Answer: b. Blind finger sweeping has resulted in the conversion of partial to complete airway obstruction when objects are displaced into the subglottic space. For this reason, the technique has lost favor as an initial maneuver in pediatric and adult patients. It is recommended that up to five back blows be delivered (with the patient in a head-down position), followed by chest thrusts. Intubation or needle cricothyroidotomy may be performed if other maneuvers fail and circumstances dictate their need.

4. A 45-year-old man was at dinner when he had a choking episode. When he recovered, he experienced new-onset wheezing and presents with the following vital signs: blood pressure 140/90 mm Hg, heart rate 110 beats/min, respiratory rate 20 breaths/min, and arterial oxygen saturation (Sao_2) 92%. On chest radiograph, you see a flat, fixed diaphragm on the right with a mediastinal shift to the left and inadequate left-sided expansion. What is the next step in the management of this patient?
   a. Albuterol nebulizers and steroids intravenously
   b. Consult pulmonary for bronchoscopy
   c. CT scan of the chest with intravenous contrast
   d. Needle decompression of the left side
   e. Needle decompression of the right side

Answer: b. Air trapping and atelectasis are the most common early clues to airway foreign body presence, with bronchiectasis and bronchial stenosis developing later. In air trapping, a comparison of inspiratory and expiratory films shows a flat, fixed diaphragm on the involved side, and the heart and mediastinum shift to the uninvolved side during expiration. When the foreign object is distal to the oropharynx, however, subspecialty consultation is the safest and most expeditious means for foreign body removal. As a general rule, early bronchoscopy in any patient with a suspected foreign body is key to reducing morbidity and mortality.

5. A concerned father brings in his toddler, who has swallowed a button battery. Which of the following management strategies is most appropriate for this patient?
   a. Endoscopy is indicated if it is above the lower esophageal sphincter.
   b. Endoscopy is not indicated if it is found in the esophagus.
   c. Expectant management is appropriate.
   d. If it is in the small bowel, further surveillance is not indicated.

Answer: a. If a disk battery has been ingested, its location must be ascertained with immediate removal if it has lodged in the esophagus. If the button battery has passed distal to the esophagus, the patient can be observed, with follow-up radiography to confirm spontaneous passage through the gastrointestinal tract. Nifedipine is occasionally effective in managing food boluses but should not be used to manage nonorganic foreign bodies.

6. Which of the following is an initial management option for esophageal food bolus impactions in the ED?
   a. Glucagon
   b. Nifedipine
   c. Papain
   d. Sublingual nitroglycerine

Answer: a. Although none of the medical therapies are as good as endoscopy, Glucagon is likely more efficacious than nitroglycerin and nifedipine. Enzymatic degradation of an impacted meat bolus using the proteolytic enzyme papain, should not be performed because of risks of esophageal perforation. The gold standard intervention strategy for esophageal foreign body removal is endoscopy.

7. What do you expect to see on the chest radiograph of a child who has swallowed a coin?
   a. Foreign body anterior to tracheal air column
   b. Foreign body causing air trapping on the left side
   c. Visualized flat foreign body in the coronal plane
   d. Visualized round foreign body in the coronal plane
   e. Visualized round foreign body in the transverse plane

Answer: d. Esophageal foreign objects usually align themselves in the coronal plane and are posterior to the tracheal air column on lateral view. Coins in the esophagus lie in the coronal position in virtually all cases because the opening into the esophagus is much wider in this orientation.

Mammalian Bites

Wesley P. Eilbert

KEY CONCEPTS

- Mammalian bites require an evaluation for both trauma and their risk of infection.
- Cat and human bites are at higher risk for infection than dog bites.
- Most mammalian bite wound infections are polymicrobial. *Pasteurella* species are the most common pathogens in dog and cat bites.
- Preventing infection from mammalian bites relies more on vigilant cleaning, debridement, and irrigation than prophylactic antibiotics.
- Prophylactic antibiotics are most effective when started within 3 hours of the bite. The recommended duration of treatment is 5 days.
- Amoxicillin-clavulanate (Augmentin) is the prophylactic antibiotic of choice for dog, cat, and human bites.
- The decision to close mammalian bite wounds must weigh the benefit of improved cosmesis against the risk of wound infection.
- Given the risk of infection, mammalian bite wounds to the hand should not be closed primarily. Most facial bites can safely be closed if done so within 24 hours of the bite.
- Clenched-fist injuries or "fight bites" have high rates of damage to deep structures and infection.
- Mammalian bites to the hand should receive prophylactic antibiotics. Infected human bites to the hand are treated on an inpatient basis with intravenous antibiotics, operative debridement, and irrigation.

FOUNDATIONS

Background and Importance

It is estimated that 50% of individuals will sustain an animal bite during their lifetime, with more than 90% of these from a domestic animal.[1] Bite wounds account for 5% of all traumatic wounds evaluated in the emergency department and approximately 1% of all emergency department visits.[2] Dogs are responsible for more than 80% of animal bites in the United States, with cats accounting for 5% to 10%. Although few studies exist that have examined the incidence of wild mammalian bites, rodents are the most common offender in this group. Bites from other species include monkeys, ferrets, raccoons, foxes, bears, cougars, bats, livestock, and other wild mammals but comprise only a small percentage of reported bites.

Bites cause damage to skin and underlying structures including muscle, blood vessels, nerves, tendons, joint spaces, and bony structures. All bite wounds are contaminated with the oral flora of the biting animal and 10% to 20% of bite wounds become infected.[3] The potential for tetanus and rabies exposure must also be considered. Tetanus is discussed in Chapter 118 and rabies is covered in Chapter 119B.

DOG BITES

Foundations

Background and Importance

Of the nearly 4.5 million Americans bitten by dogs every year, approximately half are children.[4] Dog bites more often occur during summer months, with the dog being known to the victim in the majority of cases.[5] The arm and hand are most often bitten. Compared with adults, children are more likely to be bitten on the head and neck.[5] More than 30 dog bite fatalities occur in the United States each year, with American pit bull terriers responsible for the majority of these attacks.[6] Dog bites to the head and neck are of cosmetic concern and are at greater risk of life-threatening injury. The lips, cheek, and nose are the facial structures most likely to be bitten.[7] Young children are at greatest risk for mortality from a dog bite, with exsanguination after carotid trauma as the major cause of death. Craniofacial fractures and penetrating skull injuries have been reported in young children as a result of dog bites.[8,9]

Dog bite infection rates range from 1% to 30%, with hand bites at highest risk for infection.[1,10] Bites to the face and scalp are at lower risk for infection due to their rich blood supply. The type of wound appears to influence infection rates, with puncture wounds at higher risk for infection than superficial wounds, lacerations, or wounds limited to skin and soft tissue defects.[11] Cellulitis is the most common type of infection occurring after a dog bite, with tenosynovitis and septic joints more common after hand bites.[3,12]

Anatomy, Physiology, and Pathophysiology

Dog biting pressures exert forces estimated to be between 300 and 450 pounds per square inch, and dogs often shake the victim vigorously.[8] This causes a "hole and tear" effect resulting in complex lacerations and avulsions.

Clinical Features

Dog bite wounds may cause contusions or ecchymosis without a break in the skin, but more commonly are puncture wounds, lacerations, abrasions, and avulsions.[13] Most dog bite injuries are superficial, and the majority of patients are treated with medications, dressings, or suturing. Larger breeds cause more severe crush injuries due to the higher pressures exerted by their jaws and pose a greater risk of major organ or vessel injury than smaller breeds. Bites from pit bulls and dogs such as German shepherds used in law enforcement are at increased risk for associated orthopedic injuries when compared with other dog bites.[14]

Dog bites to the hand are often occlusive, with the crush injury component increasing the risk of infection. Hands are the most common

bite site to develop infection and long-term morbidity due to the number of bones and joints adjacent to the skin surface, small enclosed compartments and fascial planes, and small nerves that are present.[11] Tenosynovitis, septic arthritis, abscess formation, and traumatic digit amputation from dog bites have been reported.

Dog bite wound infections are usually polymicrobial, with an average of five bacterial isolates per wound culture. The responsible bacteria are a mixture of canine flora, environmental organisms, and the victim's skin flora. Approximately half of dog bite-related infections contain a mixture of aerobic and anaerobic bacteria, with anaerobes more likely to be present in abscesses and purulent wounds. *Pasteurella* species are the predominant organisms in infected dog bites, present in approximately 50% of cases. Other common anaerobic bacteria include *Fusobacterium, Bacteroides, Porphyromonas, Prevotella,* and *Propionibacterium* species. Common aerobic isolates from infected dog bites include streptococci, staphylococci, *Neisseria* species, *Corynebacterium* species, and *Moraxella* species.

Capnocytophaga canimorsus

C. canimorsus was first identified as a cause of systemic infection following dog bites. It is a slow-growing gram-negative rod found in the normal oral flora of both cats and dogs. *C. canimorsus* is a rare cause of systemic illness. Transmission is related to a bite in the majority of cases, although it has been documented from licks, scratches, and close animal contact. Most cases involve interaction with a dog, with only a small percentage occurring after contact with a cat.[15] In a small percentage of cases no animal source of infection is identified. The disease is more common in individuals over 50 years of age and affects men more than women. Approximately 50% of patients are immunocompromised by splenectomy, alcoholism, malignancy, or other condition.[15]

C. canimorsus may be associated with localized wound infection in a minority of cases but can cause systemic illness, sepsis, and disseminated intravascular coagulopathy (DIC) in immunocompromised individuals.[15–17] Symptoms of systemic illness typically begin within 10 days of the exposure with a mortality rate as high as 26%.[15]

Diagnostic Testing

Obtain radiographs if there is a likelihood of damage to underlying bones and joints. Bite penetration of joint capsules may be seen as air in the joint on plain radiographs. Scalp bites in children younger than 2 years old may require computed tomography (CT) imaging because intracranial penetration and injury may occur. Preemptive wound cultures sent from fresh bites are rarely of value and are generally not indicated.

C. canimorsus grows slowly and requires special media and growth conditions. In cases of sepsis without an obvious source following a dog or cat bite, *C. canimorsus* is a consideration and the laboratory should be notified to arrange for appropriate testing. Polymerase chain reaction (PCR) and detection of characteristic gene coding by molecular testing are the gold standard for detection of *C. canimorsus* infection.[17,18]

Differential Diagnoses

The differential diagnosis of dog bites includes bites from other domestic pets such as cats, and bites from wild canines including coyotes and wolves. The differential diagnosis for the patient with symptoms suggestive of *C. canimorsus* infection is extensive. Given its relative rarity and initial symptoms that are indistinguishable from other bacterial infections, *C. canimorsus* infections are likely to be misdiagnosed and treated as other more common infections initially. A history that includes mammalian bites may be the only diagnostic clue. Consider *Neisseria meningitidis* or *Streptococcus pneumoniae* in patients presenting with fever, headache, hypotension, and evidence of DIC.

Management

Management hinges on several historical elements that can be divided into three main parts: (1) the circumstances of the attack, (2) information about the biting animal, and (3) information about the bite victim. The timing of the bite should be determined. Untreated bites more than 6 hours old are at higher risk for infectious complications. When possible, it should be determined whether the bite was provoked or unprovoked, because this may influence the decision to administer rabies prophylaxis. Information about the biting animal should include ownership and immunization status, as well as the animal's current location. With dog bites, inquiring about the specific breed is important, because certain breeds (e.g., German shepherds, Rottweilers, and pit bulls) deliver more severe bites with a higher risk of damage to underlying structures. Information about the bite victim should include their medical history, current medications, and tetanus status.

The general principles of wound management apply to bite wound patients (see Chapter 50). Adequate analgesia is vital to allow for appropriate examination and wound care. Washing the wound with soap and water, ideally with gentle scrubbing with a fine pore sponge to minimize additional tissue trauma, should be performed. A virucidal agent such as povidone-iodine solution should be used on the skin surface surrounding the bite but can be toxic to exposed tissue beneath the skin. Irrigate wounds under pressure with saline or sterile water as this is the most effective method of reducing bacterial counts (see Chapter 50).

Examination of bite wounds should ideally take place in a bloodless field to allow for adequate visualization of deep structures. A blood pressure cuff inflated above the patient's systolic pressure for up to 20 minutes can be used for this purpose. Examine the wound for damage to tendons and possible joint capsule violations. Remove any retained teeth fragments. It is often helpful to extend the margins of puncture wounds in high-risk areas (e.g., overlying joints and tendons) to allow for better visualization. A neurovascular assessment is required in all extremity bites.

Primary closure of mammalian bites is controversial. Ultimately, the benefit of improved cosmesis of primary closure must be weighed against the increased risk of infection. Studies have found no significant difference in rates of infection between repaired dog bite wounds and those left open. Carefully selected dog bites closed primarily have an overall infection rate of 5%, similar to sutured non-bite wounds. When closing bite wounds, use subcutaneous sutures cautiously as the presence of additional foreign material increases the risk of infection. To optimize cosmetic outcome in those wounds deemed too high risk for infection for primary closure, loosely approximating the wound edges using adhesive strips may be performed. Another option is to reevaluate the wound in 48 to 72 hours and if no evidence of infection is present, perform a delayed primary closure.

Given the available data, we recommend the following guidelines summarized in Table 52.1. Bite wounds of the face and scalp from any species that are less than 6 hours old may be sutured after appropriate wound preparation. It is probably safe to suture most other uncomplicated dog bite wounds, although bites of the hands and feet are at high risk for infection and should rarely be sutured. Puncture wounds, wounds more than 12 hours old, and wounds infected at presentation should not be sutured.

Prophylactic antibiotics. The value of prophylactic antibiotics given for mammalian bites is secondary to the value of vigilant cleaning, debridement, and irrigation. Antibiotics should ideally be given within 3 hours of the bite to achieve a prophylactic effect

TABLE 52.1 Recommendations for Bite Wound Closure and Prophylactic Antibiotics

Species	Suturing	Prophylactic Antibiotics
Dogs, coyotes, wolves	The majority except hands and feet	Hand and foot wounds High-risk wounds[a]
Cat	Face only	All wounds extending through the epidermis
Human	Face only (up to 24 h after the bite)	All wounds extending through the epidermis
Monkey	Face only (up to 24 h after the bite)	All wounds extending through the epidermis
Rodent	All (but rarely needed)	No
Ferret, pig, horse, camel, bear, big cats	Face only	All wounds extending through the epidermis

[a]High-risk wounds: Deep puncture wounds, crush injury or damage to deep structures, delayed presentation (>6 h), wounds closed primarily, and high-risk patients (see Table 52.2).

TABLE 52.2 Risk Factors for Bite Wound Infections

Factor	High Risk	Low Risk
Species	Cat (domestic and wild) Human Monkey Pig Camel Bear	Dog (excluding hands and feet) Rodent
Location of wound	Hand (especially clenched-fist injuries [CFIs]) Foot	Face Scalp
Wound type	Puncture Crush injury or damage to deep structures Presence of devitalized tissue Delayed presentation (more than 6 hours) Closed primarily	Laceration Superficial
Patient characteristics	Age over 50 Diabetes Renal failure Liver disease Alcoholism Immune disorder Malnutrition Use of corticosteroids or other immunosuppressive medications Peripheral vascular disease Chronic edema of the bitten area	

and then continued for 5 days. Although there are mixed data on the efficacy of prophylactic antibiotics used for dog bites, they have consistently shown value when used in the treatment of hand bites. Ultimately, the use of prophylactic antibiotics should take into account the characteristics of the bite and the individual bitten. We advise giving prophylactic antibiotics to immune compromised patients and to those with dog bite wounds of the hand, foot, and other high-risk wounds (Table 52.2).

No clinical trials have reliably demonstrated the superiority of one antibiotic regimen over another, but a regimen that covers *Pasteurella* species is recommended. We recommend amoxicillin-clavulanate (Augmentin) for dog bite prophylaxis. Treatment failure of *Pasteurella* infections caused by dog and cat bites using monotherapy with erythromycin, clindamycin, penicillinase-resistant penicillins, and first-generation cephalosporins has been described. A fluoroquinolone, such as ciprofloxacin or moxifloxacin, or clindamycin combined with trimethoprim-sulfamethoxazole may be used in penicillin-allergic patients (Table 52.3). Empirical antibiotic options for those patients with established dog bite wound infections are similar to those used for prophylaxis. Parenteral antibiotic options for those patients requiring admission are listed in Table 52.3.

Although no clinical trials have evaluated antibiotic selection in *C. canimorsus* infections, most strains are susceptible to fluoroquinolones, macrolides, carbapenems, clindamycin, and third generation cephalosporins. *C. canimorsus* is typically resistant to trimethoprim-sulfamethoxazole and aminoglycosides.[15–17]

Disposition

Indications for admission after a dog bite are listed in Box 52.1. Reevaluate patients deemed appropriate for outpatient therapy in 24 to 48 hours.

CAT BITES

Foundations

Background and Importance

Females are twice as likely as males to be the victim of a cat bite, with a peak age incidence in the third decade. Approximately two thirds of cat bites are to the upper extremity, typically involving the hand and fingers.[19] More than 80% of cat bites are caused by a domestic pet that is owned by the victim. Most cat bites are perceived as minor injuries and often go unreported, with the majority of patients seeking medical care only after complications have developed.[19,20]

Anatomy, Physiology, and Pathophysiology

Cats possess narrow, sharp teeth that easily penetrate skin and the underlying soft tissues like a needle. This mechanism creates a small break in the skin that heals quickly, trapping the bacteria in the deeper structures, often resulting in invasive infection. Because of this, cat bites are more likely to become infected than dog bites, with a reported infection rate of more than 50%.[2] This increased rate of infection is multifactorial: the higher incidence of puncture wounds, a higher proportion of hand bites, an older average age of cat bite victims, and a higher likelihood of *Pasteurella* species in the feline flora.

