have resolved.

Electrocardiogram and Echocardiogram

An electrocardiogram reveals tachycardia and evidence of right-sided heart strain, including right axis deviation, P wave abnormalities, tall R waves in the precordial leads, and S waves in the lateral leads. Hemodynamic studies reveal increased pulmonary vascular resistance, elevated pulmonary artery pressures, and normal pulmonary wedge pressures. Echocardiographic studies demonstrate high estimated pulmonary artery pressures, pulmonary vascular resistance, and normal left ventricular function.

Management

Descent

In remote settings, where oxygen and medical expertise may be unavailable, immediate descent to treat HAPE may be lifesaving. Delay of descent (e.g., waiting hours for rescue personnel to initiate evacuation) can lead to rapid HAPE progression and death. Descents of 3000 feet are generally adequate for a rapid recovery; however, descent should continue until symptoms resolve.

Oxygen Therapy

To minimize cold- or exercise-induced pulmonary hypertension, HAPE patients should be kept warm and should minimize exertion (Fig. 132.6). Patients with mild cases of HAPE under expert supervision have been successfully treated at altitude with oxygen, medications, and 1 or 2 days of bed rest. Oxygen administration increases the rate of improvement. Moderate cases can be treated without descent if bed rest, experienced providers, and adequate supplies of supplemental oxygen are available. Any treatment plan that does not include descent necessitates serial examinations by clinicians with experience in management of high-altitude illness.

If difficult terrain or weather conditions hamper efforts to descend, oxygen administration (or hyperbaric therapy) can be a lifesaving measure. If immediate evacuation to lower altitudes

Fig. 132.6 Clinical photograph of high-altitude pulmonary edema (HAPE) patient being treated with immediate descent in rural Nepal. Patient is provided with oxygen and descending with minimal exertion. (Courtesy Lara Phillips, MD.)

will be delayed, rescue personnel should air drop oxygen supplies. Deliver oxygen at rates of 6 to 8 L/min by mask to victims with severe HAPE until clinical improvement is seen. As patients improve, flow rates can then be lowered until recovery or descent is completed with a goal peripheral oxygen saturation greater than 90% likely sufficient. Delivery of oxygen with a continuous positive airway pressure mask will decrease work of breathing and improve alveolar fluid clearance.

Hyperbaric therapy simulates descent by increasing the available oxygen at a given altitude, as the amount of oxygen available is a function of the percentage of inspired oxygen multiplied by the barometric pressure. Although preferred with oxygen, if supplies are low, hyperbaric therapy may be employed without administration of supplemental oxygen. Several portable, lightweight (approximately 15 pounds), fabric hyperbaric chambers are available. They are pressurized manually (Fig. 132.7) and generate approximately 103 mm Hg (2 psi) above the ambient pressure. This simulates a descent of 4000 to 5000 feet at moderate altitudes, and at the summit of Mt. Everest it would simulate a descent of approximately 9000 feet. These devices can be lifesaving in patients with HAPE and HACE. They should only be used as a temporizing treatment when descent is not immediately feasible. Some previously nonambulatory patients are able to descend under their own power after a few hours of treatment in these hyperbaric chambers.

Most of the pharmacotherapies used for HAPE treatment derive their presumed efficacy from studies examining their abilities to prevent HAPE in a "HAPE-susceptible" subject population. There are few robust studies directly examining pharmacologic treatments for HAPE. Oxygen and descent remain the mainstays in treatment.

Fig. 132.7 Clinical photograph of Gamow bag, a lightweight, portable hyperbaric chamber used for rapid treatment of severe altitude illness. Note the attached foot-operated pressure pump. (Courtesy Reuben Tabner.)

Nifedipine

In addition to oxygen and descent to treat HAPE, medications that lower pulmonary artery pressure, pulmonary blood volume, and pulmonary vascular resistance or enhance alveolar fluid clearance may be useful adjuncts. Unlike pulmonary edema secondary to acute CHF, HAPE results from increased pulmonary vascular tone. It does not result from excessive intravascular volume or failed cardiac pump function. As such, diuretic therapy has no role in the treatment of HAPE and may further exacerbate volume loss in patients who are already intravascularly depleted.

One of the better studied agents for both prophylaxis and treatment of HAPE is the calcium channel blocker nifedipine. Acting as a pulmonary vasodilator, nifedipine is especially useful when oxygen is not readily available or descent is impossible. Nifedipine does not improve pulmonary hemodynamics as much as oxygen or descent do, and it does not have an additive effect when it is administered with oxygen. Treatment with 30 mg of a slow-release nifedipine preparation administered twice daily is recommended. Patients should be monitored for the development of hypotension during nifedipine administration.

Other Medications

Although phosphodiesterase type 5 inhibitors (including tadalafil and sildenafil) are known to be useful for HAPE prevention, are widely used, and are unlikely to cause acute harm in this indication, they remain unstudied for HAPE treatment. Alveolar fluid clearance is upregulated by beta-adrenergic agonists in animal models, and inhaled beta-agonists (salmeterol 125 μg inhaled twice daily) have been used anecdotally for therapy of HAPE.

The mainstay of HAPE treatment remains immediate oxygen administration (when available) and descent. Nifedipine treatment is recommended if these treatments are unavailable. No compelling evidence suggests the concurrent use of these medications with oxygen has additional benefit beyond the use of oxygen alone.

Disposition

Mild to moderate cases of HAPE can be treated with oxygen, rest, and careful monitoring. Experienced clinicians in recreational areas at moderate altitudes (e.g., Colorado ski resorts or dedicated high-altitude clinics in Nepal) administer oxygen and observe HAPE patients to ensure adequate oxygenation. These patients are then discharged to their local lodging with supplemental oxygen and monitored for improvement or deterioration. In severe HAPE, or milder cases that do

not improve with therapy, descent is warranted. Rapid recovery is usually seen after descent to lower altitudes, and observation of the patient in the emergency department to ensure adequate room air oxygenation is generally adequate. On occasion, admission to the hospital is indicated to maintain the Sao_2 greater than 90%. In the hospital, continuous positive airway pressure may improve gas exchange and decrease work of breathing in HAPE patients. Hypocapnia, alkalosis, and radiographic evidence of HAPE may persist for several days. Thoracic ultrasound allows for frequent reassessments and has been shown to closely follow resolving edema and increasing oxygen saturations.

If oxygen saturation can be maintained at greater than 90% on room air and clinical improvement is apparent, the patient can be discharged. If the patient requires air travel to return home (cabin pressures equal approximately 8000 feet), additional recovery time before travel or arrangement for supplemental oxygen administration is advised. Assessment for structural cardiac abnormalities with echocardiography is indicated if a heart murmur is detected in a patient with HAPE. An evaluation for underlying congenital heart disease is warranted after an episode of HAPE in a young child.[10]

Patients may be able to re-ascend (generally in 2 to 3 days) when symptoms resolve and oxygen levels remain acceptable off supplemental oxygen at rest and with mild exercise. Re-ascent with pulmonary vasodilator medication may be considered.

Prevention

As with all forms of serious altitude illness, two key teaching points are the most effective means of prevention and must be understood by the patient: (1) a gradual or staged ascent to allow sufficient time to acclimatize is critical, and (2) immediate cessation of further ascent at the onset of symptoms can be lifesaving. Individuals with a prior history of HAPE should also avoid extreme exertion during the first 2 days at altitude. Consider prophylactic therapy with nifedipine (30 mg extended release twice daily for 3 days) in patients with a prior history of HAPE. Less evidence exists to support the routine use of other pulmonary vasodilators for HAPE prevention.

Phosphodiesterase type 5 inhibitors are selective pulmonary vasodilators that increase cyclic guanosine monophosphate availability. Sildenafil (40 mg every 8 hours) and tadalafil (10 mg every 12 hours) have been found to be effective in preventing HAPE in HAPE-susceptible subjects. The phosphodiesterase type 5 inhibitors have the added benefit that they are less likely than calcium channel blockers to induce systemic hypotension. However, as with other indicated uses, they should not be administered to individuals concurrently taking nitroglycerin.

Although high-quality data are lacking, a few additional medication options may be considered for prevention. Dexamethasone (8 mg every 12 hours) started 2 days before ascent may prevent HAPE. To enhance alveolar fluid clearance, salmeterol 125 μg inhaled twice daily may be used as an adjunct to nifedipine in patients with a history of HAPE, although side effects are common at this high inhaled dose. Finally, clinical experience suggests that acetazolamide aids in acclimatization and prevents HAPE, with additional benefits of reducing hypoxic pulmonary vasoconstriction.

HIGH-ALTITUDE CEREBRAL EDEMA

Clinical Features

HACE is the least common but most lethal form of high-altitude illness (Box 132.6). Death from HACE typically occurs above 12,000 feet. Mild AMS can progress to severe HACE with coma in as few as 12 hours. Although severe symptoms usually develop within 1 to 3 days, they may not occur until 5 to 9 days. HACE is characterized by evidence of global cerebral dysfunction. The symptoms of severe AMS (headache, fatigue, and vomiting) as well as those of HAPE (cough and dyspnea) are often present. Patients with HACE invariably have had prior, unheeded symptoms of worsening AMS over hours to days. HACE-specific signs include ataxia, slurred speech, and altered mental status, which can range from mild emotional lability or confusion, to hallucinations and worsening obtundation that may advance to coma and death. Less commonly, generalized seizures and rarely, focal neurologic deficits may occur. HACE can also occur in children.[11]

Altered mental status and cerebellar ataxia are the most sensitive signs of early HACE. The early appearance of ataxia reflects the particular sensitivity of the cerebellum to hypoxia. Ataxia alone is an indication for immediate descent. Retinal hemorrhages are common and rarely of clinical significance. Papilledema and occasionally cranial nerve palsy also occur in the setting of increased intracranial pressure.

BOX 132.6 High-Altitude Cerebral Edema

Incidence: Lower than 1% or 2%, uncommon as a pure entity; usually associated with the presence of severe AMS and HAPE.

Symptoms and signs: Ataxia, severe headache, nausea and vomiting, altered mentation, seizures, coma.

Treatment: Immediate evacuation to a lower altitude; oxygen, bed rest, dexamethasone (8 mg PO or IV, then 4 mg q6h). Hyperbaric therapy if unable to immediately descend.

AMS, Acute mountain sickness; *HAPE,* high-altitude pulmonary edema.

BOX 132.7 High-Altitude Cerebral Edema Differential Diagnoses

- Acute cerebral vascular accident (CVA)/transient ischemic attack
- Intracranial hemorrhage
- Hypoglycemia
- Carbon monoxide (CO) poisoning
- Meningitis/encephalitis
- Hypothermia
- Intracranial mass
- Vertebral/carotid dissection or stenosis
- Acute toxidrome—alcohol, other
- Acute alcohol withdrawal/delirium tremens
- Seizure
- Transient global amnesia

Differential Diagnoses

Paroxysmal onset of symptoms should prompt consideration of other etiologies, such as hypothermia, hypoglycemia, CO poisoning, and acute cerebral vascular accidents (CVAs) (Box 132.7). A cerebral vascular lesion is suggested by abrupt onset, presence of a dense hemilateral palsy, a lack of preceding symptoms of AMS, or the persistence of signs despite adequate treatment of high-altitude illness.

Diagnostic Testing

Without advanced imaging, differentiating between HACE and acute CVA may be difficult – regardless, both are acute neurologic emergencies. Although not common, the occurrence of cerebral thrombosis and transient ischemic attacks, in the absence of high-altitude illness, have been documented at high altitude. Subsequent MRI studies of patients with HACE reveals white matter changes consistent with vasogenic edema (Fig. 132.8).[12]

Management

Successful therapy for HACE requires early recognition and immediate descent. Administer high-flow oxygen, if available. Oxygen alone reduces intracranial blood flow at high altitude. Steroid therapy is recommended and may result in recovery from HACE without neurologic deficits. The initial dose of dexamethasone is 8 mg parenterally or orally in mild cases, followed by 4 mg every 6 hours.

Patients with severely altered levels of consciousness require tracheal intubation. Increase oxygenation, both by increasing Fio_2 and barometric pressure by descent or hyperbaric treatment. Hyperventilation, diuretics (e.g., furosemide), and hypertonic solutions (e.g., mannitol) have been used to manage severely elevated intracranial pressure, but extreme caution is warranted. Many patients with HACE are already volume depleted from poor fluid intake; diuretic use could compromise adequate intravascular volume and reduce cerebral perfusion pressure.

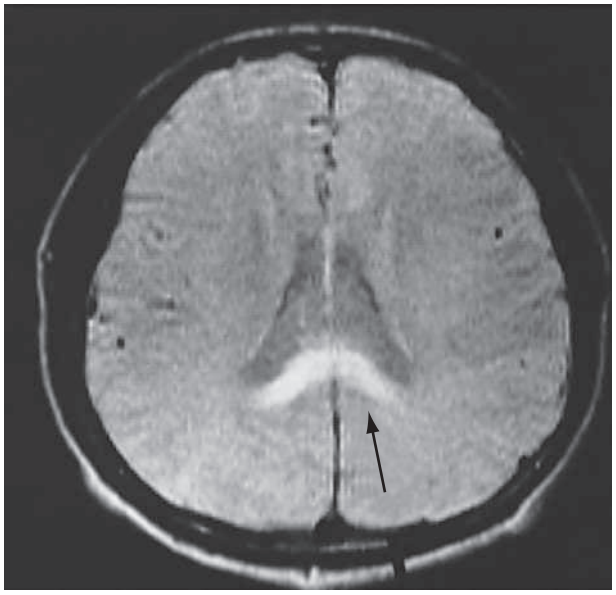

Fig. 132.8 Diagnostic image of axial proton-weighted magnetic resonance image of a mountain climber with high-altitude cerebral edema (HACE). The *arrow* demonstrates the markedly increased signal (edema) in the splenium of the corpus callosum. (Courtesy Peter Hackett, MD.)

Hyperbaric treatment of HACE is also effective and may result in temporary improvement and allow self-rescue and descent. Conversely, coma may persist for several days even after descent to lower altitudes.

Disposition

When safe and feasible, immediate descent is essential. If immediate descent to definitive care is an option, placing HACE patients in a hyperbaric device may only delay the more comprehensive care available in the hospital setting.

Long-term neurologic deficits including ataxia and cognitive impairment have been reported after recovery from acute episodes of HACE. Both transient and long-lasting neurobehavioral impairments can occur in mountaineers after climbing to extreme altitude without experiencing clinical HACE. Because of the potential for long-lasting neurologic injury, the clinician must maintain awareness of the early manifestations of HACE. Early treatment of HACE generally results in good outcomes, but after coma is present, the mortality rate exceeds 60%. Patients who have suffered HACE should be referred to a neurologist for further evaluation.

SPECIAL CONSIDERATIONS

High-Altitude Retinal Hemorrhage

High-altitude retinal hemorrhage (HARH) is the most common type of retinopathy in visitors to high altitude. These hemorrhages are common at altitudes above 17,500 feet, although they can occur at lower levels.

The exact incidence of HARH is unknown because most patients are asymptomatic, with HARH noted only on retinoscopy. HARH is not generally related to the presence of mild AMS but does seem to be related to strenuous exercise at high altitude. At any altitude, in the setting of severe HAPE or HACE, retinal hemorrhages are commonly noted, but the mechanism remains unclear.

Hemorrhages usually spare the macula (Fig. 132.9) and most often resolve without treatment in 2 or 3 weeks. With macular involvement, central scotomas may be noticed and only gradually resolve. In some cases, these visual defects are permanent. HARH is more likely to occur among individuals with a previous history of such hemorrhages and those on anticoagulation therapy. The underlying risk remains unclear. They usually do not pose a contraindication to return to high altitude unless the macular region is involved. Altitude related changes in intraocular pressure are not associated with AMS.

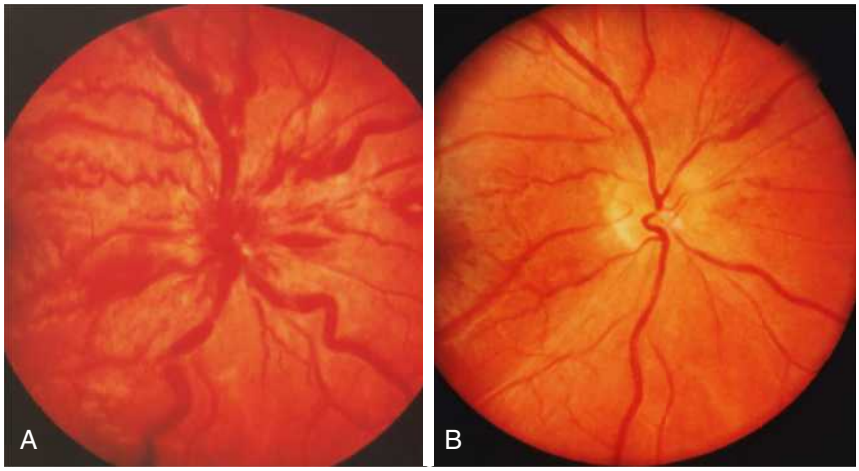

Fig. 132.9 Diagnostic image of high-altitude retinal hemorrhages (HARHs). (A) Acute. (B) After 1 week of resolution. (Courtesy Charles Houston, MD.)

Carbon Monoxide Poisoning

CO poisoning is not uncommon at altitude, typically from the use of fires and combustion stoves to keep warm or to prepare food in the high-altitude environment. CO poisoning at altitude can be more devastating because of preexisting hypobaria-induced hypoxia. As CO avidly binds to hemoglobin, it prevents oxygen transport and exacerbates tissue hypoxia. CO poisoning and AMS are clinically indistinguishable. If suspected, immediate removal of the patient from the potential CO source with assay of carboxyhemoglobin levels using cooximetry or lab testing is indicated. Importantly, empirical treatment with oxygen hyperbaria will benefit both conditions. If CO poisoning is suspected, test the patient's affected indoor space and assess other victims who may have been exposed. If testing is not available, the patient should not return to the enclosed space and should descend or use supplemental oxygen, if available.

ALTITUDE AND UNDERLYING MEDICAL CONDITIONS

Individuals with preexisting diseases such as sickle-cell disease, moderate to severe chronic obstructive pulmonary disease (COPD) and coronary artery disease (CAD) may have a more difficult time acclimatizing, because these disease states can be aggravated by the hypoxic atmosphere at higher elevations. eBox 132.1 describes the risk associated with travel to altitude in individuals with a variety of underlying comorbidities.

Respiratory Illnesses

Travelers with COPD have underlying anatomic and physiologic changes that predispose them to development of hypoxemia, sleep apnea, pulmonary hypertension, and ventilation disorders at even moderate altitudes. COPD is a risk factor for the development of AMS. Although oxygen saturation remains more than 90% in a healthy, awake individual until an altitude of 8000 feet, patients with COPD may desaturate below 90% at lower altitudes. High altitude increases hypoxic pulmonary vasoconstriction and may potentiate the development of cor pulmonale, which is known to adversely affect survival at sea level. Individuals with chronic COPD should be advised of the potential need for oxygen supplementation when traveling to moderate altitude, especially if they are already using oxygen at sea level or if dyspnea or fatigue becomes worse. Use of a pulse oximeter can guide the need for increased oxygen supplementation.

Patients with asthma, on the other hand, may have fewer problems at altitude because of decreased ambient allergens and pollutants as well as decreased airflow turbulence. Even those with exercise-induced bronchospasm do not have worsening symptoms while exercising at 5000 feet. In addition, AMS incidence is not increased in asthmatics. People with asthma traveling to higher elevations should continue their usual medications and carry a rescue supply of bronchodilators and steroids.

Patients who ascend to high altitude with preexisting primary or secondary pulmonary hypertension are considered HAPE susceptible, and those with primary pulmonary hypertension are considered at increased risk for HAPE. Patients with known pulmonary hypertension should be advised against travel to higher elevations. If travel cannot be avoided, supplemental oxygen should be used. Prophylactic sustained release nifedipine, 30 mg twice daily for the duration of the stay at altitude, can decrease the risk of HAPE. Phosphodiesterase type-5 inhibitors and dexamethasone may also be used.

Cardiovascular

Individuals with a history of CHF, CAD, dysrhythmias, or coronary bypass surgery are infrequently studied in the high-altitude setting. In theory, people with diseased myocardium should avoid high altitude because of decreased environmental oxygen availability. No studies report increased mortality in visitors to these locations, however. To the contrary, long-term residents at high altitude may be protected from coronary artery disease (CAD) by increased collateral vessel formation or a decrease in the development of atherosclerosis.

All travelers have increased sympathetic activity on initial exposure to high altitude. In patients with heart disease, the resultant increase in heart rate and blood pressure increases cardiac work and myocardial oxygen consumption, which could increase angina symptoms and dysrhythmias. Although both cardiac rhythm abnormalities and ST segment and T wave electrocardiographic changes are reported, none of these changes are associated with clinical evidence of myocardial ischemia. Limited data suggest no increased risk for sudden cardiac death or myocardial infarction at altitudes up to 8000 feet in patients with asymptomatic CAD. When individuals with stable angina are exercised, there is conflicting evidence for the probability of inducing malignant dysrhythmias. Travelers with heart disease who ascend to moderate altitudes do not appear to have an increased incidence of AMS.

Travelers with mild stable CAD should be advised to ascend gradually, to limit activity especially in the first few days at elevation, and to continue anti-anginal and antihypertensive medications. Individuals who have more severe, symptomatic coronary disease or those in a high-risk group (low ejection fraction, abnormal stress test results, and high-grade ventricular ectopy) should avoid travel to high altitudes. Ascent to moderate elevations can be suggested on an individual basis with the previously mentioned precautions. Individuals with heart failure who travel to altitude may require increased use of diuretics to promote diuresis and acclimatization. Patients previously prescribed nitroglycerin should be instructed not to take phosphodiesterase type-5 inhibitors. Acetazolamide prophylaxis may be useful to speed acclimatization and to prevent AMS and its accompanying fluid retention.

Hypertension

High-altitude travel produces a rapid, mild increase in blood pressure and heart rate in healthy individuals because of increased sympathetic tone. This increase is maximal at 2 or 3 weeks, and returns to baseline values over time because of a downregulation of adrenergic receptors if one stays at high altitude or upon descent to sea level. No studies demonstrate an increased predisposition for altitude illness in patients with underlying hypertension.

The incidence of hypertension in sea-level dwellers traveling to high altitude is 10% to 25%. On travel from sea-level to low altitudes (3000 feet), no differences are noted in either normotensive or hypertensive individuals. Above 9800 feet, more significant increases may occur. This suggests that people with severe hypertension should travel to high altitude only under careful monitoring. For individuals who have mild preexisting hypertension, additional treatment is not routinely necessary. Monitor patients with moderate hypertension during the first few days at altitude and continue all antihypertensive medications. For hypertensive patients with a rapid rise in blood pressure who will be staying at altitude for several weeks, an alpha-blocker, nifedipine, or angiotensin-converting enzyme inhibitor are recommended agents to add to the patient's daily regimen.

Seizures

Numerous reports of altitude-provoked seizures exist, but compelling epidemiologic data are lacking. Seizures attributable to high altitude are typically generalized tonic-clonic in nature and a new-onset focal seizure at altitude should prompt a thorough evaluation for a structural brain lesion. Several pathophysiologic mechanisms are implicated. These include sleep deprivation from periodic breathing, hyperventilation, and the direct effect of hypobaric hypoxia. These mechanisms are postulated to induce a metabolic state that lowers the seizure threshold.

EBOX 132.1 Risk Associated With Travel to Altitude in Individuals With a Variety of Underlying Comorbidities

Advisability of Exposure to High Altitude for Common Conditions (Without Supplemental Oxygen)

Little Additional Risk

Young and old
Fit and unfit
Mild obesity
Diabetes
Previous coronary artery bypass grafting (without angina)
Mild chronic obstructive pulmonary disease (COPD)
Asthma
Low-risk pregnancy
Controlled hypertension
Controlled seizure disorder
Psychiatric disorders
Neoplastic diseases
Inflammatory conditions

Caution

Moderate COPD
Asymptomatic pulmonary hypertension
Compensated congestive heart failure (CHF)
Morbid obesity
Sleep apnea syndromes
Troublesome arrhythmias
Stable angina or coronary artery disease (CAD)
High-risk pregnancy
Sickle cell trait
Cerebrovascular diseases
Any cause of restricted pulmonary circulation
Seizure disorder (not taking medication)
Radial keratotomy

Contraindicated

Sickle cell anemia (with history of crises)
Severe COPD
Symptomatic pulmonary hypertension
Uncompensated CHF

Modified from: Luks AM, Hackett PH. High altitude and preexisting medicine conditions. In: Auerbach PS, Cushing, TF, Harris NS, eds. *Auerbach's Wilderness Medicine*, 7th ed. Philadelphia: Mosby/Elsevier; 2017: 29-39.

Seizures not responding to supportive care can be treated with benzodiazepines. Should an epileptic who is already taking seizure medicine experience a breakthrough seizure at altitude, standard seizure evaluation is warranted, and acetazolamide at 125 to 250 mg twice daily may be added. Acetazolamide itself has antiepileptic properties and may ameliorate the altitude-related metabolic derangements. As discussed previously, any patient with seizure activity at high altitude should also be assessed for possible HACE.

Sickle Cell Disease

In patients with sickle cell disease, exposure to even low to moderate altitudes (4000 to 6500 feet) will provide additional hypoxic stress. Up to 20% of patients with hemoglobin sickle cell and sickle cell–thalassemia disease may experience a vaso-occlusive crisis, even under pressurized aircraft conditions. Oxygen is therefore advised for air travelers who have sickle cell disease.

Although most people with sickle cell trait remain asymptomatic, this subgroup can experience the development of left upper quadrant pain as a result of splenic ischemia or infarction.

Pregnancy

Studies of permanent high-altitude residents in Colorado and Peru show an increased incidence of complications in maternal, fetal, and neonatal life. Infants born at high altitude have a lower birth weight compared with infants born at sea level because of a combination of factors, including altitude-related effects on fetal growth, changes in uterine blood flow, and increased premature births. As supported by evolutionary genetic studies, patient ethnicity is relevant. At the same elevation, newborns of recently immigrated Han Chinese have lower birth weights than indigenous Tibetans.

Pregnancy-induced hypertension, proteinuria, and peripheral edema (manifestations of toxemia and preeclampsia) are more common at high altitudes and may also be related to maternal and uterine hypoxemia. Although hypertension in pregnancy is more common at high altitudes, no evidence exists for an increase in spontaneous abortions, abruptio placentae, or placenta previa.

Travel by pregnant women to moderate altitudes appears to be safe, but caution is advised for lowland women with normal pregnancies who wish to travel above 13,000 feet, for pregnant women who wish to remain at high altitude for a prolonged period, and for women with complicated or high-risk pregnancies.

Radial Keratotomy

Patients with a history of radial keratotomy may experience hyperopic (farsighted) visual changes with ascent above 9000 feet. This results from corneal swelling from ambient hypoxia because the cornea is markedly sensitive to both systemic and ambient oxygen tension. In normal corneas, this swelling is uniform. After radial keratotomy, the swelling is exacerbated and inconsistent secondary to the pattern of the incisions. Photorefractive keratotomy and LASIK, which use laser techniques that do not produce incisions but instead shave the cornea and corneal stroma, respectively, do not result in similar problems.

CHAPTER 132: QUESTIONS AND ANSWERS

1. Which of the following individuals has the highest risk of developing high-altitude pulmonary edema (HAPE), assuming all are generally healthy, live at the same altitude, and travel to the same altitude?

a. A 16-month-old boy
b. A 19-year-old man
c. A 19-year-old woman
d. A 42-year-old man
e. A 42-year-old woman

Answer: B. Many factors contribute to the development of HAPE including total altitude, sleeping altitude, time at altitude, previous acclimatization, and the presence of comorbidities. However, in general, both females and the elderly have been found to be less likely to develop HAPE. Also, whereas younger males are more at risk, HAPE is extremely rare in individuals younger than 2 years old regardless of gender.

2. Which of the following symptoms must be present to establish a diagnosis of acute mountain sickness (AMS)?

a. Dizziness
b. Fatigue
c. Headache
d. Dyspnea
e. Nausea

Answer: C. To diagnose AMS, a patient must have a recent gain in altitude, be at that altitude for several hours, and have a headache. In addition, at least one of the following must also be present: gastrointestinal upset, fatigue, dizziness or light-headedness. Exertional dyspnea is common at high altitude. Resting dyspnea is concerning for potential HAPE.

3. Which of the following medications used to treat acute mountain sickness (AMS) actually accelerates acclimatization?

a. Acetazolamide
b. Ibuprofen
c. Dexamethasone
d. Oxygen
e. Prochlorperazine

Answer: A. Acetazolamide is a carbonic anhydrase inhibitor and induces a metabolic acidosis that results in increased ventilation. Ibuprofen is an appropriate treatment for the headache associated with AMS. Dexamethasone and oxygen both improve all symptoms of AMS but do not aid acclimatization. Prochlorperazine is appropriate treatment for the gastrointestinal upset caused by AMS and is preferred over promethazine because it does not depress the respiratory centers.

4. Which of the following conditions occurs more commonly at high altitude?

a. Congestive heart failure (CHF)
b. Myocardial infarction
c. Pericarditis
d. Pneumothorax
e. Pulmonary embolism (PE)

Answer: E. Altitude may contribute to hypercoagulability from hyperviscosity due to elevated hematocrit and dehydration. Venous stasis is also more common at altitude due to the relative immobility of sleeping in confined spaces (sleeping bags and small tents) and long flights that tend to precede vacations at altitude. Together, these facts lead to an increased risk of PE. Occasionally, PE may be misdiagnosed as high-altitude pulmonary edema (HAPE) and treated inappropriately.

5. The acute hypoxic stresses of high altitude can cause a range of symptoms suggestive of both cardiovascular and CNS dysfunction. Although high-altitude pulmonary edema (HAPE) and acute mountain sickness (AMS) share the same pathophysiologic trigger (decreased available oxygen), the treatment and prognosis are different. Which of the following features is indicative of HAPE as opposed to AMS?

a. Frequent urination
b. Dyspnea at rest
c. Headache
d. Lower-extremity edema
e. Symptom onset immediately after arrival at altitude.

Answer: B. Dyspnea on exertion is nearly universal at altitude and is not indicative of a pathologic process. Dyspnea at rest is not normal and is an early symptom of HAPE. Cough is common at altitude or any time when one breathes cold dry air. Fluid retention and peripheral edema are common manifestations of AMS, whereas an alkaline diuresis can be a sign of acclimatization. Neither AMS nor HAPE commonly occurs immediately after arrival at altitude. AMS usually occurs within 24 hours and HAPE usually occurs after 2 to 4 days.

6. The definitive treatment for high-altitude pulmonary edema (HAPE) is oxygen and descent to lower altitudes. Which of the following medications is also useful in the treatment of HAPE?

a. Hydrochlorothiazide
b. Metoprolol
c. Nifedipine
d. Nitroglycerin
e. Furosemide

Answer: C. Nifedipine is a nonselective pulmonary vasodilator and is useful in the treatment and prevention of HAPE. Sildenafil and

CHAPTER 132: QUESTIONS AND ANSWERS—cont'd.

tadalafil may also be useful in the prevention of HAPE. These phosphodiesterase–5 inhibitors increase cyclic guanosine monophosphate availability and result in pulmonary vasodilation. As a non-cardiac form of pulmonary edema, neither nitroglycerin or furosemide has a role in the treatment of HAPE.

7. Which of the following signs or symptoms is specific for high-altitude cerebral edema (HACE) as opposed to acute mountain sickness (AMS) or high-altitude pulmonary edema (HAPE)?

a. Ataxia
b. Dizziness
c. Dyspnea at rest
d. Headache
e. Vomiting

Answer: A. Ataxia, seizures, slurred speech, focal neurologic deficits, and altered mentation are all concerning to HACE and require immediate descent and treatment. Dizziness, headache, and vomiting can all be seen in AMS. Dyspnea at rest is nearly universal in HAPE.

8. You are the doctor on a group expedition to Denali. Recently, some of the climbers have complained of headaches, dyspnea, nausea, and difficulty sleeping. At breakfast this morning, one of the climbers, a 28-year-old female, is noted to have difficulty speaking and some slurred speech, which she attributes to a restless night's sleep. What treatment is mandated for this patient?

a. 24 hours of rest before further ascent
b. Acetazolamide
c. Descent to lower altitude
d. Nifedipine
e. Ibuprofen

Answer: C. This patient has an acute neurologic emergency, most likely high-altitude cerebral edema (HACE) until proven otherwise. Any hard neurologic finding (ataxia, slurred speech, focal neurologic deficits, seizure, or altered mentation) at altitude is suggestive of HACE, but acute CVA and other malignant etiologies must be considered. Unlike acute mountain sickness (AMS) or high-altitude pulmonary edema (HAPE), which can occasionally be treated without descent, descent is mandatory for all cases of HACE. Dexamethasone should also be given to all patients with HACE.

9. You are the doctor on a group expedition to Denali and are currently at an elevation of 10,000 feet. One of the members of the group experiences headache, lightheadedness, and nausea. You diagnose him with acute mountain sickness (AMS) and treat him with acetazolamide and oxygen. He wants to know when he can continue climbing the mountain. What do you tell him?

a. You may ascend if your oxygen saturation (as measured by pulse oximetry) is higher than 90%.
b. You may ascend when all your symptoms resolve.
c. You may never ascend any higher than this altitude.
d. You may not ascend any higher on this expedition but may try again in 1 or 2 months.
e. You may only sleep 1000 feet higher than your current altitude.

Answer: B. Management of AMS must adhere to the axiom, "After the symptoms of altitude illness occur, further ascent to a higher sleeping altitude is contraindicated."

Drowning

David B. Richards

KEY CONCEPTS

- Drowning is a leading cause of death and loss of years of life with over 90% of cases occurring in lower- and middle-income countries. Cost-effective prevention strategies have been developed for settings where resources limit treatment for drowning victims.
- Significant drowning injuries induce pulmonary injury and hypoxia in proportion to the amount of water aspirated and the duration of submersion.
- Pulmonary and neurologic support is essential to optimize the victim's chance of a favorable outcome.
- Electroencephalography is used in obtunded drowning victims to assess for subclinical seizures.
- No prognostic scale or clinical presentation accurately predicts long-term neurologic outcome after significant drowning injuries. Normal neurologic recovery is documented in patients despite prolonged submersions, persistent coma, cardiovascular instability, and fixed and dilated pupils on presentation.
- Hyperventilation, corticosteroids, diuresis, barbiturate coma, and neuromuscular blockade do not improve outcome following resuscitation of a drowning victim.
- Comatose patients who have been resuscitated after reasonable submersion time regardless of rhythm should not be rewarmed above 34°C.

FOUNDATIONS

Background and Importance

Traditionally, the terminology describing drowning injuries has been confusing and impractical. In the past, *drowning* referred to death within 24 hours of suffocation from submersion in a liquid, whereas *near-drowning* described victims who survived at least 24 hours past the initial event regardless of the outcome. The World Health Organization (WHO) published a new policy defining drowning to clarify documentation and to better track drowning injuries worldwide. *Drowning* was defined as "the process of experiencing respiratory impairment from submersion/immersion in liquid." Furthermore, the WHO policy states, "Drowning outcomes should be classified as: death, morbidity, and no morbidity; the terms wet, dry, active, passive, silent, and secondary drowning should no longer be used." Also, the term *near-drowning* should not be used, and the associated term *drowning with a fatal outcome* should be abandoned.

Immersion syndrome refers specifically to syncope resulting from cardiac dysrhythmias on sudden contact with water that is at least 5°C lower than body temperature. The risk is proportional to the difference between body temperature and water temperature. Wetting of the face and head before entrance into the water may prevent the inciting sequence of events. Putative mechanisms for the syndrome are vagal stimulation leading to asystole and ventricular fibrillation secondary to QT prolongation after a massive release of catecholamines on contact with cold water. The resultant loss of consciousness leads to secondary drowning.

Each year an estimated 360,000 people die of drowning worldwide, a rate of approximately 40 individuals an hour, most of whom are children. Low- and middle-income countries account for more than 90% of all drowning deaths and a disproportionate share of years of life lost. Drowning is among the top ten causes of mortality for children and young people worldwide.

In the United States, drowning is the tenth most common cause of unintentional death, accounting for 3709 deaths (1.1 per 100,000) in 2017. Among children 1 to 4 years old, drowning is the leading cause of injury mortality; for 5- to 9-year-olds, it is second only to motor vehicle crashes.[1]

The incidence of drowning with nonfatal outcomes is not well documented. The Centers for Disease Control and Prevention (CDC) estimates that for every child who dies by drowning in the United States, another five receive emergency department (ED) care for a drowning event, and half of these children require hospitalization.[2] Among all age groups, an estimated one to four hospitalizations secondary to nonfatal drownings occur for every drowning death. The economic implications of drowning injuries are profound. In Australia, drowning-related injuries have the highest average lifetime cost ($40,000 USD per patient) of any injury type.

Drownings occur in domestic settings such as swimming pools, hot tubs, bathtubs, large buckets, and rainwater tanks and in all forms of natural bodies of water. A review of all drowning deaths among individuals younger than 20 years old in the United States during a 1-year period revealed that 55% of infants younger than 1 year old drown in bathtubs, and nearly 16% drown in large household buckets. Most (56%) children 1 to 4 years old drown in artificial pools, whereas most (63%) deaths among older children occur in natural bodies of fresh water.

Because of natural disasters, the incidence of drowning injuries and fatalities is rising. In disasters such as floods and tsunamis, older populations are disproportionately affected. A study from hurricane Katrina found that 49% of fatalities were in people 75 years old or older.

Age, gender, and race affect incidence of drowning. Toddlers (1–3 years old) and those over 80 years old are at greatest risk of death by drowning, with annual incidences of 2.5 and 2.1 per 100,000, respectively. Males account for almost 75% of victims.[1] Indigenous American and Alaska Native children between 1 and 4 years old have the highest annual incidence of drowning mortality (3.8 per 100,000), and black teenagers between 11 and 12 years old drown in swimming

pools at ten times the rate of white children of the same age. The risk of death by drowning for all ages of the American Indigenous and Alaska Native population is 80% higher than the United States population as a whole.[3,4]

Ethanol consumption in proximity with water is a major risk factor for drowning. Acute ethanol intoxication may be a contributing factor in up to 50% of drownings among adults and adolescents.[5] The risk of death from drowning while using watercraft is directly proportional to an operator's blood ethanol concentration (BEC). The odds ratios of fatality from drowning follow a trend from 2.8 for a BEC of 1 to 49 mg/dL to 37.4 for a BEC of 150 mg/dL or greater compared with sober case controls.

Drowning in the United States is seasonal, with most occurring during the summer months. Two-thirds of pediatric deaths occur between the months of May and August. Drowning injuries are 48% more likely to occur on weekends than weekdays and drowning victims older than 20 years old are most often participating in water sports or using watercraft.[6]

The relationship between swimming ability and the risk of drowning is unclear. No direct evidence exists to suggest that inexperienced swimmers are more likely to drown. On the contrary, skilled swimmers have greater exposure time in water and may be more prone to drowning incidents.

Numerous medical conditions confer an increased likelihood of drowning injury. Seizure disorders increase the chance of drowning among children and adolescents nearly 20-fold and longitudinal studies of patients with epilepsy found that 10% of deaths were due to drowning. Autism and other developmental and behavioral disorders increase risk in children as well. Immersion in cold water extends the QT interval, thus increasing the risk of dysrhythmias in individuals with baseline prolonged QT syndrome.

Anatomy, Physiology, and Pathophysiology

Unexpected submersion triggers breath-holding, panic, and a struggle to surface. Air hunger and hypoxia develop, and the victim begins to swallow water. As breath-holding is overcome, involuntary gasps result in aspiration. The quantity of fluid aspirated, rather than the composition, determines subsequent pulmonary system derangement.

The pathophysiologic differences between freshwater and saltwater aspiration with respect to resultant electrolyte imbalance, hemolysis, and fluid compartment shifting do not occur until the amount of aspirated water is significantly more than the typical drowning victim aspirates. In one review of the hospital treatment of drowning victims, no patient required emergent intervention for a significant electrolyte abnormality. Aspiration of 1 to 3 mL/kg of either fresh water or saltwater destroys the integrity of pulmonary surfactant, leading to alveolar collapse, atelectasis, noncardiogenic pulmonary edema, intrapulmonary shunting, and ventilation-perfusion mismatch. Profound hypoxia and metabolic and respiratory acidosis ensue, leading to cardiovascular collapse, neuronal injury, and ultimately death.

The classic hypothesis was that 10% to 15% of drowning victims die without aspiration of a significant amount of water. Death from such dry drowning purportedly results from severe laryngospasm causing hypoxia, convulsion, and death without entry of fluid into the lungs. An exhaustive review of the literature failed to corroborate this hypothesis. Dry drownings more appropriately reflect deaths from other causes (e.g., fatal cardiac dysrhythmias and severe hypothermia) than from simple submersion.

Many factors may influence the pathophysiologic sequence of events in drowning and affect the chance of survival, including age, water temperature, duration and degree of hypothermia, diving reflex, and effectiveness of resuscitative efforts. Children have a lower ratio of body mass to surface area and, therefore, develop hypothermia more quickly and to a greater degree after immersion in cold water than adults do. Hypothermia lowers cerebral metabolic rate and is neuroprotective to some extent for victims of submersion injury. Despite dramatic case reports of patients surviving prolonged submersion in cold water with full neurologic recovery, hypothermia is generally a poor prognostic finding. Cold-water immersion speeds the development of exhaustion, altered consciousness, and cardiac dysrhythmia. The *diving reflex*, an involuntary physiologic response to cold submersion that includes apnea, bradycardia, and increased peripheral vascular resistance, may play a protective role in infant and child submersions. The diving reflex works to shunt blood centrally to the heart and brain, thereby prolonging the duration of submersion tolerated without central nervous system (CNS) damage. The evidence to date, however, has not shown a clear correlation between outcome and water temperature.

CLINICAL FEATURES

History and Physical Examination

Many drowning episodes are witnessed. Toddler drownings are an important exception, however, often occurring because of a lapse in supervision. Signs of pulmonary injury may be obvious in a drowning victim who is hypoxic, cyanotic, and in respiratory distress or arrest. More subtle clues, such as increased respiratory rate and audible rhonchi, rales, or wheezes on pulmonary auscultation, should alert the clinician to evolving respiratory compromise. Drowning victims swallow a significantly greater volume of water than is aspirated, and gastric distention from positive-pressure ventilation during rescue is common. As a result, 60% of patients vomit soon after a drowning event. Aspiration of gastric contents greatly compounds the degree of pulmonary injury and increases the likelihood that acute respiratory distress syndrome (ARDS) will ensue. In addition, aspiration of particulate contaminants such as mud, algae, sewage, and bacteria may obstruct the smaller bronchi and bronchioles and greatly increase the risk of infection (both bacterial and fungal in nature).

Victims with CNS injury may present with symptoms ranging from mild lethargy to coma with fixed and dilated pupils. CNS injury results from the initial hypoxic or ischemic insult and from the cascade of reperfusion injury that follows reestablishment of cerebral blood flow after a cardiopulmonary arrest. The release of inflammatory mediators and the generation of oxygen free radicals in the post-resuscitative period contribute to cytotoxic cerebral edema, compromise of the blood-brain barrier, and increased intracranial pressure.

Cardiac dysrhythmias may incite drowning or develop as a consequence. Hypoxemia, acidosis, and, potentially, hypothermia are the primary factors responsible for dysrhythmias ranging from ventricular tachycardia and fibrillation to bradycardia-asystole. Electrolyte disturbances are rarely significant enough to be dysrhythmogenic.

Other clinical sequelae of drowning may include acute renal injury, which is present on admission in approximately 50% of patients as the result of lactic acidosis; prolonged hypoperfusion; and, in some instances, rhabdomyolysis. Hypothermia-related coagulopathy or disseminated intravascular coagulation (DIC) may occur.

Prognostic Factors

Many factors help predict patients who will survive a drowning injury neurologically intact. Hypoxia, which is usually dependent on submersion time, is the most important factor related to outcome and subsequent quality of life in drowning victims. Drowning victims who arrive in the ED alert with normal hemodynamics are unlikely to experience neurologic impairment. Victims younger than 3 years old, submersion for longer than 5 to 10 minutes, and initiation of cardiopulmonary

resuscitation (CPR) more than 10 minutes after rescue portend a poor prognosis. Adverse neurologic findings on initial presentation do not preclude full neurologic recovery, although in general, patients whose duration of submersion or resuscitation exceeds 10 minutes have an unfavorable outcome.[7] With the exception of victim age, however, such measurements are often unknown or inaccurately estimated at the time of a patient's arrival in the ED. On arrival, objective findings associated with an unfavorable prognosis include hypothermia, severe acidosis, unreactive pupils, a Glasgow Coma Scale score of 3, and asystole or the need for ongoing CPR. Neurologically intact survival is reported for individual patients even with several of these factors present; however, none of the proposed scoring systems using combinations of these variables has 100% predictive power.

Children who present with an abnormal head computed tomography (CT) scan (e.g., intracranial bleed, cerebral edema) within the first 24 hours have a nearly 100% mortality rate. Furthermore, an abnormal head CT scan at any time is associated with poor outcome (persistent vegetative state (PVS), post-coma unresponsiveness (PCU) or death).

DIFFERENTIAL DIAGNOSES

The precipitants of a drowning, such as drug or ethanol intoxication, cardiac arrest, hypothermia, hypoglycemia, seizure, and attempted suicide or homicide, should be considered in patients found unresponsive in water. For pediatric victims, child abuse or neglect should also be considered a potential cause. Potential head or cervical spine injury is an important consideration in drowning associated with diving injuries or trauma.

DIAGNOSTIC TESTING

Initiate cardiac monitoring and obtain an electrocardiogram (ECG) to determine the presence of significant dysrhythmias, QT prolongation, or ischemia. Monitor pulse oximetry, capnography, and arterial or venous blood gases closely for signs of hypoxemia, hypercarbia, and acidosis. Blood glucose, serum creatinine, and electrolyte values should be obtained, although serum creatinine concentration and electrolyte levels are usually normal on initial presentation. Similarly, complete blood count is often normal with the exception of leukocytosis. Serum ethanol levels and urine toxicology screening may be appropriate for illicit drugs, depending on the circumstances of the drowning. Subsequently, evidence of renal failure, hepatic dysfunction, and DIC may be noted on laboratory testing.

The initial chest radiograph is often unremarkable and may underestimate the severity of pulmonary injury. Infiltrates or pulmonary edema may be evident within hours; therefore, repeat radiographs are indicted with persistent respiratory symptoms. Initial chest radiographs are often unremarkable even in the setting of serious and evolving pathologic processes.

Electroencephalography to assess for seizure activity should be performed, if available, in the obtunded drowning victim. Head CT scans are rarely initially contributory unless significant trauma or other pertinent injury is suspected. Magnetic resonance imaging (MRI) of the brain may predict neurologic outcome after drowning, but its prognostic value is not optimal until 3 or 4 days have elapsed and is therefore not indicated in the emergency setting.

MANAGEMENT

Salient details of the events surrounding the incident should be ascertained rapidly from family, friends, or EMS personnel. Resuscitation of pulseless and apneic patients should be attempted initially in most cases because bystander estimates of total submersion time are often inaccurate. The clinical presentation of severe hypothermia often mimics death, and functional recovery is possible for hypothermic individuals submerged for significant periods of time.

For a victim without measurable vital signs or signs of life, outcome depends on the interval preceding CPR.[8] Since most cases are hypoxia-driven cardiac arrests, CPR with assisted ventilations may be more effective than compression-only CPR, although this has not been well studied. Mouth-to-mouth ventilation while in the water should be attempted but not at the cost of prolonging the extrication.[9] Chest compressions are impractical before extrication but should be initiated as soon as the individual is placed on a solid surface, such as a boat deck, poolside, or beach.

Cervical spine injuries are rare in drowning victims. Patients more likely to have cervical spine injuries tend to have either clinical signs of serious trauma or a history of motor vehicle crash, fall from height, or diving into the water. Unless such factors are present, routine cervical spine immobilization for submersion victims is not warranted.

On arrival in the ED, cardiac monitoring and continuous pulse oximetry should be established. A core temperature obtained with a low-reading probe is indicated for any unstable or lethargic patient. Values obtained by use of infrared ear thermometry are unreliable in drowning victims. Rewarming of a hypothermic patient may suffice for hemodynamic stabilization and improvement in mental status. A spontaneously breathing patient should be monitored for signs of developing pulmonary injury.

As with any patient, expected clinical course, mental status and objective determination of the adequacy of oxygenation and ventilation should determine the decision for tracheal intubation. If an arterial blood gas is obtained, a partial pressure of carbon dioxide ($Paco_2$) greater than 50 mm Hg should warn the clinician that intubation and lung protective ventilation is likely needed. Patients unable to maintain oxygen saturation greater than 90% despite high-flow supplemental oxygen, require positive airway pressure to increase alveolar recruitment, decrease intrapulmonary shunting, and reduce ventilation-perfusion mismatch. In awake patients, this may be accomplished by face or nasal mask (continuous positive airway pressure), but the risk of potential gastric distention, vomiting, and aspiration should be considered. Otherwise, tracheal intubation and lung-protective ventilation are indicated. The hemodynamic consequences of positive end-expiratory pressure should be monitored carefully, because increased intrathoracic pressure may compromise venous return and cardiac output. Decreased cranial venous return may impede cerebral perfusion.

No consensus exists with regard to the appropriate length of resuscitative effort for hypothermic drowning victims in the ED. The safest parameter is to continue until the core temperature reaches at least 32°C to 35°C, because cerebral death cannot be diagnosed accurately in severely hypothermic patients with temperatures below this level. This parameter may not always be practical, however, because brain-dead patients are often poikilothermic.

The administration of corticosteroids in the setting of drowning and potential ARDS does not improve outcome. Barbiturate-induced coma, diuresis, neuromuscular blockade, and hyperventilation do not improve neurologic outcome and, particularly in the case of hyperventilation, may be harmful. Similarly, empirical antibiotics do not increase survival and should be administered only to the patient who was submerged in grossly contaminated water or who shows signs of infection or sepsis.

Interventions, such as induced or permissive hypothermia, aimed at attenuation of reperfusion injury after anoxic brain insult are the

focus of intense investigative effort. Drowning victims in cardiac arrest are usually colder than 30°C and require warming. Comatose patients who have been resuscitated after reasonable submersion time regardless of rhythm should not be rewarmed above 34°C. Rewarming only up to 34°C followed by a 24-hour mild hypothermic treatment before normothermia is reached may be advantageous because of decreased pulmonary reperfusion injury and reduced secondary brain injury. Emerging resuscitation literature indicates an emerging role for therapeutic hypothermia in drowning victims.[10]

DISPOSITION

Symptomatic patients should be admitted for treatment. Patients with a history of apnea, unconsciousness, intoxication, or hypoxia and any patients who manifest cardiac dysrhythmias or an abnormal chest radiographs also require admission. Patients who are asymptomatic on presentation to the ED, maintain normal room air oxygen saturation, and have no chest radiograph abnormalities can be discharged safely after an observation period of 8 hours.[11,12] Careful instructions about symptoms or signs of delayed pulmonary complications are necessary, and the patient should be discharged in the care of a competent adult.

Preventive Efforts and Discharge Education

For survivors of a drowning episode, discharge instructions with a focus on parental education and future preventative measures are critical. Canadian research has shown that drowning was in the top three causes of death and costs per hospitalization for youths under the age of 19 years and identified prevention of drowning as a high-yield priority.[13] An Australian study highlighted this by demonstrating a $830 million annual economic burden in Australia alone.[14] In low-income countries, drowning deaths (particularly in children) are on the rise. In high-income countries, drowning morbidity and mortality are on the decline although the exact causes of this decline are unclear. An increased public awareness of preventive measures and an emphasis on public education with regard to bystander CPR and the dangers of ethanol use in conjunction with water-related activities are contributing significantly to the reduction in fatalities, in some locations by over 80%.

Parental education about the danger of pediatric drowning is an important focus of preventive efforts. Inadequate supervision of children playing in or near water is one of the most common causes of pediatric submersion death, underscoring the importance of increasing awareness of the need for constant oversight of children in this setting. Most pediatric submersion injuries in swimming pools occur at the victim's home. In most cases, the child is last seen in the house, is left unattended for a moment, and enters the pool on an unfenced side closest to the home with no audible splash or screaming. Fully circumferential fencing with functioning door locks or latching mechanisms of residential pools is a current recommendation of the American Academy of Pediatrics (AAP). Drowning or submersion is 3.7 times more likely in a nonfenced pool than in a properly fenced pool. In Australia, safety legislation is associated with a 30% reduction in drowning rates in young children. Unfortunately, legislation requiring appropriate fencing is poorly adhered to, and only 40% of households are compliant. Legislation requiring personal floatation device usage in recreational boaters in Australia has resulted in a significant decrease in drowning deaths.

Effective approaches to prevention efforts in low- and middle-income countries differ from those in high-income countries.[15] Data from almost 100,000 children in Bangladesh either entered into swim lessons or kept in a common supervision area in the community showed relative risks of drowning of 0.072 and 0.181, respectively. Both interventions were found to be extremely cost effective.[16]

Emergency care providers are a vital resource for enhancement of public awareness of the importance of these measures. The literature supports the concept that education in the ED highlighting drowning prevention can have a positive impact on patient and family awareness of steps to lessen the likelihood of catastrophic drowning injury.

CHAPTER 133: QUESTIONS AND ANSWERS

1. Which of the following is the greatest risk factor for death from drowning?

a. Ethanol
b. Male gender
c. Poor swimming ability
d. Saltwater drowning
e. Warm water

Answer: A. Ethanol is a major risk factor for drowning and for death from drowning. Ethanol is a contributing factor in up to 50% of drowning incidents among adolescents and adults. More males drown than females, but male gender alone does not increase the risk of death from drowning. No direct evidence exists relating swimming ability to risk of death from drowning. Although frequently cited in older literature, there is no significant difference between saltwater and freshwater drowning. Although case reports of survival from cold-water drowning exist, overall mortality is greater in cold water than in warm water.

2. A 13-year-old boy is brought to the emergency department (ED) after an apparent drowning. Family and paramedics report the patient was submerged for approximately 4 minutes. Bystanders began cardiopulmonary resuscitation (CPR) immediately. Paramedics intubated the patient and continued CPR, which has now been ongoing for 10 minutes. On arrival in the ED, the patient has a Glasgow Coma Score (GCS) of 3, unreactive pupils, no pulse, and is in asystole on the cardiac monitor. What is the most appropriate next step?

a. Cessation of treatment/pronounce death
b. External cardiac pacing
c. Induction of hypothermia
d. Intravenous epinephrine
e. Unsynchronized defibrillation

Answer: D. Although this patient will likely have a poor outcome, asystolic victims of drowning have a higher incidence of full neurologic recovery than patients with asystole from other causes. Poor prognostic indicators are age younger than 3 years old, submersion greater than 5 minutes, delay in initiation of CPR greater than 10 minutes, hypothermia, severe acidosis, unreactive pupils, GCS of 3, and asystole. The decision to cease care must be made on a case-by-case basis, but initial treatment of asystole should be begun in drowning victims following standard advanced cardiac life support (ACLS) protocols and as in this case, administration of intravenous epinephrine. Experiments with induction of hypothermia are ongoing in drowning victims, but the results are not definitive.

3. A 16-year-old boy presents with tachypnea and coughing. Family members state that they were swimming in a nearby lake when they noticed the patient with the previously mentioned symptoms. The patient is awake and alert but in obvious distress. He has a respiratory rate of 35 breaths per minute, with the remainder of his vital signs within normal limits. His oxygen saturation as measured by pulse oximetry is 84% while on high-flow oxygen. Pulmonary examination reveals diffuse rales. There is no evidence of trauma. In addition to intubation, which of the following is indicated?

a. Administer intravenous diuretics.
b. Administer intravenous corticosteroids.
c. Obtain an electrocardiogram (ECG).
d. Perform maneuvers to remove fluid from the lungs.
e. Place the patient in cervical spine precautions.

Answer: C. Dysrhythmias are frequently associated with drowning, especially when no obvious cause is found. ECGs should be performed on all drowning patients. Antibiotics, steroids, and diuretics have all been studied in drowning victims, and none show any benefit. Cervical spine precautions are often initiated in all drowning victims but are not needed unless the patient has clinical signs of trauma or a history of motor vehicle crash, fall from height, or diving into the water. Maneuvers to remove fluid from the lungs (Heimlich, Patrick maneuvers) are ineffective and potentially dangerous.

CHAPTER 133: QUESTIONS AND ANSWERS—cont'd.

4. An 18-year-old man is brought to the emergency department (ED) after submersion in his swimming pool. Per witnesses, once the patient was brought out from the water, he initially had severe coughing and complained of shortness of breath. On arrival to the ED, the patient denies shortness of breath and is not coughing. Vital signs as well as oxygen saturation are all within normal limits. Electrocardiogram (ECG) and chest radiographs are normal. What is the appropriate disposition of this patient?

a. Admission to telemetry for 23-hour observation
b. Admission to the general hospital for 23-hour observation
c. Admission to the intensive care unit for 23-hour observation
d. Discharge home after observation in the ED for 8 hours
e. Discharge home now

Answer: D. Any symptomatic patients or patients with a history of apnea, unconsciousness, or hypoxia should be admitted. Likewise, patients with dysrhythmias or abnormal chest radiographs should be admitted. Some effects of drowning can be delayed, so asymptomatic patients should be observed for 8 hours in the ED but can be safely discharged if they continue to be asymptomatic and can maintain normal room air oxygen saturation. They should be discharged in the care of a responsible family member or friend.

Radiation Injuries

Jillian L. Theobald and J. Marc Liu

KEY CONCEPTS

- Patients contaminated with radiation pose minimal risk to health care providers when appropriate precautions and decontamination procedures are employed.
- Decontamination should not delay or impede emergency stabilization of patients with radiation exposure.
- Tissues with greater rates of cellular division, particularly the hematopoietic and gastrointestinal systems, are most radiosensitive. Children are more radiosensitive than adults.
- Vomiting, diarrhea, and skin burns occurring shortly following radiation exposure are predictors of severe radiation injury.
- The 48-hour absolute lymphocyte count is the most important prognostic indicator and should be drawn on suspected radiation exposure patients.
- Most therapy is supportive with symptomatic measures except for exposures involving the ingestion or inhalation of radioactive material, when directed therapy with blocking or chelating agents may be indicated.
- Formal consultation at the hospital, regional, and national levels is available 24 hours a day and should be used for assistance when managing patients with radiation injuries (Table 134.4).

FOUNDATIONS

Background and Importance

Radiation is energy that travels through space in the form of a particle or wave.[1] It is produced by radioactive decay of an unstable atom (radionuclide or radioisotope) or by the interaction of a particle with matter. *Particle radiation* consists of particles that have mass and energy and may carry an electric charge. Examples of particle radiation include alpha particles (helium nuclei), protons, beta particles (electrons ejected from the nucleus), and neutrons. *Electromagnetic radiation* consists of photons that have energy but no mass or charge. Radiation can be either ionizing or nonionizing depending on its energy and ability to penetrate matter. Electromagnetic radiation varies by frequency and wavelength as shown in Figure 134.1.

Radioactive decay (radioactivity) is the process by which a nucleus of an unstable atom loses energy by emitting ionizing radiation in the form of high-energy particles or rays. Radioactive decay can emit particles (e.g., alpha and beta) or rays such as gamma or x-rays. Gamma rays and x-rays are high-energy photons that differ in their place of origin: gamma rays are emitted from the nucleus, whereas x-rays are produced as the result of changes in the positions of electrons orbiting the nucleus.

The type and rate of radioactive decay varies by radionuclide. The rate of decay is measured by the radioactive half-life (the time for half the radioactive nuclei in any sample to undergo radioactive decay) and varies from a few microseconds to billions of years. Radiation exposure can be external (e.g., exposure to x-rays) or internal, resulting from the inhalation, ingestion, or injection of radioisotopes.

Radiation Measurements

The four different but interrelated units for measuring radiation (radioactivity, exposure, absorbed dose, and dose equivalent) are shown in Table 134.1. These units are also commonly expressed as fractions of whole units using the terms and abbreviations milli (m; 1/1000th) and micro (μ; 1/1,000,000th).[1]

Radiation Protection

The principles of radiation protection include time, distance, shielding, and quantity. Reducing the time of radiation exposure will reduce the absorbed dose. The intensity of radiation is a function of distance from the source and follows the inverse square law: the dose of radiation decreases inversely with the square of the distance. For instance, if you double the distance from the source you decrease the radiation exposure by a fourth. Shielding is the placement of an absorber (material that reduces radiation) between the person and the source. The effectiveness of shielding varies with the type of the radiation. For example, alpha particles can be stopped by a thin piece of paper or even the dermal cells in the outer layer of the skin, whereas thick, dense shielding like lead or concrete is necessary to protect against gamma rays. Limiting the quantity of radioactive material in the work area will also decrease exposure. National and international regulatory bodies set acceptable limits for occupational and population exposures to radiation.

Radiation Sources

Ionizing radiation and radioactive substances are natural and permanent features of the environment. The average annual radiation dose per person in the United States is 6.2 mSv (620 mrem). Fifty percent of this average dose comes from background radiation and 48% from medical procedures. The major sources of background radiation are radon and thoron (37%), cosmic radiation (5%), naturally occurring internal radioisotopes (e.g., potassium-40 [5%]), and terrestrial background radiation (3%). The major medical sources include computed tomography (CT; 24%), nuclear medicine (12%), interventional fluoroscopy (7%), and conventional radiography and fluoroscopy (5%). The remainder of the average annual radiation dose comes from occupational and consumer sources.[2]

Radon is a naturally occurring radioactive gas that is formed from the radioactive decay of uranium. Radon can accumulate in homes and is the second leading cause of lung cancer in the United States after tobacco exposure.[3] Radon exposure is estimated by measuring radon

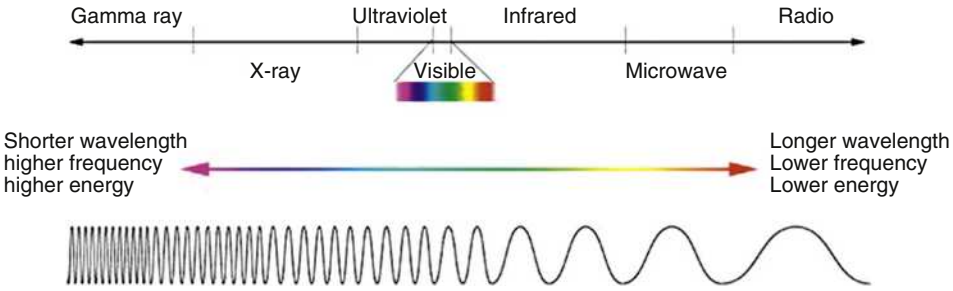

Fig. 134.1 Electromagnetic radiation varies by frequency and wavelength. (National Aeronautics and Space Administration: Imagine the universe: the electromagnetic spectrum. Available at: http://imagine.gsfc.nasa.gov/science/toolbox/emspectrum1.html.)

TABLE 134.1 Radiation Units Description and Conversion Factors

Measure	Description	United States Units	International Units	Conversion
Radioactivity	Amount of ionizing radiation released by a material	Curie (Ci)	Becquerel (Bq)	1 Bq = 2.7×10^{-11} C
Exposure	Amount of radiation traveling through air	Roentgen (R)	Coulomb (C)/kg	1 C/kg = 3875.9 R
Absorbed dose	Amount of radiation absorbed by a person	Radiation absorbed dose (Rad)	Gray (Gy)	1 Gy = 100 rad
Dose equivalent (effective dose)	Combines the amount of radiation absorbed with the tissue damaging potential of the type of radiation	Roentgen equivalent man (Rem)	Sievert (Sv)	1 Sv = 100 rem

levels in the air using inexpensive and readily available kits. If indoor levels of radon are 4 pCi/L or greater, then the US Environmental Protection Agency (EPA) recommends that the homeowner consult a certified radon mitigation specialist to reduce radon air levels in the home.

Although radiation-related incidents are rare, the consequences of exposure or significant internal contamination can be fatal. The Radiation Emergency Assistance Center at Oak Ridge National Laboratory maintains a worldwide registry of serious radiation incidents. Between 1944 and 2012, there have been 454 radiation incidents recorded worldwide. The greatest numbers of serious exposures have occurred with sealed sources, which include brachytherapy sources used in radiation oncology and industrial radiography devices (n = 214), followed by x-ray devices (n = 86). Radioisotopes used in medical diagnosis and therapy have caused approximately 10% of major radiation incidents.

Serious nuclear power incidents include the Fukushima Daiichi disaster (2011), the Chernobyl disaster (1986), Three Mile Island (1979), and the SL-1 accident (1961). The radioisotopes most commonly released from nuclear reactor accidents include iodine, cesium, and strontium. Chernobyl had the largest number of radiation-related injuries. About 150 individuals who received very high whole-body doses were treated for acute radiation sickness; 28 of these died within a relatively short time, and approximately 20 more have since died from radiation-related diseases.[4] Radiation to the thyroid from radioisotopes of iodine released during the Chernobyl event has caused several thousand cases of thyroid cancer, with children being the most susceptible population.

The detonation of nuclear bombs has the greatest potential to produce mass casualties. The acute and long-term effects following the bomb blasts in Hiroshima and Nagasaki in 1945 (18 and 22 kilotons) have been well documented. Today's nuclear weapons are orders of magnitude potentially more devastating. Another threat is the detonation of a low-yield nuclear bomb by terrorists. A 10-kiloton nuclear detonation within a city in the United States would result in a zone of destruction of more than 2 miles from ground zero and would expose hundreds of thousands of people to radiation.[5] A more likely terrorist scenario is the explosion of a *dirty bomb*. A dirty bomb is the combination of a conventional explosive with a radioisotope. The radioisotopes most likely to be used in a dirty bomb are cesium-137, cobalt-60, or strontium-90.[6] Although the acute radiation risks from a dirty bomb detonation are low, the localized residual radiation contamination would likely cause widespread panic.

Anatomy, Physiology, and Pathophysiology

The biologic effects of radiation exposure are determined by the type of radiation, the total dose, the dose rate, the volume of tissue or anatomic body part irradiated, and individual susceptibility factors. The amount of energy released in matter (linear energy transfer) varies by type of radiation. Different types of radiation are assigned a quality factor (QF) based on their ability to produce biologic damage in exposed tissue. The higher the QF, the more biologically damaging the radiation is. Gamma rays, x-rays, and beta particles have a QF of 1. Alpha particles (internal exposure only) have a QF of 20, whereas neutrons have a QF range of 3 to 20, depending on their energy.

Ionizing radiation includes particles and photons that have sufficient energy to detach electrons, thus causing ionization of the atoms that they encounter. Alpha particles, beta particles, and neutrons are examples of particle ionizing radiation. Only the high-frequency portion of the electromagnetic radiation spectrum (gamma rays, x-rays, and far-ultraviolet) has sufficient energy to produce ionization. Other frequencies and wavelengths (near-ultraviolet, infrared, microwaves, radio waves, and very or extremely low frequency radiation) are considered *nonionizing*. The health effects of exposure to nonionizing radiation depend on the frequency and wavelength. For example, ultraviolet light can produce sunburns, visible light (such as lasers), can produce corneal and retinal burns, and microwaves can produce heating of body tissues.

The effects of ionizing radiation on tissue can be *direct* or *indirect*. Direct effects include single- and double-strand DNA breaks. Indirect effects act through generation of free radicals that then attack other molecules in the cell. Cells vary in their sensitivity to radiation. In general, cells that are undifferentiated, divide quickly, and have high metabolic activity are most radiosensitive. Examples of these types of cells include bone marrow stem cells, lymphocytes, spermatogonia, ovarian cells, intestinal crypt cells, and epidermal basal cells. Less radiosensitive tissues and organs are made up of cells with little or no turnover such as connective tissue or the central nervous system. The effects of radiation can be *deterministic* or *stochastic*. Deterministic effects are those in which the severity of injury is a function of dose (e.g., bone marrow suppression). Stochastic or probabilistic effects are those in which the probability of an effect, rather than its severity, is a function of dose. An example of a stochastic effect is the development of radiation-induced cancer.

For external exposure, the site of the body that is irradiated (e.g., bone marrow vs. upper extremity) is an important determinant of the resulting effects. For internal exposure, the biodisposition of the radioisotope, its radiologic and biologic half-lives, as well as the types of radioisotopes produced during radioactive decay are important determinants of the effects. *Biodisposition* refers to the absorption, distribution, metabolism, and excretion of a radioisotope.

The *effective half-life* reflects both the radiologic and biologic half-life and can be calculated as 1/effective half-life = 1/biologic half-life + 1/physical half-life.[7] For example, iodine-131 has an approximate biologic half-life of 57 days and a radiologic half-life of 8 days. The resulting effective half-life is approximately 7 days.

Radioisotopes will have their greatest effects at the sites in the body where they are concentrated. For example, radioiodine concentrates in the thyroid gland and the resulting effects, such as thyroiditis or thyroid cancer, occur at the site of concentration.

Routes of Exposure

An individual can be exposed to radiation by one or a combination of three processes: irradiation, incorporation, and contamination.

Irradiation occurs when an object or person is exposed to a radioactive source. An object does not become radioactive unless neutron activation occurs. When a person is irradiated, such as a patient who has just received a CT scan or x-ray, no hazard exists to medical personnel who come into contact with the patient.

Contamination is the presence of radioactive matter on or in an object. Contamination usually occurs externally but may be internal if the radioactive material is ingested or inhaled with continued radiation emitted by the contaminating substance. However, in almost all cases, contamination is not an acute threat to the life of the patient or the health care provider, and its presence should not preclude institution of lifesaving measures. The radioactive particulate matter may emit radiation with an effect that is directly related to the time of exposure, distance from the source, and type of contamination.

Incorporation occurs when a radioactive material is taken up by a tissue, cell, or organ. This can occur through ingestion, inhalation, or absorption via an open wound.

CLINICAL FEATURES

Acute Radiation Syndrome

Acute radiation syndrome (ARS) occurs after a patient is exposed to whole body radiation. ARS from external or internal exposure to radiation varies in nature and severity by dose, dose rate, dose distribution, and individual susceptibility. There are three phases to ARS: prodromal, latent, and manifest illness. The progression and patterns of symptoms and signs of the phases of ARS can overlap. The timing of the progression through the phases can be accelerated with increasing radiation doses.[8]

In the *prodromal phase,* initial symptoms are typically nonspecific, and include anorexia, nausea, vomiting, and fatigue. This phase is useful to help predict the severity of the radiation injury. The presence, onset, and frequency of nausea and vomiting, although nonspecific, can serve as a prognostic factor. Early onset or persistent nausea and vomiting as well as the presence of diarrhea, indicate a more severe radiation injury.

The *latent phase* is a period of initial symptom improvement. Patients may even become symptom-free. Those victims with lethal radiation doses may not have a symptom-free period and progress from the prodromal phase directly to the manifest illness phase.

The *manifest illness phase* has three sub-syndromes that may occur and overlap depending on the radiation dose received (Table 134.2). All organs are affected by radiation. However, the relative sensitivities of the organ systems exposed to radiation determines the clinical symptoms. Tissues with greater rates of cellular division, particularly the hematopoietic and gastrointestinal systems, are most radiosensitive.

TABLE 134.3 Local Irradiation Symptoms by Dose

Threshold Dose (Gy)	Symptoms	Time To Onset (Days)
3	Epilation	14 to 18
6	Early erythema	14 to 21
10	Dry desquamation	25 to 30
15	Wet desquamation	20 to 28
>20	Ulceration and necrosis	>21

The hematopoietic sub-syndrome is the first sub-syndrome seen. This sub-syndrome can appear at doses greater than 1 Gy and typically results in bone marrow suppression. At doses less than 1 Gy (100 rem), most cells survive but may be susceptible to radiation-induced cancer.[9] Lymphocytes are the first cell line to decrease and with high doses of radiation this drop will occur sooner and with greater severity. The hematopoietic system in children has been estimated to be more than twice as radiosensitive as in adults.[10]

The gastrointestinal sub-syndrome begins to occur at doses nearing 6 Gy, about 1 week after exposure. Patients will display nausea, vomiting, gastrointestinal bleeding, malabsorption, and fluid losses, potentially leading to hypovolemia and cardiovascular collapse. These symptoms are due to death of the intestinal epithelial precursor cells and resultant denuding of the intestinal epithelial surface. Thrombocytopenia and immunosuppression from the accompanying hematopoietic sub-syndrome also predispose patients to infection and bleeding.[11]

The neurovascular sub-syndrome results from doses greater than 10 Gy and is typically lethal. Patients will develop irritability, altered mental status, seizures, prostration, ataxia, and hypotension. Coma and death usually occur within a few hours. Because of the high dose of radiation needed to produce these findings, patients often die without experiencing a latent phase.[11]

Local Radiation Injury

Cutaneous involvement can occur following a radiation exposure. It can be one component of ARS with other organ involvement or it can occur alone.[11] Radiation injury limited to the skin and the tissues located directly beneath the area of injury is termed a *local radiation injury (LRI).*This injury typically happens after a patient handles or has close contact with an industrial radioactive source. LRI can also result from medical testing or therapy, such as fluoroscopy, nuclear medicine studies, and CT scans.[12] Inflammation, oxidative damage, and damage to the microvasculature are all involved in the pathophysiology of LRI. Hair loss occurs after exposure to 3 Gy, and erythema is seen after exposure to 6 Gy. Wet desquamation, a loss of epithelial thickness and integrity leading to fluid loss, occurs after 15 Gy, and necrosis occurs after 20 to 25 Gy of localized skin exposure (Table 134.3).[13,14]

DIFFERENTIAL DIAGNOSES

The initial signs and symptoms following radiation exposure are nonspecific and include anorexia, nausea, vomiting, and fatigue. In the absence of an exposure history, these symptoms in the prodromal phase of acute radiation sickness can be confused for gastroenteritis with its long list of differential diagnoses. Neutropenia seen after whole body radiation exposure also has many other etiologies, including viral infections, medication-induced, certain autoimmune or oncological disorders, and nutritional deficiency.

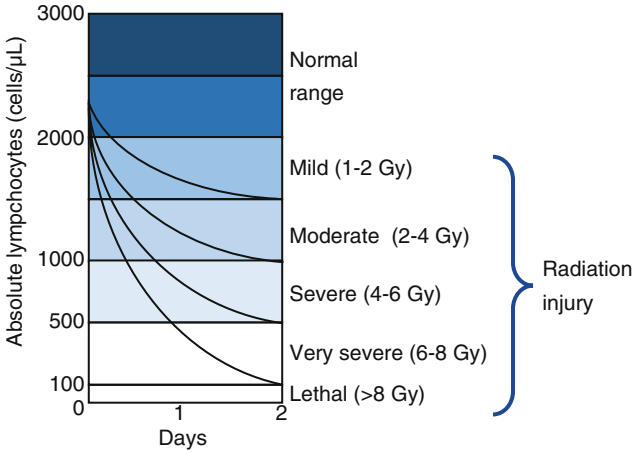

Fig. 134.2 Lymphocyte decrease over time following radiation injury. (Adapted from: Andrews GA, Auxier JA, Lushbaugh CC. The importance of dosimetry to the medical management of persons exposed to high levels of radiation. In: *Personal Dosimetry for Radiation Accidents.* Vienna: International Atomic Energy Agency; 1965.)

The severe symptoms following high-dose radiation injury resulting in the neurovascular sub-syndrome can occur with any catastrophic cardiovascular or neurologic event. Local radiation injuries can appear similar to thermal or sun exposure burns but differ in their progression over time.

DIAGNOSTIC TESTING

If contamination with radioactive material is a possibility, then the patient should be surveyed with a contamination survey instrument (e.g., Geiger Muller detector). These very sensitive detectors measure the presence of radioactive material in counts per minute. There are a variety of other radiation detection devices that are designed to measure field strength in units of mrem/hour or μSv/hour. These latter types of instruments are most often used to measure radiation fields at an incident scene or "hot zone." The hospital radiation safety officer should be consulted to assist in performing radiation surveys of potentially contaminated patients or objects.

Quantifying the absorbed dose of radiation can be challenging, especially in the emergency department (ED). Information on the radiation source, field strength, time of exposure, distance, shielding, and routes of exposure is often incomplete. Although radiation doses can be reconstructed at a later time by health physicists, emergency clinicians will most often rely on biodosimetric tools, such as time to vomiting and lymphocyte depletion kinetics. These online tools are available at www.remm.nlm.gov/ars_wbd.htm#vomit.

A baseline complete blood count (CBC) with differential and absolute lymphocyte count should be obtained and repeated every 6 hours for the first 24 hours and at least daily thereafter. The absolute lymphocyte count at 48 hours after exposure is a good predictor of radiation injury (Fig. 134.2). If the absolute lymphocyte count at 48 hours is greater than 1200 cells/μL, it is unlikely that the patient has received a clinically significant dose of radiation. If the absolute lymphocyte count falls between 100 and 500 cells/μL at 48 hours, a significant or even lethal dose of radiation should be suspected. A level in this range is an indication for neutropenic precautions.[11] Thrombocytopenia and anemia may develop weeks later because these cell lines are less radiosensitive. Serum lipase, liver function tests, and C-reactive protein (CRP) should also be obtained and repeated daily. If the patient has been internally exposed to radioisotopes, rather than just external radiation,

TABLE 134.4 Available Resources for Assistance and Consultation During a Radiation Incident and Informational Resources

obtain nasal and mouth swabs and collect 24-hour urine and feces specimens for radiation bioassay.[7] Hospital nuclear medicine departments may have equipment that can be adapted and used for the diagnosis of internal contamination (e.g., thyroid scanners and gamma cameras).

MANAGEMENT

Prehospital Care

Gathered information regarding the exposure event includes: the numbers and types of patients potentially affected, the radionuclide involved, the route of exposure, and the estimated dose of radiation. Multiple triage guidelines exist to help guide transport and decontamination of individuals in the prehospital setting and are available to the public (Table 134.4).[15,16] Most communities will have a disaster plan for radiation incidents, which should be activated if a significant number of patients are involved.

Decontamination should be initiated at the scene. Patients with abnormal vital signs need partial decontamination, such as clothing removal, at the scene before expeditious transportation to an ED or medical facility. Unstable patients, however, should be rapidly transported in lieu of decontamination measures. Pre-arrival contact and up-to-date information should be provided to the receiving hospital as far in advance as possible to facilitate preparations and local safety measures. If the community disaster plan has a designated hospital for radiation-contaminated victims, patients should be transported directly to that facility, bypassing other hospitals less equipped to care for these complicated patients.

Emergency Department

Preparation

The chaos that occurs following radiation exposure incidents highlights the need for a community disaster plan with a predetermined incident command structure empowered to make decisions about evacuation and other issues concerning the at-risk population. On notification of the numbers and types of patients involved in a radiation exposure, incident commanders make a decision about implementation of a full disaster plan versus a limited response. The hospital radiation control officer should be contacted immediately. The radiation control officer monitors all patients and medical personnel with a radiation counter and supervises the "clean-up" and routing of patients to minimize "tracking," or spread, of contamination. Information dissemination to the public is critical. Timely and accurate information and instructions should be given to a public relations representative for dissemination to the news media to minimize the chaos and paranoia that inevitably result from such incidents.

External Contamination

Radiation contamination is *not* an acute threat to the life of the patient, first responder or health care provider, and its presence does not preclude institution of lifesaving measures. If standard precautions are taken, the risk to the health care providers is minimal. This was true for the providers caring for Alexander Litvinenko, a former agent of the Federal Security Service of the Russian Federation who was poisoned with a radioactive substance. It was 3 weeks before it was determined that he was internally contaminated with polonium 210.[17] Because the risk is minimal, care for life-threatening conditions and evaluation for severe traumatic injuries takes precedence over decontamination measures. A general approach to the patient exposed to radiation developed by the Radiation Emergency Assistance Center/Training Site of Oak Ridge Associates Universities is shown in Figure 134.3.

When a person is irradiated without any contamination, as in a patient who has just received a CT scan or x-ray, no hazard exists to medical personnel and the patient may be handled like any other emergency patient.

If a patient is determined to be contaminated with radioactive material by survey with a radiation counter (such as a Geiger counter), then they require decontamination. Universal precautions, including rubber gloves, eye protection, hair covers, shoe covers, and respirators (if airborne contamination is suspected), are effective in protecting personnel and the work area from contamination. The only variation from standard precautions is to wear two sets of gloves and to change the outer pair when appropriate to avoid cross-contamination.[15] Removing the patient's clothing and placing it in a plastic bag is paramount because exposed garments are responsible for 70% to 90% of the radiation from the patient.[15] If possible, soap and water cleansing of exposed skin should be performed. All materials, including wash water, should be placed in containers and labeled as radioactive waste. After decontamination, a repeat survey is performed. Decontamination is repeated until the patient's radiation reading is equal to or below two times the background radiation level. If decontamination methods are causing damage or injury to the skin, they should be discontinued regardless of the patient's radiation survey results.[7]

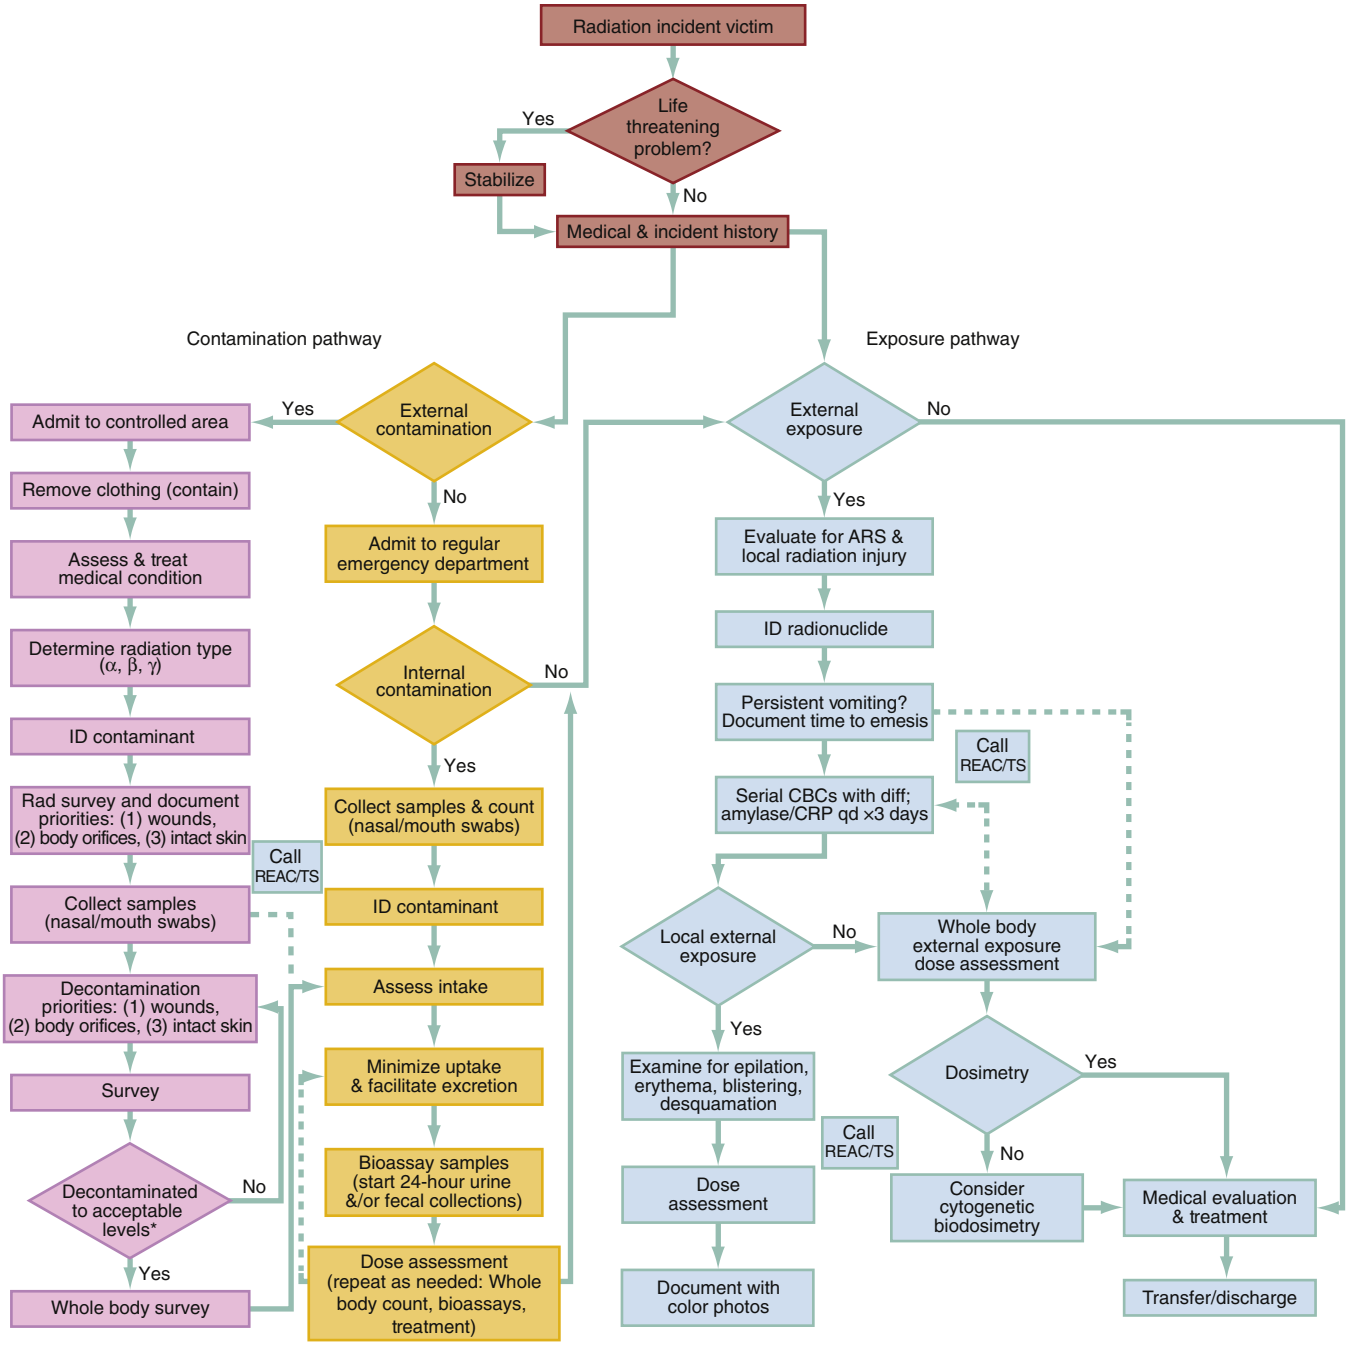

Fig. 134.3 Radiation patient treatment algorithm. *, <2–3× Natural background or no reduction in counts, medical priorities dictate stopping decontamination, health physics consultation warranted. *ARS,* Acute radiation syndrome; *CBC,* complete blood count; *CRP,* C-reactive protein; *diff,* differential; *ID,* identification; *qd,* on prescription; *REAC/TS,* Radiation Emergency Assistance Center/Training Site. (Used with permission and originally published by ORISE and REAC/TS under contract number DE-AC05-06OR23100 between the US Department of Energy and ORAU.)

Wounds can be decontaminated with saline or water. Using high pressure for irrigation is more important than the type of irrigation solution.[18] Remove foreign bodies and safely set these aside for further analysis. Repeat irrigation until the survey reveals decreased wound radiation. If further attempts at decontamination do not result in a decreased amount of radiation in the wound, then clinicians can proceed with standard medical treatment or surgical closure. Attempts to surgically decontaminate the wound should be avoided because this will potentially cause more localized damage.[19]

Internal Contamination

Assessing a patient for internal contamination can be difficult because most beta and alpha emitters will not be detectable with standard handheld survey devices. If a patient is externally contaminated, they have a higher risk of being internally contaminated. For internally contaminated patients, management focuses on decreasing absorption, enhancing elimination, and blocking distribution to target organs.[7] Treatment directed at internal contamination by particular radionuclides can include potassium iodide for radioactive iodine exposures,

TABLE 134.5 Radionuclides of Interest, Primary Decay Pattern, Half-Life, Major Routes of Exposure, and Recommended Treatment

	Name	Isotope	Decay	Half-Life	Route of Exposure	Treatment

bicarbonate for uranium, Prussian blue for cesium, and DTPA for plutonium and transuranics (Table 134.5).

Acute Radiation Syndrome

Hematopoietic Sub-Syndrome. Colony-stimulating factors (cytokines) that induce bone marrow hematopoietic cells to proliferate may have substantial benefit with little risk to victims who are predicted to have moderate or severe bone marrow failure. Cytokine therapy should be started for the following reasons: a greater than 2 Gy dose exposure, decrease in lymphocyte count, or if leukopenia is expected to last more than 7 days. Cytokines are started within 24 hours of exposure and continued until the absolute lymphocyte count is above 1000 cells/μL. Bone marrow transplant is considered for patients who continue to have prolonged leukopenia (2 to 3 weeks) in spite of cytokine treatment; however, the patients must not have other significant organ involvement.[11] Prophylactic antibiotics are given in accordance with the Infectious Disease Society of America recommendations for neutropenia.[19]

Gastrointestinal Sub-Syndrome. Treatment for the gastrointestinal sub-syndrome is largely supportive with antiemetics (preferably serotonin receptor antagonists such as ondansetron), antidiarrheals, fluid resuscitation, antibiotics, and monitoring for signs of gastrointestinal perforation.

Neurovascular Sub-Syndrome. Patients who develop signs and symptoms consistent with this sub-syndrome within the first 24 hours should be provided palliative comfort care, because they likely sustained a lethal dose of radiation.

Local Radiation Injury

Patients who sustained an LRI are managed in a manner similar to thermal burn patients.[14,20] Treatment at a burn center is preferred for débridement and wound care. Eventual extremity amputation may be necessary in patients who present with symptoms such as pain and erythema shortly after radiation exposure. Due to the chronic vascular injury and the potential for even minor trauma to the area to recapitulate the injury, the following are important in the treatment of LRI: topical corticosteroids, hyperbaric oxygen (HBO) therapy, pentoxifylline and vitamin E therapy, and appropriate wound care. New treatments currently under investigation include gene therapy, topical administration of growth factors, and laser therapy.[20]

Psychological Consequences

The general public harbors a profound fear of radiation and its effects on the body. Radiation is one of the most dreaded components of a terrorist attack or industrial disaster.[21] People are fearful of the long-term effects of radiation exposure, such as cancer, and especially with their children. This fear can lead to ostracizing people or things associated with the event. Furthermore, those who develop ARS or other illnesses related to radiation may have significant fear and depression requiring psychological posttraumatic support. Moreover, both health

care providers and communities as a whole are also at risk for psychological effects from a radiation incident. As a result, proper information dissemination to the public and incorporation of behavioral health professionals early into the disaster response are extremely important.

DISPOSITION

The disposition will depend in part on the scale of the event and the availability of medical resources. A mass casualty event may place a strain on surge capacity, requiring disaster triage and resource rationing. Fortunately, large-scale radiation events are rare, and most radiation incidents have generated small numbers of patients requiring emergency or intensive care. The time of onset to vomiting can be useful in determining likelihood of survival. Patients who experience vomiting within 2 hours of exposure will require hospitalization and careful medical observation, because they are likely to have sustained life-threatening doses of radiation. Patients with severe burns and those requiring surgical management should be transferred to a burn unit, preferably within 72 hours from the time of radiation exposure.

ADDITIONAL RESOURCES

Many resources are available for both assistance in diagnosing and managing radiation injuries and for reporting of incidents. Table 134.4 lists resources that can help guide diagnosis and treatment of radiation emergencies and provide evidence-based information for those without formal radiation medicine expertise.

The authors wish to thank and acknowledge Daniel O. Hryhorczuk for his expertise and contributions to this chapter in previous editions.

CHAPTER 134: QUESTIONS AND ANSWERS

1. Your Emergency Department receives a report of a "dirty bomb" explosion with multiple injuries and deaths on scene. Which injuries would you be *most* likely to see?

a. Cutaneous (local) radiation injuries
b. Gastrointestinal radiation injuries
c. Hematopoietic radiation injuries
d. Neurologic radiation injuries
e. Soft tissue and orthopedic injuries

Answer: E. "Dirty bomb" is a term for a traditional explosive device to which an amount of radioactive material has been added. The greatest risk of injury is from traditional blast/explosive effects. The risk of radiation injury and contamination from a "dirty bomb" is extremely low. The small amount of radioactive material that survives the explosion is concentrated in the area immediately around the explosion, where victims are likely killed by the blast itself.

2. Which of the following is the proper sequence for caring for patients from a mass casualty incident involving potential radiologic contamination?

a. Decontamination, assess with radiation meter, emergency stabilization, mass casualty triage
b. Assess with radiation meter, decontamination, mass casualty triage, emergency stabilization
c. Assess with radiation meter, decontamination, emergency stabilization, mass casualty triage
d. Mass casualty triage, emergency stabilization, assess with radiation meter, decontamination
e. Decontamination, emergency stabilization, mass casualty triage, assess with radiation meter

Answer: D. In radiation incidents, the immediate risk to patients and providers from radiation injury is low. The most immediate risks are from traditional ABCD compromises. Thus, mass casualty triage and emergency stabilization take precedence, followed by an assessment for radiologic contamination, and decontamination if needed. This is in contrast to chemical or biologic incidents, where decontamination takes precedence.

3. A worker in your hospital's blood bank comes into the emergency department (ED) complaining that he has been exposed to radiation on an ongoing basis for approximately 1 month. He reports his job duties include irradiating blood products to be used in the hospital and that he has not been wearing protective clothing. He reports a burning sensation in his hands. His physical examination is normal. What is the appropriate course of action?

a. Admit for observation
b. Decontaminate the patient, admit for observation
c. Decontaminate the patient, discharge home
d. Decontaminate the patient, place on isolation, admit for observation
e. Educate patient and arrange appropriate follow-up

Answer: E. This patient has been irradiated but not contaminated. Patients who are exposed to external beam radiation are not made radioactive and are not a hazard to others. Decontamination and isolation are not necessary. With a normal physical examination and minimal symptoms, this patient can be followed as an outpatient. The most important action in this instance is to educate the patient.

CHAPTER 134: QUESTIONS AND ANSWERS—cont'd.

4. What is the most important laboratory test to be performed 48 hours after exposure in determining the prognosis of a patient exposed to a significant radiation source?
   a. Absolute lymphocyte count
   b. Absolute neutrophil count
   c. Genetic karyotype
   d. Platelet count
   e. Aspartate aminotransferase

Answer: A. Monitoring the kinetics of lymphocyte depletion during the first 48 hours following a radiation exposure is very useful at estimating the radiation dose received. The 48-hour absolute lymphocyte count is the most important prognostic indicator. Levels greater than 1200/μL indicate a clinically insignificant dose of radiation and an excellent prognosis. Levels less than 500/μL indicate a significant and possibly lethal exposure. None of the other answer choices carry prognostic significance.

5. Which of the following symptoms within the first 24 hours after a significant radiation exposure would indicate a lethal dose of radiation?
   a. Bruising
   b. Gait ataxia
   c. Nausea and vomiting
   d. Skin burns
   e. Shortness of breath

Answer: B. The neurologic system is the most resistant to radiation injury, requiring at least a 10 Gy dose to be affected. The development of neurologic symptoms (such as altered mental status, focal weakness/paralysis, dizziness, ataxia, seizures) within 24 hours of exposure indicates a lethal dose of radiation. The hematopoietic system is the most radiosensitive (can be affected by as little as 0.5 to 1 Gy), followed by the gastrointestinal system (more than 5–7 Gy). The skin will be affected by local doses of radiation greater than 3 to 5 Gy.

6. A 45-year-old man is inadvertently exposed to a radiation field of 850 mSv/hour for 4 hours while working on the clean-up of a nuclear power plant. In addition to general supportive care, which of the following medications may improve his survival?
   a. Acyclovir
   b. Colony-stimulating factor (cytokines)
   c. Diethylenetriaminepentaacetate (DTPA)
   d. Erythropoietin
   e. Potassium iodide

Answer: B. This patient's radiation dose is sufficient to produce the hematopoietic component of acute radiation syndrome (ARS). Cytokines or colony-stimulating factors have shown modest effects in improving survival. Irradiated patients may develop oral herpes, and acyclovir can be used for treatment but does not affect survival. Anemia is present in most irradiated patients but is typically not clinically significant, and erythropoietin has no role. DTPA is a chelating agent that can be used for patients with internal exposure to plutonium or transuranics. Potassium iodine is useful if a patient is exposed to radioactive iodine, because it will compete with the radioactive iodine for uptake into the thyroid gland, resulting in overall less radioactive uptake.

135

Care of the Poisoned Patient

Timothy J. Meehan

KEY CONCEPTS

- Toxidromes are constellations of signs and symptoms based primarily on vital signs and neuropsychiatric functions that are characteristic manifestations of certain toxic exposures. Recognition of the presence of a toxidrome can suggest a potential intoxicant and guide early interventions and management strategies. Examples of toxidromes include sympathomimetic, antimuscarinic, cholinergic, sedative-hypnotic, and opioid categories.
- Qualitative urine drug assays have limited roles in the clinical setting and are inferior to quantitative serum levels in terms of guiding specific therapy.
- Syrup of ipecac is not indicated in the emergency department (ED) care of a poisoned patient. Gastric lavage is not part of routine care. When given in a timely fashion (1-hour post ingestion), activated charcoal may be indicated for potentially lethal agents in alert, cooperative patients as noted in Figure 135.1. Whole-bowel irrigation is rarely useful for management of poisoned patients but is potentially helpful for specific poisonings, such as metals, illicit drug packets, or sustained-release medications.
- Serum alkalinization enhances urinary drug elimination for certain drugs and is indicated for significant poisoning caused by salicylates, phenobarbital, and methotrexate.
- Hemodialysis is best suited to remove poisons of low molecular weight, low protein binding, and high water solubility; examples include methanol, ethylene glycol, lithium, and salicylates.
- Regional Poison Control Centers (US: 1-800-222-1222) or a medical toxicologist can assist with antidotal therapy and may help facilitate patient disposition.
- If the motivation behind the toxic exposure was self-harm, a psychiatric consultation is warranted. Patients with substance use disorders should be referred to a detoxification center or designated program.

PRINCIPLES OF TOXICITY

Most poisoned patients seen in the emergency department (ED) are adults with intentional drug overdoses. The second most common scenario involves accidental poisoning in children, which actually represents the majority of calls to regional poison control centers.[1] Additionally, other frequent causes of toxicity include: illicit drugs of abuse, accidental poisoning from pharmaceutical agents (drug-drug interactions as well as chronic toxicity), environmental exposures, and envenomations. Occupational chemical exposures, both industrial and agricultural, represent other important sources of potential toxicity. In the ED, it is important to evaluate and recognize scenarios where there may be immediate or delayed toxicity, in order to guide strategies for decontamination, enhanced drug elimination, and administration of antidotes when indicated.

When evaluating a patient with a particular ingestion, essential historical points include: the agent itself, the route of exposure, the amount ingested, possible co-ingestants, and the timing of the exposure. Knowing these facts can help make a determination regarding the expected course of care in the ED and help to mobilize diagnostic and therapeutic resources.

CLINICAL FEATURES

Toxicologic History and Physical

Oftentimes, the poisoned patient may be altered, obtunded, or uncooperative with the examiner. This leaves the history limited to that which can be gleaned from witnesses, such as paramedics or family, and the information generated from physical examination findings over which the patient does not have conscious control.

Historical information should be pulled from all available sources. A family member or friend may offer insight into the circumstances behind the patient's exposure (e.g., intentional or accidental). Information regarding what medications or substances were available to the patient, and the timing of ingestion also is important. Paramedics should bring in all medication bottles present at the scene, not just the patient's prescribed medications or alleged ingestion; if they do not, someone should be sent to the patient's dwelling to retrieve them. Frequently, confusion as to what exactly was ingested can occur (e.g., ibuprofen mistaken for aspirin or acetaminophen) and this can lead a provider down the wrong path. A patient attempting suicide may intentionally mislead the ED staff, or medications may have been stored in mislabeled containers. Other sources of potentially useful information include state controlled-substance registries, pharmacy records, and previous medical records. Accessing the patient's text-messaging history also may be helpful, if the patient consents to this or if friends and family provide this collateral information of their own accord.

For chemical exposures in either the home or workplace, avoid exposure to other individuals in the ED. Proper identification of the substance is important to initiate care and obtain product safety information, such as a Material Safety Data Sheet. Consequently, one could consider taking a picture of the label including any precise chemical

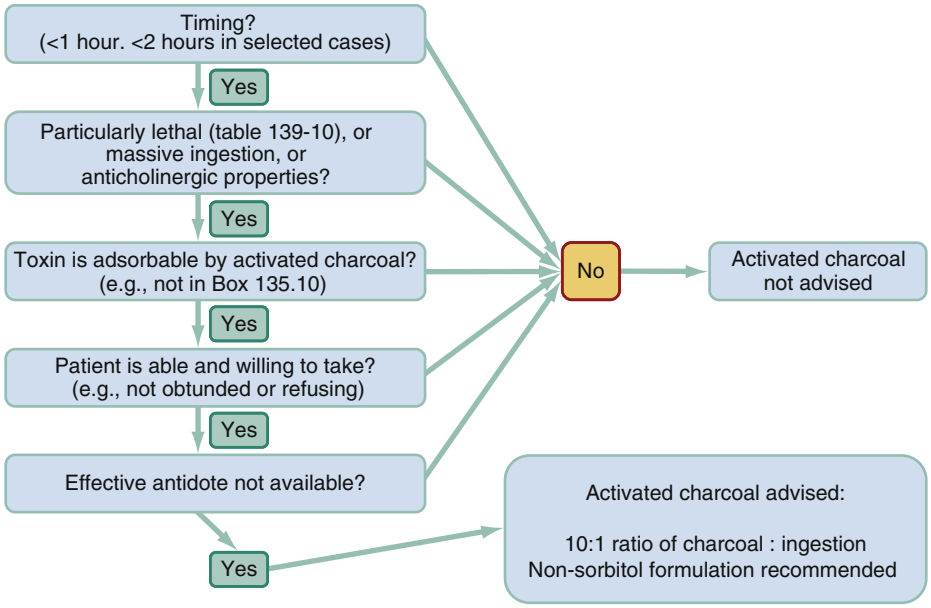

Fig. 135.1 Indications for early administration of activated charcoal 1 hr post-ingestion.

BOX 135.1 Agents Affecting Pupil Size

Miosis (COPS)
Cholinergics, clonidine, carbamates
Opioids, organophosphates
Phenothiazines (antipsychotics), pilocarpine, pontine hemorrhage
Sedative-hypnotics

Mydriasis (SAW)
Sympathomimetics
Anticholinergics
Withdrawal syndromes

Toxicology acronyms listed in Boxes (135.1–12) were created and previously published by Timothy B. Erickson (used and modified with permission.)

BOX 135.2 Agents Causing Coma or Seizures

Coma (LETHARGIC)
Lead, lithium
Ethanol, ethylene glycol, ethchlorvynol
Tricyclic antidepressants, thallium, toluene
Heroin, hemlock, hepatic encephalopathy, heavy metals, hydrogen sulfide, hypoglycemics
Arsenic, antidepressants, anticonvulsants, antipsychotics, antihistamines
Rohypnol (sedative hypnotics), risperidone
Gamma-hydroxybutyrate (GHB)
Isoniazid, insulin
Carbon monoxide, cyanide, clonidine

Seizures (OTIS CAMPBELL)
Organophosphates, oral hypoglycemics
Tricyclic antidepressants
Isoniazid, insulin
Sympathomimetics, strychnine, salicylates
Camphor, cocaine, carbon monoxide, cyanide, chlorinated hydrocarbons
Amphetamines, anticholinergics
Methylxanthines (theophylline, caffeine), methanol
Phencyclidine (PCP), propranolol
Benzodiazepine withdrawal, botanicals (water hemlock, nicotine), bupropion, GHB
Ethanol withdrawal, ethylene glycol
Lithium, lidocaine
Lead, lindane

numbers; if a substance is brought to the ED, take appropriate steps to avoid further exposure, such as sealing in an airtight container.

Poisoned patients are frequently unwilling or unable to participate in an interactive physical examination. The toxicologic physical examination, therefore, rests upon observing factors that do not require cooperation to elicit. Many ingested substances can cause derangement of the pulse, respiratory rate, as well as blood pressure. Rapid and accurate recording of the patient's vital signs, including pulse oximetry and a rectal core temperature, should be done and repeated at appropriate intervals depending on the suspected toxin. Patients with hemodynamic instability or obtundation should be considered for continuous monitoring, at least initially until stabilized. The overall level of consciousness, pupillary size, and presence or absence of seizure activity may suggest a particular agent (Boxes 135.1 and 135.2). Examination of the skin and mucous membranes with particular attention to discoloration and level of moisture may suggest poisoning by any of several agents (Box 135.3); it may also reveal evidence of injection drug abuse, such as "track marks" or ulcerations from "skin popping." A careful neurologic examination focusing on the level of muscle tone, clonus, or hyperreflexia can assist in the diagnosis of serotonin syndrome or neuroleptic malignant syndrome (NMS). Certain intoxicants may have particular odors associated with them; the presence of such an odor ought to alert the clinician to the possibility of poisoning by one of these agents (Table 135.1); however, the absence of a characteristic smell does not exclude it.

Toxidromes

Toxidromes are constellations of signs and symptoms based on autonomic and neurochemical processes that can suggest a particular class of exposure and direct management and therapy. The five traditionally described entities include the sympathomimetic, anticholinergic (antimuscarinic), cholinergic, sedative/hypnotic, and opioid toxidromes.

BOX 135.3 Agents Causing Skin Findings

Diaphoretic Skin (SOAP)
Sympathomimetics
Organophosphates
Acetylsalicylic acid or other salicylates
Phencyclidine (PCP)

Dry Skin
Antihistamines, anticholinergics

Bullous Lesions or Blisters
Barbiturates and other sedative-hypnotics
Mustard gas
Snakes and spiders

Flushed or Red Appearance
Anticholinergics, niacin
Boric acid
Carbon monoxide (in morbid states)
Cyanide (rare)

Cyanosis
Ergotamine
Nitrates
Nitrites
Aniline dyes
Phenazopyridine
Dapsone
Agent causing hypoxemia, hypotension, or methemoglobinemia

Acneiform Rash
Bromides
Chlorinated aromatic hydrocarbons

TABLE 135.1 Agents With a Characteristic Odor

Odor	Possible Source
Bitter almonds	Cyanide
Carrots	Cicutoxin (water hemlock)
Fruity	Diabetic ketoacidosis, isopropanol
Garlic	Organophosphates, arsenic, dimethyl sulfoxide (DMSO), selenium
Gasoline	Petroleum distillates
Mothballs	Naphthalene, camphor
Pears	Chloral hydrate
Pungent aromatic	Ethchlorvynol
Oil of wintergreen	Methylsalicylate
Rotten eggs	Sulfur dioxide, hydrogen sulfide
Freshly mowed hay	Phosgene

In addition, withdrawal disorders, serotonin syndrome, and NMS have been well described.

Sympathomimetic

This toxidrome is defined by a state of sympathomimetic excess, typically causing those effects expected from the "fight or flight" reaction. Patients are often in an altered state and may be delusional—especially with ingestion of substituted amphetamines, such as *N*-methyl-3,4-methylenedioxyamphetamine (MDMA: "ecstasy" or "molly") or synthetic cannabinoids. Patients typically present with hypertension, tachycardia, and tachypnea. They may also be hyperthermic as a consequence of an increased metabolic rate. Mydriasis and diaphoresis may also be present. In severe overdoses, derangement of cardiac output can occur. Decreased diastolic filling time coupled with dysrhythmogenesis can result in circulatory collapse and shock, which may be refractory to fluid resuscitation and pressor agents.

Anticholinergic

The anticholinergic toxidrome is frequently encountered, because many pharmaceuticals have antimuscarinic properties. It manifests as a consequence of blocking normal cholinergic tone, causing an alteration in the normal homeostatic balance between the sympathetic and parasympathetic arms of the autonomic nervous system. This allows the sympathetic side to function unopposed and generates a state of relative sympathomimesis. Therefore, many of the symptoms attributable to the anticholinergic toxidrome—delirium, hyperthermia, mydriasis, and cutaneous flushing—share similarity with the sympathomimetic toxidrome. In contrast, because the secretory glands of the skin and mucous membranes contain muscarinic acetylcholine receptors, these patients are typically dry and not diaphoretic as found in the sympathomimetic toxidrome. The typical signs and symptoms can be recalled by the mnemonic "mad as a hatter, hot as a hare, blind as a bat, red as a beet, and dry as a bone." Patients with severe anticholinergic toxicity are often altered and may be delusional, often requiring sedation in the emergency department (see Management section).

Cholinergic

The cholinergic toxidrome results from overstimulation of the parasympathetic portion of the autonomic nervous system, which maintains the "rest and digest" functions. These patients typically have "fluids coming from every orifice" as a consequence of increased glandular secretion, and present with diaphoresis, urination, miosis, bronchorrhea, emesis, lacrimation, lethargy, and salivation (Box 135.4). Agents of concern are primarily anticholinesterase agents, such as organophosphates and carbamate insecticides. These substances are readily available as pesticides; but they have also been engineered as weapons of mass destruction, typically referred to as nerve gases (e.g., sarin gas) and more recently the novel or *Novichok* agents. It is important to rapidly recognize this toxidrome because patients frequently die from excessive bronchorrhea, effectively drowning in their own secretions, unless timely antidotal therapy and cholinesterase regenerators are given.

Nicotine poisoning from tobacco can occur in children who ingest detritus, such as used cigarettes or chewing tobacco, as well as liquids from electronic cigarettes.[2] Nicotine stimulates the nicotinic acetylcholine receptors in the autonomic nervous system. This is the first postsynaptic step in both the sympathetic and parasympathetic subsystems. Given the role of nicotine in both the central and peripheral autonomic nervous systems, the clinical picture in these poisonings may resemble both sympathomimetic and cholinergic toxidromes as noted in Box 135.4.

Sedative/Hypnotic

This toxidrome primarily presents with sedation and occurs on a spectrum depending on the particular substance, route, and potency. In severe ingestions, a state of general anesthesia may be reached with loss of muscle tone and airway protective reflexes. Additionally, overdose can be severe enough to cause hypothermia through suppression of muscular thermogenesis. The sedative/hypnotic toxic syndrome is well known in the ED, largely because ethanol intoxication is frequently seen. Other agents such as benzodiazepines and barbiturates will also cause a similar picture, as will illicit substances such as

BOX 135.4 Toxidrome Symptoms

Cholinergic

Muscarinic (DUMBELLS)

Diarrhea, diaphoresis
Urination
Miosis
Bradycardia
Bronchorrhea
Emesis
Lacrimation
Lethargic
Salivation

Nicotinic: Days of Week

Mydriasis
Tachycardia
Weakness
Tremors
Fasciculations
Seizures
Somnolence

Anticholinergic

Hyperthermia (HOT as a hare)
Flushed (RED as a beet)
Dry skin (DRY as a bone)
Dilated pupils (BLIND as a bat)
Delirium, hallucinations (MAD as a hatter)
Urinary retention (DRY as a bone)
Tachycardia

Opioid

Acute Intoxication/Overdose

Miosis
Hypoventilation
Depressed mental status/coma

Withdrawal

Withdrawal
Diarrhea
Mydriasis
Goose flesh
Tachycardia
Lacrimation
Hypertension
Yawning
Cramps
Hallucinations
Seizures (with ethyl alcohol [ETOH] and benzodiazepine withdrawal)

Sympathomimetic

Hyperthermic
Flushed
Diaphoretic
Mydriatic
Agitated
Tachycardic
Seizures

gamma-hydroxybutyrate (GHB). The incidence of concomitant traumatic injuries (from falls or syncope) may be high in these patients, and providers should exclude their presence.

Opioid

Similar to sedative/hypnotics, the opioid toxidrome also involves sedation and a diminished respiratory drive. With the notable exception of pentazocine and propoxyphene, this toxidrome causes pupillary miosis. The diagnosis is confirmed by noting a rapid response to naloxone, a direct opioid receptor antagonist. However, because certain opioids have higher potencies, a lack of response to this reversal agent does not exclude opioid intoxication. Furthermore, this is a clinical diagnosis because not all opioids will be detectable by the standard drug screen (discussed later).

Serotonin Syndrome

A state of serotonergic excess defines this toxidrome, and it is often precipitated by the addition of a new serotonergic agent or a substance that interferes with the metabolism of a previously tolerated agent. Typically described with selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOIs), it has been reported with cyclic antidepressants, atypical antipsychotics; and nonpsychiatric medications such as tramadol and ondansetron. Serotonin syndrome typically occurs within hours to days of introduction of a new medication, although it has been described in a delayed fashion due to the prolonged half-lives of some antidepressants. The manifestations of serotonin syndrome include altered mental status, agitation, autonomic instability (hyperthermia, diaphoresis, hypertension), and most notedly, neuromuscular abnormalities (hyperreflexia and clonus).

BOX 135.5 Altered Mental Status

AEIOU

Alcohol/acidosis
Encephalopathy/electrolytes
Infection
Opioids/overdose
Uremia

Tips

Trauma
Insulin (hypoglycemia/hyperglycemia)
Psychosis
Seizure/stroke

Neuroleptic Malignant Syndrome

Similar to serotonin syndrome, NMS also presents with altered mental status, agitation, autonomic instability, severe hyperthermia, and neuromuscular abnormalities. Unlike serotonin syndrome, however, peripheral muscular effects tend toward rigidity and hyporeflexia rather than clonus and hyperreflexia. It is due to dopaminergic depletion secondary to chronic use of dopamine antagonists, such as antipsychotics.

DIFFERENTIAL DIAGNOSES

Frequently, poisoned patients have some level of delirium as part of their presentation. As such, excluding other causes of altered mental status while initiating appropriate toxicologic therapy is appropriate (Box 135.5). Any "intoxicated" patient presenting to the ED should

BOX 135.6 Predicting Toxicity from Vital Signs

Bradycardia (PACED)
Propranolol (β-blockers), poppies (opioids), propoxyphene, physostigmine
Anticholinesterase drugs, antiarrhythmics
Clonidine, calcium channel blockers
Ethanol or other alcohols
Digoxin, digitalis

Tachycardia (FAST)
Free base or other forms of cocaine, Freon
Anticholinergics, antihistamines, antipsychotics amphetamines, alcohol withdrawal
Sympathomimetics (cocaine, caffeine, amphetamines, phencyclidine [PCP]), solvent abuse, strychnine
Theophylline, tricyclic antidepressants (TCAs), thyroid hormones

Hypothermia (COOLS)
Carbon monoxide
Opioids
Oral hypoglycemics, insulin
Liquor (alcohols)
Sedative-hypnotics

Hyperthermia (NASA)
Neuroleptic malignant syndrome (NMS), nicotine
Antihistamines, alcohol withdrawal
Salicylates, sympathomimetics, serotonin syndrome
Anticholinergics, antidepressants, antipsychotics

Hypotension (CRASH)
Clonidine, calcium channel blockers
Rodenticides (containing arsenic, cyanide)
Antidepressants, aminophylline, antihypertensives
Sedative-hypnotics
Heroin or other opioids

Hypertension (CT SCAN)
Cocaine
Thyroid supplements
Sympathomimetics
Caffeine
Anticholinergics, amphetamines
Nicotine

Rapid Respiration (PANT)
Phencyclidine (PCP), paraquat, pneumonitis, phosgene
Acetylsalicylic acid (ASA) and other salicylates
Noncardiogenic pulmonary edema, nerve agents
Toxin-induced metabolic acidosis

Slow Respiration (SLOW)
Sedative-hypnotics (barbiturates, benzodiazepines)
Liquor (alcohols)
Opioids
Weed (marijuana)

have the reversible causes of altered mental status excluded, such as hypoglycemia and nutritional deficiencies.[3] Trauma is frequently coincident with intoxication, so a careful unclothed examination looking for evidence of head trauma and other traumatic injuries should be part of the initial evaluation.

The physical examination may also reveal findings that could suggest specific intoxicants, as noted in Box 135.6. The most important diagnostic approach is maintaining a broad differential diagnosis of both toxicologic and non-toxicologic causes for the patient's presentation and avoid making a premature conclusion to the case. In these cases, differential diagnoses may be extremely broad such as when ingestion of a toxin is not known or felt unlikely.

DIAGNOSTIC TESTING

Diagnostic testing is guided by the clinical findings and suspected toxin(s) involved. When a patient presents with altered mental status and hyperthermia, testing may focus on differentiating a toxic cause from thyrotoxicosis or acute infectious diseases. Patients with intoxication and evidence of trauma may require evaluation for head trauma as a cause of their altered mental status. In many instances, it is known that the patient has a potentially toxic exposure but some or all of the involved toxins have not been implicated or identified. The approaches to individual toxins and syndromes are outlined in the relevant chapters. In the setting of an unknown overdose or exposure, a broad array of laboratory testing is often used to screen for abnormalities and potentially elucidate the clinical picture. The diagnostic studies routinely checked are: complete blood count, serum chemistry with renal function, liver function tests, urinalysis (with a pregnancy test if appropriate), urine toxicology screen, serum ethanol concentration, arterial blood gas, serum lactate, and a bedside glucose.

BOX 135.7 Commonly Available Serum Drug Levels

Acetaminophen
Acetylsalicylic acid (salicylate)
Carbamazepine
Carbon monoxide
Digoxin
Ethanol
Ethylene glycol
Iron
Isopropyl alcohol
Lead
Lithium
Methanol
Methotrexate
Phenobarbital
Phenytoin
Valproic acid

Based on these results, or when the ingestion is known, other tests such as specific serum concentrations may be obtained; Box 135.7 lists those drug levels commonly available in most hospitals. When assays for a particular agent are not available, or are not performed on site, empirical treatment generally begins before results are available. Reference laboratories are available to analyze specific and unique assays, but the turn-around time is often delayed and not clinically applicable in the emergency department.

If the blood gas shows the presence of a metabolic acidosis, calculating the anion gap can further refine the possible etiologies.

The calculation is: [Na] − ([HCO_3] + [Cl]). The normal range is 8 to 12 mEq/L.

Metabolic acidosis without an anion gap typically results from loss of bicarbonate (diarrhea, renal tubular acidosis) or gain of chloride-containing compounds (ammonia, calcium chloride). Metabolic acidosis associated with an anion gap results from an increase in unmeasured serum anions and suggests several specific toxins and disease states (Box 135.8).

BOX 135.8 Substances Causing Wide Anion-Gap Acidosis

Metal Acid Gap

M Methanol, Metformin, Massive overdose
E Ethylene glycol
T Toluene
A Alcoholic ketoacidosis
L Lactic acidosis
A Acetaminophen (large overdose)
C CO, Cyanide, Colchicine
I Isoniazid (INH), Iron, Ibuprofen
D Diabetic ketoacidosis (DKA)
G Generalized seizure inducing drugs
A ASA (salicylates)
P Paraldehyde, Phenformin

When ingestion of a toxic alcohol (such as methanol, ethylene glycol, or isopropanol) is suspected, calculating the osmolal gap may be helpful because early in the poisoning course the patient may be minimally or non-acidemic. Furthermore, urine fluorescence is not sufficiently sensitive to be reliable and its absence cannot be used to "rule out" ethylene glycol ingestion. The osmolal gap is discussed in Chapter 136.

Toxicology "screens" may also be helpful in diagnosing an unknown ingestion, provided that the limitations of these panels are understood. Blood toxicology screens can be falsely negative if the ingested drug has a short half-life and the sample is not drawn soon enough after the exposure. Urine toxicology screens are more reliable, because they typically have a longer time period for positive detection, typically 24 to 72 hours. Urine toxicology screens typically include phencyclidine (PCP), cocaine, opioids, amphetamines, and cannabinoids; however, these can vary among institutions, so knowing what is available in one's facility is important in interpreting a positive or negative screen. The urine screen is also a qualitative, not a quantitative test; as such, a positive result does not necessarily imply acute toxicity. A urine toxicology screen can be falsely positive due to cross-reactivity between agents (such as a "positive" phencyclidine or PCP screen in the setting of dextromethorphan ingestion). Alternatively, urine screens can be falsely negative if the substance ingested does not cross-react with the tested analyte—such as methadone, which does not cross-react with the opiate component of the urine toxicology screen (Table 135.2). Ultimately, the diagnosis of intoxication is clinical; urine drug screening may be confirmatory but should

TABLE 135.2 Urine Drug Screen Limitations

Assay	False Positive	True Positive (Therapeutic Use)	False Negative
Amphetamines	Many; some clinically relevant ones include: Amantadine Bupropion Labetalol Promethazine Ranitidine Trazodone	ADHD medications: Dextroamphetamine, methamphetamine Phenylephrine Pseudoephedrine	"Designer amphetamines" Molly Ecstasy
Benzodiazepines	Sertraline Oxaprozin		Alprazolam Flurazepam Midazolam "Z" drugs (zolpidem, zaleplon, zopiclone, eszopiclone)
Cannabinoids	Dronabinol Efavirenz PPI	Medical marijuana CBD oil (contaminant)	Synthetic marijuana: K2/Spice
Opiates	Dextromethorphan Diphenhydramine Quinolones		Synthetic opioids: Demerol, fentanyl, methadone, propoxyphene Semisynthetic opioids (may have some cross-reactivity): Hydrocodone, hydromorphone, oxycodone
Phencyclidine (PCP)	Dextromethorphan Diphenhydramine Ibuprofen Tramadol	Ketamine	
Cocaine	Coca leaf tea	Cocaine-containing anesthetics (topical TAC)	

ADHD, Attention deficit hyperactivity disorder; *PPI,* proton pump inhibition; *TAC,* tetracaine, adrenaline (epinephrine), and cocaine.

not supplant clinical evaluation and judgment nor should it delay therapy.

In addition to the blood work discussed earlier, one should obtain an electrocardiogram (ECG) if the patient is tachycardic or bradycardic or may have ingested a cardiotoxic agent that can prolong the QRS complex or QT intervals, such as cyclic antidepressants, antimalarials (e.g., chloroquine), and antipsychotic agents. Table 135.3 provides guidance regarding for which patients an ECG should be obtained.

MANAGEMENT

The general management of a poisoned patient involves providing appropriate supportive care, undertaking decontamination, enhancing elimination, and providing specific antidotal therapy when indicated. Specific strategies will be discussed at length in the following chapters regarding specific poisons. However, the basic framework remains the same.

Antidotes do not exist for every potential poisoning, and thus supportive care is the cornerstone of managing the poisoned patient. Providing resuscitation by ensuring airway protection and adequacy of ventilation while maintaining the circulatory status of the patient with crystalloids and vasopressor support is the prime focus. If the airway is compromised or in danger of becoming so, or if the respiratory effort is insufficient to maintain appropriate ventilation, intubation is usually the preferred course (with special care in the situation of a salicylate poisoning, which is discussed in Chapter 139).

Vascular access needs to be obtained, with peripheral or central venous catheters, intraosseous lines are also viable access points from the toxicologic perspective, because there are no known contraindications to antidotal therapy through this route. Once supportive care has been initiated and the patient stabilized, one should then progress to a systematic assessment of decontamination strategies, enhanced elimination, focused therapy (antidotes), and obtaining consultation.

Decontamination

Decontamination is the process of preventing systemic absorption. In the case of ocular or dermal exposure, this is achieved by copious irrigation with water, after removal of contaminated clothing to expose the area. Water irrigation is not used for metallic potassium, magnesium, or sodium (found in "tracer" ammunition, for example), because these can ignite on contact with water. Instead, in these very rare exposures, the area should be covered with petroleum jelly or mineral oil.

SYRUP OF IPECAC

Inducing emesis with syrup of ipecac is not indicated in the care of any poisoned patient in the ED. Syrup of ipecac use is associated with significant side effects (e.g., dehydration due to intractable vomiting) and complications (e.g., aspiration pneumonitis, Mallory-Weiss tears, and gastric rupture). There are also insufficient data and evidence showing improvement in clinical outcomes with poisonings.[4]

GASTRIC LAVAGE

Gastric lavage, the process of directly removing an ingested substance from the stomach using a 30 Fr or larger orogastric tube, also has little data or evidence showing its efficacy and should not be performed routinely for the treatment of poisoned patients. Given the risks of aspiration and esophageal trauma, the American Association of Poison Centers suggests it only be employed "within an hour of ingestion of a potentially life-threatening poison which does not adsorb to activated charcoal or for which no antidote exists" and, even then, in a center with "sufficient expertise" to perform the procedure safely.[5] Only a rare overdose (such as colchicine) will meet all these criteria; and hence, despite its once widespread use, gastric lavage is mostly of historical interest only.

SINGLE-DOSE ACTIVATED CHARCOAL

Historically, single-dose activated charcoal (SDAC) has been the mainstay of gastric decontamination in medical toxicology. Activated charcoal is a carbonaceous substance that has been exposed to high heat and steam—i.e., "activated"—which results in a large surface area to volume ratio. This provides ample surface space for intralumenal ingested substances to adsorb, and thus decreases absorption into the body. Current understanding of the role of activated charcoal in poison management is based on pharmaco-toxicologic data (lethality, availability of antidotes, or alternative detoxification therapies); pharmacokinetics (area under the concentration versus time curve in controlled volunteer studies); clinical trials in patients with overdose; and collective, empirical clinical experience.[6] Studies involving healthy volunteers ingesting small (safe) doses of various agents do not accurately replicate the overdose (large ingestion) situation, so are of limited value. In addition, there are very few appropriately designed clinical studies assessing the benefit from SDAC. Therefore, due to the lack of convincing evidence demonstrating benefit in clinical outcome in human overdose, we do not recommend

TABLE 135.3 Toxicologic Electrocardiogram Manifestations

Segment/Interval	Appearance	Agent(s)	Segment/Interval	Appearance	Agent(s)
P wave	Absent	Digoxin Cholinergics Hyperkalemia	QT/QTc	Prolonged	Antipsychotics (typical and atypical), citalopram, hydrofluoric acid, methadone, ethylene glycol (oxalate byproduct)
	Notched	Quinidine			
PR interval	Prolonged	Beta-antagonists, calcium-channel antagonists, magnesium, lacosamide	T wave	Peaked	Hydrofluoric acid (hyperkalemia)
				Flattened	Lithium
QRS interval	Prolonged	Type 1 antidysrhythmics, cocaine, diphenhydramine, tricyclic antidepressants	U wave		Barium, beta-agonists, lithium, methylxanthines (caffeine, theophylline), toluene
ST segment	Scooped	Digoxin ("Salvador Dali's moustache")			

the routine use of activated charcoal following ingestion.[7] We do, however, recommend its use in certain overdose scenarios.

Although few studies have shown a reduction of morbidity or mortality attributable to activated charcoal administration, and there have been reports of pulmonary aspiration of activated charcoal with serious patient harm, these aspiration events have occurred in a minority of patients receiving activated charcoal; therefore it is considered a relatively low-risk intervention. With certain toxic exposures, SDAC administration may be reasonable after a consideration of the risk versus benefit for the patient in the context of the quantity and toxicity of the ingested substance, the time elapsed between ingestion and treatment, and the availability of alternative antidotes or decontamination procedures (e.g., hemodialysis). Benefits include decreasing primary absorption or binding during enterohepatic recirculation of a potentially toxic xenobiotic. These benefits are more likely to occur if:

- The activated charcoal is administered within one hour after ingestion, *and*
- The patient is alert, able, and willing to cooperate with administration, and anticipated to remain alert and protective of airway reflexes, *and either*
  - The substance ingested has high toxicity or is a toxic sustained-release agent, *or*
  - There is evidence of a massive ingestion of a toxic agent (e.g., salicylates)

If the patient is sedated, has an unprotected airway, or is unwilling to drink the charcoal suspension, administration is contraindicated. This may be particularly true for young children with limited ability to drink the slurry. Furthermore, one should not place a nasogastric tube solely to administer activated charcoal, because of the risk of aspiration or direct instillation of activated charcoal into the lungs, thus changing the risk-benefit ratio.

Considering all of this information, how does one decide whether activated charcoal is indicated in a specific overdose? First, the ingested drug must have a high potential for toxicity and lethality. These drugs are listed by class in Box 135.9. If the drug ingested has low toxicity (e.g., ibuprofen, diazepam), or there is an effective antidote available (e.g., *N*-acetylcysteine for acetaminophen, digoxin immune fab for digoxin), activated charcoal administration is not advised.

Second, the ingestion must be recent. For most overdoses, this means that the activated charcoal needs to be administered within one hour of the ingestion. For certain overdoses (sustained-release products, anticholinergic agents, massive ingestions), either because of pharmacokinetics or the quantity ingested, activated charcoal may be given up to 2 hours after ingestion. Many patients arrive at the ED more than 2 hours after the ingestion or ingest the drugs over a period of several hours, often with alcohol, and do not meet this time requirement. Third, the ingestion must be amenable to adsorption by activated charcoal. This eliminates rapidly absorbed toxins (e.g., alcohols) and those agents listed in Box 135.10. Fourth, the patient must be alert and anticipated to remain alert and be willing to take the activated charcoal slurry voluntarily. An algorithm guiding the administration of activated charcoal is shown in Figure 135.1. We recommend consultation with a regional poison center or medical toxicologist if there is uncertainty regarding the indications for activated charcoal.

Activated charcoal historically has most often been given in a dose of 50 to 100 grams (or 1.0 g/kg in young children), but we advise customizing the dose to the dose of the ingested agent by administering activated charcoal in a weight ratio of 10:1 (ratio of activated charcoal to drug).

BOX 135.9 Potentially Lethal Toxins Where Early Activated Charcoal Administration May Be Indicated

The Killer Cs
Cyanide
Colchicine
Calcium channel blockers
Cyclic antidepressants
Cardio glycosides
Cyclopeptide mushrooms *(Amanita phalloides)*
Cocaine
Cicutoxin (water hemlock)
Salicylates

WHOLE BOWEL IRRIGATION

In certain ingestions such as extended-release preparations, illicit drug packets, or metals (e.g., iron and lead), continuous whole-bowel irrigation may be indicated. Whole bowel irrigation (WBI) is performed with a balanced polyethylene glycol solution that does not participate in fluid exchange nor become absorbed into the body. To be effective, it requires a rate of 2 liters per hour in an adult; consequently, this will require nasogastric tube placement.[8] However, if a patient is critically ill, has hypoperfusion of the gut, or has obstruction of the bowel, WBI is contraindicated because there have been reports of increased morbidity and mortality in these clinical settings.

Enhanced Elimination

Once a toxin has been absorbed into the body, it undergoes metabolism and elimination primarily via hepatic and renal pathways. Certain substances are amenable to enhancing these elimination pathways either ex vivo as is the case with hemodialysis and its related therapies, or in vivo as is the case with multiple-dose activated charcoal (MDAC) and urinary alkalinization.

Hemodialysis and its related therapies are best suited to remove poisons of low molecular weight, low protein binding, and high water solubility; examples include toxic alcohols, lithium, and salicylates, as listed in Box 135.11. All forms of extracorporeal removal have been studied and found to be efficacious; the selection of a specific type of

BOX 135.10 Substances That Do *Not* Bind to Activated Charcoal

Ethylene glycol
Depakote (valproic acid—in massive overdose)

elimination modality ought to be made based on patient-specific factors and early consultation with a nephrologist in conjunction with a medical toxicologist or poison control center.[9]

MULTIPLE-DOSE ACTIVATED CHARCOAL

Unlike preventing absorption of a drug as is the case for SDAC, multiple dose activated charcoal (MDAC) is intended to facilitate removal of a toxin that has already been absorbed. MDAC decreases xenobiotic absorption and elimination half-life when large amounts of the toxin are ingested and dissolution is delayed (e.g., concretions, bezoars, or extended release formulations). It also is believed to create a hemoperfusion substrate for the gut wall microcirculation to permit "gastrointestinal dialysis," which generates a concentration gradient into the stool for certain poisons, which are then eliminated by defecation. In addition, certain drugs are excreted in the bile, then reabsorbed by the gut, only to be re-excreted in the bile, a process called *enterohepatic circulation*. MDAC also may interfere with reabsorption of these drugs by binding them during their transit of the gastrointestinal tract. Drugs with significant enterohepatic circulation are listed in Box 135.12. As with SDAC, MDAC administration may cause pulmonary aspiration and intestinal obstruction. Aspiration is best avoided by applying the same conditions for administration as for SDAC—patient is awake, alert, and cooperating and is anticipated to remain so. Obstruction is more difficult to predict and prevent, although avoidance in situations with delayed gut motility (e.g., critical illness, opioid or anticholinergic effects) is recommended to reduce this risk.

When MDAC is indicated, the initial loading dose of an activated charcoal–to-xenobiotic ratio of 10:1 is followed by subsequent doses of 50% of the initial dose every 4 to 6 hours for up to 24 hours. MDAC may be discontinued when the patient's measurable serum levels are no longer considered in the toxic range. Take care to only use non-sorbitol containing formulations when administering MDAC; sorbitol, a non-absorbable sugar added to charcoal slurries to enhance palatability, can induce significant fluid shifts and cause profound electrolyte abnormalities (particularly in children) such as hypernatremia when a large amount is ingested, as in the case of MDAC.

SERUM ALKALINIZATION

Certain water-soluble drugs such as salicylates, methotrexate, and phenobarbital will undergo ion-trapping and enhanced urinary elimination if the serum is sufficiently alkalinized. This is especially important with salicylate poisonings, because alkalinization not only promotes elimination but also prevents salicylate crossing the blood-brain barrier into the central nervous system (CNS). Monitor the serum pH and bicarbonate level, as well as the urinary pH, with the goal being a serum pH of approximately 7.5 and a urinary pH of approximately 8.0. Also ensure that the serum potassium level is normal, because alkalinization will cause an intracellular shift of potassium and consequently increase urine reabsorption of potassium by excreting hydrogen ions into the urine; this will eliminate the pH gradient and dissipate the benefits of this process. To accomplish this, combine 150 mEq (3 amps) of 8.4% sodium bicarbonate into a liter of dextrose 5% in water (D5W) and add potassium (20 to 40 mEq total) to the intravenous fluid as well. This solution should be infused at a rate not to exceed 250 mL/hour. Barring concerns for fluid overload (particularly in elderly and renal failure patients) we recommend infusing at 250 mL an hour.

BOX 135.12 Substances Amenable to Multiple-Dose Activated Charcoal

ABCDQ
Aminophylline/theophylline
Barbiturates
Carbamazepine/concretion forming drugs (e.g., salicylates)
Dapsone
Quinine

INTRAVENOUS FAT EMULSION (INTRALIPID)

Intravenous fat emulsion (IFE) is utilized for poison-induced cardiogenic shock or intractable seizures. This therapy was first described for treatment of toxicity from local anesthetics, such as bupivacaine. IFE is proposed to work primarily by two separate mechanisms: (1) the lipid sink and (2) enhanced cardiac metabolism.[10] The lipid sink theory posits that fat-soluble drugs are "soaked up" and removed from the site of toxicity, effectively increasing the volume of distribution for a fat-soluble drug. This is the predominant theory behind the use of IFE. A second theory involves optimization of cardiac metabolism. The heart under physiologic circumstances prefers free fatty acids; in times of stress, it switches to glucose metabolism for energy. A dose of IFE theoretically provides a large supply of free fatty acids to optimize energy use in the heart. In addition to providing supplemental energy for myocytes, IFE may also enhance activation of cardiac calcium channels.

Indications for IFE are not universally agreed upon. In addition to anesthetic agents, successful resuscitations have been described with refractory B-blocker overdose, calcium channel blockers, cyclic antidepressants, and bupropion and cocaine toxicity. Although originally described as a treatment for overdose patients in cardiac arrest, several reports now exist describing the successful use of IFE in critically ill patients prior to circulatory collapse and cardiac arrest. Dosing for IFE also varies in the literature. If indicated, we recommend an initial bolus of 1.5 mL/kg of 20% lipid solution given over 2 to 3 minutes followed by an infusion of 0.25 mL/kg/min over 30 to 60 minutes, based on the most commonly recommended and described protocols; this can be given via peripheral, central, or intraosseus access.

With the exception of local anesthetic systemic toxicity (LAST), where IFE is considered front-line therapy, intralipids should only be administered to overdoses when resuscitative efforts have been refractory to other more conventional therapies (e.g., vasopressor agents, sodium bicarbonate, calcium, high-dose insulin-dextrose therapy). When considering administration of IFE therapy to an unstable overdosed patient, consultation with a medical toxicologist or regional poison center is recommended.

Despite recent enthusiasm for IFE, its use has associated complications, including extreme lipemia resulting in lab interference with blood tests (complete blood counts, chemistries, and coagulations studies), as well as acute pancreatitis, and acute respiratory distress syndrome.[11]

Focused Therapy

Although the majority of poisonings require supportive care alone, in selected ingestions specific antidotal therapy may be available. Evidence and experience support the use of several antidotes, which should be available either immediately (e.g., hospital stocked) or rapidly accessed (e.g., transported within a few hours). These antidotes and their indications can be found in Table 135.4, and their use is discussed in the relevant chapters.[12]

Toxicology Consultation

Most poisoning cases are straightforward and appropriately handled by the emergency clinician. When the poisoning is severe, high risk,

TABLE 135.4 Selected Antidotes and Their Indications

Antidote	Indication (Poison)
N-acetylcysteine	Acetaminophen
Fomepizole (4-MP)/ethanol	Methanol/ethylene glycol
Oxygen/hyperbarics	Carbon monoxide
Naloxone	Opioids, clonidine
Physostigmine	Anticholinergics
Atropine/pralidoxime (2-PAM)	Organophosphates

involves unfamiliar or multiple toxins, or occurs in a patient with significant comorbidity, we recommend consultation with a Poison Control Center or, if available, a medical toxicologist. Consultation can assist the bedside clinician in the determination of an unknown ingestion, critical management decisions, or whether an antidote or invasive procedure, such as hemodialysis, is advisable.

In the United States, a national toll-free phone number has been established that will route a practitioner to their nearest Poison Control Center. This number is 1-800-222-1222.[1]

DISPOSITION

Patients with severe toxicity (for example seizures, persistent cardiovascular instability, airway compromise, or significant metabolic derangements) should be admitted to an intensive care setting. Patients who are asymptomatic on arrival but have ingested a potentially dangerous substance or an extended-release preparation that could cause significant deterioration in their clinical status, ought be admitted to either an inpatient setting or an observation unit for 24 hours, or until peak toxicity has passed and the patient is physiologically stable. For patients who are asymptomatic after an ingestion of a minimally toxic substance and for whom other ingestions and psychiatric issues have been addressed, discharge after the ED visit, which typically takes at least 4 to 6 hours, is appropriate.

If the motivation behind the ingestion, was suicidality, or self-harm, a psychiatric consultation is warranted. If a suicidal patient is to be admitted medically for observation, it is important to ensure that a dedicated sitter or other type of secure environment is available to prevent any further patient inflicted self-injury.

CHAPTER 135: QUESTIONS AND ANSWERS

1. A 23-year-old man presents with confusion. His vital signs are blood pressure 105/77 mm Hg, heart rate 69 beats per minute, respiratory rate 10 breaths per minute, temperature 37.0°C, and arterial oxygen saturation (SaO_2) 96% on 2 L NC. His eyes open only to pain, he localizes to pain, but he does not follow commands and his speech is confused. Otherwise, his physical examination is normal. After intravenous (IV) access is obtained and he is placed on continuous cardiac monitoring, what is the most appropriate next step?

a. Check arterial blood gases (ABG).
b. Check bedside serum glucose.
c. Give 50% dextrose 1 amp IV.
d. Give naloxone 2 mg IV.
e. Perform electrocardiogram (ECG).

Answer: B. All patients with altered mental status should have a rapid determination of their glucose. Although this patient has several abnormal vital signs, none necessitate immediate action. His Glasgow Coma Score (GCS) is 11, and it appears that his respiratory status is adequate. Dextrose should not be given unless hypoglycemia is documented. Naloxone is an opioid antagonist, and it could reverse the patient's confusion if it is caused by opioids. This drug could be considered once other more easily reversible causes of confusion (e.g., hypoglycemia) have been ruled out. ABG and ECG are both occasionally needed in patients with altered mental status, but neither is as urgent as glucose testing.

2. The odor on a poisoned patient can provide clues as to the substance causing the poisoning. If a patient smells of garlic, what should you be concerned about?

a. Cyanide
b. Hydrogen sulfide
c. Methyl salicylate
d. Organophosphates
e. Toluene

Answer: D. Arsenic, dimethyl sulfoxide (DMSO), yellow phosphorus, selenium, and tellurium can also have a garlic odor. Odors associated with the other answer choices are as follows: cyanide, bitter almonds; hydrogen sulfide, rotten eggs; methyl salicylate, wintergreen; and toluene, glue. Odors can aid in making the diagnosis but should not be relied on as completely diagnostic. Also, the lack of odors cannot be used to rule out a poisoning resulting from that substance.

3. A 17-year-old girl presents with delirium, tachycardia, dry skin, flushed face, decreased bowel sounds, dilated pupils, and urinary retention. A friend states that the patient had recently ingested some unknown medications in a suicide attempt. Which of the following medications is most likely responsible for the constellation of signs?

a. Alprazolam
b. Clonidine
c. Diphenhydramine
d. Hydrocodone
e. Pseudoephedrine

Answer: C. The patient is expressing the signs of classic antimuscarinic poisoning. Central nervous system (CNS) effects include the delirium and typical "picking movements" of the fingers. Suppression of the cholinergic system results in tachycardia. All secretory functions are inhibited, causing the dry, flushed skin, decreased bowel sounds, and urinary retention. Unopposed sympathetic activity results in dilated pupils. Alprazolam, clonidine, and hydrocodone can all cause the sedative toxidrome. Pseudoephedrine can lead to the sympathomimetic toxidrome, which typically has diaphoretic skin but can otherwise appear similar to an anticholinergic presentation.

4. A 27-year-old individual presents to the emergency department via emergency medical services after being "found down" with pinpoint pupils, slow breathing, and depressed mentation. The patient was given 2 mg of naloxone via the intranasal route and by the time of arrival in the ED is now awake, alert, and cooperative—and asking to leave. There is no evidence of trauma, and the patient has no other complaints. Based on your knowledge of the half-life of naloxone, when do you feel the patient will be safely dischargeable?

a. 30 minutes
b. 1 hour
c. 2 hours
d. 4 hours
e. 6 hours

Answer: D. The exact elimination half-life of naloxone is closer to 1.1 hours (1 hour 6 minutes). This is markedly shorter than the half-life of almost all opioids. For comparison, morphine has a half-life of approximately 2 hours, hydrocodone has a half-life of approximately 4 hours, and methadone has a half-life up to 30 hours. This means that repeat dosing of naloxone is often necessary when treating opioid overdose. A drug similar in action to naloxone, nalmefene, has a half-life of 10 hours and may sometimes be useful.

CHAPTER 135: QUESTIONS AND ANSWERS—cont'd.

5. You suspect a patient has a cholinergic syndrome. Which of the following, if found, would make you question your diagnosis?
   a. Confusion
   b. Diaphoresis
   c. Diarrhea
   d. Fasciculations
   e. Mydriasis (dilated pupils)

   Answer: E. The typical cholinergic patient is "wet." A common mnemonic used to remember the symptoms is SLUDGE—salivation, lacrimation, urination, defecation, gastrointestinal cramping, and emesis. Confusion can be present but is nonspecific. Frequently, cholinergic syndrome is caused by organophosphate poisoning, so fasciculations are common. Another common sign is miosis, not mydriasis.

6. Gastric decontamination with activated charcoal can decrease the absorption of certain toxins. However, before charcoal can be given, it must be determined that the risk of aspiration is low, the likelihood of reduction of toxicity or improved patient outcome is high, and that the ingestion occurred recently (within approximately 1 hour). Also, it must be determined that the substance ingested is actually adsorbed by charcoal. Which of the following substances is adsorbed by charcoal?
   a. Gasoline
   b. Hydrofluoric acid
   c. Iron
   d. Methanol
   e. Metoprolol

   Answer: E. Charcoal does not adsorb hydrocarbons (i.e., gasoline), ionic substances (i.e., strong acids or bases), metals (e.g., iron), or alcohols. It does adsorb most therapeutic drugs with potential major toxicity, such as β-blockers, calcium channel blockers, and cyclic antidepressants.

7. A 6-year-old boy is found playing with liquid pesticide by family members. The family states that he was drinking the solution. Paramedics find the child sitting in a puddle of liquid that smells strongly of pesticide. He is acting normally. During transportation to the hospital, the paramedics report that the child is now sleepier than previously but still easily aroused with a loud voice. His vital signs are within normal limits. They ask what they should do next. What do you advise?
   a. Administer IV atropine
   b. Administer oral activated charcoal
   c. Administer naloxone
   d. Perform rapid sequence intubation
   e. Remove the child's clothing and wash the skin

   Answer: E. This child's clothing has been impregnated with poison, and as long as the child is clothed, he will continue to absorb the poison. Ideally, all patients should be decontaminated on scene to expedite decontamination as well as to minimize the risk of contaminating others. Although this child may have ingested some poison, it is likely that far more is being absorbed from his skin than through his gastrointestinal tract. In addition, charcoal can cause complications, whereas removal of contaminated clothing is relatively safe. Although this child may eventually require intubation, he does not need it now. Most pesticides are organophosphates, so this patient may require atropine, but removal from the poison (taking off his clothing) will provide the greater immediate impact on his condition.

8. A patient suffering from serotonin syndrome will experience myriad physiologic abnormalities, including altered mental status, fever, agitation, tremor, and myoclonus. Many of the symptoms are nonspecific. Which of the following diagnoses is often mistaken for serotonin syndrome?
   a. Anticholinergic syndrome
   b. Brown recluse envenomation
   c. Opioid withdrawal
   d. Sepsis
   e. Sympathomimetic overdose

   Answer: E. Serotonin syndrome is characterized by altered mental status, fever, agitation, tremor, myoclonus, hyperreflexia, ataxia, incoordination, diaphoresis, shivering, and diarrhea. Similar symptoms are seen with overdoses of sympathomimetics, lithium, and monoamine oxidase inhibitors (MAOIs). Similar symptoms are also seen with neuroleptic malignant syndrome (NMS) and malignant hyperthermia. The antimuscarinic syndrome will give a "dry" patient without diaphoresis. Brown recluse envenomation produces local pain and possibly skin necrosis, as well as systemic symptoms of fever, nausea, and vomiting. Opioid withdrawal produces similar symptoms and will cause myalgias but without other musculoskeletal effects. Sepsis likewise can produce many of the systemic signs and symptoms seen in serotonin syndrome but without the musculoskeletal effects.

Toxic Alcohols

Michael E. Nelson

KEY CONCEPTS

- The classic finding of an elevated osmolar and anion gap should raise suspicion of methanol or ethylene glycol toxicity but may not be present depending on the timing of ingestion. Early ingestion has a high osmolar gap without acidosis, and late ingestion has acidosis without an osmolar gap.
- Serum osmolarity is calculated by the following equation:

$$\text{Calculated osmolarity (mOsm/kg)} = 2\text{Na}^+ + (\text{BUN}/2.8) + (\text{glucose}/18) + (\text{ethanol}/4.6)$$

The measured osmolar gap is the difference between the measured serum osmolality and calculated serum osmolarity, with a normal range of –15 to +10 mOsm.

- It is important to note that a normal osmolar gap does not exclude toxic alcohol ingestion.
- Initiate therapy based on strong clinical suspicion of exposure to methanol or ethylene glycol. Block alcohol dehydrogenase preferably with fomepizole, but ethanol can be used if fomepizole is unavailable.
- The main priorities in toxic alcohol exposure are correction of acidosis using bicarbonate solution and hemodialysis, inhibition of the production of toxic metabolites, and elimination of the parent alcohol and its toxic metabolites.
- The presence of acidosis indicates the accumulation of the toxic metabolites of methanol (formic acid) and ethylene glycol (glycolic and oxalic acid). Consult nephrology for emergent hemodialysis to correct acid-base disturbances and remove the parent compound as well as its toxic metabolites.
- Severe acidosis is a poor prognostic factor, with high mortality rates in methanol and ethylene glycol ingestions. A comatose state at the time of presentation also is associated with a higher mortality outcome.
- The findings of an elevated osmolar gap with ketonemia or ketonuria and no development of acidosis indicate isopropanol ingestion. Patients can have a prolonged period of inebriation and can be comatose. Alcohol dehydrogenase inhibition is not indicated in these cases.
- Hypotension and gastrointestinal bleeding are poor prognostic factors in isopropanol ingestion.
- Diethylene glycol can result in acidosis and renal failure and should be managed similarly to ethylene glycol poisoning with fomepizole and hemodialysis.

Ethyl alcohol (ethanol) is ubiquitously consumed worldwide on a daily basis and contributes to a multitude of acute and chronic disease processes and traumatic events. Although ethanol certainly can be viewed as a toxic alcohol, its use, abuse, and related conditions are discussed in Chapter 137. This chapter focuses on methanol, ethylene glycol (EG), and isopropyl alcohol (IPA; isopropanol).

METHANOL

Foundations

Methanol (methyl alcohol; CAS 67-56-1; H_3COH) is a clear, volatile, colorless, slightly sweet-tasting alcohol at room temperature. It is also known as wood alcohol due to methanol being produced from the destructive distillation of wood. Methanol is mainly used as a solvent or octane booster in gasoline. It is manufactured frequently as an intermediate in chemical reactions. As a solvent, it is present in many items found in the home, including cleaning solutions, adhesives, enamels, stains, dyes, and paint removers. Methanol is also commonly found in windshield washer fluid, antifreeze (particularly brake line antifreeze), embalming fluid, and fuel for camp stoves.

Many mass methanol poisonings have occurred throughout history, including outbreaks in Estonia (2001), Norway (2002–2004), the Czech Republic (2012), Libya (2013), Kenya (2014), Nigeria (2015), and Iran (2018).[1,2] Despite vast knowledge and experience with methanol, these outbreaks demonstrate the diagnostic challenge and difficulty in treating these patients. In 2018, 1828 single substance exposures to methanol were reported to US poison centers. The vast majority were unintentional exposures (89.4%), with few major complications (1.6%) and only 11 deaths.[3] These data, however, rely on voluntary reporting and likely underrepresent the true burden of methanol exposures and mortality outcomes from forensic data in the United States.

Principles of Toxicology

Methanol is rapidly absorbed from the gastrointestinal (GI) tract with an average absorptive half-life of 5 minutes and reaches peak concentration in 30 to 60 minutes. While the majority of exposures occur through oral ingestion, occupational and recreational inhalation of methanol from cleaning and cooling fluids has resulted in toxicity causing neurologic dysfunction and necessitating antidote therapy and hemodialysis (HD).[4–6] Transdermal exposure as well can lead to significant methanol toxicity. High-risk occupations for exposure to methanol include painting, varnishing, lithography, printing, and glazing.

Methanol itself has very low toxicity, but its metabolism results in toxic metabolites, in particular, formic acid, which dissociates into formate and hydrogen ions. Methanol is primarily metabolized in the liver by alcohol dehydrogenase (ADH) into formaldehyde. Formaldehyde is then metabolized by aldehyde dehydrogenase (ALDH) very rapidly, with a half-life of 1 to 2 minutes, into formic acid (Fig. 136.1). Formic acid can combine with tetrahydrofolate (THF) to form 10-formyl THF, which can be metabolized into carbon dioxide and water.

Elimination of methanol is mainly characterized via zero-order kinetics in the poisoned patient but does have first-order metabolism

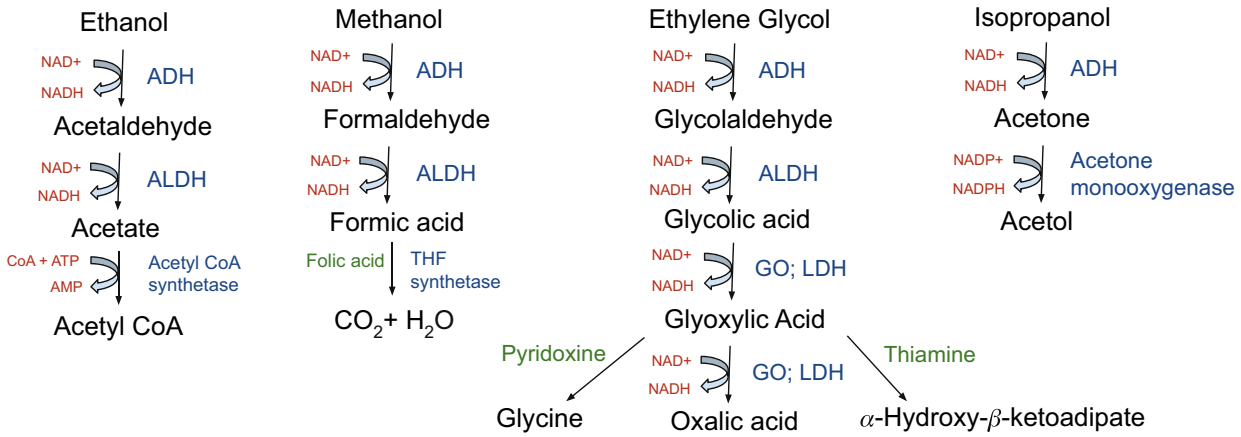

Fig. 136.1 Metabolism of alcohols. *ADH,* Alcohol dehydrogenase; *ALDH,* aldehyde dehydrogenase; *AMP,* adenosine monophosphate; *ATP,* adenosine triphosphate, *GO, Glycolate oxidase, LDH,* lactate dehydrogenase, *NAD+,* nicotinamide adenine dinucleotide; *NADH,* reduced form of nicotinamide adenine dinucleotide, *THF*, tetrahydrofolate.

at very low concentrations, with an elimination half-life of about 2 to 3 hours at low concentrations. Small amounts of methanol are eliminated by the renal and pulmonary systems.

At toxic concentrations, the elimination half-life of methanol is nearly 24 hours. The metabolite, formic acid, has a half-life of nearly 20 hours. With ADH inhibition by concurrent consumption of ethanol or administration of fomepizole, the half-life of methanol extends upward to more than 50 hours. With dialysis, the half-life of methanol is approximately 3 to 4 hours.

Formic acid will accumulate due to its slower metabolism as it exceeds the elimination rate. Formic acid binds iron efficiently, resulting in mitochondrial cytochrome oxidase inhibition, and interferes with oxidative metabolism in a manner similar to that of cyanide, carbon monoxide, and hydrogen sulfide. The dissociation of formic acid into formate and hydrogen ions leads to acidosis. The interference of oxidative metabolism, combined with acidosis, further promotes lactate production and worsens the acidotic state. Decreasing pH promotes formic acid diffusion across cell membranes, in particular to the central nervous system (CNS). Also, inhibition of cytochrome oxidase by formic acid is potentiated with decreasing pH. The net effect of this vicious cycle, coined the "*circulus hypoxicus*," is tissue hypoxia and inhibition of intracellular respiration.[7] Further mechanisms of toxicity include free radical formation, lipid peroxidation, and impairment of antioxidant reactions.

Formic acid uniquely targets the optic disk of the retina and retrolaminar optic nerve, potentially due to the high amount of blood and cerebrospinal fluid (CSF) flow through the choriocapillaris. These cells are more susceptible to cellular hypoxia due to low levels of mitochondria and cytochrome oxidase, making formic acid oxidation slower in the eye compared to the brain.[8] Inhibition of mitochondrial cytochrome oxidase results in decreased adenosine triphosphate (ATP) production, leading to myelin sheath damage and loss of vision. Worsening acidosis potentiates these effects by enhancing the diffusion of formic acid across cell membranes into the neurons.

The basal ganglia and subcortical white matter are affected by formic acid in a similar manner to the ocular toxicity. Neuroimaging and autopsy findings classically demonstrate putamen hypodensity, with hemorrhages and necrosis. Bilateral putamen changes are not specific to methanol toxicity and can be found in Wilson disease, Leigh disease, Kearns-Sayre syndrome, toxic encephalopathy (e.g., carbon monoxide, cyanide, hydrogen sulfide), hemolytic-uremic syndrome, and hypoxic-ischemic injury. The severity of findings and extent of necrosis on imaging do not necessarily correlate with clinical outcomes. The vulnerability of the basal ganglia to formic acid toxicity may be due to its high metabolic activity, with poor venous drainage and inadequate arterial flow.

Clinical Features

Clinical signs and symptoms of methanol intoxication typically involve the GI tract, CNS, and optic system. Shortly after exposure, patients appear similar to other alcohol ingestions, with GI irritation, inebriation, and CNS depression. Methanol has a less inebriating effect than ethanol but causes similar slurred speech, ataxia, confusion, and CNS depression. Abdominal discomfort and vomiting occur from mucosal irritation, and patients can develop acute pancreatitis. Severe mucosal irritation can also result in hemorrhagic gastritis. A latency period, ranging from 1 to 72 hours, depending on the amount ingested, can occur with the improvement of inebriation symptoms and development of visual symptoms as methanol metabolizes and formic acid accumulates.

As formic acid accumulates, the most characteristic feature is some degree of visual disturbance, including seeing spots with blurred vision (commonly referred to as "snowstorm vision"), altered visual fields, and blindness. Visual disturbances occur in 30% to 70% of patients.[9] Early ophthalmologic findings include reduced pupillary response to light and hyperemia of the optic disc. Peripapillary retinal edema and loss of optic disk cupping follow and often lead to decreased visual fields and central scotomata. Retinal dysfunction can be reversible. Blurred vision from formic acid induced retinal injury, is typically transient, and vision recovers. Optic atrophy and optic neuropathy suggest a poor prognosis for visual recovery. The incidence of ophthalmologic abnormalities correlates directly with the degree of acidosis. Long-term visual sequelae are associated with visual deficits at presentation, coma, and brain lesions on imaging.[10,11]

As acidosis progresses, compensatory tachypnea develops. Acidosis can be profound, with many patients presenting with an arterial pH less than 7.0 and serum bicarbonate level less than 10 mEq/L. Tachycardia is often noted, but patients rarely have significant cardiac dysrhythmias. Also, shock, seizures, myoglobinuria, and rhabdomyolysis have been reported. Death typically results from respiratory failure and sudden respiratory arrest, with cerebral edema and multiorgan failure.

TABLE 136.1 Causes of Elevated Osmolar and Anion Gaps

Osmolar Gap	Anion Gap (*A Cat Piles Mud*)	Double Gap	Distinguishing Features
Methanol	***A***lcoholic ketoacidosis	Methanol	Vision loss—methanol

Prognosis after methanol ingestion correlates with the degree of acidosis, time to presentation, and initiation of treatment. The strongest predictor of morbidity and mortality is the degree of acidosis, with high mortality rates observed at a pH less than 7.0. A comatose state at presentation also portends a worse outcome with high mortality rates and long-term neurologic sequelae.[12] Aggregated data from mass methanol poisoning events demonstrate that a comatose state with a pH less than 6.74 has an 83% mortality rate and 100% of survivors had neurologic sequelae, while non-comatose patients with a pH greater than 7.0 had a 5% mortality rate and only 16% of survivors had neurologic sequelae.[12] Patients that survive the acute toxicity of methanol can have permanent complications, including blindness and neurologic deficits. A Parkinson-like extrapyramidal syndrome, with bradykinesia, tremor, and dementia, can occur. These findings are generally associated with necrosis of the putamen and subcortical white matter on neuroimaging studies. Other neurologic sequelae include polyneuropathy, encephalopathy, ataxia, and cognitive deficits. Permanent vision deficits and evidence of brain hemorrhages on magnetic resonance imaging (MRI) are associated with decreased quality of life in survivors of methanol poisoning.[13]

Differential Diagnoses

The differential diagnoses for methanol intoxication are broad, making it difficult to detect, particularly at the initial presentation. The inebriated state of the patient can easily be confused with ethanol intoxication. Further causes of altered mental status (AMS) include hypoglycemia, hypoxia, carbon dioxide narcosis, infections, trauma, seizures, metabolic disturbances, endocrinopathies, and encephalopathy. Poisoning or intoxication by other substances, including opiates, carbon monoxide, sedative-hypnotics, and benzodiazepines, often presents with AMS. The GI irritation can occur with ethanol intoxication and with other intra-abdominal pathologies, such as gastritis and pancreatitis.

After ingestion of methanol, serum osmolality will be elevated and can lead to an elevated osmolar gap. Other substances that contribute to an elevated osmolar gap include EG, isopropanol, ethanol, mannitol, glycerol, propylene glycol (PG), sorbitol, fructose, diatrizoate (IV dye), acetonitrile, and ethyl ether (Table 136.1). Additionally, hyperlipidemia, hyperproteinemia, and sick cell syndrome cause an increase in the osmolar gap by decreasing the measured sodium concentration.[14]

As the parent compound methanol is metabolized, the production of formic acid results in an elevated anion gap (AG) acidosis. In addition to methanol, causes of AG acidosis include lactic acidosis of varying causes (e.g., sepsis, ischemia), diabetic ketoacidosis, alcoholic ketoacidosis, uremia, inborn errors of metabolism, and toxins (e.g., salicylates, isoniazid, iron, carbon monoxide, cyanide, metformin, toluene, paraldehyde, PG, and EG; see Table 136.1). Worsening acidosis, despite adequate fluid hydration and no evidence of underlying ischemia producing lactic acidosis, should raise the concern for toxic alcohol ingestion.

The presence of a so-called double gap (elevated osmolar and AGs) is classically described for toxic alcohol ingestion. Many other situations, however, can cause a similar picture, including diabetic ketoacidosis, alcoholic ketoacidosis, renal failure, multiple organ failure, and septic shock (see Table 136.1). This double gap picture is also dependent on the timing of presentation because early presenters will have only an osmotically active parent compound and late presenters will have acidosis without an elevated osmolar gap (Fig. 136.2).[15]

The development of ocular manifestations with worsening acidosis is a strong indicator of methanol poisoning. Other toxins, however, can cause ophthalmologic conditions and blindness such as cinchonism with quinine intoxication, but this lacks the elevated osmolar and AGs. Cortical blindness can occur with various causes of toxic leukoencephalopathy, including carbon monoxide, hydrocarbons, steroids, metals (organic mercury), and various chemotherapeutic agents (e.g., carboplatin, cisplatin).

Diagnostic Testing

The classically described presentation of toxic alcohol ingestion includes an AG metabolic acidosis and an elevated osmolar gap. Due

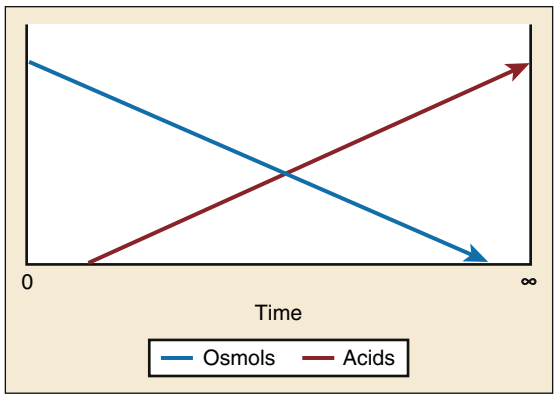

Fig. 136.2 Relationship of osmotically active parent alcohol to acid metabolite over time. (Adapted and modified with permission from Mycyk MB, Aks SE. A visual schematic for clarifying the temporal relationship between the anion gap and the osmol gaps in toxic alcohol poisoning. *Am J Emerg Med.* 2003;21:333–335.)

to the latency period of methanol metabolism, a normal AG does not exclude methanol ingestion. The AG is commonly calculated by the following equation:

$$AG = [Na^+] - ([HCO_3^-] + [Cl^-])$$

with a normal AG of 8 to 12 mEq/L. Decreased albumin can falsely elevate the AG; the AG can be corrected by using the Figge equation:

$$AG\ corrected = AG + (2.5 \times [44 - measured\ serum\ albumin]),\ (albumin\ expressed\ as\ g/dL)$$

Mortality correlates highly with the degree of acidosis and formate concentration rather than with a specific methanol concentration. Visual dysfunction occurs with a formate concentration greater than 20 to 30 mg/dL. Indicators for a poor prognosis include a formate concentration of more than 50 mg/dL and a pH less than 7.0

Many formulas exist for calculating serum osmolarity, but the most commonly used is the following:

$$Calculated\ osmolarity\ (mOsm/L) = 2Na^+ + (BUN/2.8) + (glucose/18) + (ethanol/4.6)$$

where blood urea nitrogen (BUN), glucose, and the ethanol concentrations are measured in mg/dL. The difference between measured serum osmolality and calculated serum osmolarity is as follows:

$$Osmolar\ gap = measured\ osmolality\ (mOsm/kg) - calculated\ osmolarity\ (mOsm/L)$$

If using the International System of Units (SI units), there are no corrections, and the various serum levels are simply added or subtracted. The normal osmolar gap has been arbitrarily defined as normal if it is less than 10 mOsm. However, a wide range of osmolar gaps is observed in the population, from −15 to +10 mOsm. As a result, individuals who begin with a negative osmolar gap can have significantly elevated concentrations of toxic alcohols but have a so-called normal osmolar gap. Many other substances can contribute to an osmolar gap and can be misleading. Also, if patients are acidotic, the parent compound (methanol, EG) has been metabolized into its respective acid and does not contribute to the osmotic load. Thus, a normal osmolar gap cannot exclude toxic alcohol ingestion. Methanol, however, is more likely than EG to have an elevated osmolar gap. An extremely elevated osmolar gap (>20–25 mOsm) however is highly suspicious for toxic alcohol ingestion.[16–18] In methanol ingestions, the metabolite formic acid can be measured using enzymatic analysis but this test is not routinely available.[14,19]

Neuroimaging with MRI and computed tomography (CT) can be performed for patients with AMS. The most consistent finding for methanol poisoning is bilateral necrosis of the putamen. However, this finding is not specific for methanol poisoning, and neuroimaging is typically normal in the first 24 hours after methanol exposure because findings typically lag behind clinical symptoms. Patients with evidence of putaminal necrosis on imaging are at risk for an irreversible Parkinson-like extrapyramidal syndrome and chronic disability limiting daily functioning.[13] The measurement of visual evoked potentials (VEP) is sensitive to detect impairment in the optic system.[8]

Ultimately, the definitive diagnosis requires laboratory confirmation of the presence of methanol. Once toxic alcohol ingestion is suspected, directly measure methanol and EG concentrations and begin empirical therapy. Peak methanol concentrations less than 20 mg/dL are generally not associated with toxicity, but peak methanol concentrations greater than 50 mg/dL indicate significant and serious exposure. Peak methanol concentrations occur shortly after ingestion due to rapid GI absorption. Due to the variability of the timing of patient presentation, the methanol level interpretation must be based on clinical findings (e.g., AMS, vision complaints) as well as additional laboratory findings (e.g., metabolic acidosis, elevated osmolar gap). Depending on the location of the practice and laboratory capabilities, specific serum concentrations of methanol or EG may not be readily attainable in most hospitals, and blood specimens may need to be transported to regional reference laboratories for emergent analysis.

Management

Alcohols are rapidly absorbed from the GI tract, so GI decontamination has limited to no value. Gastric suctioning via a nasogastric or orogastric tube may be considered in a large volume exposure (such as an entire bottle of windshield washer fluid or antifreeze) in someone who presents immediately after ingestion, but there is no evidence to support routine use and gastric lavage is generally not recommended. Activated charcoal is not indicated for toxic alcohol ingestions. Aside from standard stabilization and resuscitation, the main priorities in toxic alcohol exposure are correction of acidosis, inhibition of the production of toxic metabolites, and elimination of the parent alcohol and its toxic metabolites. Therapy should be initiated based on strong clinical suspicion. Treatment should not be delayed while waiting for specific serum concentrations to be determined.

Because the degree of acidosis correlates with severity and outcome, treat a serum pH less than 7.3 with intravenous (IV) sodium bicarbonate to normalize the pH. Worsening acidosis from formic acid accumulation potentiates mitochondrial cytochrome oxidase inhibition and anaerobic metabolism, also generating lactic acidosis. Based on supporting patient data, correction of acidosis likely improves outcomes and ophthalmologic symptoms. Bicarbonate can be administered via intermittent boluses, combination of a bolus and infusion, or infusion alone based on the severity of symptoms. Administer bolus sodium bicarbonate at 1 to 2 mEq/kg and infuse 150 mEq/L of sodium bicarbonate in 5% dextrose at 1.5 to 2 times the maintenance fluid rate until normalization of the serum pH (7.35–7.45). Large amounts of bicarbonate may be necessary for even partial correction of acidosis due to metabolism of the parent alcohol into its toxic acid. With bicarbonate administration, monitor for the development of hypernatremia and hypokalemia. The use of bicarbonate should not deter definitive elimination of the parent alcohol and its toxic metabolites via HD.

Prevent the further production of formic acid by inhibiting ADH with fomepizole (methylpyrazole, 4-MP) or ethanol. Fomepizole is preferable due to its safety profile and ease of administration, with a

BOX 136.1 Criteria for Initiation of Alcohol Dehydrogenase Blockade for Methanol or Ethylene Glycol Poisoning

Documented plasma methanol or EG concentration ≥20 mg/dL
or
History of ingestion of methanol or EG and an osmolar gap >10 mOsm/L
or
Strong clinical suspicion of ingestion of methanol or EG and at least two of the following:
1. Arterial pH <7.3
2. Serum bicarbonate <20 mEq/L (mmol/L)
3. Osmolar gap >10 mOsm/L
4. Urinary oxalate crystals present (for EG ingestion)

EG, Ethylene glycol.

BOX 136.2 Fomepizole Dosing

- Loading dose—15 mg/kg IV
- Maintenance dose—10 mg/kg IV every 12 h for up to 48 h
- After 48 h—15 mg/kg every 12 h
- If undergoing HD—same doses as above, but start maintenance schedule 6 h after loading dose and then administer every 4 h during HD

sevenfold reduction in adverse drug event rate versus ethanol.[9,18,20] No contraindication exists for fomepizole use except for a severe allergic reaction, but currently, there have been no reported cases.[18] Most adverse reactions to fomepizole are transient and do not require discontinuation of treatment.[21] Specific indications for initiating ADH blockade are a documented methanol or EG concentration more than 20 mg/dL, documented history of methanol or EG ingestion with an osmolar gap more than 10 mOsm/L, or suspected methanol or EG ingestion with an arterial pH less than 7.3, serum carbon dioxide (bicarbonate) level less than 20 mmol/L, or oxalate crystalluria (Box 136.1).

In clinical practice, however, initiate fomepizole therapy with a strong clinical suspicion for serious ingestion, and send for confirmatory levels, because a delay in ADH blockade can lead to the development of acidosis and deleterious consequences. Fomepizole dosing involves a loading dose of 15 mg/kg followed by 10-mg/kg doses every 12 hours, up to 48 hours. After 48 hours, give 15 mg/kg every 12 hours because repeated dosing of fomepizole induces its own cytochrome P-450 metabolism. Of note, the fomepizole dosing frequency does need to be adjusted with HD (Box 136.2). Side effects of fomepizole include headache, nausea, dizziness, phlebitis, and reversible liver transaminase level elevation. One case of hypotension and bradycardia due to the rapid infusion of fomepizole has been described.[15,20]

If fomepizole is not available, and ethanol therapy is used to inhibit ADH, maintain serum ethanol concentrations between 100 and 150 mg/dL. The affinity of ADH for ethanol is 10 times greater than for methanol. Ethanol dosing is complex, however, and can cause worsening CNS and respiratory depression, with hypotension, vomiting, phlebitis, and hypoglycemia, particularly in children or malnourished individuals.[18,20] Given the widespread availability of fomepizole and its safety profile versus that of ethanol, the dosing of IV ethanol is not discussed here because its routine use is not recommended with the exception of mass outbreaks or lack of fomepizole availability.[12,22] With ADH inhibition, the half-life of methanol is significantly extended upward of 50 hours. Patients who present early after methanol ingestion without acidosis can potentially be treated with ADH inhibition alone but may have prolonged hospitalizations due to the extended half-life of the parent compound.

Elimination of the parent alcohol via HD is the mainstay of therapy in severe toxic alcohol ingestions, and consultation with a regional poison center or medical toxicologist will help determine whether the patient is a candidate. HD serves multiple purposes in that it removes the parent alcohol and its metabolites, corrects acidosis, and aids in fluid management and cardiovascular stabilization. Additionally, it can shorten the course and cost of hospitalization, particularly in methanol ingestions, due to methanol's long half-life.[11] Intermittent HD is preferred over continuous renal replacement therapy (CRRT) but CRRT is acceptable if HD is not available[15,23]

HD is indicated for acidosis (pH < 7.3), renal failure, vision abnormalities with methanol exposure, electrolyte imbalances unresponsive to conventional therapy (i.e., hyperkalemia), hemodynamic instability, and methanol or EG concentration more than 50 mg/dL.[15] Traditional endpoints for discontinuing HD or ADH inhibition are a normal acid-base status and methanol-EG concentration less than 20 mg/dL.[15] Ophthalmologic disturbances are not an indication for continued dialysis after correction of the acid-base disturbance and removal of methanol. There is no specific treatment for methanol-induced persistent optic nerve injury. Formic acid is converted to carbon dioxide and water via THF synthetase; therefore, folinic acid (leucovorin) may aid in formic acid elimination, but there have been no human trials to support its efficacy. The recommended dose is 1 mg/kg (maximum dose: 50 mg) of folinic acid IV every 4 to 6 hours until methanol has been eliminated and the acidosis resolves. The use of folinic acid (leucovorin) should not deter emergent HD if indicated.