Clinical Features

The majority of infected cat bites (90%) will manifest symptoms within 48 hours of the bite.[20] Although not as likely to cause damage by crush injury as dog bites, cat bites are more likely to cause infection in deeper structures, including osteomyelitis and soft tissue abscesses. Of infected cat bite wounds, over 50% present with cellulitis, 20% with tenosynovitis, 15% with osteomyelitis or septic arthritis, and 10% with an abscess. Mixed aerobic and anaerobic bacteria infections are the rule, being present in more than 60% of cases. One-third of cat bite infections are due to only aerobic bacteria. *Pasteurella* species are the most common pathogens, present in 70% to 75% of infected cat bites, with *Bacteroides, Fusobacterium, Porphyromonas, Propionibacterium*, and *Prevotella*

TABLE 52.3 Suggested Antibiotic Regimens for Bite Wound Prophylaxis and Inpatient Treatment of Establishing Infections

Species	Prophylaxis	Inpatient Treatment of Established Infection
Dog and cat	Amoxicillin/clavulanate (Augmentin) 875/125 mg q12h for 5 days Ciprofloxacin, 500 mg BID for 7 to 14 days Moxifloxacin 400 mg po qd for 7 to 14 days Clindamycin 300 mg QID plus trimethoprim- sulfamethoxazole 160/800 mg BID for 7 to 14 days	Ampicillin/sulbactam (Unasyn) 1.5 g (1 g ampicillin plus 0.5 g sulbactam) to 3 g (2 g ampicillin plus 1 g sulbactam) q6h for 7–14 days Piperacillin/tazobactam (Zosyn) 3.375 g (3 g piperacillin and 0.375 g tazobactam) IV QID for 7–14 days Imipenem 500 mg IV q6h or 1 g IV q8h Meropenem 500 mg IV q8h Ertapenem 1 g/day IV/IM Ciprofloxacin or moxifloxacin plus metronidazole (Flagyl) 250–500 mg QID Ciprofloxacin 600 mg BID or 400 mg IV BID or moxifloxacin 400 mg PO/IV qd plus clindamycin 300 mg QID
Human and monkey	Amoxicillin-clavulanate 875/125 mg q12h Ciprofloxacin 500 mg twice per day or trimethoprim sulfamethoxazole 160/800 mg BID plus clindamycin 300 mg QID	Ampicillin/sulbactam) 1.5 g (1 g ampicillin plus 0.5 g sulbactam) to 3 g (2 g ampicillin plus 1 g sulbactam) q6h Imipenem 500 mg IV q6h or 1 g IV q8h Meropenem 500 mg IV q8h Ertapenem 1 g/day IV/IM Ceftriaxone 1 g IVPB BID plus metronidazole 250 to 500 mg TID Clindamycin 600 mg QID plus ciprofloxacin 500 mg BID or 400 mg IV BID
Rodent	Not recommended	
Ferret, pig, horse, bear, big cats, coyotes, wolves	Same as for cats and dogs	Same as for cats and dogs
Camel	Ciprofloxacin 500 mg q12h Ofloxacin 400 mg po q12h	Same as for cats and dogs

BOX 52.1 Indications for Admission After an Animal Bite

Structural

Injury to deep structures (bones, joints, tendons, arteries, or nerves)
Injuries requiring reconstructive surgery
Injuries requiring general anesthesia for appropriate wound care

Infectious

Rapidly spreading cellulitis
Significant lymphangitis or lymphadenitis
Evidence of sepsis
Infection in patients at high risk for complications (see Table 52.2)
Infections involving bones, joints, tendons
Infection with failed outpatient therapy

species also common anaerobic pathogens. Common aerobes include streptococci, staphylococci, and *Moraxella* species.

Pasteurella multocida

An important factor contributing to the risk of infection after cat bites is the presence of *P. multocida,* a highly virulent, facultative anaerobic, gram-negative rod found in the normal oral flora of up to 90% of cats. It can also be found in the oral flora of the majority of dogs and several wild animals. Most human infections with *P. multocida* are caused by cat bites or scratches, dog bites, or open wounds that have been licked by a dog or cat.

The most common initial manifestation of *P. multocida* infection is a rapidly spreading cellulitis, usually presenting within 12 to 24 hours of the exposure. A low-grade fever and serosanguineous or purulent discharge at the site may be present. Regional lymphadenopathy is often present. Local infectious complications may occur if left untreated, most commonly subcutaneous abscesses and tenosynovitis. Less often, septic arthritis and osteomyelitis may occur. Systemic illnesses from *P. multocida* including bacteremia, pneumonia, endocarditis, and meningitis have been described in small case series. Up to 11% of patients with *Pasteurella* infections will have an associated bacteremia, which carries with it a 30% mortality.[21] The majority of patients with systemic illness have an underlying medical condition, with liver disease, malignancy, and chronic obstructive pulmonary disease being the most frequent comorbidities.

Differential Diagnoses

P. multocida cellulitis has a more rapid onset and progression than cellulitis caused by more common pathogens. Cat scratch disease, an infection caused by *Bartonella henselae* associated with a cat scratch or bite, presents with regional lymphadenopathy often with an associated fever. A preceding cat or dog bite may be the only initial clue that indicates *P. multocida* as the cause of a systemic illness, such as bacteremia.

Diagnostic Testing

As with dog bites, obtain radiographs if there is a likelihood of a retained tooth or damage to underlying bones and joints. Bite penetration of joint capsules may be seen as air in the joint on plain radiographs. Preemptive wound cultures sent from fresh bites are rarely of any value and are generally not indicated.

Management

P. multocida is not susceptible to many oral antibiotics typically given for skin and soft tissue infections, including dicloxacillin, cephalexin, vancomycin, and clindamycin. In most cases, treatment with

amoxicillin-clavulanate or a second- or third-generation cephalosporin is effective. Fluoroquinolones, azithromycin, doxycycline, and trimethoprim sulfamethoxazole may be used in penicillin allergic patients.[22]

Similar to dog bites, studies have demonstrated varying efficacy of prophylactic antibiotics used for cat bites, though they show consistent value when used in the treatment of hand bites. We advise giving prophylactic antibiotics to all cat bites that penetrate through the epidermis regardless of location, given the high-risk nature of these bites for infection. With similar common pathogens as dog bites, we recommend amoxicillin-clavulanate (Augmentin) for prophylaxis. (see Table 52.3)

Disposition

Indications for admission after an animal bite are listed in Box 52.1. Those patients deemed appropriate for outpatient therapy should be reevaluated in 24 to 48 hours.

OTHER MAMMALS

Monkeys

Foundations

Background and Importance. Monkey bites are rare in the United States, occurring primarily in laboratory workers involved in biomedical research. Monkey bites are more prevalent in other countries including India, where they are the second most commonly reported animal bite. Although not well studied, monkey bites are reported to have a high rate of infection and complications, such as osteomyelitis. The major concern with monkey bites is B virus (*herpesvirus simiae, herpesvirus B,* and *monkey B virus*) exposure. It causes disease in monkeys resembling that of human herpes viruses. Asymptomatic infected monkeys harbor the virus in their conjunctiva, buccal mucosa, and genital areas and may shed the virus, being more likely to do so when ill, under stress, immunocompromised, or breeding. The incidence of seropositivity for the B virus is widely variable in non-captive monkeys depending on geographic location and ranges from 80% to 100% in monkeys of the genus *Macaca* (macaques) used for biomedical research.[23] More than 50 cases of B virus infection in humans have been reported, with the vast majority of these in the United States being in laboratory workers.

Anatomy, physiology, and pathophysiology. Monkey bites may present with superficial bruising, puncture marks, or small, grouped lacerations. Superficial and deep soft tissue infections can occur. In contrast to human bites, preventing viral transmission and infection is the primary concern. In addition to bites, transmission via scratches, exposure to animal tissue, and needlestick injuries has been reported.

Clinical features. B virus disease in humans has an incubation period as short as 2 days but more commonly 2 to 5 weeks. The disease often starts with vesicular lesions at the site of exposure with concomitant influenza-like symptoms. Paresthesias and muscle weakness may develop and proceed proximally along the affected extremity. Signs of central nervous system dysfunction develop when the virus enters the brain and include altered mental status, cranial nerve palsies, ataxia, coma, and respiratory failure. Left untreated, the mortality rate of disseminated B virus infection is estimated to be 80%.

Differential diagnoses. The bacteria isolated from infected monkey bites is similar to that from infected human bites, with a predominance of *Staphylococcus* and *Streptococcus* species, *Eikenella corrodens,* and anaerobes including *Bacteroides* and *Fusobacterium* species.

Management. While under studied, monkey bites may also have a risk profile for bacterial infection similar to human bites and should receive similar antibiotic prophylaxis (see Table 52.3). The most critical period for the prevention of B virus infection is during the first few minutes after exposure. Scrub the area with soap, detergent, or iodine for 15 minutes and then irrigate with running water for 15 to 20 minutes.[24] Prophylaxis of high-risk bites with acyclovir or valacyclovir is recommended (Box 52.2). Postexposure prophylaxis is started as soon as possible after the bite and continues for 5 days. Treatment of suspected disseminated B virus infection involves intravenous acyclovir or ganciclovir.[24]

Disposition. The majority of monkey bites can be safely discharged home from the emergency department (ED) following local wound care, appropriate antibiotics, and reassurance of outpatient follow-up. Those patients with systemic symptoms of infection may require admission for intravenous antibiotics and antivirals if active B virus infection is suspected.

BOX 52.2 Prophylaxis for Monkey Virus B Exposure

Prophylaxis Recommended

Skin exposure (with loss of skin integrity) or mucosal exposure to a high-risk source (e.g., a macaque that is ill, immunocompromised, known to be shedding virus, or has lesions compatible with B virus disease)
Inadequately cleaned skin exposure (with loss of skin integrity) or mucosal exposure
Deep puncture bite
Laceration of the head, neck, or torso
Needlestick associated with tissue or fluid from the nervous system, eyelids, mucosa, or lesions suspicious for B virus
Puncture or laceration after exposure to objects contaminated with either fluid from monkey oral, genital, or nervous system tissues or any object known to be contaminated with B virus
A post cleaning wound culture is positive for B virus

Prophylaxis Considered

Laceration (with loss of skin integrity) that has been adequately cleaned
Needlestick involving blood from an ill or immunocompromised macaque
Puncture or laceration occurring after exposure to either objects contaminated with body fluid (other than from a lesion) or potentially infected cell culture
Drug of first choice: Valacyclovir 1 g by mouth every 8 hours for 14 days
Alternative drug: Acyclovir 800 mg by mouth five times/day for 14 days

Prophylaxis Not Recommended

Skin exposure in which the skin remains intact
Exposure associated with non-macaque species of nonhuman primates

Rodents

Foundations

Background and importance. As with monkey bites, laboratory workers are frequent rodent bite victims because these animals are commonly used in biomedical research. Rat bites tend to occur in urban areas and in patients of lower socioeconomic class. Children are more commonly bitten than adults. The majority of these bites occur while the victim is asleep, with the face and upper extremity most often affected. Squirrel bites occur almost exclusively on the hand, typically occurring while trying to feed the animal or rescue it from a dangerous situation.

Anatomy, physiology, and pathophysiology. Infection and systemic illness, "rat bite fever," is caused by bacteria from *Streptobacillus moniliformis* or *Spirillum minus*, organisms found in the nasopharyngeal flora of healthy rats.

Clinical features. Disease transmission may occur by bite, scratch, handling a rat, or by ingestion of contaminated food or water. The

incubation period ranges from 3 days to over three weeks but typically is less than 7 days. At disease onset, fever is prominent, followed by a migratory polyarthralgia. Nearly 75% of patients develop a maculopapular, petechial, or purpuric rash most prominent on the extensor surfaces of the extremities. Endocarditis is a well described complication. Untreated, rat bite fever has a mortality of approximately 10%.

Differential diagnoses

A number of systemic diseases may be transmitted by rodent bites including rat bite fever, leptospirosis, tularemia, sporotrichosis, murine typhus, and plague.

Management. Rodent bites are at low risk for local wound infection and require only appropriate wound care without antibiotic prophylaxis. Intravenous penicillin is the treatment of choice for proven or highly suspected cases of rat bite fever, with erythromycin, clindamycin, and tetracycline reasonable options for penicillin allergic patients.[25,26] Antibiotic prophylaxis for rat bite fever is not recommended given the low risk for infection after a bite.

Disposition. The vast majority of rodent bites can be safely discharged home from the ED with wound care instructions and outpatient follow-up.

UNCOMMON ANIMAL BITES

Ferrets

Ferrets *(Mustela putorius furo)* are in the same family as badgers, weasels, and skunks, and became increasingly popular as pets in the United States in the 1980s. Initially bred to hunt rats and rabbits, ferrets are known for their exceptionally vicious attacks, with infants and small children often their victims. Unlike dog and cat bites, many ferret bites are unprovoked and will frequently require plastic and reconstructive surgery. Although the oral flora of ferrets is known to contain *Pasteurella* and other aerobic species and *Fusobacterium* and other anaerobic species, no known reports exist that have examined the rates of infection or common pathogens with ferret bites.

DOMESTIC HERBIVORES

Sheep, Cattle, and Pigs

Bites from sheep and cattle are rarely reported in the medical literature. Pig bites are a common occupational hazard among farmers and slaughterhouse workers and most commonly occur on the posterior aspect of the thigh. Males have large, sharp tusks capable of deep penetrating wounds with injury to deeper structures. Bites from females are less damaging. Pig bite infections are often polymicrobial with organisms including *Pasteurella*, *Actinobacillus*, and *Streptococcus* species.[27] Methicillin-resistant *Staphylococcus aureus* has been a reported in infected pig bites.

Horses

Of all horse-related injuries, most are from falls and less than 5% are due to bites. Horse bite injuries range from superficial trauma to amputation of digits. Horse bite infections are typically polymicrobial with a mix of aerobic and anaerobic species. *Actinobacillus* species are gram-negative coccobacilli that are part of the normal oral flora of horses and common pathogens in infected bites. Other common pathogens include *Staphylococcus* and *Streptococcus* species, *Pasteurella* species, as well as *Fusobacterium* and *Bacteroides* species.[28]

Camels

Camel bites are commonly reported in Africa, the Middle East, and the Indian subcontinent. Camel bites are more likely to occur during their mating season from December through March, with most injuries occurring to the upper extremities. Camels have a strong jaw and canine teeth that may reach up to 4 cm in length, which result in serious injury and even death from their bites. Approximately one half of upper extremity bites have associated fractures, and bites to the head have been associated with skull fractures and intracranial injury.[29] Camel bites have a high infection rate with *Staphylococcus*, *Aeromonas*, *Pasteurella*, and *Actinobacillus* species as common pathogens.[30]

WILD ANIMALS

Bears

Bear attacks are rare in North America, occurring at a rate of 10 or fewer per year, with most occurring in the western United States and Canada. The incidence of bear attacks on humans appears to be increasing due to increasing human encroachment into bear habitat for living and recreation.[31] Bear attacks are more common in the warm weather months and have a reported mortality rate of up to 20%. Grizzly bears are responsible for an inordinate number of serious or fatal injuries caused by bears in North America. Most bear bites are to the head and face, often with underlying bony injury.[32] Although not well studied, bear bites have a reported infection rate of 44%. *Staphylococcus*, *Streptococcus*, and *Serratia* species are reported pathogens in bear bite infections.

Wild Cats

Most attacks by big cats (lions, tigers, leopards, jaguars, cougars, and cheetahs) now occur in captive conditions, such as zoos, animal farms, and circuses, although attacks in the wild are still reported with some frequency in Asia and Africa. Large cats target the neck of their prey, causing damage to the spine, trachea, and large blood vessels. As humans encroach on their natural habitat, cougars are responsible for the majority of big cat attacks in North America, with children and hikers the most common victims and the nape of the neck the most commonly bitten area. Common injuries from these attacks include neck lacerations and internal carotid, tracheal, and cervical spine injuries.[33] As is true for domestic cats, *Pasteurella multocida* is the most frequently isolated pathogen in wounds from large cats. Hyenas, which are related to cats, have been known to attack humans in the wild in Africa and Asia. Unlike the big cats, hyenas tend to bite the central face of their victims, causing damage to the cheeks, nose, and lips.

Coyotes and Wolves

Bites from coyotes and wolves are similar to dog bites and should be treated as such.

Management

As with all bite-related lacerations, location, type of wound, time to treatment, and patient factors all contribute to the risk of wound infection. Delay in wound cleaning and suboptimal cleaning techniques will increase infection risk. The animal responsible for the bite also is a factor in determining the risk of infection (see Table 52.2). Although there are no studies to firmly guide practice, antimicrobial prophylaxis for bites from other mammals is often provided. Ferrets, pigs, horses, bears, big cats, coyotes, and wolves have bite wound pathogens similar to those of dogs and cats, so in the absence of other data, prophylactic antibiotics given for these bites is similar. The unique mixture of camel bite wound pathogens is most adequately covered by fluoroquinolone antibiotics (see Table 52.3). Consider tetanus prophylaxis for all bite wounds. Rabies immunization should be considered following bites from bats, coyotes, wolves, foxes, raccoons, skunks, and stray dogs outside of the United States (see Chapter 119B). Bites from rodents,

squirrels, and lagomorphs (i.e., rabbits) do not require rabies prophylaxis. Indications for admission after an animal bite are listed in see Box 52.1. Those patients deemed appropriate for outpatient therapy should be reevaluated in 24 to 48 hours.

Human Bites

Foundations

Background and importance. Human bites tend to occur during summer months, typically on weekends, and most often involve acts of aggression. Sporting event altercations and sexual or physical abuse injuries are less common, but important causes. Males are more likely to be the victims of human bites, with a peak incidence in the 10- to 34-year-old age group.[19,34] The hands and upper extremities are the most commonly bitten location, followed by the head and neck. In victims of sexual crimes, the breast is the most commonly bitten area, and the arm is the most frequently bitten site in victims of child abuse. For various reasons, including embarrassing circumstances and possible legal repercussions, adult human bite victims may delay seeking medical care until a complication ensues. This is especially true for human bites of the hand.

Anatomy, physiology, and pathophysiology. Human bites can be divided into two categories: occlusive bites and clenched-fist injuries (CFIs). Occlusive bites are those caused by closure of the perpetrator's teeth onto the victim's skin. CFIs, or "fight bites," are injuries to the dorsum of the metacarpophalangeal joints of the fist as it strikes the teeth of an adversary. The overwhelming majority of CFIs occur in young adult males and frequently involve alcohol consumption.[35,36] Human bites have infection rates ranging from 5% to 50%, with hand bites and CFIs having the highest rates of infection. Children, in whom human bites are usually superficial, tend to have lower rates of infection (<10%) as compared with adults.

Clinical features. **Fight bites (clenched-fist injury).** Acute CFIs typically present as an innocuous appearing 3- to 8-mm laceration over the dorsal aspect of the second, third, fourth, or fifth metacarpophalangeal (MCP) joint (Fig. 52.1). Despite their initial benign appearance, CFIs often have extensive deep structure damage. Damage to underlying bones occurs in approximately half of all CFIs, and over half will have violation of a joint capsule.[35,37] Up to 20% of CFIs will have an associated tendon injury. Injury to the extensor tendons occurs with the fist clenched. When the fist is relaxed, the tendons retract carrying bacteria deeper into the hand and extending infection to other spaces. Retained tooth fragments in the wound may also occur.[38] CFIs have high rates of osteomyelitis (16%), septic arthritis (12%), and tenosynovitis (22%). Many patients will be reticent to discuss the details of their injury, and approximately one third of CFI patients will initially offer an alternative explanation for their hand laceration.

Other human bites. Human occlusive bites generally cause less tearing and crush injury than dog bites, and do not penetrate soft tissues as readily as cat bites. Occlusive human bites that are superficial, do not involve the hands or feet, and are not over joints or cartilaginous structures have a very low rate of infection. Intraoral and oral-cutaneous wounds caused by the patient's own teeth are usually a result of blunt facial trauma. These bite wounds are typically small and confined to the oral mucosa, requiring no specific intervention. Larger wounds and those that communicate with the overlying facial skin (i.e., "through and through" wounds) may require closure for functional or cosmetic reasons. Infection rates of these wounds range from 5% to 30%. Organisms cultured from these infected wounds include *Staphylococcus* and *Streptococcus* species, *Bacteroides*, and *Corynebacterium*. In the absence of any current clear evidence-based recommendation regarding the use of prophylactic antibiotics for these wounds, we advise prophylactic penicillin be used in those lacerations requiring primary closure and through-and-through injuries that communicate with the overlying skin.

Human saliva can contain up to 10^9 organisms per mL and may contain as many as 190 different species of bacteria. As with other mammalian bites, cultures sent from fresh, uninfected human bite wounds do not predict which patients will become infected, nor do they reveal the responsible pathogens in those who do. Information on the bacteriology of infected human bite wounds has come primarily from hand bites, with the majority being CFIs. Polymicrobial infections are the rule with human bites, with an average of four isolates per wound culture. Approximately half contain a mixture of aerobic and anaerobic species, with less than 5% containing only anaerobes. *Staphylococcus* and *Streptococcus* species, as well as *Corynebacterium* and *Fusobacterium* species, are common pathogens. *Eikenella corrodens,* a fastidious facultative anaerobe, is present in up to 30% of infected human bites. It is resistant to multiple antibiotics including erythromycin, antistaphylococcal penicillins, and first-generation cephalosporins.