Disposition

Admission is generally necessary for patients being treated for methanol exposure. Consult with nephrology early for possible HD. If HD is not available, administer fomepizole and transfer the patient to an institution where emergent HD can be initiated. Consult the regional poison center (1-800-222-1222) or a medical toxicologist to guide management. Consult an ophthalmologist to evaluate visual fields and the retina for methanol-induced ocular injury within 24 hours. Patients with a methanol concentration less than 20 mg/dL and no clinical symptoms or laboratory abnormalities may be discharged. If the patient has psychiatric issues or intent of self-harm, a psychiatric consultation is indicated.

ETHYLENE GLYCOL

Foundations

EG (ethane-1,2-diol, CAS 107-21-1, $C_2H_6O_2$) is a colorless, odorless, sweet-tasting liquid. It is a common component of antifreeze and deicing solutions because it lowers the freezing point of water. Additional sources of EG include hydraulic brake fluids, industrial solvents, foam stabilizer, paints, and cosmetics. Because EG has a sweet taste, it is often substituted for ethanol and has led to mass poisonings historically. In 2018, 6599 single substance exposures to EG were reported to US poison centers. Most of these were unintentional (82%) but resulted in roughly 10.5% of patients having moderate to severe effects and a total of 19 deaths.[3] Like methanol, the data rely on voluntary reporting and likely underestimate the true burden of EG exposures and mortality outcomes.

EG is rapidly absorbed from the GI tract with peak blood levels occurring within 1 to 4 hours after ingestion. EG is highly water-soluble and, unlike methanol or isopropanol, is not volatile at room

temperature. Thus, transdermal and pulmonary absorption of EG are extremely limited, and toxicity from these routes of exposure is not expected or observed.

Metabolism of EG primarily occurs in the liver via the conversion of ADH into glycolaldehyde, which is rapidly converted by ALDH into glycolic acid. Glycolic acid is further metabolized into glyoxylic acid (glyoxylate) and oxalic acid (see Fig. 136.1). The conversion of glycolic acid into glyoxylic acid is slow, and the accumulation of glycolic acid generates a profound metabolic acidosis. Pyridoxine and thiamine are cofactors in the metabolism of glyoxylic acid; however, given the slow conversion of glycolic acid to glyoxylic acid, these cofactors likely do not contribute significantly to EG detoxification. A small amount of oxalate will precipitate with calcium to form calcium oxalate crystals. These metabolic oxidation steps result in the conversion of nicotinamide adenine dinucleotide (NAD^+) to nicotinamide adenine dinucleotide (NADH). The increase of NADH to NAD^+ converts pyruvate to lactate and generates lactic acidosis.

Calcium oxalate crystals precipitate in the proximal renal tubules and are the main contributing factor in the development of acute tubular necrosis and renal failure. Calcium oxalate deposits also occur in the brain, intestinal mucosa, lungs, heart, and spleen, although the contribution of these deposits to the clinical picture is less clear. Further findings of EG toxicity include diffuse petechial hemorrhages in the heart, lungs, and brain, as well as the development of cerebral edema. Myonecrosis and rhabdomyolysis can occur. The chelation of calcium by oxalate can lead to systemic hypocalcemia.

Elimination of EG occurs mainly in the liver, but roughly 20% to 25% of EG is excreted unchanged in the urine. The reported half-life of EG ranges from 3 to 9 hours, but when metabolism is inhibited by ethanol or fomepizole, the half-life increases up to 20 hours. With HD, the half-life of EG is about 2 to 3 hours, depending on flow rates.

Clinical Features

The clinical picture of EG toxicity is typically divided into three stages: (1) acute neurologic stage; (2) cardiopulmonary stage; and (3) renal stage. As with methanol, delayed neurologic sequelae are described. An extreme amount of clinical variability occurs, stages may overlap, and mortality may occur at any stage. Poor prognostic factors at admission include hyperkalemia, severe metabolic acidosis, renal failure, seizures, coma, and delays in treatment. Seizures are highly prognostic for death.[20] The co-ingestion of ethanol can delay the onset of symptoms.

EG is a gastric irritant and can produce nausea and vomiting shortly after ingestion. The acute neurologic stage occurs over 30 minutes to 12 hours after ingestion with EG, producing inebriation and euphoria similar to ethanol. In severe poisonings, CNS depression can progress to coma, hypotonia, and seizures. Additional findings include nystagmus, ataxia, and myoclonic jerks. Cerebral edema can develop from calcium oxalate crystal deposition and cytotoxic damage contributing to CNS depression.

The cardiopulmonary stage occurs 12 to 24 hours after ingestion, with patients developing tachycardia with severe metabolic acidosis and compensatory tachypnea. The acidosis occurs from the generation of glycolic acid. Hypoxia with pulmonary edema and acute respiratory distress syndrome (ARDS) can cause hypoxia. Multiorgan failure with circulatory collapse can occur, and most deaths ensue during this stage.

The renal stage occurs 24 to 72 hours postingestion with the development of acute renal failure (ARF) from calcium oxalate crystal deposition. Conscious patients may complain of flank pain and have costovertebral tenderness. Hematuria and proteinuria can occur. Renal failure can be anuric, oliguric, or nonoliguric. Renal dysfunction frequently necessitates HD and, in some cases, for months after exposure. Renal function usually returns to normal following EG intoxication, but occasionally renal damage can be permanent. Long-term HD is rarely necessary.

Delayed neurologic sequelae commonly present as bulbar palsy from 5 to 20 days after ingestion, with cranial nerve VII being most commonly implicated. Other cranial nerve involvement has been documented; clinical findings include ophthalmoplegia, diplopia, nystagmus, facial droop, facial sensory loss, hearing loss, dysphagia, and vertigo.[24] The term *facial auditory nerve oxalosis* has been used to describe this delayed syndrome and its predilection to affect cranial nerves VII and VIII noted on autopsy. In addition to the cranial nerves, an autonomic nerve dysfunction has been described, with postural hypotension and gastroparesis. The exact pathogenesis for these neurologic findings is unclear, but postulated mechanisms include calcium oxalate deposition resulting in mechanical nerve injury, inflammatory response causing nerve dysfunction, and depletion of thiamine and pyridoxine cofactors. Neuroimaging studies can demonstrate the focal infiltration of calcium oxalate with inflammation and necrosis of the basal ganglia. Despite significant MRI pathology, individuals with neurologic complications can have a full recovery.[25]

Differential Diagnoses

The differential diagnoses for EG intoxication are broad and similar to methanol. See earlier, "Methanol: Differential Diagnoses," for a more in-depth explanation, especially regarding the initial presentation of inebriation and AMS, proceeding through elevated osmolar and AGs (see Table 136.1).

Unlike methanol, however, the hallmark of EG toxicity involves renal failure with calcium oxalate crystalluria. Many other substances cause ARF, including antimicrobials (e.g., aminoglycosides, vancomycin, sulfa-based drugs, ciprofloxacin, penicillins, polymixins), nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, HMG-CoA reductase inhibitors, antivirals (e.g., acyclovir, foscarnet, antiretrovirals), amphotericin B, chemotherapeutics (e.g., methotrexate, cisplatin, ifosfamide), diethylene glycol (DEG), bisphosphonates, radiocontrast media, heavy metals, proton pump inhibitors, lithium, and acetaminophen. Calcium oxalate crystalluria is not specific for EG and is only present in up to 50% of cases of EG ingestion. Healthy individuals with excess dietary intake of vitamin C or foods rich in oxalate (e.g., garlic, tomatoes, spinach, rhubarb, and tea) may have incidental calcium oxalate crystalluria.

Xenobiotic-induced hypocalcemia can occur from proton pump inhibitors, bisphosphonates, other phosphate-containing substances (e.g., laxatives and sodium phosphate), loop diuretics, glucocorticoids, calcitonin, cisplatin, pentamidine, interferon-alfa, fluorides (e.g., hydrofluoric acid), citrate, phenytoin, phenobarbital, carbamazepine, estrogens, and ethylenediaminetetraacetic acid. Hypocalcemia, metabolic acidosis, ARF, and calcium oxalate crystalluria, however, strongly suggest EG toxicity. Ultimately, the definitive diagnosis requires laboratory confirmation of EG concentrations in blood or serum.

Diagnostic Testing

Diagnostic testing for EG is similar to that for methanol; for a more detailed discussion of AG acidosis and elevated osmolar gap calculations, see earlier, "Methanol: Diagnostic Testing." The contribution of EG to the osmolar gap is relatively small compared to other alcohols, and an EG concentration of 50 mg/dL will only cause an 8- to 10-mOsm rise in the osmolar gap. Thus, an elevated osmolar gap can suggest EG ingestion, but a normal gap does not exclude it.

Glycolic acid is structurally similar to lactate and can cause a false positive lactate elevation in laboratory equipment using a lactate oxidase-based system measuring hydrogen peroxide generated from the metabolism of lactate to pyruvate. These machines tend to be

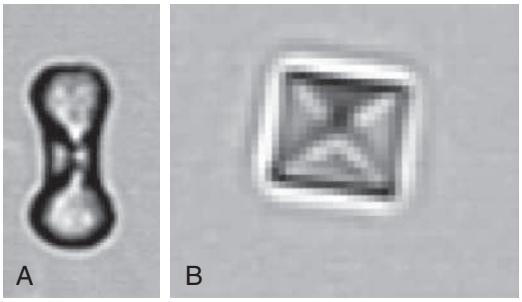

Fig. 136.3 Calcium oxalate crystals. Illustrated are calcium oxalate monohydrate (A) and dihydrate (B) crystals in the urine. The monohydrate whewellite crystals typically are needle-like or dumbbell-shaped and strongly birefringent, whereas the dihydrate weddellite crystals are octahedral, envelope-shaped, and weakly birefringent.

point-of-care tests such as whole blood arterial or venous blood gas analyzers. This can create a "lactate gap" in EG ingestion where a point-of-care lactate is extremely elevated but a formal laboratory analysis of lactate using a lactate dehydrogenase system is markedly less.[26,27]

Calcium oxalate crystalluria can be of two major forms, needle-shaped calcium oxalate monohydrate or polyhedron-shaped calcium oxalate dihydrate crystals. The calcium oxalate monohydrate crystals may be mistaken for hippuric acid crystals. Crystals can be found in the urine 4 to 8 hours after exposure. Additional urinary findings include hematuria and proteinuria (Fig. 136.3).

Fluorescein dye is often added to antifreeze agents to assist in the detection of automobile radiator leaks, so patients who ingest antifreeze EG-containing agents may exhibit urinary fluorescence under a Woods lamp. Urinary fluorescence, however, is neither specific nor sensitive for diagnosing or excluding EG intoxication. The fluorescence of gastric contents soon after EG ingestion may be more definitive.

The EG concentration itself does not predict severity as much as it depends on the timing of presentation and initiation of intervention. Serum EG concentrations greater than 50 mg/dL, however, are associated with serious ingestion and toxicity. The degree of acidosis (particularly a pH <7.2–7.3) does predict an increase in the creatinine level and mortality outcome. A peak EG concentration less than 20 mg/dL is generally not associated with significant toxicity.

In EG intoxication, the serum glycolic acid concentration is the driving force for acidosis. Glycolic acid concentrations greater than 99 mg/dL are strongly associated with severe CNS toxicity and mortality. Levels greater than 76 mg/dL have nearly 100% sensitivity for predicting ARF.[28] Glycolic acid levels greater than 60 mg/dL could be an indication for HD, but this is not well validated.[28] Serum glycolic acid concentrations typically are not readily available in a timely fashion to aid in most clinical situations and only a small percentage of reference laboratories perform this test.[28]

Management

Many of the management principles of EG toxicity overlap with those of methanol. EG, like methanol, is rapidly absorbed from the GI tract; thus, gut decontamination has a limited to no role in EG ingestion. Correction of metabolic acidosis with sodium bicarbonate (pH < 7.3) may increase the urinary excretion of EG and delay calcium oxalate-induced ARF. Initiate ADH blockade, preferably with fomepizole, as soon as possible to prevent the development of toxic metabolites (see Boxes 136.1 and 136.2). Ethanol therapy can be used if fomepizole is unavailable, although its routine use is not recommended. Consider HD for the indications stated earlier, particularly for an acid-base imbalance and renal failure. EG, however, has a shorter half-life than methanol, and patients without acidosis or renal compromise can be managed with fomepizole alone, thus preventing the need for HD in adult and pediatric patients. Continue treatment until serum EG concentrations are less than 20 mg/dL, and a normal acid-base status is present.

Pyridoxine and thiamine are cofactors in EG metabolism. Pyridoxine aids in the conversion of glyoxylic acid metabolism to glycine. Thiamine stimulates conversion of glyoxylic acid to α-hydroxy-β-ketoadipate (see Fig. 136.1). No clinical data, however, support the effectiveness of these cofactors in otherwise healthy patients with EG ingestion. These cofactors should be given to patients with vitamin deficiencies, such as alcoholics and malnourished individuals. The recommended adult doses are thiamine 100 mg IV daily, and pyridoxine 100 mg IV daily, for 2 days. If patients have symptomatic hypocalcemia (interval changes on the electrocardiogram and dysrhythmias), replete with calcium gluconate or calcium chloride as needed.

Disposition

Admission is generally necessary for patients being treated for EG exposure. Consult nephrology early for possible HD. If HD is not available, initiate ADH inhibition and transfer the patient to an institution where emergent dialysis is available. Consult the regional poison center (1-800-222-1222) or a medical toxicologist to guide management. Patients with an EG concentration less than 20 mg/dL and no laboratory abnormalities or clinical symptoms may be discharged. If the patient has psychiatric issues or intent for self-harm, a psychiatric consultation is indicated.

ISOPROPYL ALCOHOL

Foundations

IPA (isopropanol, 2-propanol, CAS 67-63-0, C_3H_7OH) is a clear, colorless liquid with a fruity odor and bitter taste. IPA is found in numerous household and commercial products, including rubbing alcohol, antifreeze, disinfectants, cleaning solutions, skin and hair products, and hand sanitizers. IPA is commonly used as a solvent for industrial applications. It is the second most commonly ingested alcohol after ethanol. Exposures to IPA, either as a single substance or combined with other substances, reported to US poison centers have ranged from about 15,000 to 21,000 cases/year.[3] In 2018, 12,730 single substance IPA exposures occurred, with 82% unintentional in nature, 1% having moderate to major effects, and zero deaths, reflecting a low case-fatality rate.[3]

Isopropyl alcohol is rapidly absorbed from the GI tract with peak plasma concentrations occurring within 30 minutes. Oral ingestion is the major route of exposure, but absorption can occur transdermally, rectally, or via inhalation. Children are especially susceptible to systemic symptoms from the dermal application of IPA used to reduce fever.

Metabolism occurs primarily in the liver by ADH into acetone. Acetone is metabolized to acetol (hydroxyacetone) by acetone monooxygenase (see Fig. 136.1). Further metabolic products include PG, methylglyoxal, lactate, formate, and acetate. Many of these minor metabolic products are then converted to glucose. Acetone reaches a peak plasma concentration from 7 to 30 hours postexposure and has a half-life of up to 24 hours. IPA follows first-order kinetics, with a half-life of 2.5 to 8 hours. ADH inhibition increases the half-life to 16 to 27 hours. Elimination primarily occurs via the kidneys, with up to 20% of IPA excreted unchanged in the urine.

Isopropyl alcohol directly acts as a CNS depressant and is considered to be twice as inebriating as ethanol. Acetone can also contribute to CNS depression. A concomitant respiratory depression can

occur with profound CNS depression. With larger doses, peripheral vasodilation and decreased cardiac inotropy can cause hypotension. Topical exposure leads to corneal de-epithelialization, with dermal irritation.

Clinical Features

Isopropyl alcohol irritates mucosal surfaces, and GI effects typically occur early after ingestion. Nausea, vomiting, and abdominal pain typically ensue, but hemorrhagic gastritis, hematemesis, and significant blood loss can result with larger ingestions. As with other alcohols, pancreatitis is a potential complication. Aspiration of IPA can cause hemorrhagic tracheobronchitis and pulmonary edema.

CNS depression ranges from lethargy to stupor or coma. Headache, dizziness, ataxia, hypotonia, hyporeflexia, dysarthria, and seizures have been reported. Pupil size is variable, but miosis is commonly observed. Loss of consciousness is associated with respiratory depression, hypoxia, and aspiration pneumonitis. Hypotension and hypothermia can occur with very large ingestions. Hypotension signifies severe poisoning with increased mortality risk. Injuries from prolonged immobilization with CNS depression can lead to compartment syndrome and rhabdomyolysis. Myoglobinuria can cause ARF. Hypoglycemia has not been reported with IPA as it has for other alcohols. Dermal contact causes a defatting dermatitis with drying and cracking of the skin, and pediatric patients can sustain chemical burns. Ketosis without acidosis is a classic finding in IPA ingestion.

Differential Diagnoses

Patients with significant IPA ingestion appear intoxicated similar to ethanol. IPA will elevate the osmolar gap but, unlike methanol and EG, not the AG. See earlier, "Methanol: Differential Diagnoses" for causes for AMS and an elevated osmolar gap. As IPA is converted to acetone, ketosis will occur. Ketosis is present in conditions such as diabetic ketoacidosis, alcoholic ketoacidosis, starvation ketosis, salicylism, and cyanide and acetone ingestion. Those chronically dependent on ethanol may consume IPA to prevent alcohol withdrawal and can have a mixed picture of alcoholic ketoacidosis with IPA ingestion.[29] ARF can develop from rhabdomyolysis but the differential for ARF is extensive.

Diagnostic Testing

The most common laboratory abnormality is ketosis without acidosis and euglycemia. As IPA is metabolized, acetone accumulates. Acetone does not elevate the AG, but IPA and acetone do contribute to the osmolar gap. Acetone can be detected within 30 minutes in serum and within 3 hours in urine postexposure. Acetone can interfere with the assay for creatinine and cause a pseudo-renal failure measurement with an isolated elevated creatinine but normal BUN level. If patients are hypotensive from a large IPA ingestion, lactic acidosis can occur, which can then cause a confounding AG acidosis.

The measurement of the IPA concentration is the definitive method of diagnosis. Occasionally, IPA can be detected in patients with acetonemia not exposed to IPA because acetone is converted to IPA in vivo. Serum concentrations of IPA do not correlate well with clinical outcomes—deaths have been reported with concentrations as low as 20 mg/dL. The scant data available suggest that a concentration of more than 50 mg/dL is associated with toxicity, and some authors suggest HD for levels greater than 400 mg/dL, hypotension, or lactic acidosis, although there has been no clear evidence for these recommendations[9]

Management

Supportive care is the mainstay of therapy for IPA ingestion. There is no role for GI decontamination. Wash the skin with soap and water for dermal contamination. Provide proton pump inhibitors (e.g., pantoprazole, 80 mg IV push and a drip at 8 mg/h for 72 hours, or until the patient can tolerate oral foods and fluids) for hemorrhagic gastritis. Consult gastroenterology for endoscopy to exclude other causes of upper GI bleeding or to intervene for persistent bleeding causing hemodynamic instability, necessitating transfusion, or worsening clinical condition. For deeply comatose patients, airway protection is indicated. Hypotension generally responds to IV crystalloid solution. For significant hypotension, initiate 1 to 2 L of normal saline as a bolus infusion, followed by repeated 500-mL boluses at 30-minute intervals until a mean arterial pressure (MAP) of 65 mm Hg is achieved. If the target MAP cannot be achieved or maintained with 4 L of normal saline boluses, start a norepinephrine infusion and titrate to the target MAP. Additional vasopressor support can be added with fluids, as needed. If the patient is persistently hypotensive, despite standard resuscitative measures, HD is indicated. ADH blockade with fomepizole or ethanol is not indicated because this will only prolong the hypotensive and CNS depressant effects of IPA.

Disposition

Due to IPA's rapid absorption on its onset of action, patients who are stable and alert 6 hours after ingestion are unlikely to develop significant complications and can be monitored until no longer clinically intoxicated and discharged from the emergency department (ED). Patients with significant inebriation or AMS should be admitted as an inpatient or placed in an observation unit for 24 hours. Consult gastroenterology for patients with hemorrhagic gastritis for endoscopy. Consult nephrology for patients with a comatose state or refractory hypotension for HD. Consult the regional poison center (1-800-222-1222) or medical toxicologist to help guide management.

OTHER ALCOHOLS OF CLINICAL SIGNIFICANCE

DEG is an odorless, viscous, sweet-tasting liquid commonly used as a solvent. It is found in brake fluid, antifreeze, lubricants, wallpaper strippers, and artificial fog machine solutions. Most exposures to DEG occur in epidemics in which DEG is substituted in pharmaceutical preparations for more expensive glycols. The first epidemic occurred in the United States in 1937, with DEG being used as a solvent for sulfanilamide, and led to the passing of the 1938 Federal Food, Drug, and Cosmetic Act requiring drug manufactures to demonstrate product safety prior to marketing. Other epidemics include those in South Africa (1969), Spain (1985), Nigeria (1990), Bangladesh (1990–92), Haiti (1996), India (1998), Panama (2006), and Nigeria (2008). DEG toxicity resembles that of EG, with initial GI irritation and CNS depressant effects, followed by metabolic acidosis. ARF without urinary calcium oxalate crystals occurs. Patients who survive ARF, unlike EG, typically require lifelong HD. Neurologic symptoms develop 5 to 10 days postingestion and can include lethargy, cranial neuropathies, peripheral polyneuropathies, and quadriparesis. DEG is metabolized into 2-hydroxyethoxyacetic acid and does not metabolize into EG, as once believed. Management is similar to that of methanol and EG and includes ADH blockade and early consideration for HD.[9,18]

PG is commonly used as a solvent in various pharmaceutical products and in antifreeze and hydraulic fluids. Common medications that use PG as a diluent include IV phenytoin, lorazepam, diazepam, etomidate, nitroglycerin, phenobarbital, hydralazine, and trimethoprim-sulfamethoxazole.[30] PG is metabolized to lactic acid and can produce metabolic acidosis. Also, it can contribute to an elevated osmolar gap. Because PG has a short half-life, the osmolar gap rapidly returns to normal once the medication diluent or exposure is discontinued.

Underlying renal insufficiency and hepatic dysfunction increase the risk for toxicity. Case reports have noted acute kidney injury from proximal tubular necrosis with PG toxicity. Additionally, PG toxicity can mimic a systemic inflammatory response syndrome and cause a confounding picture, with an elevated osmolar and AG triggering exploration for methanol and EG exposure. Approximately 20% of intensive care unit patients on continuous lorazepam infusions can have some degree of PG toxicity. Treatment typically involves stopping the offending agent, but HD and ADH blockade can be considered for severe acidosis and metabolic abnormalities.[9]

CHAPTER 136: QUESTIONS AND ANSWERS

1. A 24-year-old man presents after intentional methanol ingestion. The patient reports that 1 or 2 hours ago he drank approximately 8 ounces of windshield washer fluid in a suicide attempt. He is not sure of the product name. His only current complaint is slight nausea. His vital signs and physical examination are within normal limits. Serum chemistry reveals the following: sodium, 142 mEq/L, potassium, 4.5 mEq/L, chloride, 110 mEq/L, bicarbonate, 22 mEq/L, blood urea nitrogen (BUN), 18 mg/dL, creatinine, 1.5 mg/dL, and glucose, 111 mg/dL. Serum methanol levels are not obtainable at your hospital. The psychiatry service asks if the patient is medically cleared. Which of the following is the most appropriate response?

a. The patient is cleared; he has a normal anion gap, so no significant methanol ingestion occurred.

b. The patient is cleared; ingestion of 8 ounces is below the toxic level regardless of the concentration.

c. The patient is not cleared; he has an elevated anion gap and needs to receive treatment for methanol toxicity.

d. The patient is not cleared; he has evidence of renal failure and needs to receive treatment for methanol toxicity.

e. The patient is not cleared; not enough time has elapsed from the ingestion to determine if significant toxicity has occurred.

Answer: e. Windshield washer fluid can contain high concentrations of methanol. Methanol itself does not cause toxicity or an anion gap acidosis but its metabolites do, specifically formic acid. It can take 12 to 24 hours for acidosis to develop and even longer if a significant amount of ethanol has also been ingested. This patient should be observed and treated. This patient's anion gap is 10 mEq/L, which is within normal limits. Ingestion of very small amounts of methanol can be fatal or cause permanent neurologic or ophthalmologic damage. As little as 15 mL of 40% methanol can cause death in adults.

2. A 44-year-old woman complains of abdominal pain and headache. Her family reports that the patient drank "something" approximately 8 hours ago in a suicide attempt. The patient is sleepy but arouses with manual stimulation. Her speech is confused, but she follows all simple commands. Her vital signs are blood pressure,

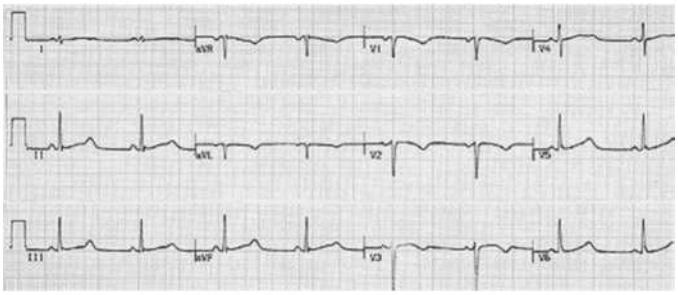
CHAPTER 136: QUESTIONS AND ANSWERS—cont'd.

124/82 mm Hg, heart rate, 108 beats/min, respiratory rate, 26 breaths/min, and temperature, 37.0°C (98.6°F). Her physical examination is unremarkable. Her serum chemistry reveals an anion gap of 24 mEq/L. Other laboratory work is pending. Which of the following treatments should be administered initially?

a. Diuresis
b. Hemoperfusion
c. Intravenous flumazenil
d. Intravenous fomepizole
e. Oral activated charcoal

Answer: d. Intravenous fomepizole should be administered. This patient has likely ingested methanol or ethylene glycol, both of which can cause these symptoms, as well as an anion gap metabolic acidosis. The definitive treatment for both ingestions is hemodialysis, which can take some time to arrange. Treatment should be started with fomepizole, even before a definitive diagnosis has been made. Fomepizole and ethanol act by inhibiting the conversion of methanol or ethylene glycol to toxic substances, thereby allowing elimination of the much less toxic parent compounds. Diuresis and hemoperfusion are not effective for methanol or ethylene glycol. Flumazenil will reverse the effect of benzodiazepine but should always be used with caution so as not to induce seizure activity in chronic users. Oral charcoal is not effective for methanol or ethylene glycol, especially after such a long delay.

3. A 20-year-old man presents after ingesting antifreeze. His electrocardiogram (ECG) is shown below. Which electrolyte abnormality is most likely responsible for the findings on the ECG?



a. Hypercalcemia
b. Hyperkalemia
c. Hypocalcemia
d. Hypokalemia
e. Hypomagnesemia

Answer: c. Hypocalcemia is a cause of QT prolongation. Ingestion of ethylene glycol can result in hypocalcemia, which is caused by calcium precipitation with oxalate. Although ethylene glycol ingestion can result in renal failure that can then cause hyperkalemia, it is not associated with QT prolongation. Hypokalemia and hypomagnesemia can both cause QT prolongation; neither is generally associated with ethylene glycol ingestion.

4. An otherwise healthy patient presents after suicidal ethylene glycol ingestion. He is drowsy. His serum pH is 7.1. You have started treatment with fomepizole and have contacted the nephrologist to arrange hemodialysis. In the meantime, what should be done about the patient's acidosis?

a. Normal saline should be administered to facilitate clearance of the acid.
b. Nothing should be done; dialysis will correct the acidosis.
c. Nothing should be done; the fomepizole will correct the acidosis.
d. Nothing should be done; the patient is not truly acidotic, but ethylene glycol interferes with the laboratory determination of pH.
e. Sodium bicarbonate should be administered to neutralize the exogenous acid.

Answer: e. Unlike lactic acid, which will be metabolized to bicarbonate, the acidic metabolites of methanol and ethylene glycol cannot be metabolized to bicarbonate and can cause severe acidosis if not treated. Dialysis will correct the acidosis, but the early treatment of the acidosis can reverse some of the adverse effects of methanol or ethylene glycol poisoning. Fomepizole prevents the conversion of methanol or ethylene glycol into toxic metabolites but does nothing to those toxic metabolites already produced. Forced saline diuresis is not beneficial and may increase the incidence of acute respiratory distress syndrome.

5. Which of the following is an indication for hemodialysis after methanol or ethylene glycol ingestion?

a. Metabolic acidosis
b. Blood level of 10 mg/dL
c. Elevated anion gap
d. Hypocalcemia
e. Hypokalemia

Answer: a. Metabolic acidosis, renal compromise, visual symptoms, deterioration despite intensive supportive care, and electrolyte abnormalities unresponsive to conventional therapy are all indications for hemodialysis. Although an anion gap is often associated with metabolic acidosis, an anion gap in and of itself is not an indication for hemodialysis. There is debate about the alcohol levels that indicate the need for hemodialysis. Recommendations have been made to dialyze patients with levels of methanol or ethylene glycol between 25 and 50 mg/dL.

6. Which of the following cofactors helps with the elimination of methanol and should be considered in patients with methanol poisoning?

a. Folinic acid (leucovorin)
b. Hydroxocobalamin (vitamin B_{12})
c. Niacin (vitamin B_3)
d. Pyridoxine (vitamin B_6)
e. Thiamine (vitamin B_1)

Answer: a. Folinic acid is a cofactor in the degradation of formic acid to carbon dioxide and water, the final step in the metabolism of methanol. Give folinic acid 50 mg IV every 4 hours to adults with methanol poisoning. Thiamine and pyridoxine are indicated for patients with ethylene glycol poisoning and should be considered. Niacin and hydroxocobalamin are antidotes but play no role in the treatment for ethanol or ethylene glycol poisoning.

7. Which of the following statements comparing the effects of isopropyl alcohol and ethylene glycol is true?

a. Isopropyl alcohol causes less CNS depression and is less toxic than ethylene glycol.
b. Isopropyl alcohol causes less CNS depression and is more toxic than ethylene glycol.
c. Isopropyl alcohol causes more CNS depression and is less toxic than ethylene glycol.
d. Isopropyl alcohol causes more CNS depression and is more toxic than ethylene glycol.
e. Isopropyl alcohol has the same effects as ethylene glycol.

Answer: c. Isopropyl alcohol causes twice the central nervous system (CNS) depression of ethanol, which causes more depression than ethylene glycol. Isopropyl alcohol is metabolized to acetone, which also causes CNS depression but is relatively nontoxic, except in very high doses.

CHAPTER 136: QUESTIONS AND ANSWERS—cont'd.

8. A patient presents with decreased mental status after drinking some homemade alcohol. Serum chemistry reveals sodium, 140 mEq/L, potassium, 4.5 mEq/L, chloride, 108 mEq/L, bicarbonate, 22 mEq/L, BUN, 28 mg/dL, creatinine, 1.0 mg/dL, glucose, 90 mg/dL, and serum osmolality, 320 mOsm/kg. Urinalysis is positive for ketones. Which of the following is the most likely alcohol ingested?

a. Ethanol
b. Ethylene glycol
c. Isopropyl alcohol
d. Methanol
e. On the basis of this information, the patient probably did not ingest an alcohol.

Answer: c. This patient has a normal anion gap of 10 but an elevated osmolal gap of 25. The osmolal gap equals the measured serum osmolarity minus the calculated serum osmolarity. The calculated osmolarity is

$$(\text{Sodium} \times 2) + (\text{BUN}/2.8) + (\text{glucose}/18)$$

In this case, it is 295 mOsm/kg. Ethylene glycol and methanol both cause a double gap or elevated anion and osmolal gaps. Ethanol and isopropyl alcohol generally elevate only the osmolal gap. Isopropyl alcohol ingestion causes more CNS depression than ethanol ingestion and results in ketonemia and ketonuria as it is metabolized to acetone.

137

Alcohol-Related Disease

John T. Finnell

As eloquently stated by Paracelsus in the 16th century, "all substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy."

KEY CONCEPTS

- Moderate alcohol consumption is defined as one or two drinks/day for men and one drink/day for women.
- DSM–5 integrates alcohol abuse and alcohol dependence into a single disorder called *alcohol use disorder* (AUD), with mild, moderate, and severe sub-classifications.
- Benzodiazepines are the main treatment of alcohol withdrawal and alcohol withdrawal-induced seizures. Minor alcohol withdrawal occurs as early as 6 h and usually peaks at 24–36 h after the cessation of or significant decrease in alcohol intake.
- Major alcohol withdrawal occurs after 24 h and usually peaks at 50 h (but may take up to 5 days) after the decrease or termination of drinking.
- Delirium tremens is the extreme end of the alcohol withdrawal spectrum; it consists of gross tremors, profound confusion, fever, incontinence, and frightening visual hallucinations.
- Alcohol withdrawal seizures occur 6–48 h after the cessation of drinking, with 60% of patients experiencing multiple seizures within a 6-h period.
- Alcohol withdrawal should be assessed and managed using a validated scale, such as the CIWA-Ar scale.
- Brief intervention and screening (SBIRT—***s***creening, ***b***rief ***i***ntervention, and ***r***eferral to ***t***reatment) can reduce alcohol consumption and is feasible and effective in the emergency department.

FOUNDATIONS

Excess alcohol consumption places a significant burden on individuals and society. Globally, alcohol consumption is the seventh leading risk factor for both death and the burden of disease and injury. 2016 data from the World Health Organization (WHO) state that 5.3% of all deaths globally were attributable to alcohol consumption.[1] The overall costs associated with alcohol use represent more than 1% of the gross national product in high- and middle-income countries, with the costs of social harm (e.g., violence and road accidents) being far greater than health costs alone. In short, except for tobacco, alcohol accounts for a higher burden of disease than any other drug.[2]

From 2002 to 2010,[3] the rate of emergency department (ED) visits for alcohol-related diagnoses increased by 38%. In addition to the number of visits, current National Hospital Ambulatory Care survey data indicates that the total time and the length of stay (LOS) for ethanol-related visits are increasing as well.[4]

Twenty-seven percent of the US population admits to alcohol misuse.[5] Alcohol misuse accounts for more than 100,000 deaths in the United States every year, making it the fourth leading preventable cause of death in the United States and the 12th leading cause of death overall and is associated with over 200 diseases.[5,6] Alcoholism permeates all levels of society. Studies reveal a complex association between alcohol consumption and socioeconomic status (SES),[7] where people of lower SES show greater susceptibility to the damaging effects of alcohol.

Alcohol use and misuse also have social and financial costs, with estimates of over $220 billion in societal costs in the United States annually.[8] The literature refers to harmful, hazardous, and risky drinking interchangeably as a pattern of drinking that increases the risk of harm for the person consuming alcohol or others. The International Classification of Disease 10th Revision (ICD-10), draft ICD-11, and the *Diagnostic and Statistical Manual of Mental Disorders 4th Edition* (DSM-4) use the term "alcohol dependence." Alcohol dependence is a result of repeated use leading to a person having impaired control over the use of alcohol despite physical, psychological, and social harms. The fifth edition of the Diagnostic and Statistical Manual (DSM-5) combines diagnostic criteria for alcohol abuse and dependence under the term "alcohol use disorder," with severity modifiers of "mild," "moderate," or "severe," based on the number of criteria met. DSM-5 AUD of moderate or greater severity is essentially equivalent to DSM-4 and ICD-10 criteria for alcohol dependence. DSM–5 integrates alcohol abuse and alcohol dependence into a single disorder called alcohol use disorder (AUD), with mild, moderate, and severe sub-classifications.

At least 24% to 31% of ED patients meet National Institute Alcohol Abuse and Alcoholism (NIAAA) criteria for "at-risk" or heavy drinking. At-risk drinking is defined as an average of 14 or more standard drinks/week or 5 or more per occasion for men and 7 or more drinks weekly or 3 or more per occasion for women and people older than 65 years. (Table 137.1: Terms and Definitions of Unhealthy Alcohol Use.[9])

Patients, their families, and society, in general, should be aware that AUDs are not a result of any individual weakness or moral failing but arise from a complex interaction of individual, social, cultural, and biological factors. Most people with AUD are difficult to identify because they are likely to have jobs and families and to present with general complaints, such as malaise, insomnia, anxiety, sadness, or a range of medical problems.

In 2013, the US Preventive Services Task Force (USPSTF) recommended that clinicians screen adults 18 years or older for alcohol misuse and provide brief behavioral counseling interventions to those engaged in risky or hazardous drinking behaviors.[10] Of the available screening tools, the USPSTF determined that 1-item to 3-item screening instruments have the best accuracy for assessing unhealthy alcohol use in adults 18 years or older. These instruments include the abbreviated Alcohol Use Disorders Identification Test–Consumption (AUDIT-C) and the NIAAA-recommended Single Alcohol Screening Questionnaire (SASQ).[9] This high

TABLE 137.1 Terms and Definitions of Unhealthy Alcohol Use

Term	Source	Definition
Low-risk use/lower-risk use	ASAM	Consumption of alcohol below the amount identified as hazardous and in situations not defined as hazardous
Risky/at-risk use	NIAAA	Consumption of alcohol above the recommended daily, weekly, or per-occasion amounts but not meeting criteria for alcohol use disorder For all women and men 65 years or older: No more than 3 drinks/day and no more than 7 drinks/week for men (21 to 64 years): No more than 4 drinks/day and no more than 14 drinks/week Should avoid alcohol completely: Adolescents, women who are pregnant or trying to get pregnant, and adults who plan to drive a vehicle or operate machinery, are taking medication that interacts with alcohol, or have a medical condition that can be aggravated by alcohol For adolescents: NIAAA defines moderate- and high-risk use based on days of alcohol use in the past year, by age group: Moderate risk: Ages 12–15 years: 1 day/year Ages 16–17 years: 6 days/year Age 18 years: 12 days/year Highest risk: Age 11 years: 1 day Ages 12–15 years: 6 days Age 16 years: 12 days Age 17 years: 24 days Age 18 years: 52 days
Unhealthy use	ASAM	Any alcohol use that increases the risk or likelihood of health consequences (hazardous use [see below]) or has already led to health consequences (harmful use [see below])
Hazardous use	WHO	A pattern of substance use that increases the risk of harmful consequences; in contrast to harmful use, hazardous use refers to patterns of use that are of public health significance, despite the absence of a current alcohol use disorder ¡n the individual user
	ASAM	Alcohol use that increases the risk or likelihood of health consequences; does not include alcohol use that has already led to health consequences
Harmful use	WHO	A pattern of drinking that is already causing damage to health; the damage may be either physical (e.g., liver damage from chronic drinking) or mental (e.g., depressive episodes secondary to drinking) The description for *ICD-10* code F10.l, also labeled "Alcohol Abuse" in the 2018 *ICD-10-CM* codebook
	ASAM	Consumption of alcohol that results in health consequences in the absence of addiction
Alcohol use disorder	*DSM-5*	A maladaptive pattern of alcohol use leading to clinically significant impairment or distress, as manifested by 2 (or more) of the following, occurring within a 12-month period: 1. Having times when the patient drank more, or longer, than intended 2. More than once wanted to cut down or stop, tried It, but could not 3. Spending a lot of time drinking or being sick/getting over the aftereffects of drinking 4. Wanting to drink so badly that they could not think of anything else 5. Found that drinking (or being sick from drinking) often interfered with taking care of home or family responsibilities, caused problems at work, or caused problems at school 6. Continuing to drink even though it was causing trouble with family and friends 7. Given up or cut back on activities that were important or interesting ¡n order to drink 8. More than once gotten into situations while or after drinking that increased the chances of getting hurt (e.g., driving, swimming, unsafe sexual behavior) 9. Continued to drink even though it was causing depression or anxiety, other health problems, or causing memory blackouts 10. Having to drink much more than previously ¡n order to get the desired effect, or finding that the usual number of drinks had much less effect than previously 11. Experiencing the symptoms of withdrawal after the effects of alcohol were wearing off, such as trouble sleeping, shakiness, restlessness, nausea, sweating, racing heart, or seizure Severity is determined based on the number of symptoms present: Mild: 2–3 symptoms Moderate: 4–5 symptoms Severe: ≥6 symptoms

(Continued)

TABLE 137.1 Terms and Definitions of Unhealthy Alcohol Use—cont'd.

Term	Source	Definition
Binge drinking/heavy drinking	NIAAA	A pattern of drinking that brings blood alcohol concentration levels to 0.08 g/dL, which typically occurs after 4 drinks for women and 5 drinks for men-in about 2 h
Episodes[3]	SAMHSA	Drinking ≥5 alcoholic drinks on the same occasion on at least 1 day in the past 30 days
Heavy drinking	SAMHSA	Drinking ≥5 drinks on the same occasion on each of ≥5 days in the past 30 days
Alcohol dependence	*WHO/ICD*-10-CM	≥3 of the following at some time during the previous year:
		A strong desire or sense of compulsion to take the substance
		Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use
		A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by the characteristic withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms
		Evidence of tolerance, such that increased doses of the psychoactive substance are required ¡ή order to achieve effects originally produced by lower doses (clear examples of this are found in alcohol- and opiate-dependent individuals who may take daily doses sufficient to incapacitate or kill nontolerant users)
		Progressive neglect of alternative pleasures or interests because of psychoactive substance use, increased amount of time necessary to obtain or take the substance, or to recover from its effects
		Persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm

[a] According to the American Society of Addiction Medicine, the preferred term; is "heavy drinking episode."
Data from US Preventive Services Task Force, Curry SJ, Krist AH, et al. Screening and Behavioral Counseling Interventions to Reduce Unhealthy Alcohol Use in Adolescents and Adults: US Preventive Services Task Force Recommendation Statement. *JAMA*. 2018;320(18):1899–1909.

burden of alcohol-related injury and disease indicates a need to increase awareness of AUD and its effective treatment options (see Box 137.3).[11]

Metabolism of Alcohol

While some alcohol is absorbed in the stomach, the vast majority is absorbed in the small intestine. It is distributed uniformly to all organ systems, including the placenta. Although 2% to 10% of alcohol is excreted through the lungs, urine, and sweat, most is metabolized to acetaldehyde, primarily by alcohol dehydrogenase (ADH). The oxidation of alcohol is a complex process involving three enzyme systems, all contained in the hepatocyte. Acetaldehyde is then quickly converted to carbon dioxide and water, primarily through aldehyde dehydrogenase (ALDH). The common forms of ADH decrease the alcohol concentration in blood by about 4.5 mmol/L ethanol/h (the equivalent of about one drink/h):

$$\text{Ethanol ADH} \xrightarrow[\text{NAD}\rightarrow\text{NADH}]{\text{Alcohol hydrogenase}} \text{Acetaldehyde ADH} \xrightarrow[\text{NAD}\rightarrow\text{NADH}]{\text{Alcohol dehydrogenase}} \text{Acetyl coenzyme A} \xrightarrow[\text{Cycle}]{\text{Critical acid}} CO_2 + H_2O$$

where NAD is nicotinamide adenine dinucleotide and NADH is reduced nicotinamide adenine dinucleotide.

At least two variations of ADH genes (*ADH1B*2* and *ADH1C*1*) produce a slightly more rapid breakdown of alcohol and therefore potentially faster production of acetaldehyde, which is rapidly metabolized by *ALDH2*. However, about 40% of Asian people (Japanese, Chinese, and Koreans) have an inactive *ALDH2* mutation that results in much higher acetaldehyde levels after drinking than normal. About 10% of people who are homozygous for this gene form cannot drink alcohol without becoming sick and have almost no risk of AUD, whereas those who are heterozygous have a relatively low rate of AUD.

An alternative pathway, the microsomal ethanol-oxidizing system (MEOS), is induced by chronic alcohol exposure. The primary component of the MEOS is the molecule cytochrome P_{450}, which exists in several variants. The variant most important for alcohol metabolism is cytochrome P_{450} 2E1 (CYP2E1). Many effects of alcoholism are produced by the toxic byproducts (hydrogen, acetaldehyde), acceleration of the metabolism of other drugs, and activation of hepatotoxic compounds by these metabolic pathways.

Although the liver is the major site of ethanol metabolism, other tissues contribute to its metabolism. ADH is found in the gastric mucosa, but the gastric metabolism of alcohol is decreased in women and those of Asian descent. This increased bioavailability of ethanol or decreased first-pass metabolism may explain the greater vulnerability of women to acute and chronic complications of alcohol.

Alcohol metabolism has two elimination rates. The alcohol elimination rate approximates zero-order kinetics (constant rate) for lower

TABLE 137.2 Physiologic Effects and Blood Ethanol Levels

Blood Ethanol Concentration (mg/dL)	Effects[a]
20–50	Diminished fine motor control
50–100	Impaired judgment, impaired coordination
100–150	Difficulty with gait and balance
150–250	Lethargy, difficulty sitting upright without assistance
300	Coma in the novice drinker
400	Respiratory depression

[a]These effects are for the occasional drinker. Chronic drinkers can function at much higher alcohol concentrations because of tolerance. On the other hand, patients may become comatose with low levels of alcohol in mixed alcohol-drug overdose.

ethanol levels and first-order kinetics (amount of drug removed over time is proportional to the concentration of the drug) for higher levels, especially in chronic alcoholics; most likely, through induction of the MEOS pathway, the elimination rate is increased at higher blood levels.

The absorption and elimination rates of alcohol vary by individual and depend on many factors. There is enormous variation among patients in the rate of elimination of ethanol from the blood, ranging from 9 to 36 mg/dL/h in published data. Although the clearance rate may be as high as 36 mg/dL/h in some chronic drinkers, 20 mg/dL/h is a reasonable rate to assume in a typical intoxicated ED patient.

Physiologic effects vary directly with the blood alcohol level (Table 137.2). Diminished fine motor control and impaired judgment appear with alcohol concentrations as low as 20 mg/dL (0.02 mg%), but wide individual variability exists. Chronic alcoholics can exhibit impressive tolerance. The blood alcohol concentration of a person cannot be accurately determined without quantitative testing. More than 50% of the adult population is obviously intoxicated with a level of 150 mg/dL (0.15 mg%). As the ethanol level rises, the patient's level of consciousness declines, eventually ending in a coma. Death is caused by aspiration or respiratory depression.

CLINICAL FEATURES

Alcohol Withdrawal Syndrome

Alcohol is a central nervous system (CNS) depressant. Chronic alcohol use results in a down-regulation of γ-aminobutyric acid (GABA) receptor activity and disinhibition of the dopaminergic reward pathway.[12] This down-regulation of GABA receptors is thought to lead to an increase in the desirable effects of alcohol and vulnerability for dependence due to the presence of increased synaptic GABA. The hallmark of alcohol withdrawal is CNS excitation, with increased cerebrospinal fluid, plasma, and urinary catecholamine levels. Alcohol withdrawal syndrome (AWS) is a continuum of syndromes that begins after a decrease in the amount of intake of ethanol. Therefore, only a reduction, not the abrupt cessation, of ethanol intake may result in withdrawal.

AWS is often divided into three sets of symptoms. The first set consists of autonomic hyperactivity, which appears within hours of the last drink and usually peaks within 24 hours.

Symptoms may occur as early as 6 hours after cessation of or a significant decrease in alcohol intake and usually peaks at 24 to 36 hours. It is characterized by mild autonomic hyperactivity—anorexia, nausea, vomiting, anxiety, coarse tremor, tachycardia, hypertension, hyperreflexia, and sleep disturbances such as insomnia and vivid dreams.

BOX 137.1 DSM-5 Criteria for Withdrawal Delirium (Delirium Tremens)

Criteria for Alcohol Withdrawal

Cessation of or reduction in heavy and prolonged use of alcohol

At least two of eight possible symptoms after reduced use of alcohol:

- Autonomic hyperactivity
- Hand tremor
- Insomnia
- Nausea or vomiting
- Transient hallucinations or illusions
- Psychomotor agitation
- Anxiety
- Generalized tonic-clonic seizures

Criteria for Delirium

Decreased attention and awareness

Disturbance in attention, awareness, memory, orientation, language, visuospatial ability, perception, or all these abilities change from the normal level and fluctuate in severity during the day

No evidence of coma or other evolving neurocognitive disorders

From the American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington DC: American Psychiatric Publishing; 2013.

The second symptom set includes additional neuronal excitation, with epileptiform seizures and global confusion, usually occurring within 24 to 48 hours of abstinence and usually peaks at 50 hours after cessation of or a significant decrease in alcohol intake but occasionally takes up to 5 days. The syndrome is characterized by pronounced anxiety, insomnia, irritability, tremor, anorexia, tachycardia, hyperreflexia, hypertension, fever, decreased seizure threshold, visual and auditory hallucinations, and finally delirium.

The third set of symptoms features delirium tremens or alcohol withdrawal delirium (AWD). While only 5% of patients hospitalized for alcohol withdrawal have delirium tremens, this syndrome is a life-threatening manifestation of alcohol withdrawal and consists of gross tremor, frightening visual hallucinations, profound confusion, agitation, and a hyperadrenergic state characterized by a temperature above 101°F (≈38.5°C), blood pressure higher than 140/90 mm Hg, and tachycardia. It seldom appears before the third post abstinence day.

The criteria for withdrawal delirium, as described in Box 137.1, are delirium and alcohol withdrawal. Alcohol withdrawal is the most common alcohol-related illness that may require inpatient admission and is associated with adverse events such as uncontrolled agitation with the potential for over-sedation, generalized seizures, and prolonged hospital stay.[3] Emergency clinicians should be familiar with the commonly used withdrawal rating instrument known as the Clinical Institute Withdrawal Assessment of Alcohol Scale, revised (CIWA-Ar). See Table 137.3.

Alcohol-Related Seizures

Patients presenting to the ED with seizures should be questioned about alcohol intake (Box 137.2). Of seizure patients presenting to an ED, 20% to 40% will have their seizures related to alcohol use or abuse. The primary consideration in the initial care of seizure patients who regularly consume alcohol is the recognition of treatable, life-threatening causes. Alcohol may act in one of several ways to produce seizures in

TABLE 137.3 Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

Components of Scale	Most Severe Manifestations
Nine items[a]	
• Nausea or vomiting	Constant nausea with vomiting
• Tremor	Severe tremor, even with arms extended
• Paroxysmal sweats	Drenching sweats
• Anxiety	Acute panic
• Tactile disturbances (e.g., itching, numbness, sensation of bugs crawling on or under the skin)	Continuous hallucinations
• Auditory disturbances (e.g., sensitivity to sound, hearing things that are not there)	Continuous hallucinations
• Visual disturbances (e.g., sensitivity to brightness and color, seeing things that are not there)	Continuous hallucinations
• Headache, sensation of a band around the head	Extremely severe headache
• Agitation	Pacing during most of an interview with clinician or thrashing about
One item—orientation and clouding of sensorium[b]	

[a]Scored on a scale ranging from 0 (no symptoms) to 7 (most severe symptoms).
[b]Scored on a scale ranging from 0 (no symptoms) to 4 (disoriented with respect to place or person).
Adapted from Sullivan JT, Sykora K, Schneiderman, J, et al. Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (CIWA-Ar). *Br J Addict*. 1989;84:1353–1357.

BOX 137.2 Differential Diagnosis of Alcohol-Related Seizures

Withdrawal (alcohol or drugs)
Exacerbation of idiopathic or posttraumatic seizures
Acute intoxication (e.g., amphetamines, anticholinergics, cocaine, isoniazid, organophosphates, phenothiazines, tricyclic antidepressants, salicylates, lithium)
Metabolic (e.g., hypoglycemia, hyponatremia, hypernatremia, hypocalcemia, hepatic failure)
Infectious (e.g., meningitis, encephalitis, brain abscess)
Trauma (e.g., intracranial hemorrhage)
Cerebrovascular accident
Sleep deprivation
Noncompliance with anticonvulsants

patients by its partial or absolute withdrawal after a period of chronic intake by, an acute alcohol-related metabolic disorder (e.g., hypoglycemia, hyponatremia), an acute event leading to cerebral trauma, precipitation of seizures in patients with idiopathic or posttraumatic epilepsy, or lowering of the seizure threshold in patients with prior existing intracerebral disease states.

Alcohol Withdrawal Seizures

Withdrawal seizures may occur 6 to 48 hours after the cessation of drinking. Of patients with seizures, 90% have one to six generalized tonic-clonic seizures, and 60% experience multiple seizures within a 6-hour period. The incidence of partial seizures, common with posttraumatic epilepsy, is increased during alcohol withdrawal. The term *alcohol withdrawal seizure* is reserved for seizures with these characteristics. The term *alcohol-related seizure* is used to refer to all seizures in the aggregate associated with alcohol use, including this subset of alcohol withdrawal seizures.

Alcoholic Hallucinosis

Alcoholic hallucinosis is clinically distinct from delirium tremens and is characterized by hallucinations presenting within 12 to 24 hours of abstinence and resolve within 24 to 48 hours, in contrast to delirium tremens that presents at least 48 to 72 hours after abstinence. Hallucinations are typically visual, although tactile hallucinations have been described. Alcoholic hallucinosis is also generally not associated with autonomic instability such as tachycardia, hypertension, or hyperthermia.

Cardiovascular Effects

Acute and chronic ethanol consumption can affect the mechanical function of the heart, produce dysrhythmias, and exacerbate coronary artery disease (CAD). It may alter myocardial function by direct toxic effects, by associated hypertension, or indirectly by altering specific electrolytes. Acute intoxication can decrease cardiac output in alcoholic and nonalcoholic patients with preexisting cardiac disease (see Table 137.4).[13]

Studies have linked moderate alcohol consumption (two drinks/day in men and one drink/day in women) with a reduced risk of cardiovascular disease.[14–16] There is a strong biological plausibility that moderate wine consumption may have a positive effect on organs and systems. Whether the positive effect of wine on health is attributed to ethanol, to wine micro-constituents, or to their synergistic effect, is still unanswered.[17] Low to moderate alcohol consumption decreases platelet aggregation, raises plasma levels of endogenous tissue plasminogen activator, and lowers insulin resistance and likely poses little cardiovascular risk.[14]

Heavy alcohol consumption has a detrimental effect on those with preexisting CAD. It reduces exercise tolerance, induces coronary vasoconstriction, and raises heart rate and blood pressure. These patients also have a significantly higher incidence of peripheral arterial disease.[18] The additive cardiovascular effects of ethanol and nicotine contribute to dysrhythmias and sudden death in patients with CAD.[19]

Alcohol abuse is a known risk factor for the development of alcoholic cardiomyopathy which presents as a dilated cardiomyopathy that can lead to heart failure.[14,20] Heavy drinkers have increased odds of having a prolonged QTc interval and supraventricular dysrhythmias.[21] Supraventricular (usually atrial fibrillation) and ventricular (usually transitory ventricular tachycardia) dysrhythmias, commonly referred to as "holiday heart," have been documented in alcoholic patients who have been drinking heavily. Tachydysrhythmias as a result of episodic

TABLE 137.4 Cardiovascular Effects of Alcohol

Condition	Probable Relationship With Alcohol		Potential Epidemiological Consequences
	Lighter drinking[a]	Heavier drinking[b]	
Dilated Cardiomyopathy	Unrelated	One (of several) causes; ? requires cofactors	↑ risk of HF, AF, cardioembolic stroke and HS if on ACs
Systemic HTN	Little or none	Probably causal in susceptible persons	↑ risk of HF, AF, IS, and HS
CAD	Protective	? less protective or ↑ risk	↑ risk of HF, cardioembolic stroke, and AF; t risk of HS if on ACs
Supraventricular arrhythmia	Little or none	Probably a causal factor, especially with binges	↑ risk of cardioembolic stroke, and HS if on ACs
HS	? unrelated or slight ↑ risk	↑ risk	Disability and ↑ risk of VTE
IS	Protective	Probable ↑ risk; varies with subtype	Disability and ↑ risk of VTE
Heart failure	Indirectly protective	Varies with underlying CV condition	Disability and ↑ risk of VTE

AC, Anticoagulant; *AF*, atrial fibrillation; CAD, coronary artery disease; *HS*, hemorrhagic stroke; *HTN*, hypertension;; *IS*, Ischemic stroke; VTE, venous thromboembolism; cv, cardiovascular; t, increase; 4, decrease; ?, possibly.
[a]Less than three standard-sized drinks per day; [b]Three or more standard-sized drinks per day.
Data from Klatsky AL. Alcohol and cardiovascular diseases: where do we stand today? *J Intern Med*. 2015;278(3):238—250.

drinking commonly revert to sinus rhythm with abstinence and do not require immediate intervention if the patient is hemodynamically stable.

Pulmonary Effects

There is a clear and statistically significant relationship between alcohol consumption and the risk of community-acquired pneumonia (CAP). Consuming drinks that contain 10 to 20 g of alcohol per day is linked to an 8% increased risk of acquiring CAP.[22] Pneumococcal pneumonia is the most common type of pneumonia in both healthy individuals and heavy alcohol users. In addition, *Klebsiella pneumoniae* also is increased in people with AUD and seems to cause disproportionate rates of lung infection and high mortality in this population.[23]

For centuries, it has been known that people with AUD are more likely to have pulmonary infections such as pneumonia and tuberculosis. Over the past two decades, it has become clear that other conditions such as RSV and ARDS also are linked to high-risk alcohol consumption.[23]

Gastrointestinal and Hepatic Effects

Esophagus and Stomach

Alcoholic patients have a higher incidence of esophagitis, gastric cancer, and esophageal carcinoma than in the general population. Acute alcohol ingestion also decreases lower esophageal sphincter pressure, delays gastric emptying, and disrupts the normal gastric mucosal barrier. Alcohol consumption, because of its inherent toxicity, has been shown to eliminate infection of the gastric mucosa by *Helicobacter pylori*. Forceful or persistent emesis can lead to a Mallory-Weiss tear or more severely, Boerhaave syndrome.

Gastrointestinal Bleeding

Alcohol is closely associated with gastrointestinal (GI) bleeding. Causes and contributing factors include Mallory-Weiss tears, esophagitis, esophageal varices, acute and chronic gastritis, thrombocytopenia, portal hypertensive gastropathy, qualitative and quantitative platelet disorders, and prolonged clotting times. Alcohol may exacerbate gastric mucosal damage when it is combined with nonsteroidal antiinflammatory drugs (NSAIDs), but ethanol itself is not a risk factor for peptic ulcer disease. Peptic ulcer disease is the most common cause of bleeding in alcoholic patients with upper GI hemorrhage, as well as in those who do not regularly consume alcohol.

Liver Damage

Hepatic damage has been recognized for centuries as the hallmark of chronic alcohol abuse. Above a certain quantity, alcoholic consumption can elicit a spectrum of liver lesions among which steatosis is present in nearly all drinkers who consume in excess of 40 g/day regularly.[24] The activation of the immune system with the production of cytokines such as tumor necrosis factor-alpha is one of the earliest events in many types of liver injury. This cascade stimulates Kupffer cells and the production of other cytokines that together enlist inflammatory cells, kill hepatocytes, and initiate healing through fibrogenesis.

Alcoholic liver disease is the most common liver disorder in the Western Hemisphere and, along with hepatitis C (HCV), is a leading cause of liver transplantation. Alcohol use is associated with more persistent HCV infection and more extensive liver damage than no alcohol use because of interactions between alcohol use and HCV that affect immune responses, cytotoxicity, and oxidative stress.[2] No safe level of alcohol consumption has been determined for patients with HCV.[2]

Alcoholic Hepatitis

Alcoholic hepatitis is a pro-inflammatory chronic liver disease that is associated with high short-term morbidity and mortality (25% to 35% in 1 month) in the setting of chronic alcohol use.[25] It is a clinical syndrome characterized by right upper quadrant pain, a tender enlarged liver, fever, jaundice, leukocytosis, and altered liver function test results. aspartate transaminase (AST) levels are usually less than 400 IU/L, and ALT levels are typically less than half the AST level. It is associated with profound immune dysfunction with a primed but ineffective immune response against pathogens.[26]

Alcoholic hepatitis has a range of clinical manifestations from mildly symptomatic hepatomegaly to fulminant hepatic failure. The severity of the disease can be estimated in the ED by a prolonged prothrombin time/international normalized ratio (INR) or with the use of the Maddrey discriminant factor. The ABIC (***a***ge, ***b***ilirubin, *I*NR, ***c***reatinine) score and model for end-stage liver disease (MELD) are also helpful in predicting mortality in these patients.

Cirrhosis

The causal association between alcohol intake and alcoholic liver disease has been well documented, yet liver cirrhosis develops in only 10% to 20% of heavy drinkers.[2] Cirrhosis is the disruption of the normal architecture of the liver by scarring and regenerating nodules of parenchyma. Alcoholism is the most common cause of cirrhosis in the United States and is responsible for approximately 48% of all cirrhotic-induced deaths.[27] Alcoholic cirrhosis usually requires 10 to 15 years of chronic drinking, often punctuated by one or more episodes of acute alcoholic hepatitis. The clinical outcome is determined by the development of complications of portal hypertension and hepatic dysfunction. Alteration of the normal hepatic architecture by fibrosis and nodule formation may eventually lead to portal hypertension. Portal hypertension may be complicated by ascites and esophageal varices. Although cirrhosis is irreversible, its progression may be halted with abstinence.

Pancreatitis and Malabsorption

The association of ethanol with acute and chronic pancreatitis is well established, but the exact pathogenesis is unclear. Hypotheses include reflux of duodenal contents and bile into the pancreatic duct, obstruction by a plug of pancreatic juice rich in proteins, and a direct toxic effect of ethanol.

The diagnosis of alcoholic pancreatitis can be difficult because asymptomatic alcoholics may have an elevated amylase level. Conversely, up to 30% of patients with acute alcoholic pancreatitis have an amylase value within normal limits. The serum lipase level rises after amylase, remains elevated longer, and is a more reliable indicator of alcoholic pancreatitis, especially when it is more than three times the normal range.

Neurologic Effects

Neuropathy. A symmetric sensorimotor polyneuropathy is common with chronic alcohol abuse, usually in the lower extremities. It is thought to be a combination of nutritional deficiency with thiamine or vitamin B_{12} deficit and a direct neurotoxic effect of alcohol. Burning pain and paresthesia are common complaints. Findings on physical examination include loss of light touch, decreased pinprick sensation, and reduced lower extremity deep tendon reflexes. Distal muscle weakness is a delayed finding. The neuropathy may lead to nonhealing ulcers on the feet. Treatment of alcoholic neuropathy is abstinence, adequate diet, and thiamine. Complete recovery is rare.

So-called "Saturday night palsy" or "honeymooner's syndrome" is a wrist drop caused by radial nerve compression. The patient usually has spent the night with his or her arm drooped over the back of a chair, bench, or companion; compressing the radial nerve against the humerus producing neurapraxia. Loss of function due to radial nerve neuropraxia usually returns after a few weeks to months.

Wernicke-Korsakoff Syndrome. There are high rates of dementia reported in patients with AUD, and up to 25% when all types of severe cognitive impairment are considered. Previously, two main disorders were described: Wernicke-Korsakoff syndrome (WKS) and alcohol-related dementia (ARD). Now, the DSM-5 introduces major neurocognitive disorder as an alternative term to dementia, with a subtype related to substance or medication use. WKS and ARD could be a direct result of alcohol neurotoxicity or the consequence of a concurrent underlying pathology (such as thiamine deficiency) or both (neurotoxicity associated with nutritional deficiencies).[28]

Although they are similar pathologically and are caused by thiamine deficiency, Wernicke and Korsakoff syndromes are clinically distinct. Wernicke encephalopathy, a medical emergency with a mortality rate of approximately 17%, remains a clinical diagnosis and is often unrecognized. Contemporary criteria require two of these signs—dietary deficiencies, oculomotor abnormalities (nystagmus being the most common), cerebellar dysfunction, and an altered mental state or mild memory impairment. Mental abnormalities include lethargy, inattentiveness, abulia, and impaired memory, progressing without treatment to coma.

Korsakoff psychosis or amnesic state also called an alcohol-induced persisting amnestic disorder, is a disorder with recent memory impairment, inability to learn new information or recall previously learned information, apathy, and confabulation. Although it is common, confabulation is not essential for the diagnosis. Whereas 80% of patients with acute Wernicke's encephalopathy have Korsakoff syndrome, age older than 40 years and many years of heavy alcohol use are additional risk factors.

Treatment of WKS consists of abstinence, adequate diet, and thiamine. The ophthalmoplegia and nystagmus usually have a good response to thiamine administration within hours to days. The ataxia and mental changes may take days to weeks to improve and usually have a poorer prognosis. Less than 25% of patients show any real recovery, 50% show some recovery, and the remainder show no response, despite adequate thiamine replacement. Because magnesium is a cofactor for this enzyme system, its serum levels should be corrected. Patients with WKS require admission with thiamine and magnesium repletion.

Alcoholic Cerebellar Degeneration

Characterized by ataxia of the extremities, cerebellar ataxia of alcoholism results in a wide-based stance and uncoordinated gait. Lower extremity involvement predominates, although the arms may rarely be involved. Pathologic changes consist of the degeneration of elements in the cerebellum, especially the Purkinje cells. The diagnosis is based on history, physical examination, and findings on magnetic resonance imaging or computed tomography (CT), which shows severe cerebellar atrophy. Treatment consists of abstinence, adequate nutrition, and thiamine.

Infectious Disease

Chronic alcohol exposure depresses the development and expression of cell-mediated immunity. This depression may contribute to the high incidence of head, neck, and upper GI cancers in alcoholics. The suppression of macrophage function by alcohol reduces the reticuloendothelial system's ability to clear particles. This may contribute to spontaneous bacteremia, spontaneous bacterial peritonitis, pneumonia, and tuberculosis.

The most common infection in alcoholism is pneumonia. Although alcoholic patients may contract a variety of bacterial pneumoniae, *Streptococcus pneumoniae* is still the most common organism. Periods of alcoholic stupor with incomplete glottic closure and subsequent aspiration can lead to aspiration pneumonia or lung abscess. *K. pneumoniae,* classically associated with alcoholism, is currently more common in patients with cytotoxic chemotherapy, hematologic malignant disease, and transplantation than in the chronic alcoholic. Chronic alcohol consumption increases the risk and severity of chronic infections with HIV; hepatitis C virus (HCV); and *Mycobacterium tuberculosis*.[29]

Endocrine Effects

Alcohol dependence adversely affects many endocrine systems. Peripheral thyroid hormone dysfunction and central hypothalamic-pituitary-thyroid axis deregulation are seen. Male hypogonadism and feminism are seen in chronic male alcoholics. Alcohol's effects on the testes and hypothalamus decrease testosterone production in men. Alcohol may cause impotence by CNS sedation, secondary depression, or decreased testosterone production. Decreased testosterone, increased estrogen (in patients with liver disease), and

increased prolactin levels can lead to decreased libido, feminization, and gynecomastia in male alcoholics and to abnormalities in lactation and menstruation in women. In female alcoholics, increased levels of testosterone and estrogen are found. Estrogen replacement therapy may increase hormonal levels threefold and thus increase the risk of cholelithiasis and breast cancer.

Metabolic Effects

Carbohydrates

Alcohol-induced hypoglycemia occurs in up to 4% of chronic alcoholics. Coma, seizures, hemiparesis, and a variety of other neurologic signs have been described in patients presenting with alcohol-induced hypoglycemia. Starvation, depletion of liver glycogen stores, decreased plasma cortisol levels, the impaired release of growth hormone, and inhibition of gluconeogenesis contribute to this phenomenon.

Hyperglycemia and diabetes may be found in chronic alcoholism. Alcohol abuse can lead to chronic pancreatitis, resulting in the underproduction of insulin by the damaged pancreatic cells. Alcohol also impairs peripheral glucose utilization, causing relative insulin resistance (similar to type 2 diabetes).

Lipids

Ethanol increases the hepatic synthesis of triglycerides. Abstinence is necessary to reverse elevated triglyceride levels. Except for its relationship to fatty infiltration of the liver, the clinical significance of this hyperlipidemia is unknown.

Electrolytes

Ethanol has numerous effects on electrolytes and mineral metabolism, as summarized in Table 137.5. Hyponatremia and hypokalemia are common in active drinkers. Vomiting, diarrhea, magnesium depletion, malnutrition, and metabolic alkalosis contribute to these abnormalities.

Alcoholism is the most common cause of severe magnesium deficiency in adult outpatients. Magnesium deficiency is seen in 30% of alcoholics as a result of malabsorption, malnutrition, diarrhea, vomiting, and increased urinary losses. Oral magnesium supplementation in chronic alcoholics improves liver function test results, electrolyte balance, and muscle strength.

Hypocalcemia is common in alcoholic patients with magnesium depletion. The mechanism is related to diminished parathyroid hormone secretion, decreased tissue responsiveness to parathyroid hormone, decreased vitamin D metabolism, and decreased calcium release from bone, which is independent of parathyroid hormone. Correction of magnesium depletion is necessary to restore calcium to normal levels. Hypoalbuminemia, pancreatitis, or vitamin D deficiency also contribute to low serum calcium levels or low total-body stores of calcium in alcoholic patients.

Hypophosphatemia is found in up to 50% of hospitalized patients with alcoholism. Phosphorus depletion results from malnutrition, vomiting, respiratory alkalosis, diarrhea, enhanced release of calcitonin, phosphate-binding antacids, and urinary loss (related to vitamin D deficiency and secondary hyperparathyroidism). Hypophosphatemic patients often have low magnesium levels. Rehydration, carbohydrate repletion, and parenteral alimentation further exacerbate phosphorus depletion. Glucose bolus and infusions have been shown to produce a significant fall in serum inorganic phosphate levels. Severe hypophosphatemia (<1 mg/dL) has been associated with acute respiratory failure, myocardial depression, CNS irritability, dysfunction of erythrocytes, leukocytes, and platelets, and rhabdomyolysis.

Although chronic alcoholics who require admission often have potassium, magnesium, and phosphate depletion, empirical treatment with potassium and phosphate is discouraged. Serum levels and renal function should be determined first. Unintended hyperkalemia and hyperphosphatemia can produce significant morbidity, and phosphate infusion exacerbates hypocalcemia if present. Because most magnesium is intracellular, a normal serum magnesium level does not rule out decreased total-body magnesium stores. If the serum level is normal, total-body levels may still be low. As long as renal function is adequate, empiric magnesium treatment can be considered. Abstinence and a proper diet resolve electrolyte and nutritional deficiencies in the alcoholic patient who is healthy enough to be treated as an outpatient.

Alcoholic Ketoacidosis

Twenty-five percent of patients who are admitted to the hospital with an alcohol-related disorder develop alcoholic ketoacidosis.[30] Alcoholic ketoacidosis occurs most frequently in severe chronic alcoholics who have had a recent binge followed 1 to 3 days later by protracted vomiting, decreased food intake, dehydration, and abstinence. Nausea, vomiting, and abdominal pain are common presenting complaints. Serum glucose levels are usually less than 200 mg/dL. Normal blood pH may be found despite ketonemia because of coexisting respiratory alkalosis and metabolic alkalosis.

Treatment of alcoholic ketosis consists of the administration of normal saline, glucose, and thiamine with correction of hypokalemia. This can be accomplished with 5% dextrose in normal saline and 30 mEq of potassium chloride or 30 mEq of oral potassium. If no serious complicating illness is present, ketosis is often reversed within 12 to 24 hours of treatment.

Hematologic Effects

Chronic alcohol use is associated with significant alterations in the immune system that predispose people to viral and bacterial infections and cancer development. The alcoholic presents with myriad hematologic abnormalities. The direct toxic effect of ethanol and its metabolites, secondary nutritional deficiency, and hepatic disease, individually or in combination, affect red blood cells, white blood cells, platelets, hemostasis, and the immune system.

Anemia

Several mechanisms cause anemia, which is common in the alcoholic. Megaloblastic anemia resulting from folate deficiency is the most common anemia in alcoholics. The mean corpuscular volume (MCV) is typically increased but may be normal when iron deficiency coexists. Malnutrition, the inability of the cirrhotic liver to store folate, excessive urinary loss, and malabsorption decrease folate stores. Alcohol accelerates the development of megaloblastic anemia in individuals with depleted folate stores (MCV > 100 fL) by less clearly defined mechanisms.

Iron deficiency anemia is common and is usually a result of blood loss from the GI tract. With iron deficiency anemia, the serum iron level is decreased, total serum iron-binding capacity is elevated, and serum ferritin level is decreased. Alcoholics frequently have chronic inflammatory diseases that produce anemia of chronic disease.

Leukocyte Abnormalities

Leukopenia is common in alcoholic patients and has several possible causes. Sepsis, folate deficiency, and hypersplenism all lead to a decreased white blood cell count. Alcohol has a direct toxic effect on white blood cell production in the bone marrow. Granulocyte mobilization (chemotaxis) and adherence are also impaired, resulting in decreased inflammatory responses.

TABLE 137.5 Electrolyte Disturbances[30]

Disturbance	Mechanism or Cause	Comment	Treatment
Acid-Base			
Alcoholic ketoacidosis	Anion-gap metabolic acidosis due to decrease in insulin: glucagon ratio	Increased NADH:NAD ratio favors formation of/3-hydroxybutyric acid	Administer 5% dextrose in 0.9% (normal) saline and treat other disorders if present
Lactic acidosis	Increased NADH:NAD ratio due to ethanol metabolism	Average lactate level 3 mmol/L consider sepsis or thiamine deficiency with higher levels	Administer 5% dextrose in 0.9% (normal) saline and treat other disorders if present
Hyperchloremic normal-gap metabolic acidosis	Indirect loss of bicarbonate due to loss of ketoacid salts in urine	Regeneration of bicarbonate by kidneys repairs deficit	Provide conservative management
Metabolic alkalosis	Vomiting	Increase in anion gap greater than decrease in bicarbonate concentration when combined with alcoholic ketoacidosis	Restore volume of extracellular fluid with chloride-containing fluids, correct hypokalemia
Respiratory alkalosis	Alcohol withdrawal, chronic liver disease, pain, sepsis	Often the primary disorder in a mixed acid-base disturbance	Administer benzodiazepines for alcohol withdrawal; treat underlying disorders
Hypophosphatemia	Alcohol-induced urinary loss, magnesium deficiency, acidemia, increased parathyroid hormone level, nutritional deficiency, decrease in gastrointestinal absorption, cellular shift due to insulin release, respiratory alkalosis, β_2-adrenergic stimulation	Muscle weakness, rhabdomyolysis, tissue ischemia, hemolysis, cardiac dysfunction; urine phosphate excretion >100 mg/24 h r or fractional excretion ≥5% indicates renal wasting	Oral supplements preferred; for complications, administer 42–67 mmol phosphate over 6 to 9 hr, not to exceed 90 mmol/day to avoid decrease in calcium and magnesium levels
Hypomagnesemia	Alcohol-induced urinary loss, phosphate deficiency, nutritional deficiency, decreased gastrointestinal absorption, cellular shift due to insulin release, respiratory alkalosis, β_2-adrenergic stimulation	Persistent renal wasting can last several weeks, accounting for recurrence of hypomagnesemia after initial correction; urinary magnesium excretion >25 mg/ 24 h or fractional excretion >2% indicates renal wasting	Oral supplements preferred; intravenous magnesium indicated in patients with arrhythmias or neuromuscular irritability
Hypocalcemia†	Decrease in parathyroid hormone level and resistance due to magnesium deficiency, alcohol-induced urinary loss, vitamin D deficiency	Correct for a low albumin concentration as follows: corrected calcium=serum calcium in mg/dL + [0.8× (4.0-serum albumin in g/dL)]; bicarbonate therapy can decrease ionized fraction	Correct the magnesium deficit; correct the deficiency in vitamin D
Hypokalemia	Urinary loss due to coupling of increased distal sodium delivery and increased aldosterone level, magnesium deficiency, diarrhea, cellular shift due to insulin release, correction of acidosis, respiratory alkalosis, β_2 adrenergic stimulation	A low or normal potassium level in patients with rhabdomyolysis suggests a significant underlying total-body deficit of potassium; urinary potassium >30 mmol/24 h or urinary potassium: creatinine ratio >13 (in millimoles of potassium per gram of creatinine) indicates renal wasting	Oral supplements preferred; for complications, administer intravenous potassium chloride at 10–20 mmol/h; administer potassium before Bicarbonate in patients with acidemia
Hyponatremia	Increased release of vasopressin due to volume depletion; decreased solute excretion in beer potomanía	Increased risk of osmotic demyelination	Restore volume and increase protein intake; limit rate of correction to 6–8 mmol in first 24 hours, to slow rate with 5% dextrose in water, desmopressin, or both

Data from Palmer BF, Clegg DJ. Electrolyte Disturbances in Patients with Chronic Alcohol-Use Disorder. *N Engl J Med*. 2017;377(14):1368–1377.

Platelet Disorders

Thrombocytopenia can occur with folate deficiency, marrow suppression, sepsis, disseminated intravascular coagulation, or splenic sequestration. The direct toxic effects of alcohol decrease measured survival time and impair the production of platelets in the bone marrow, but marrow toxicity rarely reduces the platelet count below 30,000/mm^3. Qualitative platelet function is also impaired. Binge drinking is associated with a reactive thrombocytosis potentially responsible for acute stroke and sudden death.

Hemostasis

Alcoholic patients have a bleeding diathesis for many reasons, including thrombocytopenia, qualitative platelet disorders, deficient production of hepatic clotting factors, GI variceal formation, and vitamin K deficiency. Bleeding associated with coagulation abnormalities may require fresh-frozen plasma for the immediate correction of coagulation factor depletion; vitamin K (10 mg IV) takes 6 to 10 hours to reverse the vitamin K–dependent factors II, VII, IX, and X. Because of poor diet and impaired hepatobiliary function, alcoholics may have

insufficient vitamin K storage and benefit from vitamin K delivery. However, alcoholic patients with profound liver failure are unable to produce the precoagulation factors II, VII, IX, X, and IV, so vitamin K therapy is ineffective. Platelet transfusions should be started in the ED for adult patients with active bleeding when the platelet count is less than 50,000/mm^3.

Oncologic Effects

While alcohol itself is not carcinogenic, its metabolite, acetaldehyde, has emerged as an important contributor; it can form stable DNA adducts, trigger mutations in tumor suppressors and oncogenes, and interfere with DNA repair. Over 5% of all new cancer occurrences and 6% of all cancer deaths worldwide were estimated to be attributable to alcohol.[31,32]. Alcohol consumption has been highly associated with specific oncological diseases such as oral, pharyngeal, laryngeal, esophageal, hepatic, colorectal, and breast cancers.[31,32]

Hypothermia

Acute alcohol ingestion is one of the most common precipitating factors for accidental hypothermia and occurs in 33% to 75% of patients presenting with a core temperature below 35°C (95°F). Alcohol exacerbates hypothermia of other causes, with depressed hypothalamic thermoregulation, peripheral vasodilation producing heat loss, CNS depression, sepsis, inability to shiver, hypoglycemia, and increased risk of environmental exposure. Hypothermia may be the presentation of Wernicke syndrome, possibly caused by lesions of the posterior hypothalamus, hypoglycemia, or sepsis.

Psychiatric Effects

Depression and antisocial personality are the two most common psychiatric disorders that correlate with alcoholism, with a prevalence of 30% to 60% in most studies. Of alcoholic men admitted to a psychiatric ward, approximately 40% have another psychiatric disorder unrelated to substance abuse—in particular, antisocial personality disorder, schizophrenia, mood disorders, and anxiety disorders.

Mental illness and substance use often co-occur and heavy alcohol use and AUDs are known risk factors for violence.[33] Secondary depression may be caused by alcoholism, or the primary affective disorder may be present with secondary alcoholism. Mild depressive symptoms are also common in alcohol withdrawal. Alcoholism, major depression, and antisocial personality all predispose to suicide, and interaction among the three is particularly dangerous, but the acute risk on any given day is difficult to assess.[34] Alcohol increases the lifetime risk of suicide, with over 15% of all alcoholics eventually dying by suicide.

Toxicologic Effects

Alcohol has long been known to have additive or even synergistic effects with several drugs including opioids and sedative hypnotic agents. Acute intoxication decreases the rate of drug metabolism, which is partially explained by competition for the same enzymatic process in the liver. Ethanol increases aspirin-induced prolongation of bleeding time and reduces the metabolism of warfarin, leading to increased anticoagulant effects. There is an increased risk of upper GI bleeding when alcohol is combined with NSAIDs.

Disulfiram and Similar Reactions

Most patients pretreated with disulfiram (Antabuse) who then consume even small amounts of alcohol experience an extremely unpleasant reaction. These patients have a hypersensitivity to ethanol and experience a direct response within 15 minutes, lasting 30 minutes to several hours. The reaction consists of skin flushing on the head that spreads to the trunk, along with nausea, vomiting, headache, chest and abdominal discomfort, diaphoresis, vertigo, palpitations, and confusion. A severe reaction may produce hypotension, seizures, and dysrhythmias. The disulfiram-ethanol reaction is thought to occur by the accumulation of acetaldehyde secondary to inhibition of the ALDH enzyme, which may be deficient in many Asians, or another unknown toxic factor. The common ink cap mushroom *(Coprinopsis atramentatia)*, while nontoxic when ingested alone, causes a similar disulfiram reaction if consumed with alcohol. Treatment for disulfiram reaction is generally observation, cardiac monitoring, an antiemetic for symptoms, and intravenous (IV) fluids.

Other Considerations—Patient Groups Affected

Adolescents. Excessive high school and college drinking continues to be prevalent and problematic. Approximately 1.2 million youths aged 12 to 17 met the criteria for SUDs in 2015 (5% of this population).[35] Alcohol is by far the most commonly used substance among youth, with 37% of 18-year-olds endorsing alcohol use and 24 % reporting being drunk in the past month.[36] Alcohol is the most commonly used drug and is a common contributor to the leading cause of death, unintentional injury, homicide, and suicide among adolescents (10 to 20 years old) in the United States.

Adolescent onset of alcohol use has been associated with an increased risk for developing an AUD later in life.[37] Although underage youth may drink less often than adults, they typically drink in larger quantities than adults when they do drink, and often binge drink.[38] Binge drinking, as defined by the NIAAA, is a pattern of alcohol consumption that brings blood alcohol concentration to .08 g/dL, which typically occurs following the intake of five or more standard alcohol drinks by men and four or more by women over a period of approximately 2 hours. In 2011, the NIAAA produced a two-question Youth Alcohol Screening Tool which asks about the frequency of alcohol consumption and friends' alcohol use in the past year (Table 137.6).[39]

Older Patients. Alcohol use is a growing public health concern for elderly adults. Elderly patients, meaning patients ages 65 years and older, comprise the fastest-growing portion of the US population. By 2040, the elderly will comprise more than 20% of the total population. Compared with all other substances, alcohol is the most commonly used among the elderly, and thus, the risks of drinking by older individuals will undoubtedly become an increasing issue as this population rises over the coming decades.[40]

Common screening tests (e.g., the CAGE questionnaire) tend to be less sensitive in this age group. Alcohol may exacerbate underlying disease by masking anginal chest pain, worsening hypertension, and inducing dysrhythmias. Older adults who consume low to moderate levels of alcohol, however, may have a decreased risk for the development of dementia and heart failure.

Older patients are more likely to have neuropsychiatric complications of alcoholism, such as sleep problems, anxiety, depression, and dementia. Alcohol is involved in one-third of suicides in older adults. Older subjects also perform less well than younger subjects on tests of perception and attention when under the influence at all blood alcohol levels. This may result in an increased risk of fractures from falling and osteoporosis. However, evidence has suggested that compared with abstinence, consumption of up to one drink/day is associated with a decreased risk of osteoporotic hip fracture, and there is a beneficial effect of moderate alcohol consumption on bone density.

Pregnant Women. There is no known safe level of alcohol consumption during pregnancy. Alcohol is a known teratogen that can impact fetal growth and development during all stages of pregnancy. The current recommendation from the American College of Obstetricians and Gynecologists, Center for Disease Control (CDC),

TABLE 137.6 The NIAAA Youth Alcohol Screening Tool

Age:	First Question:	Second Question:
Elementary School (ages 9–11)	Friends: Any drinking? "Do you have any friends who drank beer, wine, or any drinking containing alcohol in the *past year?"*	Patient: Any drinking? "How about you —have you *ever* had more than a few sips of beer, wine, or any drink containing alcohol?
Middle School (ages 11–14)	Friends: Any drinking? "Do you have any friends who drank beer, wine, or any drinking containing alcohol in the *past year*	Patient: How many days? "How about you—in the *past year, on how many days* have you had more than a few sips of beer, wine, or any drink containing alcohol?"
High School (ages 14–18)	Patient: How many days? in the *past year, on how many days* have you had more than a few sips of beer, wine, or any drink containing alcohol?"	Friends: How much? "If your friends drink, *how many drinks* do they usually drink on an occasion?"

Surgeon General, and medical societies from other countries all recommend complete abstinence during pregnancy.[41]

Alcohol readily crosses the placenta with fetal blood alcohol levels approaching maternal levels within 2 hours of maternal intake. There are a wide variety of developmental defects that result from alcohol exposure, including brain abnormalities, CNS dysfunctions, and growth deficiencies of developing organs and body systems. These adverse effects on the developing fetus are known collectively as fetal alcohol spectrum disorders (FASDs).[42] FASDs cause dysfunctions in learning, emotion, cognition, motor performance, and can lead to behavioral as well as social problems.[42] FASDs are characterized by a triad of CNS defects, including mild to moderate mental retardation, dysmorphology, involving mostly facial structures, and growth deficiencies, usually consisting of short stature and microcephaly. FASDs are now considered the most common identifiable source of mental retardation. Children exposed to prenatal alcohol exhibit increased activity levels, cognitive and attention deficits, perseverative behavior, and language and motor problems, which persist into adulthood.

Alcohol has the ability to freely pass through a lactating mother's milk and thus lactating mothers who decide to continue to drink should avoid breastfeeding 3 to 4 hours after moderate to high consumption of alcohol.[41]

Trauma

Injury is a leading cause of death in those between the ages of 1 and 44 years, accounting for more than 50 million injuries/year and approximately 26,000 deaths/year. In the United States, alcohol is the major risk factor for virtually all categories of intentional and unintentional injury. In addition to increasing the frequency and severity of the injury, alcohol consumption significantly impacts the management of the trauma victim. Alcohol intoxication often complicates the initial assessment of injury severity, resulting in an increased need for invasive diagnostic and therapeutic procedures (e.g., intubation and ventilation, CT imaging, intracranial pressure monitoring).

Alcohol may diminish the patient's capacity to respond to hemorrhagic shock by altering hemodynamic effects and the acid-base balance. Volume depletion as a result of the diuretic effect of alcohol or vomiting can impair the reserve of the intoxicated trauma patient. Peripheral vasodilation caused by alcohol may contribute to hypotension and hypothermia. Although these effects may be transient, they underscore the need for early and adequate fluid resuscitation in these patients. Intoxicated patients with severe non-neurologic trauma may have lower blood pressures and carbon dioxide levels, indicative of compensatory hyperventilation, on hospital arrival compared with sober patients. More importantly, a poorly understood cardiac depressant effect also increases the depth of shock and volume requirements for resuscitation. Alcohol-induced skin vasodilation may be accompanied by an increase in skeletal muscle, mesenteric, and renal bed constriction and left ventricular stroke work. Thus, the overall effect on systemic vascular resistance and blood pressure may be balanced.