Differential diagnoses. Human bites have resulted in transmission of tetanus, syphilis, actinomycosis, and herpes. Herpetic whitlow, an infection of the finger by HSV types 1 and 2, is an occupational hazard of nurses, physicians, dentists, and oral hygienists and classically described in sporting events like wrestling (Fig. 52.2). Although the presence of human immunodeficiency virus (HIV) inhibitors in saliva render the virus non-infective in most cases, there are several case reports of HIV transmission by human bites.[37] Infection with hepatitis B virus (HBV) has also been reported and carries a greater transmission risk than HIV.[38] The infectivity of the hepatitis C virus (HCV) from a bite is believed to be midway between that of HIV and HBV, and there are case reports of its transmission by human bites.[38] The risk of

Fig. 52.1 Acute Clenched Fist Injury. (Courtesy Jeffrey E. Keller, MD.)

Fig. 52.2 Herpetic Whitlow. (Courtesy Gary M. White, MD.)

transmission of HIV, HBV, and HCV from a bite is more likely if blood was present in the mouth of the biter at the time of injury.[39,40]

Diagnostic testing. Due to their high incidence of deep structure injury and the possibility of retained tooth fragments, we advise obtaining radiographs in hand bites. A "skyline" view of the distal metacarpals may aid in the identification of vertical articular fractures of the metacarpal heads caused by CFIs.

Management. Treatment should focus on the mechanism of the bite (occlusive or CFI), the health of the bite victim including medical history and tetanus status, and the potential for transmission of viral hepatitis or HIV. If the biter is available for testing, local law enforcement may permit testing even without consent depending on the particular circumstances.

Treatment of occlusive human bites is generally similar to that of other mammalian bites. Although some authors have advocated surgical exploration of all CFIs in the operating room, nonoperative management in the ED for those patients presenting within 24 hours of injury has been proven sufficient.[36] Such an approach is predicated on thorough wound exploration in a bloodless field. The hand should be examined through its entire range of motion, including in the closed-fist position when the fingers are flexed, because extensor tendon injuries and cartilage damage may not be evident in any other position. Admit patients for operative debridement and irrigation in whom exploration shows signs of infection or injury to the joint or joint capsule, tendons, or bones. It is typical for patients with CFIs to present several days after the injury with evidence of an infected wound. These patients will also require surgical exploration and irrigation in the operating room.

Given their propensity for infection, only human bites to the face should be closed primarily. Case series of human facial bites closed primarily have reported infection rates of up to 10%, although all of these studies reported delays of treatment of up to several days. We recommend primary closure of human bites to the face for up to 24 hours after the bite has occurred (see Table 52.1). CFIs not requiring operative intervention should be cleaned, debrided, and irrigated, then left open with the hand splinted in a position of comfort.

HIV post-exposure prophylaxis is recommended for both the bite victim and the bite source if either party is known to be HIV-positive or at high risk and blood exposure has occurred. Postexposure prophylaxis is also indicated in all bites if either party is known to be HBV-positive or at high risk and blood or saliva exposure has occurred.

BOX 52.3 Indications for Admission for Human Bites of the Hand

- Infection present at the time of presentation
- Deep structure violation (tendon or tendon sheath, joint, or bone)
- Wounds requiring operative intervention for debridement of devitalized tissue or foreign body removal
- Patients at high risk for wound infection (see Table 52.2)
- Patients with likely social support or compliance issues

No current postexposure prophylaxis is recommended for HCV, so serologic testing with appropriate follow-up and counseling should be offered if the bite resulted in blood exposure, and either party is known HCV positive or at high risk.[41]

Prophylactic Antibiotics

Studies have consistently demonstrated the value of prophylactic antibiotics in the treatment of human bites. We recommend prophylactic antibiotics for any human bite that penetrates deeper than the epidermis regardless of body location, with the exception of those bites greater than 72 hours old without evidence of infection. We recommend beta-lactam/beta-lactamase inhibitor combination antibiotics, such as amoxicillin-clavulanate (Augmentin), or clindamycin combined with either trimethoprim sulfamethoxazole or ciprofloxacin (see Table 52.3). As with other prophylactic antibiotics, the first dose should be given ideally within 3 to 4 hours of the injury and continued for 5 days.

Disposition

Delay in presentation with human bites to the hand is strongly correlated with infection-related complications, and these patients should be admitted for parenteral antibiotics. Other indications for admission with human bites of the hand are listed in Box 52.3. Localized infections of human bites elsewhere on the body in immunocompetent patients can be treated as an outpatient. All patients with human bites discharged from the ED should have their wounds reevaluated in 24 to 48 hours. Patients with CFIs have notoriously high rates of noncompliance with follow-up care.[36] It is reasonable to admit patients who might predictably fall into this category.

CHAPTER 52: QUESTIONS AND ANSWERS

1. A 75-year-old woman presents with a puncture mark on her hand. She reports being bitten by her cat the previous night. Which of the following statements regarding this patient's injury is *true?*

a. *Capnocytophaga canimorsus* is the organism of concern.
b. Cats are very clean animals and do not carry any virulent strains.
c. Cats produce superficial infections because their teeth are not long enough to inoculate past the dermis.
d. Concern exists for a virulent gram-negative bacterium, which can produce a rapid cellulitis.
e. Irrigation and topical antibiotics are indicated.

Answer: d. Cats have long, slender, pointed teeth that can penetrate tendons, joints, and bone, inoculating bacteria deep into these tissues. Cat bites have a substantially higher risk of infection than dog bites do. Another important factor in the development of wound infection after cat bites involves the presence of *Pasteurella multocida,* a highly virulent, gram-negative, facultatively anaerobic rod found in the oral cavity or nasopharynx of 70% to 90% of healthy cats.

2. What is the most appropriate antibiotic prophylaxis for a cat bite?

a. Amoxicillin-clavulanate
b. Clindamycin

c. Erythromycin
d. First-generation cephalosporins
e. Vancomycin

Answer: a. In vitro, *P. multocida* is sensitive to penicillin, ampicillin, tetracycline, fluoroquinolones, amoxicillin-clavulanate, second- and third-generation cephalosporins, and trimethoprim-sulfamethoxazole.

3. A 19-year-old man presents 10 hours after sustaining a dog attack. He has multiple lacerations on his head and right hand. What is the appropriate management of this patient?
a. Repair the hand and the head lacerations
b. Repair the hand laceration but not the head laceration
c. Repair the head laceration but not the hand laceration
d. Use Steri-Strips on all and give him a prescription for amoxicillin-clavulanate (Augmentin)
e. Wound cleansing and bandaging

Answer: c. For dog bites, the infection rate of hand wounds is as high as 30%, regardless of suturing, whereas the infection rate of dog bites elsewhere averages 9%. Similarly, dog bites of the face and neck (including punctures) have lower infection rates of 0% to 5% even when they are sutured. Bite wounds of the face and scalp from any species that are less than 12 hours old may be cleansed well and sutured. Most other bite wounds that are going to be closed should have this done within 6 hours.

4. Selected monkey bites require postexposure prophylaxis with which of the following medications?
a. Amoxicillin clavulanate
b. Clindamycin
c. Flagyl
d. Tetracycline
e. Valacyclovir

Answer: e. Valacyclovir to prevent herpes B virus infection. Other terms for this virus include *herpesvirus simiae, herpesvirus B,* and *monkey B virus*. This virus has serologic cross-reactivity with herpes simplex virus (HSV) type 1 and type 2, which cause herpetic lesions in humans. Seventy-five to 100% of monkeys of the genus *Macaca* (macaques) used for biomedical research are seropositive for the B virus. Other antibacterials may be needed if cellulitis infection ensues.

53

Venomous Animal Injuries

Amelia M. Curtis and Timothy B. Erickson

KEY CONCEPTS

- Snake venom causes neurotoxicity and hematotoxicity, but one usually predominates, depending on the species of snake.
- Pit vipers have triangular or arrow-shaped heads, elliptical pupils, and characteristic pits found bilaterally midway between the eye and the nostril.
- The amount of crotalid antivenom given depends the severity of the bite. Currently, Crotalidae polyvalent immune Fab (CroFab) and F(ab′)2 (Anavip) are the antivenoms of choice for crotalid bites. Children require the same amount of antivenom as adults.
- Envenomation from exotic international snakes such as cobras, kraits, and mambas often require antivenom for life-threatening neurologic and hematologic toxicity.
- Arthropods such as hymenoptera account for more deaths from envenomation than snakes, usually as a result of allergic or anaphylactic reactions.
- Black widow spider bites are neurotoxic, causing severe pain and muscle spasms; an antivenom is available but used only in severe cases. Brown recluse spider bites cause necrotizing skin wounds.
- Nematocyst (jellyfish) stings should be neutralized with vinegar or hot water, and fish stings with hot water. Stings from venomous fish (e.g., lionfish and sting rays) are treated with circulating hot water to denature the toxin and cause vasodilation.
- Marine antivenoms are available for severe box jelly fish, stonefish, and sea snake envenomation.

FOUNDATIONS

Venomous animals account for considerable morbidity and mortality worldwide. Southeast Asia, India, Brazil, and areas of Africa lead the world in snakebite mortality. Snakes alone are estimated to inflict 2.5 million venomous bites annually, with approximately 150,000 deaths. The World Health Organization (WHO) estimates that up to 2 million people in Asia and 580,000 people in Africa are envenomated by snakes yearly. It is a challenge to estimate the worldwide morbidity and mortality resulting from other venomous animals, such as bees, wasps, ants, and spiders.

Approximately 45,000 snakebites occur annually in the United States; 7000 to 8000 are inflicted by venomous snakes, and fewer than 5 result in death. Worldwide, arthropods are responsible for 50% of venomous deaths, snakes for 30%, and spiders for 15%. Specifically, bees are responsible for the most fatalities, followed by rattlesnakes, wasps, and spiders.

The American Association of Poison Control Centers' 30-year experience shows a significant number of exposures by bite or sting but relatively few deaths. From 2012 to 2018, more than 370,000 total bites and envenomations, with 41 reported deaths, were reported to the American Association of Poison Control Centers. Although these data include most of the United States, there is no requirement that hospitals, emergency departments (EDs), coroners, or public health agencies report deaths or exposures to regional drug and poison information centers. This decline in deaths may be caused by an actual decrease in mortality or may be a result of inadequate reporting. Meaningful morbidity data, such as the number of amputations, hospitalizations, and disabilities, do not exist. The number of exposures and deaths from nonnative snakes seems to be increasing, possibly because of interest in collecting "exotic" or venomous varieties, such as cobras, mambas, and vipers.

An estimated 40,000 to 50,000 marine envenomation occur annually. In recent years, the number of injuries caused by these animals has increased dramatically because of the greater number of people living and vacationing near coastal waters, scuba divers, snorkelers, surfers, and others engaging in water sports.

In the northern hemisphere, most venomous exposures occur from April to October, which is when animals are most active and potential victims are outdoors and involved in activities that might increase their risk for envenomation. Many spider bites and exotic animal envenomation that occur indoors can take place at any time. Most deaths seem to occur in very young, elderly, or inappropriately treated patients.

Venom Delivery

Animals that have developed specific venom glands and venom delivery systems can be found in every class, including birds. The toxin and toxic apparatus vary from class to class. For example, the rattlesnake has modified salivary glands and maxillary teeth and uses this system primarily to obtain food. The bee has a modified ovipositor that is used mainly for defense. Poisonous and venomous animals are not the same and should be differentiated. Animals can be considered *poisonous* because of various toxins distributed in their tissues. For example, certain shellfish, toads, and barracuda have been known to cause death after ingestion. However, only animals with specific glands for producing venom connected to an apparatus for delivering that venom to another animal can be considered *venomous.*

VENOMOUS REPTILES

Snakes

Foundations

Of the 3000 species of snakes, approximately 800 are venomous. All venomous snakes belong to four of the 14 families of snakes—Viperidae, Elapidae, Colubridae, and Atractaspididae. Snakes are found throughout most of the earth's surface, including fresh and saltwater. The major exceptions are the Arctic and Antarctic zones, New Zealand, Malagasy, and many small islands. With recent trends in climate change, many of these geographic regions are in a state of flux and have altered snake biodiversity. The activity and native distribution of snakes

TABLE 53.1 Families of Venomous Snakes

Family	Subfamily	Examples
Viperidae	Viperinae (true vipers)	Gaboon viper, puff adder, saw-scaled viper, Russell viper
	Crotalinae (pit vipers)	Crotalus timber rattlesnake, eastern diamondback rattlesnake, western diamondback rattlesnake, sidewinder, Mojave rattlesnake
		Sistrusus pygmy rattlesnake, massasauga
		Agkistrodon copperhead, cottonmouth, bushmaster, cantil, fer-de-lance
Elapidae		Eastern coral snake, Texas coral snake, cobras, kraits, mambas
Hydrophiidae, Hydrophiianae		yellow-bellied sea snake
Colubridae		boomslang, bird snakes

are restricted to a fairly narrow range given they are poikilotherms; however, nonnative snakes, including venomous snakes, are popular pets worldwide and often transported out of their natural habitat illegally. All snakes are carnivorous, and their venom apparatus evolved for the purpose of obtaining food.

Approximately 5000 to 10,000 snakebites are reported to US poison centers every year. The incidence of reported venomous snakebites in the United States is greatest in the southern states, especially in Arizona and Texas. Within the United States, the vast majority of snakebites result from native pit vipers, although snakebites from coral snakes and nonnative species are also represented.[1]

Snakebites are often classified by the inflicting species, the age and gender of the victim, the location of the wound, and whether it followed intentional or unintentional contact with the snake. Men are more likely than women to have snakebites as a result of intentional contact, and snakebites following intentional contact are more likely to affect an upper extremity.[1] Overall, the majority of reported venomous snakebites in the United States result from unintentional contact with snakes and affect a lower extremity.[1]

In addition to native venomous snakes, imported venomous snakes are a problem throughout the United States and worldwide. In the past, only zoos, research centers, and herpetologists kept exotic venomous snakes. Today, private owners have easy access to a wide variety of exotic pets including venomous snakes through a 15 billion USD global industry in exotic animal trade. Emergency providers may lack experience treating exotic snakebites, and, depending on the species, may lack access to antivenoms crucial for patient management. In the United States, laws designed to limit exotic pet ownership have proven difficult to enforce. Approximately 30–50 snakebites from exotic venomous species are reported to US poison centers annually. Worldwide, venomous snakebites are an increasing public health threat with more than 150,000 estimated deaths annually, most occurring in tropical regions of Africa, the Middle East, Southeast Asia, and South America.

Classification and Characteristics

The four venomous families of snakes are the Colubridae, Elapidae, Viperidae, and Atractaspididae (Table 53.1). The Colubridae, although representing 70% of all species of snakes, have very few venomous members dangerous to humans; these include the boomslang and bird snake. They are rear-fanged snakes, and although many possess venom, they generally do not envenomate humans. The Elapidae are more common and include deadly cobras, kraits, mambas, and coral snakes. The Hydrophiidae are sea snakes and a subfamily of the Elapidae. The yellow-bellied sea snake, *Hydrophis platurus*, has been found off the coast of southern California, western Mexico, Japan, and the Korean peninsula, but bites from this snake are uncommon. The Viperidae, or true vipers, are represented by the Russell viper, puff adder, Gaboon viper, saw-scaled viper, and European viper. The Crotalidae, or pit vipers, are sometimes considered a separate family or subfamily (Crotalinae) of the Viperidae. Among the pit vipers are the most common American venomous snakes, such as rattlesnakes, water moccasins, copperheads, the bushmaster, cantil, and the fer-de-lance. The Atractaspididae are the mole vipers, which have side-positioned fangs; they rarely envenomate humans and are found only in Africa and the Middle East.

Pit vipers, the most prevalent venomous snakes in the United States, are native to every state except Maine, Alaska, and Hawaii. They are classified into three main groups: true rattlesnakes (genus *Crotalus*), copperheads and water moccasins (genus *Agkistrodon*), and pygmy or Massasauga rattlesnakes (genus *Sistrurus*). Pit vipers account for nearly all venomous snakebites in the United States.

The other major group of venomous snakes in the United States are the coral snakes. The eastern coral snake *(Micrurus fulvius)* is found in North Carolina, South Carolina, Florida, Louisiana, Mississippi, Georgia, and Texas. Envenomation from the eastern coral snake can be deadly. The Texas coral snake *(Micrurus tener)* and the western or Arizona coral snake *(Micruroides euryxanthus)* are found in the western United States and generally considered less dangerous than the eastern variety.

Anatomy and Identification

There are two key principles for identifying venomous snakes: only experts should handle live snakes, and even dead snakes can envenomate careless handlers.

It is not difficult to differentiate between pit vipers and harmless snakes found in the United States (Fig. 53.1). Pit vipers, as their name implies, have a characteristic pit midway between the eye and the nostril on both sides of the head. This pit is a heat-sensitive organ that enables the snake to locate warm-blooded prey. Pit vipers may be identified through other methods, but this characteristic is very consistent. The triangular shape of the head, the presence of an elliptical pupil, the tail structure, and the presence of fangs are useful characteristics but are inconsistent. The arrangement of subcaudal plates may be used for Crotalinae if the head has been damaged or is unavailable. An individual specimen may not fit the classic description, depending on the age of the snake, the time of the year, and the condition of the tail and mouthparts. Neither color nor skin pattern is a reliable method of identifying pit vipers.

Coral snakes can be readily identified by their color pattern. At first glance, they resemble one of several varieties of king snake found in the southern United States. The coral snake can be differentiated from the king snake by two characteristics: The nose of the coral snake is black, and the red and yellow bands are adjacent on the coral snake but separated by a black band on the king snake (Fig. 53.2). The popular rhyme is as follows:

Red on yellow, kill a fellow.

Red on black, venom lack.

This rhyme can be used only in the United States because there is significant color variation in coral snakes from other regions of the world.

Size is not an important factor in identifying venomous reptiles. Venomous snakes range in length from several inches to several feet. Although a 6-foot eastern diamondback rattlesnake is much more dangerous than a 10-inch copperhead, all venomous snakes are able to envenomate from birth and should be treated as though they are dangerous.

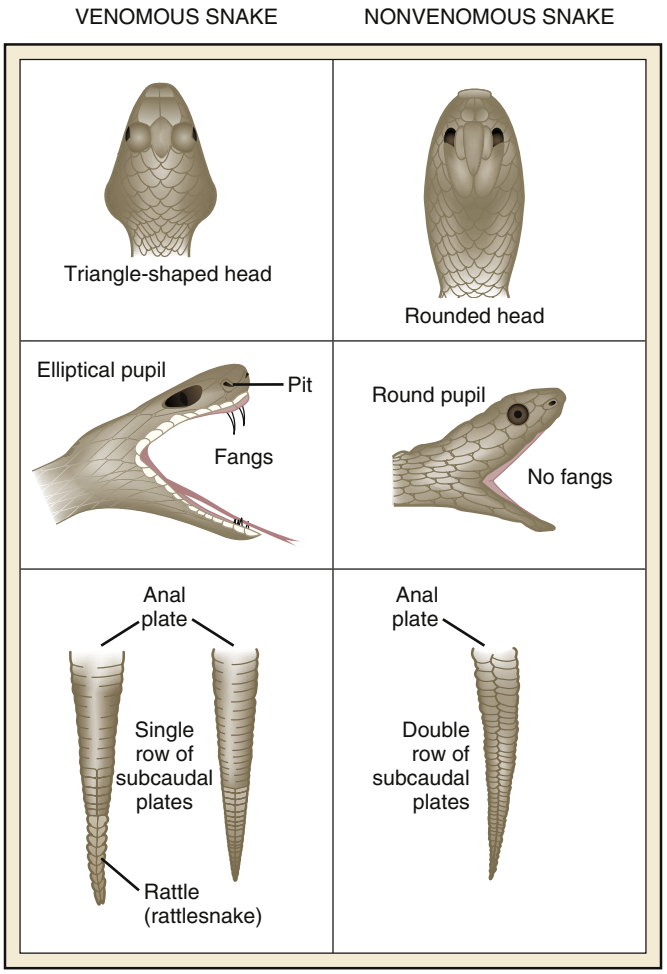

Fig. 53.1 Identification of Venomous and Nonvenomous North American Snakes.