Intoxication renders the signs and symptoms of intra-abdominal and retroperitoneal injury less reliable than usual. If the risk of an intra-abdominal injury exists, further evaluation (e.g., diagnostic ultrasonography, CT imaging) should be considered. Alcohol intoxication predisposes to abdominal wall laxity and therefore less protection from blunt trauma. These patients are also likely to have full stomachs, increasing the risk of gastric injury after trauma and predisposing to vomiting and aspiration, especially during acute airway management. The fatty liver changes in alcoholism can result in hepatomegaly. Portal hypertension in alcoholics may produce splenomegaly. These organs can become more vulnerable to the effects of trauma because of their enlarged size, protrusion beneath the protection of the ribs, and increased intracapsular pressure.

The American College of Surgeons Committee on Trauma requires screening for problem drinking for designation at a level I or II trauma center. In addition, level I trauma centers must provide intervention for identified problem drinkers. Although many institutions use blood alcohol levels to determine at-risk drinking in trauma patients, the Alcohol Use Disorders Identification Test (AUDIT) offers a practical alternative (Box 137.3).[43]

DIFFERENTIAL DIAGNOSIS

Acute alcohol intoxication is a diagnosis of exclusion. Before it is assumed that a patient's behavior is caused only by alcohol, other conditions should be considered, particularly co-ingestion of other substances and pharmaceutical agents, head trauma, and infection. Hypoglycemia, hypoxia, carbon dioxide narcosis, mixed alcohol-drug overdose, ethylene glycol poisoning, isopropanol or methanol poisoning, hepatic encephalopathy, psychosis, severe vertigo, postictal state, and psychomotor seizures can be manifested in a manner similar to that of ethanol intoxication.

AWS can initially be confused with acute schizophrenia, encephalitis, drug-induced psychosis, thyrotoxicosis, anticholinergic poisoning, and withdrawal from other sedative hypnotic agents. Alcohol withdrawal and alcohol-induced hypoglycemia also present with similar clinical presentations.

DIAGNOSTIC TESTING

Determination of a blood ethanol level is not routinely necessary in caring for the intoxicated patient when there is clear evidence of

BOX 137.3 AUDIT-C Questions

1. How often did you have a drink containing alcohol in the past year?
   a. Never (0 points)
   b. Monthly or less (1 point)
   c. Two to four times a month (2 points)
   d. Two to three times per week (3 points)
   e. Four or more times a week (4 points)
2. How many drinks containing alcohol did you have on a typical day when you were drinking in the past year?
   a. 0–2 (0 points)
   b. 3–4(1 point)
   c. 5–6 (2 points)
   d. 7–9 (3 points)
   e. 10 or more (4 points)
3. How often did you have six or more drinks on one occasion in the past year?
   a. Never (0 points)
   b. Less than monthly (1 point)
   c. Monthly (2 points)
   d. Weekly (3 points)
   e. Daily or almost daily (4 points)

Adapted from Miller LB, Brennan-Cook J, Turner B, et al. Utilizing an Evidence-Based Alcohol Screening Tool for Identification of Alcohol Misuse. *J Addict Nurs*. 2018;29(2):90–95.

alcohol intake (e.g., confirmation by the patient). When the mental status is sufficiently altered that an adequate history cannot be obtained, there is evidence of head trauma, or the patient fails to improve (detoxify) as expected, a serum ethanol level or measurement by a breathalyzer should be determined. If the degree of obtundation is not commensurate with the measured (or breathalyzed) level, and other laboratory test results (e.g., toxicology screen, electrolyte levels, metabolic profile) do not explain the altered mental status, a head CT scan is indicated. Adequate history from paramedics, patient, and family members, serial physical examinations (especially mental status), and bedside testing, such as serum glucose level and oximetry, can help clarify the clinical situation and guide further testing.

Blood tests can be useful if the history is in doubt and can also help patients recognize that alcohol has adversely affected their health. The utilization of direct metabolites of ethanol is considered more accurate biomarkers of recent alcohol consumption. Three of these biomarkers, ethyl glucuronide (EtG), ethyl sulfate (EtS), and phosphatidylethanol (PEth), are gaining acceptance, although they are not currently available for routine testing.[5,44]

Tests of liver function that measure AST and ALT levels can identify heavy drinking and AUDs with sensitivities of 25% to 45% and specificities as high as 90%. A ratio of AST to alanine transaminase (ALT) higher than 2 suggests that alcohol is the cause of liver injury.

Laboratory Tests

In the apparently intoxicated patient with altered mental status, the serum glucose level, usually as a point of care test, should be measured to assess for hypoglycemia. In the alcoholic patient, electrolyte levels and acid/base status should be determined to look for hypomagnesemia, hypophosphatemia, hyponatremia, and metabolic acidosis. A complete blood count is obtained to evaluate for anemia, leukopenia, and thrombocytopenia and a serum lipase level to evaluate for pancreatitis if the patient has severe upper abdominal pain or tenderness, especially if accompanied by vomiting. A complete blood count, peripheral smear, platelet count, reticulocyte count, thrombin time, prothrombin time and INR, and partial thromboplastin time help evaluate episodes of significant alcohol disease-induced bleeding.

Liver function tests are followed in a serial manner in cases of alcoholic hepatitis. An electrocardiogram (ECG) is indicated for tachydysrhythmias or chest pain (e.g., holiday heart, acute ischemia). A CT scan of the head or cervical spine imaging may be indicated if head trauma or seizures are suspected or confirmed or if the patient's mental status does not improve in step with the metabolism of alcohol. A chest radiograph is obtained to rule out cardiomyopathy, infectious pneumonia, or aspiration pneumonitis.

Alcohol Screening Questionnaires

Detection of risky drinking behaviors can be through clinical history or the administration of short alcohol screening tools in the ED setting. The screening tools with superior sensitivity and specificity are the SASQ, AUDIT, and AUDIT-Consumption (AUDIT-C), see Box 137.3.

As part of the initial assessment and in alignment with national recommendations, computerized screening programs could be used as an effective method for detecting at-risk alcohol use in ED patients. Identification of AUD and brief, sentinel event advice in the ED can be an effective and cost-effective method to reduce levels of alcohol consumption and alcohol-related harm.

The SASQ From the NIAAA can be used to streamline the screening process—it includes only 1 question: "How many times in the past year have you had x or more drinks in a day?" (where x is 5 for men and 4 for women).

MANAGEMENT

Comatose or stuporous patients may require assisted ventilation and intubation. If the bedside serum glucose level identifies hypoglycemia, IV glucose, as $D_{50}W$ or an infusion of D_5W, is indicated. Patients with evidence of poor nutrition should receive thiamine, 100 to 250 mg IM or IV once daily for 3 to 5 days. If an opioid overdose is suspected, naloxone may be diagnostic and therapeutic. Because magnesium is a necessary cofactor for thiamine metabolism, consider administering magnesium, 2 g IV. When possible, hypoglycemia should be documented before the empirical administration of glucose. With the airway maintained and respirations supported, the patient's liver eventually metabolizes the alcohol, and most patients recover.

Intoxicated patients who do not appear capable of appropriate decision making require evaluation and treatment in the ED, regardless of their willingness to cooperate. It is incumbent on the emergency clinician to establish that the patient understands the nature of the problem, whether intoxication alone or intoxication in the context of acute illness or injury and is capable of making reasoned and responsible decisions about care. Inappropriate discharge and failure to diagnose are two common areas of liability in the treatment of the alcohol-dependent patient. Discharge can be considered when a patient is clinically sober enough to be able to dress, walk, make reasonable decisions, and function independently, as judged and well documented by the treating emergency clinician. When possible, it is ideal to have another sober adult who is willing to take responsibility for and remain with the patient for the next 24 to 48 hours. Once clinically sober and cleared for discharge, patients should be reminded not to drink and drive.

Alcohol Withdrawal Syndrome

Family, friends, bystanders, or paramedics often give more reliable historical data than the patient does. Accurate vital signs are essential; this may require a rectal temperature. Hyperthermia, hypothermia,

tachypnea, or tachycardia may suggest serious disorders that often accompany the alcohol-dependent patient. A rapid and thorough physical examination should be performed, with attention to the level of consciousness, signs of hepatic failure, or coagulopathy. Signs of trauma are sought, as well as a thorough neurologic examination.

The AWS should be promptly recognized and treated. The CIWA-Ar is a validated tool for symptom-based prescribing of benzodiazepines for alcohol withdrawal. Scores on the CIWA-Ar ranges from 0 to 67; scores lower than 8 indicate mild withdrawal symptoms that rarely require the use of medications, scores from 8 to 15 indicate moderate withdrawal symptoms that are likely to respond to moderate doses of benzodiazepines, and scores higher than 15 indicate severe syndromes that require close monitoring to avoid seizures and AWD (or delirium tremens).

Pharmacologic Treatment

Patients suffering from alcohol withdrawal should receive pharmacologic intervention along with supportive care. The ideal drug for alcohol withdrawal should have a rapid onset, a wide margin of safety, metabolism not dependent on liver function, and limited abuse potential. Although no one drug class meets all these requirements, benzodiazepines are clearly the mainstay of treatment.

Benzodiazepines. Benzodiazepines have anticonvulsant activity, dose-dependent respiratory and cardiovascular depressive effects, and and be given IV/IM if necessary. By interacting with receptors linked to the GABA-associated chloride ion channel, benzodiazepines substitute for the withdrawal of the GABA-potentiating effect of alcohol and abate withdrawal signs and symptoms. Numerous benzodiazepines have been studied, but there is no evidence of the clear superiority of any one benzodiazepine.

Lorazepam has good bioavailability with the oral, intramuscular, and IV routes. It may be given via an IM injection in agitated patients with no IV access. The half-life of lorazepam is ~12 hours and it does not have any active metabolites.. Excessive sedation, confusion, and ataxia are potential complications of all benzodiazepines with prolonged half-lives. Lorazepam is metabolized (conjugated) in the liver, yielding inactive products. Although the half-life of lorazepam increases in patients with cirrhosis or liver failure, it is much shorter than the increase with chlordiazepoxide. The elimination of lorazepam is only minimally altered in patients with renal failure and in older adults. Lorazepam may be given IV in a dose of 1 to 4 mg, depending on the severity of the withdrawal. Dosing can be repeated at 5 to 15-minute intervals for patients in severe withdrawal. Although it is not ideal, an intramuscular dose of 1 to 4 mg can be used every 30 to 60 minutes until the patient is calm and then every hour, as needed, for light somnolence.

Diazepam is another commonly used benzodiazepine to treat patients with alcohol withdrawal. When given IV, it has a rapid onset (1 to 3 mins) and a duration of 1 to 2 hours, though its half-life can be increased significantly in patients with liver dysfunction. Since diazepam has a more rapid onset than lorazepam, its dosing interval can be much shorter. One such dosing strategy involves giving diazepam 5 mg IV every 5 to 10 minutes for patients with major withdrawal symptoms. The dose can be repeated in 5 to 10 minutes. If the second dose of 5 mg is not working, consider 10 mg for the third and fourth doses every 5 to 10 minutes. If this is not effective, consider 20 mg for the fifth and subsequent dose until adequate sedation has been obtained.

Butyrophenones. Haloperidol, a dopamine antagonist, can be considered in patients with major alcohol withdrawal or delirium tremens and acute agitation or behavioral issues not responding to IV benzodiazepines. However, antipsychotics should never be used alone or as a first-line treatment for alcohol withdrawal as they do not treat the underlying pathophysiology. Haloperidol has little effect on myocardial function or respiratory drive, and its safety and efficacy by the IV, intramuscular, or oral route in the ED has been established. The typical dose is 2 to 5 mg q4–8h prn; q1h may be required with acute agitation; but not to exceed 20 mg/day. Haloperidol has no anticonvulsant properties; however, extrapyramidal effects may be seen. Caution should be used in patients who may be susceptible to a prolonged QTc interval. Droperidol has effects and risks similar to those of haloperidol and remains a safe and effective treatment for acutely agitated patients in the ED. The recommended adult dose is 2.5 mg IV/IM; additional doses of 1.25 mg may be given to a desired effect if the clinical benefit outweighs the potential risk.

Other Agents. Patients being treated for major alcohol withdrawal may be given thiamine (100 mg IV) and magnesium (2 g IV). Although magnesium sulfate does not decrease the severity of withdrawal symptoms, the incidence of delirium, or seizures, it carries no significant risk with adequate renal function. For patients who require intubation for refractory withdrawal or for other reasons, an infusion of propofol or a benzodiazepine should be initiated to treat the patient's alcohol withdrawal.

Neurologic Examination

New-Onset Seizures

Patients with new-onset, alcohol-related seizures should be thoroughly evaluated. This includes alcoholics who claim to have had seizures but for whom no documentation or appropriate evaluation is available. Metabolic disorders, toxic ingestion, infection, and structural abnormalities should also be considered.

If the initial physical examination findings, imaging studies, and laboratory test results are within normal limits, patients who remain seizure-free and symptom-free, with no sign of withdrawal after 4 to 6 hours of observation, may be discharged. It may be unclear whether the patient has had a pure alcohol withdrawal seizure or a new-onset seizure disorder in the setting of alcohol ingestion. Long-term treatment with antiepileptic drugs is not useful in unprovoked new-onset seizures that have resolved or when a clear relation to alcohol consumption can be identified.

Optimal outpatient treatment includes follow-up and referral to a detoxification or rehabilitation program. Ideally, the assistance of a reliable family member or friend who is not a drinking partner and can remain with the patient for at least 1 or 2 days is helpful.

Prior History of Seizures During Withdrawal

The risk of seizure increases significantly in alcoholic patients with manifestations of alcohol withdrawal who relate a history of alcohol withdrawal seizure. Detoxification with benzodiazepines reduces alcohol withdrawal seizures and should be initiated early because most seizures occur within the first 24 hours after alcohol withdrawal. An initial dose of 2 mg of lorazepam or 5 mg of diazepam can be given IV. These doses frequently need to be repeated, as noted in the Benzodiazepine section.

Abnormal Neurologic Examination

New-Onset Partial Seizures. Partial seizures account for up to 50% of alcohol-related seizures. Conversely, approximately 20% of patients with partial alcohol-related seizures have structural lesions—hematomas, tumors, vascular abnormalities, or stroke. These primary causes of partial alcohol-related seizure, such as prior head trauma, may be easily missed in the history taking. As a result, an emergent CT scan of the head is indicated to evaluate new-onset partial seizures. The patient with a history of a focal alcohol-related seizure who has been previously evaluated does not require an emergency CT scan provided a return to baseline occurs promptly.

Patients Taking Anticonvulsants. A patient currently taking antiepileptic drugs for an antecedent seizure disorder who presents with a seizure while intoxicated falls into a different category. Such

an episode could be an isolated event in a usually compliant patient without a history of chronic alcohol abuse. In this patient, a seizure in the setting of a subtherapeutic antiepileptic drug level may represent the consequences of noncompliance with antiepileptic medication, coingestants, or sleep deprivation versus alcohol withdrawal seizure.

DISPOSITION

Most patients with acute alcohol intoxication are managed in the ED or observation unit and then discharged home. Patients who achieve sufficient sobriety to be ready for discharge are offered detoxification or alcohol treatment programs. Most alcoholics suffer from a combination of medical, psychiatric, and social problems. Hospitalization may be necessary to diagnose and treat these multiple problems. Moreover, with alcoholics who are no longer able to care for themselves, hospitalization is often dictated for this reason alone. Unfortunately, many managed care and Medicaid plans limit or do not cover inpatient detoxification. In choosing medical versus psychiatric admission, a medical illness usually takes priority. Optimal outpatient therapy for chronic alcoholics includes the involvement of concerned family or friends to ensure that the patient takes his or her medications properly, keeps follow-up appointments, abstains from alcohol, and maintains an adequate diet. Alcoholic patients who undergo outpatient treatment need close supervision; therefore, a follow-up clinic appointment within 24 to 48 hours should be considered.

Acute Intoxication

Acute intoxication alone seldom requires admission. However, a combined alcohol-drug overdose or associated medical, psychiatric, or social problems may require hospitalization. Acute alcohol intoxication is a diagnosis of exclusion reached after adequate observation to ensure that the altered mental status resolves and that the patient is hemodynamically stable.

Alcohol levels that may be tolerated by an adult can be lethal in children. It is prudent to admit young pediatric patients with acute intoxication and ensure close psychosocial follow-up for adolescent patients. Children presenting with hypoglycemia or medical complications should be admitted. Child abuse or neglect should always be considered.

Alcohol Withdrawal

Outpatient treatment consists of lorazepam, 1 to 2 mg TID tapered over 3 to 6 days, chlordiazepoxide, 25 to 100 mg TID tapered over 3 to 6 days, or diazepam, 30 mg once daily tapered over 5 days, depending on the severity of symptoms. Adequate diet, abstinence, and participation in a rehabilitation program in the community are also desirable. Any patient requiring 300 mg of chlordiazepoxide or 60 mg of diazepam/day to control withdrawal should be considered for admission.

Patients with signs of major withdrawal (fever, hallucinations, confusion, extreme agitation) require admission for close monitoring, serial neurological checks, and repeated medication dosing. Risk factors for clinical deterioration in patients with moderate to severe withdrawal include older patients who may be at greater risk for delirium tremens and may not tolerate the systemic stress of major withdrawal. Patients with delirium tremens generally require ICU admission. Criteria for ICU admission may also include patients with hemodynamic instability, electrolyte or acid-base disturbance, persistent hyper or hypothermia, rhabdomyolysis, renal insufficiency, and co-morbid conditions such as severe infection or pancreatitis.

Patients with mild alcohol withdrawal can be observed in the ED. After 4 to 6 hours of observation and treatment, the alert-oriented patient whose vital signs, physical examination findings, and results of laboratory analysis are within normal limits may be released with appropriate medications and aftercare instructions. Nevertheless, the patient can benefit from treatment for the underlying disease of alcoholism and should be advised or referred accordingly.

Seizures

The alcoholic patient with a first-time, alcohol-related seizure may be discharged to a suitable social situation in these situations: (1) when the patient's alcohol withdrawal is mild and controlled by supportive care or low-dose benzodiazepines; (2) the diagnostic evaluation, including a head CT scan, is unremarkable; (3) the patient has had fewer than two seizures; and (4) the patient has been observed to be alert and oriented, with stable vital signs and physical examination findings, normalized laboratory study results since the last seizure, and appropriate outpatient follow-up can be ensured.

Patients with a documented history of alcohol-related seizures can be discharged if they have had no more than two alcohol-related seizures during a 6-hour period, with a lucid interval between seizures, and are observed to be seizure-free and at baseline mental and physical status for at least 6 hours after their last alcohol-related seizure. Three to five brief, self-limited seizures may occur with alcohol withdrawal seizures. We recommend prolonged observation in the ED or observation unit for patients with two or more seizures because of the potential for deterioration to status epilepticus. Such patients should be observed until at least 6 hours have passed since their last seizure and they have a normal mental status and neurologic examination.

Patients with partial seizures or focal neurologic findings on physical examination require admission unless these findings have been previously documented. Patients with seizures associated with head trauma or mixed alcohol-drug withdrawal are admitted. Status epilepticus or recurrent seizures during ED observation indicate a lack of seizure control and require further hospitalization, often in a critical care setting.

Psychiatric and Social Problems

Alcoholic patients requiring admission with acute intoxication, alcohol-related seizure, alcohol withdrawal, or medical or surgical disorders are usually best managed in acute care units rather than by a general psychiatric service. Some psychiatric and social conditions in the alcoholic can be better handled on a general psychiatric unit—psychosis, exacerbation of schizophrenia, depression with suicidal tendencies, any patient who is a danger to self or others, or alcoholic hallucinosis with an otherwise clear sensorium.

Patients who are no longer able to care for themselves may also require admission. Although these patients' ultimate destination is a rehabilitation center or a border care program, hospitalization may be necessary to rule out medical or psychiatric illness and treat impending withdrawal symptoms. Patients who wish to stop drinking are usually referred to a detoxification unit for treatment of impending withdrawal.

Psychosocial interventions are the basis of long-term treatment, but medications are also often used. However, the data surrounding the use of medications are weak.[45] The FDA has approved three medications for alcohol dependence in the United States: disulfiram, naltrexone, and acamprosate. A fourth drug, nalmefene (oral), is approved throughout the European Union and is taken on an "as needed" basis prior to anticipated drinking occasions.

Other medications for AUDs have shown limited efficacy, and there is a high degree of variability in treatment response. Baclofen for the long-term treatment of alcohol dependence shows no clear-cut evidence from randomized, double-blind studies.[1,45] Gabapentin is used as monotherapy or as an add-on pharmacotherapy in outpatient settings in the control of alcohol consumption and craving

and in helping patients achieve abstinence.[46] Ondansetron may show benefit in early-onset but not in late-onset alcoholics. Risperidone for agitation has minimal effects on vital signs with or without a benzodiazepine, suggesting that risperidone is a safe option for patients presenting with acute agitation even in the setting of alcohol intoxication.[47]

Brief intervention and screening (SBIRT—***s***creening, ***b***rief ***i***ntervention, and ***r***eferral to ***t***reatment) can reduce alcohol consumption and is feasible and effective in the ED.[48] An ultra-BI (less than 10 minutes face-to-face time) or employing technology such as computers and mobile phones reduces previously identified barriers to ED clinician utilization.[49] Internet-based interventions show promise for reducing alcohol consumption, especially among those meeting criteria for hazardous or harmful drinking. Telephone contact after the ED visit may be another effective tool to screen injured patients for hazardous drinking and offer a brief intervention while avoiding interruptions to patient flow. Providing internet-based interventions is more effective than no intervention at all to reduce binge drinking among college-aged students. The Internet could be an economic and acceptable form of delivering brief interventions and is a preferred approach to reach binge drinkers in college.[50]

Most communities have an Alcoholics Anonymous (AA) chapter or treatment center for anyone who desires help with alcohol. Sobering centers can have a prominent role in the care for those with acute alcohol intoxication, particularly those individuals with chronic public intoxication who are likewise homeless. In smaller communities, clergy or social workers can usually arrange rehabilitation. Psychosocial treatments such as brief counseling, motivational enhancement therapy, the community reinforcement approach, guided self-change, behavior contracting, and social skills training were among the top ten most effective interventions for AUDs, together with various pharmacological interventions.

CHAPTER 137: QUESTIONS AND ANSWERS

1. A 56-year-old man presents with alcohol intoxication. He is drowsy but arousable to painful stimuli. He is confused. Vital signs are within normal limits, and there is no evidence of trauma. Routine testing should include which of the following first?
   a. Basic metabolic panel
   b. Glucose
   c. Serum blood ethanol level
   d. Urine toxicology screen

Answer: b. Chronic alcoholics have decreased glycogen stores and frequently experience hypoglycemia. While a basic metabolic panel could provide you with additional information, the primary electrolyte of interest is glucose. Serum blood ethanol and urine drug screens may be helpful in the undifferentiated patient with altered mental status, but these patients still require a bedside glucose test first.

2. A 42-year-old woman presents with agitation, confusion, and fever. She is noted to experience visual hallucinations during your interview. Her vital signs reveal hypertension, tachycardia, and fever. Physical examination is otherwise unremarkable. Diagnostic studies (including head CT scan and lumbar puncture) are nonspecific. Which diagnosis is most consistent with this patient's presentation?
   a. Acute schizophrenia
   b. Alcohol withdrawal
   c. Anticholinergic poisoning
   d. Thyrotoxicosis

Answer: b. Patients are often confused and agitated and exhibit autonomic instability, resulting in hypertension, tachycardia, and, often, fever. Hallucinations are typically visual. Schizophrenia typically results in auditory hallucinations and, although patients are delusional, they are not typically confused. Patients with anticholinergic poisoning typically present with confusion but also have dry mouth, dry eyes, dry skin, hypoactive bowel sounds, and urinary retention. Thyrotoxicosis patients exhibit lid lag, tremor, and gastrointestinal complaints.

3. In addition to altered mental status (AMS), which of the following is a criterion for diagnosing Wernicke encephalopathy?
   a. Alcohol intoxication
   b. Fever
   c. Oculomotor abnormalities
   d. Seizure

Answer: c. Criteria to diagnoses Wernicke encephalopathy require two of the following: (1) dietary deficiencies; (2) oculomotor abnormalities; (3) cerebellar dysfunction; and (4) AMS or mild memory impairment. Although it is most often diagnosed in alcoholics, alcohol consumption is not required. Treatment is with replacement of dietary deficiencies, particularly thiamine. Magnesium levels should be checked and treated if low. Magnesium is a cofactor for thiamine and is often depleted in chronic alcoholics.

4. Given that brief intervention and screening (SBIRT—***s***creening, ***b***rief ***i***ntervention, and ***r***eferral to ***t***reatment) can reduce alcohol consumption and is feasible and effective in the emergency department, which of the following interventions are particularly effective and preferred for college students?
   a. AA meetings
   b. In-person counseling
   c. Internet-based interventions
   d. Pharmacologic-based interventions

Answer: c. Studies show that providing internet-based interventions is more effective to reduce binge drinking among college students. The Internet could be an economic and acceptable form of delivering brief interventions and is a preferred approach to reach binge drinkers in college. AA Meetings, counseling, and pharmacologic treatment are likely to occur later in the treatment process.

5. A 28-year-old man with alcohol use disorder presents with fever, chills, and a productive cough. The x-ray reveals right lower lobe pneumonia. Which of the following is the most likely etiology of this infection?
   a. *Klebsiella pneumoniae*
   b. *Mycobacterium tuberculosis*
   c. *Mycoplasma pneumoniae*
   d. *Streptococcus pneumoniae*

Answer: d. Pneumococcal pneumonia is the most common type of pneumonia in both healthy individuals and heavy alcohol users. Other infections such as *Klebsiella pneumoniae* and Mycobacterium are also increased in patients with alcohol use disorders and cause disproportionate rates of lung infection, but not the most common. *Klebsiella pneumoniae,* classically associated with alcoholism, is currently more common in patients with cytotoxic chemotherapy, hematologic malignant disease, and transplantation than in the chronic alcoholic.

Acetaminophen

Michael Ganetsky

KEY CONCEPTS

- Acetaminophen concentration should be measured in patients with intentional oral overdoses. Acetaminophen poisoning is relatively silent clinically until serious hepatotoxicity ensues.
- Repeated supratherapeutic dosing of acetaminophen can lead to life-threatening toxicity.
- Use the acetaminophen concentration on the nomogram at 4 hours or later post-ingestion to determine whether *N*-acetylcysteine (NAC) therapy is indicated for acute ingestions.
- IV NAC is preferable to PO NAC. When initiating NAC, continue it until the protocol is completed with adequate clearance of acetaminophen, and there is no evidence of liver injury. If there is evidence of liver injury or acetaminophen concentration remains >10 μg/mL, continue NAC until acetaminophen is undetectable, clinical signs of liver injury have resolved, and liver enzymes are declining (aspartate aminotransferase [AST] <1000 IU/L).
- For maximum benefit, NAC treatment should not be delayed beyond 8 hours after ingestion. If more than 8 hours have passed since ingestion, initiate treatment with ongoing assessment of the amount of ingestion (serial serum acetaminophen levels) and development of hepatotoxicity (elevated transaminases, coagulopathy, and encephalopathy).
- Late or prolonged administration of NAC is beneficial even with low or absent acetaminophen concentrations if hepatotoxicity is evident.
- NAC is safe in pregnancy and is used in the same protocol as for the nonpregnant patient.

FOUNDATIONS

Acetaminophen (known internationally as paracetamol) is one of the most important toxins encountered in emergency care because of its ready availability, high potential lethality, and absence of symptoms in the early period after acute ingestion, during which administration of the antidote is most effective. Acetaminophen is found as an isolated product or in combination medications for the treatment of pain and febrile illness. An intravenous (IV) formulation is also available. Given its widespread availability and occult clinical presentation, acetaminophen toxicity is a concern in the vast majority of intentional ingestions, as well as with repeated supratherapeutic dosing, prescription drug misuse, and use by patients with alcohol use disorder. Acetaminophen toxicity is one of the leading causes of hospital admission, antidote use, and fatalities from oral poisonings in the United States.[1]

Protocols have been established for the assessment and management of acute and chronic acetaminophen ingestion through decades of research and experience; however, controversy continues to exist, and management of acetaminophen exposures continues to evolve.

Acetaminophen is absorbed rapidly, with peak plasma concentrations generally occurring within 1 hour and complete absorption within 4 hours. Once absorbed, acetaminophen inhibits prostaglandin E_2 (PGE_2) synthesis, leading to antipyresis and analgesia. Inhibition of PGE_2 synthesis is either by direct cyclooxygenase-2 (COX-2) inhibition or inhibition of membrane-associated prostaglandin synthase.

In therapeutic doses, 85% to 90% of acetaminophen is conjugated or sulfated into nontoxic metabolites that are excreted in the urine (Fig. 138.1).[2] A small percentage (<5%) is oxidized by cytochrome P_{450} 2E1 (CYP2E1) (and to a lesser extent 1A4 and 3A4) to a highly cytotoxic metabolic intermediary, *N*-acetyl-*p*-benzoquinone imine (NAPQI).[2] In therapeutic doses, NAPQI is short-lived, combining rapidly with glutathione and other thiol-containing compounds to form nontoxic metabolites that are excreted in the urine. With typical therapeutic acetaminophen dosing, glutathione stores and the ability to regenerate glutathione easily detoxify any NAPQI that is produced.

After large acute ingestions or repeated supratherapeutic ingestions, the amount of NAPQI produced begins to overwhelm glutathione stores and the liver's ability to regenerate glutathione, leading to unbound NAPQI. The highly reactive electrophile NAPQI covalently binds to cell proteins in the liver, which initiates a cascade of events that leads to hepatic cell death. Renal injury may also occur with or without liver injury and may be mediated by renal cytochrome P_{450} (CYP) enzymes or activation of prostaglandin synthase.

Acetaminophen-induced liver damage initially occurs in hepatic zone III (centrilobular), because oxidative metabolism is concentrated in this area. With severe toxicity, necrosis of the entire liver parenchyma may occur. The clinical effects of acetaminophen toxicity are the result of fulminant liver failure rather than a direct acetaminophen effect. These effects include multiorgan failure, systemic inflammatory response syndrome, hypotension, cerebral edema, and death. In the setting of massive ingestions, patients can present with altered mental status and metabolic acidosis. They typically have serum acetaminophen concentrations greater than 300 to 500 mg/L, and are at increased risk of developing hepatotoxicity despite early NAC administration.[3,4]

The principal therapy for acetaminophen toxicity is *N*-acetylcysteine (NAC),[5] which is effective via two separate mechanisms. Soon after overdose, NAC serves as a glutathione precursor and a sulfur-containing glutathione substitute (see Fig. 138.1) binding to, and thereby detoxifying, NAPQI. NAC may also decrease NAPQI formation by enhancing acetaminophen conjugation with sulfate to nontoxic metabolites.

Even after acetaminophen hepatotoxicity is evident, NAC acts as a free-radical scavenger and an antioxidant and alters hepatic microcirculation and oxygen delivery. In patients with acetaminophen-induced hepatic failure, IV NAC decreases the rates of cerebral edema, hypotension, and death even when no detectable acetaminophen remains in the serum.[5,6]

CLINICAL FEATURES

Adolescent and adult patients typically present after an acute, intentional ingestion of acetaminophen, either alone, or in combination with other drugs. Patients with chronic toxicity fall into two main categories: persistent supratherapeutic dosing (>4 g/day over 48 to 72 hours) or therapeutic or regular use in the presence of comorbidities that predispose to acetaminophen-induced hepatic injury. This latter group includes chronic alcohol users, patients with dehydration, malnutrition, and those taking other potentially hepatotoxic agents (e.g., isoniazid, valproic acid). Patients with chronic toxicity typically present with abdominal pain, anorexia, nausea, vomiting or new onset of jaundice. Careful questioning about acetaminophen use in patients with unexpected transaminitis is important, particularly when the cause of the abnormalities is not clear. Early after acute acetaminophen ingestion, patients are asymptomatic or have mild nonspecific symptoms (e.g., nausea, vomiting, anorexia, malaise, and diaphoresis) (Table 138.1). Liver injury becomes evident after a period of 8 to 36 hours as an elevation in aspartate transaminase (AST).[2] Once liver injury has ensued, patients may develop right upper quadrant (RUQ) pain or tenderness, vomiting, and jaundice. AST concentrations continue to rise rapidly and usually peak in 2 to 4 days, corresponding to maximal liver injury. Alanine transferase (ALT), prothrombin time (PT), and bilirubin typically begin to rise and peak several hours after AST values. With severe toxicity, AST, ALT, and PT may all be elevated within 24 hours (Fig. 138.2). With maximal liver injury, patients develop signs and symptoms consistent with fulminant liver failure, including metabolic acidosis, coagulopathy, and hepatic encephalopathy. Death may occur from hemorrhage, adult respiratory distress syndrome, sepsis, multiorgan failure, or cerebral edema. The risk of renal injury increases with the severity of hepatic injury (known as the hepatorenal syndrome), occurring in 1% to 2% of patients without hepatotoxicity and in 25% of patients with severe hepatotoxicity.

If hepatotoxic patients recover, aminotransferases return to baseline concentrations over a 5- to 7-day period (see Fig 138.2), although complete histologic resolution of liver injury may take months. Once histologic recovery is complete, there are no long-term sequelae to the liver and patients are not at risk for chronic hepatic dysfunction.

Differential Diagnoses

Until excluded, acetaminophen should be considered a co-ingestant in patients with intentional oral overdoses regardless of whether they state that they ingested acetaminophen. Other causes of injury in patients with elevations in aminotransferases, bilirubin, prothrombin time and international normalized ratio (PT/INR), or creatinine, include acute tubular necrosis, rhabdomyolysis, ischemic hepatitis, alcoholic hepatic disease, cyclopeptide-containing mushroom toxicity, viral hepatitis, and Wilson disease. Other hepatic toxins include valproic acid, isoniazid (INH), statins, herbal medications (such as chaparral and pennyroyal oil), vinyl chloride, and polychlorinated biphenyls.

DIAGNOSTIC TESTING

The goals of patient assessment after acetaminophen ingestion are (1) the determination of the patient's risk, (2) diagnostic testing, and (3) treatment with the antidote NAC when indicated.

We recommend serum acetaminophen testing for intentional ingestion patients, whether or not they report acetaminophen ingestion. Patients with a known acetaminophen exposure should have the following laboratory testing: serum acetaminophen concentration at four hours post-ingestion, serum salicylate concentration (since patients often confuse these over-the-counter analgesics), AST, ALT, bilirubin, PT/INR, bicarbonate (screening for metabolic acidosis), and creatinine (to assess renal function). If a patient has signs of liver injury (elevated

TABLE 138.1 Time Course and Clinical Stages of Acetaminophen Toxicity

Stage	Time Course	Name	Symptoms	Signs
1	0 to 12 (up to 24 to 36) hours	Preinjury	Nausea, vomiting, anorexia, malaise	Elevated serum acetaminophen concentration
2	8 to 36 hours	Liver injury	Nausea, vomiting, RUQ abdominal tenderness	Aminotransferase elevation (AST begins to rise 8 to 36 hours after ingestion)
3	2 to 4 days	Maximum liver injury	Liver failure (encephalopathy, coagulopathy, hemorrhage, acidosis)	Hemorrhage, ARDS, sepsis/SIRS, multiorgan failure, cerebral edema
4	>4 days	Recovery	None	Complete hepatic histologic recovery

ARDS, Acute respiratory distress syndrome; *AST,* aspartate transaminase; *RUQ,* right upper quadrant; *SIRS,* systemic inflammatory response syndrome.

AST or ALT), a venous blood gas and serum lactate should be measured. Acetaminophen exposures may be classified as acute or chronic, and each type requires different testing and risk assessment. An acute ingestion is defined as a single ingestion or a series of ingestions within an 8-hour period. All other ingestions, including accidental repeated supratherapeutic ingestions and intentional ingestions spread over longer than 8 hours, are considered to be chronic.

Risk Assessment With Acute Acetaminophen Ingestion

The initial diagnostic strategy of an acute ingestion is well-established. The first step is to determine the patient's risk of developing acute liver injury. Patients who report an acute intentional ingestion of acetaminophen should have laboratory risk stratification regardless of the reported amount ingested, because history alone is not reliable. In an otherwise healthy adult patient, ingestions of less than 10 grams in total or 150 mg/kg (approximately thirty 325 mg [regular strength] or twenty 500 mg [extra strength] tablets for an 70 kg adult) in an acute ingestion will not cause significant liver toxicity. A serum acetaminophen concentration should be checked in all intentional overdose patients, regardless of whether they report taking it, unless it is certain that the patient could not have had access to acetaminophen. Acetaminophen has been detected in the serum of up to 8% to 10% of patients with intentional ingestions who deny acetaminophen ingestion. Also, there is a high prevalence of unrecognized acetaminophen toxicity among subjects presenting with indeterminate acute liver failure.

Once an acute acetaminophen overdose is identified, establish the time of ingestion as accurately as possible using all available information. If no accurate time of ingestion can be determined, it is best to assume the earliest possible time of ingestion or to begin NAC therapy empirically if the time of ingestion is indeterminate.

A serum acetaminophen concentration 4 hours post-ingestion, or as soon as possible after 4 hours, determines the need for antidotal therapy by plotting the serum acetaminophen concentration against the time since ingestion on the treatment nomogram (Fig. 138.3). A serum acetaminophen concentration above the treatment line (that starts at 150 μg/mL at 4 hours and decreases to 4.7 μg/mL at 24 hours), indicates need for treatment with NAC. If the serum acetaminophen concentration is below the treatment line and the highest risk scenario has been assumed for the time of ingestion, then the patient requires no antidotal therapy. Use of the treatment line is indicated for otherwise healthy patients presenting after single acute ingestions. Alternative approaches in patients with alcohol use disorder, patients with co-ingestions of antimuscarinic agents, patients with unknown ingestion times, and after IV formulations have been suggested, but these are not supported by trial data.[2] In a patient with an antimuscarinic (i.e., diphenhydramine) co-ingestion who has an elevated serum acetaminophen concentration at 4 hours that does not meet criteria for treatment, we recommend rechecking an acetaminophen concentration at 8 hours to ensure that appropriate clearance has occurred with no delayed absorption.

Measurement of serum acetaminophen concentration prior to 4 hours post-ingestion is not indicated. There is insufficient evidence to support claims that a serum acetaminophen concentration of less than 10 μg/mL between 1 and 4 hours excludes significant ingestion of acetaminophen. Absorption of acetaminophen may not be complete prior to 4 hours, and serum acetaminophen concentrations measured prior to 4 hours cannot be plotted on the treatment nomogram. There is no known benefit to administering NAC before the recommended 4 to 8-hour window after ingestion. Patients treated with NAC within 8 hours after ingestion, even after very large overdoses, have no increased risk of hepatotoxicity regardless of their serum acetaminophen concentration. For patients who have developed hepatotoxicity at presentation, those with preexisting liver disease, or those in whom a serum acetaminophen concentration cannot be obtained prior to 8 hours after ingestion, a loading dose of NAC is recommended along with consultation with a medical toxicologist or poison center. (See Box 138.1 listing indications for a medical toxicology consultation)

Risk Assessment With Chronic Ingestion

With repeated or chronic exposure, risk assessment is more complex, and the treatment nomogram cannot be used. Determination of the need for NAC is based on assessment of the risk for hepatotoxicity and measurement of serum concentrations of acetaminophen and AST.

The risk of hepatotoxicity from chronic ingestion of acetaminophen increases with total dose of acetaminophen and the duration over which it has been ingested in supratherapeutic quantities. Laboratory testing for serum acetaminophen concentration and AST should be initiated in any patient who fits the criteria outlined in Table 138.2.

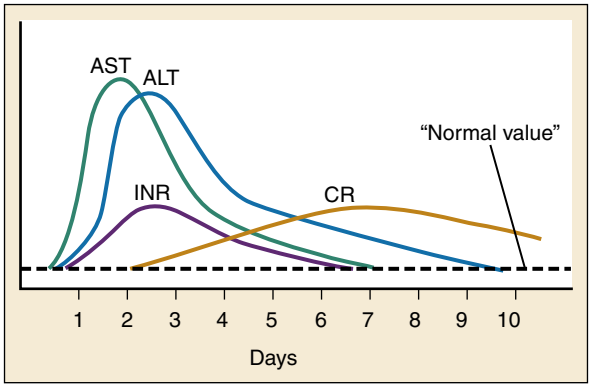

Fig. 138.2 A typical time course of rise, peak, and fall of laboratory values in patients with acetaminophen-induced hepatic dysfunction who survive. Peaks are not proportional. Not all laboratory abnormalities occur in all patients, and significant individual variation may occur. *ALT,* Alanine transaminase; *AST,* aspartate transaminase; *CR,* creatinine; *INR,* international normalized ratio. BOX 138.1 Indications for Medical Toxicology Consultation for Acetaminophen Toxicity

- Patients who have developed hepatotoxicity at presentation
- Patients with preexisting liver disease
- Patients in whom a serum acetaminophen concentration cannot be obtained prior to 8 hours after ingestion
- Patients with hepatotoxicity following a chronic acetaminophen ingestion where an acetaminophen concentration cannot be plotted on the treatment nomogram.
- Patients with massive ingestions (serum acetaminophen concentrations >900 mcg/mL)
- Patients with metabolic acidosis, hepatorenal syndrome, or hepatic encephalopathy

TABLE 138.2 Indications for Initiating Testing for Serum Acetaminophen Concentration and Aspartate Transaminase in Chronic Acetaminophen Ingestions

Age ≥6 years old;	Ingestion of >10 g/d (or >200 mg/kg/d) (whichever is smaller) over a 24-hour period
or	Ingestion of >6 g/d (or >150 mg/kg/d) (whichever is smaller) over a 48-hour period or longer
or	Symptomatic (e.g., RUQ pain/tenderness, jaundice, vomiting)
Children <6 years old;	Ingestion of >200 mg/kg/d over a 24-hour period
or	Ingestion of >150 mg/kg/d over a 48-hour period
or	Ingestion of >100 mg/kg/d over a 72-hour or longer period
or	Symptomatic (eg, RUQ pain/tenderness, jaundice, vomiting)

AST, Aspartate transaminase; *RUQ,* right upper quadrant.

Ingestion of therapeutic amounts of acetaminophen appears to be quite safe, although subclinical transaminitis can occur. Studies of patients presenting after taking 4 grams per day have shown ALT elevation of greater than 3 times the upper limit of normal in up to one-third of patients at one week, although no subject had clinical side effects, and all recovered without antidotal treatment. The implication of these findings is unclear but could be helpful to explain certain clinical scenarios. Some patients may be at increased risk for liver injury, possibly due to genetic variation or to specific risk factors. For example, patients who chronically ingest INH or ethanol may have increased CYP2E1 activity and may be at higher risk for chronic acetaminophen toxicity. Similarly, patients who are malnourished or have severe dehydration may be at higher risk for hepatotoxicity. Patients who ingest the liquid acetaminophen formulation may have lower risk of hepatotoxicity because the common diluent, propylene glycol, is a CYP2E1 inhibitor.[7]

Once serum acetaminophen concentration and AST are obtained, further risk assessment is necessary. Patients with chronic ingestions (e.g., >4 grams/day over a period of 48 to 72 hours) may benefit from antidotal therapy if they have evidence of liver injury (AST >2 times normal, or 120 IU/L) *or* if they have evidence of acetaminophen excess (serum acetaminophen concentration >30 mcg/mL) with a prolonged half-life that may lead to liver injury. After a typical therapeutic dose of acetaminophen, serum acetaminophen concentration peaks at less than 30 µg/mL and declines to less than 10 µg/mL at 4 hours. In patients who are asymptomatic, who have a minimal AST elevation, who do not report an intentional ingestion, we recommend a recheck of serum aminotransferases after 4 hours. If there is not a sharp increase as would be expected to occur with acetaminophen acute liver injury, NAC therapy is not indicated.

Risk Assessment in Pregnant Women

The risk assessment and diagnostic approach to pregnant women is the same as for nonpregnant women. In acute overdoses, a serum acetaminophen concentration should be drawn and plotted on the treatment nomogram. NAC therapy should be initiated if the serum acetaminophen concentration plots above the treatment line. With chronic exposure, the same criteria strategy as outlined earlier should be instituted.

MANAGEMENT

Stabilization and Supportive Care

The mainstay of management is antidotal therapy with NAC, complemented by supportive measures. Supportive care includes management of co-ingestions, nausea and vomiting, hepatic injury, and renal dysfunction related to acetaminophen poisoning. Treatment of these problems is based on general treatment principles and is not acetaminophen-dependent (see Chapters 76 and 83). When questions exist regarding initiation of NAC or there are confounding clinical issues present (e.g., preexisting liver disease), clinicians may consult with a regional poison center (1-800-222-1222 in the United States) or a medical toxicologist for advice.

Decontamination

Activated charcoal (AC) effectively binds acetaminophen in vitro, and some studies have suggested that early administration of AC (within 1 to 2 hours post-ingestion) may decrease the number of patients that require antidotal therapy. In massive ingestions (≥40 grams), AC was shown to decrease acetaminophen concentrations and rate of hepatotoxicity up to 4 hours after ingestion.[3] However, many patients have co-ingestions that may depress mental status, and patients with severe acetaminophen poisoning often develop vomiting and are not able to tolerate AC. Given the lack of demonstrated efficacy in terms of improved outcomes from single-dose AC and the existence and availability of a very effective antidote, we do not recommend the routine use of AC for acetaminophen overdose, except in circumstances where the patient is asymptomatic and AC administration may prevent need for NAC, such as pediatric accidental ingestions.

Enhanced Elimination

Hemodialysis is not routinely used for acetaminophen overdose, because there is a highly effective antidote with good clinical outcomes when given within 8 hours of ingestion. However, acetaminophen is removed by hemodialysis, which may be helpful when the absorbed acetaminophen burden is sufficient to cause hepatotoxicity despite standard doses of NAC.[4] We recommend consultation with a poison center or medical toxicologist and nephrologist for initiation of hemodialysis for patients presenting following an acute massive ingestion with the characteristics outlined in Box 138.2. These are based on consensus guidelines from the Extracorporeal Treatments in Poisoning (EXTRIP) workgroup.[8]

Antidote Therapy

N-Acetylcysteine

NAC should be administered as early as possible when the acetaminophen concentration obtained at or after 4 hours post-ingestion is determined to be above the treatment line. NAC is also indicated when the liver function tests are noted to be elevated in a chronic

BOX 138.2 Indications for Emergent Hemodialysis Following Acute Acetaminophen Ingestion

- If the serum acetaminophen concentration >1000 mcg/mL and NAC is NOT administered
- If the patient presents with altered mental status, metabolic acidosis, an elevated lactate, and a serum acetaminophen concentration >700 mcg/mL and NAC is NOT administered
- If the patient presents with an altered mental status, metabolic acidosis, an elevated lactate, and a serum acetaminophen concentration >900 mcg/mL even if NAC is administered[a]

[a] NAC therapy should be continued during hemodialysis.

supratherapeutic ingestion. NAC is highly efficacious at preventing hepatotoxicity when administered at any time within 8 hours after an acute ingestion; delaying more than 8 hours after ingestion increases the risk of hepatotoxicity (Fig. 138.4).

NAC can be administered by mouth (PO) or IV. Both methods are efficacious in most situations, with advantages in favor of IV administration. All formulations of NAC (PO or IV) are effective when started within 8 hours of ingestion, with reductions in effectiveness when started between 8 and 24 hours post-ingestion. The risk of liver injury (i.e., AST >1000 IU/L) in patients treated with NAC within 8 hours is less than 1% and the mortality rate approaches zero (see Fig. 138.4).[9]

Once liver failure is evident (e.g., acidosis, coagulopathy, encephalopathy) NAC is given intravenously. IV NAC decreases the risk of hypotension, cerebral edema, and death in patients with acetaminophen-related hepatic failure. Oral NAC should only be used if IV NAC is not available. Even when there is no acetaminophen detectable in the serum, if a patient has AST greater than 1000 IU/L and there is a history or suspicion for acetaminophen ingestion or exposure, NAC should be started because there is evidence it decreases the need for liver transplantation and overall mortality.[6] There is an acetaminophen protein adducts assay in development that can discriminate liver injury due to acetaminophen and in the future may help to determine when NAC is indicated in the setting of liver failure with no detectable acetaminophen concentration in the serum.[10]

The main differences between IV and PO NAC are in their side effect profiles (Table 138.3). Approximately 5% of patients treated with IV NAC develop significant anaphylactoid reactions, although rates of up to 30% have been reported in prospective trials. The majority of these reactions are mild and self-limited consisting of sneezing, transient skin rashes, and flushing. More severe reactions have been reported in less than 1% of patients and include angioedema, bronchospasm, hypotension, and rarely death. Symptoms occur within 30 minutes of the start of the loading infusion. These anaphylactoid reactions are dose, rate, and peak NAC concentration dependent.[9]

Anaphylactoid reactions are less frequent with PO NAC. Skin rash, serious systemic reactions, and anaphylactic reactions are rarely reported with the PO formulation. However, approximately 15% of patients receiving PO NAC vomit (versus 7% with IV NAC), delaying timely antidote delivery. PO NAC is extremely unpalatable largely due to a sulfur or "rotten egg" odor and taste. Palatability may be improved by administering NAC diluted with either soda or juice and serving it in a covered container through a straw. Any dose that is vomited within 1 hour of administration should be repeated. If vomiting occurs, an antiemetic such as ondansetron can be trialed, but antiemetics administered prophylactically are not indicated.

Anaphylactoid reactions to IV NAC are typically mild (e.g., flushing) and occur during the initial loading infusion. Mild reactions can be managed with parenteral diphenhydramine, 25 mg IV, without stopping the infusion. If hypotension develops, we recommend slowing or pausing the infusion, giving a 500 mL fluid crystalloid bolus, and administering diphenhydramine, 25 mg IV, and restarting the NAC infusion at a slower rate. For reactions persisting despite these steps, administer methylprednisolone 80 mg IV and treat as indicated for severe allergic reaction. Epinephrine is rarely required. These reactions require observation and treatment, but do not preclude subsequent doses, and treatment with diphenhydramine should be continued.[11]

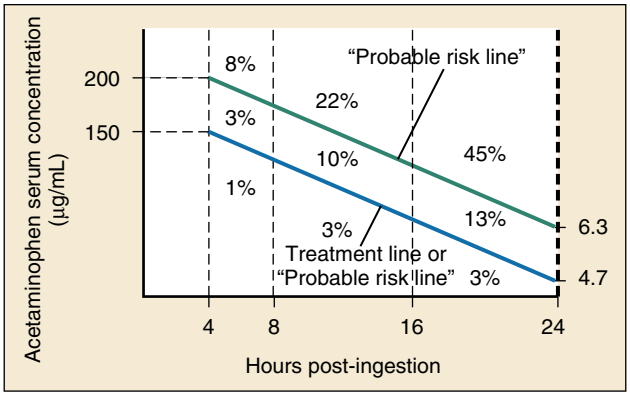

Fig. 138.4 Risk of liver injury (alanine transaminase >1000 IU) based on initial acetaminophen concentration and time to administration of oral *N*-acetylcysteine (NAC). (Adapted from Rumack BH: Acetaminophen hepatotoxicity: the first 35 years. *J Toxicol Clin Toxicol.* 2002;40:3.)

TABLE 138.3 Side Effect Profile for *N*-Acetylcysteine Formulations

N-Acetylcysteine Formulation	Common Side Effects	Severe Side Effects
PO NAC	Vomiting (13%), inability to tolerate due to smell	Very rare
IV NAC	Mild anaphylactoid reactions (e.g., rash, flushing, pruritus, vomiting), 2% to 18%	Severe anaphylactoid reactions (e.g., hypotension, bronchospasm), <1%

IV, Intravenous; *NAC, N*-acetylcysteine; *PO, per os* (by mouth).

Use in Pregnancy

Acetaminophen crosses the placenta, but the fetus in the first trimester of development is only at risk for injury if the mother suffers hepatotoxicity because fetal CYP enzymes have not fully developed. If the fetus is near-term (third trimester of development), there is a risk for direct fetal and neonatal hepatotoxicity, because the liver is more developed at this stage. Treating the mother with NAC is safe and effective, and NAC effectively crosses the placenta. NAC is used with the same protocols as for the nonpregnant patient. We recommend IV NAC when treating a pregnant patient. IV administration circumvents first-pass metabolism, therefore likely delivering higher doses to the fetus via higher maternal serum concentrations.

Duration of Therapy

There are two well-established protocols for NAC administration in cases of acute acetaminophen toxicity, depending on the route of administration: a 21-hour IV protocol and a 72-hour PO protocol. The standard IV NAC protocol in adults is a loading dose of 150 mg/kg up to a maximum of 15 gm in 200 mL of dextrose 5% in water (D5W)

TABLE 138.4 Inpatient Predictors of the Severity of Illness in Patients With Acetaminophen Toxicity

Score	Predictive Variables	Outcome Predicted	Notes
Kings College Criteria	pH <7.3 *or All three:* • Cr >3.3 *and* • INR >5 (or PTT >100s) *and* • Encephalopathy more than grade III (patient comatose)	Death or transplant	Arterial pH is measured *after* fluid resuscitation. The presence of any one of the Cr, INR, encephalopathy variables alone has a lower specificity for transplant than all 3 combined, but still has significant sensitivity to prompt consideration of transfer to transplantation center.
APACHE II	APACHE II score >20	Death or transplant	Confounders include co-ingested medications that may alter the APACHE II score.
Lactate	Lactate >3.5 mmol/L prior to resuscitation	Death or transplant	Lactate was drawn a mean of 55 hours after ingestion. The predictive ability of an early lactate draw is unknown.

APACHE II, Acute Physiology and Chronic Health Evaluation II; *Cr,* creatinine; *INR,* international normalized ratio; *PTT,* partial thromboplastin time.

infused over 60 minutes followed by a first maintenance dose of 50 mg/kg (up to a maximum of 5 gm) in 500 mL D5W infused over 4 hours. This is followed by a second maintenance dose of 100 mg/kg (up to a maximum of 10 gm) in 1000 mL D5W infused over 16 hours (6.25 mg/kg/hour).

Oral NAC is given as a 140 mg/kg loading dose, either by mouth or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg is given every 4 hours for an additional 17 doses (total treatment duration of 72 hours).

Several other regimens, including 48 hours IV, 36 hours IV, 36 hours PO, and 20 hours PO protocols are described; however, none of these are generally accepted as standard of care.[9] Recently, a "two-bag" protocol has been developed as an alternative to the 21-hour IV NAC protocol: 200 mg/kg NAC (in 500 ml D5W or 0.9% saline) over 4 hours followed by 100 mg/kg NAC (in 1 L D5W or 0.9% saline) over 16 hours. This protocol has demonstrated fewer adverse reactions and fewer medication errors with similar efficacy as the 21-hour protocol and is now being used in many centers.[12-14] Until further clinical trials are conducted to prove the clinical efficacy of these alternative dosing regimens, we recommend using the traditional 21-hour IV protocol.

Patients with very large acetaminophen ingestions may develop hepatotoxicity despite early and appropriate NAC dosing, and we recommend early consultation with a medical toxicologist in such cases (see Box 138.1.) We also advise consultation with a nephrologist or transfer to a capable center for possible hemodialysis for patients with the characteristics outlined in Box 138.2. Patients with hepatic failure and persistently elevated serum acetaminophen concentrations that do not decrease as expected are also at risk of failing NAC therapy. There have been various recommendations to increase NAC dosing based on very elevated 4-hour concentrations, but none are universally accepted. One recommendation is to increase the NAC rate to 12.5 mg/kg/hr (200 mg/kg NAC in 1 L over 16 hours) when the concentration is greater than the 300 µg/mL at 4 hour treatment line.[15] We do not recommend routinely using this dosing regimen until further clinical trials are conducted proving its clinical efficacy or unless recommended in consultation with a medical toxicologist..

For delayed, chronic, or supratherapeutic dosing toxicity, NAC therapy should continue until acetaminophen is undetectable in the serum (<10 mcg/mL) and signs of liver injury have resolved (i.e., no encephalopathy, improvement of the coagulation profile with INR <2.0, resolution of metabolic acidosis, and AST less than 1000 IU/L with a downward trend).

DISPOSITION

Asymptomatic patients who meet criteria for treatment should be treated with NAC, which is started in the ED and continued in a medical inpatient unit or an ED observation unit. The motivation behind any ingestion needs to be evaluated, and psychiatric consultation obtained when appropriate.

Patients showing evidence of hepatotoxicity and those at risk for fulminant hepatic failure may require admission to a monitored bed or an ED or inpatient intensive care unit. These patients require frequent neurologic checks, monitoring of vital signs, and repeated laboratory studies.

Need for Transplantation

The King's College Criteria are the most commonly accepted decision rule for determining risk for needing liver transplantation.[16] Clinical rules for identifying patients at risk for developing fulminant hepatic failure are listed in Table 138.4, and patients meeting these criteria should be transferred to a tertiary care center that specializes in the management of patients with hepatic failure with potential need for liver transplant.

CHAPTER 138: QUESTIONS AND ANSWERS

1. Which of the following is true regarding pregnant patients with an acute acetaminophen ingestion?

- **a.** All pregnant women should be treated with *N*-acetylcysteine (NAC) after any known ingestion of acetaminophen.
- **b.** Pregnant women in the third trimester should be treated with NAC if their acetaminophen concentration is ever elevated above 50 μg/mL.
- **c.** Pregnant women should be treated with NAC if their acetaminophen concentration is above the treatment line on the nomogram.
- **d.** Pregnant women should be treated with NAC if they ingest >75 mg/kg PO acetaminophen over less than 8 hours.
- **e.** The treatment line on the nomogram is lowered to a line starting at 100 μg/mL at 4 hours after ingestion.

Answer: C. Pregnant patients with an acute ingestion of acetaminophen should have the same initial treatment as nonpregnant patients. After measurement of an acetaminophen concentration, plotting of the acetaminophen concentration on the nomogram treatment with NAC should be given if the concentration is above the treatment line on the nomogram. Both acetaminophen and NAC do cross the placenta, but the fetus is at risk only if the mother becomes ill. Patients with first trimester pregnancies are at risk of miscarriage if the mother becomes ill, and fetuses that are near-term may be at risk for fetal/neonatal hepatotoxicity.

2. A 30-year-old woman presents with drowsiness, nausea, and vomiting. She reports taking several pills in a suicide attempt. Despite your best efforts, she cannot describe what she ingested or how many she ingested. She states she took the pills "last night" and refuses to be more specific. Currently, it is 6 a.m. A family member is present and found the patient vomiting at 4 a.m., at which time she informed the family member she took some pills. The family member further states that the patient was in an argument with a friend at 12 p.m. and may or may not have ingested the pills at that time. The family was with the patient at 8 p.m. and is sure that she had not ingested the pills at that time. What time should be used as the time of ingestion?

- **a.** 2 a.m.—the time that is 4 hours prior to presentation
- **b.** 4 a.m.—the time the patient was found abnormal
- **c.** 6 a.m.—the time of presentation
- **d.** 8 p.m.—the time the patient was last seen and known to be prior to the ingestion
- **e.** 12 p.m.—the time the patient was last seen prior to becoming symptomatic

Answer: D. If the exact time of ingestion cannot be determined, then the "worst case" scenario should be assumed. The longer a patient goes without therapy, the worse the outcome. Therefore, the time of ingestion should be assumed to be the last time the patient was seen normal prior to any possible ingestion.

3. A 20-year-old man is brought to the emergency department by family with a complaint of "overdose." The patient is drowsy but arousable. His vital signs are normal. His physical examination is normal except for appearing to be intoxicated. He has no complaints. The family reports the ingestion of unknown "pills" as well as alcohol and possibly "street drugs." The ingestion occurred approximately 6 hours ago after an argument. Routine supportive care is initiated. What test must be ordered on this patient because it may affect the immediate treatment plan?

- **a.** Acetaminophen concentration
- **b.** Chest radiograph
- **c.** Head computed tomography (CT) scan
- **d.** Serum alcohol concentration
- **e.** Urine drug screen

Answer: A. The antidote should be given within 8 hours of ingestion to prevent development of hepatotoxicity.

CHAPTER 138: QUESTIONS AND ANSWERS—cont'd

4. What is the typical peak serum acetaminophen concentration after a therapeutic oral ingestion?
   - **a.** Undetectable
   - **b.** 10 μg/mL
   - **c.** 30 μg/mL
   - **d.** 50 μg/mL
   - **e.** 100 μg/mL

Answer: C. This concentration is typically reached approximately 1 hour after ingestion. Four hours after a therapeutic ingestion, the concentration is typically less than 10 μg/mL. Concentrations higher than this should lead one to consider the possibility of chronic ingestion or a person who does not properly metabolize acetaminophen.

5. Two 20-year-old patients present to the emergency department 1 hour after ingesting 15 grams of acetaminophen each in a suicide pact. You are confident of the time of ingestion and that time is confirmed by text messages sent by the patients. Patient A has a 4-hour acetaminophen concentration of 130 mg/dL. Patient B's 4-hour acetaminophen concentration is 170 mg/dL. What is the appropriate treatment for both patients?
   - **a.** Neither patient requires treatment because the acetaminophen concentrations are below the treatment cutoff.
   - **b.** Neither patient requires treatment because they received activated charcoal (AC).
   - **c.** Patient A should receive immediate *N*-acetylcysteine (NAC); patient B should *not* receive NAC.
   - **d.** Patient A should *not* receive NAC; patient B should receive immediate NAC treatment.
   - **e.** Both patients should receive immediate NAC therapy.

Answer: D. In this case, your confidence of the time of ingestion is high. The treatment line crosses 150 mg/dL at 4 hours. Therefore, if the 4-hour acetaminophen concentration is >150 mg/dL, treatment is indicated. In the case above, patient A does not require NAC therapy, but patient B does require treatment with NAC.

6. What is the antidote for acetaminophen ingestion?
   - **a.** Dimercaprol
   - **b.** Hydroxycobalamin
   - **c.** *N*-acetylcysteine (NAC)
   - **d.** *N*-acetyl-*p*-benzoquinone imine (NAPQI)
   - **e.** Succimer

Answer: C. Hydroxycobalamin is an antidote for cyanide; succimer is an antidote for lead; and dimercaprol is an antidote for arsenic, lead, and mercury. NAPQI is the toxic metabolite of acetaminophen.

7. A 42-year-old man presents to the emergency department with complaints of nausea and vomiting. He has no other complaints. His symptoms started approximately 12 hours ago. His history is significant for "back pain," which has been worse than normal recently. He states that he finished a bottle of 60 "pain pills" during the past 2 days. His vital signs are normal. Other than right upper abdominal tenderness, his physical examination is normal. Routine laboratory tests including complete blood count, chemistry, and liver panel are normal except an aspartate transaminase (AST) concentration of 1265 IU/L. You are concerned for possible repeated supratherapeutic acetaminophen poisoning. What should you do next?
   - **a.** Admit the patient for observation and repeat AST testing; because this is a repeated supratherapeutic ingestion, treatment with *N*-acetylcysteine (NAC) is not beneficial.
   - **b.** Initiate treatment with activated charcoal (AC) now.
   - **c.** Initiate treatment with NAC now.
   - **d.** Obtain two serum acetaminophen concentrations 1 hour apart to determine the drug's elimination half-life to decide if treatment with NAC is indicated.
   - **e.** Plot the acetaminophen concentration on the acetaminophen treatment nomogram to determine if treatment with NAC is indicated.

Answer: C. Many prescription and nonprescription analgesics contain acetaminophen, so although a patient may deny use of acetaminophen, suspicion should remain high. A patient with chronic acetaminophen ingestion should have an AST and acetaminophen concentration checked. If the AST is significantly elevated, treatment with NAC should be initiated. Many patients with repeated supratherapeutic ingestion will not have a markedly increased acetaminophen concentration, and the treatment nomogram is not used with repeated supratherapeutic dosing. Regardless of how long ago the ingestion occurred, if a patient displays signs or symptoms of liver damage, NAC should be given because it will still have beneficial effects.

8. A 55-year-old man has taken 10 grams of acetaminophen per day over the last 8 days for a toothache. He arrives to the emergency department with severe right upper quadrant (RUQ) pain, jaundice, and hypoglycemia. His aminotransferases, bilirubin, and acetaminophen concentration are highly elevated, and he is resuscitated and started on intravenous (IV) *N*-acetylcysteine (NAC). Which of the following laboratory findings is a very poor prognostic indicator and indicates that he is a candidate for immediate liver transplant?
   - **a.** Aspartate transaminase (AST) >10,000 IU/L
   - **b.** Bilirubin >5 mg/dL
   - **c.** Lactate >5 mmol/L
   - **d.** Acetaminophen concentration >150mg/dL
   - **e.** pH <7.4

Answer: C. The patient has severe liver failure due to repeated supratherapeutic dosing of acetaminophen. Prognostic variables that are used to determine immediate hepatic transplant are the Kings College Criteria (a pH <7.3[or lactate >3.5 mmol/L] after resuscitation *or* the combination of Cr >3.3 and PTT >100s [or INR >5] and grade 3 or 4 encephalopathy). Other criteria that indicate high mortality are the APACHE II score >20. If a patient in the emergency department meets these criteria, transfer to a center with liver transplant capabilities is indicated.

9. A 27-year-old woman is brought to the emergency department by emergency medical service (EMS). The patient is lethargic and cannot provide a history. A suicide note indicates that she ingested 50 g of acetaminophen approximately 24 hours ago. The patient is noted to be jaundiced with right upper quadrant (RUQ) tenderness. General supportive care is initiated. Her aspartate transaminase (AST) is 1072 IU. A serum acetaminophen concentration is pending. Which of the following statements is true regarding treatment with *N*-acetylcysteine (NAC)?
   - **a.** Treatment with NAC should be delayed until the acetaminophen concentration is obtained.
   - **b.** Treatment with NAC should be initiated because an ingestion of 50 g of acetaminophen is potentially fatal.
   - **c.** Treatment with NAC should be initiated because the patient has liver injury secondary to acetaminophen poisoning.
   - **d.** Treatment with NAC will not alter the outcome; this patient will require a liver transplant.
   - **e.** Treatment with NAC will not be beneficial because the ingestion occurred more than 10 hours ago.

CHAPTER 138: QUESTIONS AND ANSWERS—cont'd

Answer: C. Ideally, NAC treatment is initiated within 8 hours of ingestion, but treatment with NAC is still beneficial even after hepatotoxicity has developed. An acetaminophen concentration should be obtained, but there is no reason to delay treatment. Ingestion of 50 g is potentially toxic, but decisions should be based on the patient's current condition. Occasionally, hepatotoxicity from acetaminophen is severe and liver transplant is required, but most cases of hepatotoxicity resolve with NAC treatment.

Aspirin and Nonsteroidal Agents

Benjamin W. Hatten

KEY CONCEPTS

- In the overdose setting, salicylates are profoundly toxic and can be fatal. Salicylate overdose requires vigilant assessment and treatment. The other nonsteroidal antiinflammatory drugs (NSAIDs) generally have self-limited toxicity and respond to supportive measures. There is no specific antidote for any of these drugs.
- Salicylism should be considered in the differential diagnosis of altered mental status, particularly in the elderly.
- Acidemia signifies loss of respiratory compensation and acceleration of toxicity.
- The Done nomogram is no longer used and is not recommended in the evaluation and treatment of salicylate toxicity.
- Salicylate concentrations and blood gas draws should occur every 2 hours until the serum salicylate level is less than 30 mg/dL and is steadily declining at least 10% between assays in the absence of measures to enhance elimination.
- Potassium stores are rapidly depleted in patients with salicylate intoxication and should be repleted with a goal serum level of 4.5 to 5.0 mEq/L (4.5–5.0 mmol/L).
- When possible, mechanical ventilation should be avoided in cases of severe salicylate poisoning. Acidosis may rapidly worsen due to loss of adequate ventilation during the intubation procedure, and it is difficult to maintain ventilation at the level of physiologic hyperventilation.
- If intubation is necessary, a bolus of sodium bicarbonate (50 to 100 mEq) should be given before intubation and post-intubation; minute ventilation should be increased to match pre-intubation respiratory compensation.
- Enhanced elimination through urinary alkalinization with an intravenous sodium bicarbonate drip should be initiated in acute toxicity with a serum level >30 mg/dL.
- Consultation with nephrology and preparation for emergent hemodialysis should occur if the salicylate concentration is above 80 mg/dL or is rising rapidly.
- Hemodialysis is recommended for signs of pulmonary or cerebral edema, coma, seizures, hepatic failure, renal failure, circulatory collapse, or refractory metabolic acidosis along with acute serum levels greater than 100 mg/dL and chronic levels over 40 mg/dL.
- Altered mental status in the setting of salicylate toxicity warrants IV dextrose supplementation.
- Most NSAID overdoses are asymptomatic or cause only minor gastrointestinal symptoms.
- Ibuprofen, along with other propionic acid derivatives, has been associated with sporadic cases of aseptic meningitis.
- The management of NSAID overdose is supportive, and there is no specific antidote. Hemodialysis is reserved for patients with massive overdose (>400–500 mg/kg) and pH <7.1.
- Patients who have ingested a pyrazolone or fenamate require observation for possible seizures for 8 to 12 hours following ingestion.

ASPIRIN

Principles of Toxicity

Overview

Aspirin, or acetylsalicylic acid, is widely consumed for its analgesic, antiinflammatory, and antiplatelet effects. Although its therapeutic use is ubiquitous, salicylate toxicity is not a benign condition and causes a complex set of life-threatening metabolic derangements with significant morbidity and mortality.

Epidemiology

In 2017, twenty-three deaths were reported to United States Poison Control Centers due to aspirin alone.[1] This is consistent with reports to Poison Control Centers of twenty to thirty deaths per year for the past decades. One analysis identified salicylate toxicity as the most common preventable death due to poisoning that reached medical attention, suggesting an opportunity to impact mortality through proper management.[2] Elderly patients with chronic medical problems and young patients diagnosed with an acute illness are particularly at risk for delay in diagnosis with consequent severe adverse clinical effects.[3] In addition, increasing age has been identified as an independent predictor of severe outcomes and has been associated with lower peak levels in fatal cases.[4,5]

Salicylate-Containing Products

Aspirin is the most common salicylate-containing product. Other potential sources of salicylate toxicity include topical salicylates, analgesic balms, oil of wintergreen, willow bark, Alka Seltzer®, and bismuth subsalicylate. Ingestion of oil of wintergreen is of particular concern given that 1 mL of 98% solution contains the equivalent of 1.4 grams of aspirin.[6]

Pathophysiology

Salts of salicylic acid are rapidly absorbed intact from the gastrointestinal (GI) tract with appreciable serum concentrations typically occurring within 30 minutes after ingestion of a therapeutic dose with peak levels delayed from 2 to 4 hours. Large ingestions frequently slow gastric emptying. Aspirin, particularly enteric-coated preparations, tends to form concretions or bezoars in the stomach. These properties often result in prolonged absorption with rising serum levels for 12 hours or more.[3]

In the intestinal wall, liver, and red blood cells, aspirin is hydrolyzed to free salicylic acid, which reversibly binds to albumin. Free salicylate is eliminated by renal excretion. At therapeutic salicylate concentrations, elimination follows first-order kinetics. Once serum salicylate concentrations are greater than 30 mg/dL, elimination follows zero-order kinetics. The metabolic pathways become saturated,

BOX 139.1 Acid-Base Disturbance and Progression of Toxicity in Acute Salicylate Overdose

Early (0 to 4 hours; level 20 to 60 mg/dL): Respiratory alkalosis with alkalemia; gastrointestinal (GI) distress, mild to moderate hyperpnea, tinnitus, lethargy

Moderate (2 to 12 hours; level 50 to 90 mg/dL): Respiratory alkalosis and metabolic acidosis with alkalemia or neutral pH; severe hyperpnea, lethargy or agitation, hyperthermia

Severe (6 to 24 hours: level >80 mg/dL): Respiratory alkalosis or acidosis and metabolic acidosis with acidemia; severe hyperpnea, coma or acute delirium, hyperthermia, pulmonary or cerebral edema, seizure, cardiovascular collapse

and the pH-sensitive urinary excretion of salicylic acid determines the half-life, prolonging significantly (up to 15 to 30 hours) with large overdoses.[3]

The initial physiologic effect of salicylates is direct stimulation of the medullary respiratory center. In addition, salicylic acid increases the sensitivity of the respiratory center to pH and partial pressure of carbon dioxide (P_{CO_2}). Hyperventilation develops early, subsequently becoming a compensatory mechanism for metabolic acidosis. Prolonged high serum concentrations eventually depress the respiratory center. Respiratory alkalosis is compensated by the buffering capacity of the hemoglobin-oxyhemoglobin system, the exchange of intracellular hydrogen ions for extracellular cations, and the urinary excretion of bicarbonate. Loss of bicarbonate decreases buffering capacity and exacerbates the degree of metabolic acidosis (Box 139.1).[3]

Toxicity results primarily from salicylate interference with aerobic metabolism by uncoupling of mitochondrial oxidative phosphorylation. Inhibition of the Krebs cycle increases production of pyruvic acid and increases conversion to lactic acid. Increased lipid metabolism generates ketone bodies. Metabolic rate, temperature, tissue carbon dioxide, and oxygen consumption are increased. Tissue glycolysis predisposes to hypoglycemia, particularly in children. Inefficiency of anaerobic metabolism results in decreased production of adenosine triphosphate, with energy released as heat causing the hyperthermia frequently attributed to salicylate poisoning.

Only nonionized particles can cross the lipophilic cell membrane and accumulate in the brain and other tissues. Because salicylic acid has a pK_a of 3.5, the majority of salicylate is ionized and unable to enter tissue at the physiologic pH of 7.4. However, as serum pH decreases, more particles become un-ionized and cross the cell membrane and blood-brain barrier, markedly increasing the movement of salicylate into the tissues and central nervous system (CNS).

The rapid depletion of potassium stores in salicylate toxicity is caused by multiple factors. Immediate losses occur due to vomiting, which is secondary to stimulation of the medullary chemoreceptor trigger zone. In addition, increased renal excretion of sodium, bicarbonate, and potassium occurs as a compensatory response to the respiratory alkalosis, and salicylate-induced increased permeability of the renal tubules causes further loss of potassium. A final factor is inhibition of the active transport system, secondary to uncoupling of oxidative phosphorylation.[6]

Salicylate-related decreases in renal blood flow or direct nephrotoxicity may cause acute nonoliguric renal failure. Drug-induced, inappropriate secretion of antidiuretic hormone may also affect renal function. The exact mechanism by which salicylates increase alveolar capillary membrane permeability is not clearly defined. Theories include inhibition of prostacyclin, changes in platelet-vessel interaction, and neurogenic influences.

In adults, risk factors for salicylate-induced pulmonary edema include age greater than 30 years old, long-term cigarette smoking, chronic salicylate ingestion, metabolic acidosis, neurologic symptoms, and serum salicylate concentration greater than 40 mg/dL. Risk factors in children include high serum salicylate levels (>80 mg/dL), large anion gap acidosis, decreased serum potassium concentration, and low pCO_2.

Salicylates severely affect the CNS in two ways. First, there is a poorly elucidated aspect of toxicity that ultimately results in cerebral edema. This pathway is presumably related to increased energy requirements, acidemia, and direct cellular toxicity. Second, the consumption of glucose in the brain may outpace the supply. This occurs even in the face of normal serum glucose. One or both of these mechanisms can cause altered mental status, seizures, and coma.

At moderate to high tissue burden, salicylates induce a classic finding of toxicity—tinnitus, or the sensation of ringing in the ears. This phenomenon is due to a combination of central and peripheral effects. Cochlear toxicity is thought to be the result of alterations in *N*-methyl-D-aspartate (NMDA) activity, decreased blood flow, and increased membrane permeability. Cochlear toxicity combines with hyperactivity in the auditory cortex to cause tonotopic shifts where upper and lower frequency sounds are perceived in the 10 to 20 hertz tinnitus range, and sounds within this range become hyperacute. Salicylate-induced hearing disturbance may take days to resolve after the tissue burden normalizes.

At therapeutic dosing, salicylates increase bleeding risk via irreversible inhibition of platelet cyclooxygenase (COX). In overdose, vitamin K epoxide reductase is inhibited in a manner similar to warfarin. This acquired coagulopathy prolongs prothrombin time measurements and is associated with a substantial risk of clinically significant bleeding.[7]

Physiologic changes of aging predispose elderly patients to toxicity from chronic therapeutic ingestion. Decreased liver blood flow limits biotransformation of salicylate, and decreased renal function reduces salicylate clearance. Chronic ingestion decreases albumin binding, increasing the free salicylate that can enter the cell, and allows salicylates more time to pass through the blood-brain barrier. Therefore, a patient with chronic salicylate toxicity and a serum concentration of 40 mg/dL may be more ill than a patient with an acute ingestion and serum concentration of 80 mg/dL.

Clinical Features

Salicylate toxicity initially generates gastrointestinal (GI) distress followed by tachypnea with an accompanying respiratory alkalosis, tinnitus, and hearing disturbances due to concentration-dependent reversible ototoxicity, diaphoresis, and an evolving anion gap acidosis. As the toxicity progresses, hyperthermia, coagulopathy, cerebral and pulmonary edema, cardiovascular collapse, and, ultimately, death occur. Chronic poisoning may be more subtle, manifesting as a waxing and waning combination of the above manifestations of toxicity.[6]

Differential Diagnoses

Salicylism mimics sepsis, CNS infection, withdrawal syndromes, and alcoholic or diabetic ketoacidosis. This is especially true in chronic toxicity given that the serum salicylate concentration is relatively low. Thus, the severity of poisoning is often not recognized or not fully appreciated. In addition, co-ingestion is common, so evaluation for other toxic exposures is warranted. Other pain relievers and fever reducers such as acetaminophen and ibuprofen are often confused with aspirin by patients. Other toxins that cause a metabolic acidosis with an elevated anion gap include colchicine, iron, isoniazid, methanol, ethylene glycol, metformin, and cyanide. Other toxins that can cause

tinnitus include aminoglycosides, loop diuretics, opioids, methotrexate, cisplatin, and antimalarial agents containing quinine.

Diagnostic Testing

The serum salicylate concentration, acid-base status, serum potassium, and glucose are key diagnostic studies. Be mindful of the laboratory units of measurement when interpreting salicylate levels. Serum salicylate concentrations are reported as mg/dL, mg/L, or mmol/L by various labs but are listed in mg/dL in this text. The Done nomogram, historically used for aspirin toxicity, should not be used to determine prognosis or treatment of the salicylate-poisoned patient.

Measure an initial salicylate concentration on arrival with a second sample obtained 2 hours later. A low initial salicylate level may be deceptive as early salicylate levels have not been shown to predict severity of outcome.[4] Obtain concentrations every 2 hours to monitor for continued absorption, which may be prolonged. Serum salicylate levels should be repeated every 2 hours until three consecutive levels are less than 30 mg/dL and are declining by at least 10% to 20% on each measurement while the patient is no longer undergoing therapy to enhance elimination. In one series, 3.5% of cases demonstrated peak serum levels greater than 30 mg/dl despite a nondetectable initial level with the longest interval from ingestion to detection of 225 minutes.[8] Thus, given sufficient clinical suspicion, continue to obtain salicylate levels up to 4 hours post-ingestion even if the initial level is undetectable.

Acid-base status can change quickly, and monitoring of pH every 2 hours is important to guide treatment. Use early and frequent arterial or venous blood gas determinations in symptomatic patients to rapidly assess acid-base and compensatory status. Developing acidemia portends severe disease. The pH begins to drop when the patient is unable to compensate for acidemia. Lactic acid accumulates, and serum bicarbonate is consumed. A serum lactate greater than 2.25 mmol/L is a predictor of severe outcome.[4] When serum pH is less than 7.4 and both P_{CO_2} and bicarbonate level are low, hemodynamic instability rapidly develops.[6]

A metabolic panel is necessary to guide electrolyte replacement (with a focus on serum potassium) and to assess renal function and glucose metabolism. However, anion gap determination on a metabolic panel is not a substitute for obtaining a salicylate level or measuring the pH. Measurement of protime/INR will assist in guiding vitamin K therapy in the setting of coagulopathy. A serum acetaminophen concentration should also be obtained to screen for ingestion of this common, clinically occult analgesic overdose.

Management

Stabilization and Supportive Care

Accurate ascertainment of vital signs is the initial step in assessment, including oxygen saturation, respiratory rate, and a reliable temperature. Chest auscultation can provide evidence of pulmonary edema, and altered mental status may suggest CNS toxicity. Dehydration occurs early in salicylate intoxication because of the hypermetabolic state, and initial fluid requirements may be as high as 4 to 6 L. Fluid administration should be guided by the patient's apparent deficit to maintain urine output of 2 to 3 mL/kg/hr. Correct potassium depletion to maintain a serum level between 4.5 and 5.0 mEq/L (4.5–5.0 mmol/L).[6]

Unless the patient is rapidly decompensating, early mechanical ventilation should be avoided in the aspirin poisoned patient. Similar to diabetic ketoacidosis, it is difficult to artificially achieve adequate minute ventilation that sufficiently matches the patient's own respiratory compensation. In addition, the loss of ventilation during the intubation procedure results in rapid loss of respiratory compensation and worsening acidemia. If the patient is critically ill and requires intubation, worsening of acidosis during apnea is potentially harmful. Thus, we recommend bolus administration of 50 to 100 mEq (1 to 2 amps) of sodium bicarbonate ($NaHCO_3$) immediately prior to the procedure irrespective of the serum pH to temporarily compensate for a respiratory acidosis in addition to the bicarbonate drip being administered for enhanced elimination. Attempt to adjust the tidal volume post-intubation to optimally match the pre-intubation P_{CO_2} level. In addition, establish an elevated minute volume and obtain frequent arterial blood gases to guide ventilator management to maintain respiratory compensation.[6]

BOX 139.2 Treatment of Acute Salicylate Poisoning

- Treat dehydration; maintain urine output at 2 to 3 mL/kg/hr.
- Correct potassium depletion with goal serum level of 4.5–5.0 mEq/L.
- Consider oral activated charcoal (AC); 25 grams every 2 to 4 hours for two to four doses if tolerated.
- Alkalinize urine with goal urine pH of 7.5 to 8.0.
  - Infuse bicarbonate drip: 132 to 150 mEq (three 50-mL ampules of 7.5% or 8.4% sodium bicarbonate ($NaHCO_3$) in 1 L of dextrose 5% in water (D5W) + 40 mEq of potassium chloride (KCl) running at 2 to 3 mL/kg/hr.
  - Allow serum pH up to 7.55.
  - Do not attempt forced diuresis.
- Initiate hemodialysis if any of the following occur:
  - Altered mental status, coma, seizure
  - Renal failure
  - Hepatic failure
  - Pulmonary edema or respiratory failure
  - Severe acid-base imbalance (pH <7.1 to 7.2)
  - Deterioration in condition
  - Need for intubation
  - Failure of urine alkalinization
  - Rapidly rising salicylate level
  - Serum salicylate concentration ≥100 mg/dL after acute ingestion
  - Serum salicylate concentration ≥40 mg/dL after chronic ingestion
- Administer intravenous (IV) dextrose 0.5 to 1 g/kg IV for any central nervous system (CNS) abnormalities (altered mental status, coma, agitation, seizure).

Decontamination

Activated charcoal (AC) has been shown to reduce salicylate absorption in both animal studies and human volunteer trials. Evidence in the overdose setting is less clear. We recommend administering multiple-dose oral AC (25 to 50 gm via a nasogastric tube) every 2 to 4 hours for 2 to 4 doses if the patient's GI distress, mental status, and hemodynamic stability can tolerate, because large salicylate ingestions tend to form gastric concretions. AC is not used in chronic salicylate poisoning because the presentation occurs long after absorption from the GI tract.[6]

Enhanced Elimination

Specific treatment of salicylate toxicity has two objectives: (1) to correct fluid deficits and acid-base abnormalities and (2) to increase excretion (Box 139.2). Because salicylates have a low pK_a and are renally excreted, alkaline urine traps the salicylate ion and increases excretion. Urine alkalinization is advisable in patients with salicylate levels greater than 30 mg/dL, significant acid-base disturbance, or increasing salicylate levels. This is most often achieved via administration of a bicarbonate drip: 132 to 150 mEq (three 50 mL ampules) of 7.5% or 8.4% $NaHCO_3$ in 1 L of dextrose 5% in water (D5W) plus 40 mEq

of potassium chloride (KCl) running at 2 to 3 mL/kg/hr. Salicylate clearance varies in direct proportion to renal flow rate but increases exponentially with pH. A urine pH of at least 7.5 to 8.0 is ideal to increase excretion. Urine alkalinization is difficult to achieve because the excretion of salicylic acid in the urine decreases urine pH. In addition, potassium depletion must be corrected to attain alkaline urine as the kidney exchanges hydrogen for potassium in the setting of hypokalemia, further acidifying the urine. In most patients, a serum pH of up to 7.55 is well tolerated. Forced diuresis should not be performed, because it does not significantly increase salicylate excretion and may potentiate fluid overload, as well as cerebral and pulmonary edema.[3,6]

Hemodialysis is highly effective in treating severe salicylate toxicity. It is indicated for patients with any of the following: serum salicylate levels greater than 100 mg/dL in acute and over 40 mg/dL in chronic salicylate poisoning; altered mental status, including coma; seizure; endotracheal intubation (other than for co-ingestions); renal or hepatic failure; pulmonary edema; severe acid-base imbalance (pH <7.1 to 7.2); rapidly rising serum salicylate level; and failure to respond to more standard treatments previously described. Of note, the levels recommended here are the maximum levels permissible for initiation of hemodialysis. Early consultation with nephrology to prepare for hemodialysis should occur prior to reaching a serum salicylate concentration of 100 mg/dL. In one series, over half of peak levels in fatal cases were less than 100 mg/dl. A concentration of 80 mg/dL, or even lower if concentrations are rising rapidly, should prompt nephrology consultation or transfer to a higher level of care with extracorporeal capabilities in anticipation of emergent hemodialysis.[3,5,6,9]

Greater salicylate concentration on the fetal side of the placenta and relative fetal acidemia contribute to fetal distress from maternal salicylate poisoning. Salicylate poisoning during pregnancy is associated with fetal demise, and therefore the mother should be treated expeditiously. Consultation with an obstetrician to facilitate delivery of the distressed fetus in the third trimester of pregnancy is indicated if the fetus is viable.[3]

Antidote Therapy

There is no specific antidote for salicylate toxicity. Central hypoglycemia may be responsible for altered mental status in the setting of salicylate toxicity. In all cases of altered mental status, even in the face of a normal serum glucose measurement, supplemental intravenous (IV) dextrose (0.5 to 1 gm/kg) should be administered. Additional glucose supplementation may be required and should be administered in response to recurrent altered mental status.[6]

In the setting of major bleeding with elevated protime/INR measurements, administer prothrombin complex concentrate along with vitamin K 5 to 10 mg IV. Platelet transfusion may also be helpful in the setting of bleeding to correct irreversible platelet inhibition.

Disposition

In patients with acute intoxication, hospital admission to an intensive care setting is recommended for pulmonary edema, CNS symptoms (other than tinnitus), seizures, pH less than 7.3, electrolyte disorders, dehydration, renal insufficiency, or increasing serum levels during serial testing. In patients with chronic intoxication, low serum salicylate concentrations (40 mg/dL) may accompany severe salicylism. These patients should be admitted to a monitored setting for observation, serial serum levels, and metabolic assessment. Consultation with a medical toxicologist may allow for emergency department (ED) observation management of the salicylate poisoned patient not requiring hemodialysis.

In patients with acute ingestion, repeated serum salicylate measurements are essential to determine that the serum concentration is decreasing before the patient is discharged. Serum salicylate levels should be repeated every 2 hours until three consecutive levels are both less than 30 mg/dL and decreasing by at least 10% to 20% on each measurement when no longer undergoing therapy to enhance elimination. In addition, the patient should not be symptomatic (aside from residual tinnitus) at the time of discharge. With any case of intentional overdose, psychiatric evaluation is recommended.[3,6]

NONSTEROIDAL AGENTS

Principles of Toxicity

The nonsteroidal antiinflammatory drugs (NSAIDs) have analgesic, antiinflammatory, and antipyretic activities. Ibuprofen and naproxen, both propionic acid derivatives, are available over the counter in the United States and are the most commonly encountered NSAIDs. The therapeutic antiinflammatory effect of the NSAIDs is achieved by inhibition of cyclooxygenase (COX) and consequent blockade of prostaglandin production.[10]

NSAIDs are almost completely absorbed from the upper small intestine after oral administration. NSAIDs are highly bound to plasma proteins and therefore have small volumes of distribution (0.10 to 0.17 L/kg). They are eliminated by hepatic biotransformation. Metabolites are typically inactive with the notable exception of phenylbutazone. Plasma half-lives are relatively short (1 to 4 hours), except for naproxen (12 to 15 hours), oxaprozin (25 to 50 hours), piroxicam (45 hours), and phenylbutazone (50 to 100 hours). Elimination half-lives are not substantially prolonged in overdose.[11]

Clinical Features

Most NSAID overdoses are asymptomatic or cause only minor gastrointestinal symptoms. Ibuprofen is the most common NSAID ingested in overdose. Such exposures typically follow a benign, self-limited course. Symptomatic overdose occurs only after ingestion of at least 100 mg/kg, and symptoms develop within 4 hours of ingestion. Life-threatening toxicity is rare with most cases limited to mild GI disturbance that resolves in hours. Less common clinical effects include metabolic acidosis, muscle fasciculations, mydriasis, diaphoresis, hyperventilation, bradycardia, hypotension, dyspnea, tinnitus, and rash. Rare cases of coma, seizure, hypotension, and metabolic acidosis have been reported in acute massive overdoses (>400–500 mg/kg).[11]

Renal dysfunction is seen only after large acute overdose and in association with a period of relative hypovolemia with hypotension. It is usually reversible and generally responds to supportive measures. There are sporadic cases of acute liver injury with a predominantly hepatocellular pattern. This occurs both in therapeutic and supratherapeutic NSAID exposure. Diclofenac was the most common agent identified in a North American acute liver injury registry whereas nimesulide presented the highest risk. Both ibuprofen and ketoprofen were also identified as culprits in a European study.[12,13]

All propionic acid derivatives have been associated with sporadic cases of aseptic meningitis. This complication is most common with ibuprofen. It occurs in an idiosyncratic fashion—both in overdose and with therapeutic dosing.

Mefenamic acid, a fenamate, is associated with a high rate of CNS toxicity in overdose compared to other NSAIDS. In particular, there is a high incidence of seizures, which occur 2 to 8 hours after supratherapeutic ingestion. Rapid recovery is the rule with supportive care and IV doses of benzodiazepines administered in the case of seizure activity.[14]

Phenylbutazone, a pyrazolone, is now rarely prescribed because of its association with aplastic anemia and agranulocytosis. Although phenylbutazone overdose is rare, the course is much more severe than with other NSAIDs. Severely poisoned patients have early onset of GI

distress, coma, seizure, hyperthermia, hyperventilation, alkalosis or acidosis, hypotension, electrocardiographic abnormalities, or cardiac arrest. Late sequelae of severe poisoning (2 to 7 days) include renal, hepatic, and hematologic dysfunction. The clinical course is prolonged compared with that of other NSAID poisonings, reflecting the long elimination half-lives of phenylbutazone and its principal metabolite, oxyphenbutazone.

Differential Diagnoses

Given that NSAID overdoses rarely cause substantial morbidity and are almost never fatal, the differential diagnosis should focus on toxicity due to possible co-ingestions. Patients often confuse NSAIDs with other pain relievers and fever reducers, including acetaminophen and salicylates. Other over-the-counter medications that can cause GI distress include iron preparations, vitamins, herbal supplements, as well as acetaminophen and salicylates.

Diagnostic Testing

Plasma NSAID concentrations are not clinically useful and are rarely available in the ED. With larger overdoses (>100 mg/kg), a complete blood count, metabolic profile, and assessment of renal function are recommended. Because patients often confuse and mix pain relievers, screening serum acetaminophen and salicylate levels are also recommended.

Management

Stabilization and Supportive Care

The management of NSAID overdose is largely supportive, and there is no specific antidote. Pyrazolone (e.g., phenylbutazone) and fenamate (e.g., mefenamic acid) toxicity is associated with significantly higher morbidity and may require more supportive care measures, including control of seizures with benzodiazepines, crystalloid fluid resuscitation, correction of electrolyte disturbances, and ventilatory support. Hypotension is managed with a 1 to 2 L bolus of normal saline or lactated Ringer solution, which may be repeated or supported by infusions at two to three times maintenance rate. If perfusion compromise persists, initiate a vasopressor, such as norepinephrine, and titrate to maintain an adequate mean arterial pressure for perfusion. Although it is rarely indicated and understudied, extracorporeal membrane oxygenation (ECMO) has been used to successfully manage refractory hypotension after massive ibuprofen overdose.

Decontamination

There is no evidence supporting the use of gastric emptying, AC or whole bowel irrigation in NSAID overdoses.

Enhanced Elimination

Because of high protein binding and rapid metabolism, enhanced elimination is not useful in most cases. In the rare case of a massive overdose (>400–500 mg/kg) with pH less than 7.1, hemodialysis should be considered to correct acidemia. Consultation with a nephrologist or transfer to a facility capable of emergently dialyzing the patient is indicated. In this situation, hemodialysis may also remove the free drug once protein binding is overwhelmed. Plasmapheresis has been attempted in severe phenylbutazone poisoning.

Antidote Therapy

There is no specific antidote for NSAID poisoning.

Disposition

Patients who are mildly symptomatic or asymptomatic for more than 4 hours after an NSAID overdose do not require further medical care. Patients who have ingested a pyrazolone or fenamate require observation for possible seizures for 8 to 12 hours after ingestion. Those with CNS symptoms, acidosis, or renal insufficiency and who require further supportive care should be admitted for ongoing treatment. Patients with mild to moderate symptoms may be observed in the ED until they are asymptomatic or improving. Patients for whom the ingestion represents a suicidal gesture should undergo psychiatric assessment.

CHAPTER 139: QUESTIONS AND ANSWERS

1. What type of acid-base disorder is caused by salicylate overdose?
- **a.** Metabolic acidosis and respiratory acidosis
- **b.** Metabolic acidosis and respiratory alkalosis
- **c.** Metabolic alkalosis and respiratory acidosis
- **d.** Metabolic alkalosis and respiratory alkalosis
- **e.** No acid-base disorder

Answer: B. Early in overdose, salicylates stimulate the respiratory center, causing hyperventilation and a respiratory alkalosis. Later, salicylates inhibit mitochondrial oxidative phosphorylation, resulting in anaerobic metabolism and a metabolic acidosis. This is the classic situation but is later followed by respiratory compensation, resulting in the possibility of a triple acid-base disorder.

2. A 22-year-old man presents 6 hours after an aspirin overdose in an attempt to commit suicide. His only complaint is of tinnitus, and his vital signs and physical examination are normal. His salicylate level is 47 mg/dL. His serum pH is 7.3, with an anion gap of 18 and a serum bicarbonate level of 17 mmol/L. Which of the following is the most appropriate therapy?
- **a.** Forced diuresis
- **b.** Hemodialysis
- **c.** Observation only
- **d.** Oral activated charcoal due to chronic poisoning
- **e.** Urinary alkalinization

Answer: E. Salicylates are acidic compounds and therefore readily ionize in an alkali environment. Only in the nonionized state can they traverse cell membranes. Thus, once ionized in the urine, they are effectively "trapped" and can be easily excreted. Urinary alkalinization is indicated in patients with a salicylate level greater than 30 mg/dL, significant acid-base disturbances, or increasing salicylate levels. Forced diuresis does not increase excretion, increases the risk for pulmonary and cerebral edema, and is never indicated. Hemodialysis is the ultimate treatment for salicylate poisoning but is generally reserved for patients with more severe signs or symptoms, more severe acid-base disturbances, or acute salicylate levels greater than 100 mg/dL. Observation alone would be indicated in a patient with a history of salicylate overdose but with no symptoms and normal laboratory values. AC can decrease the amount of salicylate absorbed if given within 1 hour of ingestion. Because large salicylate ingestions tend to form gastric concretions, multiple doses of AC may be indicated. AC is not used in chronic salicylate poisoning because the presentation occurs long after gastrointestinal absorption.

3. Which of the following patients does not require hemodialysis?
- **a.** A 9-year-old boy with acute salicylate ingestion and an initial salicylate level of 30 mg/dL
- **b.** A 20-year-old pregnant woman with acute salicylate overdose and an initial salicylate level of 100 mg/dL
- **c.** A 24-year-old man with acute salicylate overdose and salicylate level of 110 mg/dL despite urinary alkalinization
- **d.** A 30-year-old woman with chronic salicylate ingestion and salicylate level of 50 mg/dL
- **e.** A 42-year-old woman with acute salicylate overdose and salicylate level that has risen from 50 to 90 mg/dL despite urinary alkalinization

Answer: A. Indications for hemodialysis in the setting of salicylate toxicity include levels of 100 mg/dl or greater in an acute overdose, a rising level reaching values at or above 80 mg/dl despite urinary alkalinization in an acute overdose, or a level greater than 40 mg/dl in the setting of chronic toxicity. Fetal distress is associated with salicylate toxicity, although recommended salicylate concentration thresholds for hemodialysis are not different than the general population. Rather, discussion with obstetrics regarding emergent delivery should occur if the mother presents in the third trimester of pregnancy.

4. A 41-year-old man presents after an intentional ibuprofen overdose. He complains of epigastric pain, nausea, and one episode of vomiting. He reports that approximately 2 hours ago he took "a handful" of 200-mg ibuprofen tablets in a self-harm attempt. Which of the following is the appropriate next step?
- **a.** Hemodialysis
- **b.** Check serum acetaminophen and salicylate levels
- **c.** Observation for resolution of symptoms
- **d.** Oral activated charcoal (AC)
- **e.** Urinary alkalinization

Answer: B. Oftentimes, patients are unable to differentiate various over-the-counter analgesics. Obtaining salicylate and acetaminophen concentrations in the setting of a reported ibuprofen overdose is essential because occult toxicity due to those compounds may be life-threatening

CHAPTER 139: QUESTIONS AND ANSWERS—cont'd.

whereas nonsteroidal antiinflammatory drugs (NSAIDs) are generally safe in overdose. Specifically, ibuprofen overdose often results in mild self-limited gastrointestinal (GI) upset. Typically, at least 100 mg/kg of ibuprofen needs to be ingested to cause symptoms. All symptoms are treated with supportive care. Symptoms almost always develop within 4 hours of ingestion. In general, patients may be discharged in cases of small overdoses (<100 mg/kg), once symptoms resolve or after a 4-hour period of observation.

140

Anticholinergics

Jason A. Hoppe and Andrew A. Monte

KEY CONCEPTS

- Anticholinergic (antimuscarinic) intoxication is common and can occur as a result of ingestion of a variety of plants and drugs, both prescription and over-the-counter.
- Most patients with antimuscarinic toxicity do well with supportive care and observation.
- Antimuscarinic syndrome varies in clinical presentation with either peripheral or central manifestations predominating.
- Central antimuscarinic delirium is most effectively treated with physostigmine.
- Contraindications to physostigmine administration include narrow angle glaucoma, atrioventricular (AV) blockade, bradycardia, and seizure precipitated by overdose.

PRINCIPLES OF TOXICOLOGY

Overview

Anticholinergic agents cause toxicity through inhibition of muscarinic, nicotinic, parasympathetic, or sympathetic acetylcholine receptors. Nicotinic receptor inhibition and ganglionic acetylcholine inhibition at parasympathetic and sympathetic locations are covered in Chapter 152. This chapter will focus on antimuscarinic effects and toxicity. The terms *anticholinergic* and *antimuscarinic* are used synonymously though the mechanism of toxicity is more accurately described by the term "antimuscarinic," and thus that term will be used in this chapter.

Antimuscarinic effects are due to competitive inhibition of acetylcholine at muscarinic receptors. Muscarinic receptors are found on peripheral postganglionic cholinergic nerves in smooth muscle (intestinal, bronchial, and cardiac), the secretory glands (salivary and sweat), the ciliary body of the eye, and the central nervous system (CNS).

Antimuscarinic agents have been used medicinally from antiquity to the present day. Mandrake plant remains were found in the coffin of Tutankhamen, the Old Testament of the Bible references its use as an aphrodisiac, and antimuscarinic plants were used as anesthetics in Greek and Roman settlements in the 1st century. Atropine, hyoscyamine, and scopolamine are naturally occurring tertiary amine antimuscarinic agents that remain in wide clinical use today. The tertiary amine structure allows the agent to cross the blood-brain barrier; therefore, these agents may precipitate CNS toxicity. Quaternary amine antimuscarinic agents, such as the anti-sialagogue glycopyrrolate, have been developed to mitigate CNS side effects due to their limited ability to cross the blood-brain barrier, though mild delirium may occur in the setting of a large overdose.

CLINICAL FEATURES

Over 600 compounds contain antimuscarinic activity, including prescription drugs, over-the-counter drugs, and plants. The effects of muscarinic receptor blockade are utilized for clinical purposes including pupillary dilation, antispasmodics, sleep aids, treatment of motion sickness, allergic reactions, drying of airway secretions, reactive airway disease, treatment of bradycardia, treatment of Parkinsonism, and the management of urinary incontinence and bladder spasm. The agents that most commonly precipitate antimuscarinic toxicity, such as H1 antihistamines and some antipsychotics, often affect several neurotransmitters and receptor systems in addition to antagonism at muscarinic receptors. This may complicate the clinical presentation and some clinical symptoms may be unique to the specific etiologic agent (Box 140.1).

Antimuscarinic toxicity has both central and peripheral manifestations (Fig. 140.1). Peripheral muscarinic antagonism causes tachycardia, hypertension, hyperthermia, mydriasis, dry mouth, lack of sweating, skin flushing, decreased bowel motility, and urinary retention. Central nervous system blockade of muscarinic receptors may produce delirium characterized by confusion, mumbling speech, agitation, hallucinations, hand picking gestures, myoclonus, tremor, and coma. Manifestations of the toxidrome are frequently incomplete and either peripheral or central components may predominate depending upon which antimuscarinic agent is involved, the dose, and the individual patient (Table 140.1). In one large series of antimuscarinic poisoning, only 28% of patients had all three classic manifestations of tachycardia, dry skin/axilla, and mydriasis. Therefore, most patients will not present with all of these features.[1] Duration of toxicity may be prolonged (18–72 hours) depending on the specific agent, dose, and the pharmacologic effect of delayed gastric emptying.[1]

DIFFERENTIAL DIAGNOSES

The differential diagnosis of altered mental status is broad. Consider antimuscarinic toxicity when there is a history of exposure or if there are physical exam findings consistent with the antimuscarinic toxidrome (Box 140.2).

DIAGNOSTIC TESTING

Laboratory

Patients with mild toxicity, a reliable history of exposure, and symptoms consistent with antimuscarinic toxicity do not require specific laboratory testing. Patients with an unclear history of exposure, other potential etiologies, moderate to severe toxicity or hyperthermia should be evaluated for causes of altered mental status and end-organ toxicity including: serum glucose, electrolytes, cardiac biomarkers, renal function, creatinine kinase to evaluate for rhabdomyolysis, and acid-base status. Patients with an overdose of unclear history should be evaluated for co-ingestion since antimuscarinic agents are often formulated with other potentially toxic agents. Serum acetaminophen and

salicylate levels should be measured. Physostigmine may be used as a diagnostic test (see section on management).

Electrocardiogram

An electrocardiogram (ECG) should be obtained in cases of suspected tricyclic antidepressant or diphenhydramine toxicity to assess for possible sodium channel blockade (widened QRS interval > 120 ms or terminal R wave in lead aVR > 3 mm). Prior to the use of physostigmine, an ECG should be reviewed for bradycardia or atrioventricular (AV) block which would preclude the use of the antidote.

BOX 140.1 Signs and Symptoms of Antimuscarinic Toxicity

Mydriasis: "blind as a bat"
Altered mental status: "mad as a hatter"
Dry mucous membranes: "dry as a bone"
Dry, flushed skin: "red as a beet"
Hyperthermia: "hot as hades"
Urinary retention: "full as a flask"
Decreased bowel sounds/ileus
Tachycardia

MANAGEMENT

Stabilization

Initial management should focus on evaluation and stabilization of cardiovascular and neurologic toxicity. Sodium bicarbonate boluses of 50 mEq (1 amp) in adults and 1 to 2 mEq/kg in children should be given for evidence of sodium channel blockade with a QRS interval greater than 120 msec. Benzodiazepines should be considered for treatment of agitation and recurrent seizures. Patients with drug-induced hyperthermia should be treated with rapid cooling with progression to paralysis, ventilation and airway control, with sedation, when noninvasive cooling measures fail.

Decontamination

Most patients do well with symptomatic care alone. Gastric decontamination with activated charcoal may be considered though the risk of aspiration due to CNS depression or seizures generally outweigh the benefits. Activated charcoal may decrease ongoing absorption in patients that have ingested antimuscarinic plants or patients with decreased gastric motility. Theoretically this may decrease symptom duration. If considered, activated charcoal should only be administered early in the clinical course in awake, cooperative patients with a low risk of seizures or aspiration. There is little role for gastric lavage in antimuscarinic poisoned patients. There is no role for dialysis.

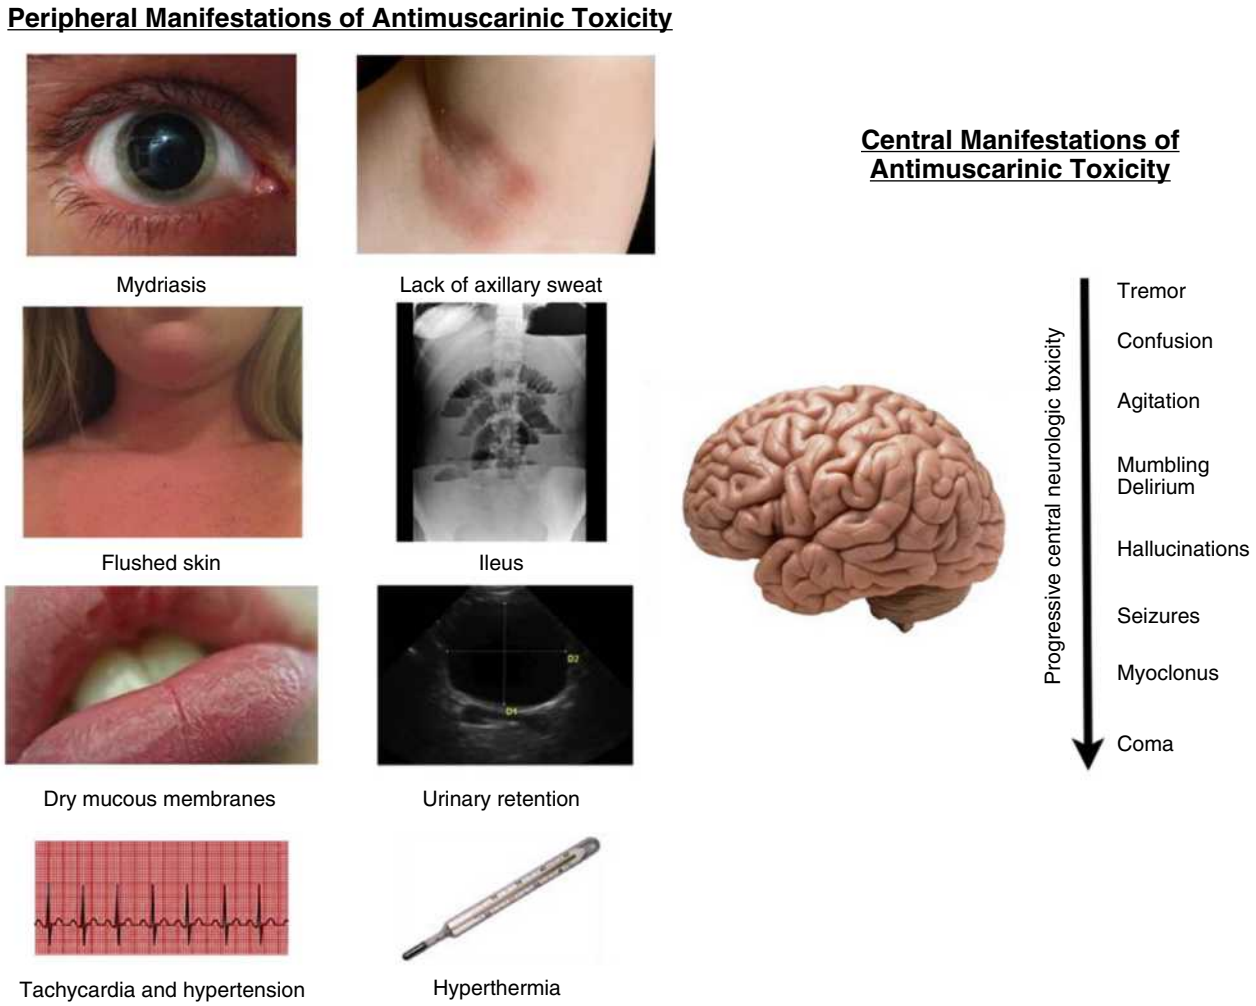

Fig. 140.1 Signs and symptoms of antimuscarinic toxicity.

TABLE 140.1 Specific Antimuscarinic Agents and Their Unique Clinical Manifestations

Antimuscarinic Agent	Toxic Dose	Unique Clinical Manifestations and Receptors Antagonized.
Datura spp.	Seeds contain high concentrations of hyoscyamine and scopolamine. The toxic dose depends upon the species and the mode of ingestion. In general 5 to 10 seeds may be toxic.	Classic peripheral and central antimuscarinic features M_1
Diphenhydramine	2.5 mg/kg, >10 mg/kg may result in cardiovascular and neurologic toxicity	CNS depression, QRS prolongation and ventricular dysrhythmias, seizures M_1, H_1, Na^+ channels
Doxylamine	>20 mg/kg associated with rhabdomyolysis	CNS depression, seizures, rhabdomyolysis M_1, H_1
Tricyclic antidepressants (TCA)	2.5 mg/kg, >10 mg/kg may result in cardiovascular and neurologic toxicity.	CNS depression, QRS prolongation, ventricular dysrhythmias, seizures, hypotension, antimuscarinic symptoms may manifest late in the course. M_1, H_1, α_1, Na^+ channels
Atypical antipsychotics	Varies depending upon agent.	CNS depression, hypotension, antimuscarinic symptoms may manifest late in the course. M_1, H_1, α_1, D_2, $5\text{-}HT_{2A}$

M_1, Muscarinic; D_2, dopamine; $5\text{-}HT_{2A}$, serotonin; H_1, histamine; α_1, alpha adrenergic.

BOX 140.2 Common Differential Considerations With Overlapping Signs and Symptoms of Antimuscarinic Toxicity

Differential Diagnosis Considerations

Toxicological

Sympathomimetic toxicity
Serotonin toxicity
Neuroleptic malignant syndrome
Lithium toxicity
Antidepressant toxicity
Antipsychotic toxicity

Central Nervous System

Intracranial hemorrhage
Seizure
Infectious
Sepsis
CNS infections

Metabolic

Hyperthyroid
Encephalopathy
Psychiatric
Delirium
Dementia
Bipolar disorder

BOX 140.3 Antimuscarinic Reversal Agent: Physostigmine

Physostigmine Salicylate

Indications: Diagnosis and treatment of antimuscarinic toxicity.
Contraindications: narrow angle glaucoma, AV blockade, bradycardia, and seizures due to current overdose.
Adverse effects: bradycardia, seizure, vomiting
Route: IV or IM.
Kinetics/dynamics: Time of onset: within 5 to 10 minutes following IV administration, 20 to 30 minutes following IM administration. Half-life: 16 ±3 minutes. Plasma cholinesterase inhibition 84 ±5 minutes.
Adult dosing: 1 to 2 mg bolus slowly (no faster than 1 mg/min). Start infusion at 1 mg/hour titrated every 30 minutes to clinical effect. Pediatric dose: 0.02 mg/kg (max 0.5 mg/dose) IV over 5 min, repeat every 5 min PRN (max total dose: 2 mg)

Pharmacologic Intervention and Antidote Treatment

Control of delirium is the most common reason for emergency intervention in antimuscarinic poisoned patients. Sedation or antidotal treatment should be considered in patients whose delirium places them at risk of physical harm; falling out of bed, becoming combative with staff, need for physical restraints, or pulling out intravenous (IV) access necessary for treatment. Sedation can be accomplished with IV benzodiazepines, such as lorazepam (0.05–0.1 mg/kg), midazolam (0.05–0.1 mg/kg), or diazepam (0.1–0.5 mg/kg), titrated every 15 minutes to sedation. However, benzodiazepines are inferior to physostigmine for control of delirium and agitation.[1]

Physostigmine salicylate is the antidote for antimuscarinic toxicity. It may be used for diagnostic and therapeutic purposes (see Box 140.3 for indications, contraindications, and dosing). Physostigmine is a tertiary amine carbamate that reversibly inhibits cholinesterases in both peripheral and central nervous systems.[1] This allows for acetylcholine accumulation and subsequent competition with the antimuscarinic blocking agent occupying the receptor. It has a short half-life, approximately 20 minutes,[1] though inhibition of the esterase, which yields the pharmacodynamic effects, lasts considerably longer with a half-life of 80 minutes.

When used diagnostically in an antimuscarinic poisoned patient, a response is expected rapidly, within 10 minutes. Near complete reversal of delirium is expected in a matter of minutes and may decrease the need for more invasive testing, such as lumbar punctures (to exclude meningitis) or neuroimaging. Therefore, if antimuscarinic poisoning

is considered, appropriate doses of physostigmine may be considered early in the course.

Physostigmine may be used for treatment of delirium. Multiple observational studies have found that patients with antimuscarinic poisoning have delirium controlled with physostigmine in a large proportion of cases, 79% to 96%.[2-4] Further, benzodiazepines controlled agitation in only 24%, were ineffective for reversal of delirium in antimuscarinic poisoned patients, and were associated with a longer time to recovery.[1] A prospective observational study of 154 poisoned patients reported the odds of delirium control with physostigmine were six times greater than non-antidotal treatment.[3] Importantly, a retrospective study of 1815 patients with antimuscarinic toxicity within a clinical toxicology registry found a significantly decreased rate of intubation (1.9% versus 8.4%, OR 0.21) with physostigmine alone when compared to other treatments.[4]

Repeat dosing of physostigmine may be necessary in severely symptomatic patients. In case series of patients with antimuscarinic poisoning receiving the antidote, 30% to 39% needed re-dosing within 5.5 hours and the longest time between the first and last dose was 6.5 hours.[5] This suggests patients that remain asymptomatic beyond 6.5 hours are unlikely to have recurrence of symptoms. Severely poisoned patients requiring frequent re-dosing, such as *Datura stramonium* poisoned patients, may benefit from an infusion of the antidote. We recommend that the dose for the intravenous infusion be the same dose required for reversal of delirium, given per hour. The infusion should be stopped every 4 to 6 hours to reevaluate for ongoing need of the antidote.

Adverse drug events associated with physostigmine are manifestations of excess acetylcholine at neuromuscular junctions and thus can approximate cholinergic poisoning.[5] Symptoms may include salivation, nausea, vomiting, diarrhea, bradycardia, bronchospasm, muscular weakness, or seizures.[2,5] Physostigmine use in antimuscarinic patients is associated with very low rates of adverse events (5% to 9%), with serious events attributable to the underlying overdose, rather than the antidote.[2,5] However, it is advisable to avoid physostigmine in patients who have had a seizure temporally related to the overdose. Adverse drug events may be more common in antimuscarinic poisoned patients treated with benzodiazepines compared with physostigmine, largely due to airway complications secondary to respiratory depression associated with high-dose benzodiazepines.

Physostigmine has traditionally been contraindicated in patients with tricyclic antidepressant (TCA) overdose. This is based on a few well-publicized case reports that subsequently discouraged use of the antidote. The consistent ECG manifestations in these cases were AV blockade and bradycardia. The role of physostigmine as an etiology of the subsequent cardiac dysrhythmias has been questioned given that tricyclic antidepressants have inherent cardiac toxicity. Many patients in case series examining the safety and efficacy of physostigmine were found to have ingested TCAs.[2,3] This suggests that the antidote may be used safely when tricyclic antidepressant toxicity is manifested as antimuscarinic delirium, which occurs at low doses or late in the course. We, however, do not recommend use of physostigmine in the treatment of acutely TCA poisoned patients with cardiovascular toxicity. Use of the antidote should be avoided in overdosed patients with bradycardia or AV block.

Overall, physostigmine should be considered as a safe diagnostic and therapeutic intervention in patients with antimuscarinic toxicity without overdose-induced seizure, AV blockade, or bradycardia, especially when the antimuscarinic-induced delirium places the patient or staff at risk.

DISPOSITION

Most patients do improve with supportive care alone (sedation, hydration, temperature control, and observation). Length of observation and need for admission depend on the agent, the dose, the intent, and the patient. Antimuscarinic agents slow gut motility, which increases the time to peak symptoms. As such, long-acting agents, plant seeds, or large ingestions should be considered for extended observation of up to 24 hours even if asymptomatic. Patients at extremes of age are at increased risk for toxicity and should be considered for observation over a similar period of time. Patients with an unreliable history or concern for self-harm should have extended observation and psychiatric consultation.

Observation at Home

Asymptomatic reliable patients with low-dose accidental exposures are safe to be observed at home by a trustworthy adult.

Emergency Department Observation

Patients with mild toxicity, normal mental status, normal vital signs, and small ingestions can potentially go directly home or may be observed in the ED for 4 to 6 hours for resolution of symptoms.

Hospital Admission

Patients with large ingestions or moderate toxicity (abnormal vital signs, altered mental status) should be observed for progression of toxicity or until symptoms improve. Ingestion of large amounts of pills or plant seeds should be expected to require prolonged observation (up to 24 hours) due to decreased gastrointestinal motility.

ICU Admission

Patients with agitated delirium, hyperthermia, dysrhythmia or seizures will benefit from intensive care unit admission for monitoring, redosing of reversal agents, and airway control if high doses of sedatives or additional physostigmine administration is necessary.

Consultations

Medical toxicology or poison center consultation should be considered when there are questions about exposure, diagnosis, or the appropriateness of antidotal therapy.

CHAPTER 140: QUESTIONS AND ANSWERS

1. A 21-year-old man presents after drinking an "herbal tea" with some friends. He reports visual hallucinations. He has a resting tachycardia and a mildly elevated temperature. On physical examination, he is noted to have dry mucous membranes, dry and flushed skin, and absent bowel sounds. In addition to certain plants, which of the following medications can also cause these symptoms?

a. Amiodarone
b. Clonidine
c. Diphenhydramine
d. Lidocaine
e. Morphine

Answer: C. This patient is experiencing the antimuscarinic toxidrome. In addition to the signs and symptoms described here, patients may also have mydriasis and bladder distention. Mental status can be agitated or depressed. Myoclonus or choreoathetoid movements can also be seen. Amiodarone can cause hypothyroidism or hyperthyroidism and skin discoloration, as well as several other long-term effects. Clonidine can cause dry mouth, drowsiness, bradycardia, and hypotension. Lidocaine can cause headaches, dizziness, confusion, tinnitus, and tremor, as well as bradycardia and hypotension. Morphine can cause respiratory cerebral depression, as well as miosis, bradycardia, and hypotension.

2. Many signs and symptoms of the antimuscarinic syndrome are similar to those of other toxic syndromes, including the sympathomimetic syndrome, serotonin syndrome, and neuroleptic malignant syndrome. Which of the following antimuscarinic findings is most likely to distinguish the antimuscarinic syndrome from the other syndromes listed?

a. Altered mental status
b. Altered movements
c. Dry skin
d. Fever
e. Mydriasis

Answer: C. All the other syndromes often have some degree of diaphoresis. Hyperthermia, altered mental status, and mydriasis can occur in all the named syndromes. Myoclonus can occur in the antimuscarinic syndrome, tremor in the serotonin syndrome, and rigidity in the neuroleptic malignant syndrome.

3. A 31-year-old woman presents with altered mental status after ingesting an unknown quantity of an unknown medication. Her vital signs are significant for tachycardia and hyperthermia. Her physical examination reveals mydriasis, dry mucous membranes, dry skin, decreased bowel sounds, and hypotension. Her electrocardiogram (ECG) reveals a wide QRS complex, at 130 msec, and prolonged QT interval. Which of the following medications is associated with this toxidrome?

a. Amitriptyline
b. Dextroamphetamine
c. Diphenhydramine
d. Fluoxetine
e. Lithium

Answer: A. This patient is experiencing many of the signs and symptoms of antimuscarinic syndrome. However, pure antimuscarinics rarely if ever cause cardiac dysrhythmias (other than sinus tachycardia). Tricyclic antidepressants (TCAs) frequently cause antimuscarinic signs and symptoms but also cause dysrhythmias. Although selective serotonin reuptake inhibitors, stimulants, and lithium can all cause similar signs and symptoms, electrocardiographic abnormalities such as those described here are rare.

4. Which diagnostic test should be performed in almost all patients presenting with the antimuscarinic syndrome?

a. Arterial blood gas analysis
b. Computed tomography (CT) scan of the brain
c. Electrocardiography
d. Electroencephalography
e. Urine drug screen

Answer: C. Patients with a clear presentation and mild symptoms do not necessarily require any diagnostic evaluation. However, patients with more severe symptoms should have measurements of serum electrolytes, renal function, creatine kinase, and glucose concentration performed. Electrocardiography is most helpful because cyclic antidepressants are a common cause of antimuscarinic symptoms and can cause fatal cardiac dysrhythmias. Arterial blood gas analysis might be helpful if the patient has respiratory depression. Head CT might be indicated in patients with altered mental status of unknown cause. Electroencephalography would be indicated only if there is a suspicion of unrecognized seizures. Urine drug screens are almost never helpful in determining treatment, especially in the case of antimuscarinic syndrome because they will not detect most of the medications responsible for this syndrome.

5. What is the best initial treatment of hyperthermia in patients with antimuscarinic syndrome?

a. Acetaminophen
b. Cooling blankets
c. Dantrolene
d. Evaporative cooling
e. Physical restraints

Answer: D. Evaporative cooling is the most effective and noninvasive way to decrease temperature. Death has occurred because of untreated hyperthermia in patients with antimuscarinic syndrome. Antipyretics such as acetaminophen are ineffective at reducing temperature because hyperthermia is not "fever." Dantrolene is useful in malignant hyperthermia but has no role in hyperthermia of other causes. Cooling blankets are ineffective. Physical restraints are likely to worsen the problem and to increase the risk of rhabdomyolysis and myoglobinuric renal failure. If a patient is dangerously agitated from antimuscarinic toxicity, physostigmine is the agent of choice to decrease agitation, muscle activity, and related metabolic activity that contribute to hyperthermia.

CHAPTER 140: QUESTIONS AND ANSWERS—cont'd

6. Which of the following medications crosses the blood-brain barrier and is potentially useful in the treatment of antimuscarinic syndrome?

a. Edrophonium
b. Metoclopramide
c. Neostigmine
d. Physostigmine
e. Pyridostigmine

Answer: D. Metoclopramide is an antiemetic and prokinetic medication that has no role in antimuscarinic syndrome. All of the other agents are acetylcholinesterase inhibitors, but only physostigmine crosses the blood-brain barrier and so it is the only drug that can reverse the central and peripheral effects of antimuscarinic medications. However, physostigmine can cause cardiac dysrhythmias and thus should be used carefully in patients with bradycardia or AV block.

7. Which of the following is a contraindication to physostigmine use in a patient with antimuscarinic syndrome?

a. Altered mental status
b. Bradycardia and atrioventricular (AV) blockade
c. Coexisting myasthenia gravis
d. Hyperthermia
e. Bladder distention and urinary retention

Answer: B. Physostigmine is an acetylcholinesterase inhibitor that is useful to reverse the effects of antimuscarinic medications. However, it is contradicted with narrow angle glaucoma, AV blockade, bradycardia, and seizures due to the causal overdose. The main benefit of physostigmine is to reverse the altered mental status and agitation caused by the antimuscarinic medication. Physostigmine is occasionally used to treat myasthenia gravis. Hyperthermia and urinary retention can occur as symptoms of the antimuscarinic syndrome, and although neither is directly treated with physostigmine, they are not a contraindication to its use.

Antidepressants

Michael D. Levine and Anne-Michelle Ruha

KEY CONCEPTS

- Although rarely used for depression, MAOIs are used in the treatment of Parkinson disease.
- Because serious symptoms can occur after a lengthy latent period, patients with reported MAOI overdose should be admitted for 24 hours, regardless of symptoms. Toxicity is characterized by tachycardia, hypertension, and CNS changes, and later cardiovascular collapse.
- The primary manifestations of TCA toxicity are seizures, tachycardia, hypotension, and intraventricular conduction delay. IV sodium bicarbonate should be administered for QRS prolongation.
- SSRIs are relatively benign in overdose and generally managed with supportive care alone.
- SNRI ingestions can result in seizures, tachycardia, and occasionally intraventricular conduction delay.
- The hallmark feature of serotonin syndrome is lower extremity rigidity with spontaneous or inducible clonus, especially at the ankles.
- Serotonin syndrome is primarily treated with supportive care, including discontinuation of the offending agent, and benzodiazepines.

PRINCIPLES OF TOXICITY

Depression is one of the most common medical conditions in the United States and is associated with significant morbidity. Worldwide, depression is the third leading cause of disability.[1] Whereas many treatment strategies are used in the management of depressed patients, pharmacotherapy remains a cornerstone of modern practice. Modern antidepressant therapy hinges on the monoamine hypothesis, which suggests that depressive symptoms are mediated through an imbalance of the dopaminergic, noradrenergic, and serotonergic systems.[1] Consequently, numerous antidepressant classes have emerged in an attempt to increase synaptic monoamine concentrations.

In the early 1950s, isoniazid and iproniazid were introduced for the treatment of tuberculosis. Shortly after, it was noted that these patients had improved mood, which was attributed to the ability of iproniazid to inhibit monoamine oxidase (MAO). Iproniazid subsequently became one of the first drugs used specifically as an antidepressant.[2] This led to the advent of other monoamine oxidase inhibitors (MAOIs). In 1956, the antidepressant effect of imipramine, a tricyclic agent, was recognized, and it was marketed the following year. The MAOIs and tricyclic antidepressants (TCAs) became the mainstay for treatment of depression for several decades until the advent of the safer selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs).

The morbidity of antidepressants in overdose varies greatly by specific class. Overall, however, there were more than 132,000 overdoses on antidepressants reported to United States poison control centers in 2017. Despite representing only 5.2% of calls, they accounted for 9.4% of fatalities.[3]

MONOAMINE OXIDASE INHIBITORS

MAO is located on the outer mitochondrial membrane and is responsible for breakdown of cytoplasmic catecholamines. Monoamine oxidase type A (MAO-A) primarily deaminates serotonin and norepinephrine; monoamine oxidase type B (MAO-B) primarily deaminates phenylethylamine.[2] Tyramine and dopamine are metabolized equally by both isoenzymes.[2] Whereas most tissues contain both isozymes, MAO-A is primarily found in the placenta, sympathetic nerve terminals, and intestinal mucosa; MAO-B is found primarily in platelets and the basal ganglia.

Drugs targeting the MAO system can act as specific or nonspecific inhibitors. The first-generation MAOIs are nonselective and irreversible. Drugs belonging to this class include phenelzine, isocarboxazid, and tranylcypromine. The second-generation MAOIs can preferentially inhibit either MAO-A or MAO-B.

MAOIs have fallen out of favor for treatment of depression due to side effects from adverse drug and food interactions. However, their use in treatment of Parkinson disease is increasing.

Drugs that selectively inhibit MAO-B disproportionately increase dopamine concentrations in the striatum.[2] Selegiline is an irreversible MAO-B inhibitor used in the treatment of Parkinson disease. Importantly, the selectivity for MAO-B is only present at low doses.[4]

Rasagiline is also an irreversible inhibitor of MAO-B and has similar clinical efficacy as selegiline.[5] Furthermore, unlike selegiline, which is metabolized to L-methamphetamine, rasagiline is not metabolized to an amphetamine derivative. Table 141.1 summarizes the MAO-inhibitors currently available for use in the United States. In addition to its antibiotic properties, linezolid, an oxazolidinone class antibiotic, is a reversible inhibitor of MAO, producing significant inhibition of MAO-A.

As a class, MAOIs are rapidly absorbed from the gastrointestinal tract and are bound extensively to plasma proteins. With overdose, the MAOIs initially stimulate release of neurotransmitters from the presynaptic neuron but later inhibit their release.

Clinical Features

Patients may develop toxicity from an MAOI either as a result of an interaction with a medication or food, or because of an overdose. Depending on the scenario that leads to toxicity, the clinical presentation may vary. Obtaining a thorough medication history is critical to establishing the diagnosis of MAOI toxicity. After acute overdose, a patient may remain asymptomatic for up to 24 hours before life-threatening toxicity develops. After this asymptomatic period, hyperadrenergic symptoms, including tachycardia, hypertension, and hyperthermia, can develop. Seizures, rhabdomyolysis, coma, and

TABLE 141.1 Summary of Monoamine Oxidase Inhibitor Agents Currently Available.

Generic Name	Route	Selectivity	FDA-Approved Uses
Tranylcypromine	Oral	Nonselective	Depression
Phenelzine	Oral	Nonselective	Depression

ultimately cardiovascular collapse can occur once presynaptic catecholamines are depleted.

Patients who take nonselective MAOIs in therapeutic doses are at risk for food-drug interactions. Tyramine is an indirectly acting sympathomimetic amine that is present in foods including aged cheeses, red wine, smoked or pickled and aged meats. Usually, tyramine is metabolized in the gut and liver by MAO, rarely causing systemic effects. When MAO-A is inhibited, tyramine is absorbed systemically and enters presynaptic vesicles, ultimately causing release of norepinephrine and serotonin into the synapse, leading to a hypertensive crisis. This tyramine syndrome, which can occur within minutes to hours of ingestion of foods with high tyramine content, is characterized by headache, hypertension, flushing, and diaphoresis. This syndrome can occur up to 3 weeks after discontinuation of a nonselective MAOI. Although it is theoretically possible, this syndrome is rare with therapeutic use of MAO-B inhibitors. A drug-drug interaction may result when MAOIs are combined with other agents that have serotonergic effects. A variety of prescription and over-the-counter medications may interact with MAOIs to produce a constellation of symptoms referred to as *serotonin syndrome* (see later section). This syndrome may be life-threatening, therefore the use of medications with serotonin-potentiating activity should be avoided in patients taking MAOIs.

Differential Diagnoses

The differential diagnosis for MAOI toxicity includes sympathomimetic drugs of abuse such as cocaine and amphetamine derivatives, anticholinergic (or antimuscarinic) toxicity (e.g., diphenhydramine, cyclic antidepressants, anti-Parkinson drugs, and jimson weed), and methylxanthine toxicity (e.g., theophylline and caffeine). Other toxicologic considerations include acute withdrawal states (e.g., ethanol and benzodiazepines), neuroleptic malignant syndrome (NMS), and the serotonin syndrome from other serotonergic drug combinations. Nontoxicologic causes to consider include environmental hyperthermia or heatstroke, febrile illness from infectious causes (e.g., meningitis and encephalitis), pheochromocytoma, carcinoid syndrome, thyroid storm, and hypertensive emergency.

Diagnostic Testing

Laboratory abnormalities are nonspecific but can include hyperglycemia and leukocytosis, secondary to a hyperadrenergic state, and elevated creatine kinase due to rhabdomyolysis. Immunoassay urine drug screens that are commonly used in the emergency department do not detect MAOIs, and even gas chromatography–mass spectroscopy of urine may fail to detect the presence of an MAOI. Patients taking selegiline will test positive for methamphetamine because methamphetamine is a metabolite. Spectral analysis is needed to differentiate illicit methamphetamine from selegiline.

Symptomatic patients presenting after an MAOI overdose should have an electrocardiogram (ECG) to assess the QT and QRS intervals and for evidence of cardiac ischemia. Patients with chest pain should be evaluated for myocardial infarction. Measurement of serum glucose and electrolytes are indicated if the patient is obtunded. Because of the potential for intracranial hemorrhage in the setting of severe MAOI-induced hypertension, patients with a seizure or focal neurologic deficit should undergo a non–contrast-enhanced head computed tomography (CT) scan.

Management

As with most intoxications, supportive care is paramount. Central nervous system (CNS) excitation should be treated with intravenous (IV) administration of benzodiazepines such as lorazepam and diazepam in titrated doses. Lorazepam may be given IV in a dose of 1 to 4 mg, depending on the severity of symptoms. Dosing can be repeated at 5- to 15-minute intervals for patients with severe toxicity. Alternatively, diazepam, 5 mg IV every 5 to 10 minutes, can be given until the patient is stabilized. Hyperthermia should be treated with external cooling using evaporative techniques and strategic ice packing. Antipyretics such as acetaminophen or nonsteroidal antiinflammatory medications have no role in the management. Hyperthermia that persists, despite administration of benzodiazepines and external cooling measures, may need intubation, ventilation, and chemical paralysis with a nondepolarizing neuromuscular blocker, such as rocuronium (0.6 to 1.2 mg/kg IV). The use of succinylcholine is discouraged as this may cause hyperkalemia if rhabdomyolysis has occurred, and fasciculation from succinylcholine may further increase metabolic heat production. Furthermore, many of these patients are already acutely hyperkalemic, which is a relative contraindication to succinylcholine. Mild hypertension should not be treated, but sustained severe hypertension (e.g., systolic blood pressure exceeding 200 mm Hg or a diastolic exceeding 100 mm Hg) is best managed with a rapid onset, short-acting agent such as phentolamine (titrated slowly by repeated IV doses of 1 mg every 3 minutes) or nitroprusside (0.25 to 0.5 mcg/kg/min by IV infusion). Treatment should target a 25% reduction in the mean arterial pressure. Hypotension should first be managed by volume resuscitation with normal saline. Persistent or severe hypotension requires treatment with infusion of a direct-acting catecholamine such as norepinephrine or epinephrine. Because hypotension and cardiovascular collapse after MAOI overdose are due to catecholamine depletion, the use of indirect-acting agents such as dopamine are not likely to be beneficial. Extracorporeal elimination methods such as hemodialysis are also unlikely to be beneficial because of extensive protein binding and large volume of distribution of MAOIs.

Patients presenting with a tyramine reaction may have spontaneous resolution of symptoms within 6 hours. Severe hypertension higher than 200 mm Hg systolic with symptoms such as headache, flushing, or chest pain should be treated with phentolamine or nitroprusside. Patients with persistent severe headache and hypertension should have a head CT scan to assess for intracranial hemorrhage. Patients with chest pain should be evaluated for myocardial infarction (see Chapter 64).

Treatment of suspected serotonin syndrome is supportive (see later section) and consists primarily of benzodiazepine administration and active cooling measures.

Disposition

Patients presenting with an MAOI overdose should be admitted to a monitored setting for 24 hours due to the risk of delayed, rapid deterioration and development of hyperadrenergic symptoms. Asymptomatic patients chronically taking an MAOI who present out of concern for a possible drug-food interaction can be discharged after 6 hours if no signs of toxicity develop over that period. The care of any patient with suspected toxicity from an MAO inhibitor should be discussed with a medical toxicologist or poison control center (800-222-1222).

TRICYCLIC ANTIDEPRESSANTS

Principles of Toxicity

In the 1950s, imipramine became the first TCA used for the treatment of depression. Until the introduction of the SSRIs, TCAs remained the primary agents for treatment of depression. The therapeutic benefit of TCAs results from monoamine reuptake inhibition.[6] Whereas use of TCAs for treatment of depression has waned, use for other conditions, including treatment of migraines, various neuropathies, trigeminal neuralgia, and nocturnal enuresis has increased.

Clinical Features

Cyclic antidepressant toxicity can result from overdose of a TCA or drug interactions. Overdose is more commonly associated with life-threatening toxicity, but toxic effects can also occur when a TCA is combined with drugs that impair its metabolism through cytochrome P450. Tertiary amine TCAs such as amitriptyline, imipramine, and clomipramine are substrates of CYP2C19 and CYP1A2. Doxepin is also a substrate for CYP2D6. Drug-induced inhibition of these enzymes as well as genetic polymorphisms of these isoenzymes can decrease metabolism of these drugs, resulting in unexpectedly high serum concentrations and clinical toxicity. Conversely, inhibition of CYP2D6 and other P450 enzymes by these TCAs can also lead to increased serum concentrations of other drugs metabolized by the same enzymes. Because desipramine and nortriptyline are only weak CYP2D6 inhibitors, they cause fewer drug interactions. Another toxicity that can occur with TCAs is serotonin syndrome, which can result when a TCA is combined with another serotonergic drug such as an MAOI or SSRI.

Following a TCA overdose, clinical toxicity typically begins within 1 to 2 hours. When smaller quantities are ingested, symptoms may be minimal and resolve quickly; patients who take large amounts may deteriorate rapidly soon after ingestion. Severely poisoned patients typically have symptoms within 1 to 2 hours after ingestion, but nearly always by 6 hours after ingestion. Early cyclic antidepressant toxicity (within the first 2 hours) is primarily characterized by anticholinergic effects. These findings include dry mucosal membranes, urinary retention, and hot dry skin. Despite having potent antimuscarinic properties, the pupils are often small due to competing *alpha* effects. Patients may be alert and confused, severely agitated, hallucinating, or even deeply comatose. Speech is often rapid and mumbling in character. Seizures may occur and are likely to be multifactorial, resulting from increased synaptic monoamines, sodium channel inhibition, and gamma-aminobutyric acid (GABA) receptor antagonism. Early hypertension is common from the anticholinergic effects of the TCA and excess norepinephrine in the synapse from blockade of norepinephrine reuptake, but hypotension may also be due to alpha-receptor antagonism and also norepinephrine depletion.

Later (2 to 6 hours post ingestion), myocardial depression resulting from severe sodium channel antagonism may also lead to hypotension and bradycardia. Significant sodium channel blockade is associated with widening of the QRS interval. The degree of widening is prognostic for both arrhythmias and seizures.[7] Tricyclic antidepressants also block potassium efflux, which leads to a prolonged QT interval. Clomipramine and amitriptyline are especially associated with QT prolongation. Furthermore, clomipramine is associated with significant QT dispersion, which has been shown to be a risk for ventricular arrhythmias and mortality.[8] With severe poisoning, the combined effects of the TCA on various receptors and ion channels lead to depressed level of consciousness, seizures, hypotension, and wide-complex cardiac arrhythmias.

Fig. 141.1 Augmented vector right *(aVR)* demonstrating tall R wave.

Chronic toxicity from drug interactions or decreased ability to metabolize the drug because of genetic polymorphism may be manifested in a less evident fashion. Confusion, urinary retention, and prolonged corrected QT (QTc) interval are common. Chronic toxicity presents more gradually and should be considered in any confused patient taking therapeutic doses of a cyclic antidepressant.

Differential Diagnoses

Many agents with anticholinergic properties produce similar clinical features as TCAs. Diphenhydramine and carbamazepine, in particular, can also produce seizure and sodium-channel blockade. Agents that produce sympathomimetic toxicity (e.g., cocaine, amphetamines) or serotonin syndrome (e.g., SSRIs, MAOIs) should be included in the differential diagnosis. Other drugs with sodium channel blockade, and hence a wide QRS complex, include the Vaughn-Williams class IA antidysrhythmics (e.g., procainamide, disopyramide, quinidine) and class IC antidysrhythmics (e.g., flecainide, encainide, and propafenone), along with amantadine, carbamazepine, cocaine, diphenhydramine, mesoridazine, and thioridazine. Propoxyphene and propranolol can also cause an intraventricular conduction delay by sodium channel blockade but typically cause a bradycardic rhythm rather than a tachycardic rhythm. The constellation of early anticholinergic symptoms, decreased level of consciousness followed by seizures, wide QRS and cardiovascular collapse, is highly suggestive of acute TCA overdose.

Diagnostic Testing

After overdose, the ECG can yield prognostic information. Early anticholinergic effects cause sinus tachycardia, which occurs uniformly before other effects. Whereas the serum tricyclic concentrations are not particularly beneficial in predicting adverse events, the ECG is prognostic. Historically, it is felt that QRS duration longer than 100 milliseconds is predictive of seizures, whereas QRS duration longer than 160 milliseconds is predictive of ventricular dysrhythmias, but hard evidence does not exist for either of these assertions. Additional findings on the ECG include a rightward shift of the terminal 40 milliseconds of the QRS complex seen as an R wave in augmented vector right (aVR) longer than 3 milliseconds. Figure 141.1 demonstrates lead aVR following a tricyclic ingestion. QT prolongation has less prognostic value than the QRS duration.

Urine drug of abuse screens commonly test for the presence of TCAs, but a positive test result suggests only use of a TCA or another xenobiotic that cross-reacts with the screen (e.g., antipsychotic medications, antimuscarinic agents, carbamazepine, or the muscle relaxant cyclobenzaprine). Quantitative serum tricyclic levels do not correlate well with severity of illness.

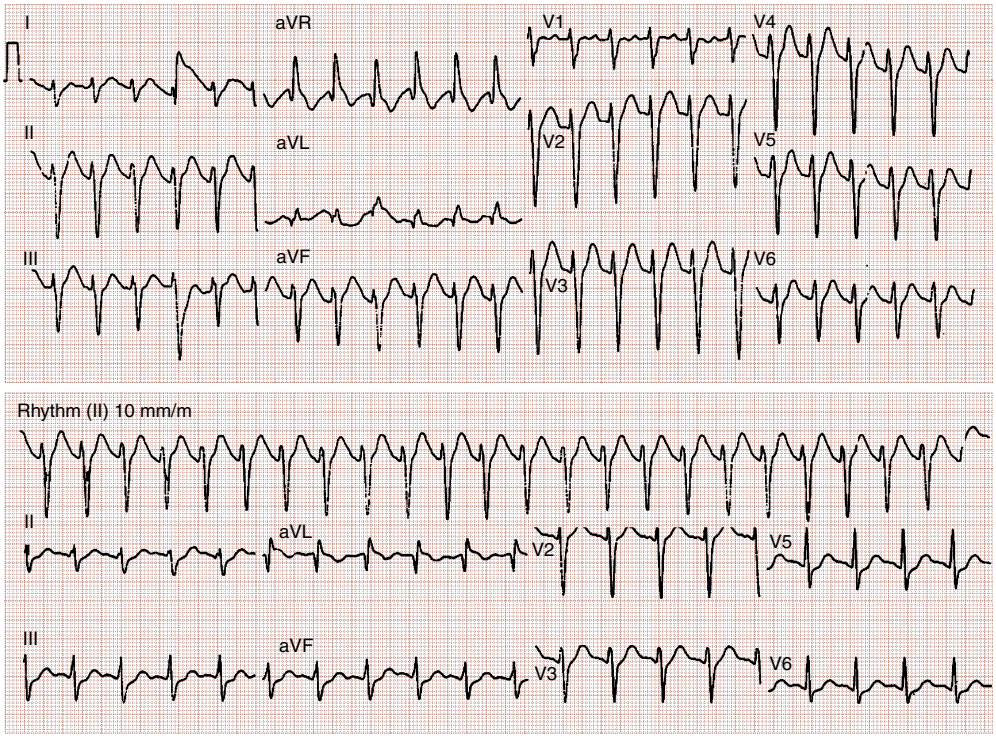

Fig. 141.2 *Top,* Initial 12-lead electrocardiogram (ECG) demonstrating substantial intraventricular conduction delay (QRS 141 milliseconds). *Bottom,* Repeated ECG after bicarbonate therapy. *aVF,* Augmented vector foot; *aVL,* augmented vector left; *aVR,* augmented vector right.

Management

Ensuring stability of the airway, with adequate ventilation, and volume repletion are of primary importance. There are no randomized controlled trials demonstrating improved patient-oriented outcomes and decreased mortality with activated charcoal administration in patients with cyclic antidepressant overdose. Nonetheless, because of the high lethality of the acute overdose, a patient who presents within 1 hour after an overdose and who is awake, alert, and cooperative and is not exhibiting any signs of toxicity (e.g., no tachycardia or intraventricular conduction delay) can be given oral activated charcoal. Patients who are not cooperative or who are not willing to drink charcoal should not have a nasogastric tube inserted for the sole purpose of administering charcoal. Due to risk of seizures with subsequent aspiration, activated charcoal is not routinely recommended in patients with an unprotected airway who are already exhibiting toxicity. There is no role for gastric lavage.

Patients with sinus tachycardia alone do not need specific treatment but should be monitored to detect QRS widening early in the clinical course. Early hypertension should not be treated. Hypotensive patients should first receive fluid resuscitation with an isotonic crystalloid. Patients who remain hypotensive should be treated with direct-acting vasopressors such as norepinephrine and epinephrine.

Hypertonic sodium bicarbonate is given only to treat specific evidence of sodium channel blockade such as a wide QRS and ventricular dysrhythmias.[7] Sodium bicarbonate should not be given strictly to treat tachycardia. Recommendations regarding the specific administration of sodium bicarbonate vary. We recommend a conservative approach by administering a bolus of 1 to 2 mEq/kg hypertonic sodium bicarbonate intravenous push (IVP) if the QRS interval exceeds 100 milliseconds. This dose may be repeated in 5 to 10 minutes if the QRS does not narrow. After IV bolus, a sodium bicarbonate infusion can be used to maintain a serum pH between 7.50 and 7.55. Such an infusion can be created by the addition of 150 mEq sodium bicarbonate and 850 mL of dextrose 5% in water (D5W). The infusion should be created with a 5% dextrose solution, and not normal saline, due to the risk of hypernatremia with the latter. The infusion should be administered at twice the normal maintenance rate, titrating to QRS width and serum pH. Alternatively, infusions of 1 mEq sodium bicarbonate per milliliter of fluid may be used if volume overload is a concern. Additional IV boluses of sodium bicarbonate may be necessary if the QRS widens. The use of a bicarbonate-containing infusion should not be a substitute for IV sodium bicarbonate boluses for the initial treatment of intraventricular conduction delay. Figure 141.2 demonstrates a 12-lead ECG from a patient poisoned with a TCA before and after sodium bicarbonate therapy. If ventricular dysrhythmias persist despite maximal alkalinization (pH > 7.55), 3% hypertonic saline (in an adult) can be used. Class Ia or Ic antidysrhythmics should be avoided. Seizures are best treated with an IV benzodiazepine (lorazepam 1 to 4 mg IVP; diazepam 5 to 10 mg IVP) along with sodium bicarbonate. Refractory seizures can be treated with phenobarbital (15 to 20 mg/kg IV loading dose). Because seizure leads to acidosis and worsens the cardiac status, patients with intractable seizures who do not respond to benzodiazepines or phenobarbital should be rapidly paralyzed, intubated, and mechanically ventilated to prevent increasing metabolic acidosis.

Physostigmine, the antidote of choice for pure anticholinergic toxicity (see Chapter 140), is considered by many experts to be relatively contraindicated in the management of TCA overdose. Asystole has been reported after physostigmine use in TCA toxicity, particularly in patients with bradycardia and AV block. It is not advised to administer this agent to patients with QRS or QTc prolongation following TCA overdose. However, we recommend it be considered in patients with delirium of unclear etiology who are therapeutically taking anticholinergic agents and in whom toxicity is suspected, but only if there is no

bradycardia, no history of seizures, and the PR, QRS, and QTc intervals are normal. Physostigmine (1 to 2 mg slow IV infusion over 5 minutes in adults) should be given with caution in a monitored setting, because it may exacerbate bradycardia, AV block, and seizures related to the overdose (see Chapter 140).

Intravenous lipid emulsion (ILE) therapy has gained interest recently for reversal of toxicity caused by lipophilic drugs, including TCAs.[9-10] Although the exact mechanism of ILE is not clearly defined, it likely involves redistribution of a lipophilic drug from the tissue receptors back into the vascular compartment in the context of a large bolus of concentrated lipid solution, the so-called *lipid sink phenomenon.*[10] Other mechanisms such as enhanced cardiac metabolism are also possible explanations. Because not all studies reveal beneficial effects from ILE in the treatment of TCA toxicity and due to the potential for iatrogenic harm, its use is currently reserved for life-threatening toxicity that remains refractory to sodium bicarbonate administration.[11] ILE should be administered only on advice of a medical toxicologist or regional poison center. If ILE is to be administered, there are several different dosing strategies. We recommend 1.5 mL/kg of a 20% lipid solution over 2 to 3 minutes. This bolus can be repeated once in 5 minutes if there is no clinical improvement. If clinical improvement does occur, the bolus may be followed by an infusion of 0.25 mL/kg/min.[12]

Complications of ILE include extreme lipemia resulting in interference with laboratory blood tests (complete blood counts, chemistries, and coagulation studies), as well as acute pancreatitis, and acute respiratory distress syndrome.[13]

Disposition

If the heart rate has not exceeded 100/minute for a sustained period of time (at least 10 to 15 minutes), ECG intervals are normal, level of consciousness is normal, and no seizures have developed within 6 hours of a TCA overdose, it is unlikely that toxicity will occur. The patient can be medically cleared from the ED for psychiatric evaluation and disposition if needed. Patients with signs of cyclic antidepressant cardiotoxicity, seizures, or coma should be admitted to an intensive care unit.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Principles of Toxicity

In recent years, SSRIs have become the mainstay for treatment of depression. As implied by their name, these drugs prevent the presynaptic reuptake of serotonin without affecting the synaptic concentration of other monoamines. Some of the more commonly used SSRIs available today include escitalopram and its enantiomer citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline.

SSRIs have a wide therapeutic index. Most SSRIs undergo hepatic metabolism. There is considerable variability in their half-life; however, paroxetine has one of the shortest half-lives (17 hours) compared with fluoxetine, which has one of the longest half-lives (53 hours for parent drug, 240 hours for active metabolite).

Clinical Features

Overdoses of SSRI agents alone are usually well-tolerated and rarely fatal, with ingestions of up to 30 times the daily dose associated with few or no symptoms. Gastrointestinal upset and mild CNS depression can occur with large overdoses. Coma and seizures are rare, with incidences of approximately 2% for each. The incidence of serotonin syndrome after SSRI overdose is variable, but remains relatively uncommon in most series.

Citalopram overdose deserves special mention because of a reported higher rate of QTc prolongation and seizures compared with other SSRIs.[14] There has been some suggestion that the QT prolongation may be delayed with citalopram ingestion. However, there are not convincing data to support this delayed onset of toxicity. The risk of QT prolongation at therapeutic dosing may be over-stated.[15] In overdose, however, QT prolongation does appear to be dose-dependent. Despite a risk of QT prolongation, torsade de pointes associated with citalopram is relatively rare.[16] Escitalopram appears to be less toxic than citalopram, with a lower incidence of seizure and QT prolongation. Therapeutic administration of SSRIs may be associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Most cases of hyponatremia develop shortly after commencing use. The overall incidence is not well documented. Studies have documented that approximately 12% of elderly patients taking an SSRI may have SIADH.

Abrupt discontinuation of an SSRI may be associated with a mild withdrawal state, in which individuals feel anxious, jittery, and have some gastrointestinal upset. This withdrawal syndrome is not life-threatening.

Differential Diagnoses

The differential diagnosis for SSRI toxicity includes toxicity due to cyclic antidepressants, MAOIs, sedative hypnotics (e.g., benzodiazepines, barbiturates), SNRIs, neuroleptic agents, and atypical antipsychotics.

Diagnostic Testing

Diagnosis of SSRI toxicity is often dependent on obtaining a history of overdose. Clinical features of toxicity are similar to those seen after overdose of many other toxicants. An ECG can assess for conduction disturbances, especially QT prolongation. Specific SSRI levels are not performed by most hospital laboratories and do not influence management, although they may help confirm overdose retrospectively. A standard urine drug of abuse screen will not detect an SSRI.

Management

Treatment of an SSRI overdose is largely supportive. Activated charcoal has not been demonstrated to change outcomes following SSRI overdose but may be considered if the patient presents alert and cooperative within an hour of ingestion. Only rarely will patients require tracheal intubation because of loss of airway reflexes. For adult patients with a QTc interval greater than 500 msec, 2 grams of IV magnesium sulfate should be administered. IV administration of benzodiazepines (1 to 4 mg/kg of lorazepam via IV push; or 5 to 10 mg/kg diazepam via IV push) should be used to treat agitation and seizures.

Disposition

Patients who overdose with an SSRI who are asymptomatic after 6 hours of monitoring are unlikely to have toxicity. A patient who presents following an SSRI ingestion can be medically cleared after a six-hour observation period, assuming the patient has remained asymptomatic with a normal ECG. For citalopram or escitalopram, we recommend a repeat ECG be performed at the six-hour mark prior to providing medical clearance. Some advocate for extending this observation period to 12 hours following ingestions of more than 1000 mg of citalopram or escitalopram. Symptomatic patients should be admitted to a monitored care setting. Those patients with an intent of self-harm should be evaluated by a psychiatric service.

SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS AND NOREPINEPHRINE REUPTAKE INHIBITORS

Principles of Toxicity

Duloxetine, venlafaxine, desvenlafaxine, milnacipran, and levomilnacipran are collectively referred to as *serotonin-norepinephrine*

reuptake inhibitors (SNRIs). All of these agents, except milnacipran, are approved for use in the United States for treatment of major depression. Milnacipran, despite being used as an antidepressant in Europe, is only approved for treatment of fibromyalgia in the United States. Some of these agents are also approved for other disorders. For example, venlafaxine can be used to treat panic disorder, generalized anxiety disorder, or social phobia, whereas duloxetine is also used to treat chronic musculoskeletal pain, diabetic neuropathy, fibromyalgia, and generalized anxiety disorder. Venlafaxine and its active metabolite desvenlafaxine are both available medicinally. The SNRIs may also produce dose-dependent inhibition of sodium channels. Reboxetine is an isolated norepinephrine reuptake inhibitor. It is also used for the treatment of depression.

Clinical Features

Unlike the SSRIs, which are relatively benign in overdose, ingestion of any of the SNRIs can be dangerous. Fatal ingestions have been described with virtually all of the SNRIs. The SNRIs may produce hyperadrenergic symptoms, including tachycardia and hypertension.[16] Rarely, hypotension can be observed after massive overdose.[17] Acute cardiac dysfunction, including impaired biventricular function, has been demonstrated following acute overdose.[17-18] Seizures can occur following ingestion of the SNRIs.[16] Unlike bupropion, however, which can have delayed onset of seizures, the onset of seizures following an SNRI ingestion is expected to occur within the first several hours post ingestion.

Rhabdomyolysis has been reported independent of seizure activity following ingestions of venlafaxine. Venlafaxine and desvenlafaxine overdoses can result in cardiovascular toxicity, manifesting as intraventricular conduction delay and ventricular dysrhythmias. Venlafaxine has also been associated with QT prolongation. In addition, based on their mechanism of action, serotonin syndrome may develop after ingestion of these agents.[16]

Differential Diagnoses

The differential diagnosis for SNRI toxicity includes toxicity due to cyclic antidepressants, MAOIs, sedative hypnotics, SSRIs, neuroleptic agents, bupropion, and atypical antipsychotic medications.

Diagnostic Testing

Specific drug levels are not rapidly available and do not aid management. An ECG can detect QRS or QT interval prolongation. SNRIs are not detected by urine drug of abuse screens, but venlafaxine and desvenlafaxine may be associated with a false-positive phencyclidine screen.[19] In cases of a venlafaxine ingestion, creatinine kinase and renal function tests should be obtained to assess for acute rhabdomyolysis. As with any multidrug ingestion, serum acetaminophen and salicylate levels should be measured.

Management

Care of the patient with an SNRI overdose is supportive, with focus on ensuring airway patency and adequate ventilation. While oral activated charcoal has not been clearly demonstrated to be beneficial in the setting of an SNRI overdose, if the patient presents within an hour and is awake and alert and cooperative, the use of charcoal can be considered. Hypotension (systolic blood pressure <90 mm Hg) should first be treated with a 20 cc/kg bolus of 0.9% normal saline. This bolus can be repeated if necessary. If hypotension still persists, a direct-acting vasopressor (such as epinephrine or norepinephrine) should be used. Intraventricular conduction delay with a widened QRS on ECG should be treated with sodium bicarbonate infusions (as previously described in the tricyclic antidepressants section). First-line treatment of seizures is the IV administration of a benzodiazepine such as lorazepam, diazepam, or midazolam.

Disposition

Patients who are asymptomatic with a normal 12-lead ECG after an observation period of 6 hours can be cleared for discharge after appropriate psychiatric consultation. Patients with an intentional ingestion who develop manifestations of neurologic or cardiovascular toxicity (such as sedation, hypotension, or tachycardia) should be observed in a monitored setting. Those with profound CNS depression or hemodynamic instability warrant intensive care unit admission.

SEROTONIN MODULATORS AND STIMULATORS

Vilazodone and vortioxetine belong to a new class of antidepressants, referred to as serotonin modulators and simulators (SMS). While both of these drugs inhibit serotonin reuptake, they are also partial agonists at various serotonin receptors.[20-21] Clinical experience with these drugs in overdose is relatively limited. Unlike the SSRIs, in which serotonin syndrome is unlikely to occur with a single-agent ingestion, there are multiple case reports in which serotonin syndrome has been reported following isolated vilazodone ingestions.[21] In addition, gastrointestinal upset (e.g., vomiting), tachycardia, central nervous system depression, and seizures have been reported.[21-22]

The toxicologic differential diagnoses of these agents includes toxicity from the SNRIs, tricyclic antidepressants, bupropion, and trazodone. The primary aspects of management include ensuring the patient has adequate airway patency. Severe central nervous system depression may warrant intubation and mechanical ventilation. Seizures, should they occur, should be treated with benzodiazepines (e.g., lorazepam, diazepam, or midazolam). Hypotension should be first treated with rapid crystalloid fluid resuscitation. Refractory hypotension should be treated with a direct-acting vasopressor, such as norepinephrine or epinephrine. Patients who remain asymptomatic after a six-hour observation period can be medically cleared for psychiatric disposition.

MISCELLANEOUS ANTIDEPRESSANTS

Bupropion

Bupropion is an atypical antidepressant, belonging to a unique class (aminoketone).[23] It is widely used not only as an antidepressant, but also for smoking cessation. The primary mechanism of action is inhibition of dopamine and norepinephrine reuptake, but it also acts as a noncompetitive inhibitor of nicotinic acetylcholine receptors.[23]

Seizure activity is a dose-dependent phenomenon and can occur with therapeutic dosing or overdose of bupropion.[24] Seizures are relatively common after overdose and occur in approximately 30% of cases, the majority of which are initially tachycardic.[24-26] Sinus tachycardia, tonic-clonic seizures, and agitation are common after overdose.[24-26] Unlike many agents that produce seizures acutely following overdose, ingestion of extended-release bupropion can produce delayed onset seizures. The risk of seizures is not only dose dependent, but also preparation dependent; the immediate release is the least likely to cause seizures, whereas the XL preparation is the most likely.[27] Both QRS and QT prolongation can occur with toxicity.

Treatment is primarily supportive. Activated charcoal has not been clearly demonstrated to be beneficial in this setting, but its use can be considered if the patient is awake and alert and presents within one hour of ingestion. Patients with large overdoses may require endotracheal intubation and mechanical ventilation because of CNS and respiratory depression. Lorazepam, diazepam or midazolam are effective for terminating seizures. If seizures persist, phenobarbital or other GABA

agonists may be used. Sodium bicarbonate (150 mEq IV or 3 mEq/kg for pediatric patients) should be administered for any QRS prolongation, although because the mechanism of action of intraventricular conduction delay appears to be related to gap junction inhibition, rather than to sodium channel blockade, it tends to be less responsive to sodium bicarbonate therapy. Resuscitative ILE therapy, as well as extracorporeal membrane oxygenation (ECMO), has been described in anecdotal case reports of severely poisoned patients who are refractory to standard management measures.[28] Intravenous lipid emulsion should be undertaken only on the advice of a medical toxicologist or regional poison center (as described in the tricyclic antidepressant section).

Although pediatric patients may have seizures with accidental or exploratory ingestions, the risk of seizures is much less than in older children, where the exposure is typically the result of a suicidal attempt.[29] Nonetheless, because of the risk of delayed seizures, we recommend admission and monitoring for adult patients who ingest more than 450 mg of an ER or XL preparation or more than 8 mg/kg in pediatric patients.

Trazodone

Trazodone is an atypical antidepressant that is used for its hypnotic and anxiolytic properties. In addition to weakly inhibiting serotonin reuptake, it is a relatively strong blocker of the alpha$_1$ receptor.[30] Its use as an antidepressant has been historically somewhat limited by adverse effects, including orthostatic hypotension, priapism, and sedation. Priapism is probably a result of trazodone's alpha-antagonism, with an incidence of 1/100 to 1/10,000. Whereas many drugs are associated with priapism, particularly those with alpha-antagonism or inhibition of type 5 phosphodiesterase, trazodone is responsible for a disproportionate number of reported cases.

After overdose, sedation and hypotension due to vasodilation are expected. Priapism is not typically associated with overdose of trazodone. Prolongation of the QT interval may occur. Management is supportive, with airway protection, IV fluid resuscitation, and use of alpha-adrenergic agonists such as norepinephrine as needed for refractory hypotension. Activated charcoal has not been clearly demonstrated to be beneficial in this setting. If the patient is awake and alert, however, and presents within one hour of ingestion, its use can be considered.

Nefazodone

Nefazodone, a phenylpiperazine antidepressant, is structurally similar to trazodone. It acts as an antagonist at the 5-HT$_{2A}$ receptor, and chronic administration is associated with receptor downregulation. Nefazodone is associated with weak inhibition of norepinephrine and serotonin reuptake. It is metabolized to several active metabolites. After overdose, most patients remain asymptomatic. Antagonism of the alpha$_1$ receptor is responsible for the orthostatic hypotension that can occur. Treatment is primarily supportive.

SEROTONIN SYNDROME

Principles of Toxicity

Serotonin syndrome is a potentially lethal condition resulting from excess serotonin accumulation in the synaptic cleft.[31] This syndrome may occur after an isolated overdose of an SSRI, but it is more commonly a result of drug interactions, especially with drug combinations that raise synaptic serotonin concentrations by different mechanisms. Agonism of the 5-HT$_{2A}$ receptor appears to be largely responsible for this condition in humans.[31] Whereas numerous xenobiotics have been implicated in causing serotonin syndrome, some of the most common are the SSRIs, SNRIs, TCAs, MAOIs, dextromethorphan, amphetamines, and designer amphetamines, including methylenedioxymethamphetamine ("ecstasy"), cocaine, meperidine, lithium, tramadol, buspirone, lysergic acid diethylamide (LSD), and linezolid (Box 141.1). Serotonin syndrome is more likely to develop when drugs from different classes are combined, resulting in increased serotonin in the synaptic cleft from different mechanisms (e.g., increased release and impaired uptake).

BOX 141.1 Xenobiotics Commonly Implicated in Serotonin Syndrome

Analgesics: Tramadol, meperidine, pentazocine
Drugs of abuse: Cocaine, amphetamine derivatives (e.g., methylenedioxymethamphetamine), lysergic acid diethylamide (LSD)
Monoamine oxidase inhibitors (MAOIs) (e.g., isocarboxazid, linezolid, phenelzine, moclobemide, selegiline)
Miscellaneous: Dextromethorphan, lithium, metoclopramide, St. John's wort
Selective serotonin reuptake inhibitors (SSRIs) (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)
Serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., milnacipran, venlafaxine)
Tricyclic antidepressants (TCAs) (e.g., amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline)

Clinical Features

Serotonin syndrome is described as a triad of mental status changes, autonomic instability, and increased neuromuscular activity, but the condition exists along a spectrum; some patients have only mild tremor and diarrhea, whereas others exhibit life-threatening manifestations. Clinical features may include tremor, akathisia, gastrointestinal illness, clonus (inducible or spontaneous), rigidity, fever, seizures, and autonomic instability. The clonus is typically more pronounced in the lower extremities (most notably the ankles) than in the upper extremities. After an acute overdose of a serotonergic agent, symptom onset typically begins within several hours. With proper treatment, symptoms usually resolve within 24 hours but can persist for several days in severe cases.

Differential Diagnoses

The differential diagnosis of serotonin syndrome includes NMS, malignant hyperthermia, sympathomimetic toxicity, anticholinergic toxicity, strychnine toxicity, bupropion toxicity, and GABA withdrawal. Nontoxicologic considerations include thyroid storm, meningitis, idiopathic seizure, intracranial hemorrhage, and hypoglycemia.

Diagnostic Testing

There is no "gold standard" for the diagnosis of serotonin syndrome. Laboratory studies cannot be used to confirm or to exclude the diagnosis of serotonin syndrome. Rhabdomyolysis and hyperkalemia can occur as a result of increased neuromuscular activity, and these should be screened for as indicated on the basis of the clinical examination.

The Sternbach criteria were developed in the 1990s and became the first widely used diagnostic algorithm. Additional criteria, including the Hunter criteria and the Boyer and Shannon criteria, have been developed. The Hunter criteria (Box 141.2) appear to be more sensitive than the Sternbach criteria, with fewer false positives.

In general, a history of overdose or of recently starting an additional serotonergic agent along with clinical findings consistent with this diagnosis should raise the concern for serotonin syndrome.

BOX 141.2 The Hunter Criteria for Serotonin Syndrome

In the setting of exposure to a known serotonergic agent, serotonin syndrome can be diagnosed by the presence of any of the following:

- Spontaneous clonus
- Inducible clonus *and* agitation or diaphoresis
- Ocular clonus *and* agitation or diaphoresis
- Tremor and hyperreflexia
- Hypertonic with temperature >38°C *and* ocular clonus or inducible clonus

Management

Management is supportive, with removal of the offending agents being paramount. Mild cases may require only discontinuation of the agent and low-dose benzodiazepines (e.g., 5 to 10 mg of IV diazepam) for rigidity. More severe cases may require IV fluid resuscitation and large doses of benzodiazepines (e.g., 10 to 20 mg of IV diazepam, with titration in 10 mg aliquots) or other sedative-hypnotic agents to gain control of symptoms. Cyproheptadine, a 5-HT_{2A} antagonist, is an adjunctive therapy for more severe cases, but there are no randomized controlled trials demonstrating improved benefit with cyproheptadine over supportive care and benzodiazepines alone. If cyproheptadine is available, the syndrome is severe or refractory to treatment, and the clinician is confident with the diagnosis, we recommend a single oral dose of 12 mg of cyproheptadine for patients with serotonin syndrome. If anticholinergic toxicity remains on the differential diagnosis, cyproheptadine should not be given, because it can worsen anticholinergic toxicity. Patients with hyperthermia that does not respond promptly to sedation with benzodiazepines should receive a nondepolarizing neuromuscular blocking agent (e.g., rocuronium) during rapid sequence intubation. Typically, only a single dose of a long-acting neuromuscular blocking agent is required. If additional doses are required, we recommend a single IV dose of 10 mg of vecuronium.

Disposition

Patients with all but the mildest forms of serotonin syndrome should be admitted to a monitored care setting. Those with unresponsiveness, autonomic instability, hyperthermia, and rigidity should be admitted to an intensive care unit.

DISCONTINUATION SYNDROMES

After the abrupt discontinuation of certain antidepressants, patients can experience a withdrawal, or discontinuation, syndrome. Unlike potentially life-threatening GABA withdrawal from ethanol or benzodiazepines, the discontinuation syndrome from antidepressants is rarely life-threatening but can result in significant discomfort. One notable exception involves neonates born to mothers using TCAs, who can have serious, potentially life-threatening withdrawal. Antidepressant discontinuation syndrome does not always develop, but when it does, it typically starts within the first 3 days after therapy is stopped. This syndrome is difficult to distinguish from recurrence of the underlying depression, which has overlap of some symptoms.

Antidepressant discontinuation syndrome occurs with all major classes of antidepressants. Withdrawal from SSRIs involves both physical and psychological symptoms, most commonly nausea, lethargy, headache, and dizziness. The symptoms can be divided into six general categories: dysequilibrium (e.g., dizziness, ataxia), sleep disturbances, gastrointestinal symptoms, affective symptoms (e.g., irritability, anxiety), sensory symptoms (e.g., electric shock–like sensation, paresthesias), and general somatic symptoms (e.g., headache, tremor, anorexia, diaphoresis). The syndrome is more common after discontinuation of drugs with shorter half-lives (e.g., paroxetine) than of drugs with longer half-lives (e.g., fluoxetine). TCA withdrawal is similar to SSRI withdrawal, although sensory abnormalities and equilibrium disturbances are rare with TCA discontinuation. Non–life-threatening arrhythmias are rare after discontinuation of the TCAs.

Patients with mild withdrawal symptoms do not require any specific therapy. For those patients with more severe symptoms, treatment involves restarting of the antidepressant, followed by a gradual tapering dose.

CHAPTER 141: QUESTIONS AND ANSWERS

1. A 42-year-old woman presents after ingesting an unknown number of pills in a suicide attempt. She does not know the name of the medication she ingested but knows it is an antidepressant. She denies taking any co-ingestants. Currently, she has no complaints; her vital signs, physical examination findings, and electrocardiogram (ECG) are normal. To receive a psychiatric evaluation, she must be transferred off-site. How long should she be observed in the emergency department before transfer to a psychiatric facility?

a. 1 hour
b. 2 hours
c. 6 hours
d. 12 hours

Answer: C. The most dangerous class of antidepressants is the cyclic antidepressants. Typically, peak plasma concentrations and therefore peak effect occur in 2 to 4 hours. However, in overdose, the anticholinergic effects of these agents may result in delayed gastric emptying and delay peak absorption to 6 hours. Most serious signs and symptoms occur within 30 to 60 minutes of ingestion. If the patient has tachycardia or seizure or decreased level of consciousness at 6 hours, she should be admitted for medical observation. If any of these pills were a monoamine oxidase inhibitor (MAOI), however, the patient should be admitted to the hospital for 24 hours.

2. After sinus tachycardia, what is the most common electrocardiographic abnormality seen in cyclic antidepressant overdose?

a. Left bundle branch block
b. PR prolongation
c. QRS prolongation
d. QT prolongation
e. Right bundle branch block

Answer: C. After sinus tachycardia, QRS prolongation of more than 100 milliseconds is the most common specific finding and results from sodium channel–blocking effects of the cyclic antidepressant. Prolonged PR and QT intervals, as well as a right bundle branch block, can also occur but are less common.

CHAPTER 141: QUESTIONS AND ANSWERS—cont'd

3. Which of the following treatment options would be the most appropriate to consider in the awake, asymptomatic patient who presents within 1 hour of a large overdose of a tricyclic antidepressant (TCA)?
   a. Activated charcoal
   b. Endotracheal intubation
   c. Gastric lavage
   d. Physostigmine
   e. Sodium bicarbonate

   Answer: A. Physostigmine should never be prophylactically administered and its use in TCA overdose is generally considered contraindicated, particularly in patients with bradycardia, AV block, and seizures related to the overdose. Sodium bicarbonate should not be prophylactically administered either, but it should be administered as an intravenous (IV) bolus for patients with intraventricular conduction delay and QRS widening. Endotracheal intubation is indicated for patients with significant central nervous system (CNS) depression who are not able to protect their airway. Gastric lavage is not indicated. Activated charcoal can be considered in an awake individual presenting within one hour of ingestion. It should not be "forced" on someone who will not voluntarily drink it (e.g., by placement of a nasogastric tube for the purpose of administering charcoal) because of the increased risk of aspiration and subsequent charcoal pneumonitis.

4. A 23-year-old man presents after an ingestion of a cyclic antidepressant. His initial vital signs are normal. During your initial evaluation, the patient begins to seize. Which agent should be administered first?
   a. Lorazepam
   b. Phenobarbital
   c. Phenytoin
   d. Propofol
   e. Valproic acid

   Answer: A. Lorazepam or any other benzodiazepine is the first-line treatment of toxin-induced seizures. Intravenous phenytoin can increase the incidence of ventricular tachycardia and is not generally effective in controlling toxin-induced seizures. Phenobarbital and propofol are effective but take longer to give and typically are used after benzodiazepines. Valproic acid is not likely to be effective.

5. A 57-year-old woman presents with altered mental status. A friend states that the patient takes antidepressant medications and has recently been complaining of symptoms of an upper respiratory tract infection. The patient is noted to have a temperature of 39.2°C and a pulse of 135 beats/minute. Otherwise, her vital signs are within normal limits. On examination, she has a tremor, myoclonus, and diaphoresis. Which of the following is the most consistent with this presentation?
   a. Anticholinergic syndrome
   b. Cocaine intoxication
   c. Cyclic antidepressant overdose
   d. Neuroleptic malignant syndrome (NMS)
   e. Serotonin syndrome

   Answer: E. Symptoms of serotonin syndrome include altered mental status, agitation, ataxia, diaphoresis, diarrhea, hyperreflexia, hyperthermia, myoclonus, shivering, and tremor. Many of the symptoms are similar to symptoms caused by NMS and sympathomimetic overdoses; however, myoclonus is unique to the serotonin syndrome. Additional historical features consistent with the serotonin syndrome are the fact that the patient is taking an antidepressant, possibly a selective serotonin reuptake inhibitor (SSRI), and has likely added an over-the-counter "cold" medication. Many of these medications contain dextromethorphan, which also decreases serotonin reuptake and can precipitate the serotonin syndrome in patients taking SSRIs.