Fig. 53.2 (A) The nose of the coral snake is black, with adjacent red and yellow body bands. (B) Body bands are separated by a black band on the scarlet king snake. (A, From Norris RL, Pfalzgraf RR, Laing G. Death following coral snake bite in the United States—first documented case (with ELISA confirmation of envenomation) in over 40 years. *Toxicon.* 2009;53(6):693–697.)

Exotic or international snakes that are *not* pit vipers are not as easily identified. If possible, rather than capturing and transporting an unidentified snake, a safe-distanced digital picture can be taken and electronically sent to an expert for positive identification. Local zoos, herpetologists, poison control centers, and universities often have resources to assist in identification of unknown snakes.

Other Reptiles

Only two venomous lizards are found in the world, both in the southwestern United States and Mexico. They are the Gila monster *(Heloderma suspectum)* and the Mexican beaded lizard *(Heloderma horridum)*. Fortunately, both of these lizards are nonaggressive and rarely encountered. Bites usually result from handling the animals in captivity and victims are usually male. The Gila monster and the Mexican beaded lizard are easily identifiable. Both have thick bodies, beaded scales, and either white and black or pink and black coloration (Fig. 53.3).

Fig. 53.3 Gila Monster *(Heloderma suspectum)*. (From Furman BL. The development of Byetta (exenatide) from the venom of the Gila monster as an anti-diabetic agent. *Toxicon.* 2012;59(4):464–471.)

Pathophysiology and Toxins

The two main factors influencing the pathophysiology of any venomous animal injury are the toxic properties of the venom and the victim's response to these toxins. In the past, snake venoms were classified as either neurotoxic or hematotoxic, depending on the observed response of the victim to the various venoms. Modern toxicologic investigation has shown that this classification is inadequate because most snake venoms contain compounds that have many toxic properties. However, it is true that the venom of a particular species of snake may cause a systemic clinical response that is predominantly neurotoxic or hematotoxic.

Between different species, the components of snake venom are variable. Between individual snakes of the same species, there is also

considerable variability of venom components depending on factors such as age, geographic location, and diet. The toxic components of snake venom include a mixture of small molecules and peptides. Peptides and proteins, which account for most of the toxic manifestations, make up to 90% to 95% of the venom. Common peptide/protein families include phospholipases A2, three-finger toxins, metalloproteases, and serine proteases.[8] Phospholipases A2 are a major component of elapid and viper venom.[2] The phospholipases A2 are a diverse group of enzymes whose activity is responsible for a wide variety of clinical effects, including neurotoxicity through inhibition of acetylcholine release from axon terminals as well as tissue damage through calcium dependent lipid hydrolysis. Metalloproteases are also major components of elapid and viper venom and have an important role in causing hemorrhage as well as local tissue damage.[2] The major component of elapid venom are the three-finger toxins.[2] The three-finger toxin family is extensive, with a wide variety of targets and resulting clinical effects including neurotoxicity and cardiotoxicity. Although there are many other protein families in snake venoms, the shared components of venoms across species have important medical implications regarding cross-neutralization by specific antivenoms and the possibility of a universal antivenom.[2]

Heloderma venom is perhaps most famous for its use in drug design. The identification of exedins in *Heloderma* venom led to the development of exanatide, a GLP-1 receptor agonist used in the treatment of diabetes. Exendins in venom functional similarly to stimulate glucose-dependent insulin release. Other components of *Heloderma* venom include phospholipases A2, helofensin, kallikrein, helofensin, and cysteine-rich secretory protein.

Venom Delivery

The mechanism for delivering venom is fairly standard among snakes. It consists of two venom glands, hollow or grooved fangs, and ducts connecting the glands to the fangs. The glands, which evolved from salivary glands, are located on each side of the head above the maxillae and behind the eyes. Each gland has an individual muscle and a separate nerve supply that allow the snake to vary the amount of venom injected. The venom duct leads from the anterior portion of the gland along the maxilla to the fangs. Pit vipers have fangs that are large anterior maxillary teeth. These teeth are hollow and rotate outward from a resting position to a striking position. The coral snake has fixed, hollow maxillary teeth that are much smaller than those of pit vipers. The fangs in most snakes are shed and replaced regularly, and it is not unusual to see a snake with double fangs on one or both sides of its mouth.

The snake can control the amount of venom injected. In biting a human, a prey much too large to swallow, the snake may inject little or no venom (a "dry" bite), especially if injured or surprised. It is estimated that up to one-third of potentially venomous bites to humans are actually "dry" bites. However, the snake may inject more than 90% of the contents of the gland for the same reasons.

Heloderma have venom glands located in the lower jaw that deliver venom through ducts into grooved lower teeth. *Heloderma* are known for prolonged, "chewing" bites.

Clinical Features

The signs and symptoms of a venomous snakebite vary considerably and depend on many factors. Clinical signs can include local tissue damage, myolysis, kidney injury, coagulopathy, cardiotoxicity, and neurotoxicity. Up to 50% of venomous snakebites result in little or no envenomation. A person with comorbidities including impaired cardiovascular, renal, or pulmonary function is less able to cope with even a moderately severe envenomation. The victim's autopharmacologic response to the envenomation must also be taken into account. An immunoglobulin E (IgE)-mediated anaphylactic-type reaction may develop in victims of a previous snakebite when reexposed to the venom or in individuals sensitized to snake proteins through frequent handling. Because of these multiple variables, the individual clinical response is the best judge of the severity of a venomous snakebite. Factors that influence the effects of a snakebite are the age, health, and size of the snake; the relative toxicity of the venom; the condition of the fangs; whether the snake has recently fed or is injured; the size, age, and medical problems of the victim; and the anatomic location of the bite. In the Americas, clinical features including time to presentation of greater than 6 hours, age 12 years of younger, bites from adult snakes, presence of ptosis, and evidence of coagulopathy on initial labs are associated with more severe envenomations.[3]

Elapidae and Hydrophiidae venoms have predominantly systemic effects, whereas Colubridae, Viperidae, and Crotalinae venoms have significant local effects. There are many exceptions to this general division. For example, the venom of the Mojave rattlesnake *(Crotalus scutulatus)* may show minimal local effects and significant systemic neurotoxic effects, whereas the venom of the Indian cobra *(Naja naja)* may cause extensive local tissue destruction.

Gila monster and beaded lizard bites are generally associated with pain, edema, and weakness. Hypotension is common with severe bites. There are no reported deaths from *Heloderma* bites, although myocardial infarctions have been reported.

Crotalids (Pit Vipers)

The most consistent symptom associated with pit viper bites is immediate burning pain in the area of the bite. Swelling typically develops minutes after envenomation and may progress for several hours to days; however, onset may be delayed. Ecchymosis, petechiae, blebs, and bullae may develop early at the site of envenomation (Fig. 53.4). The cytotoxic effects of envenomation including pain and paresthesias may suggest a developing compartment syndrome; however, a true compartment syndrome is rare in North American snakebites, even in the setting of severe edema, because most bites are subcutaneous in nature and not intramuscular. Systemic effects are generally less common but can include weakness, nausea, fever, vomiting, sweating, numbness and tingling around the mouth, metallic taste in the mouth, muscle fasciculations, and hypotension.

Hematotoxicity is especially common after North American rattlesnake envenomation. Laboratory abnormalities can include thrombocytopenia, hypofibrinogenemia, increased prothrombin time, and increased partial thromboplastin time. These laboratory abnormalities do not always correspond to clinical bleeding; however, the risk of bleeding increases with the presence of both thrombocytopenia and coagulopathy. Hypofibrinogenemia can occur for up to 2 weeks after treatment with Crotalidae polyvalent immune Fab (CroFab).

Neurotoxicity can be seen with several species of North American pit vipers including the Mojave rattlesnake *(C. scutulatus)* and Timber rattlesnake *(Crotalus horridus)*. There is significant geographic variation in Mojave rattlesnake venom; however, envenomation by snakes with venom type A (phospholipase A2 [PLA2] dependent neurotoxin [PLA2]-dependent neurotoxin) can result in cranial nerve dysfunction, skeletal muscle weakness, paralysis, and respiratory failure. Type A venom does not have significant hematotoxic effects, whereas type B venom contains a large component of fibrinogenolytic metalloproteinases responsible for hematotoxicity. Although most Mojave rattlesnakes carry one phenotype or the other, there are small populations of Mojave rattlesnakes with both type A and type B venom phenotypes. Similarly, the Timber rattlesnake has a largely neurotoxic type A venom and a proteolytic and hemorrhagic type B venom. There are small populations of Timber rattlesnakes with both type A and type B venom phenotypes.

Fig. 53.4 (A and B) Northern copperhead *(Agkistrodon contortrix mokasen)* bite on right hand with normal left hand for comparison. (C) Northern Copperhead bite to upper extremity showing diffuse swelling, and hemorrhagic bullae formation.

Coral Snakes

Signs and symptoms can vary considerably with bites of coral snakes. Coral snakes are not aggressive, and a significant number of bites are "dry bites" that do not result in envenomation. Unlike many crotalid bites, envenomation by coral snakes typically causes minimal local pain and swelling. The neurotoxic effects of the eastern coral snake are often delayed for several hours but can progress rapidly after onset. Neurologic symptoms can include ptosis, vertigo, paresthesias, fasciculations, slurred speech, drowsiness, dysphagia, restlessness, increased salivation, nausea, and proximal muscle weakness. Although rare, the usual cause of death after coral snake envenomation is respiratory failure.

Infection

Although snakebite envenomation has been stressed here, any bite or puncture wound carries a risk for secondary bacterial contamination. There are significant geographic differences in rates of secondary infection, causative microorganisms, and standard use of prophylactic antibiotics following snakebites. In the United States, the rate of secondary infection after rattlesnake bite is less than 1%.[4] The majority of bacteria isolated from these infections were human skin flora and not rattlesnake oral flora.[4] This is in stark contrast to victims of viper bites in Costa Rica, where more than 20% of patients developed secondary infection, and isolated organisms were commonly snake oral flora.[5] Secondary infections may include osteomyelitis, cellulitis, or gas gangrene, and these infections may occur with or without associated envenomation. In the United States, routine prophylactic antibiotics are not recommended; however, it is reasonable to offer patients with deep puncture wounds from any mechanism antibiotic prophylaxis if they are at high risk for secondary infection. Risk factors may include immunodeficiency, delay to care, and heavily contaminated wounds. Antibiotics for infected wounds should include gram-negative coverage for snake oral flora and coverage for human skin flora.

Differential Diagnoses

The differential diagnosis of venomous snakebites includes dry bites, bites from nonpoisonous snakes, spider and tick bites, scorpion and

hymenoptera stings, dermatologic disorders such as toxic epidermal necrolysis (TEN), Stevens-Johnson syndrome, and methicillin-resistant *Staphylococcus aureus* (MRSA) infections.

Diagnostic Testing

Diagnosis of snakebite relies largely on clinical history and examination. Diagnostic testing following pit viper envenomation should include complete blood count, prothrombin time, partial thromboplastin time, and fibrinogen levels at presentation and repeated in 4 to 6 hours. Patients with evidence of systemic illness following snakebite should also have renal function, electrolytes, and electrocardiogram (ECG) assessed. Depending on clinical presentation, a creatinine kinase and urinalysis may also be indicated. Detection of venom in blood or urine by enzyme-linked immunosorbent assay is possible, although the results of these assays are too delayed to have any clinical impact in the ED. There are no standard laboratory or imaging diagnostics recommended in suspected *Heloderma* envenomation.

MANAGEMENT

Out-of-Hospital Care

All venomous snakebites are considered an emergency, and any victim should be medically evaluated. Out-of-hospital care should focus on safely separating the victim from the snake, addressing airway compromise and abnormal vital signs, and transportation to a medical facility. A stick, pole, or other object longer than the snake can be used to move the snake away from the victim or, if necessary, to kill the snake by striking it behind the head. Any constricting jewelry or clothing should be removed from an extremity to prevent a tourniquet effect proximal to the swelling. The affected limb can be immobilized. Identification or capture of a snake should not delay transport to a medical facility and may result in repeated bites to the victim or bystanders. First responders should be aware that even dead snakes can cause envenomation.

Multiple different techniques for neutralizing venom, removing venom, or limiting the rate of systemic venom absorption have been proposed, although none have been proven to be both effective and reliably feasible.[6] Tourniquets, wound incision or excision, suction, ice water immersion, and electrotherapy should be avoided. These techniques are either directly harmful or serve as unnecessary delays to proper treatment.

Pressure immobilization bandages are used in the prehospital care of suspected neurotoxic snake envenomation in Australia. When applied correctly, this technique slows the rate of systemic venom absorption. However, multiple studies have shown that, despite training, pressure immobilization is often incorrectly executed. Pressure immobilization is not recommended in the prehospital care of North American crotalid snakebites given the potential to worsen local effects of envenomation. Animal studies have shown possible survival benefit after eastern coral snake envenomation with use of pressure immobilization; however, significant local tissue damage including necrosis not typically seen in coral snake envenomation was attributed to the use of this technique.[7] We do not recommend pressure immobilization or tourniquet application for treatment after envenomation by native North American snakes.

Emergency Department Care

Emergency care of a snakebite focuses on supportive care and rapid treatment with the appropriate antivenom when indicated. By the time the emergency clinician examines a snakebite victim, the venom may have already caused significant damage, both locally and systemically. In this case, the emergency clinician must be prepared to support the victim's cardiovascular and respiratory systems.

Patient History

Specific historical information includes time elapsed since the bite, the number of bites, whether first aid was administered and what type, location of the bite, and symptoms (e.g., pain, numbness, nausea, tingling around the mouth, metallic taste in the mouth, muscle cramps, dyspnea, and dizziness). A brief medical history includes the last tetanus immunization, medications, and cardiovascular, hematologic, renal, and respiratory problems. An allergy history with emphasis on symptoms after exposure to horse or sheep products, previous injection of horse or sheep serum, and a history of asthma, hay fever, urticaria, or allergy to wool, papain, chymopapain, papaya, or pineapple should be obtained if antivenom treatment is being considered.

Patient Examination

The bite area is examined for signs of fang marks, scratches, or bleeding and local signs of envenomation (e.g., extremity edema, petechiae, ecchymosis, and bullae). The area distal to the bite is checked for pulses. A general physical examination is performed, with emphasis on the cardiorespiratory system and the neurologic examination, especially if a Mojave rattlesnake, coral snake, or exotic snake is suspected. The leading edge of local injury should be noted and marked. If the bite involves an extremity, the circumference of the extremity at the site of the bite and approximately 5 inches proximal to the bite should be measured and recorded.

Initial Medical Care

Initial medical management of snakebites should address the patient's airway, breathing, and circulation status. Snakebite victims with or without initial clinical evidence of envenomation should have an intravenous line with normal saline placed in an unaffected extremity as onset of systemic symptoms can be delayed but precipitous.

Following crotalid envenomation, the affected limb should be immobilized and elevated to prevent dependent edema. The leading edge of injury should be serially assessed. Intravenous opioids can be given for analgesia. Tetanus prophylaxis should be administered if the patient is not current on their immunization status. Labs including complete blood count, fibrinogen, and prothrombin time are obtained during initial evaluation. The emergency clinician should then determine if there is any evidence of envenomation by local signs (swelling, ecchymosis, blebs), laboratory abnormalities, or systemic signs (hypotension, neurotoxicity, abnormal bleeding). Bedside ultrasonography can be used by trained providers in conjunction with their physical exam to assess for underlying injury and edema.[8] If signs of envenomation are present, the need for antivenom is then assessed.

Pit Viper Envenomation Classification

Crotalid envenomation may be classified according to severity into five grades, from grade 0 (no sign of envenomation) to grade IV (very severe envenomation) (Table 53.2). Patient management, including the use of antivenom, can be correlated and guided with the grade of envenomation.

Antivenom

Any victim of a pit viper snakebite with moderate or severe envenomation is a candidate for antivenom. CroFab was approved by the US Food and Drug Administration (FDA) for treatment of North American pit viper envenomations. CroFab is derived from Fab fragments of immunoglobins from sheep immunized with one of four species of pit vipers in the United States: the western diamondback rattlesnake *(Crotalus atrox)*, eastern diamondback rattlesnake *(Crotalus adamanteus),* Mojave rattlesnake *(C. scutulatus),* and the cottonmouth *(Agkistrodon piscivorus).* In 2015, the FDA approved Anavip, an F(ab′)2

TABLE 53.2 Pit Viper Envenomation Classification

Grade	Clinical Features	Antivenom	Disposition
0 (None)	No evidence of envenomation. A fang wound may be present. Pain is minimal, with less than 1 inch of surrounding edema and erythema. No systemic manifestations are present during the first 12 h after the bite. No laboratory changes occur.	No	Observe for 8–12 h. May be discharged if repeat labs are normal and no signs of envenomation develop.
I (Minimal)	Pain is moderate or throbbing and localized to the fang wound, surrounded by 1–5 inches of edema and erythema. No evidence of systemic involvement is present after 12 h of observation. No laboratory changes occur.	No	Admission for 12–24 h. Repeat labs every 6 h. May be discharged if repeat labs are normal and no signs of envenomation develop.
II (Moderate)	There is more severe and widely distributed pain, edema spreading toward the trunk, and petechiae and ecchymoses limited to the area of edema. Nausea, vomiting, and a mild elevation in temperature are usually present.	Yes	Admission to intensive care unit
III (Severe)	This may initially resemble a grade I or II, however within 12 h, edema spreads up the extremity and may involve part of the trunk. Petechiae and ecchymoses may be generalized. Systemic manifestations may include tachycardia and hypotension. Laboratory abnormalities may include an elevated white blood cell count, creatine phosphokinase, prothrombin time, and partial thromboplastin time, as well as elevated fibrin degradation products and D-dimer. Decreased platelets and fibrinogen are common. Hematuria, myoglobinuria, increased bleeding time, and renal or hepatic abnormalities may also occur.	Yes	Admission to intensive care unit
IV (Very severe)	Sudden pain, rapidly progressive swelling that may reach and involve the trunk within a few hours, ecchymoses, bleb formation, and necrosis. Systemic manifestations, often commencing within 15 min of the bite, usually include weakness, nausea, vomiting, vertigo, and numbness or tingling of the lips or face. Muscle fasciculations, painful muscular cramping, pallor, sweating, cold and clammy skin, rapid and weak pulse, incontinence, convulsions, and coma may also be observed. An intravenous bite may result in cardiopulmonary arrest soon after the bite.	Yes	Admission to intensive care unit

immunoglobulin derived from horses immunized against the fer-de-lance *(Bothrops asper)* and tropical rattlesnake *(Crotalus durissus)*. Anavip has a similar safety profile compared with CroFab and a longer half-life that results in lower rates of recurrent or late onset coagulopathy.[9] Anavip has a lower cost per vial than CroFab; however, it is unclear how many vials of Avavip will be needed for treatment of severe envenomation. Given the low rates of severe coagulopathies with copperhead envenomation, the efficacy of Anavip in treatment of copperhead envenomation is still yet to be determined. Avavip became commercially available in 2019.