6. A 24-year-old man presents after taking an overdose of his antidepressant. He does not know the name of the drug. He has no complaints, and his vital signs and physical examination findings are normal. Soon after completing your evaluation, the patient experiences a tonic-clonic seizure. Which of the following antidepressants is most likely to produce seizures without other symptoms of severe toxicity?
   a. Amitriptyline
   b. Bupropion
   c. Fluoxetine
   d. Phenelzine
   e. Trazodone

   Answer: B. Bupropion can induce seizures even at therapeutic levels. Other adverse effects include tachycardia, tremulousness, hallucinations, and QRS prolongation. Cyclic antidepressants (amitriptyline), selective serotonin reuptake inhibitors (SSRIs; fluoxetine), and monoamine oxidase inhibitors (MAOIs; phenelzine) can also cause seizures but less frequently than bupropion and usually with other symptoms of serious intoxication such as central nervous system (CNS) depression or QRS prolongation.

7. A patient is prescribed a new medication that he takes each night. After 4 days, he is drowsy and noted to have orthostatic hypotension, nausea, vomiting, and priapism. What medication is most likely involved?
   a. Amitriptyline
   b. Bupropion
   c. Fluoxetine
   d. Phenelzine
   e. Trazodone

   Answer: E. Trazodone and nefazodone may cause orthostatic hypotension and lethargy. Priapism is a relatively unique complication of trazodone and is more common with therapeutic use rather than in acute overdose.

8. A patient presents after a substantial accidental overdose of her monoamine oxidase inhibitor (MAOI), which she confused with her megavitamin therapy. There is no need for psychiatric evaluation. She is asymptomatic and has normal vital signs and a normal physical examination. What is the appropriate disposition?
   a. Admit to intensive care unit for a minimum of 24 hours of observation
   b. Admit to ward for a minimum of 24 hours of observation
   c. Discharge home
   d. Observe for 6 hours, then discharge home
   e. Observe for 12 hours, then discharge home

   Answer: A. All patients who overdose on MAOIs should be admitted for at least 24 hours of observation because symptom onset is often delayed. In addition, the effects of overdose may be severe and require aggressive therapy.

CARDIOACTIVE STEROIDS (DIGOXIN)

KEY CONCEPTS

- Digoxin toxicity is often occult and should be considered in any patient who is on digoxin and presents with gastrointestinal or visual disturbance and a new dysrhythmia, conduction disturbance or hemodynamic instability, particularly in the setting of ingestion of a natural weight-loss supplement.
- Digitalis Fab is the specific antidote for digoxin toxicity and is dosed based on chronicity of poisoning; most patients require only 1 (chronic poisoning) or 2 (acute poisoning) vials. If full reversal is needed for patients in extremis, dosing is based on total body load of digoxin, not by patient weight.
- Indications for digitalis Fab include progressive and hemodynamically significant bradydysrhythmias and serum potassium >5.0 mEq/L, as summarized in Box 142.4. Of note, Fab therapy should be used before pacing or antidysrhythmic drugs.
- Hyperkalemia in acute digoxin toxicity is best treated with Fab fragments. Conventional treatment as for any other cause of hyperkalemia is also appropriate when Fab fragments are not immediately available. Hyperkalemia in chronic poisoning is likely multifactorial and should be treated with Fab fragments followed by usual hyperkalemia treatments as needed.

Foundations

Digoxin is derived from the Grecian foxglove plant, *Digitalis lanata* (Fig. 142.1); the trade name for digoxin (Lanoxin) is derived from the Latin name of this plant. Digitoxin, which is no longer in clinical use in the United States, comes from *Digitalis purpurea* (Fig 142.2).[2] Despite centuries of experience with digitalis preparations, chronic and acute poisonings still occur. Medication errors, including failure to account for drug-drug and disease-drug interactions (particularly kidney disease), account for a substantial number of poisonings.[3] Though the use of digoxin continues to be controversial, it is still commonly prescribed, particularly for patients with concomitant heart failure and atrial fibrillation.[4]

Digoxin is used therapeutically (1) to increase the force of myocardial contraction to increase cardiac output in patients with heart failure and (2) to decrease atrioventricular (AV) conduction to slow the ventricular rate in atrial fibrillation. The basis for its first effect is inhibition of membrane sodium-potassium–adenosine triphosphatase (Na^+, K^+-ATPase) pumps; this inhibition results in increased intracellular sodium and extracellular potassium concentrations.[5] This increase in intracellular sodium concentration results in dysfunction of the sodium-calcium ion exchanger, which normally extrudes intracellular calcium after systole. This subsequent increase in intracellular calcium concentration results in a larger amount of calcium pumped into the sarcoplasmic reticulum so that upon calcium release during subsequent action potentials, a larger amount of calcium is released into the cell, causing a more powerful contraction and thus increased stroke volume and subsequent cardiac output. Molecules containing an aglycone steroid moiety with this specific effect are classified as cardioactive steroids.[6] Cardiac glycosides (such as digoxin) are merely cardioactive steroids with additional sugar moieties attached to their steroid nucleus.[5] At therapeutic doses, the effects of digoxin on serum electrolytes are minimal. With toxic concentrations, digoxin paralyzes the Na^+, K^+-ATPase pump, potassium cannot be transported into cells, and serum potassium concentration can rise as high as 13.5 mmol/L.

Digoxin exerts direct and indirect effects on sinoatrial (SA) and AV nodal fibers. At therapeutic concentrations, digoxin indirectly increases vagal activity. At toxic concentrations, digoxin can directly block the generation of impulses in the SA node, depress conduction through the AV node, and increase the sensitivity of the SA and AV nodes to catecholamines. Catecholamines, whether endogenous or administered to treat bradydysrhythmias or hypotension, play an important role in digoxin toxicity. Because bradydysrhythmias and tachydysrhythmias can appear and alternate in the same patient, administration of antidysrhythmic agents to treat tachycardias may later contribute to more refractory bradycardias and AV block.

Digoxin also exerts three primary effects on Purkinje fibers: (1) decreased resting potential, resulting in slowed phase 0 depolarization and conduction velocity; (2) decreased action potential duration, which increases sensitivity of muscle fibers to electrical stimuli; and (3) enhanced automaticity resulting from increased rate of phase 4 repolarization and delayed after-depolarizations. These mechanisms account for an increase in premature ventricular contractions, which is the most common electrocardiographic manifestation of digoxin toxicity. At extremes of toxicity, these effects result in a hypersensitivity to mechanical and electrical stimulation. Interventions with pacemaker wires, catheters, and cardioversion can result in asystole, ventricular tachycardia, and ventricular fibrillation.

Unlike most cardiovascular drugs, digoxin can produce virtually any dysrhythmia or conduction block, and bradycardias are as common as tachycardias (Box 142.1). However, none is unique to digoxin, and because they can all occur in the setting of ischemic and other heart disease, digoxin toxicity remains a clinical rather than an electrocardiographic diagnosis.

The volume of distribution (V_d) of digoxin is 5 L/kg for adults but varies from 3.5 L/kg in premature infants to 16.3 L/kg in older infants. This indicates that only a small fraction of digoxin remains in the intravascular space, and the drug is highly concentrated in cardiac tissue. The myocardial-to-serum ratio at equilibrium ranges from 15 : 1 to 30 : 1.

The elimination half-life of digoxin, which is primarily excreted in the urine, is 36 hours.

Protein binding varies from 20% to 30% for digoxin. The significant protein binding and large volumes of distribution of digoxin suggest that hemodialysis, hemoperfusion, and exchange transfusion are ineffective. The long half-lives have therapeutic implications for

temporizing measures such as pacemakers, atropine, and antidysrhythmic drugs compared to the more definitive treatment of Fab fragments.

Multiple drugs and disease states can alter absorption, V_d, protein binding, and elimination, rendering the heart more susceptible to digoxin toxicity. The factors listed in Box 142.2 are especially important risk factors in chronic intoxication.

Clinical Features

The symptoms and signs of chronic digoxin toxicity are nonspecific. The most common symptoms are nausea, anorexia, and fatigue; but a variety of gastrointestinal, neurologic, and ophthalmic disturbances also occur (Box 142.3). Visual disturbances include decreased visual acuity, scotomata, photophobia, and chromatopsia (aberrations of color vision, classically yellow, but may occur in a variety of colors). Digoxin intoxication should be considered in any patient receiving maintenance therapy who has consistent symptoms, no matter how vague, particularly if presenting with new conduction disturbances or dysrhythmias.

There are significant differences between acute and chronic toxicity (Table 142.1). Chronic poisoning has an insidious onset and is accompanied by a higher mortality rate that is likely due in part to underlying heart disease and chronic accumulation of the toxin. In cases of chronic intoxication, the level with a 50% mortality (LL_{50}) is only 6 ng/mL. The LL_{50} for acute poisoning is much higher, especially in children. Although toxicity increases with greater body load, there is no clear correlation with amount ingested, especially in children, and many patients with large acute ingestions or high serum levels become only mildly symptomatic. The association of hyperkalemia with acute toxicity is more apparent given the mechanism of digoxin; either hypokalemia or hyperkalemia may occur with chronic toxicity.

Pediatric Considerations

Children with healthy hearts can tolerate massive acute oral ingestions and may not require Fab treatment. This excludes therapeutic errors, children who are taking digoxin therapeutically, and children with heart disease.

Medication errors account for the most common causes of preventable iatrogenic cardiac arrests. Therapeutic errors, especially accidental IV overdoses, often result in death within 1 to 4 hours.

Fig. 142.2 The common foxglove plant *Digitalis purpurea*, the source of digitoxin. The flowers are typically purple but may also be white. White flowers may mature to purple or may remain white. (Photos courtesy of Ann Arens, MD.)

BOX 142.1 Dysrhythmias Associated With Digoxin Toxicity

Nonspecific Dysrhythmias
PVCs, especially bigeminal and multiform
AV heart blocks of all degrees
Sinus bradycardia
Sinus tachycardia
SA block or arrest
Atrial fibrillation with slow ventricular response
Atrial tachycardia
Junction (escape) rhythm
AV dissociation
Ventricular bigeminy and/or trigeminy
Ventricular tachycardia
Ventricular fibrillation

More Specific but Not Pathognomonic
Atrial fibrillation with slow, regular ventricular rate (AV dissociation)
Nonparoxysmal junctional tachycardia (rate usually 70–130 beats/min)
Atrial tachycardia with block (atrial rate usually 150–200 beats/min)
Bidirectional ventricular tachycardia

AV, Atrioventricular; *PVCs*, premature ventricular contractions; *SA*, sinoatrial.

BOX 142.2 Factors Associated With an Increased Risk of Digoxin Toxicity

Concomitant kidney injury or underlying kidney disease
Concomitant or underlying heart disease
- Congenital heart disease
- Ischemic heart disease
- Heart failure
- Myocarditis

Electrolyte disturbances
- Hyperkalemia
- Hypokalemia
- Hypomagnesemia
- Hypercalcemia

Alkalosis
Hypothyroidism
Sympathomimetic drugs (e.g., cocaine)
Cardiotoxic co-ingestions
- Beta-blockers
- Calcium channel blockers
- Class IA or IC antidysrhythmics (e.g., flecainide)
- Tricyclic antidepressants

Drug interactions (may increase serum digoxin concentration)
- Quinidine
- Amiodarone
- Erythromycin
- Nifedipine

Drug Interactions (may increase serum digoxin concentration and cause synergistic bradycardia)
- Verapamil
- Diltiazem

Signs and symptoms in children with digoxin poisoning are different than in adults (Table 142.2). Vomiting, somnolence, and obtundation are more common than in adults. Conduction disturbances and bradycardias are more common than ventricular dysrhythmias in children, especially following acute ingestion.

BOX 142.3 Noncardiac Symptoms of Cardioactive Steroid Intoxication

General
Weakness
Fatigue
Malaise

Gastrointestinal
Nausea and/or vomiting
Anorexia
Abdominal pain
Diarrhea

Ophthalmologic
Blurred or snowy vision
Photophobia
Chromatopsia (yellow, green, red, brown, blue vision changes)
Transient amblyopia, diplopia, scotomata, blindness

Neurologic
Dizziness
Headache
Confusion, disorientation, delirium
Visual and/or auditory hallucinations
Somnolence
Abnormal dreams
Paresthesias and/or neuralgia
Aphasia
Seizure

TABLE 142.1 Acute Versus Chronic Digoxin Poisoning

Acute	Chronic
Lower mortality	Higher mortality (LL_{50} = 6 ng/mL)
Bradycardia and AV block more common	Ventricular dysrhythmias more common
Typically, younger patients	Typically, elderly patients
Underlying heart disease generally less common, decreased morbidity and mortality	Underlying heart disease more common, increased morbidity and mortality

AV, Atrioventricular; *LL_{50}*, level with a 50% mortality.

Differential Diagnoses

No sign or symptom, including dysrhythmia, is unique to digoxin poisoning, so its differential diagnosis is broad. Intrinsic cardiac disease as well as other cardiotoxic drugs should be considered, particularly beta-blockers and calcium channel blockers. Cardioactive steroid poisoning from plants is rare in the United States but presents similarly to digoxin toxicity. Common examples include oleander (*Nerium oleander*) and lily-of-the-valley (*Convallaria majalis;* Fig. 142.3). Recently, there has been an increase in the use of natural products containing cardioactive steroids for the purpose of weight loss.[7] Several cardioactive-steroid containing plants have been purported to be "natural" agents for weight loss, including pong-pong seeds (*Cerebra odollam*) and yellow oleander (*Thevetia peruviana*), both of which have resulted in fatal poisonings.[8,9] Yellow oleander is particularly problematic in that its seeds bear a physical resemblance to the seeds of another minimally toxic plant

(that does not contain cardioactive steroids but is also purported to aid in weight loss) commonly called candle nuts (*Aleurites moluccana*). The substitution of yellow oleander for candle nuts has resulted in at least one accidental fatality; it is likely other cases have gone unrecognized.[9] In some parts of the world, such as Southeast Asia and India, ingestion of plants containing cardioactive steroids (e.g., pong-pong or yellow oleander seeds) is a common method of suicide[10]; ingestion of 1 or 2 yellow oleander seeds has resulted in death.[6] Aconitine, a sodium-channel opening poison found in common Monkshood plants *(Aconitum napellus),* may also mimic digoxin poisoning.[11]

Central nervous system (CNS) depression or confusion may be due to various depressant drugs (e.g., opioids, sedative hypnotic agents, alcohol) and toxins, as well as infection, trauma, inflammation, and metabolic derangements. Visual disturbances caused by digoxin are binocular and are often not reported by the patient; they are not specific to digoxin poisoning. Methanol, metformin, ethambutol, ethyl chloride, quinine, and other antimalarial medications are all capable of producing visual disturbances. Gastrointestinal disturbances are common and nonspecific and may be misdiagnosed as gastritis, enteritis, or colitis.

TABLE 142.2 Age Difference in Digoxin Intoxication

Adult	Pediatric
Toxic at lower concentrations	Asymptomatic at higher concentrations
Nausea, fatigue, and visual disturbances more common	Obtundation and vomiting more common
Tachydysrhythmias as common as blocks and bradydysrhythmias	Bradydysrhythmias and blocks more common
Allergic reactions to Fab fragments uncommon (<1%)	Allergic reactions extremely rare
V_d less variable (5–7.5 L/kg)	V_d more variable (3.5–6.0 L/kg in premature infants, 8.0–16.3 in infants 2–24 months old)

V_d, Volume of distribution.

Diagnostic Testing

Diagnosis and management rely on serum digoxin concentrations, but it is the steady state, rather than peak concentration, that correlates with tissue toxicity and is used to calculate antidote dosages. Peak concentrations after an oral dose of digoxin occur in 1.5 to 2 hours, with a range of 0.5 to 6 hours. Steady-state serum concentrations are not achieved until after alpha distribution, or 6 to 8 hours after a therapeutic or toxic dose and may be only 20% to 25% of the peak concentration. The ideal serum digoxin concentration for patients with heart failure is considered to be 0.7 to 1.1 ng/mL, although laboratory "normal ranges" are often reported up to 2.0 ng/mL. Serum steady-state digoxin concentrations of 1.1 to 3.0 ng/mL are difficult to interpret; that is, concentrations as low as 1.1 ng/mL have been associated with toxicity, and patients with levels up to 3.0 ng/mL can be asymptomatic. The incidence of digoxin-incited dysrhythmia reaches 10% at a concentration of 1.7 ng/mL and rises to 50% at a concentration of 2.5 ng/mL. Determination of a serum digoxin concentration measured too early after the last maintenance dose falsely suggests toxicity, especially in cases of chronic intoxication, in which significant morbidity and mortality can occur at levels of 2 to 6 ng/mL. After an acute massive overdose in a patient who is rapidly becoming symptomatic, however, it is impractical to wait 6 to 8 hours for the first measurement. It is unlikely that early concentrations exceeding 10 to 20 ng/mL will fade to clinical insignificance at 6 to 8 hours after ingestion.

Management

Fab Fragments (DigiFab)

The primary treatment of significant digoxin poisoning is the administration of digoxin-specific fragment antigen-binding (Fab) antibodies (DigiFab); all other interventions are considered complementary.

The mortality rate of digoxin poisoning before Fab fragment therapy was 23% despite all of the interventions described in this section.

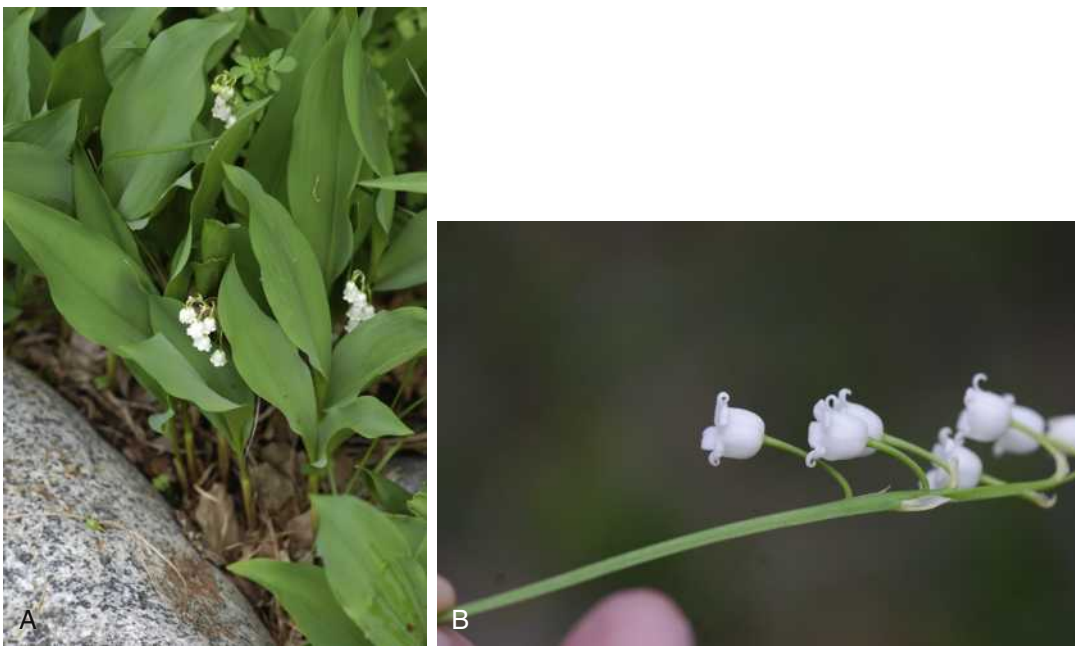

Fig. 142.3 Lily-of-the-valley (*Convallaria majalis*), which contains the cardiac glycoside convallatoxin. (Photos courtesy of Gary Bebeau and Friends of the Eloise Butler Wildflower Garden, Minneapolis, Minnesota.)

Fig. 142.4 A vial of digoxin antibody fragments (DigiFab) next to a cutting of *Digitalis purpurea*, demonstrating the darkening of the purple flowers as they age. (Photo courtesy of Laurie Wilhite, PharmD, CSPI.)

Fab fragment treatment is well established in both chronic and acute poisonings, with a successful response rate approaching 90%. Nonresponders usually receive Fab fragments too late, have concomitant poisoning, or are compromised by underlying comorbidities.

Digoxin antibodies are derived from sheep. Allergic reactions occur in less than 1% of cases but are slightly more common in patients with asthma. Reactions have included erythema, urticaria, and facial edema, all of which are responsive to the usual treatments for allergic reactions (e.g., diphenhydramine, corticosteroids, epinephrine). Other infrequent reactions when Fab fragments neutralize digitalis include hypokalemia, heart failure exacerbation, and increase in ventricular rate with atrial fibrillation. Two Fab fragment preparations were previously available; however, DigiFab is the only available product in the United States (Fig. 142.4). Previous products required a 0.22-μm membrane filter for proper use; such a filter is not required for DigiFab.

Fab fragment treatment is best reserved for cases of serious cardiovascular toxicity rather than for routine or prophylactic administration with higher than expected serum concentrations. Fab fragments should be used for a serum potassium level above 5.0 mEq/L or unstable dysrhythmias such as symptomatic bradycardia, ventricular dysrhythmias, or second- or third-degree heart block unresponsive to atropine. Fab fragment therapy should be used before transvenous pacing, because the latter is believed to carry a higher risk of ventricular dysrhythmia, although the evidence for this is mixed. Large acute overdoses (>0.1 mg/kg in a child or 10 mg in a healthy adult) are also likely to require Fab fragments.

The median time to initial response is 19 minutes after completion of the Fab infusion, but complete resolution of digitalis-induced toxic dysrhythmias may require hours. Late administration of Fab fragments has resuscitated up to 54% of patients who have suffered cardiac arrest secondary to digoxin toxicity. Fab fragments should be administered whenever hemodynamic compromise occurs in the setting of a digoxin-induced toxic dysrhythmia or heart block; a full list of indications is included in Box 142.4.

Dosing of Fab fragments is based both upon the patient's clinical status and acuity of poisoning. Patients in cardiac arrest, or in the midst of a life-threatening ventricular dysrhythmia, generally require full reversal. In chronic poisoning, however, the benefit of Fab fragments is less clear. Recently published prospective data on chronic digoxin-poisoned patients shows that small doses (median dose 1.5 vials) results in complete binding of free digoxin, with minimal improvement in clinically important parameters such as heart rate, blood pressure, or serum potassium.[12,13] These prospective data, which compared chronically digoxin-poisoned patients with similar physiologic parameters receiving Fab fragments with those who received supportive care only, showed no difference in vital signs, potassium, or mortality, despite complete binding of all available free digoxin. These data call into question the utility of Fab fragments in chronically poisoned patients. Nevertheless, in hemodynamically unstable patients, such as those with hypotension, treatment with Fab fragments is still considered the standard of care.

If the patient is in cardiac arrest, the maximum number of vials of Fab fragments available (up to 10) should be administered undiluted as an intravenous (IV) bolus. If, in acute or chronic toxicity, the patient is in a life-threatening ventricular dysrhythmia or heart block and the serum digoxin concentration *is unknown* but the amount of digoxin ingested is known, we recommend full reversal based upon the following concept: one vial of DigiFab contains 40 mg of Fab fragments, which bind 0.5 mg of digoxin (Box 142.5). In the same patient, if the steady-state serum digoxin concentration *is known*, we recommend full reversal with Fab fragments based upon the digoxin concentration utilizing the formula in Box 142.6. An exception to the above regimens is the case of yellow oleander poisoning, where a high case fatality rate and poor cross-reactivity of Fab fragments with the offending cardioactive steroids necessitates higher dosing. Therefore, with acute yellow oleander poisoning, 20 to 30 vials (if available) are recommended.

In hemodynamically stable patients, we recommend a more conservative dosing regimen of Fab fragments. The total body burden of digoxin is often overestimated. Furthermore, the incidence of life-threatening dysrhythmias, even in reported large ingestions, is low,

BOX 142.4 Recommendation for Administration of Digoxin Antibody Fragments

1. Ventricular dysrhythmias more severe than PVCs
2. Progressive and hemodynamically significant bradydysrhythmias unresponsive to atropine
3. Serum potassium >5.0 mEq/L
4. Rapidly progressive rhythm disturbances or rising potassium
5. Co-ingestion of cardiotoxic drugs (for examples, see Box 142.2)
6. Ingestion of plant known to contain cardioactive steroids plus severe dysrhythmia or potassium >5.0 mEq/L
7. Acute ingestion of >10 mg or 0.1 mg/kg in a child *plus* any one of factors 1 through 6
8. Steady-state digoxin concentration > 6 ng/mL *plus* any one of factors 1 through 6

BOX 142.5 Sample Calculation of Digitalis Fab Fragments based on Ingested Dose

Case: A toxic-appearing 40-year-old woman has acutely ingested fifty 0.25-mg digoxin tablets.

$$\text{Body load} = \text{amount ingested} \times 0.8\ (\text{bioavailability of digoxin tablets}) = 12.5\ \text{mg} \times 0.8 = 10\ \text{mg}$$

$$\text{Dose of digoxin Fab fragments (in vials)} = 10\ \text{mg} \div 0.5\ \text{mg bound per vial} = 20\ \text{vials}$$

BOX 142.6 Sample Calculation of Digitalis Fab Fragments Based on Steady-State Digoxin Concentration

Case: A toxic-appearing 4-year-old child weighing 20 kg has a digoxin level of 16 ng/mL 8 hours after ingestion of an unknown number of digoxin tablets.

Dose (in number of vials) = (serum digoxin concentration × weight in kg) ÷ 100
= (16 × 20) ÷ 100
= approximately 3 vials

suggesting most patients do not require Fab fragments.[13] Pharmacokinetic modeling of digoxin toxicity suggests smaller doses of Fab fragments than previously recommended are adequate to reverse toxicity.[14] Therefore, in acute digoxin poisoning, if the patient has an indication for Fab fragments (see Box 142.4) but is not in an immediately life-threatening ventricular dysrhythmia or heart block, we recommend two vials, repeated as needed using clinical markers of toxicity such as evidence of shock or severe dysrhythmias. For similar patients with chronic poisoning, the recommended dose is one vial with a repeat dose at 60 minutes if the patient remains symptomatic. Earlier repeat dosing is reasonable if the patient becomes unstable.

Because most assays measure both bound and unbound drug, digoxin concentrations will be elevated for up to one week after Fab fragments administration, with values often greater than 100 ng/mL once Fab fragments have been administered. If laboratory measurement of free serum digoxin is available, these levels more accurately follow a patient's clinical status.

Electrolyte Correction

In cases of chronic toxicity, which may be exacerbated by hypokalemia, normalization of the serum potassium is an important early treatment. Potassium can be administered orally in the alert patient (which is safer) or intravenously at a rate of 20 mEq/hr or less.

In acute poisoning, serum potassium concentration may begin to rise rapidly within 1 to 2 hours of ingestion. Potassium should be withheld, even if mild hypokalemia is measured initially. The initial serum potassium concentration may in fact be a better predictor of mortality than the initial digoxin concentration. Before Fab fragments were available, up to 50% of the patients with serum potassium concentrations between 5.0 and 5.5 mEq/L died. In the setting of acute digoxin poisoning, we recommend initiating Fab fragment treatment based solely on a serum potassium concentration greater than 5 mEq/L.

The decision to administer calcium to patients with hyperkalemia and digoxin poisoning represents a clinical dilemma. Classic teaching is that in the setting of the increased intracellular calcium concentration from digoxin poisoning, administration of exogenous calcium will result in a "stone heart" (cardiac tetany) from excessive intracellular calcium. This concept has been in the literature since 1927, based primarily on animal studies. Documented cases of cardiac arrest after calcium administration are exceedingly rare, and the temporal relationship is dubious. More recent human data indicate that the IV administration of calcium for hyperkalemia in the setting of digoxin toxicity is safe. Unequivocally, however, the best treatment of hyperkalemia due to acute digoxin toxicity is Fab fragments. The treatment of hyperkalemia in a patient with chronic digoxin toxicity and renal failure is less clear. Patients with hyperkalemia and chronic digoxin poisoning often have multiple reasons for hyperkalemia in addition to digoxin toxicity (e.g., acute worsening of renal function, concomitant use of potassium-sparing diuretics). Furthermore in chronic digoxin-poisoned patients, even when full digoxin reversal is performed, potassium levels rarely decline further than with supportive care alone.[13] Regardless, the evidence that calcium salts will be harmful in chronic digoxin poisoning is lacking. As such, treatment of hyperkalemia related to digoxin toxicity is similar in indication and approach to that for hyperkalemia from other causes after Fab fragments have been administered (see Chapter 114).

Hypomagnesemia enhances the effects of cardioactive steroids. Therefore, any patient with suspected poisoning should have serum magnesium concentrations measured. This is further supported by evidence of magnesium reversing digoxin-induced tachydysrhythmias. If significant magnesium depletion is present, 1 to 2 g of magnesium sulfate should be administered over 10 to 20 minutes (child: 25 mg/kg), followed by a constant infusion of 1 to 2 g/hr until magnesium concentrations are normal, accounting for concomitant kidney injury. We do not recommend administration of magnesium in digoxin-induced bradydysrhythmias and conduction blocks, because hypermagnesemia can impair impulse formation and AV conduction.

Atropine

Atropine is generally used for symptomatic bradycardia (pulse < 50 beats/min) and advanced AV block. We recommend using atropine as a temporizing measure for symptomatic patients while Fab fragments are being administered. We also recommend atropine for bradycardia refractory to Fab fragments. Standard dosing (0.02 mg/kg in children with a minimum of 0.1 mg; 1 mg IV in adults) should be used. Doses can be repeated every 3 to 5 minutes. In general, an external pacemaker should be readied once atropine has been administered.

Pacing and Cardioversion

Transvenous pacing is a mainstay of treatment for severe bradycardia. There is some evidence that the catheter may induce ventricular tachydysrhythmias in a myocardium made irritable by digoxin, although convincing studies on this question are lacking. Iatrogenic accidents of cardiac pacing are frequent (36%) in one study and can be fatal (up to 13%). Transvenous pacing should be used only if external pacing fails. Pacing usually is required only temporarily while waiting for Fab fragments to take clinical effect. Cardioversion in the setting of digoxin poisoning should be reserved for life-threatening dysrhythmias such as pulseless ventricular tachycardia or ventricular fibrillation.

Phenytoin and Lidocaine

Fab fragments are the preferred therapy for dysrhythmias, but a dysrhythmia may require intervention while Fab fragments are readied or until they begin to have effect after infusion.

Although both phenytoin and lidocaine are believed to be safe for control of tachydysrhythmias in the setting of digoxin toxicity, we prefer phenytoin. Indications for phenytoin include unstable tachydysrhythmias when Fab fragments are unavailable and unstable tachydysrhythmias that occur while waiting for Fab fragments to take effect. Phenytoin may enhance AV conduction. We recommend administering phenytoin in 100 mg boluses every 5 minutes until dysrhythmias improve or until the standard loading dose of 18 mg/kg is reached. No data exist to support or refute the substitution of fosphenytoin for phenytoin in this scenario. We recommend lidocaine only if the patient has a contraindication to phenytoin or if the maximum dose of phenytoin has been reached. When given, we recommend a loading dose of 1.5 mg/kg IV push, followed by an infusion of 1 to 4 mg/min (30 to 50 μg/kg/min), started at 1 mg/min and titrated up based on response to therapy. Most other cardiac drugs (isoproterenol, procainamide, amiodarone, beta-blockers, calcium antagonists) may worsen dysrhythmias or depress AV conduction in digoxin poisoned patients and should not be administered in this setting.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO has been successfully used to treat cardioactive steroid poisoning, though cases are rare and data are limited.[15] Due to the relatively high survival rate in patients with cardiac arrest from digoxin poisoning treated with Fab fragments, we recommend ECMO in this instance only if Fab fragments are ineffective in establishing return of spontaneous circulation, or in the rare instance of cardiac arrest or refractory cardiogenic shock at an institution where ECMO is readily available, but high doses of Fab fragments are not.

Disposition

Patients who are symptomatic from digoxin toxicity with hyperkalemia, dysrhythmia, AV block, or significant comorbidity should be admitted to an intensive care unit after treatment with Fab fragments. Asymptomatic patients reporting an acute ingestion of digoxin should be observed for at least 12 hours of continuous cardiac monitoring. Chronically poisoned patients should be admitted to a monitored setting because they often have concomitant comorbidities and underlying heart disease.

BETA-BLOCKERS

KEY CONCEPTS

- Beta-blocker intoxication causes bradydysrhythmias and occasionally AV block.
- Noncardiac symptoms such as obtundation, seizures, and hypoglycemia may occur early in the course and are classically associated with propranolol toxicity.
- Volume expansion, atropine, calcium, and glucagon are early treatment measures, but absent a response, begin a high-dose insulin (HDI)/glucose infusion.
- When using HDI/glucose infusions, concentrated glucose solutions are recommended to avoid fluid overload.

Foundations

Principles of Toxicity

Beta-adrenergic blocking drugs (commonly referred to as beta-blockers) became widely used in Europe in the 1960s for treatment of dysrhythmias. Their antihypertensive effects were later appreciated. By the 1970s, they were one of the most widely prescribed classes of drugs in the United States. Current indications include supraventricular dysrhythmias, hypertension (although the drugs have fallen out of favor for this indication), angina, thyrotoxicosis, migraine, and glaucoma. Of the numerous beta-blockers available, overdose with propranolol has the highest fatality rate. In 2018, United States poison centers received more than 26,000 calls regarding beta-blocker exposures.[1] Over 1000 of these calls were regarding patients with life-threatening symptoms. While the vast majority of beta-blocker overdoses have favorable outcomes,[16] deaths from isolated ingestions still occur regularly.

Pathophysiology

Beta-blockers structurally resemble isoproterenol, a pure beta-agonist. They competitively inhibit endogenous catecholamines such as epinephrine at beta-adrenergic receptors, blocking the catecholamine effects of inotropy (increased myocardial contraction), dromotropy (enhanced cardiac conduction), and chronotropy (increased heart rate). These are all β_1 effects. Complex β_2 effects include vascular (smooth muscle relaxation and vasodilation), liver (glycogenolysis, gluconeogenesis), lung (bronchodilation), adipose tissue (release of free fatty acids), and uterus (smooth muscle relaxation) effects. Important additional properties, which vary from one beta-blocker to another, include cardioselectivity (β_1 selectivity), membrane-stabilizing activity (fast cardiac sodium channel blocking properties), lipophilicity, and intrinsic sympathomimetic activity (Table 142.3). Although cardioselectivity is masked in overdose, cardioselective beta-blockers such as atenolol, metoprolol, and esmolol still have lower mortality rates than that of propranolol.[1]

Beta-blockers are rapidly absorbed after oral ingestion, with peak effects varying among drugs (Table 142.3). Hepatic metabolism on first pass results in significantly less bioavailability after oral dosing than with IV injection (e.g., 1 : 40 for propranolol, 1 : 2.5 for metoprolol). Because volume of distribution for most beta-blockers generally exceeds 1 L/kg, hemodialysis is not efficacious for most beta-blocker overdoses.

Clinical Features

The most common initial clinical sign is bradycardia. Hypotension and unconsciousness are also common. While unconsciousness may be from a lack of brain perfusion due to cardiotoxic effects, beta-blockers (particularly propranolol) may also cause direct CNS depression and apnea. Hypoglycemia, due to blockade of the counter-regulatory effects of epinephrine, is often described, but rare. Though uncommon in all patients, hypoglycemia is more common in children than adults. In overdose, signs and symptoms are identical among beta-blockers, with the exception of propranolol which tends to cause seizures.[16] Much of propranolol's unique toxicity derives from its lipophilic nature combined with its membrane-stabilizing activity, which allows it to penetrate the CNS, causing obtundation, respiratory depression, and occasionally seizures. Of note, bronchospasm is rarely a problem in beta-blocker overdose, even with nonselective beta-blockers. The few cases of symptomatic bronchospasm respond to usual doses of nebulized bronchodilators.

Propranolol, nadolol, betaxolol, and acebutolol have membrane-stabilizing activity that impairs SA and AV node function and leads to bradycardia and AV block. Ventricular conduction is also depressed secondary to membrane-stabilizing activity (similar to tricyclic antidepressants or class IA/IC antidysrhythmics), which manifests as QRS widening on ECG, with ventricular dysrhythmias and cardiogenic shock. The intrinsic sympathomimetic activity of some beta-blockers (e.g., pindolol, oxprenolol, acebutolol, carteolol) can lead to some unusual manifestations such as ventricular dysrhythmias and tachycardia instead of bradycardia. Labetalol and carvedilol also block α_1-adrenergic receptors, giving an additional mechanism for hypotension and distributive shock, however clinically they present similarly to other beta blockers due to their respective $\beta : \alpha$ blockade ratios. Labetalol's beta-blockade is three times more potent via the oral route, and seven times more potent intravenously than its α-blockade. Carvedilol is even more beta-selective; its blockade of β_1 and β_2 receptors is 10 times more potent than α_1.

In contrast to digoxin, beta-blocker toxicity has a more rapid onset. Life-threatening CNS and cardiovascular effects can occur 30 minutes after oral overdose. With the exception of sotalol, which causes QT prolongation and torsades de pointes, toxicity from beta-blocker poisoning is usually apparent within 6 hours of ingestion. Patients ingesting delayed-release preparations, however, may remain asymptomatic for several hours, followed by a prolonged period of toxicity of up to 24 hours. For additional clinical features, see Table 142.5.

TABLE 142.3 Selected Pharmacologic Characteristics of Common Beta-Blockers

Drug	Time to Peak (hrs, oral form)	T1/2 (hrs)	V_d (L/kg)	Lipophilicity	Protein Binding (%)	MSA	ISA	Comments
Non-Selective Beta-Blockers								
Propranolol	1–4 (6–14 ERF)	4.0	4.0	+	93	Yes	No	Most fatalities
Nadolol	3–4	10–20	1.9	0	20	No	No	Dialyzable
Timolol	1–2	3–5	1.4–3.4	+	10	No	No	Dialyzable; available as ocular drops
Pindolol	1	3–4	3–6	+	51	Yes	Yes	
Labetalol	1–2	4–6	10	0	50	Yes	No	α_1-blockade
Oxprenolol	3	2	1.3	+	78	Yes	Yes	
Sotalol	2–4	7–18	1.6–2.4	+	0	No	No	Dialyzable, QT prolongation & risk of torsades de pointes
Carvedilol	5	6–10	1.5–2	+	95	No	No	α_1-blockade
Selective Beta-Blockers								
Metoprolol	1–2 (4–5 ERF)	3–4	5.5	+	12	No	No	
Atenolol	2–4	5–8	0.7	0	5	No	No	Dialyzable
Esmolol (IV only)	rapid	0.13	2	0	55	No	No	
Acebutolol	2–4	2–4	1.2	+	26	Yes	Yes	Dialyzable, QT prolongation & risk of torsades de pointes
Bisoprolol	2–4	10–12	2.9	0	30	No	No	
Betaxolol	1.5–6	12–22	5 - 13	0	55	No	No

Differential Diagnoses

The combination of bradycardia and hypotension suggests beta-blockade, calcium channel blockade, or digoxin poisoning. Centrally acting α_2-adrenergic agonists such as clonidine and tizanidine or imidazoline receptor agonists such as tetrahydrozoline and oxymetazoline may also cause this constellation of symptoms. Without a history of beta-blocker ingestion, the diagnosis can be challenging, especially when non-cardiac effects such as CNS depression and seizures predominate. Sodium channel poisoning with QRS widening can occur, suggesting other antidysrhythmic drugs or cyclic antidepressants. The differential diagnoses also include sedative-hypnotic drug overdose, hypoglycemic drug ingestion, opioid overdose, CNS injury or infection, various endocrine and metabolic disorders, sepsis, and acute myocardial infarction.

Diagnostic Testing

Diagnosis and management depend entirely on the clinical picture, and the only essential testing is a point-of-care glucose monitoring and a 12-lead electrocardiogram (ECG) with continuous ECG monitoring. Serum concentrations of beta-blockers correlate poorly with severity of intoxication and are not readily available. Most urine toxicology screens do not identify antidysrhythmic drugs and are not helpful. Known access of the patient to a beta-blocker and consistent clinical features such as bradycardia and hypotension should lead the clinician to consider beta-blocker intoxication and begin empirical treatment. Whereas some authors believe that a serum lactate concentration can help predict mortality in overdose patients,[17] this has not held true in pure beta-blocker ingestions.

Management

Immediate measures include IV fluids for hypotension, supplemental oxygen as needed for hypoxia, and monitoring of cardiac rhythm and respirations. Whole-bowel irrigation is cumbersome and because there is a lack of evidence for efficacy in clinical trials, we recommend against its use in beta-blocker poisoning.[18] The clinical efficacy of gastric lavage is also unproven, the procedure is cumbersome, and benefit is outweighed by procedural risks. Please see Chapter 135 for further information on gastrointestinal decontamination, including the use of activated charcoal.

Hypotension, Bradycardia, and Atrioventricular Block

The first step in the treatment of beta-blocker overdose is bolus administration of crystalloid fluids. In hypotensive patients, 20 to 40 mL/kg of normal saline or lactated Ringers solution can be infused. Further doses of isotonic fluids, however, can lead to pulmonary edema and should be avoided particularly in older patients with underlying

TABLE 142.4 Selected Pharmacologic Characteristics of Calcium Channel Blockers

Drug	Time to Peak (hrs, oral form)	T1/2 (hrs)	V_d (L/kg)	Protein Binding (%)	Comments
Non-dihydropyridines					
Verapamil	1–2 (5–11 ERF)	3–12	4	90	Most lethal in overdose; impairs contractility and AV conduction more than most other calcium channel blockers
Diltiazem	2–4 (10–18 ERF)	3–7.9	1.7–5.3	70–80	AV node suppression similar to verapamil, contractility inhibition generally less than verapamil
Dihydropyridines					
Amlodipine	6–12	30–50	21	98	Vasodilation; additional vasodilation from nitric oxide production
Nifedipine	1 (6–11 ERF)	1–5	1.4–2.2	92–98	Vasodilation
Nimodipine	1	1–2	0.94–2.3	95	Vasodilation
Nicardipine	0.5–2 (1–4 ERF)	8–9	0.64	95	Vasodilation
Clevidipine (IV only)	Rapid	0.25	0.17	>99.5	Formulated in lipid emulsion for infusion
Felodipine	2.5–5	10	10	99	Vasodilation
Isradipine	1–1.5	1.9–16	3	95	Vasodilation
Nisoldipine	4–14	7–12	4–5	99	Vasodilation
Amine Calcium Channel Blocker					
Bepridil	2–6	33–42	8	99	Blocks sodium channels as well; QT prolongation & risk of torsades de pointes; no longer sold in United States

TABLE 142.5 Clinical Characteristic of Poisoning from Beta-Blockers and Calcium Channel Blockers

Organ System	Beta-Blockers	Calcium Channel Blockers
Cardiovascular	Bradycardia & hypotension	Bradycardia & hypotension in non-DHPs, tachycardia & hypotension with DHPs
Pulmonary	Apnea (likely central) Bronchospasm (rare)	Pulmonary edema
Neurologic[a]	Drowsiness/coma in lipophilic BBs, seizures possible, preserved consciousness in non-lipophilic BBs until shock ensues	Generally preserved mental status until shock ensues
Endocrine	Hypoglycemia (rare)	Hyperglycemia

[a]Regardless of lipophilicity, both classes may cause obtundation once shock ensues.
BB, Beta-blocker; *DHP*, dihydropyridine.

cardiac disease. Frequent monitoring of volume status, such as with point-of-care ultrasound (by measuring the diameter and collapsibility of various large vessels including the inferior vena cava and common carotid artery) is recommended to avoid volume overload. Atropine at standard doses noted earlier may be used for bradycardia but is rarely effective. We recommend atropine for a heart rate of less than 50 beats per minute with concomitant hypotension and symptoms of severe bradycardia such as weakness, drowsiness, or obtundation. Infusion of more potent drugs or cardiac pacing is often necessary, and we recommend that atropine is best used as a temporizing measure to the therapies noted later.

Calcium

The final common pathway for stimulation of beta-adrenergic receptors is an increase in intracellular calcium concentration, and deleterious effects on calcium transport may contribute to beta-blocker toxicity. Therefore, IV administration of calcium can be used for treatment of hypotension. One gram of calcium gluconate contains 4.65 mEq of elemental calcium, whereas 1 g of calcium chloride contains 13.4 mEq. Calcium chloride is an acidifying salt and can cause significant tissue damage and necrosis if extravasation at the IV site occurs. Thus, it should be administered through a central venous catheter (or a secure large-bore antecubital peripheral line if the patient is in extremis). Indications for calcium include hypotension unresponsive to crystalloid fluids or symptomatic bradycardia. Typically, the heart rate should be less than 60 beats per minute, while considering whether the patient may have relative bradycardia. We recommend an initial dose of 13 to 25 mEq of calcium in adults (1 to 2 g calcium chloride, 3 to 6 g calcium gluconate) infused over 10 minutes. Patients in extremis may receive the initial dose over one minute. If a response is observed, repeated

doses may be given in 20 minutes, and a constant infusion may be started at 20 mg/kg/hr of calcium chloride (60 mg/kg/hr of calcium gluconate). If ionized calcium is measured instead of total calcium, we recommend not to exceed 1.5 times the upper limit of normal. The total serum calcium concentration can be as high as 18 mg/dL within 15 minutes after a bolus of just 5 mL of 10% calcium chloride, so calcium concentrations should be measured at least 30 minutes after bolus dosing has finished.

Glucagon

Glucagon has both inotropic and chronotropic effects and does not depend on beta-adrenergic receptors for its action; therefore, it has long been used for beta-blocker toxicity. It stimulates the production of intracellular cyclic adenosine monophosphate independently of the beta-adrenergic receptor. Furthermore, it helps counteract the hypoglycemia induced by beta-blocker overdose. Although not well studied, the initial recommended dose of glucagon is a 3- to 10-mg IV bolus (0.05 mg/kg for children). If a response occurs to glucagon, specifically if heart rate, blood pressure, or symptom improvement is observed, an infusion can be started at 3 to 5 mg/hr. Because glucagon is rarely used in large quantities, many hospitals may not stock enough glucagon to facilitate a long-term infusion. Additionally, glucagon is only available in 1 mg/1 mL vials that must be reconstituted, and preparation of it is labor-intensive and may be prolonged. Thus, clinicians administering glucagon should simultaneously ready themselves for additional therapies, such as high-dose insulin (HDI). We recommend glucagon for patients with bradycardia or hypotension not responsive to crystalloid fluids, atropine, and an initial bolus of calcium. In addition to stocking problems in most facilities, glucagon has a short (20-minute) half-life, and its effect is often transient. Vomiting is a common complication of glucagon, particularly if administered too rapidly, so the airway should be secured or monitored closely to prevent aspiration. With cumulative large doses, glucagon should be diluted in 5% glucose in water for constant infusion. Side effects also include hypokalemia. The response to glucagon alone is often inadequate, and glucagon is likely to be less effective than HDI for severe poisoning. From clinical experience, we find glucagon most useful as a transient therapy to bridge patients to HDI therapy, unless a glucagon bolus effectively resolves symptoms.

High-Dose Insulin

Despite glucagon's longer history for treatment of beta-blocker toxicity, HDI is a superior therapy. HDI is not a vasopressor; it is a potent inotrope with vasodilating properties.[19] The mechanism for HDI is not fully elucidated but probably involves both optimization of the use of carbohydrates for fuel by cardiac myocytes and modulation of intracellular calcium. HDI improves cardiac output significantly in beta-blocker toxicity from an increase in stroke volume more than heart rate.[20] Dosing of HDI is not universally agreed on; dosing in humans successfully treated with HDI has ranged from 0.5 to 22 U/kg/hr.[21] Human evidence for years was limited to case reports and small case series, however recommendations for HDI use with beta-blocker poisoning is increasing.[22] Multiple centers have reported favorable outcomes with HDI.[22,23] In the largest HDI study to date of 199 patients (103 of which were poisoned with beta-blockers), the overall survival was 84%. In this study, 21% of patients suffered cardiac arrest; however, of those experiencing arrest, 25% survived. Median peak HDI infusion in this study was 8 U/kg/hr. In beta-blocker poisoning, we recommend a bolus of 1 U/kg of regular insulin IV, followed by an infusion at 1 U/kg/hr titrated up by 2 U/kg/hr every 10 minutes (up to a maximum of 10 U/kg/hr) based on hemodynamic response to achieve adequate end-organ perfusion. Regardless of HDI dosing, we recommend that patients receive a bolus of 25 g glucose (1 traditional "amp" of D50) prior to insulin administration unless the serum glucose is greater than 200 mg/dL. A dextrose infusion (preferably a concentrated solution such as D50)[22] is administered via a central line because patients receiving HDI therapy are at higher risk of fluid overload.[24] Glucose concentration should be monitored as frequently as every 15 minutes until a steady state of glucose use is achieved. Although glucose requirements in HDI are typically higher with beta-blockers than with calcium channel blockers,[22] in neither scenario do glucose requirements increase with increasing doses of insulin.[23] Potassium concentration should also be monitored closely and replaced as needed because patients may become hypokalemic. Clinicians should be aware that metabolic abnormalities are common in HDI; hypoglycemia occurs in 31% to 73% of patients and hypokalemia occurs in 29% to 82% of patients, though in both cases careful monitoring and replacement prevents adverse outcomes.[22,23] In addition, hypoglycemia is less common if concentrated glucose infusions are used.[22] We recommend HDI for patients experiencing hypotension despite crystalloid fluid, atropine, and a single bolus of calcium. We also recommend a central venous catheter and an arterial catheter be placed upon the decision to initiate HDI. Of note, the inotropic effects of HDI do not typically occur until 20 minutes after the insulin bolus. As such, patients may need the bridging therapies described above, while HDI takes effect.

Sodium Bicarbonate

Sodium channel blockade from beta-blockers with membrane-stabilizing activity such as propranolol occasionally causes QRS widening, which mechanistically should respond to sodium bicarbonate. Bicarbonate should be dosed at 1 to 2 mEq/kg IV as a bolus repeated every 3 to 5 minutes until the QRS narrows to less than 120 ms. It is our experience that this is typically a late or even moribund finding in propranolol overdose. We recommend sodium bicarbonate for patients poisoned with a membrane-stabilizing beta-blocker who have an acute change in QRS duration to greater than 120 ms and demonstrate clinical signs of shock.

Vasopressors and Other Inotropes

Catecholamines are indicated when mean arterial pressure (MAP) cannot be maintained at 60 mm Hg or above, despite use of crystalloid infusion, calcium, atropine, glucagon, and HDI. We recommend against the use of vasopressors before HDI, because animal data show worse outcomes with vasopressors than HDI,[25] or even placebo.[26] A clinical conundrum exists regarding the use of vasopressors for toxin-induced shock in that animal studies generally show no benefit or even harm, while human data (which is limited to case reports and case series) show generally favorable outcomes.[27] Recent data in pigs poisoned with propranolol demonstrate rapid death with a combination of norepinephrine and epinephrine, and that HDI was a superior therapy in terms of mortality.[25] HDI, however, did not confer universal survival, and in fact both survival and brain perfusion improved when norepinephrine was added to HDI.[25] Given the extensive body of evidence demonstrating the safety and effectiveness of norepinephrine in other forms of shock, we recommend it as our first-line vasopressor, titrated to a MAP of 60 mm Hg up to a dose of 0.5 mcg/kg/min. In the selection of cardioactive medications to supplement HDI, glucagon, and norepinephrine, we recommend early assessment of cardiac contractility with bedside echocardiography. If contractility and heart rate are adequate, therapeutic focus should shift to providing support with vasopressors. Our second-line vasopressor of choice is vasopressin, dosed at a constant infusion of 0.01 to 0.04 U/min. If the clinical picture is still uncertain, an assessment of systemic vascular resistance and cardiac output by either indirect or direct measurements

is recommended to determine if either cardiogenic or distributive shock exists. We recommend third-line vasopressors or inotropes be chosen based upon these measurements used in conjunction with bedside echocardiography. Refractory cases of bradycardia may respond to an external or transvenous pacemaker. A pacemaker is particularly useful when cardiac contractility is vigorous, but bradycardia is persistent.

Intravenous Fat Emulsion (Intralipid)

Intravenous fat emulsion (IFE) is an adjunctive therapy for cardiotoxic shock. This therapy was first described for treatment of toxicity from local anesthetics such as bupivacaine.[28] The pharmacologic rationale for the use of IFE is discussed in Chapter 135. Enthusiasm for IFE for beta-blocker poisoning was high after the publication of positive animal studies and several case reports describing good outcomes,[29] but subsequent larger studies cast significant doubt on the effectiveness of IFE for oral overdoses, as in beta-blockers.[30,31] One study found that in 91% of published IFE cases, a concomitant resuscitative therapy was administered that could also explain the observed positive outcome.[30] A recent systematic review and collaborative expert panel found the evidence for non-local anesthetic poisoning to be of very low quality, and did not recommend in favor or against the use of IFE, even as a salvage therapy.[32] A national toxicology organization's position statement recently stated there is no standard of care to use or not use IFE for oral overdoses, and that in circumstances where there is significant hemodynamic instability secondary to a lipid-soluble drug, that IFE is a reasonable consideration for therapy. As such, we recommend IFE in patients with persistent bradycardia or hypotension not responding to IV fluids, calcium, HDI, and at least three vasopressors or inotropes at maximum recommended infusion rates and if extracorporeal membrane oxygenation (ECMO) is unavailable. Dosing for IFE is also not universally agreed upon.[33] We recommend an initial bolus of 1.5 mL/kg of 20% lipid solution given over 2 to 3 minutes, followed immediately by an infusion of 0.25 mL/kg/min. If a response occurs at this infusion rate, the infusion dose may be decreased to 0.025 mL/kg/min (1/10th the initial rate) to sustain lipemic serum for a longer period of time.[33,34] The 1.5 mL/kg bolus can be repeated up to two additional times for refractory shock or cardiac arrest, although clinicians should avoid exceeding 10 mL/kg unless hemodynamic compromise requires otherwise. Response, when it occurs, is typically within minutes of the bolus.

The use of IFE is associated with several complications, including extreme lipemia resulting in lab interference with blood tests (complete blood counts, chemistries, and coagulation studies), as well as acute pancreatitis, acute kidney injury, acute respiratory distress syndrome, fat overload syndrome, and cardiac arrest.[35]

Ventricular Dysrhythmias

Although it is uncharacteristic, ventricular tachydysrhythmias can occur following beta-blocker toxicity. Cardioversion and defibrillation are indicated for ventricular tachycardia and ventricular fibrillation, respectively, following American Heart Association guidelines. Pulsatile ventricular tachycardia can most safely be treated with lidocaine. For dosing recommendations, please see the Management of Cardioactive Steroids section of this chapter. Antidysrhythmic drugs, especially of classes IA and IC, should be avoided because they may potentiate AV block or be prodysrhythmic because of additive membrane-stabilizing activity. Sotalol, unlike other beta-blockers, has class III as well as class II effects causing prolongation of the QT interval and can induce torsades de pointes and other ventricular dysrhythmias. Overdrive pacing with isoproterenol or a pacemaker and magnesium sulfate are specific therapies for torsades de pointes.

Extracorporeal Elimination and Circulatory Assistance

Hemodialysis or hemoperfusion may be beneficial for beta-blockers with lower V_d, lower protein binding, and greater hydrophilicity (see Table 142.3), though due to limited evidence[36] we recommend hemodialysis only if another indication for hemodialysis is present (e.g., severe metabolic acidosis, acute renal failure, fluid overload, hyperkalemia, or other electrolyte disturbances).

Unlike overdoses of other drugs, toxicity from cardiovascular drugs do not destroy tissue, and if circulation can be supported, complete recovery can be expected. Intra-aortic balloon pumps,[22] percutaneous left ventricular assist devices,[36-38] and cardiopulmonary bypass have all been successfully employed as salvage therapies. However, with the proliferation of extracorporeal cardiopulmonary resuscitation (eCPR) programs[39] the availability of ECMO for poisonings has increased substantially in the past decade.[15,40-43] As such, ECMO is our recommended mechanical support therapy in cases where patients have hypotension refractory to HDI, and at least three vasoactive agents or in cases with bradycardia or cardiogenic shock unresponsive to inotropes and a pacemaker.

Pediatric Considerations

Severe pediatric beta-blocker poisonings are rare. In the cases reported, CNS, cardiac, and metabolic toxicities are similar to those in adult overdoses. Symptomatic hypoglycemia, however, is more common in children and occurs even after therapeutic doses. Therefore, serum glucose concentration should be measured in children. Risk factors include young age, fasting state, and diabetes mellitus. Obtunded children should receive empirical glucose, 1 to 2 mL/kg of 25% glucose IV. In general, 5% glucose infusions have been sufficient to maintain euglycemia, especially with concomitant use of glucagon and catecholamines, which stimulate glucose release.

Seizures also occur in cases of pediatric beta-blocker overdose; hypoglycemia may be a contributing factor. They are more common with the lipid-soluble beta-blocker propranolol. Benzodiazepines in standard doses are generally effective. Children generally fare well after beta-blocker ingestion, with symptoms in only 2% of potential beta-blocker exposures.

Sequential Approach to Beta-Blocker Poisoning

The management of beta-blocker poisoning begins with a 20 mL/kg bolus of IV fluid, repeated once if needed (Table 142.6). Symptomatic bradycardia, typically a heart rate of 50 bpm or less in adults, should be treated with atropine, 1 mg every 3 minutes up to a total of 3 mg. If hypotension (systolic pressure <90 mm Hg) persists, 3 to 6 g of calcium gluconate should be infused over 10 minutes. If hypotension persists after calcium infusion, HDI should be initiated. Glucagon, given as a 5-mg bolus, can be used to bridge to HDI. One "amp" of D50 should be administered followed by 1 U/kg of regular insulin as a loading dose. An infusion of 25 g/hr of concentrated glucose should be initiated in addition to an infusion of insulin at 1 U/kg/hr. The insulin infusion should be increased by 2 U/kg/hr every 10 minutes until hypotension resolves or a maximum rate of 10 U/kg/hr is reached. Glucagon may be repeated during HDI titration if hypotension persists. If HDI does not resolve hypotension, norepinephrine should be administered starting at 0.1 mcg/kg/min and titrated up until hypotension resolves or until a maximum dose is reached. After maximal norepinephrine is reached, the clinician should reassess using bedside echocardiography and measurement of cardiac

TABLE 142.6 Sequential Treatment Recommendations for Poisoning from Beta-Blockers and Calcium Channel Blockers

Phase of Treatment	Beta-Blockers	Calcium Channel Blockers
Phase 1 (initial resuscitation; primarily bolus dose therapies)	Activated charcoal as indicated Isotonic fluid bolus 20–40 mL/kg Atropine Calcium Glucagon	Activated charcoal as indicated Isotonic fluid bolus 20–40 mL/kg Atropine Calcium
Phase 2 (stabilization; place central & arterial lines, consider cardiac output & SVR monitoring)	Place central & arterial lines HDI infusion Norepinephrine Vasopressin 3rd agent based on type of shock Pacemaker for bradycardia	Place central & arterial lines HDI infusion Norepinephrine Vasopressin 3rd agent based on type of shock Pacemaker for bradycardia
Phase 3 (salvage therapies)	IFE ECMO Other mechanical devices if ECMO not available	IFE Methylene blue ECMO Other mechanical devices if ECMO not available

HDI, High-dose insulin; *IFE*, intravenous fat emulsion; *SVR*, systemic vascular resistance; *ECMO*, extracorporeal membrane oxygenation.

output and systemic vascular resistance to determine if the patient needs additional inotropy, chronotropy, or vasotropy. If bradycardia is contributing to decreased cardiac output, we recommend a pacemaker; a transvenous approach will likely be necessary. Additional inotropes or vasopressors such as vasopressin, phenylephrine, epinephrine, dopamine, or dobutamine should be selected and titrated up based upon the patient's cardiac output and systemic vascular resistance. We recommend vasopressin as the second-line vasopressor at a steady-state infusion of 0.01 to 0.04 U/min. Once the patient has reached maximal doses on HDI and three vasopressors or catecholamines, depending on institutional availability we next recommend either IFE or ECMO; if ECMO is readily available, ECMO is preferred. If used, IFE may be dosed at 1.5 mL/kg IV of 20% lipid solution followed by an infusion as noted above. The bolus may be repeated; however, a maximal dose of 1000 mL of lipid solution should not be exceeded. A concern exists that if IFE and ECMO are used in tandem, clogging and malfunction of the membrane oxygenator from lipemia and fat agglutination is a concern.[44] Case reports[45] and in vitro data suggest this can occur, along with cracking of stopcocks and increased blood clotting in the circuits.[44] Nonetheless, the use of IFE is not a contraindication to ECMO. If IFE is used prior to ECMO, the infusion should be discontinued once the decision to cannulate has been made, and the perfusionist alerted that clogging of the oxygenator may occur so they may anticipate this complication.

Disposition

Patients who remain completely asymptomatic for 6 hours after an oral overdose of normal-release preparations can be safely discharged home if the overdose was accidental or referred for psychiatric evaluation if it was intentional. We recommend consultation with a poison control center or standard pharmacologic reference to confirm that peak effect of the beta-blocker in question has passed before psychiatric disposition (see Table 142.3). Patients ingesting sustained-release preparations should be admitted to a monitored bed; however, those who remain asymptomatic 8 to 12 hours after ingestion are unlikely to have toxicity. Patients with second or third-degree AV heart block, hypotension not responding to IV fluid administration, or who have hemodynamically significant dysrhythmias should be admitted to an intensive care unit.

CALCIUM CHANNEL BLOCKERS

KEY CONCEPTS

- Signs and symptoms of calcium channel blocker intoxication often occur early after overdose but may be significantly delayed with sustained-release products.
- AV block and bradydysrhythmias predominate with verapamil and diltiazem; dihydropyridine calcium channel blockers often present with tachycardia.
- Treatment is similar to beta-blockers, except glucagon is not recommended, and methylene blue is a reasonable option for vasoplegia unresponsive to maximum doses of norepinephrine and vasopressin.

Foundations

Principles of Toxicity

Verapamil and nifedipine, the earliest calcium channel antagonists, were introduced in Europe in the 1970s and in the United States in the early 1980s. Calcium antagonists have found many clinical applications: angina pectoris, hypertension, supraventricular dysrhythmias, hypertrophic cardiomyopathy, and migraine prophylaxis. Verapamil is the most lethal in overdose, but severe toxicity and death have been reported for most drugs of this class. In 2018, United States poison control centers received nearly 14,000 calls about calcium channel blockers.[1] Nearly 1200 of these calls were regarding patients with life-threatening symptoms.[1] In general, calcium channel blockers are more toxic than beta-blockers, likely because they cause both cardiogenic shock and vasoplegia.

Pathophysiology

Calcium channel antagonists block the slow L-type calcium channels in the myocardium and vascular smooth muscle, leading to coronary and peripheral vasodilation. They also reduce cardiac contractility, depress SA nodal activity, and slow AV conduction. In cases of overdose, verapamil has the deadliest profile, combining severe myocardial depression and peripheral vasodilation. Both verapamil and diltiazem act on the heart and blood vessels, whereas dihydropyridine calcium channel blockers (e.g., amlodipine) cause primarily vasodilation and

subsequent reflex tachycardia due to subtle binding differences in the α1c subunit of L-type calcium channels. As with beta-blockers, selectivity is lost after overdose and toxicity is in four domains: negative effects on heart rate, contractility, conduction, and vascular tone, with the exception of dihydropyridine calcium channel blockers, which tend to result in tachycardia until severe toxicity occurs, when bradycardia ensues.

All calcium channel blockers are rapidly absorbed, although first-pass hepatic metabolism significantly reduces bioavailability (see Table 142.4). Onset of action and toxicity may occur as early as 30 minutes after ingestion. In contrast, the poisoning from sustained-release verapamil may not manifest for 12 hours or more. High protein binding and V_d greater than 1 to 2 L/kg make hemodialysis or hemoperfusion ineffective with calcium antagonists.

Clinical Features

Severe calcium antagonism eventually affects multiple organ systems, but cardiovascular toxicity is primarily responsible for morbidity and mortality. Hypotension and bradycardia occur early, and other rhythm disturbances include AV block of all degrees, sinus arrest, AV dissociation, junctional rhythm, and asystole. Dihydropyridine calcium channel blockers (e.g., amlodipine) often cause reflex sinus tachycardia from peripheral vasodilation. Calcium channel blockade has little effect on ventricular conduction; therefore, QRS widening is not seen early on. Ventricular dysrhythmias are also uncommon. A unique feature of calcium channel blocker poisoning is endocrine dysfunction. Like many drugs, calcium channel blockers lose specificity in overdose and thus interfere with other calcium channels within the body. As calcium influx triggers the release of insulin, patients poisoned with calcium channel blockers are often hyperglycemic. In addition, edema is a common side effect of calcium channel blockers at therapeutic doses. Edema occurs because of selective dilation of vessels on the afferent side of the capillary bed while suppressing normal regulatory responses that protect capillaries from hydrostatic pressure. At therapeutic doses, peripheral edema from calcium channel blockers is common; however, pulmonary edema may occur in overdose, which is likely due to a combination of drug effect and iatrogenic volume overload.[46,47] Nearly half of patients with severe amlodipine poisoning have non-cardiogenic pulmonary edema.[48] As with digoxin and beta-blocker overdose, nausea and vomiting are common but not specific. For additional clinical features, see Table 142.5. Like beta-blockers, calcium channel blockers cause early toxicity, and symptoms commonly occur within 6 hours of ingestion of normal-release preparations. Toxicity can be delayed 12 to 24 hours with sustained-release preparations.

Differential Diagnoses

Differential diagnoses are similar to that of digoxin and beta-blocker overdoses. Until characteristic rhythm disturbances supervene, many other toxic, metabolic, traumatic, and cardiovascular disorders can cause hypotension but less commonly bradycardia. The reflex tachycardia and distributive shock seen with dihydropyridine calcium channel blockers can mimic sepsis, volume depletion, or anaphylaxis.

Diagnostic Testing

Serum levels of calcium antagonists are not readily available nor do urine toxicology screens reliably detect this class of drugs. Glucose and electrolytes (including calcium and magnesium) should be measured. Hyperglycemia secondary to insulin inhibition occurs and correlates with severity of verapamil and diltiazem poisoning; it is unknown if the same is true in dihydropyridine overdose. If hyperglycemia is present with concomitant hypotension, we recommend HDI. Please see specific dosing recommendations later. A metabolic (lactic) acidosis can occur with prolonged hypotension and hypoperfusion.

An ECG should be promptly obtained, with special attention to atrial and ventricular rates and PR, QRS, and QT intervals. The ECG should be repeated when the patient's hemodynamic status changes.

Management

Initial management includes rapid establishment of vascular access, cardiac monitoring, and frequent blood pressure measurement. Please see Chapter 135 for further information on gastrointestinal decontamination, including the use of activated charcoal. For an algorithmic approach to management, see Table 142.6.

Hypotension and Bradycardia

Hypotension can be caused by myocardial depression, inadequate heart rate, or peripheral vasodilation. Atropine may be used for bradycardia but is rarely effective. We recommend atropine at the doses noted earlier for a heart rate of less than 50 beats per minute with concomitant hypotension and symptoms of severe bradycardia such as weakness, drowsiness, or obtundation. Atropine's effect has often been minimal and short-lived, and it is at best a temporizing intervention. A bolus of crystalloid (20 to 40 mL/kg or more) should also be infused early; however, care should be taken to avoid fluid overload given the additional risk of pulmonary edema with calcium channel blocker poisoning, particularly in elderly patients or those with underlying heart disease.

After the basic supportive therapies noted previously, expert consensus recommendations include calcium salts, HDI, and norepinephrine.[49] We recommend these three agents be administered in the sequential fashion noted for beta-blocker poisoning. We do not recommend glucagon in calcium channel blocker poisoning. It has no mechanistic advantage over epinephrine or other beta-agonists, and no good evidence exists to support its use in calcium channel blocker poisoning.

IFE (e.g., Intralipid) has been described in the use of calcium channel blockers. The proposed mechanisms are discussed in Chapter 135. Similar to beta-blockers, early animal studies and case reports were promising, while larger follow-up studies showed poor outcomes in human poisoning. The same collaborative expert panel on IFE noted earlier did not recommend in favor or against the use of IFE in calcium channel blocker poisoning, even as a salvage therapy.[32] As such, we recommend IFE in patients with persistent cardiogenic shock not responding to IV fluids, calcium, HDI, and at least three vasopressors or inotropes at maximum recommended infusion rates if extracorporeal membrane oxygenation (ECMO) is not immediately available.

Methylene blue is an emerging therapy for calcium channel blocker poisoning.[50] Although traditionally used as a reducing agent for the treatment of methemoglobinemia, methylene blue is also a vasoconstrictor. Specifically, it inhibits the enzyme guanylyl cyclase, resulting in decreased production of cyclic guanosine monophosphate (cGMP) and inhibition of endothelial smooth muscle relaxation, causing an increase in systemic vascular resistance.[51] Methylene blue is particularly intriguing for the treatment of amlodipine poisoning, because amlodipine specifically causes an increase in nitric oxide production, which leads to increased cGMP and vasodilation as noted earlier. Data are limited to a small number of animal studies and human case reports,[52,53] and thus far suggest improvement is limited to hemodynamic parameters and not overall mortality.[51] Methylene blue was inferior to IFE in a rat model of amlodipine poisoning,[54] nor did it improve outcomes when compared to norepinephrine in a pig model of amlodipine poisoning.[55] We recommend the use of methylene blue only as an alternative salvage therapy for vasoplegic shock refractory to infusions of HDI, maximal norepinephrine, and vasopressin. Dosing

involves a 1- to 2-mg/kg bolus of a 1% methylene blue solution followed by an infusion of 1 mg/kg for up to 6 hours. Recently angiotensin II was FDA-approved for the treatment of vasodilatory shock;[56] its use in poisoning from calcium channel blockers (and poisoning in general) is limited to case reports requiring further study.[57] The use of angiotensin II would be a reasonable treatment for refractory vasodilatory shock in lieu of methylene blue, or as an additional therapy for profound vasoplegia refractory to maximal infusions of an α_1-adrenergic agonist (e.g., norepinephrine, phenylephrine) and vasopressin.

Pediatric Considerations

Nifedipine, verapamil, and probably other drugs in its class join the short list of medications that can kill a child with ingestion of a single tablet. Seizures may be more common in children than in adults and should be treated with benzodiazepines. Overall, death after calcium antagonist ingestion in children is rare. The IV route of administration, as with digoxin, is much more dangerous. Even therapeutic doses of IV verapamil are considered contraindicated in infants with supraventricular tachycardia because of cardiovascular collapse and cardiac arrest after injection which have been documented in case reports.[58]

Hyperglycemia occasionally occurs in children, but the elevation is usually short-lived. Although insulin has been administered in a small number of cases, it is generally not necessary unless HDI is required for hemodynamic compromise, because the hyperglycemia usually resolves spontaneously within 24 to 36 hours.

There are case reports of children in refractory shock secondary to drug toxicity who have been treated with intra-aortic balloon counterpulsation or cardiac bypass, though ECMO has gained favor as the mechanical support device of choice.[58] Aside from the differences previously noted, the presentation in children is similar to that in adults: rapid onset of toxicity with CNS depression, bradydysrhythmias (except for dihydropyridine calcium channel blockers), and hypotension.

Disposition

Because the peak effect of normal-release calcium channel blockers commonly occurs in 90 minutes to 6 hours, patients who are totally asymptomatic for 6 hours after an ingestion of immediate-release medication can be safely discharged if accidental, or according to psychiatric recommendations if intentional. Symptomatic patients or those who ingested delayed-release preparations should be admitted for at least 24 hours of continuous cardiac monitoring. Persistently hypotensive, bradycardic patients who do not respond to conventional therapy require intensive care monitoring.

CLONIDINE AND OTHER CENTRAL ALPHA-2 AGONISTS

KEY CONCEPTS

- Clonidine poisoning may mimic opioid poisoning and is best treated with crystalloid fluids followed by an infusion of norepinephrine.
- In patients at low risk for opioid dependence, naloxone, given as a 10 mg bolus from a single syringe, is recommended for obtundation.

Foundations

Clonidine is a central acting α_2-adrenergic and imidazoline agonist initially approved by the FDA as a treatment for hypertension in 1974. Since that time, its use has expanded to treat conditions such as attention deficit hyperactivity disorder (ADHD), pheochromocytoma, and withdrawal from opioids, ethanol, and nicotine. It is also used in spinal and epidural anesthesia. Based on its mechanism of action, it mimics clinical features of both opioid poisoning and poisoning from digoxin, beta-blockers, or calcium channel blockers. In 2018 United States poison centers received over 10,000 calls regarding clonidine exposures with over 2,000 suffering life-threatening effects.[1] Clonidine poisoning appears to be increasing in children.[59]

Clinical Features

Clonidine exerts its effects by binding to presynaptic α_2-adrenergic receptors in the brain, inhibiting neurons in the nucleus tractus solitarius, causing decreased norepinephrine release. This leads to bradycardia, hypotension, decreased mental status, miosis, and occasionally hypothermia. Clonidine is also an agonist at imidazole receptors; imidazoline receptors are located throughout the body, but their activation in the brain, specifically in the rostral ventrolateral medulla, causes unconsciousness, bradycardia, and hypotension, potentially exacerbating the α_2-adrenergic effects of clonidine.[60] Although clonidine overdose presents with bradycardia, hypotension, and coma, most cases have favorable clinical outcomes.[61]

Differential Diagnoses

There is a wide overlap between the clinical effects of central α_2-agonists such as clonidine and imidazole agonists. Individual drugs that are agonists at either or both receptors may belong to disparate classes. Therefore, antihypertensive medications (e.g., guanabenz, α-methyldopa), ADHD medications (e.g., guanfacine), muscle relaxers (e.g., tizanidine), and topical vasoconstrictors in dermatologic (e.g., brimonidine),[62] ocular, and nasal settings (e.g., tetrahydrozoline, oxymetazoline, and naphazoline)[63] all have similar systemic effects in overdose. The presentation of miosis and obtundation may be mistaken for opioid or sedative-hypnotic overdose, and the combination of bradycardia and hypotension may mimic digoxin, beta-blocker, or calcium channel blocker poisoning. Pontine hemorrhage should also be considered in the differential diagnoses.

Diagnostic Testing

Clonidine and other similar drugs are not routinely screened for in most blood or urine drug screens. Clonidine poisoning is a clinical diagnosis. An ECG should be obtained to evaluate for heart block and to evaluate the QRS and corrected QT (QTc) intervals, and the patient should be placed on continuous cardiac monitoring and pulse oximetry. Small doses of naloxone may help differentiate clonidine poisoning from opioid poisoning; however, if large doses are required, this may be less helpful diagnostically because large doses of naloxone have been reported to reverse clonidine toxicity.

Management

Supportive care is the mainstay of therapy for clonidine poisoning. Monitoring as described earlier is essential. Hypotension should be treated with boluses of 20 mL/kg of isotonic fluid. The concern for pulmonary edema is less than with beta-blocker or calcium channel blocker poisoning, thus the clinician can be more liberal with IV fluid administration in clonidine poisoning. We recommend treating hypotension with up to 60 mL/kg of isotonic fluid. If hypotension is worsening or persistent at a level of inadequate organ perfusion despite adequate fluid resuscitation, a catecholamine is indicated. There are no human randomized trials comparing various catecholamines in clonidine poisoning; however, because the underlying pathophysiology is a lack of systemic norepinephrine, we recommend norepinephrine initiated as 0.1 mcg/kg/min and titrated to a MAP of 60 mm Hg. When blood pressure stabilizes, downward titration of norepinephrine is initiated, with a goal of maintaining adequate organ perfusion with the

least necessary dose, ultimately weaning the patient off the vasopressor entirely.

Several authors have suggested naloxone may be a useful therapy in clonidine poisoning. Clonidine causes the spontaneous release of β-endorphin, an endogenous opioid. It is likely naloxone's antagonism of β-endorphin's opioid effects that causes reversal of CNS depression in clonidine poisoning. Although case reports of naloxone successfully reversing clonidine poisoning exist, they are rare and inconsistent. Our clinical experience is that naloxone is rarely effective for clonidine poisoning in adults, however recent data suggest clonidine may be an effective treatment in children. In a study of 51 somnolent children poisoned with clonidine, 40 (78%) woke upon administration of naloxone.[64] The authors noted greater success when 10 mg of naloxone was administered as a bolus from a single syringe, rather than a titrated approach. Because the precipitation of opioid withdrawal can be dangerous, in patients at high risk for opioid dependence we recommend escalating doses of naloxone of 0.2 mg, 0.4 mg, 2 mg, and then 10 mg if the patient is obtunded. If there is no concern for opioid dependence, we recommend naloxone be given as a 10-mg rapid bolus from a single syringe, regardless of the patient's age or size.

Disposition

Clonidine's peak effects occur 2 to 4 hours post-ingestion. Its half-life is between 5 and 13 hours. Therefore, patients with normal vital signs and mental status 4 hours post-ingestion may be discharged home if the overdose was accidental or to an appropriate psychiatric facility if intentional. Patients with persistent vital sign abnormalities or altered mental status should be admitted to a unit capable of continuous cardiac and oximetry monitoring. Patients requiring vasopressor support or with severe obtundation should be admitted to a critical care unit.

NITRATES, NITRITES, AND METHEMOGLOBINEMIA

KEY CONCEPTS

- Nitrates are contraindicated in patients who have recently taken phosphodiesterase inhibitors for erectile dysfunction.
- Patients with a methemoglobin concentration of 25% and symptoms of anemia should be treated with methylene blue.

Foundations

Principles of Toxicity

Nitrates (nitroglycerin, isosorbide mononitrate and dinitrate) are widely used as vasodilators in the treatment of heart failure and ischemic heart disease. They augment coronary blood flow, as well as reduce myocardial oxygen consumption by reducing afterload. At lower doses nitrates primarily dilate veins, but at higher doses they also dilate arteries. In addition, many exposures occur in young adults, usually male, who inhale various alkyl nitrites (amyl, butyl, isobutyl, or ethyl nitrite) in the hope of enhancing or prolonging sexual pleasure. Because of the sound they make when broken open, these products are commonly known as "poppers."[65]

Nitrates are occasionally found in rural well water contaminated by livestock or fertilizer runoff. Oral nitrates may be converted to nitrites in the gastrointestinal tract, especially in infants up to 4 months old. Nitrites, and to a lesser extent, nitrates themselves, have substantial oxidizing power and may oxidize the ferrous (Fe^{2+}) ion in hemoglobin to its ferric (Fe^{3+}) state, causing methemoglobinemia. Methemoglobin is incapable of carrying oxygen, thus it alters the shape of the hemoglobin-dissociation curve shifting it to the left, causing functional anemia via impaired oxygen delivery.

Clinical Features

Hypotension is a common complication. Typically, it is accompanied by reflex tachycardia unless the patient also has taken another agent such as a beta-blocker that slows chronotropy. Even in therapeutic doses, rapid dilation of meningeal arterioles causes headache, often leading to patient noncompliance.

Patients suffering nitrate-induced methemoglobinemia have symptoms related to impaired oxygen delivery. The concentration of methemoglobinemia and the speed with which it is achieved are directly proportional to symptom severity. Cyanosis occurs commonly when the percentage of methemoglobin exceeds 10%. Inspection of the patient's blood upon venipuncture reveals "chocolate-colored" blood due to the spectrum of light absorbed by methemoglobin; this typically occurs at a methemoglobin concentration greater than 15%. Higher concentrations of methemoglobin may result in fatigue, dyspnea, weakness, dizziness, drowsiness, syncope, coma, seizures, and death.

Differential Diagnoses

The differential diagnosis of nitrate poisoning includes all other vasodilating drugs such as diuretics, angiotensin-converting enzyme (ACE) inhibitors, and dihydropyridine calcium channel blockers, as well as oxidative phosphorylation uncouplers such as cyanide and carbon monoxide. Non-toxicologic conditions capable of mimicking nitrate poisoning include sepsis and anaphylaxis. The differential diagnosis of methemoglobinemia includes hypoxia, as well as other hemoglobinopathies such as sulfhemoglobinemia.

Diagnostic Testing

No specific mandatory diagnostic testing is recommended for nitrate poisoning. For patients with suspected methemoglobinemia, an oxygen challenge should first be attempted. If the patient is cyanotic and high-flow oxygen at 15 L/min by non-rebreather mask does not improve cyanosis, blood co-oximetry should be performed to determine the percentage of methemoglobin in the blood. If methemoglobinemia is confirmed, a hemoglobin concentration should be obtained. If anemia is present, smaller concentrations of methemoglobin may be clinically significant because the functional anemia of methemoglobinemia is synergistic with absolute anemia. Most humans have, at baseline, a methemoglobin percentage of 1% to 3%. Symptoms do not typically occur until concentrations of 10% or more.

Clinicians should be wary of interpreting pulse oximetry in the setting of methemoglobinemia. Pulse oximeters function by reading the absorbance of light at wavelengths of 660 and 940 nm, which are selected to separate oxy and deoxyhemoglobin. Methemoglobin absorbs light at both these wavelengths more than either oxy or deoxyhemoglobin. This results in unreliable pulse oximetry that typically reads near 85%, regardless of the patient's oxygenation status.

Management

Nitrate poisoning usually responds to supine positioning, IV fluids, and reduction of dose or removal of the offending agent. Hypotension is usually transient. Low-dose vasopressors are occasionally needed, but it is best to avoid them in the setting of acute coronary syndrome.

Review of the therapeutic use of nitrates offers insight into poisoning. For example, IV nitroglycerin infusions are used commonly in patients with acute pulmonary edema for afterload reduction. Infusions are usually initiated at 5 to 10 μg/min, but rates of 300 mcg/min or greater may be used. These doses may be beneficial in patients with pulmonary edema accompanied by acute hypertension, but

hypotension may develop suddenly. IV nitroglycerin has a rapid offset of action, so excessive fall in blood pressure usually responds to reduction or termination of the infusion.

Use of nitrates is contraindicated in patients who have recently taken certain drugs for erectile dysfunction, such as sildenafil (Viagra) or tadalafil (Cialis). These drugs inhibit type 5 phosphodiesterase, relaxing vascular smooth muscle, which can prolong and intensify the vasodilating effects of nitrates causing severe hypotension. If blood pressure does not normalize with IV fluids and cessation of the nitrate infusion, norepinephrine should be cautiously titrated to a MAP of 60 mm Hg, beginning at 0.1 mcg/kg/min.

Treatment of patients with methemoglobinemia involves supportive care such as supplemental oxygen and IV fluids as needed. More severely poisoned patients should be treated with IV methylene blue. Methylene blue is an oxidizing agent. However, in the presence of the red blood cell enzyme nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, it is reduced to leukomethylene blue, which then reduces methemoglobin back to hemoglobin. We recommend an intravenous dose of 1 to 2 mg/kg of 1% methylene blue solution for patients with a methemoglobin concentration greater than 25% and any symptoms of functional anemia. The infusion should be given over 5 minutes to reduce pain at the IV access site. A clinical response should occur within minutes of infusion. If cyanosis does not resolve in 1 hour, a second infusion of 1 mg/kg can be repeated. At doses exceeding 7 mg/kg, the oxidizing power of methylene blue becomes great enough that it may paradoxically worsen methemoglobinemia or cause hemolysis; thus, multiple or excessive doses are not recommended.

Disposition

Patients with refractory hypotension despite therapeutic measures discussed in the preceding section should be admitted to a monitored setting. We recommend all patients receiving methylene blue be admitted, as some poisons that cause methemoglobinemia have half-lives that exceed that of methylene blue. If the patient remains unstable and persistently cyanotic or hypoxic, or requires repeat doses of methylene blue, they should be admitted to a critical care setting.

CHAPTER 142: QUESTIONS AND ANSWERS

1. A 72-year-old man presents with a chief complaint of nausea. He also complains of blurred vision and general weakness. His vital signs and physical examination are normal. He has a past medical history significant for myocardial infarction, congestive heart failure, hypertension, and diabetes. He states that he takes all prescribed medications regularly and just took all of his medications as prescribed approximately 1 hour ago. Reviewing his medication list, you note that one of his medications is digoxin. Which of the following should be done?
   a. Administer oral potassium.
   b. Give digoxin-specific Fab fragment antibodies now.
   c. Give digoxin-specific Fab fragment antibodies only if he has an abnormal electrocardiogram (ECG).
   d. Obtain a serum digoxin level in 6 hours.
   e. Obtain a serum digoxin level now.

Answer: D. The steady-state (as opposed to peak) digoxin level is most closely correlated with toxicity. Peak level is reached in 1.5 to 2 hours, whereas steady-state levels are not reached until 6 to 8 hours after ingestion. As long as a patient is stable and a chronic ingestion is suspected, digoxin levels taken soon after ingestion are not helpful. Other diagnostic studies should be undertaken while waiting for the digoxin level, including, but not limited to, an electrocardiogram (ECG) and serum electrolyte determination.

2. In a patient with a known digoxin overdose, which of the following is an indication for administration of digitalis antibody fragments?
   a. Acute ingestion of 10 mg of digoxin
   b. Atrial fibrillation with rapid ventricular response
   c. First-degree heart block
   d. Ingestion of oleander *(Nerium oleander)*
   e. Serum potassium greater than 5 mEq/L

Answer: E. Hyperkalemia is an indication for treatment with digitalis antibody fragments. Other indications include severe ventricular dysrhythmias; hemodynamically significant bradydysrhythmias unresponsive to atropine; rapidly progressive rhythm disturbances or rising potassium level; co-ingestion of cardiotoxic drugs such as beta-blockers, calcium channel blockers, or cyclic antidepressants; or ingestion of a plant known to contain cardiac glycosides in the setting of severe dysrhythmias.

3. A 27-year-old man presents after ingesting 8 mg of digoxin in a suicide attempt. He has ventricular tachycardia on his electrocardiogram (ECG). His blood pressure is 93/54 mm Hg. Laboratory results are not available. You decide to treat with digitalis antibody fragments. How many vials would bind the entire ingestion?
   a. 2 vials
   b. 4 vials
   c. 8 vials
   d. 16 vials
   e. 20 vials

Answer: D. Each vial contains enough digitalis antibody fragments to neutralize 0.5 mg of digoxin; therefore, the patient should be given 16 vials of Fab fragments to fully treat his ingested dose.

CHAPTER 142: QUESTIONS AND ANSWERS—cont'd.

4. A 5-year-old girl presents after taking some of her grandmother's heart medications. She has sinus bradycardia and a slightly low blood pressure. The remainder of her vital signs and physical examination are nonspecific. A bedside glucose test reveals hyperglycemia. The child is not responsive to calcium therapy. The next therapeutic intervention that is likely to treat both the endocrine and cardiovascular pathology would be:
   a. Dobutamine
   b. Epinephrine
   c. High-dose insulin (HDI)
   d. Intravenous fat emulsion (IFE)
   e. Glucagon

Answer: C. Calcium channel blocker toxicity may result in bradycardia and hypotension, much like beta-blocker toxicity. Unlike beta-blocker toxicity, which can cause hypoglycemia, calcium channel blockers can cause hyperglycemia via blockade of calcium channels on beta islet cells. HDI therapy treats calcium channel blocker toxicity via increasing inotropy, as well as normalizing glucose.