A polyvalent, horse serum–derived antivenom was previously manufactured by Wyeth Laboratories for treatment of North American pit viper envenomation. Vials of this antivenom may still be found in zoos and hospitals, although most have been replaced with the ovine-derived Fab antivenom (CroFab).

The treatment of snakebites is expected to evolve as researchers discover new ways to create antivenoms. Currently, the process of creating antivenoms is highly labor intensive and antivenoms remain unavailable in many parts of the world with the most pressing need. Recently, researchers have discovered a method to culture snake venom glands from snake stem cells.[10] These cultured gland cells are functional and can secrete active toxins.[10] This breakthrough may allow for the creation of large banks of venoms for further study and also eliminate the need to "milk" venomous snakes for their venom. New research on the Indian cobra genome and transcriptome also raises the possibility of creating synthetic venom and, ultimately, a synthetic humanized recombinant antivenom.[11] At least one National Institutes of Health (NIH)-funded phase I trial is underway investigating monoclonal human-derived IgG as a potential source of a broad-spectrum, low immunogenicity antivenom (Project #1R43AI147898-01).

Dosage and Precautions

The CroFab package insert recommends an initial dose of four to six vials of CroFab intravenously (IV) as soon as possible after a rattlesnake or Crotalid bite in patients with systemic signs of envenomation or evidence of a coagulation abnormality (Table 53.3). Based on the severity of envenomation, the initial dose may be increased to a maximum dose of 12 vials. The patient should be observed for the next 1 hour to determine if initial control (defined as lack of progression in local signs of the leading wound edge, resolution in systemic symptoms, and normalization or near normalization of coagulation studies) has been achieved. If initial control is not achieved, an additional four to six vials can be administered repeatedly as needed. Once control is established, an additional two vials of CroFab are administered every 6 hours for 18 hours as maintenance. Given the high cost of antivenom, some experts will administer the maintenance vials on an as-needed basis only. This strategy can reduce intensive care unit (ICU) length of stay and the amount of antivenom administered without worsening patient outcomes; however, success rates rely on frequent bedside reevaluation by a clinician who is experienced in treating snake envenomation.[12]

The Anavip package insert recommends an initial dose of 10 vials given intravenously over 60 minutes as soon as possible after a rattlesnake or Crotalid bite in patients with signs of envenomation (see Table 53.3). A complete blood count, prothrombin time, partial thromboplastin time, serum fibrinogen, and chemistries should be obtained prior to the first dose. A repeat dose of 10 vials can be given as needed to establish initial control. Currently, there is no maximum known dose. Once initial control has been achieved, at least 18 hours of monitoring is recommended for observation of recurrence of symptoms. Initial control is demonstrated by lack of progression or improvement in local signs, resolution in systemic signs, and normalization (or near

TABLE 53.3 Antivenom Dosage for Pit Viper Envenomation

	CROFAB		ANAVIP	
Grade	**Initial**	**Maintenance**	**Initial**	**Maintenance[a]**
Moderate	4–6 vials (q1–2h until initial control achieved[b])	2 vials q6h ×3 doses	10 vials (q1–2h until initial control achieved)	4 vials (only for recurrence of symptoms)
Severe	8–12 vials (q1–2h until initial control achieved)	2 vials q6hr ×3 doses	10 vials (q1–2h until initial control achieved)	4 vials (only for recurrence of symptoms)

[a]Maintenance dosing is not required for patients who do not have recurrence of symptoms after 18 h of monitoring.
[b]Initial control is defined as lack of progression of local signs, resolution in systemic symptoms, normalization or near normalization of coagulation studies.
Anavip, crotalidae immune F(ab)$_2$ (equine); CroFab, crotalidae polyvalent immune Fab (ovine); q, every.

normalization) of coagulation studies. Return of symptoms can be treated with an additional four vials of Anavip IV.

Both CroFab and Anavip can cause severe allergic reactions. Patients who are allergic to papin, chymopapain, papaya extract, or bromelain (pineapple) may develop a hypersensitivity reaction to CroFab. Patient with allergies to sheep or horse proteins can develop anaphylactic reactions. Any evidence of hypersensitivity including wheezing, urticaria, and hypotension should be managed by immediate cessation of antivenom infusion and treatment with epinephrine, corticosteroids, and diphenhydramine as needed. Patients who are treated with a course of antivenom can become sensitized to it and should be cautiously monitored if the patient has a subsequent envenomation that requires antivenom.

The following are general guidelines to maximize patient care when antivenom is used:

1. Because anaphylaxis may occur whenever antivenom is administered, appropriate therapeutic agents (e.g., oxygen supply, airway support, epinephrine, diphenhydramine, corticosteroids, and other pressor agents such as norepinephrine) must be ready for immediate use. Any patient requiring antivenom should have two intravenous lines inserted. If an allergic reaction occurs, the line with the antivenom can be clamped and the other line used for resuscitation.
2. The pediatric antivenom dose is the same as the adult dose. A bitten child usually receives more venom in proportion to body weight and thus requires more antivenom to neutralize it. The smaller the body of the patient, the larger the relative initial dose that may be required. However, the total fluid requirements of children are lower, so the antivenom can be given in a more concentrated solution.
3. Pregnancy is not a contraindication to antivenom therapy.
4. Administration of antivenom at or around the site of the bite is not recommended.
5. The need for subsequent doses to achieve initial control is based on the patient's clinical response. The patient is monitored closely after the initial dose, and local and systemic symptoms, as well as laboratory findings, are determinants of the need for further antivenom. Additional injections of antivenom are administered every 1 or 2 hours if symptoms progress. Most hospital pharmacies do not stock large amounts of antivenom, and the pharmacy should be notified to obtain additional antivenom from surrounding hospitals or the regional poison control center for treating a severe bite.
6. Even with a history or signs of allergy, patients with severe envenomation are treated with a dilute form of antivenom and epinephrine to maximize antivenom administration but minimize allergic symptoms.
7. Consultation with an expert medical toxicologist or herpetologist should be obtained in cases of severe or complicated envenomation including allergic reactions to antivenom. Poison centers (1-800-222-1222) are an excellent resource for expert advice.

Coral and Exotic Snakes

Any patient bitten by an eastern coral snake is at risk for neurotoxicity that may not become evident for many hours. As a result, these patients require hospital admission, preferably to an ICU where they can be monitored closely for 24 hours for respiratory depression. Historically, it was recommended that all snakebite victims of the eastern coral snake *(M. fulvius)* be treated with antivenom even before any symptoms developed. North American coral snake antivenin (NACSA), a horse-derived IgG antibody, is currently in diminishing supply. Clinicians can still obtain the antivenom but might delay administration until the first signs of neurologic or respiratory compromise are observed. A local expert or certified poison center (1-800-222-1222) can help providers to determine the use of NACSA and aid in procuring it.

The stores of NACSA will eventually be depleted. Options for the future treatment of North American coral snake envenomation include prolonged supportive and respiratory care, the creation of a new antivenom, or relying on the cross-reactivity of a preexisting antivenom raised against another elapid species. Coralmyn antivenom is a polyclonal (Fab)2 fragment produced in Mexico that is obtained from horses inoculated with venom from the Black-banded coral snake *(Micrurus nigrocinctus nigrocinctus)*. Effective neutralization of both *M. fulvius* and *M. tener* venoms by Coralmyn antivenom has been demonstrated in a murine model. A murine model of *M. fulvius* envenomation was also successfully treated with an Australian tiger snake *(Notechis scutatus)* antivenom. The commercially available Australian polyvalent snake antivenom has effectively neutralized *M. fulvius* venom in another murine model.[13]

The challenges with managing bites of exotic or international snakes are threefold: Positive identification of the specimen is often difficult, even for experts; specific antivenom is not always readily available; and even if the antivenom is available, the instructions for reconstitution and dosage may not be described in English. Many zoos maintain a supply of antivenom for their exotic venomous snakes, and this may be the best source of antivenom for an exotic species. Some collectors keep appropriate antivenom on hand for the species that they collect. The Antivenom Index at the Arizona Poison Center (602-626-6016) can assist in identifying sources of exotic antivenom or in obtaining more pit viper antivenom. As with coral snakes, many patients do not show any early signs after envenomation by exotic neurotoxic snakes, so prolonged and intensive monitoring may be warranted.

Although exotic snake species are a source of concern in the United States, envenomation by these species in their native countries is a much more significant problem. The WHO estimates that up to 2 million people in Asia and 580,000 people in Africa are envenomated by snakes yearly. Many of these snakebite victims lack timely access to an

appropriate antivenom. In 2017, the WHO placed snakebites on the list of "Neglected Tropical Diseases."

Wound Care

The snakebite wound should be cleaned and examined for foreign bodies (e.g., retained fangs or teeth), the area immobilized, and proper analgesia administered. Elevation at or above heart level may relieve some of the pain. Local excision of the bitten area is not recommended. As with any puncture wound, one should ensure that tetanus immunization is current. The use of prophylactic antibiotics is previously discussed and not routinely administered with North America snakebites. Wounds should be cleansed daily with soap and water and a sterile dressing should be placed over any open wounds.

Surgical consultation may be required for management of necrotic wounds or in cases of true compartment syndrome refractory to adequate doses of antivenom. Superficial débridement of bullae allows for assessment of underlying tissue. Once necrotic tissue is identified, multiple surgeries may be needed for complete débridement of the nonviable tissue. In rattlesnake bites to the upper extremity, predictors of the development of necrosis include ecchymosis, initial cyanosis, and chronic alcohol use.[14] In the same study, cocaine use was associated with the need for surgical intervention.[14] Skin grafts are occasionally necessary after bites by pit vipers that produce large necrotic areas. Fasciotomy is rarely indicated unless compartment pressures are elevated greater than 30 mm Hg and signs of true compartment syndrome are present, which is uncommon because most snakebites involve subcutaneous layers and not deep into the musculature. Adequate doses of antivenom to lower intracompartmental pressures should be done prior to any consideration of fasciotomy in North American crotalid envenomation. Although not widely available in rural or remote settings, hyperbaric oxygen therapy is a potential adjunct to surgical management of severe snakebite wounds.[15]

Serum Sickness

Serum sickness can occur after administration of any animal protein derivative. The onset of serum sickness is typically 5 to 14 days after antivenom administration. Symptoms include fever, arthralgias, skin rash, and lymphadenopathy. Symptoms can be treated with oral antihistamines, nonsteroidal antiinflammatory drugs (NSAIDs), and corticosteroid taper. There is no role for prophylactic corticosteroids in the prevention of serum sickness.

Heloderma Envenomation

Gila monster and Mexican beaded lizard bites are treated similarly to pit viper bites with regards to first aid. No definitive medical treatment exists. Antivenom is currently not available. Local wound care, tetanus prophylaxis, use of antibiotics and analgesics, and supportive care are the extent of ED treatment for these types of envenomation.

DISPOSITION

If no envenomation is evident after a pit viper bite, the victim can be observed in the ED for 8 hours. If no sign of envenomation is seen after 8 hours and repeat diagnostic studies remain normal, the patient may be discharged home. These patients require wound care instructions as well as instructions on the types of delayed symptoms that may occur and when to return to the ED. Patients should seek medical care for worsening swelling, abnormal bleeding, signs of infection, and any development of serum sickness.

Following a minor pit viper envenomation that does not require antivenom, the patient should be monitored for 12 to 24 hours. Laboratory studies should be repeated every 4 to 6 hours. If the pain and swelling decrease and no systemic symptoms or laboratory abnormalities develop, the patient may be treated with the same precautions as a patient with no signs of envenomation. Antivenom should be considered and administered with any signs of a moderate or severe envenomation that develop during this period of observation.

Any patient with moderate or severe pit viper envenomation should be admitted for monitoring during antivenom therapy. Depending on the severity of the bite, blood products, vasopressors, and invasive monitoring may be necessary. Patients with recurrent hypofibrinogenemia following Crotalid envenomation can often be monitored in the outpatient setting; however, patients with other risk factors for bleeding may be treated with repeat doses of CroFab. Risk factors for clinically significant bleeding can include concurrent anticoagulant and antiplatelet medications, thrombocytopenia, and pregnancy.[16]

Once stable for discharge, patients who received CroFab antivenom need to be instructed to follow up for repeat laboratory testing given the risk of delayed coagulopathy. Patients should avoid high-risk activities such as contact sports and elective surgical or dental procedures. Patient treated with Anavip may not require routine follow-up testing given the longer half-life of the antivenom, but this requires further study.

Following suspected Mojave or eastern or Texas coral snake envenomation, the patient should be observed for 24 hours. Victims of unidentified exotic snakebites should also be observed for 24 hours for onset of symptoms or laboratory abnormalities. When the exotic species is identified, appropriate antivenom should be obtained if available. All patients receiving antivenom for hematotoxicity require close monitoring for recurrence of coagulopathy, which may occur several days after the initial envenomation.

VENOMOUS ARTHROPODS

Foundations

Arthropods are animals with segmented bodies and jointed appendages. The phylum Arthropoda contains approximately 80% of all known animals. The living members of this phylum are categorized into 12 classes, two of which, the Insecta and Arachnida, are of particular interest because they include numerous venomous species that are harmful to humans. The Insecta class includes wasps, bees, and ants. The Arachnida includes spiders, ticks, and scorpions. In general, arthropod species use venom as a mechanism to obtain prey or deter predators. With several exceptions, the venoms of the arthropods are largely unstudied. There is evidence that arthropod venoms evolved independently multiple times.[17]

Arthropods account for a higher percentage of deaths from envenomation than do snakes. They are found inside dwellings, as well as in deserts, forests, and lakes. Although most arthropods are more active during the warmer months, many are active throughout the entire year. Arthropods are also active 24 hours a day, and many can fly, thus increasing their range. This high level of contact results in millions of cases of envenomation annually. Most fatalities result from a hypersensitivity response by the victim rather than the toxicity of the venom. An individual stung by a bee may have a small amount of pain and local swelling or, in severe cases, an anaphylactic reaction and death.

Arthropods use three main methods of delivering venom: stinging, biting, and secreting venom through pores or hairs. Some arthropods combine multiple systems, one for offense and the other for defense. Human envenomation by arthropods is often defensive, accidental, or reflexive. Many venomous arthropods are omitted from this discussion because of their infrequent contact with humans or the relative impotence of their venom.

Fig. 53.5 Africanized Honeybee

Fig. 53.6 Female Black Widow Spider *(Latrodectus mactans)* With a Red Hourglass Marking.

Hymenoptera

Hymenoptera is a familiar order of arthropods that is composed of the families of bees, wasps, hornets, yellow jackets, and ants (Fig. 53.5). Many of these species are social insects, and their defense response is related to protection of the colony rather than the individual organism. Although most members of this order are stinging insects, several species of ants can bite and sting simultaneously. Of the more than 90,000 species of hymenoptera, less than 200 are known to envenomate humans. Of those, only honeybees, hornets, and yellow jackets are known to have killed humans through direct envenomation.[18]

Bees and wasps have similar mechanisms of delivering venom. Female insects of this type deliver venom from modified sex accessory glands through ovipositors that protrude from the abdomen. The barbed stinging apparatus of the bee is quite prominent. The stinging action pulls the stinger from the bee, thereby eviscerating the insect and killing it. The wasp, which has an unbarbed stinger, may inflict many stings without damaging itself or its stinging apparatus.

Ants can latch onto humans through a bite and then deliver a sting. In general, the stinging ants, including fire ants, cause greater symptoms in humans than those that spray noxious chemicals like formic acid. Fire ants typically sting 7 to 8 times once latched on at the bite site.

Hymenoptera venom is more widely studied than the venom of other arthropod groups. It is composed of several classes of substances varying in composition among different species. Components include enzymes such as phospholipase A and hyaluronidase, as well as biogenic amines, and peptides such as MCD-peptide and apamin. Many other antigenic substances have been identified in hymenoptera venom, and they account for the induction of hypersensitivity and anaphylaxis in humans. In the United States, 10% of all cases of anaphylaxis are attributed to hymenoptera. Purified venoms from honeybees, yellow jackets, and wasps are available to use in the diagnosis and treatment of hypersensitivity.

Spiders and Scorpions

The class Arachnida contains the largest number of venomous species known, with approximately 34,000 species of venomous spiders and 1400 species of venomous scorpions. Virtually all known species are venomous, but most are not harmful to humans. Only approximately 50 species of arachnids in the United States cause human illness, because most species do not have fangs or stingers sufficiently long to penetrate human skin. Humans commonly fear scorpions and spiders, a disorder known as arachnophobia. Ticks, which also belong to this class, are less feared but cause more morbidity because of transmission of infectious diseases, such as Rocky Mountain spotted fever and Lyme disease. Some spider bites are never diagnosed because of lack of significant symptoms and the fact that they occur while the victim is sleeping. Many nonspider bites are incorrectly diagnosed as spider bites because there is no gold standard for making an accurate diagnosis.

Black Widow Spider

The black widow spider, *Latrodectus mactans,* may be the most recognized venomous spider in the world. Several other closely related species of *Latrodectus,* or widow spiders, are found throughout the United States, including *Latrodectus hesperus, Latrodectus geometricus*, and *Latrodectus bishopi*. The diagnosis and treatment of the bites of all of these species are the same.

The black widow female is approximately twice as large as the male, and although both are venomous, only the female is able to envenomate humans. The female black widow spider is generally dark brown to glossy black, occasionally with red stripes, and has a bright red marking on the abdomen (Fig. 53.6). This marking may have an hourglass shape or may appear only as two spots. Abdominal markings may vary, and related *Latrodectus* species may be similar in appearance and toxicity. Female black widow spiders have a rounded body that is generally 8 to 10 mm in size. Window spider webs are generally in dark, protected places, such as under rocks, in woodpiles, and in outhouses and stables. The female is not aggressive except when guarding her eggs. Bites tend to occur when the web or spider is disturbed.

The venom apparatus of the black widow is a modified first appendage of the head known as the *chelicera.* The spider is able to control the amount of venom injected into its prey. Widow spider venom contains neurotoxins that effect insect and crustacean neurons, as well as one toxin, α-latrotoxin, that effects vertebrates. This toxin destabilizes neuronal membranes by opening ionic channels, causing massive exocytosis of acetylcholine, glutamate, dopamine, γ-aminobutyric acid (GABA), and norepinephrine from the mammalian presynaptic neuron.

Brown Recluse Spider

In the 1950s, several deaths were erroneously attributed to the brown recluse spider, *Loxosceles reclusa*, thus drawing the attention of the medical community. Many species of *Loxosceles*, or "brown spiders," are venomous to humans, and multiple species are found in the United States. These spiders are approximately 1 inch long, including leg span, and range in color from tan to dark brown. The most distinguishing mark is a violin-shaped darker area found on the dorsal cephalothorax (Fig. 53.7). Close examination may reveal that the brown recluse has three pairs of eyes rather than the usual four sets found in most spiders.