5. A 60-year-old man has taken an overdose of his beta-blocker medication. He is awake but lightheaded and has a pulse of 50 beats per minute and a blood pressure of 92/60 mm Hg. Which of the following is the most appropriate initial treatment?
   a. Atropine, crystalloid fluids, calcium salts, glucagon
   b. Atropine, crystalloid fluids, insulin
   c. Atropine, norepinephrine, glucagon
   d. Norepinephrine, crystalloid fluids, insulin
   e. Norepinephrine, glucagon, insulin

Answer: A. Atropine, crystalloid fluids, calcium salts, and glucagon are the initial treatments of choice for beta-blocker toxicity. If these agents are ineffective, high-dose insulin (HDI) is reasonable as next-line therapy for cardiogenic shock. If HDI is ineffective, catecholamines are a reasonable option. The catecholamine choice may vary depending on the type of shock the patient is in, and the dose needed for a response may be greater than for other conditions.

6. A patient presents after an apparent overdose of diltiazem. Which of the following findings would lead you to suspect a co-ingestant in addition to the calcium channel blocker?
   a. Atrioventricular (AV) block on electrocardiogram (ECG)
   b. Hyperglycemia
   c. Metabolic acidosis
   d. Prolonged QRS complex on ECG
   e. Pulmonary edema

Answer: D. Prolonged QRS and QT intervals are generally not seen in calcium channel blocker overdose and should prompt the search for co-ingestants. One exception is the calcium channel blocker bepridil, which can cause QRS or QT prolongation, though bepridil is no longer sold in the United States. All the other listed abnormalities are typical of calcium channel blocker overdose.

7. Treatment for beta-blocker overdose is most similar to the treatment for overdose from which other class of medications?
   a. Anticholinergics
   b. Calcium channel blockers
   c. Cyclic antidepressants
   d. Digoxin
   e. Nitrates

Answer: B. Symptoms from overdose of calcium channel blockers and beta-blockers are similar, as are the therapeutic strategies. Severe anticholinergic toxicity may respond to physostigmine administration, cyclic antidepressants to intravenous (IV) sodium bicarbonate boluses, digoxin poisoning to antibody Fab fragments, and nitrate toxicity to methylene blue therapy.

8. Which of the following drugs is most likely to kill a toddler with ingestion of a single tablet?
   a. Atenolol
   b. Chlorthalidone
   c. Lisinopril
   d. Nitroglycerin
   e. Verapamil

Answer: E. Verapamil and other calcium channel blockers can kill a toddler with the ingestion of a single tablet. Appropriate medical treatment, however, is extremely effective, and very few children die from calcium channel blocker overdose. Although beta-blockers have the potential to cause serious toxicity, propranolol is the beta-blocker most likely to cause serious toxicity. Educating parents and caregivers of young children about the potential effects of these medications is important.

143

Caustics

Christopher Hoyte

KEY CONCEPTS

- Health care workers caring for patients with caustic exposures should adhere to universal precautions to prevent additional exposure.
- All symptomatic patients should undergo endoscopy and be should be observed for at least 24 hours.
- Asymptomatic patients can undergo endoscopy in the emergency department or be discharged with close follow-up monitoring.
- Gastric emptying or GI decontamination is not indicated for the majority of caustic ingestions.
- Concentration and pH are the most important characteristics of a substance to predict esophageal and gastric injury.
- Button batteries lodged in the airway or esophagus require endoscopic retrieval.

FOUNDATIONS

Caustic or corrosive agents have the potential to cause tissue injury on contact with mucosal surfaces. Both strong acids and alkalis are capable of causing corrosive chemical injury. Alkalis are proton acceptors and result in the formation of conjugate acids and free hydroxide ions. Lye is an example of an alkali and refers to both sodium hydroxide (NaOH) and potassium hydroxide (KOH). Ammonia (NH_3) is another common alkaline corrosive. Acids are proton donors; they dissociate into conjugate bases and free hydrogen ions in solution. Acidic caustics include hydrochloric acid (HCl) and sulfuric acid (H_2SO_4). The injury from caustic agents typically increases with a pH below 3 or above 11. Other chemicals that have caustic properties include phenol, formaldehyde, iodine, and concentrated hydrogen peroxide. This chapter discusses oral exposure. Dermal and inhalational exposures are discussed in Chapter 55 and Chapter 148, respectively.

More than 40,000 exposures involving caustic agents occur in the United States every year.[1] Nearly 75% of reported caustic ingestions are intentional for the purpose of self-harm.[1] Accidental ingestions occur typically among the pediatric and elderly populations. Transfer and storage of cleaners in alternative containers that may not be "child proof," such as jars, soda bottles, and sports drink containers, contribute to unintentional ingestion. Intentional ingestions may have a greater degree of oropharyngeal sparing because of rapid swallowing but have a higher likelihood of serious injury.

Principles of Toxicity

Some household products, such as liquid drain cleaners, continue to have high concentrations of alkali (30% KOH) or acid (93% H_2SO_4) (Table 143.1). These products often do not have concentration or content information available on the label, making it difficult for clinicians to determine the severity of exposure. Industrial, agricultural (dairy pipeline cleaners containing liquid NaOH and KOH in concentrations of 8% to 25%), and swimming pool chemicals also contain caustics in high concentrations.

Crystals and solid particles can have prolonged tissue adherence, causing more severe injury. Household detergents such as laundry powders and detergent pods (LDPs) and dishwasher detergents containing silicates, carbonates, and phosphates have the potential to induce caustic burns and strictures, even when ingested unintentionally. These ingestions are limited by immediate oral pain, usually causing them to be spit out sooner than a liquid agent. The ingestion of granular automatic dishwashing detergents or brightly colored laundry detergent capsules or "pods" can be associated with devastating injuries.[2] Compared to children with traditional non-LDP exposures, LDP exposures are associated with a higher incidence of toxicity including central nervous system depression and respiratory compromise with failure. Whether the toxicity observed with LDP exposures is due to other ingredients in the products, pH, concentration, tensile strength, or the delivery vehicle remains unclear.

Crystal drain cleaners have lye concentrations as high as 74% NaOH and may cause proximal esophageal injury. Liquid dishwashing detergents and laundry detergents have a pH higher than 12, but because the titratable alkaline reserve is low, tissue equilibration occurs quickly, and there is less risk of injury after ingestion.

Liquid household bleach typically contains dilute (3% to 5%) sodium hypochlorite (NaOCl), and ingestion rarely causes consequential injury. Industrial-strength bleach, however, contains significantly higher concentrations of NaOCl, which are more likely to cause esophageal necrosis. Toilet bowl cleaners contain HCl concentrations as high as 26%. General-purpose anticorrosive cleaners, such as 31% hydrochloride acid (HCl), are sold in gallon containers for home use and as swimming pool cleaners.

The alkali powder in air bags can cause ocular burns. Perfume unintentionally sprayed in the eyes can be caustic. Cement is alkaline and causes topical burns, typically on the knees and hands. Although hair relaxer creams contain NaOH and have a pH of 11.2 to 11.9, injuries after ingestion are usually mild.

Caustic ingestions may occur when methamphetamine is produced from over-the-counter medications and household chemicals. H_2SO_4, HCl, NaOH, ammonium hydroxide, anhydrous ammonia, and metallic lithium are all used in the clandestine production of methamphetamine. Severe caustic injuries occurring from ingestion of these agents can cause stricture formation, esophageal resection, and the need for colonic interposition.

Many medication pills can cause injury when they come in contact with the esophageal mucosa for prolonged periods. Patients who take medications in the supine position or who take pills without water are at higher risk of pill esophagitis. The pills most likely to adhere are doxycycline, tetracycline, potassium chloride, antimalarials, and aspirin.

TABLE 143.1 Household Cleaning Products That Contain Caustic Chemicals

Application	Product (Manufacturer), Chemical
Drain cleaner, liquid	Heavy Duty Liquid Drain Opener (Share), H_2SO_4 93%
	Drain Out Extra (Iron Out), KOH 30%
	Liquid-Plumr (Clorox), NaOH 0.5% to 2%, NaOCl 5% to 10%
	Maximum Strength Drain Opener (Enforcer), KOH 1% to 10%, NaOCl <5%
	Drain Care Professional Strength Drain Opener, NaOH 5% to 15%
Drain cleaner, crystals	Heavy Duty Crystal Drain Opener (Roebic), NaOH 100%
	Crystal Drain Opener (Rohyme), NaOH 74%
	Crystal Drain Out (Iron Out), NaOH 30% to 60%
	Drano Pipe Cleaner (Johnson), NaOH 54%
Oven cleaner	Easy-Off Heavy Duty Oven Cleaner (Reckitt), NaOH 4% to 6%
Rust remover	Rust Remover/Carpet Care (Johnson Wax Professional), HCl 10%
	Rust Stain Remover (Whink), hydrofluoric acid 2.5% to 3%
	Rust Stripper (Certified), NaOH 50% to 75%
	Naval Jelly Rust Dissolver (Loctite), phosphoric acid 25% to 30%
Toilet bowl cleaner	Instant Power Toilet Bowl Cleaner (Scotch), HCl 26%
	Bowl and Porcelain Cleaner (Cleanline), HCl 0.10%
	Bowl/Tile/Porcelain Cleaner (Share), phosphoric acid 15% to 25%
	Husky 303 Toilet Bowl Cleaner, HCl 23%
	Misty Bolex Bowl Cleaner, HCl 26%
Swimming pool cleaner	Muriatic acid, Aqua Chem (Recreational Water), HCl 31%

H_2SO_4, Sulfuric acid; *HCl,* hydrochloric acid; *KOH,* potassium hydroxide; *NaOCl,* sodium hypochlorite; *NaOH,* sodium hydroxide.

Although uncommon, potassium chloride is particularly dangerous and can cause esophageal perforation with devastating communication with the aorta, left atrium, and bronchial artery.[3]

Pathophysiology

Factors that influence the extent of injury from a caustic exposure include type of agent, concentration of solution, volume, viscosity, duration of contact, pH, and presence or absence of food in the stomach. The titratable acid/alkaline reserve of an alkali or acid correlates with the ability to produce tissue damage. Concentrated forms of acids and bases generate heat, resulting in superimposed thermal injury.

Acidic compounds desiccate epithelial cells and cause coagulation necrosis. An eschar is formed that limits further penetration. Because acids tend to have a strong odor and cause immediate pain on contact, the quantity ingested is usually limited. Because of resistance of squamous epithelium to *coagulation necrosis*, acids are thought to be less likely to cause esophageal and pharyngeal injury, although severe esophageal and laryngeal injury still occur, particularly with intentional ingestions.[4] In many case series, acid ingestion results in equal esophageal and gastric mucosal injury.[4] Acids can also be absorbed systemically, causing metabolic acidosis as well as damage to the spleen, liver, biliary tract, pancreas, and kidneys from perforation and direct local contact.

Fig. 143.1 Gastric mucosa after ingestion of 35% potassium hydroxide (KOH).

Fig. 143.2 Gastric serosa after ingestion of 35% potassium hydroxide (KOH).

Alkaline contact, in contrast to acids, causes *liquefaction necrosis*, fat saponification, and protein disruption, allowing further penetration of the alkaline substance into the tissue. The depth of the necrosis depends on the concentration of the agent. A concentration of 30% NaOH in contact with tissue for one second results in a full-thickness burn. Alkalis are colorless and odorless, and unlike acids, they do not cause immediate pain on contact. Alkaline ingestions typically involve the squamous epithelial cells of the oropharynx, hypopharynx, and esophagus. The narrow portions of the esophagus, where pooling of secretions can occur, are also commonly involved. Alkalis may also cause gastric necrosis (Figs. 143.1 and 143.2), intestinal necrosis, and perforation. The esophagus can also be injured (Fig. 143.3). Burns below the pylorus carry a 50% mortality compared with 9% for burns above the pylorus.[5]

Fig. 143.3 Esophagus after ingestion of 35% potassium hydroxide (KOH).

Fig. 143.4 Lip burn after exposure to 35% potassium hydroxide (KOH).

Caustic damage occurs in four phases. Initially, necrosis occurs, with invasion by bacteria and polymorphonuclear leukocytes. Vascular thrombosis follows, increasing the damage. During the next two to five days, superficial layers of injured tissue begin to slough. The tensile strength of the healing tissue may be low for up to three weeks after the caustic exposure, greatly increasing the chance of delayed perforation in some cases. Between one week and several months, granulation tissue forms, collagen is deposited, and reepithelialization occurs in the burn area. Esophageal strictures may form during a period of weeks to years from contraction of the scar.

Caustic injury is categorized as first, second, and third degree, similar to a thermal burn, by appearance on endoscopy. The initial depth of injury found on esophagoscopy correlates with the risk of stricture formation. Grade I injury consists of edema and hyperemia. Grade II injury can be further divided into grade IIa, which is non-circumferential, and grade IIb, which is nearly circumferential. Overall, grade II injuries are characterized by superficial ulcers, whitish membranes, exudates, friability, and hemorrhage. Grade III injury is associated with transmural involvement with deep injury, necrotic mucosa, or perforation of the stomach or esophagus. Although grade I injuries do not progress to stricture, 15% to 30% of all grade IIa injuries and up to 75% of circumferential grade IIb injuries of the esophagus develop strictures. With grade III injury, up to 90% result in stricture. Recently, the formation of strictures is decreasing for both grade II and grade III injury, possibly because of the type and caustic intensity of the substance ingested.[4]

CLINICAL FEATURES

Airway edema and esophageal or gastric perforations are the most emergent issues. Laryngeal edema begins in minutes and occurs over several hours. Systemic toxicity, hypovolemic shock, and hemodynamic instability with hypotension, tachycardia, fever, and metabolic acidosis are ominous signs. Small ingestions of potent substances can be as serious as larger ingestions. More than 40% of patients reporting to have "only taken a lick or sip" have esophageal burns. Patients with acid or alkali ingestions present with similar initial constellation of signs and symptoms. Oral pain, abdominal pain, vomiting, and drooling are common. Patients can have wheezing and coughing, respiratory distress, hoarseness, odynophagia, dysphagia, stridor, and dysphonia. Chest pain is common. Visible burns to the face, lips, and oral cavity may be seen (Fig. 143.4), although these signs are not always clinically reliable.[5,6] Skin burns can occur from spillage or secondary contamination after vomiting. Peritoneal signs suggest hollow viscus perforation or contiguous extension of the burn injury to adjoining visceral areas. Oropharyngeal burns alone are not predictive of more distal injury, but drooling, odynophagia, dysphagia, vomiting, and stridor, especially in combination, are highly predictive of significant lesions. Tracheal necrosis is one of the most frequent causes of death after caustic ingestion.

Dysphagia usually subsides in three to four days. Patients with significant esophageal burns, particularly those that are circumferential, may develop esophageal stricture; 80% of strictures become apparent in 2 to 8 weeks. Symptoms include dysphagia and food impactions. Strictures that become symptomatic early are generally more severe. In one study of 86 adults admitted to the hospital after caustic ingestion, 18 had complications with strictures and 6 died.

Patients with significant esophageal injury have a thousand-fold increase in esophageal carcinoma, which develops 40 to 50 years after the caustic ingestion. Long-term, 2% of patients who ingest caustics develop esophageal cancer and nearly 3% of esophageal cancer patients have a history of caustic ingestion.

Significant acid ingestions may be devastating and result in a higher mortality rate than alkali ingestions. The fulminant course of some acid ingestions may be due to systemic absorption of the acid, resulting in metabolic acidosis (which may also be the result of extensive tissue necrosis), hemolysis, and renal failure. Ingestion of glacial acetic acid (80% acetic acid) is common among certain ethnic populations as a suicidal gesture or accidental ingestion during food preparation, resulting in systemic complications, including renal and hepatic insufficiency, hemolysis, and disseminated intravascular coagulation. Ingestion of H_2SO_4 and HCl typically does not cause these systemic complications.

On clinical evaluation, the goal is to identify the extent and severity of the burn. In evaluation of a patient, the history should include the time, amount, type of product ingested, and presence of suicidal intent, if any. Patients who are suicidal may minimize their symptoms or understate the ingestion. Physical examination addresses all of the above described features and should focus on the oropharynx, supraglottic area, airway, and gastrointestinal (GI) tract.

DIFFERENTIAL DIAGNOSES

The ingestion of a caustic agent is most often reported upon presentation by patient or family member. When this is not known, the differential diagnosis is essentially that of abdominal discomfort, nausea, and vomiting, until typical mucosal injury becomes apparent. Mucosal injuries can be the result of various causes. The presence of early shock or altered mental status soon after ingestion of a caustic agent should prompt the search for other causes. Gastroenteritis from the ingestion of heavy metals (e.g., iron, arsenic, inorganic mercury) and hydrocarbons can result in similar clinical effects as seen in caustic ingestions. Other GI conditions such as gastric perforation, esophageal rupture, esophagitis, and gastroesophageal reflux disease should be considered.

Patients suffering from allergic reactions progressing to anaphylaxis and angioedema can present with irritation and inflammation of the throat and larynx mimicking a caustic ingestion. Infectious sources such as aspiration pneumonitis, croup (laryngotracheobronchitis), and epiglottitis can present in a similar manner as well.

DIAGNOSTIC TESTING

Product labels are important in confirming the concentration of chemicals. If the product with the label is brought by the patient or family, call the regional poison center for product information, look up the contents, or test the pH with litmus paper.

Evaluation of the severity of caustic ingestion and determination of the likelihood of deterioration or serious injury is based on examination of the upper airway, the esophagus, and the chest and abdomen. Examination of the oral pharynx is optimized by direct visualization. Nasopharyngoscopy, after appropriate application of a vasoconstrictor (e.g., phenylephrine) and local anesthesia (e.g., 4% lidocaine), determines the extent of injury and edema posterior to the tongue and in the supraglottic area and the glottis itself. Flexible endoscopy is used to evaluate the esophagus and stomach, after completion of the airway evaluation. Computed tomography (CT) scan is much more sensitive than plain radiography for identification of perforation of the GI tract, and both chest and abdomen are scanned when there is concern for serious injury (see earlier criteria). CT scan of the chest and the abdomen is able to detect evidence of perforation, such as mediastinal and extraluminal air, with high sensitivity.[7,8,9] Another benefit of CT is the ability to evaluate surrounding tissues that cannot be directly visualized during endoscopy due to technical challenges or safety.[7,8] Although chest and abdominal radiography are often used in the early stages to determine whether perforation has occurred, they are insensitive and these tests are not indicated if CT scanning is available.

Patients with significant injury (such as grades IIb or III) may have perforations difficult to detect during endoscopic evaluation. Thus, delayed (approximately 24 hours post ingestion) esophagram with water-soluble contrast medium may detect perforations by the presence of extravasation of contrast. If there is a high clinical suspicion, we recommend barium in the case of a nondiagnostic water-soluble contrast study that does not demonstrate a leak because barium is more radiopaque. Esophageal dilation, widening of the pleuroesophageal line, and pleural reflection displacement all portend impending perforation.

Laboratory studies should evaluate for metabolic acidosis, coagulation profile, hemoglobin, and electrolyte derangements. Some ingested acids are absorbed from the gastric mucosa and subsequently hydrogen ion disassociation occurs. The accumulation of the anionic species in the vascular space contributes to an elevation in ion gap. Ingestion of acids such as HCl result in a non-anion gap metabolic acidosis because both the dissociated hydrogen and chloride ions contribute in the measurement of the anion gap. Typically, alkalis are not absorbed from the gastric mucosa into the vascular space. A lactic acidosis can result, however, due to esophageal or gastric injury and necrosis. Therefore, in the setting of significant acid or alkali ingestion, serum pH and chemistry for serum bicarbonate analysis are indicated to determine the degree of acidosis. In cases of intentional overdose, co-ingestants should be considered and measured diagnostically if levels are available and clinically indicated.

Hydrofluoric acid exposures, whether by inhalation, ingestion, or dermal contact (hand size or larger), are notorious for the effect of absorbed fluoride, resulting in hypocalcemia, and require immediate cardiac monitoring to assess for corrected QT (QTc) prolongation, torsades de pointes, or other ventricular dysrhythmias. Rapid cardiac deterioration can occur in these cases. Serum calcium, potassium, and magnesium levels should also be determined in these cases.

The depth and extent of injury cannot be predicted based on signs and symptoms alone. Patients with signs and symptoms (vomiting, drooling, stridor, or dyspnea) of intentional ingestion should undergo endoscopy within 12 to 24 hours to define the extent of the disease. Endoscopy is contraindicated, however, in patients with likely or known perforation. Endoscopy performed too early may miss the extent or depth of tissue injury. Wound softening in the subacute phase when the likelihood of perforation is greatest makes late endoscopy (after 24 hours) more hazardous. Wound strength is weakest between day 5 to day 14 and the time of greatest risk for perforation. Early endoscopy has been studied and shown to be beneficial. Early endoscopy and GI tract evaluation permits more rapid administration of nutritional support. However, it is advised that the endoscopy be terminated at the level of the most proximal circumferential burn, particularly if the burn is severe, to avoid iatrogenic perforation. A soft feeding tube or silk string can be placed in the esophagus, when burns are present, for future dilation.

MANAGEMENT

Early and continuous hemodynamic monitoring is indicated. All contaminated clothing should be removed to prevent ongoing injury to the patient as well protection of health care personnel. Appropriate personal protective equipment (PPE) and hazardous waste disposal should be used.

After a caustic ingestion, little can be done to attenuate the severity of the tissue injury. Early endotracheal intubation or upper airway endoscopic examination is warranted when there are indications of upper airway injury on nasopharyngoscopy. If there are significant symptoms or signs, such as respiratory distress, stridor, or voice alteration (hoarseness, muffling), intubation is often necessary early in the course of evaluation, before edema and secretions both threaten the airway and make intubation difficult or impossible. For this reason, upper airway examination is often done with an intubating bronchoscope so that if significant injury and edema are identified, intubation can be accomplished during performance of the bronchoscopic examination. Blind nasotracheal intubation is contraindicated. When oral intubation is planned, a video laryngoscope should be used to provide optimal view with the least amount of tissue trauma. If significant symptoms and signs are present, intubation can be anticipated to be difficult, and awake flexible endoscopy is the method of choice.

After the airway is secured, persistent hypoxia and an increasing arterial-alveolar gradient warrant early bronchoscopy. Patients should have intravenous fluid resuscitation (20 to 40 mL/kg 0.9% normal saline bolus). Oropharyngeal and GI injury secondary to caustic ingestion can result hypotension because of fluid shift from the intravascular to the interstitial space. Intravenous access should be established and a bolus of 30 mL/kg of isotonic crystalloid, usually normal saline, should be administered. Standard measures of resuscitative progress such as heart rate and urine output should be monitored closely. In alert patients who are not vomiting and can tolerate liquids, small volumes (1 to 2 cups) of water or milk can be considered within the first 5 minutes after ingestion. Because injuries occur almost immediately, later dilution is not warranted. Forcing of fluids is never indicated. Attempts to neutralize the ingested corrosive with weak acids or alkalis can cause possible thermal reactions and worsen the injury.

GI decontamination after caustic ingestion is generally not indicated and can be hazardous. Inducing emesis is absolutely contraindicated given the risk of re-induction of the caustic agent into the esophagus, oropharynx, and airway. Activated charcoal is contraindicated as well, because it has little effect and will interfere with the endoscopist's view and assessment.

Careful nasogastric aspiration may decrease the amount of acid absorbed and may be useful in the setting of significant (massive) acid ingestions presenting within 30 to 45 minutes after the event, given the ominous natural history of many of these cases and the lower risk of esophageal perforation compared with alkali ingestion.

Exceptions to the general rules of gastrointestinal decontamination regarding caustics are noted in the management of zinc chloride ($ZnCl_2$) and mercuric chloride ($HgCl_2$). Both may result in severe systemic toxicity due to cationic metal injury. The local caustic effects, while of concern, are less consequential than the effects after systemic absorption. Thus, prevention of systemic absorption should be the primary action followed by direct assessment and management of the local effects. Initial management to prevent systemic absorption includes decontamination with gentle nasogastric tube aspiration and administration of activated charcoal.

Surgical consultation is indicated for free air, peritonitis, increasing and severe chest and abdominal pain, and hypotension. The decision to perform surgery in patients with caustic ingestions is generally clear. Endoscopic or diagnostic imaging evidence of perforation, severe abdominal rigidity, or persistent hypotension are all indications for surgical intervention. Hypotension is a grave clinical finding and often indicates perforation or significant blood loss. Additionally, elevations in prothrombin and partial thromboplastin times, as well as acidemia, are associated with severe caustic injury.

There remains controversy regarding the use of corticosteroid therapy in the management of grade IIb circumferential esophageal burns due to caustic injury. A dated prospective study of 83 children with grade IIb esophageal burns compared a short (3 day) course of high-dose methylprednisolone to placebo and found a statistically significant decrease in stricture formation in the high-dose steroids group. Prior to this study, the medical literature suggested no benefit of corticosteroids because there was no demonstrated significant decrease in stricture formations after grade IIa, IIb, or III esophageal burns, but there was increased risk for hemorrhage, infectious complications, severe esophagogastric necrosis, and prepyloric ulcer formation. Steroids can also mask early signs of inflammation and inhibit resistance to infection. Accordingly, they are not indicated to reduce the extent of esophageal injury. Controversy also surrounds the administration of steroids in patients with airway edema secondary to caustic ingestion. There are no controlled studies evaluating this practice, and the same downside risks exist as for steroid use for esophageal stricture. Airway edema can be fatal, however, and a single dose of a potent corticosteroid might mitigate some of the edema with minimal risk to the patient. We recommend dexamethasone 10 mg IV when there is indication of airway edema.

Prophylactic antibiotics are not indicated. Patients with proven perforation should have an emergent surgical consultation.

The risk of perforation from esophageal dilation is decreased if the initial procedure is delayed beyond 4 weeks post-ingestion. At this time, healing, remodeling, and potential stricture formation in the esophagus have already taken place. Following perforation, patients develop clinical symptoms such as dyspnea or chest pain in the setting of associated subcutaneous emphysema or pneumomediastinum. Diagnostic imaging is recommended to identify the perforation and provide information for emergent surgical repair. Patients with stricture formation require long-term endoscopic follow-up for the presence of neoplastic changes of the esophagus that may occur with a delay of several years to decades.

DISPOSITION

Asymptomatic patients can undergo endoscopy in the emergency department. Those patients with grades 0 or I injury may be discharged home after 4 to 6 hours of observation with close follow-up monitoring with appropriate gastroenterology or otolaryngology consultants.[9] They can have a liquid diet for 24 hours and then gradually transition to soft food over the next 3 days and to a full diet thereafter if progressing well.

Surgical intervention is required in cases of hollow viscus perforation; early exploration may also be warranted in cases of suggested full-thickness burns.[9] Symptomatic patients, particularly those with potential for airway compromise, or high-grade esophageal or gastric injuries, require admission to an intensive care unit. If endoscopy is unavailable, the patient should be transferred to a tertiary care facility where it can be performed. Psychiatric evaluation is indicated in patients with intentional ingestion.

SPECIAL CASES

Ocular alkali exposures are true ophthalmologic emergencies. Immediate irrigation with at least 2 L of normal saline per eye is indicated in almost all cases except frank perforation. Management is described in Chapter 57. Dermal caustic exposures can also result in significant burn injuries (see Chapter 55). Clothing removal, copious irrigation, and local wound débridement are the most important initial treatment measures.

Povidone-Iodine

Povidone-iodine (Betadine) is used as a surgical scrub and is not a caustic agent, but ingestion of tincture of iodine can cause severe GI injury and is potentially life-threatening. Gastric irrigation with starch or milk in these cases may convert iodine to the much less toxic iodide. Either of these agents is most likely to be effective if administered within the first 30 to 45 minutes post ingestion. The goal is to convert the gastric effluent to a dark blue or purple hue.

Phenol and Formaldehyde

Ingestion of phenol or formaldehyde can also cause severe caustic injury to the GI tract. Both phenol and formaldehyde are general protoplasmic poisons and can cause protein denaturation and coagulation necrosis. Systemic symptoms, including dysrhythmias, hypotension, seizures, and coma, may also result from phenol ingestion. Acidosis may be prominent after formaldehyde ingestion because of its metabolism to formic acid. Phenol is well absorbed through the skin, and dermal exposure may result in burns and systemic toxicity. Although dermal decontamination of phenol exposures with low–molecular-weight polyethylene glycol has been suggested, there is no evidence that it is superior to irrigation with water, which is more readily accessible.

Hydrogen Peroxide

Ingestion of concentrated (>30%) hydrogen peroxide (H_2O_2) may cause GI burn injuries and the formation of gas emboli. Radiographic evaluation for the presence of gas in the chest or abdominal cavities, including the portal system, should be performed in symptomatic patients or those who ingest concentrated H_2O_2. Hyperbaric oxygen has been used successfully to treat gas emboli from H_2O_2 ingestion.

Button Batteries

Button (disk) batteries and conventional alkaline cylindrical batteries pose potential obstructive and chemical hazards if they are ingested. Ingestion of large (25-mm) wafer-sized button batteries was a common problem in the past, but the smaller button batteries of today are less likely to cause esophageal obstruction. Button batteries are usually made of a metallic salt (lithium, mercury, nickel, zinc, cadmium, or silver) bathed in NaOH or KOH. Obstruction can cause pressure necrosis, caustic

injury due to leakage of alkaline medium, or electrical injury. Caustic injury is much less common. Ulceration, perforation, and possible fistula formation occur but are uncommon. Heavy-metal toxicity in this setting has not been reported with newer-generation of disk batteries.

Evaluation of button battery ingestions includes radiography to assess the position of the foreign body. Batteries lodged in the airway or esophagus require expeditious removal. Single gastric or intestinal batteries can be treated with watchful waiting, generally in the patient's home. Checking the stool for passage of the batteries is recommended. Follow-up radiographs should be obtained one week after ingestion if the battery has not passed. If the patient becomes symptomatic with acute abdominal pain or exhibits GI bleeding, expedited reassessment is indicated.

CHAPTER 143: QUESTIONS AND ANSWERS

1. A patient presents after the intentional ingestion of hydrochloric acid (HCl). He complains of mouth, throat, and chest pain, as well as painful swallowing and nausea. His vital signs are normal. Physical examination reveals oral burns without edema. The remainder of the examination is normal. You decide that in addition to psychiatric consultation, the patient should have upper endoscopy. What is the best time for the patient to have the endoscopy?

a. Immediately
b. In 2 to 4 hours
c. In 4 to 12 hours
d. In 12 to 24 hours
e. In 2 or 3 days

Answer: D. The ideal time for endoscopy is 12 to 24 hours. Endoscopy done too soon may miss the extent or depth of injury, whereas endoscopy after 24 hours is actually more likely to cause perforation because the wounds have softened. All patients with signs or symptoms of strong acid ingestion as well as patients with intentional ingestion should have endoscopy performed.

2. A patient presents immediately after the ingestion of bleach. The patient is awake and alert and complaining only of mouth pain. His vital signs and physical examination findings are normal. You consider having the patient drink fluids to dilute the bleach. Which of the following statements regarding this therapy is *true?*

a. Dilution is beneficial only if it is done very soon after ingestion.
b. In cases of alkali ingestions, dilution with a mild acid such as acetic acid is best.
c. Large volumes of fluid should be used.
d. Milk should always be used instead of water.
e. Patients should also be encouraged to eat solids.

Answer: A. Dilution, if it is done at all, should be done early because injuries from caustics occur almost immediately. Water and milk are equally beneficial and are the agents of choice. Weak acids or alkalis should never be used for dilution, because they can cause thermal reactions that worsen the injury. Small volumes up to approximately 500 mL should be used. Solids are not beneficial and can complicate the situation and increase the risk of aspiration.

3. A patient presents after an intentional caustic ingestion. She complains of hoarseness, with mouth, throat, and chest pain. Burns are present on her lips and oral mucosa and she is drooling. Her vital signs are normal, as is the remainder of her physical examination. Which of the following is the most appropriate treatment?

a. Administer 500 mL water orally
b. Administer intravenous Solu-Medrol
c. Endotracheal intubation
d. Obtain electrocardiogram
e. Upper endoscopy

Answer: C. Early intubation is indicated if there is any evidence of airway compromise, such as hoarseness, throat pain, drooling, or edema. Because edema and secretions can both increase rapidly and can make intubation difficult or even impossible, preparations should be made for a difficult airway. Fluids for oral dilution should not be given if the patient has difficulty swallowing. Corticosteroids have been studied to decrease the incidence of stricture formation, but evidence for their benefit is lacking and serious side effects can occur. With the exception of hydrofluoric acid, an electrocardiogram is not routinely needed for caustic ingestions, and endoscopy should be performed 12 to 24 hours after the ingestion and after the airway has been secured.

4. What empirical treatment is indicated to prevent systemic toxicity from hydrofluoric acid ingestions?

a. Calcium chloride
b. Magnesium chloride
c. Potassium chloride
d. Sodium bicarbonate
e. Sodium chloride

Answer: A. Calcium chloride is indicated in significant hydrofluoric acid exposures. Although hydrofluoric acid is a weak acid, the fluoride ion is extremely electronegative and will bind with multiple cations, specifically calcium and magnesium. Profound hypocalcemia is responsible for most deaths from hydrofluoric acid exposure and can occur before a serum calcium concentration can be measured.

CHAPTER 143: QUESTIONS AND ANSWERS—cont'd.

5. A 3-year-old boy presents after swallowing a button battery. What is the most appropriate management?
   a. Endoscopic removal
   b. Inpatient observation
   c. Radiograph to assess anatomic location
   d. Surgical removal
   e. Whole-bowel irrigation

Answer: C. Outpatient observation is warranted for button batteries that are located in the stomach or intestines, which can be assessed by plain radiographs. Batteries lodged in the esophagus require endoscopic removal. Examination of the stool for passage of the battery is recommended. If it is not passed in one week, repeated radiographs should be obtained. Inpatient observation is not needed as long as close follow-up can be ensured. Surgical removal and whole-bowel irrigation are not beneficial and are potentially deleterious.

6. A patient presents after a self-harm attempt with 3% household bleach (sodium hypochlorite). The patient has normal vital signs and is asymptomatic. His physical examination is unremarkable. Which is the most appropriate treatment?
   a. Administer 500 mL water orally
   b. Administer intravenous Solu-Medrol
   c. Endotracheal intubation
   d. Obtain electrocardiogram
   e. Upper endoscopy

Answer: E. This patient is high risk for significant esophageal or gastric injury due to the self-harm attempt. Several studies evaluating for the presence or absence of oropharyngeal burns as a predictor of distal esophageal of gastric injury had found these finding to be poorly predictive. Thus, endoscopy should be a standard diagnostic tool used in the management of intentional caustic ingestions.

7. A 45-year-old female presents after an intentional caustic ingestion. She has severe chest pain, and is tachycardic, stridulous, drooling, and hoarse. She has a normal blood pressure. Due to concerns about her airway, she is intubated without difficulty. Which of the following diagnostic imaging modalities is most appropriate for this patient?
   a. Plain chest radiograph
   b. Ultrasound
   c. MRI chest
   d. CT chest
   e. Contrast esophagram

Answer: D. CT scanning is considerably more sensitive than radiography and ultrasound for detecting hollow viscus perforation, for which the patient is at high risk. MRI does not add significant benefit over CT and typically takes longer to obtain.

Cocaine and Other Sympathomimetics

Michael A. Chary and Timothy B. Erickson

KEY CONCEPTS

- Excessive use of stimulants can lead to *sympathomimetic toxicity*, manifesting as tachycardia, hypertension, mydriasis, diaphoresis, hyperthermia, hyperreflexia, and agitation. If untreated, sympathomimetic toxicity can lead to seizures, coma, and death.
- Administration of benzodiazepines is the key therapeutic intervention for sympathomimetic toxicity. Ketamine, olanzapine, and butyrophenones are alternative adjuncts if the cause of severe agitation is not clearly sympathomimetic toxicity.
- Worsening hyperthermia portends imminent death. Reduce body temperature rapidly by external cooling, sedation, and, if needed, paralysis.
- Anti-hypertensives are adjuncts to benzodiazepines. Antihypertensives do not treat as many aspects of sympathomimetic toxicity as do benzodiazepines, however, and short-acting antihypertensive agents (e.g., phentolamine, nitroglycerin, nicardipine, clevidipine) are preferred.
- Wide-complex rhythms secondary to stimulants (cocaine, bupropion) may respond to intravenous sodium bicarbonate administration.
- Cocaine body packers who develop toxicity need emergent surgical intervention to limit bowel necrosis and life-threatening sequelae caused by leaking packets.
- Novel psychoactive substances (e.g., MDMA, bath salts) combine stimulant, hallucinogenic, and psychedelic effects. They generally produce longer-lasting and more intense effects than cocaine or amphetamine.
- Screen for hyponatremia in patients with sympathomimetic or serotonin toxicity.
- If the clinical presentation does not fit the history (e.g., ingested cocaine but hypoxic and somnolent), consider a contaminant or alternate cause. Contaminants change rapidly and vary by geographic region. Consult a medical toxicologist or regional poison control center.

FOUNDATIONS

Sympathomimetics are substances that activate the sympathetic nervous system (Box 144.1). These substances stimulate release (amphetamine, phenethylamines) or decrease reuptake (cocaine, amphetamine, phenethylamines) of neurotransmitters (serotonin, norepinephrine, dopamine, epinephrine). As a result, these neurotransmitters remain in synapses longer and activate neuronal pathways more strongly and persistently.[1] Stimulants cause an acute upper effect—euphoria and increased energy. Excessive use can lead to sympathomimetic toxicity—tachycardia, hypertension, mydriasis, diaphoresis, hyperthermia, hyperreflexia, and agitation. If untreated, sympathomimetic toxicity can lead to seizures, coma, and death.

This chapter reviews the epidemiology, pathophysiology, and treatment of stimulant toxicity. Over the past two decades, many designer chemicals have emerged with properties that combine traditional drug classes. Some are stimulants and hallucinogens. Others are stimulants and sedatives. Toxicity from a stimulant, whatever its pedigree, manifests as overactivation of the nervous and cardiovascular systems. The primary goals of clinical intervention are to decrease activation of the sympathetic nervous system by sedating the patient, identify end-organ toxicity, and involve a medical toxicologist to guide further management for more complicated cases.

Cocaine

Cocaine is the canonical ubiquitous stimulant drug of abuse. The indigenous people of South America chew the cocoa leaf *(Erythroxylon coca)* for energy. Spanish colonists initially banned chewing cocoa leaves, but soon acknowledged their ergogenic properties, legalizing and taxing cocoa leaf production in the 16th century. In 1855, Friedrich Gaedcke isolated pure cocaine. This three-century delay partly reflects the difficulty in keeping cocaine warm and dry while shipping it across the Atlantic Ocean. Soon after, cocaine became a popular ingredient in beverages, pharmaceuticals, and tonics. In the 19th century, physicians such as Carl Koller and William S. Halsted explored the use of cocaine as an anesthetic, exploiting its unique ability to block sodium channels and constrict blood vessels. Victorian literature mentions cocaine's ability to "stave off the ennui of existence," and it was notably used by the character Sherlock Holmes to keep him stimulated between cases. In 1914, the U.S. Congress passed the Harrison Narcotics Tax Act, which required a physician's order to dispense cocaine and narcotics.

Epidemiology

General statistics on drug use may not distinguish between people who have ever used cocaine, those who have used in the last year, or those who have used in the last week. As a result, these studies combine different populations: the regular user, the sporadic user, the heavy user, the sampler, adults, and adolescents. Any of these groups may experience an overdose of cocaine, although anecdotal experience suggests that inexperienced drug users with psychiatric comorbidities are the population most at risk for cocaine toxicity. Regular use of cocaine accelerates vascular pathology, including coronary artery arteriosclerosis. It is more useful for the clinician to consider incidence or prevalence in terms of the at-risk population. Most information on novel psychoactive substances comes from observational studies on social media, which rarely can identify the exposure or fully define the population.

The prevalence of people in the world who reportedly used cocaine was 13 million in 2012 (0.18%), increasing to 18 million (0.24%) in 2016.[2] The fraction of 8th graders in the United States who reportedly used cocaine was 0.9%, nearly four times the global average. The fraction of 12th graders who used cocaine was 3.8%, again, nearly four times the global average.[3]

In the emergency department (ED), cocaine use is associated with up to 20% of drug misuse-related deaths in the United States[4,5] and between 20% and 50% in the European Union. These data may underestimate the incidence of morbidity and mortality attributable to cocaine, especially in trauma patients.[6] In 2017, drug overdose deaths involving cocaine increased by more than 33%, with almost 14,000 Americans dying from an overdose involving cocaine. From 2016 to 2017, the largest relative and absolute rate changes for cocaine-involved overdoses among racial/ethnic groups were highest among non-Hispanic Blacks. The highest death rate for overdoses involving cocaine in 2017 also occurred among Non-Hispanic Blacks.[7]

Formulation

Unpurified cocaine paste is converted to more usable forms of cocaine. The crystallized freebase of the cocaine alkaloid is known as crack cocaine. It is inhaled with a "crack pipe" designed to tolerate the high temperature required to volatilize pure cocaine. The high lipid solubility and rapid transport from the lungs into the brain contribute to crack's rapid onset of action (Table 144.1). The water-soluble salts of cocaine (i.e., cocaine hydrochloride and cocaine sulfate) are available as a white crystalline powder that is inhaled intranasally or dissolved and injected intravenously. Oral administration is rare except for among those patients who are smuggling or concealing drugs.

Pathophysiology

Cocaine decreases the clearance of dopamine, epinephrine, norepinephrine, and serotonin from synapses between nerve cells or between nerve cells and muscle cells (Fig. 144.1). Decreased clearance allows these neurotransmitters to stay bound to post-synaptic receptors longer, leading to autonomic stimulation (all four neurotransmitters), euphoria (dopamine and serotonin), and a sensation that things are more salient, or important, than they might be otherwise (dopamine) (see Box 144.1). Norepinephrine causes vasoconstriction by stimulation of alpha-adrenergic receptors on vascular smooth muscle. Epinephrine increases myocardial contractility and heart rate through stimulation of $beta_1$-adrenergic receptors. In addition to catecholamine release, the reuptake of these stimulatory neurotransmitters from synaptic clefts is inhibited, altering the normal balance between excitatory and inhibitory tones in the central nervous system (CNS). Subsequent stimulation propagates peripheral catecholamine release. Reuptake of serotonin is similarly inhibited and can cause serotonergic excess, as well.

Cocaine is also a local anesthetic. It blocks sodium channels, slowing nerve impulses from neuronal pain fibers by prolonging the upstroke of the action potential. Along with adrenergic stimulation, this can precipitate tachydysrhythmias such as supraventricular or, with severe sodium channel blockade, ventricular tachycardia. A clinical marker for heart sodium channel blockade is the duration of the QRS on a 12-lead electrocardiogram (ECG). QRS durations longer than 100 ms in a patient with a previously unremarkable ECG suggests sodium channel blockade. The prognostic value of the QRS in patients with preexisting bundle branch blocks or who are actively paced is less known.

The half-life of cocaine is approximately 90 minutes. Cholinesterases in the plasma and liver metabolize cocaine to the inactive metabolites—ecgonine methyl ester and benzoyl ecgonine. In the presence of ethanol, cocaine is metabolized to cocaethylene, which has the same effects as cocaine,[8] giving rise to the observation that ethanol prolongs rather than counteracts cocaine's effects. Genetic differences in the phenotypic expression of plasma cholinesterases may explain the variation across individuals in susceptibility to cocaine toxicity. Most standard urine drug screens in the ED test for benzoylecgonine, which is a metabolite only of cocaine. It can be detected in the urine within 4 hours after using cocaine and remains detectable, depending on the laboratory threshold, for up to 7 days after use.

BOX 144.1 Clinical Effects of Sympathomimetics

Central nervous system (CNS) excitation
Diaphoresis
Hypertension
Hyperthermia
Increased motor tone
Mydriasis
Tachycardia

Amphetamine and Its Derivatives

Amphetamines are structurally distinct from cocaine even though they have similar effects. They are in fact structurally more similar to dopamine than cocaine. The word "amphetamine" is an abbreviation of **a**lpha-**m**ethyl**ph**en**et**hyl**amine**. Phenethylamine is the parent compound from which amphetamines, catecholamines, cathinones (bath salts), and novel psychoactive substances such as methylenedioxymethamphetamine (MDMA) can be derived.

Amphetamines were discovered while chemists John K. Smith and Mahlon Kline were trying to develop a cheaper alternative nasal decongestant to ephedrine. Beginning in 1929, dextroamphetamine was sold as Dexedrine. It was made a prescription drug in 1959, however, owing to concerns over its addictive potential. The racemic mixture is sold as Adderall. Amphetamine-based psychostimulants with abuse potential include illicit drugs, such as methamphetamine and ecstasy, and prescription stimulants, as well. Prescription stimulants, used to treat conditions such as attention-deficit/hyperactivity disorder (ADHD), are commonly misused.

Epidemiology

Rates of overdose deaths from all psychostimulants have been increasing since 2010. More than 10,000 Americans died from an overdose involving psychostimulants with abuse potential in 2017, which was a

TABLE 144.1 Cocaine Pharmacology by Route of Administration

Route	Formula	Onset of Action	Peak Effect	Duration
Inhalation	"Crack"	8–12 s	2–5 min	10–20 min
Intranasal	Cocaine HCl	2–5 min	5–10 min	30 min
Intravenous	Cocaine HCl	Seconds	10–20 min	60–90 min
Oral	Cocaine HCl	30–60 min	60–90 min	Unknown
"Skin popping"	Cocaine HCl	Unknown	Unknown	Unknown

HCl, Hydrogen chloride.

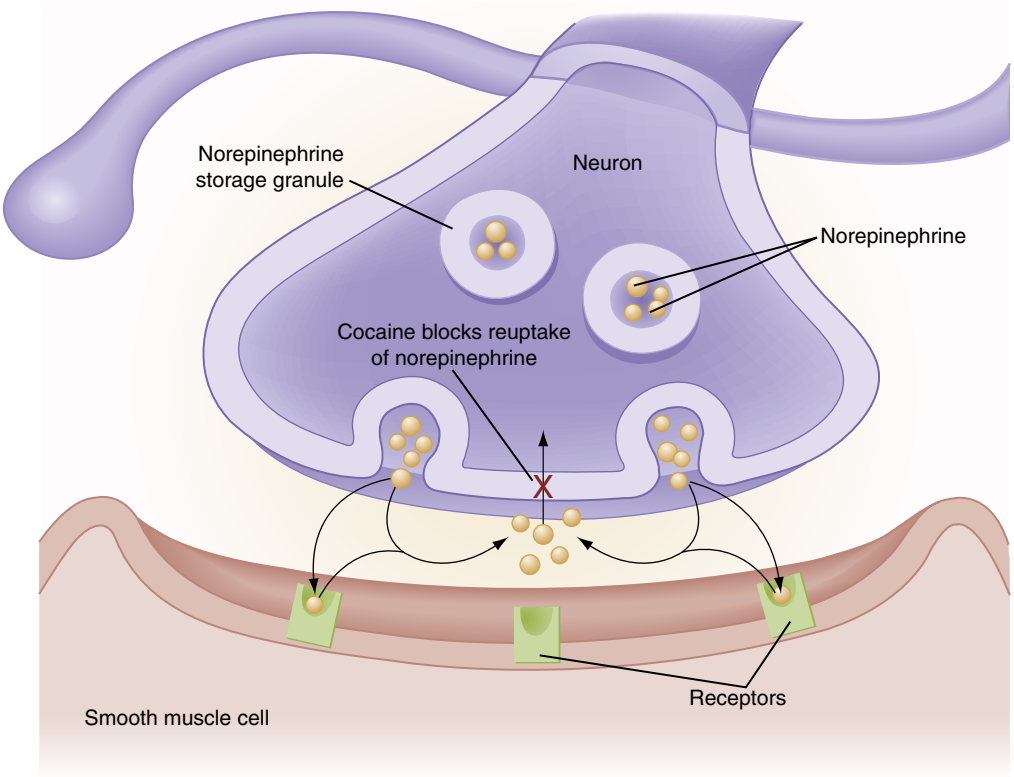

Fig. 144.1 How cocaine increases sympathetic tone by increasing neurotransmitters in the synapse.

nearly 40% increase over the previous year. From 2016 to 2017, non-Hispanic whites had the greatest percent increase in the death rate for overdoses involving psychostimulants, while the largest absolute rate change in psychostimulant-involved overdoses was in American Indian/Alaska Native (AI/AN) populations. AI/AN also experienced the highest death rate for overdoses involving psychostimulants in 2017.

The highest rate increases of psychostimulant-related overdose deaths were in the Midwest region in 2017, while the overall rate was highest in the West. However, the highest overdose death rates were in West Virginia and Alaska.[7]

Methamphetamine

Methamphetamine (methyl amphetamine) was discovered shortly after amphetamine, also as an alternative to ephedrine. Like amphetamine, it was extensively used during the Second World War, to the point that German soldiers called it "Stuka-Tabletten," referring to the pilots of the Stuka dive bombers. The effects of methamphetamine, also known as "crank" and "crystal meth," last longer. Some paranoid delusions persist for 24 hours. The production of methamphetamines requires metal salts. Lead toxicity from the drug being inappropriately produced has been reported. Injuries during illicit methamphetamine production or police raids include exposure to anhydrous ammonia, hydrochloric acid, sodium hydroxide, ether, and ephedrine, as well as burns and explosions in "meth labs." Amphetamines are usually ingested orally as pills, but can be crushed and injected, as well.

Pathophysiology

Amphetamines act by multiple mechanisms to increase norepinephrine, epinephrine, dopamine, and serotonin levels in the brain. They increase the amount of neurotransmitter released per action potential, decrease the rate of clearance from the synaptic cleft, and decrease the rate of enzymatic inactivation. The subsequent CNS stimulation results in sympathomimetic effects nearly identical to those from cocaine, but the effects generally last longer and are less intense. Patients are at risk for hyperthermia, hypertensive emergencies, dysrhythmias, myocardial ischemia, and hyperkalemia associated with rhabdomyolysis.[9] In contrast to cocaine, amphetamines do not block sodium channels. Although urine drug screens can identify amphetamines, they are of little utility in the treatment of an intoxicated patient.

Phenylethylamines, which are closely related in molecular structure to amphetamines, include the "2C" and "NBOMe" drugs, named for the location of specific structural elements along the amphetamine backbone.[10] These have powerful serotonergic, hallucinogenic effects, and patients can present with adrenergic toxicity and behavioral agitation. The brominated form (street-named "Bromo-DragonFLY" due to its structural similarity to a dragonfly) is associated with a necrotizing angiitis that can compromise blood flow to the limbs.[11] Limb or digit pain in such patients warrants comprehensive monitoring and evaluation for vasospasm and tissue ischemia.

Ephedrine and Ephedra

Ephedra is a plant-based medicinal preparation from the herb Ephedra sinica. It is an evergreen shrub-like plant native to Asia and also grows in southwestern United States. Ephedra, also known as the Chinese herbal product Ma Huang, has been associated with strokes and deaths in adolescent users. People have used ephedra for centuries in China for colds, fever, flu, headaches, asthma, nasal congestion, and wheezing. Ephedrine is the main active ingredient in ephedra. In 1997, in response to mounting concern over cardiovascular side effects, the U.S. Food and Drug Administration (FDA) banned products containing 8 mg or more of ephedrine alkaloids and required all ephedra-containing products to disclose the health risks of heart attack, stroke, and death.

Ephedra is widely used by athletes as a performance-enhancing drug, despite a lack of evidence that it improves athletic performance.

Its use has been completely banned from all sports competitions since 2003. Bitter orange is marketed as a "safer" herbal alternative to ephedrine. It contains p-synephrine, which is demethylated ephedrine. At the dose amounts generally available, bitter orange appears to have neither stimulant nor cardiotoxic effects.[12] Ephedrine (and its diastereomer pseudoephedrine) can also be used as a precursor in the manufacture of methamphetamine by dehydrating it. Ephedrine and its stereoisomer, norpseudoephedrine, cross the blood-brain barrier and lead to the release of noradrenaline and dopamine in the substantia nigra.

Caffeine

Caffeine (1,3,7-trimethylxanthine) is a widely consumed psychoactive substance noted for its ergogenic and prokinetic effects. It is a common component of energy drinks and weight loss supplements. It is also a reported adulterant in cocaine, MDMA, and many novel psychoactive substances. In one analysis of 512 street samples of cocaine from Brazil, caffeine concentration ranged between 40% and 60% by weight.[13] Caffeine potentiates the euphoric effects of cocaine in mice.[14] Caffeine is an adenosine antagonist, binding to post-synaptic adenosine receptors throughout the body. Toxic doses of caffeine (greater than 100 mg/kg, or roughly one cup of coffee per kilogram) may induce status epilepticus and tachydysrhythmias refractory to standard treatment regimens requiring hemodialysis.[15]

Novel Psychoactive Substances

Novel psychoactive stimulants are structural variants of amphetamine that combine hallucinogenic, euphoric, and stimulant properties to strike balances between auditory hallucinations, visual hallucinations, paranoia, euphoria, dysphoria, and dissociation.[16] A general rule of thumb used by informal chemists is that aromatic substitutions increase the hallucinogen/entactogen effects and aliphatic substitutions increase the stimulant effects.

Novel psychoactive stimulants are often combined with ethanol or sedatives to mitigate anxiety or dysphoria, or to prolong the perceptual alteration.[17] Novel psychoactive substances are a broader category including synthetic cannabinoid receptor agonists (K2, synthetic marijuana). This chapter does not discuss those substances as they are conceptually closer to cannabis than stimulants.

Data on the usage of most novel psychoactive substances are lacking. Epidemiologists have used wastewater analysis to quantify exposure,[18] but it is difficult to estimate usage from this method. From questionnaires, the use of mephedrone, a bath salt (cathinone), seems more prominent in the United Kingdom than the United States, where 0.5% of people aged 16 to 59 reported using mephedrone at least once in 2015 to 2016.[19]

There is a similar trajectory between derivatives of amphetamine overtaking amphetamine and derivatives of fentanyl overtaking the parent compound fentanyl. In both cases, the derivatives are often more potent than the unmodified compounds, have narrower therapeutic indices, and are generally not detected on standard drug screens. In addition, novel combinations such as methamphetamine contaminated with fentanyl (street named "goofballing") are emerging.

Ecstasy

MDMA (ecstasy, Molly) is a derivative of amphetamine. It is the canonical entactogen. An entactogen produces experiences of emotional communion, oneness, relatedness, emotional openness—that is, empathy or sympathy. The molecular structure of MDMA is in between amphetamine and serotonin, explaining its combination of sympathomimetic and serotonergic features. The term "Molly" (short for molecular) is used to describe a product with a higher concentration of MDMA, although these products may contain merely caffeine or placebos. User reports are, therefore, often unreliable in determining true exposure.

MDMA can precipitate hyponatremia via drug-induced syndrome of inappropriate antidiuretic hormone secretion (SIADH). MDMA and its metabolite increase the release of vasopressin (anti-diuretic hormone), which in the setting of high free water intake, results in free water retention.[20] Patients with MDMA-induced hyponatremia demonstrate urine with high osmolality and sodium. Chronic use of MDMA and its variants (MDA) may cause irreversible neurologic damage to serotonergic neurons in mice.[21]

Bath Salts

Bath salts are derivatives of cathinone, an active ingredient in the leaves of khat or qat *(Catha edulis)*. Cathinone is, itself, a phenethylamine derivative. Khat leaves also contain methcathinone, a similarly potent sympathomimetic.

Bath salts were first encountered in Japan in the early 2000s. The ease of synthesis and modification of specific functional groups of the parent cathinone make these drugs particularly difficult to regulate.[22,23] This led to a cat-and-mouse dynamic between internet vendors and regulatory agencies. Most initial bath salts contained mephedrone (4-methyl methcathinone). Once regulatory agencies developed tests for mephedrone, the composition of bath salts rapidly changed to include methylone, ethylone, butylone, pyrovalerone, methylenedioxypyrovalerone (MDPV), methcathinone, and ethcathinone. One cathinone, bupropion (Wellbutrin), is approved for medical use in the United States.

Bath salts may be ingested, inhaled, or injected and can result in severe agitation, sympathomimetic effects, hyperthermia, and rhabdomyolysis. One in vitro study suggests that cathinones and MDMA may have direct myotoxic effects by increasing the permeability of the outer mitochondrial membrane.[24] Smoking khat typically results in little toxicity because cathinone is heat labile. Numerous fatalities have been reported, causing the U.S. Drug Enforcement Administration (DEA) to categorize these agents as illegal Schedule I substances.[25] Synthetic cathinones are usually not detectable on routine urine drug screens. Treatment is similar to that of cocaine and amphetamine toxicity and includes adequate dosing of benzodiazepines for agitation with diazepam, lorazepam, or butyrophenone antipsychotic agents, such as haloperidol and droperidol (see Management, Pharmacologic Sedation for Agitation section).

Some users of synthetic methcathinone demonstrate an extrapyramidal syndrome similar to Parkinson disease with elevated manganese concentrations, presumably resulting from contamination during production. Chelation therapy is, in general, not useful in treating the parkinsonism associated with manganese toxicity.

Kratom

Kratom is a tropical tree *(Mitragyna speciosa)* native to Southeast Asia. Its leaves contain psychotropic compounds, the most studied of which are mitragynine and 7-hydroxymitragynine. Kratom is not currently an illegal substance and can be readily acquired over the internet. It is sometimes sold as an extract, gum, or green powder in packets labeled "not for human consumption." Kratom was traditionally chewed or brewed in a tea in a fashion similar to coca leaves. Mitragynine and 7-hydroxymitragynine exert opioid effects at low doses and stimulant effects at higher doses. This has led to the usage of kratom as a means to treat opioid withdrawal or to address problematic opioid use. There is one report of possible kratom use presenting as opioid intoxication requiring sedation after naloxone, similar to cocaine "speedballing," or cocaine contaminated with heroin.[26]

Clinical Features

The treatment of sympathomimetic toxicity begins with recognition of high-risk symptoms. The imminent life-threatening nature may necessitate treatment before the most likely cause is established. Risk-stratification begins with recognition of high-risk features of sympathomimetic toxicity, which are described in this section.

The sympathomimetic toxidrome refers to the constellation of tachycardia, hypertension, hyperthermia, tachypnea, mydriasis, diaphoresis, tremor, hyperactive bowel sounds, agitation, psychosis, and seizures. These clinical signs reflect overactivation of the sympathetic nervous system by sympathomimetic substances.

Sympathomimetic toxicity is an acute phenomenon with abnormal vital signs. Ingestions that do not develop abnormal vital signs after an appropriate period of monitoring may be medically cleared. Toxicity can range from mild tachycardia or agitation, depending on the amount ingested and the potency of the medication.

A patient with mild toxicity is alert and awake but may be diaphoretic, tachycardic, mydriatic, or hypertensive without organ damage. A patient with severe toxicity may be agitated, combative, or hyperthermic. Patients may present with focal acute pain syndromes, circulatory abnormalities, acute hypertension, coronary vasospasm, or seizures.

Additives, contaminants, or other drugs may create a mixed picture. Patients may combine intravenous (IV) heroin and cocaine ("speedballing"), presenting with signs of opioid toxicity but manifesting signs of cocaine toxicity after they receive naloxone. Patients may combine cocaine or crack cocaine with ethanol to elongate cocaine's euphoric effects.

The clinical presentation of sympathomimetic toxicity depends on the dose, route of administration, coingestants, and time elapsed between ingestion and presentation. Initial assessment should focus on rapidly fatal complications including hyperthermia, hypertensive emergencies, cardiac dysrhythmias, and hyponatremia.

Hyperthermia

Cocaine-toxic patients have increased motor tone and generate excessive heat. Vasoconstriction and salt and water depletion can compromise cooling, resulting in life-threatening hyperthermia with core temperatures exceeding 106°F (41°C). Delay in recognition and management increases the likelihood of death. Even with a normal temperature, increased motor tone can release intramuscular (IM) creatine kinase (CK), with rhabdomyolysis and its attendant renal and electrolyte complications. Acute psychomotor agitation with delirium increases the risk of hyperthermia.

Hypertensive Emergencies

Acute cocaine-induced hypertension can injure the cardiovascular and CNS systems. Reported sequelae include aortic dissection, pulmonary edema, myocardial ischemia and infarction, intracranial hemorrhage, stroke, and infarction in the distribution of the anterior spinal artery.[27] Vasospasm can also compromise perfusion. Intestinal infarctions and mesenteric ischemia can occur, particularly in body packers with large oral ingestions. Other local ischemic events include retinal vasospasm, renal infarctions, and placental insufficiency and infarction in the gravid uterus.

Cardiac Dysrhythmias

Sinus tachycardia is the most common rhythm. Atrial fibrillation and other supraventricular tachycardias can occur as a result of the surge in catecholamines. Life-threatening dysrhythmia may occur suddenly, heralded by abrupt diminution of cardiac output and loss of consciousness. Torsades de pointes from hypokalemia due to potassium shifting into the cells or wide-complex tachycardias from blockade of fast sodium channels on the myocardium may deteriorate into poorly perfusing or fatal ventricular rhythms. Transient conduction abnormalities consistent with a Brugada-type pattern are associated with cocaine, although some cases may be unmasking previously undiagnosed pathology. Hyperkalemia from rhabdomyolysis and myocardial ischemia can also cause dysrhythmias.

Cocaine Use Disorder, Stimulant Use Disorder

Cocaine's effects on the CNS can lead to craving behavior and cocaine use disorders that lead to secondary harm (cellulitis from injection, trauma, and sexually transmitted infections due to accessing drugs by risky means). Paranoia, either drug-induced or from underlying psychiatric illness, may occur even after the acute effects of the drug subside. Similar to phencyclidine (PCP), the neuropsychiatric effects of cocaine can alter behavior and judgment, increasing the risk of violent injuries.

Cardiomyopathy

Cocaine may precipitate heart failure by increasing the risk of myocardial ischemia and by direct injury to the myocardium.[28] The incidence of cardiomyopathy attributable to cocaine use is not well known, but case studies suggest that one should treat cardiomyopathy due to cocaine use just as cardiomyopathy from any other cause and encourage cessation of sympathomimetics.[29]

Washout

Those who binge on sympathomimetics have a prolonged activation of the sympathetic nervous system and reward pathways. This prolonged activation depletes catecholamine stores, disrupts salt/water balance, and may lead to malnutrition as eating falls to the wayside in the face of desire for cocaine. After a cocaine binge, users may experience cocaine washout, an obtunded state where the user is profoundly sedated but arousable and oriented when aroused, with normal vital signs or a mild sinus bradycardia. Users of MDMA report "suicide Sundays," where those who reported using MDMA on Friday night felt profoundly depressed on Sunday.

Nontoxicologic sequelae

Complications also arise from the route of administration. Inhalation may cause oropharyngeal burns. Inhaling and suppressing the cough reflex may precipitate spontaneous pneumothorax, pneumopericardium, or pneumomediastinum. Intranasal cocaine use is associated with sinusitis and nasopalatine necrosis or perforation. IV users have a high risk of infection with blood-borne viruses, local abscesses, and systemic bacterial infections, including *Clostridium botulinum* and endocarditis**.** Transdermal injection of cocaine, or "skin popping," has similar types of complications, especially skin abscesses. For chronic users, addiction or psychological dependence is mediated through specific dopaminergic neurotransmitter pathways. Although there are no well-defined syndromes constituting cocaine withdrawal, patients have strong cravings for the drug or a general feeling of dysphoria that is not physiologically life-threatening.

Some of the toxicity associated with cocaine is due to the unintentional ingestion of adulterants, rather than the formulation of cocaine or route of administration. Of a case series of 97 patients with serum cocaine levels, 31 had one of the following: atropine, phenacetin, hydroxyzine, ketamine, lidocaine, or tetramisole.[30] An analysis of 615 samples from two drug seizures in the United States identified the following contaminants: caffeine (31%), quinine/quinidine (25%), levamisole (12%), acetaminophen (8%), and procaine (8%).[31]

Levamisole is an older adulterant, related to tetramisole, used to dilute cocaine. Neither levamisole nor tetramisole is psychoactive;

rather, they have a similar consistency to cocaine. Levamisole was used to treat pediatric nephritic syndrome and rheumatoid arthritis until it was withdrawn from the market due to hematological complications and vasculopathy. Agranulocytosis, vasculopathy with thrombosis, dermal ulcers, and purpura, often affecting the earlobes, occurred from unintentional exposure to levamisole. A case series of 50 patients reports the development of long-lasting anti-levamisole antibodies that contribute to a serum sickness-like illness.[32] Clenbuterol is a beta-agonist with a similar appearance to cocaine that is used to dilute the amount of cocaine to sell more units. Clenbuterol inhalation or injection may precipitate tachydysrhythmias and hypokalemia.

DIFFERENTIAL DIAGNOSES

The differential diagnoses of the sympathomimetic toxidrome can be split into toxicologic and non-toxicologic causes. One useful rule of thumb is that all vital signs are "revved-up" in frank sympathomimetic toxicity. The heart rate, blood pressure, core temperature, and respiratory rate are all elevated.

Other causes of tachycardia are usually normotensive or hypotensive, for example tachydysrhythmias or hemorrhage. Thyroid storm presents similarly to the sympathomimetic toxidrome because thyroxine also activates the sympathetic nervous system.

A current medication list can help identify possible coingestants. Thought disorders and auditory hallucinations are not typically present, unlike acute psychotic or manic episodes (Box 144.2). It can be difficult to distinguish cocaine toxicity from withdrawal from sedative-hypnotics (benzodiazepines, ethanol, baclofen, gamma-hydroxybutyrate). A history of abstinence from sedative-hypnotics after heavy use may suggest sedative-hypnotic withdrawal if there is documented prior use and no other compelling explanation.

Toxicity from other sympathomimetic agents such as amphetamines, amphetamine derivatives, and PCP can present similarly to cocaine toxicity. Cocaine toxicity generally causes more frequent cardiotoxic effects (acute myocardial infarction, cardiac dysrhythmia, aortic dissection) than amphetamines or PCP.[33] One should also include myocardial ischemia, hyperkalemia, and drug-induced sodium channel blockade (e.g., cyclic antidepressants) in the differential for cocaine-induced wide-complex tachycardia.

Designer amphetamines such as MDMA are more likely than cocaine to cause hyponatremia, either from SIADH or excessive intake of free water. Patients abusing methamphetamine also tend to have more muscle wasting, malnutrition, and poor dental hygiene than chronic cocaine users. PCP toxicity may be distinguished by the presence of multidirectional nystagmus and highly combative behavior.

Like cocaine, patients with antimuscarinic poisoning (such as diphenhydramine, atropine, and jimsonweed; see Chapter 140) may present with agitation, tachycardia, hypertension, and mydriasis. Findings of acute urinary retention and dry mucous membranes distinguish the anticholinergic from the sympathomimetic toxidromes.

The hyperthermic state induced by cocaine toxicity should be further differentiated from classic and exertional heat stroke. Heat stroke tends to have more ambient environmental factors, dehydration, and more profound changes in mental status than cocaine toxicity. Serotonin toxicity (previously called serotonin syndrome) is often precipitated by the addition of a new serotonergic agent or a substance that interferes with the metabolism of a previously tolerated agent. Serotonin toxicity is most commonly reported with selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOIs), but it has also been reported with cyclic antidepressants and atypical antipsychotics. The cardinal signs of serotonin toxicity include altered mental status and autonomic instability (hyperthermia, diaphoresis, labile blood pressure) with hyperreflexia and clonus. The neuromuscular findings in serotonin toxicity are more prominent in the lower extremities, in contrast to many motor disorders, which prefer the upper extremities or spread diffusely. The agitation described with serotonin syndrome is less organized and the patient is unlikely to be ambulatory or severely combative. The onset is typically abrupt in the setting of serotonergic drug interactions or overdose. The finding of clonus is an important differentiating feature, because this is present in serotonin syndrome but absent in cocaine toxicity. Similar to serotonin toxicity, neuroleptic malignant syndrome (NMS) also presents with altered mental status, hyperthermia, and agitation. However, unlike serotonin toxicity, peripheral muscular effects tend toward rigidity and decreased reflexes rather than clonus and hyperreflexia. This is due to dopaminergic depletion from the use of dopamine antagonists, such as the older or classic antipsychotic agents. Patients presenting with NMS generally have a gradual course of hypokinesis and increasing resting muscle tone in the setting of escalating antipsychotic use. The alteration in mental status is more commonly a catatonic state.

BOX 144.2 Differential Diagnosis of Agitated Delirium

- Endocrine disease
  - Thyrotoxicosis
- Heatstroke
- Infections
  - Bacterial or viral meningitis or encephalitis
- Psychiatric
  - Acute mania
  - Acute schizophrenia
- Metabolic causes
  - Electrolyte abnormalities
  - Hyperammonemia
  - Hypoglycemia
  - Hypoxia
  - Uremia
- Postictal state
- Structural lesions of the CNS
  - Hemorrhage
  - Mass
  - Stroke
  - Trauma
- Toxicologic causes
  - Amphetamines and derivatives
  - Anticholinergics
  - Caffeine
  - Cocaine
- Lithium
- Neuroleptic malignant syndrome (NMS)
  - PCP, ketamine
  - Sedative-hypnotic withdrawal
  - Serotonin toxicity
  - Sympathomimetics, stimulants
  - Synthetic cannabinoid receptor agonists

CNS, Central nervous system; *PCP,* phencyclidine.

DIAGNOSTIC TESTING

Urine drug screening (UDS) for cocaine is accurate but unlikely to change treatment in the ED, except to provide diagnostic clarity when cocaine toxicity is suspected (e.g., young, otherwise healthy adult with

chest pain) to substantiate exposure in cases of abuse or neglect, to confirm cocaine as the unknown substance in body packers, or to exclude acute cocaine toxicity in an acutely paranoid patient. Most urine drug screens in the ED for cocaine are an immunoassay for benzoyl ecgonine, a chemical produced only by the metabolism of cocaine. Benzoyl ecgonine persists in the urine for 3 to 7 days after last use, depending on the detection limits. Despite popular belief, the local anesthetic lidocaine does not produce a false-positive cocaine screen.[34]

Urine Drug Screening for Amphetamines and Amphetamine Derivatives

The urine drug screen for amphetamine is less useful for providing diagnostic clarity in the ED than the urine drug screen for cocaine. In contrast to cocaine's unique structure, amphetamine, as described above, serves as a starting point for many FDA-approved medications (Adderall [amphetamine salts], Vyvanse [lisdexamfetamine], Wellbutrin [bupropion]) and novel psychoactive substances (cathinones [bath salts], NBOMes, and methamphetamine). The common starting point of these medications and novel psychoactive substances may lead to a false positive result, more accurately termed a cross-reaction. As an example, some beta blockers such as metoprolol are reported to cause a false-positive amphetamine screen.[35]

Electrocardiogram

An ECG screens for dysrhythmias, conduction abnormalities, and ischemia, and can provide insights into hyperkalemia or hypokalemia, as well as sodium channel blockade. Sodium channel blockade, which manifests as a QRS duration longer than 100 milliseconds, can precipitate wide-complex tachycardia by slowing myocardial depolarization. Cyclic antidepressants and cocaine share class IA antidysrhythmic effects with QRS widening and resultant QT prolongation. The prognostic value of QRS widening in the context of a bundle branch block is not known.

The evaluation of chest pain in cocaine ingestion is challenging because cocaine toxicity can precipitate myocardial ischemia via coronary vasospasm. Chronic cocaine use also accelerates arteriosclerosis, which itself can precipitate myocardial ischemia. Young patients may also demonstrate early repolarization, further complicating interpretation. Serial ECGs may be helpful to identify dynamic processes.

A chest radiograph may identify aspirated foreign bodies, pneumothorax, or pneumomediastinum from inhalational barotrauma when these are suspected, but is not required in most cases.

CK, a nonspecific marker for muscle injury, is often elevated with cocaine use. In users with myalgias, a serum CK and urine for myoglobin is checked to screen for rhabdomyolysis. Original data on cocaine-related coronary syndromes used CK-MB as a cardiac marker. This is now supplanted by troponin I, T, or the newer generation high sensitivity troponin assays, as for all patients evaluated for possible ischemic chest pain. Most patients presenting with troponin elevation and chest pain after cocaine use had angiographically proven obstructive coronary disease, often of a single vessel, but almost 20% have normal angiography.[36]

Even though the sensitivity and specificity of troponin cardiac markers for cocaine-related chest pain is unknown, we recommend that patients with cocaine use be evaluated for chest pain in a similar fashion as chest pain patients without cocaine use. Decisions regarding further investigation are based on the characteristics and course of the chest pain and results of serial troponin measurements and ECGs. We do not recommend routine use of diagnostic coronary computed tomographic angiography (CTA) in the evaluation of patients with chest pain in the context of acute cocaine use.

BOX 144.3 Initial Evaluation of Patients With Sympathetic Stimulation

Rapid assessment of vital signs, especially core temperature
Exclude hypoxia, hypoglycemia, and hyponatremia
Pharmacologic sedation with benzodiazepines
Electrocardiogram (ECG)
Urinalysis
Serum creatine kinase (CK)

Severe persistent headache despite normalization of blood pressure may be caused by a subarachnoid hemorrhage (SAH) and warrants evaluation (see Chapters 16 and 33).

In the rare event that a cocaine user presents with agranulocytosis or digital discoloration suggestive of levamisole, a "send-out" or reference laboratory evaluation for urine levamisole by gas chromatography–mass spectrometry can be performed. The sample is ideally obtained within 48 hours after last use.

MANAGEMENT

The altered mental status associated with the sympathomimetic toxidrome ranges from agitated to belligerent behavior. A severely poisoned patient may be combative and unable to cooperate in assessment of vital signs. Agitated delirium is associated with up to a 10% mortality rate. Actions taken during these first stages of the encounter are crucial (Box 144.3) even though the patient remains undifferentiated. Sedation with benzodiazepines serves multiple purposes. It treats agitation and reduces heat production by muscle, heart rate, blood pressure, and the overall adrenergic surge of cocaine or sympathomimetic toxicity.

In the severely agitated patient, immediate administration of IM benzodiazepines while the patient is transiently restrained may be necessary. Once more under control, staff can obtain a complete set of vital signs (including temperature), a bedside glucose measurement, and IV access. If a chest restraint is used, a mesh vest is preferred over a jacket to help limit hyperthermia. Immediate pharmacologic sedation with IM or IV administration of benzodiazepines may be necessary (see next section), which, in adequate doses, restores inhibitory tone to the CNS and decreases excessive sympathetic outflow to peripheral tissues. Sedation also facilitates measurement of vital signs (particularly core temperature), continuous electrocardiographic monitoring, and completion of the physical examination.

Pharmacologic Sedation for Agitation

Benzodiazepines are the mainstay of treatment of cocaine-induced agitation. Diazepam has a rapid onset of action, is easily titratable, and has active metabolites for a sustained effect. Diazepam can be administered intravenously in increments of 5 to 10 mg every 5 minutes in adults until sedation is achieved. Lorazepam, administered 1 to 2 mg intravenously every 5 minutes, is also an acceptable option. Midazolam in 1 to 2 mg doses IV is more rapid in onset with a shorter duration of effect. The endpoint of benzodiazepine administration in sympathomimetic toxicity is normalization of vital signs and motor tone. Persistently increased motor tone reflects an inadequate benzodiazepine dose, even if the patient appears somnolent. In that case, additional doses of diazepam, lorazepam, or midazolam can be given, with close monitoring of the patient's respiratory status.

If IV access is not possible because of agitation, IM midazolam 5 to 10 mg is the preferred approach and may be repeated every 10 to 20 minutes until the patient can be controlled. Lorazepam is a less-preferred alternative because it takes longer to reach peak

concentration (5 vs. 15 minutes) and clears less rapidly than midazolam, increasing the risk of respiratory depression. Ethanol is a common coingestant. The combination of ethanol and benzodiazepines depresses respiration more than either alone. A prudent course is to give the medication and observe for an objective response, redosing after an appropriate interval. In all patients, titration of the benzodiazepine is important, allowing the clinician to observe the effects of one dose (usually 5 minutes) before an additional dose is given. After sedation is achieved, the patient is closely observed to ensure that the patient's respiratory status is stable when peak sedation effect is achieved.

Benzodiazepines provide the cleanest pharmacologic approach to treating the agitated patient as they bind to one receptor system. However, benzodiazepines may precipitate paradoxical reactions in the pediatric and geriatric populations and may be suboptimal treatments if the ultimate diagnosis of the agitated patient is a psychotic disorder that might benefit from an antipsychotic agent.

Ketamine has been used to treat the acutely agitated patient in the ED[37] and in the prehospital setting.[38–40] Ketamine, like midazolam and haloperidol, can be administered intramuscularly with reliable onset and duration of action. Ketamine is an NMDA-antagonist that induces a dissociative state. It also produces modest increases in heart rate (on the order of 10 beats/min) and blood pressure (10 to 20 mm Hg systolic) when used in 0.3 to 0.5 mg/kg doses. Aripiprazole and ketamine reduced the time to seizure in a mouse model of cocaine toxicity.[41] A systematic review identified 330 subjects with amphetamine toxicity treated with an antipsychotic and documented a low incidence of adverse effects, including two episodes of coma and QT prolongation, with one episode of each: hypotension, NMS, cardiac arrest, and death.[42]

If the cause of delirium is unclear, careful attention to the patient's respiratory status avoids the respiratory depression caused by excessive benzodiazepine administration in the presence of other sedating agents, such as ethanol or opioids.

Most cocaine-induced agitation responds to adequate doses of benzodiazepines. The dose of benzodiazepine required to treat excessive sympathetic tone may exceed 10 times the typical dose used for anxiolysis or relaxation of musculature. Butyrophenone antipsychotic agents (e.g., haloperidol and droperidol) are rapidly effective and generally safe for drug-induced psychosis or agitation states from sympathomimetic agents, including cocaine, amphetamines, and PCP when used in patients with stable vital signs (also discussed in Chapters 13 and 90). They may, however, worsen hyperthermia and tachydysrhythmias, because of their anticholinergic properties. Haloperidol, given 2 to 5 mg IM, may be repeated every 20 to 30 minutes with consideration of other agents after a total of 10 mg. Although not approved for IV use, this route is widely used but should only be considered in the psychotic patient with stable vital signs with close cardiac monitoring in 5-mg doses to a maximum dose of 15 mg. The sedative dose for droperidol is 2.5 to 5 mg IM. Droperidol has a box warning from the FDA for QT prolongation and potentially torsades de pointes. However, most reported cases of butyrophenone-induced dysrhythmias have been in individuals receiving large doses for prolonged periods, such as hours to days, or in elderly populations (older than 60 years). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when rapid sedation is required. For these reasons, the butyrophenones remain effective agents for treatment of drug and sympathomimetic-induced agitation in carefully selected patients.

Hyperthermia

Cocaine-induced hyperthermia must be treated with rapid cooling (Box 144.4). Patients who sustain elevated core temperatures above 106°F (41°C) for more than 20 minutes will likely develop disseminated intravascular coagulation (DIC) followed by fatal multisystem organ failure. It is crucial to reduce core temperature to 102°F (38.8°C) as soon as clinically possible, ideally within 20 minutes or less. Cooling blankets are insufficient. Ice water submersion in a portable tub is preferred when available, although some favor wet sheets with large circulating fans.[43] These patients require continuous temperature monitoring and fluid resuscitation as judged by standard measures. Invasive cooling techniques are often delayed and inadequate against the vasoconstrictive effects of cocaine and other adrenergic agents. Patients should have continuous monitoring of their core temperature with a rectal probe. Heat generated by agitation and increased muscle tone can be terminated by adequate use of benzodiazepines, as described earlier, with neuromuscular paralysis and intubation as required. If paralysis is needed, we recommend rocuronium, 1 mg/kg, over succinylcholine. Succinylcholine and cocaine are metabolized by the same plasma enzyme—plasma cholinesterase. Concomitant use may prolong the effects of each drug. Succinylcholine may also worsen hyperkalemia due to rhabdomyolysis.

BOX 144.4 Management of Stimulant-Induced Hyperthermia

Cooling

Early identification of elevated core temperature
Large-bore IV access with rapid infusion of crystalloid
Sedation and muscle relaxation with benzodiazepines
Rapid cooling within 20–30 minutes[a]
Paralysis and intubation if necessary

Monitoring and Diagnostics

Urine output via Foley catheterization
Laboratory analysis for organ function
- Serum chemistries, creatinine, CK
- Liver function
- PT, PTT, fibrin split products
- Bacterial cultures
- Urinalysis for myoglobinuria

Neuroimaging if etiology unclear[b]

[a]Ideally with ice water immersion.
[b]Consider lumbar puncture or antibiotic therapy, especially in injection drug users.
CK, Creatine kinase; *IV,* intravenous; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

Acute Hypertensive Emergencies

The goal in cocaine-induced hypertensive emergencies is to lower blood pressure by counteracting alpha-adrenergic vasoconstriction. Benzodiazepines are the first line treatment. These agents restore the CNS inhibitory tone throughout the body, including the heart. We also recommend phentolamine, a direct alpha-adrenergic antagonist, given as repeated IV doses of 1 mg every 3 minutes with continuous blood pressure monitoring. If two doses fail to reduce the mean arterial pressure by at least one-third, increase each following dose by 1 mg up to 5 mg/dose until the mean arterial pressure is reduced by at least one-third. Phentolamine lasts roughly 45 minutes. Alternative agents include hydralazine, nitroglycerin, and short-acting IV calcium channel antagonists like nicardipine or clevidipine (see Chapter 70). We prefer shorter-acting antihypertensives because they can be discontinued as toxicity subsides without risk of overshoot, which may be deleterious if the patient also has a SAH or aortic dissection attributable to cocaine.

It had been previously recommended to avoid beta-adrenergic antagonists (beta blockers) in treating cocaine-induced hypertension because unopposed α-receptor activity would precipitate coronary artery spasm and hypertension. This concern was based on data that patients undergoing cardiac catheterization demonstrated decreased coronary artery diameter in the presence of injected (mainlined) cocaine and beta-adrenergic antagonists. In two retrospective studies, beta-blocker use was not associated with clinically significant hypertension, troponin elevation, or adverse events in patients presenting with acute cocaine toxicity.[44,45] A meta-analysis of five studies found no differences between patients treated with or without beta-blockers for either myocardial infarction or overall-cause mortality. Another meta-analysis found no significant difference in the odds of myocardial infarction or overall-cause mortality in patients who received a beta-blocker versus not. This second meta-analysis did not explicitly control for whether the patients were currently prescribed a beta-blocker and shared one study with the first meta-analysis.

One way to reconcile previous concerns with the evidence is to recognize that most beta blockers are also alpha-adrenergic antagonists. Beta-blockers may be a useful adjunct in treating cocaine-associated hypertension, but the clinician should be aware that beta-blockers do not treat the other toxic effects of cocaine, which are generally responsive to adequate doses of benzodiazepines. As a result, while not contraindicated, we do not postulate that beta-blockers provide a clinical benefit in this setting and do not recommend their routine use in patients presenting with cocaine-induced hypertension.

Dysrhythmias

Dysrhythmias from cocaine may be atrial or ventricular. Atrial fibrillation and supraventricular tachycardias attributable to cocaine will respond to benzodiazepines. Calcium channel blockers or beta blockers can be used if rapid atrial rhythms fail to respond to sedation, cooling, and volume resuscitation, but negative ionotropic agents (e.g., beta-1 preferential antagonists, verapamil, diltiazem) should be used with caution as cocaine is directly cardiotoxic.

Important considerations in the differential diagnosis of a wide-complex tachycardia include hyperkalemia, sodium channel blockade (cyclic antidepressants and cocaine), and myocardial ischemia. In cocaine body packers or patients presenting with cocaine-induced adrenergic toxidrome, abrupt development of a wide-complex tachycardia with a pulse should be treated with empirical sodium bicarbonate, 1 to 2 mEq/kg IV bolus, with closely recorded cardiac monitoring to observe for QRS narrowing.[46] If hypotension and QRS prolongation do not improve with sodium bicarbonate, consult a medical toxicologist to discuss possible intravenous lipid emulsion therapy. Intravenous lipid emulsion therapy was reported as "life-saving" in case reports of cocaine toxicity. However, the absence of rigorous trials prevents the American Association of Clinical Toxicologists (AACT) from recommending routine use in these cases.[47] Fluid and electrolytes should be corrected as indicated. Close monitoring is required for patients with a preexisting or unmasked Brugada-type conduction pattern.

Hyponatremia

Treatment for sympathomimetic-induced hyponatremia (e.g., MDMA) is the same as that for SIADH from other causes and includes fluid restriction and hypertonic saline (if seizing). Normal saline may worsen hyponatremia by inadvertently increasing free water retention. To our knowledge, treatment with V2-receptor antagonists has not been described for these patients.

Cocaine-Related Chest Pain

The causes of cocaine-related chest pain are diverse (Box 144.5), including aspirated foreign bodies or pneumothorax or pneumomediastinum from inhalational barotrauma. Fever and shortness of breath should prompt consideration of pneumonia, pulmonary infarction, or endocarditis with septic pulmonary emboli in IV drug abuse.

BOX 144.5 Causes of Stimulant-Induced Chest Pain

Cardiac Chest Pain
- Coronary stent thrombosis
- Endocarditis
- Ischemia, infarction
  - During acute intoxication
  - After acute intoxication
- Left ventricular apical ballooning
- Pericarditis

Noncardiac
- Aortic dissection
- Foreign body aspiration
- Infection
- Pneumomediastinum
- Pneumopericardium
- Pneumothorax
- Pulmonary infarction
- Intestinal ischemia or infarct

Cocaine acutely induces coronary vasoconstriction while increasing myocardial oxygen demand. Platelet aggregation is enhanced through thrombogenic and antifibrinolytic pathways. These cumulative effects can result in coronary insufficiency. Cigarette smoking acutely exacerbates these conditions. Chronic cocaine use may accelerate atherogenesis and induce left ventricular hypertrophy.[48] All of these factors contribute to myocardial ischemia or infarction. Of nonfatal myocardial infarctions in patients aged 18 to 45 years, 25% are attributed to cocaine, even after adjustment of other known cardiac risk factors.[49]

Identification of a patient with a cocaine-related coronary syndrome is difficult. Patients may present hours to days after use, possibly because of vasoactive metabolites. The patient may deny drug use and have atypical chest pain. Almost one-third of cocaine-using patients with elevated serum enzymes have pleuritic chest pain. There are no clear predictors for patients at risk for cocaine-related coronary syndrome, including the patient's age, route of drug use, time to presentation, and preexisting risk factors for coronary artery disease. In the setting of cocaine-related chest pain, risk stratification by thrombolysis in the myocardial infarction (TIMI) score may not adequately identify patients at risk for 30-day adverse outcomes. Cocaine history alone, however, in low-risk asymptomatic patients assessed by coronary CTA is generally not associated with increased risk of coronary artery disease. Patients with positive serum biomarkers for myocardial infarction often have significant angiographic stenosis. Of patients without positive serum markers, up to 20% may still have significant disease by angiography. Other predictors of significant disease in this group included elevated cholesterol concentration and prior diagnosis of coronary disease or myocardial infarction. Patients with previous coronary stent placement are at higher risk of thrombosis with cocaine use.

As for most complications of cocaine use, benzodiazepines decrease myocardial oxygen demand by limiting peripheral stimulation and should be given early to patients presenting with cocaine-induced chest pain, especially when signs of adrenergic excess are present. Aspirin and nitrates should be administered as for any case of suspected ischemic chest pain. In patients meeting electrocardiographic criteria for myocardial infarction with persistent chest pain and hypertension and a clear history of acute cocaine intoxication, coronary vasodilation

with IV phentolamine (1 mg) can be given slowly over 3 minutes if available. This dose can be repeated, if needed, as long as the patient's blood pressure remains stable. Morphine sulfate can be used to treat chest pain. Patients with persistent chest pain and ST segment changes strongly suggestive of myocardial infarction can be considered for percutaneous intervention or thrombolytic therapy, assuming there are no contraindications, such as uncontrolled severe hypertension.[48]

In contrast to non-cocaine-induced myocardial ischemia or infarction, beta-adrenergic antagonists, including labetalol, are generally not recommended with acute cocaine toxicity because coronary vasoconstriction may be exacerbated. In patients with cocaine-related coronary syndromes who are not acutely toxic, alpha-adrenergic vasoactive metabolites may be responsible. Outcomes of uncomplicated chest pain due to cocaine are generally good. Current guidelines for care of the patient with an acute coronary syndrome that is unrelated to cocaine do not recommend immediate administration of beta-adrenergic antagonists, but rather within the first 24 hours. As such, in patients with known or suspected cocaine-related myocardial infarction with or without ST segment elevation, there is little role for beta-adrenergic antagonists in the ED and we do not recommend their routine use. Such patients warrant further evaluations of coexisting atherosclerotic heart disease and clinical reevaluation prior to consideration of this therapy. Administration of beta-adrenergic antagonists on discharge is controversial, especially if cocaine use is likely to continue, and we advise against this routine practice.[44]

Heparin can be given, but fibrinolytic therapy is not well studied. Some mechanisms of cocaine-induced myocardial infarction would be expected to respond to fibrinolytic agents. Patients failing to respond to treatment with nitrates and phentolamine who have a known coronary artery disease or a previous ECG confirming new ST segment elevations are candidates for cardiac catheterization or fibrinolysis, if necessary. The same contraindications apply as those for non-cocaine-induced myocardial infarction. Nuclear imaging studies also may provide more diagnostic information, but their use is best considered in consultation with cardiology. Patients presenting with chest pain after cocaine use and an ECG with definitive or new ST elevations should have prompt evaluation by a cardiologist for potential cardiac catheterization intervention when such services are available.

Antiplatelet and glycoprotein IIb/IIIa inhibitors and calcium channel antagonists seem to be of benefit to some patients with myocardial infarction or ischemia of atherosclerotic origin. Theoretically, these agents may counter some of the platelet aggregation enhanced by cocaine, but data investigating their use are lacking.

Patients with cocaine-related chest pain without other cardiac risk factors who have normal ECGs and cardiac biomarkers are at low risk for myocardial infarction. The role of provocative testing in these patients is not well established.

In summary, cocaine-induced coronary ischemia is managed with benzodiazepines, nitrates, and vasodilators, preferably phentolamine. As with non-cocaine-using patients presenting with acute ischemic chest pain, we recommend use of aspirin, heparin, and antiplatelet agents in conjunction with interventional therapy as indicated.

Interventions to cease cocaine use are warranted. For patients with documented coronary artery disease, cessation of cocaine use is imperative. In studies, cocaine users presenting with chest pain who subsequently continued cocaine use after ED discharge were more likely to have recurrent ED visits than were those who stopped subsequent use.

SPECIAL TOPICS

Body Packers

A body packer is an individual who intentionally ingests a large amount of an illicit substance in multiple carefully wrapped packages to transport that substance from an area of production to an area of distribution or consumption. The substances are often wrapped tightly into condoms or other latex products and sometimes coated in wax.

Body packing is most extensively described with cocaine. Each packet can contain nearly 10 g of cocaine. Packers may swallow as many as 150 packets. To quiet peristalsis, the packer may be forced to take antimotility drugs (loperamide, diphenoxylate-atropine). On arrival at the patient's destination, a cathartic is often taken to stimulate gastrointestinal passage of the product for subsequent delivery and distribution. Body packers are likely to know the exact number of packets they ingested but may be reluctant to share that information. Treatment should be specific for each group of drugs, whether it is opioids, cocaine, or amphetamine. Surgical interventions are indicated for obstruction of the intestines or package rupture. Legal consultation should be obtained because of the legal complexity of body packing cases.

A body packer may present without symptoms to the ED. Diagnosis is made by history. The patient may not be forthcoming, owing to the presence of law enforcement or fear of retribution by the packer's handlers. The patient should be placed on continuous cardiac monitoring, with large-bore IV access. An abdominal radiograph may qualitatively confirm foreign bodies, but cannot be used to count packets. Plain radiographs do not reliably detect small or loosely packed packets; computed tomography may be warranted if suspicion is high.

The main step in body packer management is to ensure that the patient passes all of the swallowed packages.[49] We recommend whole-bowel irrigation with polyethylene glycol to facilitate passage. Endoscopic retrieval is generally discouraged because the packets may rupture during the procedure, but it has been done on occasion.[50] Patients stating that they swallowed a larger number of packets than are passed or who refuse to reveal the number ingested should have continued bowel irrigation, observation, and repeated studies. Subsequent computed tomography (CT) scans or contrast studies may be required to evaluate for remaining packets.[50] However, these radiographic studies may fail to detect isolated packets that contain potentially fatal quantities of cocaine.

Rupture of a single cocaine packet can be fatal. Each packet contains almost 10 times the lethal dose. Cocaine body packers with retained packets should be admitted to a monitored setting with a plan to facilitate removal of the packets via whole bowel irrigation. There is no indication for surgical intervention to remove drug packets from the gastrointestinal tract of an asymptomatic patient.[2] If the patient develops sympathomimetic toxicity and abdominal pain or signs of a bowel obstruction, surgery should be consulted for evaluation of urgent removal.[51,52] When evidence of cocaine toxicity is manifested, rapid surgical intervention may be the only way to rescue these patients. Benzodiazepines, neuromuscular blockade, or sodium bicarbonate administration (for wide-complex tachycardia) do not address the imminently ischemic gut.

All packets passed in the stool, through endoscopic procedures, or in the operating room should be counted carefully and promptly given to law enforcement officials. If law enforcement is not yet involved, hospital legal counsel or risk management and the hospital ethics committee may be helpful in determining the handling of the packets. If the patient fails to improve after passage of all packets intact, one should consider alternative diagnoses. As an example, one case identified a body packer with HIV who presented with tachypnea, tachycardia, mydriasis, and a temperature of 102° F. He was found to have pulmonary infiltrates on computed tomography and was eventually diagnosed with pneumococcal pneumonia.[53]

Body Stuffers

A "body stuffer" attempts to conceal evidence of possession of illicit substances by internally concealing the drug while being pursued by

law enforcement officials. Stuffing usually is by ingestion. It may also involve vaginal or anal concealment. In contrast to packing, stuffing is usually an unplanned event that involves a spontaneous insertion of small amounts of poorly packaged material. The substances are often swallowed in poorly sealed vials or glassine packets that may not be evident on radiographs. In general, patients ingest nonlethal doses and are asymptomatic. For cooperative asymptomatic oral body stuffers, the role of gastric decontamination is not well studied. We recommend activated charcoal if presenting within 3 hours after ingestion to bind and sequester any contents leaking into the GI tract. Monitoring, as described earlier with body packers, should be performed if the quantity ingested is of concern or if signs of toxicity develop. Due to lower doses and less potential lethality, the vast majority of body stuffers will not require whole bowel irrigation therapy as do body packers. Body stuffers rarely have fatal events, and these patients usually have symptoms in the first 8 hours. Asymptomatic patients who are unwilling to disclose events or cooperate with care should have monitoring in the ED regardless of status of police custody. However, if the patient is not under arrest, they are free to decline therapy and leave the ED against medical advice if they can demonstrate clear understanding of the risks, including sudden death, of leaving with retained packets. Although the ideal period of observation is uncertain, 8 to 12 hours is reasonable with admission if the patient develops signs or symptoms of toxicity. Patients with suspected vaginal or anal concealment who are asymptomatic and without signs of toxicity who refuse a physical examination should be assessed for capacity and observed in the ED as outlined earlier. Any judicial warrants for an invasive examination against the patient's will should carefully involve risk management and hospital legal counsel, because these are forensic requests and not medically emergent in the asymptomatic patient.

DISPOSITION

Most patients with sympathomimetic toxicity are young adults with a clear history of single substance ingestion. If there are no signs of end-organ damage, they may be discharged once vital signs and mental status return to baseline after a period of observation of 4 to 6 hours.

Patients who respond quickly to one to two doses of sedation, have no concerning elements in their history or presentation, and exhibit no evidence of end-organ toxicity may be safely discharged once their vital signs and mental status return to baseline. Concerning elements in the history include the presence of coingestants, concern for drug packing, human trafficking, or prior episodes of endocarditis. Some patients may be extremely lethargic from catecholamine depletion, even if not in frank washout. It is prudent to discharge them with a responsible adult. Patients may be open to drug counseling and referral while in the ED.

Patients with chest pain (Box 144.6) and who show dynamic changes on the ECG, troponin elevation, dysrhythmias, or pulmonary edema and patients requiring vasodilators or reperfusion should be admitted to a coronary care unit or a telemetry unit. These patients require further evaluation of the extent of preexisting reversible ischemia and intervention to encourage cessation of drug use. Patients in whom the chest pain is felt to be less likely attributable to cocaine (e.g., frequent user with no change in pattern of use with chest pain) may be treated and risk-stratified according to standard screening for risk factors as with non-cocaine chest pain (see Chapter 64).

BOX 144.6 Admission Criteria for Cocaine-Related Chest Pain

Cardiogenic shock
CHF
Dysrhythmias or conduction abnormalities
Electrocardiographic changes
Elevated myocardial enzymes
Multiple risk factors for CAD
Persistent chest pain, dyspnea, or abnormal vital signs
Preexisting CAD or stent placement
Requiring vasodilating pharmacotherapy
Persistent symptoms

CAD, Coronary artery disease; *CHF,* congestive heart failure.

In patients with no other risk factors for cardiovascular disease, cocaine use is not associated with an increased likelihood of coronary disease after adjustment for age, race, sex, and other risk factors for coronary disease.[48] Complications such as congestive heart failure and ventricular dysrhythmias typically manifest within the first 4 to 6 hours. Young patients who present after resolution of chest pain with normal and unchanging ECGs, no dysrhythmias and few or no risks of coronary artery disease are likely to have a good outcome. Prior studies have demonstrated that these low- to intermediate-risk patients with cocaine-associated chest pain can be safely discharged after 8 to 12 hours of observation. The goal of a more recent study was to determine the safety of an 8-hour protocol for ruling out myocardial infarction in patients who presented with cocaine-associated chest pain. Application of an abbreviated cardiac enzyme protocol (at 0, 2, 4, and 8 hours) after presentation with continuous cardiac monitoring, resulted in the safe and rapid discharge of patients presenting to the ED with cocaine-associated chest pain.

Body packers need to be observed until all packets have passed. Ideally, these patients have had several packet-free stools, a reliable packet count consistent with the ingestion, and a normal CT scan or contrast radiographic study. Body stuffers who receive activated charcoal, have normal ECGs, and remain asymptomatic with normal vital signs after 6 to 12 hours of observation may be discharged.

There are special considerations for the pediatric patient. There should be a low threshold to admit the pediatric patient in whom the intent of the ingestion is unclear, even if the patient demonstrates no current sympathomimetic toxicity. An unintentional ingestion by an adolescent of one to two short-acting sympathomimetics (e.g., Adderall) may be treated as above. An intentional ingestion not for suicidal purposes of a similar amount may be similarly discharged if evaluation by social work uncovers no other concerns and the clinician of records feels that it is a safe discharge. Any toddler presenting with sympathomimetic toxicity should be evaluated by social work and may require admission until a safe discharge can be assured. Involve a medical toxicologist early to guide clinical care and to provide insight with critically ill patients or when expanded testing is needed for forensic or medicolegal concerns.

We would like to acknowledge the scholarly efforts and expertise of the previous edition authors Drs. Rama B. Rao and Robert S. Hoffman.

CHAPTER 144: QUESTIONS AND ANSWERS

1. How long does a typical urine drug screen result remain positive after use of cocaine?
   a. 1 day
   b. 3-7 days
   c. 2 weeks
   d. 1 month

Answer: b. Urine drug screens typically detect the cocaine metabolite benzoylecgonine, which is typically present in the urine for 3 to 7 days after the last use.

2. A 24-year-old man is seen by police to be smoking crack cocaine on a street corner. On the way to jail, the patient reports a severe headache, so the police bring him to the emergency department (ED) for medical clearance. The patient is awake with normal mental status but continues to complain of diffuse head pain. His vital signs are blood pressure (BP), 195/99 mm Hg; heart rate (HR), 102 bpm; respiratory rate (RR), 18 rpm; and temperature, 37.2°C. His physical examination is normal. How should his headache be evaluated?
   a. Acetaminophen administration, discharge if headache resolves
   b. Blood pressure reduction, discharge if headache resolves
   c. Head computed tomography (CT) scan, discharge if normal
   d. Head CT scan, lumbar puncture if normal, discharge if both are normal
   e. No evaluation needed; cocaine is not associated with headache

Answer: d. Cocaine is associated with subarachnoid hemorrhage (SAH). Patients complaining of a severe headache after cocaine use should receive a complete evaluation for SAH, including head CT and lumbar puncture. In addition, elevated blood pressure should be lowered while the evaluation is being performed.

3. What is the preferred primary method for controlling a combative patient suffering from a sympathomimetic overdose?
   a. Chlorpromazine
   b. Diazepam
   c. Droperidol
   d. Haloperidol
   e. Physical restraints

Answer: b. Diazepam and other benzodiazepines are the best agents to sedate and establish control of an agitated patient. They cause sedation as well as decrease muscle tone, which can ameliorate hyperthermia. In addition, they can lower the acutely increased blood pressure often seen with sympathomimetic use. In the agitated patient when intravenous (IV) access may be difficult to establish, lorazepam is more predictably absorbed than diazepam. Chlorpromazine can be given intramuscularly to provide rapid sedation but is associated with anticholinergic effects that may exacerbate hyperthermia. Butyrophenone agents (e.g., haloperidol and droperidol) are reserved for more severe agitation and are considered secondary methods of treatment after adequate doses of benzodiazepines. Also, they may have associated dysrhythmic effects that are additive to those of cocaine. Physical restraints may be necessary initially but are not desirable, because they can also increase the risk of hyperthermia as well as increase agitation, which is associated with sudden death.

4. A 27-year-old woman presents with severe chest pain that began soon after use of a large amount of cocaine. She describes the pain as "tearing from my chest to my back." Her vital signs are blood pressure (BP), 210/112 mm Hg; heart rate (HR), 142 bpm; respiratory rate (RR) 22 rpm; and temperature, 38.0°C. A BP measurement taken in the other arm is 147/86 mm Hg. An electrocardiogram (ECG) is normal. You are highly suspicious that the patient is suffering from an aortic dissection and order a transesophageal ultrasound examination while contacting the cardiothoracic surgeon. In the meantime, what should you use to lower her blood pressure?
   a. Labetalol
   b. Nitroglycerine
   c. Nitroprusside
   d. Phentolamine
   e. Treatment should be withheld until a definitive diagnosis is made.

Answer: d. Phentolamine is a direct alpha-adrenergic antagonist and is the drug of choice for sympathomimetic-induced hypertension with end-organ damage. Labetalol and beta-blockers are not recommended, because they have little clinical benefit in this setting. Nitroprusside and nitroglycerine are acceptable agents if phentolamine is not available. Treatment should not be withheld because rapid blood pressure control could be lifesaving.

5. A 35-year-old man presents with chest pain that started approximately 2 hours ago, soon after he smoked crack cocaine. The pain occurred with exertion and has not resolved. He has no previous medical history. His vital signs are blood pressure (BP), 182/99 mm Hg; heart rate (HR), 122 bpm; respiratory rate (RR) 18 rpm; and temperature, 38.2°C. His electrocardiogram (ECG) shows sinus tachycardia with ST depression in the anterior leads. The chest radiograph is normal. Laboratory results are significant for elevations in troponin I. What is the likely explanation for his elevated serum cardiac markers?
   a. He has a completely occluded coronary artery causing ischemia.
   b. He has coronary artery spasm without ischemia.
   c. He has coronary stenosis causing ischemia.
   d. He has fever and rhabdomyolysis but no cardiac disease.
   e. His elevated blood pressure is causing cardiac strain but not ischemia.

Answer: c. Although cocaine can cause coronary spasm with resultant chest pain, patients with positive serum markers are likely to have significant angiographic stenosis. Cocaine users who have complete coronary occlusion typically develop ST elevation just as non-cocaine users do. His elevated blood pressure and fever are certainly increasing the workload on the heart but are not causing his elevated cardiac markers. Cocaine patients may suffer from rhabdomyolysis, and although the resultant renal failure can slow the clearance of the cardiac markers, it does not cause the elevation.

6. A 24-year-old man is brought to the emergency department (ED) in police custody after he admitted to swallowing multiple packets of cocaine to smuggle them through an airport. The patient has no complaints. His physical examination is normal. An abdominal radiograph shows multiple slightly radiopaque areas consistent with packets of cocaine. An electrocardiogram (ECG) is normal. What is the most appropriate management of this patient?
   a. Endoscopic removal of packets
   b. No therapy needed; the patient may be discharged
   c. Observation alone to watch for elimination of packets
   d. Surgical removal of packets
   e. Whole bowel irrigation to remove packets

Answer: e. Whole bowel irrigation with polyethylene glycol facilitates passage of the packets and is safe and effective. Endoscopic removal should be avoided, because there is increased risk of packet rupture. Emergent surgical removal is indicated if there is evidence of packet leak and the patient becomes symptomatic. The patient needs to be observed with cardiac monitoring at a center capable of emergent surgery until all packets have passed.

CHAPTER 144: QUESTIONS AND ANSWERS—cont'd

7. Which unique life-threatening electrolyte abnormality is seen with the use of *N*-methyl-3,4-methylenedioxyamphetamine (MDMA)?
   a. Hyperkalemia
   b. Hypernatremia
   c. Hypokalemia
   d. Hypomagnesemia
   e. Hyponatremia

Answer: e. Hyponatremia can occur with MDMA use and can be severe and life-threatening. MDMA alters the release of vasopressin and will induce a clinical syndrome resembling the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). The patients have concentrated urine with high urine sodium content. Seizures can occur and should be treated with hypertonic saline. In the absence of seizures or other life-threatening conditions, general supportive care with water restriction is adequate treatment.

THC and Hallucinogens

Whitney Barrett and Janetta L. Iwanicki

KEY CONCEPTS

- Hallucinogens include many types of drugs and chemicals with different associated effects, including action at serotonin receptors, dopamine receptors, and glutamate *N*-methyl-D-aspartate receptors.
- Diagnosis and management are based primarily on the history and physical examination, with hallmarks of therapy including supportive care, a calm quiet environment, and sedation with benzodiazepines such as diazepam or lorazepam. Severely agitated patients may benefit from butyrophenone antipsychotic agents such as haloperidol and droperidol.
- Screening tests for hallucinogenic drugs of abuse are of limited value in the acute management of intoxicated patients.
- Novel synthetic hallucinogens continue to emerge and may have effects from hallucinogenic, serotonergic, and dissociative toxidromes. These drugs are rarely detected by screening tests, and cases of toxicity may occur in regional outbreaks.
- Patients with phencyclidine (PCP) toxicity can have unpredictable, violent behavior, and may sustain traumatic injuries. Extreme agitation, although possible, is less common with abuse of ketamine and methoxetamine.
- Extremely agitated, violent PCP-intoxicated patients may require rapid sedation to decrease danger to the patient and health care providers. For hyperthermic patients, sufficient sedation to decrease neuromuscular hyperactivity may require intubation, paralytics, and active external cooling to decrease the risk of multiorgan failure and mortality.
- The care of patients intoxicated from cannabis and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral administration of benzodiazepines or antipsychotics. High doses of antiemetics may be necessary to treat the nausea and vomiting associated with synthetic cannabinoids and heavy daily cannabis use, referred to as the "cannabinoid hyperemesis syndrome."
- The central nervous system and physiologic effects of mescaline use are similar to those of lysergic acid diethylamide (LSD) derivatives, but more vivid hallucinations can occur. Nausea and vomiting are pronounced and almost always precede the hallucinogenic effects.

Hallucinogens include many types of drugs and chemicals with different associated effects, including action at serotonin receptors, dopamine receptors, and glutamate N-methyl-D-aspartate receptors. Diagnosis and management are based primarily on the history and physical examination, with hallmarks of therapy including supportive care, a calm quiet environment, and sedation with benzodiazepines. Severely agitated patients may benefit from butyrophenone antipsychotic agents such as haloperidol and droperidol.

Screening tests for hallucinogenic drugs of abuse are of limited value in the acute management of intoxicated patients. Novel synthetic hallucinogens continue to emerge. These drugs are rarely detected by screening tests, and cases of toxicity may occur in regional outbreaks. Patients with phencyclidine (PCP) toxicity can have unpredictable, violent behavior, and may sustain traumatic injuries. They may require rapid sedation to decrease danger to the patient and health care providers. For hyperthermic patients, sufficient sedation to decrease neuromuscular hyperactivity may require intubation, paralytics, and active external cooling. Extreme agitation is less common with abuse of ketamine and methoxetamine. The care of patients intoxicated from cannabis and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. High doses of antiemetics may be necessary to treat the nausea and vomiting associated with synthetic cannabinoids and heavy daily cannabis use, referred to as the "cannabinoid hyperemesis syndrome." The central nervous system and physiologic effects of mescaline use are similar to those of lysergic acid diethylamide (LSD) derivatives, but more vivid hallucinations can occur. Nausea and vomiting are pronounced and almost always precede the hallucinogenic effects.

The term *hallucinogen* is used to describe a variety of xenobiotics causing altered perception. A hallucination is defined as perception of an object or sensation that does not exist in reality. However, most drugs do not produce actual hallucinations. Drugs that are classified as hallucinogens are more likely to cause illusions, or misperceptions of real objects. Some hallucinogens are called psychedelics, a subset that alters cognition and perception. Hallucinogens work by several mechanisms, including stimulating the serotonergic 5-HT_{2A} receptor, hyperactivation of the dopamine D2 receptor, and blockade of the glutamate N-methyl-D-aspartate (NMDA) receptors. This chapter describes serotonergic agents, dissociative agents, and selected plants and fungi. Sympathomimetic agents are discussed in Chapter 144.

SEROTONERGIC AGENTS

Principles of Toxicity

Serotoninergic agents are a broad category of compounds that share structural similarities with serotonin (5-hydroxytryptamine [5-HT]) or enhance serotonergic tone within the body, predominantly by their action at the 5-HT_{2A} serotonin receptor subtype. These agents include various lysergic acid derivatives (lysergamides) and tryptamines (indolealkylamines). Serotonin-like agents produce changes in thought, mood, perception, and consciousness. Orientation to person, place, and time is usually preserved, but severe intoxication may cause delirium, disorientation, and altered levels of consciousness. Patients may present to the emergency department (ED) because of an acute panic reaction, excessive ingestion, or accidental exposure (e.g., children or adults who have ingested the drug unknowingly). Unlike opioids, there is no addictive component in psychedelics and no euphoria-dysphoria cycle, as occurs with sympathomimetic drugs such as cocaine. The rapid development of tolerance also limits the effect of repeated doses.

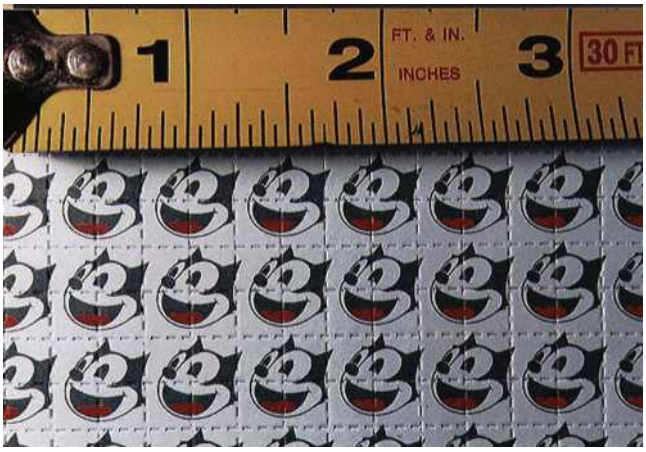

Fig. 145.1 LSD blotters (Felix the Cat). (Photo by Jon, copyright 2001, Blotterart.com. Accessed at www.erowid.org.)

Lysergamides

Lysergic acid diethylamide (LSD), or acid, is a potent psychedelic drug. Doses of 1 to 1.5 µg/kg produce psychedelic effects. The typical dose taken for an "acid trip" is approximately 25 to 100 µg. LSD is sold as a tablet (microdot), liquid, powder, gelatin square (or "windowpane"), and blotter acid. Sheets of blotting paper are sprayed with LSD, dried, and perforated into small squares. Graphics are incorporated onto the blotting paper in designs that include cartoon characters (e.g., Felix the Cat, Bart Simpson) and geometric designs (Fig. 145.1). Each sheet is composed of hundreds of squares that are placed sublingually or eaten whole. Massive ingestions are rare. Drug paraphernalia recently sold and touted as "LSD" does not actually contain lysergic acid diethylamide but synthetic cannabinoids.

In addition to synthetic LSD, several plants contain lysergic acid amide (LSA) similar in structure and action to LSD. These plants include the Hawaiian baby wood rose (*Argyreia nervosa*), Hawaiian wood rose (*Merremia tuberosa*), morning glory (*Ipomoea violacea*), and ololiuqui (*Rivea corymbosa*). Intoxication may result after ingestion of the seeds, extract, or tea.

Tryptamines

Tryptamines may be synthetic or natural compounds. For centuries, Native Central and South Americans have used tryptamine-containing beverages such as ayahuasca in their religious ceremonies. This beverage is brewed from a combination of plants containing dimethyltryptamine (DMT) and 5-methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT), as well as harmine alkaloids with monoamine oxidase inhibitor effects that increase the bioavailability of orally ingested DMT. Ayahuasca has gained recent popularity in Europe and North America.

Psilocybin and psilocin are naturally occurring tryptamines found in some species of *Psilocybe* (Fig. 145.2), *Panaeolus,* and *Conocybe* mushrooms. Psilocybin remains active when the mushrooms are dried or cooked. Street psilocybin sold as pills or capsules is frequently substituted with phencyclidine (PCP) or LSD. Naturally occurring tryptamines are also found in the parotid glands of the *Bufo* toad species. The venom of the Sonoran Desert or Colorado River toad (*Bufo alvarius*) contains 5-MeO-DMT. Smoking of the dried venom results in psychoactive effects.

Designer tryptamines such as α-methyltryptamine, diisopropyltryptamine, and diisopropyl-5-methoxytryptamine (street named foxy or foxy methoxy) have been synthesized and are orally active. The effects of these synthetic derivatives are similar to those of naturally occurring tryptamines.

Fig. 145.2 *Psilocybe cubensis* mushroom. (Photo by Gweedo, copyright 2003. Accessed at www.erowid.org.)

Clinical Features

In Western society, psychoactive agents are taken for internal mental exploration or, more commonly, for recreation. Effects include loss of boundaries between the user and environment, the sensation that colors and sounds are distorted and intensified, the sensation that perceptions are occurring via unusual pathways such as synesthesia, and the perception that usual objects appear novel, fascinating, or awe-inspiring. Users are usually aware that they are under the influence of the drug. A sense of euphoria is common, but it may alternate with an intense dysphoric experience that is accompanied by paranoia (e.g., illusions of dying or being born).

Acute panic reaction is a common adverse reaction to psychedelics. Paranoid delusions and fear of impending death can also occur. Behavior may be agitated or withdrawn. Sympathomimetic effects include mydriasis, tachycardia, hypertension, and in severe cases, hyperthermia. Mydriasis seems to parallel the intensity of the trip. The individual's altered perceptions may result in lack of awareness of dangers in the environment, resulting in injury. Psychosis after LSD trips has been reported, and schizophrenia (overt or borderline) may worsen. Transient depression sometimes occurs after LSD use. Flashbacks, or posthallucinogen perceptual disorder, are transient episodes of altered consciousness that occur months or years after LSD ingestion. Hyperactivity may also be seen, with marked auditory and visual hallucinations. Massive ingestions may result in coma and decreased responsiveness to painful stimuli. Fixed and dilated pupils, diaphoresis, vomiting, hyperthermia, rhabdomyolysis, coagulopathy, and seizures may result.

Euphoria and a distortion of reality usually occur after ingestion of one to five *Psilocybe cubensis* mushroom caps. In contrast to peyote (discussed later), vomiting is unusual. Larger doses (5–20 *P. cubensis* mushrooms) produce colorful visual hallucinations. Few adverse reactions occur, and the incidence of bad trips or panic reactions is lower than with LSD. Rarely, seizures, coma, and hyperthermia have been reported after psilocybin use.

Differential Diagnoses

Alcohol, other drugs and mixed ingestion are a possible source of the patient's symptoms, especially with coma or marked physiologic changes. Cocaine, PCP, amphetamines, and anticholinergic agents

should be considered. Acute psychosis and schizophrenic breaks may also appear similar to a psychedelic reaction. Finally, nontoxicologic diagnoses are crucial to rule out, including central nervous system infection, intracranial mass or bleed, and partial complex seizures.

Diagnostic Testing

Often, patients are in a panic or are brought in by a worried companion who may be aware of the use of hallucinogenic substances. A focus on history, especially from collateral information sources, and physical exam are important to make the diagnosis. Most patients require no laboratory testing, but a basic metabolic profile, serum ethanol, and serum glucose levels may be helpful in patients with unclear ingestions, co-ingestants, or underlying psychiatric disorders. Toxicology screening and specific testing for psychedelics is not available in a timely fashion in most clinical settings, and rarely changes management.

Management

Reassurance and supportive care are the cornerstones of management. If patients are a danger to themselves or others, they may need to be sedated with benzodiazepines (see below) or physically restrained temporarily to permit sedation. There is no specific antagonist to the effects of serotonergic agents. Empathetic reassurance in a calm, quiet environment with decreased external stimuli is an effective therapeutic modality. The drug effects typically last for hours, but most patients return to baseline after the acute effects.

Benzodiazepines are the mainstay of treatment for hallucinogenic drug-induced agitation. Diazepam, lorazepam, and midazolam have all been successfully used in this setting. Diazepam can be administered via the intravenous (IV) route in increments of 5 to 10 mg every 5 minutes in adults until sedation is achieved. Diazepam has a rapid onset of action, is easily titratable, and has active metabolites for a sustained effect. Lorazepam, 1 to 2 mg IV every 5 minutes is also an acceptable option. Additional doses of lorazepam or diazepam should be titrated to effect, until the patient is calm and relaxed. There is no true maximum dose of these medications. For an adult patient in whom IV access is not possible because of agitation, intramuscular (IM) midazolam, 5 to 10 mg, can be administered to facilitate subsequent interventions. In all patients, titration of the benzodiazepine is important. The emergency clinician should observe the effects of one dose (usually 5 minutes) before an additional dose is given. After sedation is achieved, the patient should be closely observed to ensure that respiratory status is stable when the peak sedation effect is achieved.

The vast majority of patients with hallucinogen-induced agitation respond clinically to adequate doses of benzodiazepines. Butyrophenone antipsychotic agents, such as haloperidol and droperidol, are rapidly effective and generally safe for drug-induced psychosis or agitation states from other drugs, including cocaine, amphetamines, and phencyclidine (also discussed in Chapters 144 and 150). Haloperidol, given 2 to 5 mg IM, may be repeated every 20 to 30 minutes with consideration of other agents after a total of 10 mg. Although not approved for IV use, this route is widely used but may be considered in the psychotic or severely agitated patient with stable vital signs with cardiac monitoring in 5-mg doses to a maximum dose of 15 mg. The recommended sedative dose for droperidol is 2.5 to 5 mg IM. Of note, droperidol has a black box warning from the U.S. Food and Drug Administration (FDA) for QT prolongation and potentially torsade de pointes. However, most reported cases of butyrophenone-induced dysrhythmias have been in individuals receiving large doses for prolonged periods, such as hours to days, or in elderly populations (older than 60 years). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when rapid sedation is required. For these reasons, the butyrophenones remain effective agents for treatment of more severe hallucinogenic-induced agitation in carefully selected patients.

Disposition

The majority of patients with anxiety or panic reactions can be verbally deescalated, with little clinical intervention. Acutely toxic patients who respond to sedation and do not have complications can be discharged after the acute toxicity stage resolves. We recommend discharging them accompanied by a non-intoxicated, responsible family member or friend. Patients who persist with confused or paranoid behavior should be observed until their mental status returns to baseline. Patients with altered mental status that does not normalize after 8 to 12 hours of observation in the ED, or who present after a massive ingestion with medical complications, require admission to a monitored setting for serial reassessments. Patients with self-destructive behavior or in need of addiction counselling may benefit from psychiatric intervention.

DISSOCIATIVE AGENTS

Principles of Toxicity

Dissociative hallucinogens describe a cohort of agents that result in symptoms that include dissociation from the environment that frequently have analgesic and amnestic properties. The agents in the category of dissociative hallucinogens have effects on multiple receptors that result in their unique properties, but the common thread among this group is their activity at the N-methyl-D-aspartate (NMDA) receptor. The NMDA receptor is found on neurons and normally functions as an ion channel that is activated by glutamate or glycine but modulated by various other substances that bind to the receptor. When open, it allows cations to flow into the nerve cell and propagate an impulse. The NMDA receptor in the brain is thought to play an important role in neuronal plasticity and memory. Phencyclidine (PCP) and ketamine are the two main agents included in the class of dissociative hallucinogens, although dextromethorphan and methoxetamine have emerged as drugs of abuse and have some similar symptoms of toxicity. All of these are similar in chemical structure and pharmacologic effects and at least part of their activity is on the NMDA receptor and more specifically as channel blocking agents. Despite being simple molecules, PCP, ketamine, dextromethorphan, and methoxetamine have complex pharmacology that includes activity on the NMDA receptor, dopamine-norepinephrine-serotonin reuptake pump, sigma opioid receptor, and cholinergic receptors. The combination of these pharmacologic effects, duration of the effects, and amount of agent used all contribute to the ultimate presentation and management of these patients.

Phencyclidine

PCP was initially marketed for use as a general anesthetic; however, severe emergence reactions rapidly led to its recall. In 1978, PCP was classified as a Schedule I drug. Despite well-described negative sensory effects and psychiatric effects, PCP became a common drug of abuse in the 1960s. PCP was sold as the PeaCePill, which was consumed orally and also as Angel Dust. In the mid-1970s, PCP was the most common cause of recreational drug–related emergencies, and in some regions it resulted in more hospitalizations than alcohol and schizophrenia combined.[1] Its popularity eventually decreased because of unpredictable effects, long clinical course, dysphoria, and association with violence; however, over the past decade, there has been a resurgence of PCP use.

PCP causes variable effects depending on dose. At low doses, users can experience sight and sound distortion as well as feelings of invulnerability. At high doses, users can experience hallucinations and catatonia. Violent behavior and profound psychiatric effects can be seen initially or as part of an emergence phenomenon. PCP is well absorbed

from any oral, nasal, or rectal mucous membrane and can be insufflated or smoked. It can be injected IM, subcutaneously, or IV. Ingested PCP is well absorbed, with an onset of action between 15 and 60 minutes. When smoked, PCP produces symptoms within 5 minutes, with peak activity in 15 minutes. Intoxication with PCP usually lasts 8 to 16 hours but can be prolonged in chronic users. Although enterohepatic recirculation has been proposed, a more likely cause of these prolonged effects in chronic users is gastrointestinal concretion or delayed release from lipid stores.

Ketamine

Ketamine was developed shortly after PCP in an effort to find a sedative with similar hemodynamic stability and properties as PCP that was shorter acting and without the severe emergence phenomenon commonly seen with PCP. It was first trialed in humans in 1964 and since then has become a relatively common medication with multiple indications, including as a sedative for procedural sedation, an induction agent for rapid sequence intubation (RSI), treatment of acute agitation, and treatment of depression. As a drug of abuse, ketamine is known as Vitamin K, Special K, kit kat, and cat valium; however, preparations available on the street are often adulterated with various stimulants. The most common route of use of street ketamine is by insufflation, but subcutaneous and IM injection and even rectal infusions are performed to achieve a level of intoxication or high, known as the K-hole. Similar to PCP, effects of ketamine are dose dependent and can range from mild disorientation and illusions to catatonia or complete dissociation. Ketamine is approximately an order of magnitude less potent than PCP. With ketamine, the intensity of intoxication is less pronounced, although in larger doses the effects may parallel those of PCP. Duration of action of ketamine is typically shorter, with symptoms lasting approximately 1 hour after insufflation but up to 4 to 8 hours after an oral dose. It is important to point out that chronic ketamine users, even at low doses, can experience persistent psychiatric symptoms similar to schizophrenia.[2] In addition, chronic users of ketamine both as a substance of abuse and under medical direction, have a high incidence of urologic complications such as urinary frequency and nocturia. PCP and ketamine are both highly lipid-soluble agents that undergo extensive metabolism in the liver and are eventually excreted in the urine.

Methoxetamine

Methoxetamine is a derivative of ketamine known as Special M, MXE, Mexxy, and ROFLcopter, and has been sold as a legal high and an alternative to ketamine, with reports of a lower risk of the urologic complications seen with chronic ketamine use which may make it preferable to a minority of users.[3] It is readily available on the internet as an agent often labeled as "research chemicals" and with the warning "not for human consumption." Symptoms of intoxication are similar to those seen with ketamine but may also have an increased risk of neuronal toxicity.[4] Methoxetamine appears to have a slower onset and longer duration of action than ketamine.

Dextromethorphan

Dextromethorphan is not truly a dissociative agent, but at higher doses than medically indicated dextromethorphan and its major metabolite, dextrorphan, act as an NMDA receptor antagonist that produces dissociative hallucinogenic effects similar to ketamine and PCP. With the availability of concentrated pill formulations, abusers of dextromethorphan can ingest large doses without having to drink large volumes of the less palatable cough syrup formulation. Particularly popular in the adolescent community, dextromethorphan is known as DXM, robo, skittles, triple C, and red hots. Although dextromethorphan is typically classified as an opioid, it also has a complex pharmacology. Structurally, DMX is similar to the opioids and is the methylated dextroisomer of the opioid analgesic levorphanol. Dextromethorphan not only antagonizes the NMDA receptor, resulting in its dissociative effects, but it also inhibits the uptake of serotonin, and drug interactions with selective serotonin reuptake inhibitors and monoamine oxidase inhibitors have been reported. At high dosages, dextromethorphan is an agonist at the sigma opiate receptor, and naloxone has been reported to reverse intoxication.

Clinical Features

The desired effects of dissociative agents include changes in and pleasant intensification of sensory perceptions such as a euphoric "out of body experience." In this setting, patients seldom come to the attention of emergency care providers. However, more distressing symptoms are very common, especially with PCP, and frequently result in patients or friends seeking emergency treatment. Patients with PCP intoxication presenting to EDs can have a wide spectrum of findings, including sympathomimetic signs and symptoms. Behavior may be bizarre, lethargic, agitated, confused, or violent. A blank or catatonic stare is relatively common. Vital signs frequently demonstrate moderate tachycardia and hypertension, with some patients also having hyperthermia. Physical exam can demonstrate pupils that are midsized and reactive, although there may be miosis or mydriasis. Vertical and horizontal nystagmus are often present and considered a hallmark sign of PCP intoxication. Less commonly, rotary nystagmus may be noted with PCP toxicity but should prompt a consideration for another etiology such as head injury or intracranial lesion. Additionally, bizarre posturing, grimacing, and writhing may be seen.

In more severe intoxications, other findings include ataxia, muscle rigidity, increased deep tendon reflexes, increased secretions, bronchospasm, hyperthermia, and seizures. Up to 40% of PCP patients may be violent and combative, and control of these patients may be one of the most challenging encounters in the ED. Superhuman strength is possible because of the dissociative and analgesic action of PCP. Rarely, severe hypertension with PCP overdose has caused intracerebral hemorrhage.

Hyperthermia from PCP can range from mild to life-threatening and high-output congestive heart failure has been reported. Acute rhabdomyolysis and acute myoglobinuric renal failure are also seen due to muscle damage from seizures, extreme muscle activity such as struggling against restraints, or prolonged immobility. Respiratory depression, apnea, and cardiac arrest have also been described.

Although dextromethorphan has activity at opioid receptors, the typical triad of opioid intoxication—miosis, respiratory depression, and mental status depression—is not generally encountered. Similar to meperidine, dextromethorphan may result in mydriasis through paralysis of the ciliary body with intoxication. Typical clinical findings include lethargy, agitation, slurred speech, ataxia, diaphoresis, hypertension, nystagmus, nausea, vomiting, and hallucinations.

Differential Diagnoses

PCP, ketamine, methoxetamine, and dextromethorphan intoxication can mimic other drugs of abuse and intoxicants or can mimic organic causes of the behavior. Sympathetically mediated vital sign changes can be found with numerous other agents, including cocaine, amphetamine, and LSD. Antimuscarinic compounds, such as diphenhydramine, benztropine, and tricyclic antidepressants, can also produce the tachycardia and altered mental status found with PCP or ketamine.

There are many organic causes of symptoms such as altered mental status, tachycardia, and agitation commonly found with dissociative hallucinogens. Trauma and specifically head injuries and intracranial hemorrhage should be considered. Medical etiologies include

meningitis (viral or bacterial), heatstroke, salicylate poisoning, thyrotoxicosis, and sepsis. Underlying psychiatric disease, especially if it exists in combination with substance abuse, can be very difficult to distinguish. The provider should be cautious about ascribing symptoms to substance use or abuse without considering other etiologies.

Diagnostic Testing

Many hospital laboratories use radioimmunoassays that can detect urinary PCP with a detection limit of 5 ng/mL. Urine may be positive for PCP for 2 to 4 days after use and can be positive for more than 1 week. Serum screening for PCP is of little clinical benefit because levels correlate poorly with symptoms. Several substances, including dextromethorphan, may cross-react with urine screens for PCP because of their structural similarities. Chlorpromazine, methadone, mesoridazine, ketamine, diphenhydramine, venlafaxine, meperidine, and tramadol may also cross-react with some assays, causing false-positive results. If the ingestion is known or suspected to be dextromethorphan because of the prevalence of combination medications, a serum acetaminophen level should be obtained.

If patients have not been hyperthermic and have no signs of trauma, laboratory or other diagnostic tests are generally not needed. With acutely symptomatic patients, a complete metabolic profile, renal function, and creatine phosphokinase (CPK), serum glucose, and ethanol levels should be measured. Workup for any other disease processes should also be pursued as directed by presentation. For patients with acute mental status changes that persist beyond the expected natural course, computed tomography of the head is indicated.

Of particular note, because dextromethorphan is typically formulated as a hydrobromide salt, chronic use may result in spurious hyperchloremia with a low or negative anion gap due to interference of chloride analysis by the bromide ion in the laboratory autoanalyzer.

Management

Prehospital treatment should follow usual protocols for management of agitated patients. The threat of violence to prehospital care providers from patients with PCP intoxication is important to recognize and prehospital systems should have both chemical and physical restraint protocols in place that maximize the safety of providers, patients, and bystanders. Sometimes, awaiting more help or awaiting providers who can use chemical sedation is better than engaging with these patients without adequate support. Extreme agitation, although possible, is less common with ketamine and methoxetamine. Especially when these patients have been sedated prior to hospital arrival, prehospital providers can often provide critical information regarding the patient and notify ED providers of potential trauma or other issues associated with patient care and presentation at the scene.

Sedation of patients under the influence of dissociative hallucinogens is often the first challenge. Chemical sedation is preferred to physical restraint with PCP or ketamine intoxication to reduce the incidence of rhabdomyolysis. Temporary physical restraint may be necessary to ensure patient and medical staff safety until chemical restraint has been achieved. A well-coordinated team with security personnel involvement should apply restraints simultaneously to all four extremities and the body. Assessment of mental status may not be as reliable after chemical sedation, but the benefits of protecting the patient, staff, and other patients in adjacent rooms far outweigh the disadvantages.

As discussed earlier with hallucinogenic agents, butyrophenones such as haloperidol and droperidol can be given IM with a rapid response, avoiding the danger of IV establishment. Haloperidol, 5 to 10 mg IM or IV, is usually effective but can be titrated at 10- to 15-minute intervals until the patient is calm. The sedative dose for droperidol is 2.5 to 5 mg IM. These agents may antagonize the CNS receptor sites that are responsible for much of the violent behavior in these individuals. These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when sedation is required. Droperidol and haloperidol are sometimes withheld because of the FDA black block warning about QT prolongation. It is important to note that most cases of this have been seen in patients receiving higher doses than those recommended here, given repeatedly over a longer period of time, and in patients greater than 60 years old. For these reasons, butyrophenones are still considered safe and effective agents in controlling agitated patients. Benzodiazepines such as lorazepam, 2 to 4 mg IV or IM, or diazepam, 5 to 10 mg IV, or midazolam 5 to 10 mg IM may also be used to treat agitation (see Chapters 144, 150, and 185).

Any effects of dissociative hallucinogens should be managed with symptomatic and supportive care. Hyperthermia and seizure are two of the more common severe complications. Hyperthermia is common in severe cases of PCP poisoning. All patients with significant symptoms, psychosis, or history of violent behavior should have their core temperature measured. Individuals with hyperthermia should be treated with rapid sedation to decrease neuromuscular hyperactivity and heat production. Rapid sequence intubation may be required to allow for adequate sedation and active, evaporative cooling measures (see Chapter 129). Renal status and creatine kinase level should also be monitored to detect rhabdomyolysis and myoglobinuric renal failure.

Dextromethorphan poisoning may cause agitation, or it can present with somnolence due to the opiate effects of the agent. Respiratory depression may respond to IV administration of naloxone; however, the dissociative effects of the drug do not typically respond to naloxone. Similar to mild cases of other dissociative hallucinogens, patients generally improve within 4 to 6 hours post ingestion.

Disposition

For nonviolent patients with dissociative agent intoxication, a quiet holding room is ideal for 4 to 6 hours of observation. Patients with violent behavior or obtundation sometimes require admission to the hospital, especially if they have developed significant renal insufficiency, rhabdomyolysis, require respiratory monitoring, or if their temperature does not normalize. Many of these patients, even when presenting with significant symptoms, can be medically cleared within 12 to 24 hours.

CANNABIS AND SYNTHETIC CANNABINOIDS

Principles of Toxicity

Cannabis (marijuana) is the most common federally illegal drug in the United States. It was used medicinally in ancient times for conditions such as colic and asthma and has been federally illegal since 1937. However, as of 2020, fifteen states (Alaska, Arizona, California, Colorado, Illinois, Maine, Massachusetts, Michigan, Montana, Nevada, New Jersey, Oregon, South Dakota, and Washington) and the District of Columbia have passed legislation to legalize recreational cannabis, and 29 additional states have legalized medical cannabis.

Cannabis sativa and *Cannabis indica* plants are some of the earliest plants grown by humans. Bioactive substances derived from these plants are collectively called cannabinoids. The seedless flowering tops of the female plant are referred to as sinsemilla and are the commonly grown form of cannabis in the United States. The resin from the flowers is made into hashish. Cannabis is smoked, vaporized, or eaten blended into foods. Δ^9-Tetrahydrocannabinol (THC) is the main psychoactive agent of the more than 61 cannabinoid compounds and approximately 300 other substances present in the cannabis plant, and cannabidiol (CBD) is the major nonpsychoactive component. THC has been associated with some of the adverse effects of cannabis use, including

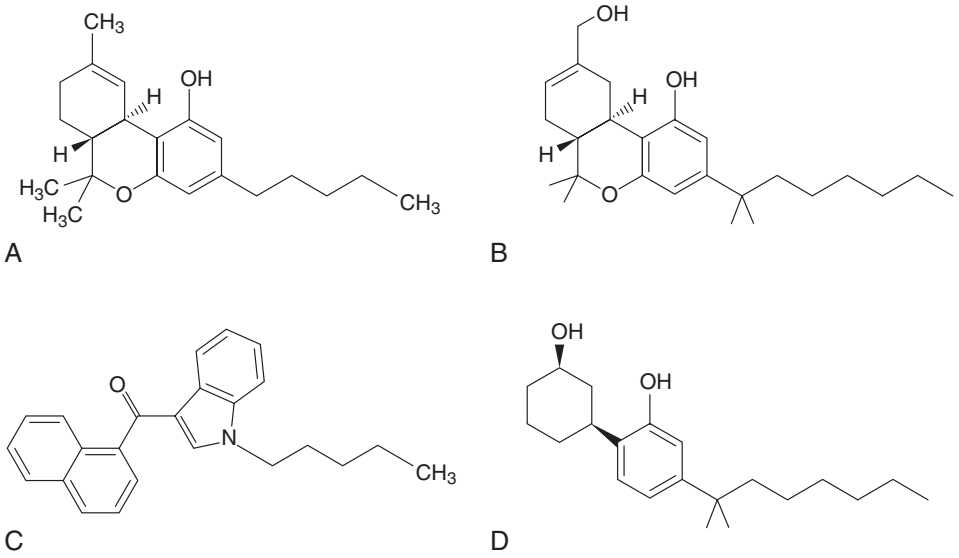

Fig. 145.3 Cannabinoid structures. (A) Δ^9-Tetrahydrocannabinol. (B) HU-210. (C) JWH-018. (D) CP-47,497.

increased agitation, anxiety, and potential for psychosis. Neuroimaging studies have shown that co-ingestion with CBD may modulate and decrease some of these effects, leading to concerns that newer, high-potency, THC-predominant strains of cannabis may lead to a higher-risk chemical profile of these plants.[5]

Synthetic cannabinoids have also become readily available. These products are often marketed as novelty herbal incense and labeled "not for human consumption." They typically come in resealable foil packages and contain various plant leaves sprayed with a solvent mixture of one or several synthetic cannabinoid compounds. Products have names such as Spice, K2 Summit, Banana Cream Nuke, Yucatan Fire, Genie, Black Mamba, Crazy Clown, and many others depending on the region of the country. The Drug Enforcement Administration (DEA) issued an order in 2011 to list five synthetic cannabinoids—JWH-018, JWH-073, JWH-200, CP-47,497, and cannabicyclohexanol—into Schedule I of the Controlled Substances Act (CSA) to avoid an imminent hazard to public safety. Previously, only one synthetic cannabinoid (HU-210), a structural analogue of THC, was listed as such. In 2014, another four compounds—PB-22, 5F-PB-22, AB-FUBINACA, and ADB-PINACA—were also listed as Schedule I after outbreaks of severe illness in several states. Because numerous synthetic cannabinoids are available, producers of spice products can simply replace a scheduled cannabinoid with others that are not on the Schedule I list, which minimizes the impact of scheduling by the DEA on long-term availability because the demand for the cannabinoid products remains high.

Cannabinoids act primarily at cannabinoid receptors CB1R, found mostly in the CNS, and CB2R, found primarily on peripheral immune cells. Discovery of these cannabinoid receptors and experiences in states with medical cannabis availability have led to interest in further exploration of the therapeutic potential of cannabinoids (Fig. 145.3).

Clinical Features

Smoking cannabis, either in the dried plant form or by smoking or vaporizing resins, extracts, or oils, leads to rapid and predictable signs and symptoms. Ingestion can cause delayed and sometimes unpredictable effects. The most common effects from smoking of cannabis include alteration of mood and usually relaxation and euphoria. The only reliable physiologic effects are a mild increase in heart rate and conjunctival injection. Other acute peripheral changes include urinary retention, decreased testosterone levels, and decreased intraocular pressure. Short-term memory is impaired, and the ability to perform complex tasks may be adversely affected. Many users report excessive appetite after cannabis use. Peak blood levels occur within 8 minutes of inhalation, with rapid distribution into tissues, especially tissues with a high lipid content. The duration of perceived effects is usually 2 to 4 hours when the drug is smoked.

Oral ingestion of cannabis edibles may be associated with longer duration of effect (≥6–12 hours), and patients with a massive oral cannabis ingestion may develop profound ataxia, vomiting, agitation, anxiety, and CNS depression requiring medical care. Edible products often carry high concentrations of THC in relatively small portion sizes and, due to a delayed onset of effect up to 4 hours after ingestion, patients may ingest escalating amounts of product while awaiting the onset of psychoactive effects.[6]

Pediatric exposures to cannabis may lead to hypothermia, ataxia, nystagmus, tremor, tachycardia, injected conjunctiva, and labile affect. Oral ingestion of potent cannabis in children can produce rapid onset of drowsiness, hypotonia, lethargy, and less commonly seizures. Large ingestions can lead to coma and airway obstruction and respiratory compromise requiring intubation and ventilatory assistance.[7] Pediatric exposures have been rising with the legalization of cannabis in several states.[8]

Whereas intoxications with cannabis and synthetic cannabinoids may have some similarities, significant differences have been described. First-generation synthetic cannabinoids such as JWH-018, JWH-073, HU-210, and CP-47 were commonly associated with tachycardia, agitation, nausea and vomiting, altered mentation, and hallucinations. Seizures were also noted with this group of cannabinoids. Second-generation synthetic cannabinoids such as ADB-PINACA and AB-FUBINACA have been associated with more profound agitation and aggression followed by CNS depression, seizures, tachycardia followed by bradycardia, hypertension followed by hypotension, and, less commonly, ischemic stroke and cardiac toxicity.

Additionally, synthetic cannabinoid use has been associated with an outbreak of anticoagulant toxicity.[9,10] In these cases, patients were exposed to brodifacoum and similar long-acting vitamin K antagonist anticoagulants that contaminated synthetic cannabinoids and presented with bleeding from multiple sites and bruising. Over 160 cases presented to hospitals in Illinois alone, with 4 reported deaths. Many

other patients required long-term management with vitamin K supplementation and close follow-up.[9]

Differential Diagnoses

The presentation that most closely resembles that of cannabis and synthetic cannabinoid intoxication is acute psychosis. Some individuals with underlying and preexisting psychiatric disorders may progress to overt psychosis after heavy or first-time cannabis use. Because cannabis is so readily available, it is commonly a co-intoxicant used with ethanol and other psychotropic agents. Pediatric patients with unknown unintentional exposures may appear similar to patients with opioid or sedative hypnotic agent overdose, sepsis, meningitis, or metabolic disorders. Rarely, cannabis can be adulterated with other substances, such as PCP and other illicit drugs used concomitantly.

Diagnostic Testing

Cannabis screening is rarely helpful in the ED. Urinary metabolites of THC are detectable within 1 hour after smoking cannabis, but a positive result on a routine urine toxicology screen does not correlate with acute intoxication. Smoking a single "joint" can be detected for 72 hours when a cutoff level of 100 ng/mL is used, and positive urine levels may persist for 3 months after chronic cannabis use. Inadvertent or passive exposure to large amounts of second-hand cannabis smoke in enclosed areas may produce positive urine test results, depending on the laboratory cutoff levels used. False-positive urine screen results may be produced by efavirenz, ibuprofen, and naproxen. An exception to the utility of a urine drug screen for cannabis exposure in pediatric patients may be an unclear cause of altered mental status.

Of the synthetic cannabinoids, only HU-210 should trigger a positive THC immunoassay screen as a result of structural homology. The majority of other synthetic cannabinoids are structurally distinct from THC and do not result in positive THC immunoassay screens.

Management and Disposition

Care of patients intoxicated from cannabis and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral administration of benzodiazepines or antipsychotics. Antiemetics (e.g., ondansetron 4–8 mg IV, or metoclopramide, 10–20 mg IV) or butyrphenones (e.g., haloperidol or droperidol 0.625–2.5 mg IV) may be used to treat nausea and vomiting induced by the cannabinoid hyperemesis syndrome associated with the synthetic cannabinoids and heavy, daily cannabis use. Hot showers are often recommended for patients suffering these symptoms. The precise mechanism whereby hot bathing produces a rapid reduction in the symptoms of CHS is not clear, but thought to be related to a peripheral tissue receptor called TRPV1, a G-protein coupled receptor that has been shown to interact with the endocannabinoid system.[11] Capsaicin cream may also have some benefit in these cases through a similar mechanism and activation of TRPV1 receptors, although discomfort with its use may limit its utility. Children who are significantly symptomatic may require admission for a 24-hour observation period.

Other Agents

Mescaline

Mescaline is a naturally occurring phenylethylamine usually consumed in the form of peyote buttons, which are derived from the small, blue-green cacti *Lophophora williamsii* and *Lophophora diffusa* (Fig. 145.4). They grow in the deserts of the southwestern United States and Mexico.

Peyote has been used in religious ceremonies for 8000 years. Mescaline is also contained in the San Pedro cactus (*Trichocereus pachanoi*) of South America and is used ritualistically by Andean Native Americans.

Fig. 145.4 *Lophophora williamsii* (peyote cactus). (Photo by Christopher B., copyright 2000. Accessed at www.erowid.org.)

These cacti contain many other alkaloids, some of which are also psychoactive. The use of peyote is legal for members of the Native American Church in some states. Adverse reactions (e.g., panic attacks) to peyote are rare in structured religious use. Mescaline has an onset of action of 45 to 60 minutes, with a duration of effect lasting 4 to 8 hours. The CNS and physiologic effects of mescaline use are similar to those of LSD, but more vivid hallucinations can occur. Nausea and vomiting are pronounced and almost always precede the hallucinogenic effects, which is an important aspect of the cleansing spiritual ritual.

Nutmeg

Nutmeg is a spice derived from the seed of the nutmeg tree, *Myristica fragrans*. Use of nutmeg as a natural and legal psychotropic agent was popularized in the 1960s. Despite lack of any in vivo human studies, myristicin and elemicin have been suggested as the agents responsible for intoxication because their chemical structure resembles that of mescaline. Reports of intoxication are uncommon. Ingestion of 5 to 30 g (1–4 tablespoons) of the spice is said to induce euphoria and hallucinations but is more likely to cause gastroenteritis.[12]

Salvia

Salvia divinorum, a perennial herb cultivated outdoors in mild climates, is a member of the mint (Lamiaceae) family. Common names for *S. divinorum* are diviner's sage, mystic sage, magic mint, sage of the seers, Sally-D, ska, and Maria Pastora. Although the plant has been used for divination and shamanism by the Mazatec Indians of Oaxaca, Mexico, *S. divinorum* has become popular in the past 20 years for recreational purposes because of its recognized hallucinogenic properties and hallmark "uncontrollable laughter" side effect. In 2004, the DEA listed *S. divinorum* as a drug of concern but, to date, *S. divinorum* and salvinorin A are not currently controlled under the CSA in the United States. Several states, however, have instituted or are considering legislation making possession, cultivation, and use of *S. divinorum* or its extracts illegal.

The active ingredient in *S. divinorum* is salvinorin A, a neoclerodane diterpene with selective agonist activity for kappa opioid receptors. Salvinorin A appears to have no activity at delta or mu opioid receptors. The threshold dose of salvinorin A to produce hallucinations is comparable to that of LSD. However, salvinorin A is distinct from more traditional hallucinogens because it does not bind to the 5-HT_{2A} serotonin receptors, as is the case with LSD.

Salvia is usually chewed and spit out or swallowed, and it seems to be absorbed more readily from the oral mucosa than from the rest of

the gastrointestinal tract. Effects produced as a result of oral mucosal absorption may persist for 1 hour. Dried leaves can also be smoked. Inhalation of smoke can produce symptoms within 1 minute that subside after 20 to 30 minutes. Sensations experienced are variable but include distortions of color and vision, laughter, and synesthesias, which are confusions of the senses, such as "seeing sounds or smelling colors." Salvinorin A is not detected by typical drug screening tests and is not known to cause interference with routine drug screens used in the clinical setting. Management of intoxication from *S. divinorum* is mainly supportive, with emphasis on injury prevention.[13] Use of naloxone, a nonspecific opioid receptor antagonist, may theoretically be helpful for the reversal of psychotropic manifestations.

Kratom

Mitragyna speciosa, or kratom, is a tree found in tropical and subtropical regions of Asia and Africa. The popularity of kratom has grown because of reports of its successful use to attenuate symptoms of opioid withdrawal. Because kratom remains easily obtainable, individuals are able to self-administer the perceived remedy, obviating the need for physician supervision. The safety of such a practice is unknown.

Although kratom extract contains more than 25 alkaloids, mitragynine is the most abundantly found in the plant. Mitragynine is an indole alkaloid with structural analogy similar to that of yohimbine and has agonist activity at mu and delta opioid receptors, producing euphoric, analgesic, and respiratory depressant effects. The respiratory depressant effects are more likely to occur when combined with opioids or other respiratory depressants. Despite its structural similarity to yohimbine, a selective antagonist of presynaptic α_2-adrenergic receptors, animal studies have suggested that mitragynine is also an agonist at postsynaptic α_2-adrenergic receptors and blocks 5-HT_{2A} receptors.

Often, kratom is ingested in powder or capsule form. The leaves may also be chewed, smoked, or brewed into a tea. Psychotomimetic effects occur within 5 to 10 minutes of use and may persist for 1 hour, with stimulatory effects at lower doses and opioid effects at higher doses. Opioid properties include analgesic, antitussive, antidiarrheal, and emetogenic effects.[14]

Currently, there are no clinical diagnostic tests available to detect the presence of kratom alkaloids. Treatment of intoxication is supportive. Although coma and opioid activity have been demonstrated with kratom, the effectiveness of opioid antagonists in reversing its effects is inconsistent. A withdrawal syndrome characterized by anxiety, restlessness, and nausea treated with an opioid agonist and lofexidine (an α_2-agonist related to clonidine) has also been reported.

The issues regarding the safety and efficacy of kratom and its mitragynine constituent require additional research. The DEA classification of the Mitragyna alkaloids as Schedule I controlled substances is likely to impede further studies on kratom.[15]

Ibogaine

Ibogaine is a naturally occurring indole alkaloid found in the roots of the African rain forest shrub *Tabernanthe iboga*. For many centuries, iboga has been ingested by the indigenous peoples of western Africa as a remedy for fatigue, hunger, and thirst and as a sacrament in religious ceremonies. As with many plant-derived agents, ibogaine's physiologic effects are highly complex and may involve opioid, dopaminergic, serotonergic, glutaminergic, γ-aminobutyric acid (GABA)–ergic, glutamatergic, adrenergic, and cellular ion channel signaling systems.

Although ibogaine is classified as a Schedule I drug, it is still sought after as a treatment to ease opioid withdrawal and diminish craving of other abused drugs. The intensity of visual hallucinations from ingestion of iboga, in contrast to other hallucinogens, is described to be more pronounced with eyes closed. Since the first report in 1990, there have been reported fatalities due to sudden cardiac death within 72 hours of ibogaine use. The mechanism appears to be blockage of the hERG/IKr channel, leading to marked QT prolongation and tachyarrhythmias. There are no specific detection tests for ibogaine, and diagnosis is dependent on a history of exposure because clinical findings are largely nonspecific. Management is predominantly supportive, although patients with markedly prolonged QT intervals and evidence of risk for torsades de pointes may require admission to a monitored setting, treatment with IV magnesium supplementation (magnesium sulfate, 2–4 g IV), electrolyte repletion, and overdrive pacing (either chemical with isoproterenol, or electric via transdermal or transvenous pacing) in severe cases.

Fig. 145.5 *Amanita muscaria* mushroom. (Photo by Mark Shubert, copyright 2004. Accessed at www.erowid.org.)

Isoxazole Mushrooms

Isoxazole-containing mushrooms include *Amanita muscaria*, *Amanita pantherina*, *Amanita gemmata*, and *Amanita cothurnata*. *A. muscaria* has a red or yellow cap, with white warty structures on its surface, and grows in forests of aspen, birch, fir, or pine trees (Fig. 145.5). It has been used in Siberia for centuries and is often described in folklore and fairy tales (also see Chapter 153).

The active ingredients are the isoxazole derivatives ibotenic acid and its decarboxylation product, muscimol, which are structural analogues of the endogenous neurotransmitters glutamic acid (excitatory) and GABA (inhibitory) and are thought to act at these respective receptor sites. The excitatory effects characterized by elation, giddiness, hyperactivity, muscle tremors, and distortion of space and time begin approximately 30 minutes to 2 hours after ingestion and are likely to be mediated by ibotenic acid. Following is a phase of tiredness and deep sleep, in which it may be difficult to arouse the patient. During this phase, vivid hallucinations and manic excitement may oscillate with periods of deep sleep. The duration of effect is up to 12 hours. Management of the excitatory phase is similar to that of other hallucinogens previously described in this

chapter, consisting of supportive care, a low stimulus environment, and benzodiazepine administration. Prolonged sleep with *A. muscaria* ingestion requires only observation and supportive care. Tonic-clonic seizures are reported, but occurrences are rare. In general, adult patients more often experience GABA-dominant symptoms, and pediatric patients more often experience glutamic acid-dominant symptoms.

Paradoxically, there has been a high incidence of mistreatment of *A. muscaria* ingestion with atropine because the name implies that it contains muscarine, a cholinergic toxin. However, the amount of muscarine is miniscule. Atropine may exacerbate the anticholinergic effects associated with isoxazole mushrooms. It is important to differentiate isoxazole-containing *Amanita* mushrooms from the potentially deadly hepatotoxic cyclopeptide-containing *Amanita* mushrooms, of which *Amanita phalloides* is a member.

CHAPTER 145: QUESTIONS AND ANSWERS

1. Intoxication with morning glory seeds will mimic intoxication with which of the following hallucinogens?
   a. Ecstasy
   b. Ketamine
   c. LSD
   d. Cannabis
   e. PCP

Answer: C. Several plants contain alkaloids similar to LSD, including morning glory and Hawaiian baby wood rose.

2. A 14-year-old boy presents with altered mental status. On examination he has mydriasis, nystagmus, and lethargy. There is a history of exposure to "skittles." His urine drug screen for drugs of abuse is presumptively positive for PCP. Which toxicant did he ingest?
   a. Dextromethorphan
   b. Ecstasy
   c. LSD
   d. Psilocybin
   e. Synthetic cannabinoids

Answer: A. Dextromethorphan presents with more of a dissociative clinical pattern than opioids. "Skittles, red hots, and triple Cs" are street names for over-the-counter tablets of dextromethorphan. Most immunoassays for PCP cross-react with dextromethorphan to give a false-positive PCP report. Ketamine can also give a similar clinical picture, so the history is also necessary to determine which is the most likely intoxicant in the differential.

3. Which of the following is likely to be detected on a typical urine immunoassay drug screen?
   a. LSD
   b. Kratom
   c. Salvia
   d. Cocaine
   e. Synthetic cannabinoids

Answer: D. The immunoassay screen for cocaine detects its metabolite, benzoylecgonine. Unlike immunoassays for amphetamines, benzodiazepines, phencyclidine, and THC, which may be highly unreliable, inconsistent, or nonspecific, the immunoassay for benzoylecgonine does not typically result in false-positives or false-negatives. Detection of benzoylecgonine is a specific indication of cocaine use in the past 3 days. LSD, kratom, salvia, and synthetic cannabinoids do not typically cross-react with immunoassays that are commonly used.

4. Which of the following mushroom species has hepatotoxic but not hallucinogenic properties?
   a. *Amanita muscaria*
   b. *Amanita pantherina*
   c. *Amanita phalloides*
   d. *Conocybe smithii*
   e. *Psilocybe cubensis*

Answer: C. *A. phalloides* mushrooms do not have hallucinogenic properties. Their toxicity is mainly hepatic due to a number of cyclopeptide toxins contained in all parts of the mushroom. *C. smithii* and *P. cubensis* contain psilocybin and psilocin tryptamines. *A. muscaria* and *A. pantherina* contain the isoxazole compounds ibotenic acid and muscimol, which are analogues of glutamic acid (excitatory) and γ-aminobutyric acid (GABA; inhibitory) neurotransmitters, respectively.

5. Which of the following agents have been used to treat acute withdrawal syndromes and chronic drug dependence?
   a. Kratom
   b. Ibogaine
   c. Buprenorphine
   d. Clonidine
   e. All of the above

Answer: E. Kratom, ibogaine, buprenorphine, and clonidine have all been used to treat acute opioid withdrawal and chronic drug dependency with varying effects and long-term outcomes.

146

Iron and Heavy Metals

Jillian L. Theobald and Mark B. Mycyk

KEY CONCEPTS

- Asymptomatic patients seeking emergency department (ED) care for an abnormal metal test need follow-up evaluation arranged with a medical toxicologist.
- Metal testing in the ED should be ordered in consultation with a medical toxicologist or regional poison center.
- Acute ingestion of the salts of most metals causes rapid severe gastrointestinal pain and emesis.
- Abnormal neurologic signs in a patient with any metal exposure warrants admission for further evaluation and chelation therapy.
- Acute iron poisoning can result in gastrointestinal symptoms, metabolic acidosis, and hepatoxicity. Serum iron levels at 3 and 6 hours after ingestion determine toxicity and need for therapy.
- The chelation agent of choice for severe iron poisoning is deferoxamine, which is indicated for peak serum iron concentrations greater than 500 μg/dL and in patients with severe signs and symptoms regardless of the iron level.
- The most important intervention for lead poisoning is removal from the source of exposure.
- The gastrointestinal decontamination method of choice for iron and lead toxicity with radiographic presence of pills or paint chips is whole bowel irrigation (WBI).
- The chelation agent of choice for acute arsenic poisoning is intramuscular British antilewisite (BAL) or oral succimer.
- Elemental mercury is nontoxic to the gastrointestinal tract but may cause pulmonary and central nervous system (CNS) toxicity from inhalation of volatilized vapors.

IRON

Foundations

Iron poisoning used to be the leading cause of poisoning death in children. In 1997 the U.S. Food and Drug Administration (FDA) required warning labels and implemented changes in the packaging of iron supplements after which there was an abrupt decrease in the number of poisonings and deaths. Although the FDA rescinded its strict packaging restrictions on iron supplements in 2003, iron poisoning currently remains relatively uncommon. In 2017, there were 6033 calls to poison centers concerning iron exposures and there were two deaths. Calls regarding multivitamins containing iron were much more common, resulting in 11,157 calls but no deaths.[1]

Iron is an important metal that is essential to the function of hemoglobin, myoglobin, and many cytochromes and enzymes. Certain disease states result from too much or too little iron, such as hemochromatosis and anemia, respectively. Iron is absorbed mostly in the small intestine. Depending on total body stores, as little as 10% or as much as 95% of the ingested iron is taken into cells. In the cell, iron has three pathway options: storage bound to ferritin, transfer to the serum where it is bound to transferrin, or loss when the intestinal cell is sloughed off. Under normal conditions only 15% to 35% of the iron-binding capacity of transferrin is used. The total iron-binding capacity (TIBC), a crude measure of the ability of serum proteins (including transferrin) to bind iron, ranges from 300 to 400 μg/dL. Normal serum iron concentrations range from 50 to 150 μg/dL. When iron concentrations rise after a significant overdose, transferrin becomes saturated. Excess iron circulates free and unbound in the serum. Unbound iron is directly toxic to target organs.

Iron has two distinct toxic effects: (1) direct caustic injury to the gastrointestinal mucosa, and (2) impaired cellular metabolism, primarily of the heart, liver, and central nervous system (CNS). The caustic effects of iron on the gut cause the initial symptoms of vomiting, diarrhea, and abdominal pain. Hemorrhagic necrosis of gastric or intestinal mucosa can lead to bleeding, perforation, and peritonitis. Metabolic acidosis occurs when unbound iron moves into cells and localizes near the mitochondrial cristae, resulting in uncoupling of oxidative phosphorylation and impairment of adenosine triphosphate synthesis. Hydration of the iron molecule creates an excess of unbuffered protons, worsening metabolic acidosis. Cell membranes are injured by free radical–mediated lipid peroxidation. Hypotension occurs as iron increases capillary permeability and leads to both arteriolar and venodilation. Direct myocardial toxicity decreases cardiac output. These effects, combined with severe gastrointestinal fluid losses, can lead to shock, cardiovascular collapse, and death.

In an iron overdose, determining the amount of elemental iron ingested is most important, because cellular toxicity depends on the effects of elemental iron. Different formulations of iron salts contain different percentages of elemental iron (Table 146.1). The total amount of elemental iron ingested can be approximated by multiplying the estimated number of tablets by the fraction of elemental iron contained in the tablet. Ingestions of less than 20 mg/kg of elemental iron usually causes no symptoms. Ingestion of 20 to 60 mg/kg results in mild to moderate symptoms, and ingestion of more than 60 mg/kg may lead to severe morbidity and mortality. Newer forms of iron are carbonyl iron and iron polysaccharide: both are non-ionic and associated with lower toxicity. Neither form is directly corrosive. The conversion to the iron ion, which is responsible for toxicity, is very slow in these newer preparations. There are no reported cases of serious toxicity or death from the ingestion of the non-ionic compounds.

Clinical Features

The clinical effects of acute iron poisoning have traditionally been divided into five stages (Table 146.2). The timing of each stage varies

for individual patients. The severity of phase 4 is primarily dose-related, and it is usually during this phase that fatality occurs.

Differential Diagnoses

Many toxins are irritating to the gastrointestinal tract and can cause nausea, vomiting, and diarrhea. Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicion for caustic ingestions, ethanol, toxic alcohols, salicylates, ibuprofen, colchicine, and other heavy metals, such as arsenic, inorganic mercury, and iron.

Diagnostic Testing

The presence of early gastrointestinal symptoms suggests a potentially serious ingestion, whereas absence of gastrointestinal symptoms is usually reassuring. A serum iron concentration measured at 3 to 5 hours after ingestion is the most useful laboratory test to evaluate the potential severity of an iron overdose. Sustained-release or enteric-coated preparations may have erratic absorption, so the serum concentration should be repeated at 6 to 8 hours after ingestion. Peak serum iron below 350 µg/dL is generally associated with minimal toxicity; 350 to 500 µg/dL with moderate toxicity; and above 500 µg/dL with severe toxicity. Because iron is rapidly cleared from the serum and deposited in the liver, the concentration of iron after a substantial ingestion may be deceptively low if it is measured several hours after its peak absorption. TIBC is an inaccurate test and is not useful to gauge the severity of iron poisoning.

A screening abdominal radiograph may also be helpful to confirm a recent large ingestion and should be interpreted in the context of serum levels, as described later. Most tablets that contain a significant amount of elemental iron are radiopaque (Fig. 146.1). False-negative radiographs may occur with chewable, liquid, and completely dissolved iron compounds, so negative radiography should not be used to exclude iron ingestion in cases of suspected or witnessed ingestion. Repeated radiographs can also demonstrate the efficacy of gastrointestinal decontamination efforts.

TABLE 146.1 Common Iron Preparations

Compound	Percentage of Elemental Iron
Ionic Compounds	
Ferrous sulfate	20
Ferrous fumarate	33
Ferrous gluconate	12
Non-Ionic Compounds	
Carbonyl iron	100
Iron polysaccharide	46

Management

Stabilization and Supportive Care

Early hypotension is often due to GI losses and should be treated with intravenous fluids. Later, direct toxic effects on the cardiovascular system occur and are best treated with vasopressors. Patients with mental status depression and concern for airway protection should be intubated and mechanically ventilated.

Decontamination

Oral activated charcoal does not bind iron. Gastric lavage and ipecac are ineffective and not recommended. Iron tablets clump together as their outer coatings dissolve, often forming large pharmacobezoars. Whole bowel irrigation (WBI) is the preferred method of decontamination for significant iron tablet ingestions, especially when confirmed by radiograph, but WBI is not useful in cases of liquid or chewable iron.[2] Early, rapid decontamination of the gastrointestinal system may obviate the need for or shorten antidotal therapy duration.

For significant ingestions, especially when the number of tablets identified by abdominal radiography indicates a likely toxic dose, WBI with a polyethylene glycol–electrolyte solution (PEG-ELS) should be initiated.[2] The solution should be administered through a nasogastric tube. The recommended rate of administration of PEG-ELS is 500 mL/hr in children 9 months to 6 years old, 1000 mL/hr in children 6 to 12

TABLE 146.2 Clinical Manifestations of Iron Toxicity Following an Acute Overdose[a]

	Phase	Clinical Features	Mechanism of Toxicity
1	Gastrointestinal (6 hours)	Vomiting Diarrhea Hematemesis Hematochezia	Corrosive effect of iron on the gastrointestinal mucosa
2	Latent (6 to 24 hours)	Resolution of gastrointestinal symptoms Tachycardia Acidosis Depressed mental status	Ongoing cellular toxicity and organ damage
3	Systemic (12 to 24 hours)	Return of gastrointestinal symptoms Acidosis Leukocytosis Coagulopathy Renal failure Lethargy or coma Cardiovascular collapse	Iron distributes to the tissues with worsening cellular toxicity and organ damage
4	Hepatic (2 to 5 days)	Fulminant liver failure Coagulopathy	Rapid absorption from portal system with resultant oxidative damage
5	Obstructive (3 to 6 weeks)	Pyloric or bowel scarring Obstruction	Healing of the injured gastrointestinal mucosa

[a]Typical duration of symptoms post-ingestion is also given.

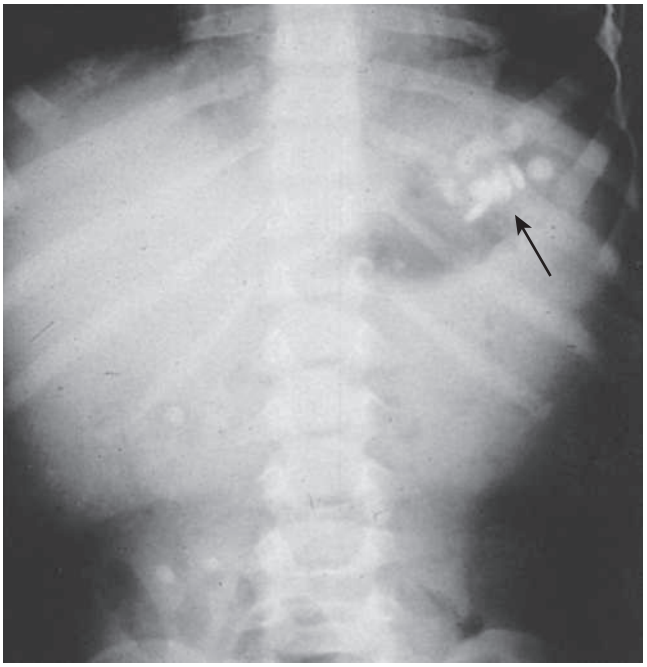

Fig. 146.1 Radiopaque iron tablets *(arrow)* seen on abdominal radiograph. (From: Craig SA. Radiology. In: Ford MD, Delaney KA, Ling LJ, et al, editors. Clinical Toxicology. Philadelphia: WB Saunders: 2001; p 62.)

years old, and 1.5 to 2 L/hr in adolescents and adults. WBI is continued until the rectal effluent is clear and there is no radiographic evidence of pill fragments.[2] This technique has been used in children, adolescents, and pregnant women without serious complications or electrolyte disturbances. Common side effects include nausea, vomiting, abdominal cramping, and bloating. WBI is contraindicated in the presence of bowel obstruction, perforation, ileus, or hemodynamic instability.[2]

Enhanced Elimination

Hemodialysis and hemoperfusion are not effective in the removal of iron because of its large volume of distribution. Early exchange transfusions have been used with some success for severely symptomatic patients. However, this should only be considered in patients who are not responding to standard chelation therapy.

Antidotal Therapy

Deferoxamine is the antidote for iron toxicity. Deferoxamine chelates iron to form the water-soluble compound ferrioxamine, which is renally excreted. Deferoxamine binds to free iron and will not chelate iron from hemoglobin, transferrin, or ferritin. Patients with an iron concentration above 500 µg/dL and those who, regardless of level, are exhibiting severe signs and symptoms of iron toxicity (metabolic acidosis, lethargy, hypotension, or signs of shock) require chelation. Pregnancy is not a contraindication to deferoxamine therapy. However, the prepregnancy weight should be used to calculate the ingested dose. Because of its short half-life, deferoxamine is administered as a continuous intravenous infusion starting at 5 mg/kg/hr and titrated to the typical goal rate of 15 mg/kg/hr, as tolerated, for 24 hours. Infusion rates of up to 35 mg/kg/hr have been reported, but this should only be considered following consultation with a toxicologist. More rapid administration of deferoxamine can lead to hypotension, which is managed by reducing the initial rate of the infusion and then slowly increasing it to the desired rate. Prolonged deferoxamine infusion has been associated with acute respiratory distress syndrome (ARDS) and also with *Yersinia* sepsis. The pulmonary complications are usually related to high dose deferoxamine for durations longer than 24 hours.

TABLE 146.3 Sources of Lead Exposure

Category	Source
Pediatric	Lead dust Paint in old homes Parent's occupation Imported toys or candies Foreign body ingestion (fishing weights, toys)
Occupational	Construction, particularly old home remodeling Lead smelters Battery recycling, repair, and manufacturing Firing range instructors Automobile mechanics Plastics manufacturing
Recreational	Moonshine Ceramics Home and car remodeling Painting
Other	Herbal remedies Retained lead bullets

Disposition

The asymptomatic patient who is reliably known to have ingested less than 40 mg/kg of elemental iron does not need additional therapy and can be discharged home after appropriate poison prevention counseling with reliable care takers. In patients who ingest more than 40 mg/kg, an iron concentration should be obtained at 3 to 5 hours post-ingestion and also 6 to 8 hours post-ingestion. If peak iron remains less than 300 µg/dL, is not rising, and the patient is asymptomatic during 6 hours of observation, the patient can be discharged home. If the patient is exhibiting signs of severe toxicity, even if the ingested dose is unknown, or meets criteria for deferoxamine chelation therapy, admission to an intensive care unit with poison center or toxicologist consultation is advised. If indicated, a psychiatric consultation should be requested.

LEAD

Foundations

Lead poisoning remains one of the most common and preventable environmentally mediated problems in the United States. The elimination of leaded gasoline and the ban on leaded paint in households in the 1970s exponentially reduced the number of lead poisonings in the United States. However, the Center for Disease Control and Prevention (CDC) estimates that approximately 535,000 children, aged 1 to 5 years old, still have elevated blood lead levels (BLLs) from various environmental exposures.[3] Immigrant and refugee children are at much greater risk for lead poisoning than children born in the United States because of exposures prior to arrival in the United States.[4,5] Adult lead poisoning has been decreasing over time and the CDC reported that in 2013, 20.4 per 100,000 adult workers had BLLs of 10 mcg/dL or greater, down from 26.6 in 2010.[6] Given the continued wide use of lead in industry, there are many potential sources of exposure. Retained bullet fragments are another important source to investigate[7] (Table 146.3).

Most lead exposures occur by ingestion in children and workplace inhalation in adults. Dermal absorption may also occur but is much less significant. Children and pregnant women absorb almost four times the amount of ingested lead than other adults. Once absorbed, lead is bound to red bloods cells and slowly distributes to the soft tissues where it is eventually stored, primarily in bone. The half-life of lead in the red blood cell is approximately 30 days, but once in the bone, the half-life can last decades. Lead easily crosses the placenta,

TABLE 146.4 Typical Blood Lead Levels and Correlative Signs and Symptoms in Children and Adults

	SYMPTOMS	
Level (μg/dl)	**Adults**	**Children**
10	None	Decreased IQ Decreased hearing Decreased growth
20	Increased protoporphyrin No symptoms	Decreased nerve conduction velocity Increased protoporphyrin
30	Increased blood pressure Decreased hearing	Decreased vitamin D metabolism
40	Peripheral neuropathies Nephropathy Infertility (men)	Decreased hemoglobin synthesis
50	Decreased hemoglobin synthesis	Lead colic
70	Anemia	Anemia Encephalopathy Nephropathy
100	Encephalopathy	Death

IQ, Intelligence quotient.

and maternal blood levels correlate with umbilical cord blood levels.[8] Neonatal lead exposure also occurs through breast milk. Most lead is ultimately excreted in the urine and bile.

There is no biologic role for lead in the human body. Lead complexes with sulfhydryl groups of proteins, which can alter enzyme and receptor function and distort structural proteins. Lead is also structurally similar to calcium and interferes with calcium-dependent cellular processes. Its toxic effects are most prominent in the hematopoietic and neurologic systems.

Clinical Features

The clinical features of lead poisoning are broad and often nonspecific (Table 146.4). Symptoms depend on the BLL, whether the patient is an adult or child, and whether the exposure is acute or chronic. Although all organ systems are affected, the most sensitive are the hematologic, vascular, and nervous systems. Lead inhibits heme biosynthesis, and the classic manifestation of hematopoietic lead toxicity is anemia. Anemia may be either normochromic or hypochromic. Chronic kidney disease and hyperuricemic gout ("saturnine gout") can also result from elevated BLLs. Chronic kidney disease consequently may worsen underlying anemia. Lead poisoning is associated with chronic hypertension. In the peripheral nervous system, segmental demyelination and degeneration of motor axons result in peripheral neuropathies. Wrist-drop and foot-drop are characteristic of adult lead poisoning but rarely seen today.[9] Importantly, lead toxicity can cause neuropsychiatric disorders. Many are difficult to distinguish during an emergency department (ED) evaluation, so collaboration with a primary care physician is essential to identify new cognitive deficits. In children, elevated BLL is associated with decreased intelligence quotient (IQ) scores, hyperactivity, decreased attention span, overaggressive behavior, learning disabilities, and criminal behavior. Severely high BLLs may present with lead encephalopathy associated with increased capillary permeability and cerebral edema.

Differential Diagnoses

The differential diagnoses of lead poisoning are broad, and because the symptoms of early poisoning are nonspecific, lead poisoning today is often initially not considered or misdiagnosed. Lead poisoning could be confused for neuropathies (such as carpal tunnel or Landry-Guillain-Barré syndrome) or abdominal or urologic pathologies (such as gastroenteritis, nephrolithiasis, or appendicitis).[9,10] The subtle neuropsychiatric signs in children can also be misdiagnosed as attention deficit hyperactivity disorder or other behavioral disturbances. Therefore, it is necessary to consider lead poisoning in the appropriate circumstance, particularly where another diagnosis is not established as the primary cause of the presentation.

Diagnostic Testing