Fig. 53.7 Brown Recluse Spider *(Loxosceles reclusa).* (From Mullen GR. Chapter 22: Spiders *(Araneae).* In: *Medical and Veterinary Entomology.* Muller GR, Durden L (eds). 2002:427–448.)

As their name implies, these spiders are not aggressive and are usually found under rocks, in woodpiles, and occasionally in attics and closets. They do not bite unless provoked. As with widow spiders, the female *Loxosceles* spiders are more dangerous to humans than males. The typical range of the brown recluse spider is concentrated in the south-central United States, especially Missouri, Kansas, Arkansas, Louisiana, eastern Texas, and Oklahoma. However, with climate change, their geographic distribution is expanding.

The venom apparatus of the brown recluse is similar to that of most spiders, including the black widow. The composition of *Loxosceles* venom has not been completely determined; however, phospholipase D, metalloproteases, and insecticidal peptides are identified as significant components.[19,20] Toxins of the phospholipase D family (previously sphingomyelinase D) cause many of the feared complications of brown recluse envenomation, including dermonecrosis, hemolysis, and renal failure. Hyaluronidases, serine proteases, venom allergens, and serpins have also been identified, however at much lower rates of expression.[19,20]

Scorpions

Scorpions are arachnids that resemble crustaceans and are among the oldest terrestrial animals. Scorpions are found throughout the world, and several species are located in the southwestern United States. One species, *Centruroides sculpturatus*, is particularly dangerous to humans. Envenomations from *Centruroides* have been reported from several states including Arizona, Nevada, and Utah.[21] Globally, there are many other scorpion species that can cause severe envenomation in humans. Most scorpion species of medical importance belong to the Buthidae family, which in addition to *Centruroides* sp., includes several other dangerous scorpion genera including *Buthus, Parabuthus, Mesobuthus, Tityus,* and *Androctus.* Scorpions are nocturnal predatory animals that usually spend the day under rocks, logs, or floors and in crevices. *C. sculpturantus,* or the bark scorpion, is found on or near trees (Fig. 53.8).

The scorpion has a tail-like structure that is actually the last six segments of its abdomen. The last segment, or the *telson,* contains the two venom glands and stinger. The toxicity of scorpion venom varies greatly from species to species; however, the systemic symptoms from severe envenomation are generally autonomic neuroexcitatory

Fig. 53.8 Arizona Bark Scorpion (*Centruroides sculpturatus,* Formerly *Centruroides exilicauda*).

symptoms. One important component of scorpion venoms is the α-toxins, polypeptides that bind to voltage-gated sodium channels and inhibit inactivation. This prolonged depolarization results in neuronal excitation and activation of the autonomic nervous system.

CLINICAL FEATURES

Hymenoptera

The signs and symptoms of bee and wasp stings vary, depending on the degree, type, and location of envenomation, as well as the characteristics of the victim. Allergic reactions, not direct venom toxicity, are typically the major clinical concern following hymenoptera envenomation. However, it is important to note that bees and wasps can cause serious injury other than allergic types of reactions, depending on the number of stings, the species of insect, the size and previous health of the victim, and the anatomic area stung. Clinically significant envenomation, with the exception of those causing allergic reactions, often require a massive number of stings resulting in venom toxicity.[22] Certain species of honeybee release a pheromone, isoamyl acetate, when the ovipositor is pulled from the abdomen after stinging a victim. This pheromone attracts other bees to the victim and thus incites multiple stings.

The most consistent finding is immediate pain at the site of the sting, followed by local swelling, redness, and itching. A sensitized victim may experience swelling, urticaria, coughing, wheezing, coma, and respiratory arrest. Some large and especially venomous hornets have been known to cause muscle necrosis, rhabdomyolysis, and renal damage. In addition, cerebrovascular accidents, intracranial bleeds, and myocardial infarction have been described following hymenoptera envenomation.[23] Most serious reactions to bee stings occur in the first 30 minutes; however, the local effects of a sting may persist for 2 or 3 days. Delayed hypersensitivity may occur 7 to 10 days after the sting.

There is little antigenic overlap among hymenoptera species, which may explain the variability in reaction to stings reported by victims. For example, victims who are allergic to honeybees and who mistakenly identify a yellow jacket as a honeybee may not have a systemic reaction and thus may think that they are no longer allergic to honeybees.

Africanized Bees

Africanized bees, or "killer bees," are a hybrid species of the East African lowland honeybee *(apis m. scutellata)* and the western honeybee. Africanized bees were first bred in the 1950s in an effort to increase honey production. In the 1950s, multiple swarms of these hybrid bees were released from a facility in Brazil and have since spread rapidly

through the Americas. Africanized bees are not more toxic than the western, or European, varieties; however, they do display different behaviors. Africanized bees are more easily provoked and have a tendency to attack in massive numbers. Multiorgan system failure can result in the days following severe envenomation (hundreds of stings). Moderate envenomation (50 to 200 stings) typically causes nausea, vomiting, anxiety, tachycardia, hypertension, rhabdomyolysis, and kidney injury. Envenomation from Africanized bees is most dangerous to very young or elderly patients and those with comorbidities.

The Asian or Japanese giant hornet *(Vespa mandarinia)* is one of the world's largest hornet. It is native to tropical areas of east and southeast Asia in including the Russian Far East. In 2019, it was sighted in the Pacific Northwest of the United States and Canada as an invasive species. Popular media have coined the term "murder hornets" because it kills and feeds on other large insects and honeybee colonies. Although rare, human fatalities from multiple stings have been reported in Asia.

Fire Ants

Another venomous hymenoptera in the United States is the fire ant (Family Formicidae). Several species of fire ant are known, some native to North America and some imported. The species responsible for 95% of clinical cases, *Solenopsis invicta,* was imported from Brazil to Alabama in the 1930s. This ant is now found in nine southern states and is replacing many native species and inhabiting new niches. The limiting factor keeping *S. invicta* from progressive migration is cold winter temperatures, but with climate change, their ranges are increasing northward. This ant is small and light reddish brown to dark brown. Its venom is unique to the animal kingdom in that 95% of its components are alkaloids, mostly 2,6-disubstituted piperidines. The remaining fraction of venom is made of proteins which are immunogenic and can sensitize an individual to the venom. Properties of this venom include hemolysis, depolarization of membranes, activation of the alternative complement pathway, and general tissue destruction. A fire ant sting is produced when the ant bites the victim with its jaws and, while holding tight, pivots around and stings the victim with its ovipositor. The sting usually produces a sterile pustule within 24 hours. Other symptoms include local burning, redness, and itching. With victims of multiple stings and in sensitized individuals, urticaria, angioedema, dyspnea, nausea, vomiting, wheezing, dizziness, and respiratory arrest may occur. Approximately half of victims have some degree of hypersensitivity reaction, including late cutaneous allergic reactions. Although the invasive species of fire ants are most often implicated in clinically significant stings, envenomation by native species of the fire ant, including *Solenopsis aurea*, has resulted in severe systemic toxicity, including disseminated intravascular coagulation.[24]

Black Widow Spider

The classic symptomatology of the black widow bite is initially a pinprick sensation that may be followed by minimal local swelling and redness. Bites are most common on the extremities, especially the lower extremities, and rare on the trunk.[25] If the area is examined closely, two small fang marks may be noticed. Sometimes the bite is not felt, especially if the victim is working or active when the bite occurs. From 15 minutes to 1 hour later, dull crampy pain develops in the area of the bite and gradually spreads to include the entire body. Usually, the pain is concentrated in the chest after upper extremity bites or in the abdomen after lower extremity bites. The abdomen may become rigid, and the patient may complain of severe crampy pain. The abdominal manifestation may mimic pancreatitis, peptic ulcer disease, or acute appendicitis. Pregnant women may go into premature labor and precipitous delivery. Associated symptoms include dizziness, restlessness, ptosis, nausea, vomiting, headache, pruritus, dyspnea, conjunctivitis, facial swelling, sweating, weakness, difficulty speaking, anxiety, and cramping pain in all muscle groups. Priapism has been reported in children. Children with priapism are also affected by more common symptoms of latrodectism, including abdominal pain and tachycardia.[26] The patient is usually hypertensive, and cerebrospinal fluid pressure can be elevated. Although extraordinarily painful, death from latrodectism is rare.

The signs and symptoms of black widow envenomation typically begin to abate after several hours, and residual muscle cramping usually resolves in 2 or 3 days. Small children and adults with preexisting cardiovascular or cerebrovascular disease are at greater risk of complications.

Brown Recluse Spider

The symptoms of a brown recluse spider bite are both local and systemic. Initially, the victim may notice some burning pain in the area of the bite. Some victims do not notice the initial bite at all. In minor envenomation, a localized cytotoxic reaction may occur, and skin findings may be limited to a small papule or localized urticaria. The vast majority of brown recluse bites do not progress past this stage. With more significant envenomation, pain usually develops within 3 to 4 hours, and a white area of vasoconstriction begins to surround the bite. A bleb then forms in the center of this area, and an erythematous ring arises on the periphery. The lesion at this stage resembles a target or "bull's-eye." The bleb darkens, necroses over the next several hours to days, and continues to spread slowly and gravitationally, with involvement of skin and subcutaneous fat. Eschar formation typically occurs after 7 to 14 days. Systemic symptoms may develop and include fever, chills, rash, petechiae, nausea, vomiting, malaise, and weakness. Hemolysis, thrombocytopenia, shock, jaundice, renal failure, hemorrhage, and pulmonary edema are signs of severe envenomation. Skin findings do not predict systemic symptoms. Although rare, fatalities are more common in children, which are most often the result of severe intravascular hemolysis.

Scorpions

Scorpion envenomation causes severe and immediate pain at the sting site. Local edema and erythema may or may not be present, depending on the species. After envenomation by *C. sculpturatus,* the victim may have heightened sensitivity to touch in the area of the sting along with local numbness, weakness, and muscle fasciculations. Wound necrosis is not typical of most scorpion stings; however, delayed necrosis is common after envenomation by *Hemiscorpius lepturus* scorpion of Iran.

Systemic symptoms may then develop. Autonomic excitation includes both early cholinergic parasympathetic effects such as diaphoresis, lacrimation, and diarrhea, as well as the adrenergic sympathetic effects of tachycardia, hypertension, and restlessness that dominate the later course of toxicity. Peripheral nervous system excitation is especially common in *C. sculpturatus* envenomation and includes "roving eye movements" and thrashing of the extremities. Increased sympathetic tone results in tachydysrhythmias, ectopy, and ST and T wave changes on ECG. Direct cardiac toxicity is not a feature of *C. sculpturatus* envenomation.

Symptoms of *C. sculpturatus* envenomation typically peak within 5 hours of the sting and may persistent for 30 hours. Pediatric patients tend to have more severe symptoms and a more rapid onset of systemic systems.

DIFFERENTIAL DIAGNOSES

Hymenoptera

The differential diagnosis of hymenoptera envenomation include stings from honeybees, wasps, hornets, yellow jackets, fire ants, scorpions, centipedes, millipedes, caterpillars, spider bites, infectious causes such

as cellulitis, and other allergic reactions, including anaphylaxis and contact dermatitis.

Black Widow Spider

The manifestations following a black widow spider bite may mimic an acute surgical abdomen, renal colic, mesenteric ischemia, tetanus, scorpion stings, myocardial ischemia, or severe alcohol or opioid withdrawal.

Brown Recluse Spider

The differential diagnosis of a brown recluse spider bite includes pyoderma gangrenosum, furuncles, viral and fungal infections, and foreign body reactions. Cutaneous anthrax has been misdiagnosed as brown recluse envenomation. The most common mimic of *Loxosceles* or other necrotic spider bite are skin and soft tissue infections, including MRSA. Other spider species, such as the orb weaver, can also cause necrosis.

The mnemonic NOT RECLUSE has been proposed to avoid false diagnosis of brown recluse bites as is as follows[27]:

N—Numerous. Bites from the brown recluse are typically solitary.
O—Occurrence. Most brown recluse bites occur after the spider is disturbed from a quiet, covered place such as a box or unused clothing.
T—Timing. Most bites in North America occur between April and October.
R—Red Center. Envenomation results in destruction of the capillary bed. The center of a recluse bite will be pale, blue, or purple.
E—Elevated. Brown recluse bites are typically flat or sunken.
C—Chronic. Only the most severe and largest brown recluse bites will have not healed by 3 months.
L—Large. Necrosis from recluse bites very rarely extends past 10 cm.
U—Ulcerates too early. Brown recluse bites typically ulcerate between 7 and 14 days.
S—Swollen. Brown recluse bites do not cause significant swelling, except when the bite is to the face or feet.
E—Exudative. Brown recluse bites are typically dry.

Scorpions

The differential diagnosis of scorpion stings includes black widow spider bites, centipede stings, and hymenoptera stings, such as bees, wasps, and fire ants.

DIAGNOSTIC TESTING

Hymenoptera

Most cases of hymenoptera stings present with localized reactions and require no diagnostic studies. Severe reactions, infections, and anaphylaxis should have a complete blood count, serum electrolytes, and their acid-base status assessed. Those demonstrating severe allergic reactions should be referred for more comprehensive allergy skin testing.

Black Widow Spider

Routine testing is not recommended in black widow envenomation; however, patients with significant comorbid conditions may benefit from laboratory testing to assess for potential complications of latrodectism. These tests may include a complete blood count, electrolytes, blood urea nitrogen, creatinine, coagulation studies, urinalysis, and an ECG. There may be electrocardiographic changes similar to those produced by digitalis. Aside from advanced forensics analysis, there are no commercially available tests to diagnose black widow envenomation.

Brown Recluse Spider

Enzyme-linked immunosorbent assay (ELISA) for *Loxosceles* venom exists but is not commercially available for clinical use in the United States. The diagnosis of a brown recluse bite depends on a consistent clinical presentation, an observed spider bite, and identification of the spider as a brown recluse. In nonendemic areas, brown recluse envenomation should not be suspected absent an observed bite from an identified brown recluse spider. When significant wounds or systemic symptoms are present, a complete blood count, renal function tests, electrolytes, coagulation profile, hepatic function profile, creatine kinase, and urinalysis are recommended. With evidence of hemolysis, a type and screen, haptoglobin, fibrin split products, D-dimer, and fibrinogen should also be considered.

Scorpions

A serum Western blot test has been developed that can differentiate various scorpion venoms and thus help with diagnosis of *Centruroides* species, but it is not commercially available. Patients with minor, localized symptoms do not need routine laboratory testing. Laboratory testing for more severely symptomatic patients will depend on the envenoming species and may include a complete blood count, renal function test, serum electrolytes, liver function tests, urinalysis, lipase, troponin, and an ECG.

MANAGEMENT

Prehospital Care

Hymenoptera

First aid for Hymenoptera envenomation depends on the degree of reaction to the sting. For simple stings, an ice bag wrapped in a towel and applied to the sting area usually relieves the pain and swelling. In the event of an anaphylactic reaction, basic life support is administered until further medical help arrives. If available, epinephrine 1 mg/mL (1:1000) solution should be administered intramuscularly. Any patient who improves with epinephrine prehospital still requires emergency evaluation.

Black Widow Spider

First aid for a black widow spider bite consists of applying an ice pack to the bite area for relief of pain and transporting the victim to a hospital where supportive, symptomatic, and definitive treatment can be administered. The patient is monitored en route to the hospital, and basic life support is initiated if necessary. Bites in the neck or mouth area may cause airway compromise through muscle spasm.

Brown Recluse Spider

The specimen is secured or photographed for later identification, and the victim is transported to a medical facility. Because the lesion develops over a period of days, local treatment of the lesion in the acute setting is generally ineffective.

Scorpions

First aid for a scorpion sting consists of applying an ice bag to the area of the sting and transporting the victim to the hospital. History includes the circumstances surrounding the sting, any previous medical problems, and a description of the scorpion or digital image (if one can be safely obtained). It is relatively difficult for a layperson to differentiate the various scorpions. Capturing or attempting to identify a specimen should not delay transport to the hospital.

Emergency Department Care

Hymenoptera

No specific antivenom exists for Hymenoptera stings. Treatment consists of local wound care and general supportive measures. When possible, any retained stinging apparatus should be removed. A history

of previous allergic reactions to bee stings, hay fever, asthma, or drug reactions is obtained. The circumstances surrounding the sting and the number and location of stings are noted. In patients with a local reaction, an ice bag is typically sufficient treatment. Local reactions can extend a few centimeters from the site of the sting and typically improve over the course of hours to days. Larger local reactions are an exaggerated local response to envenomation. These reactions tend to worsen for the 2 days following the sting before gradually improving. Ice bags, steroid tapers, NSAIDs, and oral antihistamines can be used in the treatment of large local reactions. Standard treatment of anaphylaxis including epinephrine 0.3 mg (1 mg/mL) through intramuscular injection should be initiated in adults with evidence of a systemic reaction such as dyspnea, hypotension, generalized urticaria, flushing, or edema. Careful attention to the patient's airway and hemodynamic status is essential. In addition to epinephrine, patients with systemic reactions can be treated with H1 and H2 blockers. Bronchodilators should be given for bronchospasm. Glucocorticoids have traditionally been used in the treatment of anaphylaxis; however, their routine use is no longer recommended. Glucocorticoids do not address the initial symptoms of anaphylaxis and do not prevent biphasic reactions. Intravenous epinephrine is indicated when anaphylaxis is refractory.

Treatment of allergic reactions to fire ant stings is similar to bee stings. The skin lesions should be kept clean with soap and water and the patient should encouraged not to open any pustules. Ice bags may be applied initially to relieve burning and pain. Antihistamines are recommended for pruritis. Prophylactic antibiotics are not indicated.

Black Widow Spider

Emergency care consists of obtaining a history of the circumstances surrounding the bite, a description of the appearance of the spider, any significant past medical history, current medications, and allergies to insect bites, horses, or horse serum. The wound site is inspected for fang marks and cleansed with soap and water. As with any puncture wound, the patient's tetanus immunization status is assessed.

Symptomatic treatment involves controlling the muscle cramps responsible for most of the discomfort associated with the bite. Intravenous opioid analgesics and benzodiazepines are administered as needed for relief for severe symptoms. Calcium gluconate, dantrolene, and muscle relaxants are not recommended given the lack of supporting evidence. Antivenom should be considered in high-risk patients and in those with refractory symptoms despite adequate doses of benzodiazepines and opioids.

Latrodectus Antivenom

In general, young children, pregnant patients, the elderly, and those with persistent severe symptoms are candidates for *Latrodectus* antivenom. The available antivenom is an equine-derived IgG directed against *L. mactans*. Although most effective if used early in the clinical course, symptom resolution has occurred with administration up to 3 to 4 days after envenomation. The dose of antivenom is one 2.5-mL vial diluted in 10 to 50 mL of normal saline and administered IV over a period of 15 to 30 minutes. Intramuscular administration is not recommended.

Latrodectus antivenom IgG is composed of whole equine immunoglobulin and does carry a risk of anaphylaxis and serum sickness. It is also in short supply in the United States. Skin testing does not exclude a life-threatening allergic reaction and is therefore not recommended. Latrodectism itself is generally not life threatening, so the risks and benefits of giving the antivenom should be carefully considered. Consultation with a local expert or poison center (1-800-222-1222) is recommended prior to the use of *Latrodectus* antivenom.

The efficacy and safety of a highly purified equine F(ab′)2 antibody black widow spider antivenom is currently being investigated. Preliminary studies show promising results; however, further studies are needed to assess for safety and efficacy.[28]

Brown Recluse Spider

Emergent evaluation involves a history of the circumstances surrounding the bite; the time elapsed since the bite; past history of allergic reactions, medications, or medical problems; and an assessment for systemic toxicity. If the actual spider is available, identification may be facilitated by recruiting the expertise of a local entomologist. The wound is washed with soap and water. Ice, elevation, analgesia, and antihistamines may alleviate initial symptoms. If signs of systemic toxicity develop, an intravenous line is placed in an unaffected extremity. Vital signs and urine output are closely monitored. Excision of the lesion has not been shown to aid healing and may actually be detrimental to long-term healing. Although rare, lesions have been known to cause extensive scarring, infection, and necrosis. Bites that are in fatty areas, such as the thigh or buttocks, may cause more extensive necrosis. Surgical consultation should be obtained for evaluation of the wound; however, surgery is often delayed until clear wound demarcation has occurred.

Hyperbaric oxygen has been used successfully in humans to treat nonhealing wounds caused by brown spider bites.[29] Vacuum-assisted wound closure has also been used successfully for healing of necrotic wounds. Historically, dapsone, 50 to 200 mg/day, was thought to help prevent the local tissue effects of brown recluse venom. However, dapsone may cause methemoglobinemia and hemolysis (particularly in patients with glucose-6-phosphate dehydrogenase [G6PD] deficiency), and its effectiveness has never been clinically validated. As a result, we do not recommend routine use of dapsone in patients suffering brown recluse spider bites. There is no role of prophylactic antibiotics, and the use of antibiotics should be limited to treating any secondary infections. Patients who develop rhabdomyolysis should be treated with isotonic fluids to maintain adequate urine output, typically 200 to 300 mL/hr. As with the treatment of other etiologies of heme-associated renal injury, close monitoring for signs of fluid overload is essential during aggressive fluid administration. Although rare, hemodialysis may be necessary if acute renal failure develops. Hemolysis is generally self-limited; however, plasma exchange has successfully to treat refractory hemolysis after a brown recluse spider bite.[30] The Instituto Butantan in Sao Paulo, Brazil, and Instituto Bioclon, Mexico, both produce an antivenom for *Loxosceles* sp. bites, but they are not currently available in the United States.

Scorpions

Further management of North American *Centruroides* scorpion envenomation, including the use of antivenom, can be correlated with the grade of envenomation (Table 53.4). Grade 1 and 2 envenomations are treated with local wound care and analgesia. Tetanus prophylaxis should be given if the patient is not current on his or her immunization status. *Centruroides* antivenom is indicated for grade 3 and grade 4 envenomations. Anascorp (*Centruroides* [scorpion] immune F[ab]2 equine injection) is horse serum derived and has been shown to be effective and safe in both blinded and open clinical trials. Most studies investigating the effectiveness of antivenom (Anascorp) focus on children and young adults, which corresponds to the population more often severely affected by envenomation and more likely to require antivenom.[31] At 4 hours after Anascorp administration, a significantly greater number of patients have resolution of symptoms compared to those who are not treated with antivenom.[31] In general, Anascorp antivenom is not considered an essential life-saving intervention in adults, and supportive measures are typically sufficient. However, if Anascorp is indicated, the initial dose is 3 vials given intravenously as soon as possible after a scorpion envenomation. An additional vial may be administered every 30 to 60 minutes as needed.

TABLE 53.4 North American *Centruroides* Scorpion Envenomation Grading

Grade	Clinical Features	Antivenom[a]
1	Local effects only, including pain and paresthesias at the site of envenomation	No
2	Local and remote pain and paresthesias	No
3	Cranial nerve dysfunction OR skeletal somatic neuromuscular dysfunction. Cranial nerve dysfunction may include dysphagia, abnormal eye movements, drooling, dysphagia, slurred speech. Skeletal muscle dysfunction may present as jerking/writhing of extremities, opisthotonos, emprosthotonos, and restlessness. Autonomic dysfunction is common at this grade and includes tachycardia, bronchoconstriction, salivation, and diaphoresis	Yes
4	Cranial nerve dysfunction AND skeletal somatic neuromuscular dysfunction	Yes

[a]Anascorp (*Centruroides* [scorpion] immune F[ab]2 equine antivenom).

Supportive measures after any severe envenomation include adequate analgesia, cardiorespiratory support, and relief of neuromuscular hyperactivity. Acetaminophen and NSAIDs may be sufficient for minor symptoms; however, opioid analgesia (e.g., fentanyl) may be necessary for more severe symptoms. Benzodiazepines such as midazolam or diazepam should be used for severe anxiety and muscle hyperactivity if antivenom is not used. Nitroglycerin can help to reduce preload and afterload in patients who develop pulmonary edema. Ventilatory assistance may be necessary, especially in children. Prazosin has been effective, especially in addition to antivenom, for treatment of catecholamine excess and cardiovascular compromise in *Mesobuthus tamulus* stings.[31] This species of scorpion is found in India, Nepal, and Pakistan. Use of atropine is limited to specific species such as *Parabuthus transvaalicus,* which can cause acute cholinergic toxicity.

DISPOSITION

Hymenoptera

After a hymenoptera sting, the patient is monitored, and if no further reaction is observed, they may be discharged home with instructions to return to the ED if wheezing, dyspnea, hives, dizziness, or dysphagia occurs. Any patient requiring epinephrine should be watched for at least 6 hours and may require 24-hour observation if symptoms recur. There is a possibility of recurrence of the reaction up to 72 hours, and patients should be warned of this accordingly. Patients who present with systemic hypersensitivity symptoms after hymenoptera sting should be referred for allergy testing and possible immunotherapy. These patients should be prescribed an epinephrine autoinjector and educated regarding its proper use.

Black Widow Spider

A victim of a black widow spider bite is generally observed for approximately 6 hours. If symptoms do not develop, the patient may be discharged with instructions to return to the ED if any symptoms develop. Otherwise, healthy patients with only mild symptoms of envenomation after 6 hours can be managed as an outpatient with oral analgesia. Patients with moderate or severe symptoms are admitted to the hospital and treated until symptoms subside, usually within 24 hours. Fetal monitoring is initiated for pregnant women.

All patients should be educated on basic wound care and the signs of infection at the time of discharge. Patients who received antivenom should also be counseled to seek medical attention for any symptoms or serum sickness, such as fevers, arthralgias, or rash.

Brown Recluse Spider

Patients with expanding wounds or signs of systemic envenomation require hospital admission for wound care, monitoring, and serial laboratory testing to assess for hematotoxicity.

Scorpions

It is recommended that victims with systemic symptoms be observed for 24 hours and that young children be admitted to the hospital for monitoring. Patients with localized pain at the site of the sting can be given pain medications and discharged home with wound care instructions. All patients who have been treated with Anascorp are at risk of developing serum sickness and should be instructed to monitor for symptoms such as rash, arthralgias, and fevers.

Other Arthropods

More than 40 different species of ticks have been implicated in tick paralysis, a progressive ascending paralysis in humans and animals. The two species responsible in the United States are *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick). The precise mechanism and structure of the *Dermacentor* toxins are unclear; however, neurotoxins appear to cause weakness through disruption of sodium flux across axonal membranes. The bite of the tick is usually painless, but the victim later has difficulty walking, weakness, flaccid paralysis, slurred speech, and visual disturbances. The victim is usually a child, often with a history of recent outdoor activity. Treatment is removal of the offending tick. Patients often start to improve within hours after removal of *Dermacentor* ticks; however, symptoms may continue to worsen for days after removal of *Ixodes holocyclus.* For further description of tick-borne illness, including Lyme disease (from *Ixodes scapularis* and *Ixodes pacificus*) see Chapter 123.

Several species of beetle, millipede, and caterpillar secrete irritating substances that cause severe burning pain, numbness, pustular contact dermatitis, edema, nausea, vomiting, and headache. Oropharyngeal exposure can cause mucosal edema and irritation. Deaths have rarely been reported. Treatment consists of washing the area thoroughly with soap and water and removing any spines or hairs present. Analgesics should be used as needed, and supportive therapy may be necessary for severe envenomation.

Centipedes can inflict bites that cause erythema and edema. Treatment is usually local soaks and the use of analgesics. Conenose bugs, or "kissing bugs," may cause severe local and systemic allergic reactions. Treatment with antihistamines and supportive care, depending on the degree of reaction, is generally all that is necessary. Many other arthropods can cause local skin reactions and severe allergic reactions, depending on the individual's sensitivity. Patients are treated symptomatically with local steroid creams, antihistamines, and other symptomatic supportive measures.

VENOMOUS MARINE ANIMALS

Foundations

Almost 2000 species of animals found in the ocean are either venomous or poisonous to humans. The majority of marine envenomation

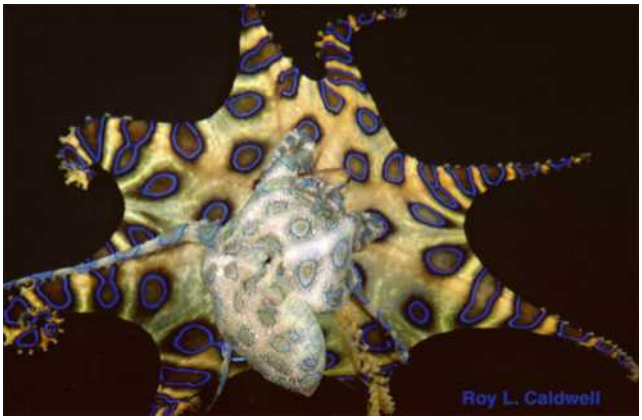

Fig. 53.9 Blue-Ringed Octopus (*Hapalochlaena maculosa*). (From Cheng MW, Caldwell RL. Sex identification and mating in the blue-ringed octopus, *Hapalochlaena lunulata*. *Animal Behavior*. 2000;60(1):27–33.)

are minor and do not require medical attention; however, many can produce severe illness or fatalities. An estimated 40,000 to 50,000 marine envenomations occur worldwide annually. In recent years, the number of injuries caused by these animals has increased dramatically because of the greater number of people living and vacationing near coastal waters, scuba divers, snorkelers, surfers, and others engaging in water sports. These animals are not typically aggressive, and many are completely immobile. Most of the venomous marine animals injure humans with defensive or food-procuring devices. Most venomous marine animals in the United States are found along the California, Gulf of Mexico, and southern Atlantic coasts. These creatures range in complexity from sponges to bony fishes and contain some of the most complex and toxic venoms known.

Pathophysiology and Venom Delivery

In general, venomous marine animals are divided into three main classes according to the mechanism of venom delivery: bites, nematocysts, and stings.

Bites

Biting animals include several species of cephalopods, most often octopuses. Several fatalities have been reported after a bite by the blue-ringed octopus, *Hapalochlaena maculosa*, a small octopus found in the shallow waters of the Indo-Pacific (Fig. 53.9). Most victims are bitten on the upper extremity because they disturb this normally nonaggressive creature. The octopus has a pair of modified salivary glands that secrete venom into puncture wounds produced by the animal's parrot-like beak. The venom contains tetrodotoxin, a potent sodium channel blocker, which causes neurologic symptoms within minutes of envenomation. No known antivenom exists, and treatment is largely supportive, with respiratory support being the most important lifesaving intervention.

Nematocyst

The second type of venom delivery is the nematocyst, a microscopic stinging organelle found in members of the phylum Cnidaria. This group of animals includes the Portuguese man o' war, true jellyfish, fire corals, stinging hydroids, sea wasps, sea nettle, and anemones. Most of these organisms are sessile, but some are free floating. Because of their large numbers, this group accounts for the greatest number of envenomations by marine animals.

Many different types of nematocyst are known, but the basic mechanism is a "spring-loaded" venom gland that can, on mechanical or chemical stimulation, suddenly evert and discharge a structure that penetrates the prey and delivers the venom through a connecting tube. Tentacular nematocysts can number in the thousands. Tentacles can be more than 100 feet long in giant species such as the Portuguese man o' war. Nematocysts can still function even if the animal is dead or if the tentacles are separated from the animal's body. These stinging organelles can remain active for weeks after an animal becomes beached. Nematocysts fire on initial contact but may also discharge later during attempted rescue and treatment. Certain marine species have evolved methods of using ingested nematocysts for their own secretory defense.

Toxicity

Nematocyst venom contains various peptides, phospholipase A, proteolytic enzymes, hemolytic enzymes, quaternary ammonium compounds, serotonin, and other toxic compounds. The severity of the envenomation can range from localized skin eruptions to life-threatening reactions. The severity of the reaction depends on multiple variables, including the envenoming species, the number of nematocysts discharged, the duration of exposure, the affected body part, and the victim's individual reaction to the envenomation.[32] Most envenomations produce minimal symptoms, and the danger is either drowning after being stung or an allergic reaction to the venom.

Clinical Features

Symptoms may range from simple isolated stings to respiratory paralysis, cardiovascular collapse, and death. The victim's autopharmacologic response to the venom may turn a relatively minor envenomation into a fatal anaphylactic reaction. Any clinician who regularly treats this type of injury should become acquainted with the common species indigenous to their region. The appearance of the wound is unlikely to aid in the clinical diagnosis.

Although potentially lethal jellyfish exist worldwide, the extremely toxic specimens are found in the Indo-Pacific waters and include the Australian box jellyfish or "sea wasp" *(Chironex flickeri)* and Irukandji *(Carukia barnesi)*. *C. flickeri* (Fig. 53.10) is responsible for several deaths along the Australian coast annually. Envenomation results in immediate severe pain with characteristic linear welts in a "frosted ladder" or crosshatched pattern. Skin ulceration and necrosis follows in 1 to 2 weeks. Systemic effects include muscle spasm, nausea, vomiting, malaise, pulmonary edema, and hemodynamic instability. Respiratory failure and cardiac arrest can occur within minutes of exposure. Envenomation by *C. barnesi* produces a devastating condition known as *Irukandji syndrome.* The initial sting is often not appreciated; however, symptoms typically become apparent after 30 minutes. Signs and symptoms are consistent with catecholamine excess and include back pain, muscle pain, difficulty breathing, nausea and vomiting, diaphoresis, and anxiety. Two known deaths have been attributed to Irukandji envenomation. Since initial description in the 1950s, Irukandji syndrome has been linked to multiple other jellyfish species globally.

Portuguese man o' war *(Physalia physalis)* are found along the southern coastline of the United States. The Portuguese man o' war is not a true jellyfish but a hydroid colony. Envenomation is usually limited to local pain, scarring, and paresthesias, but it may progress systemically to nausea, headache, chills, and even cardiopulmonary collapse. This organism has also been responsible for several deaths.

Stings

Some marine animals cause a "sting" that is produced by a specialized apparatus that punctures the victim's skin and then introduces venom. Common examples of this type of animal are sea urchins, cone shells, bristle worms, crown-of-thorns starfish, stingrays, lionfish, weever fish,

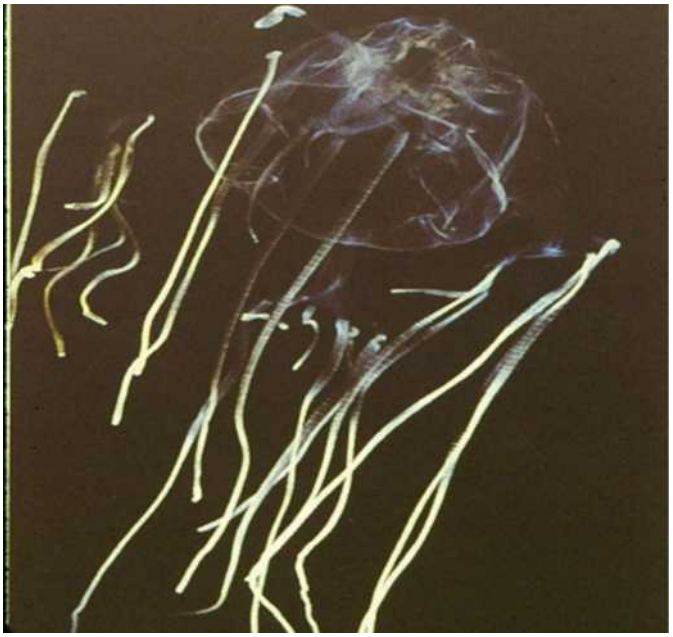

Fig. 53.10 Box Jellyfish or Sea Wasp *(Chironex fleckeri).*

catfish, stonefish, rabbit fish, and zebra fish. Deep injuries may be complicated by infection and retained foreign bodies.

Sea Urchins

Sea urchins belong to the Echinodermata phylum along with starfish and sea cucumbers. These animals produce injury and envenomation mostly through toxin-coated spines. These spines often break off and introduce calcareous material and debris into the wound, thereby potentiating infection. Symptoms often include severe local burning, pain, and discoloration, but they may progress systemically in some patients. The degree of envenomation is usually related to the number of spines involved and the species of animal encountered.

Cone Shells

Cone shells are much more toxic than sea urchins, and some species have been responsible for fatalities in the Indo-Pacific region. The venom apparatus is a tubular gland that connects to several teeth at the end of a retractable proboscis. All envenomations reported have occurred in people handling the shells. The venom typically contains hyalurondiase and multiple different toxic peptides known as conotoxins or conopeptides. Conotoxins have various different targets, including ion channels, ligand-gated channels, G-coupled proteins, and neurotransmitter transporters. Symptoms most often include pain on contact, depending on the species. Severe envenomation may cause diplopia, slurred speech, numbness, weakness, paralysis, and respiratory arrest. Onset and regression of symptoms may vary from minutes to days. No antivenom is currently available for cone shell envenomation. Airway control and supportive care are the mainstays of therapy for severe envenomation.

Stingrays

Stingrays are the most common cause of fish-related stings. The stingray is a broad, flat fish with a long, whip-like tail that contains between one and four barbed stingers that are used by the animal for self-defense. Stingrays vary in size from a few inches to several feet, and the stingers are proportional to the size of the fish. The spine has grooves lined with venom producing glandular cells and is encased in an integumentary sheath that breaks open on contact with the target. Stingrays are not aggressive and human envenomation typically occur when stingrays are mishandled or inadvertently stepped on after burying themselves in the sand of shallow water. Stingray venom contains serotonin, hyaluronidase, phosphodiesterase, and 5-nucleotidase. Following envenomation, the victim experiences an immediate, intense pain in the area of the wound, which may spread to the entire extremity. The local effects of stingray envenomation typically predominate; however, systemic symptoms can include salivation, nausea, vomiting, diarrhea, syncope, muscle cramps, fasciculations, dyspnea, cardiac dysrhythmias, and convulsions. The sheath and stinger are often broken or left in the wound. The presence of foreign material may impair healing and cause infection. In general, freshwater stingray envenomations are more severe than those caused by marine species, and tissue necrosis is nearly universal following these stings. Fatalities from marine stingrays are rare and are typically attributed to penetrating thoracic wounds.[33]

Bony Fishes

Venomous bony fish belong to the Scorpaenidae family of largely marine fishes. Bony fishes inflict their wounds through dorsal, pelvic, and anal spines. The spines and venom glands are encased in a sheath, and grooves along the spines act as channels for the venom. Venom can remain stable after the fish has died. Injuries from bony fish typically occur when the fish are stepped on in shallow water or when handled by fishermen and aquarium owners. The venom is made up of several classes of proteins, most of which are heat labile.

The family Scorpaenidae includes fishes of the genus *Pterois* (lionfish), *Scorpaena* (scorpionfish), and *Synanceja* (stonefish). Lionfish are native to the Indo-Pacific; however, since the 1990s, lionfish populations have expanded rapidly along the southern Atlantic coasts and throughout the Caribbean. The introduction of lionfish to Florida waters and its subsequent spread has been attributed to the aquarium trade.[34] Other theories include inadvertent transportation of these fish from the Indo-Pacific to the Atlantic Ocean when trapped in the ballast tanks of cargo ships.

Lionfish envenomation causes severe localized pain that increases for the first 2 hours after envenomation (Fig. 53.11). Systemic symptoms can include nausea, vomiting, diaphoresis, chest pain, abdominal pain, hypotension, and syncope. Although painful, the manifestations of lionfish stings are much less severe than the related stonefish.[35] Stonefish envenomation may cause serious and even life-threatening systemic illness, but manifestations such as cardiac and respiratory symptoms can be prevented by early administration of the appropriate antivenom. Following a stonefish sting, immediate pain and edema of the affected extremity can be followed by systemic effects of vomiting, headaches, seizures, hemodynamic instability, respiratory failure, and congestive heart failure. Wounds from stonefish envenomation can be complicated by infection, necrosis, compartment syndrome, and chronic tenosynovitis.[36,37]

DIFFERENTIAL DIAGNOSES

The differential diagnoses include nonvenomous stings, coral scrape, near drowning, diving barotrauma, shark and barracuda bites, and intoxication with water activities. In addition, skin wounds infected with MRSA or *Vibrio* sp. or those resulting in necrotizing fasciitis should be considered.

Diagnostic Testing

Diagnostic testing includes radiographs for detection of any foreign bodies. A radiograph of the involved area is recommended because many spines and sheaths are radiopaque.[38] Diagnostic ultrasound, focused computerized tomography, or magnetic resonance imaging (MRI) can be obtained for any nonhealing wounds from a marine sting.

Fig. 55.11 Lionfish Sting on the Left Hand With Normal Right Hand for Comparison.

Management

Much of the venom from marine animals can be neutralized at the scene or in the prehospital setting, and most fatalities can be prevented with timely rescue. The most important first step after any marine envenomation is to remove the victim from the water. Drownings after minimal envenomation may account for more fatalities than the toxic effects of severe envenomation. The patient should be questioned about the circumstances of the bite, allergies, and systemic symptoms. If a severe allergic reaction has occurred, the victim should be treated for this emergency before the wound is addressed.

The type of wound care largely varies according to the type of venom apparatus involved. All marine stings from either bony fish or stingrays are treated with hot water immersion at the warmest bearable temperature (typically 40°C to 42°C) for 30 minutes or until the pain resolves.[36] Care should be taken to avoid burn injuries which can occur within minutes with exposure to water warmer than 49°C. For patients at sea, hot water can be carefully obtained from an outboard engine. The mechanism of hot water immersion in relieving pain is unclear; however, direct inactivation of heat labile marine toxins and modulation of human pain receptors resulting from vasodilation are two commonly proposed mechanisms. Hot water immersion therapy usually improves pain within minutes, but supplemental analgesics may be needed. As with all wounds encountered in the ED, appropriate cleansing, investigation for foreign bodies, débridement, and tetanus prophylaxis are paramount. Prophylactic antibiotics should be considered in deep puncture wounds, those with retained foreign bodies, and in immunocompromised patients. Specific antivenoms are available for some species, such as the box jellyfish, stonefish, and sea snake.

Bites

Bite injuries are treated with basic life-support measures and general wound care consisting of cleansing, débridement, and irrigation. Systemic signs and symptoms are treated as appropriate, with attention paid to the cardiac and respiratory systems.

Nematocysts

Supportive pharmacologic therapy (e.g., analgesics, antihistamines) is indicated for all but the most trivial envenomation. Delayed cutaneous reactions may persist despite optimal therapy.

Early cardiopulmonary resuscitation offers the best chance of recovery from severe envenomation, including *Chironex fleckeri* stings. Box jellyfish antivenom is also available, although its clinical efficacy and significant morbidity or mortality benefit have not been convincingly linked to its use. Suggested indications for use in victims suspected of *C. fleckeri* stings include coma, cardiovascular instability or collapse, respiratory compromise, and severe pain.[39] Antivenom can be given via intramuscular injection by first responders or by slow intravenous injection or intravenous infusion. Magnesium sulfate is also recommended as an intravenous bolus over 5 to 15 minutes at 0.05 g/kg (maximum dose 2.5 g) to victims of *C. fleckeri* stings with cardiovascular collapse.[39]

Care must be taken to prevent further nematocyst discharge when removing nematocysts from the victim. Various topical therapies including hot water immersion, vinegar, and sea water have been proposed for this purpose. As with most steps in management of jellyfish stings, the ideal treatment to prevent nematocyst discharge is not easily defined given the lack of randomized control studies and management differences between jellyfish species. Non–evidence-based recommendations dominate most treatment guidelines. In general, freshwater application should be avoided across species because the osmotic gradient can induce further nematocyst discharge.[39] Remaining tentacles are pulled off with a gloved hand or forceps. Scraping or rubbing off of residual tentacles leads to an increase in nematocyst discharge and should be avoided.[40] The specific topical agent applied to prevent nematocyst discharge depends on the suspected species. Vinegar (4% to 6% acetic acid) application for 30 seconds following suspected box jellyfish can prevent further nematocyst discharge but will not provide relief of pain from prior nematocyst stings. Application of vinegar is also recommended in cases of suspected *C. barnesi* (Irukandji) stings but should be avoided in cases of suspected *Physalia* (bluebottle) or *Chrysaora quinquecirrha* (man-of-war) envenomation because its application results in further nematocyst discharge. For suspected bluebottle and man-of-war stings, we recommend rinsing the wound with sea water followed by hot water immersion.

Initial treatment of severe pain from Irukandji syndrome requires intravenous analgesics such as fentanyl or morphine. Persistent hypertension despite control of pain can be treated with intravenous antihypertensives such as phentolamine or nitroglycerin. Because hypotension often develops in the later stages of envenomation, there is a theoretical advantage of using rapidly titratable agents such as nitroprusside for control of initial hypertension. Intravenous magnesium was previously recommended for treatment of refractory pain; however, the evidence for its use is largely anecdotal and is no longer recommended.

Stings

Broadly, treatment of fish and stingray stings focuses on adequate pain control and prevention of secondary complications such as infection. Fish and stingray venoms are generally heat labile, and significant analgesia can be achieved by immediate submersion of the wound in hot (40°C to 42°C) water for 30 to 90 minutes or until symptoms improve. Wounds should be copiously irrigated and investigated for foreign bodies. Retained spines and stingers are removed with forceps when possible. Wound care should include tetanus prophylaxis and prophylactic antibiotics for deep puncture wounds. Surgical exploration should be considered in deeply penetrating wounds and in cases of nonhealing injuries.[41] There is no role for steroids, tourniquets, or pressure

TABLE 53.5 Species-Specific Treatment Following Envenomation

Hot Water Immersion	Acetic Acid	Available Antivenom
Bony fish (includes lionfish, stonefish)	Box jellyfish *(Chironex fleckeri)*	Box jellyfish *(Chironex fleckeri)*
Stingray	Irukandji jellyfish (*Carukia barnesi*)	Ovine IgG Fab

		Enhydrina schistose polyvalent antivenom

[a]Hot water immersion is recommended after sea water rinse.

immobilization bandaging in the standard treatment of marine stings. A specific antivenom for stonefish envenomation is available in Australia and is given in cases of severe systemic toxicity or refractory pain. As with other fish venoms, stonefish venom is heat labile and deactivated at temperatures greater than 39°C (Table 53.5).[42]

Disposition

Patients envenomated by unknown or unfamiliar organisms should be observed for systemic signs and symptoms. Careful discharge instructions are provided to the patient, warning them to return for increasing pain, numbness, difficulty breathing, and signs of infection. Patients with the potential for hemodynamic instability or airway compromise (e.g., Irukandji syndrome, box jellyfish envenomation, stonefish envenomation) or those treated with antivenom should be admitted or transferred to an ICU.

CHAPTER 53: QUESTIONS AND ANSWERS

1. Which of the following venomous snakes in the United States is a member of the neurotoxic Elapidae family?
   a. Copperheads
   b. Coral snakes
   c. Rattlesnakes
   d. Water moccasins

Answer: b. Pit vipers from the family Viperidae are the most prevalent venomous snakes in the United States. They are native to every state except Maine, Alaska, and Hawaii. They are classified into three main groups: true rattlesnakes (genus *Crotalus*), copperheads and water moccasins (genus *Agkistrodon*), and pygmy and Massasauga rattlesnakes (genus *Sistrurus*). Pit vipers account for 98% of all venomous snakebites in the United States. Other families include Colubridae, Hydrophiidae, Elapidae (to which the neurotoxic coral snake belongs), and Crotalidae.

2. A 30-year-old man complains of pain, burning, and swelling of his hand after gardening. Physical examination shows two puncture marks on his thenar eminence, as well as moderate localized swelling. When you inquire about it, he said that he did have some sudden burning pain while digging around in the ground by a bush, but he dismissed it as abrasions from sharp sticks. That was 2 hours ago. What should you do next?
   a. Apply a constricting band to impede venous and arterial flow.
   b. Discharge with instructions for rest, ice, immobilization, and use of oral antibiotics.
   c. Give tetanus and clindamycin for prophylaxis.
   d. Obtain baseline laboratory studies and observe the patient for increasing symptoms.
   e. Test compartment pressure and prepare for fasciotomy.

Answer: d. The symptoms are typical for a pit viper snakebite. The most consistent symptom associated with pit viper bites is immediate burning pain in the area of the bite, whereas pain may be minimal with bites of Elapidae and other exotic snakes. Tetanus prophylaxis may be indicated, but antibiotics are not. Fasciotomy is rarely if ever indicated for snakebite. A constricting band may be useful for first aid in the field with certain neurotoxic snakes, but not in North America. Immobilization may be helpful, but ice and antibiotics are not.

3. A 43-year-old woman sustained a snakebite while in her backyard in Florida. She was not able to secure the snake, but she remembered it to be colorful. She presents with ptosis, slurred speech, and nausea. What is true about the type of snake most likely involved in this case?
   a. Death usually occurs from coagulopathies.
   b. Eastern species are the most venomous.
   c. The snake has a heat-sensitive organ between eyes and nostrils on both sides of the head.
   d. The snake has a triangle-shaped head.
   e. The snake has elliptical pupils.

Answer: b. This woman sustained a bite from a coral snake. All of the above except B are related to pit vipers. The coral snake can be differentiated from the king or milk snake by two characteristics: the nose of the coral snake is black, and the red and yellow bands are adjacent on the coral snake. Eastern coral snake is considered more deadly as opposed to its western relative. There are no records of fatalities caused by the western species. Ptosis is common and often the first outward sign of envenomation. Other signs and symptoms include vertigo, paresthesias, fasciculations, slurred speech, drowsiness, dysphagia, increased salivation, nausea, and proximal muscle weakness.

4. Which of the following is true about snake antivenom?
   a. Antivenom may reverse symptoms of envenomation including laboratory abnormalities.
   b. Antivenom should be administered around the wound.
   c. Even mild envenomations require antivenom.
   d. Exotic snakebites require only antivenom if neurologic symptoms are present.
   e. Pregnancy is a contraindication to receive antivenom.

Answer: a. Pregnancy is not a contraindication to antivenom therapy. Any victim of a venomous snakebite with moderate or severe envenomation is a candidate for antivenom. Antivenom may reverse the local signs, systemic symptoms, and laboratory abnormalities associated with envenomation. As with coral snakes, many patients do not show any early signs after envenomation by exotic snakes. The antivenom should be administered before neurologic changes develop. All antivenom should be administered intravenously.

5. A 28-year-old man presents with a copperhead snakebite that occurred 1 hour ago. He complains of pain and moderate swelling of his right hand and wrist. He has no systemic symptoms and has a pulse of 80 bpm and a normal blood pressure. His initial coagulation studies are normal. What should be done?
   a. Admit for observation and antivenom
   b. Discharge with elevation, ice, and pain medications
   c. Give antivenom if swelling spreads to forearm
   d. Immediate antivenom, four vials intravenously
   e. Observe 12 hours for signs of increasing envenomation

Answer: e. The majority of copperhead bites do not require antivenom. Some toxicologists will administer antivenom if extremity swelling is progressive and may cause long-term disability. Copperhead bites generally cause a moderate amount of swelling that may peak 24 to 36 hours after the bite. All venomous snakebites should be observed for at least 12 hours if signs of envenomation are present. If systemic signs develop or the patient develops a coagulopathy, antivenom may be indicated.

6. Which of the following patients is most likely to be the first discharged home safely?
   a. A pregnant woman with black widow envenomation
   b. A 3-year-old child with a scorpion sting 1 hour before arrival
   c. A 55-year-old man with hypertension and coronary artery disease with black widow envenomation
   d. An 8-year-old with a coral snake bite
   e. An 18-year-old with an unknown snakebite 8 hours before arrival

Answer: e. A scorpion sting in a child should be observed for at least 6 hours. Symptomatic children with stings should be admitted. Most venomous snakes will show signs of envenomation with 6 hours. If this patient is asymptomatic, it is likely that the snake was nonvenomous or this was a "dry bite." All children with envenomation and coral snake bites should be admitted for observation. Pregnant patients and those with coexisting medical problems should be admitted after black widow envenomation.

7. While walking in shallow water, a patient accidentally steps on a stonefish. Which of the following is the least effective diagnostic and treatment intervention?
   a. Irrigating the wound with vinegar
   b. Obtaining radiographs for retained foreign body
   c. Observing for cardiovascular and respiratory symptoms
   d. Removing the spine with forceps
   e. Using hot water to relieve the pain

Answer: a. Stonefish, a type of bony fish, may cause serious cardiac and respiratory symptoms, which can be prevented by early administration of the appropriate antivenom. The fish spines of bony fish should be removed with forceps because they are thick and less likely to break off at the skin (like a bee stinger). In all cases, the wound should be copiously irrigated. Vinegar has been shown to be useful for some types of nematocyst injuries from jellyfish. Significant analgesia is achieved by submersion of the wound in hot water for 30 to 90 minutes or until improvement. There is a stonefish antivenom in limited supply for severe envenomation.

8. A patient presents with a necrotic lesion on his midthigh that started as a bleb while he was working in his woodshed 3 days ago. The wound has grown gravitationally. Her blood pressure is 110/80 mm Hg, respiratory rate 16 rpm, heart rate 110 bpm, and temperature 38.3°C. You suspect an envenomation of which of the following?

a. *Centruroides exilicauda*
b. *Hapalochlaena maculosa*
c. *Haplopelma lividum*
d. *Latrodectus mactans*
e. *Loxosceles reclusa*

Answer: e. The cobalt blue tarantula, *Haplopelma lividum,* is an aggressive spider with toxic venom. The black widow spider is *Latrodectus mactans*. *Centruroides exilicauda,* which is found in Arizona, is a particularly dangerous kind of scorpion. The blue-ringed octopus is *Hapalochlaena maculosa.* The brown recluse spider, *Loxosceles reclusa,* causes an initial white area of vasoconstriction at the site of the bite within 3 or 4 hours. A bleb then forms in the center of this area, and an erythematous ring arises on the periphery. The lesion at this stage resembles a bull's-eye. The bleb darkens, necroses during the next several hours to days, and continues to spread slowly and gravitationally.

54

Thermal Injuries

Megan M. Rybarczyk and Sean M. Kivlehan

KEY CONCEPTS

- After removing the patient from the source of injury, burns should be cooled with room temperature water while avoiding hypothermia in patients with large burns.
- Clinical signs such as facial burns, hoarseness, drooling, carbonaceous sputum, and singed nasal hairs indicate inhalation injury; however, they are poor predictors of injury severity.
- Confirmation of inhalation injury is best accomplished by direct visualization of the glottic inlet via flexible or rigid video laryngoscopy augmented by topical anesthesia and judicious sedation, when necessary.
- Worsening hoarseness, edema, or soot in the supraglottic region necessitates immediate intubation.
- Supplemental oxygen should be given in patients with suspected inhalation injury and determination of carbon monoxide levels should be performed.
- Crystalloid resuscitation is required to support vital organ perfusion and is guided by urine output. Care should be taken to avoid over-resuscitation.
- Pain relief is required for larger burns and is accomplished through both pharmacological and non-pharmacological methods. Pain levels should be assessed frequently.
- Patients with large body surface area burns (>20% for adults and >10% for children and the elderly) or deep burns will require admission to a burn center. Most other patients presenting to the ED will have small and superficial burns that can be managed with over-the-counter or commercially available topical agents.

FOUNDATIONS

Background and Importance

Thermal injuries, which consist of fire or flame injuries, scald injuries, and contact with hot object injuries, are common in the emergency department (ED). Cooling, assessment of percent total body surface area (% TBSA), depth of tissue involvement, pain control and local wound care is generally all that is necessary for minor burns. For treatment of major burns, early management of airway, breathing, and circulation as well as continuous reassessment of burn depth are essential. Careful wound care to minimize the advancement of burns to greater thickness and prevent infection is imperative.

Burn injuries result in significant morbidity and mortality worldwide. According to the World Health Organization (WHO), burn injuries result in more than 10 million disability adjust life years (DALYs) lost and more than 150,000 deaths each year, 90% of which are in low- and middle-income countries.[1] In the United States alone, there were approximately 560,000 visits to EDs for injuries or burns related to fire or a hot object or substance in 2016.[2] Data from burn admissions in the United States between 2008 and 2017 show that more than 67% of burns were less than 10% TBSA. The overall mortality rate was 3.1%; however, flame and fire injuries had an overall mortality rate of 5.6%. Patients aged 1 to 15 years comprised more than 23% of the total burns, adults aged 20 to 59 years comprised 55% of burns, and patients age 60+ year comprised 15%. Fire and flame injuries, scalds, and contact injuries account for more than 85% of cases, with scalds being most common in children under five, and fire or flame most common in other age groups. Burn injuries occur most often in men (67%) and at home (74%). Only 13% are work related, and 95% are accidents. Patients are more commonly Caucasian/White (59%).[3]

Deaths from burn injury increase with increased burn size, presence of inhalation injury, and advanced age. Pneumonia is the most common complication and is more common in patients requiring four or more days of mechanical ventilation. The hospital length of stay (LOS) is estimated as just over 1 day per percent TBSA.[3] Overall, the burnt surface area associated with a 50% case fatality (LD-50) is 70% TBSA. However, this drops to 40% to 50% TBSA at age 55, 30% to 40% at age 60, and 20% to 30% at age 65 and older.[3,4]

Anatomy, Physiology, and Pathophysiology

The skin is the largest organ of the human body and serves as a barrier between the internal and external environments minimizing fluid losses and microbial invasion. It is comprised of seven layers: five in the epidermis (serving as the protective layer or barrier) and two in the dermis (containing structures that provide thermoregulation, water balance, immune surveillance, sensation, and most of the mechanical properties of the skin). The hypodermis, or subcutaneous tissues, are not a part of the skin, but contain subcutaneous fat and connective tissue that serve to connect the skin to the underlying structures. The thickness and resiliency of the skin depends on the location on the body (thickest on the sole of the foot, thinnest on the eyelid) as well as an individual's age, with peak skin thickness occurring in the middle age. Damage or loss to the skin can result in significant volume loss, thermo-dysregulation, and possible infection.

Pathophysiology of Burns

Thermal burns are the result of exposure of body surfaces to energy in the form of heat. The extent of injury is directly related to the integrity of the skin or epithelial surface, temperature of the offending agent, and duration of exposure. Higher temperatures (starting as low as 41°C) result in denaturing of cellular proteins and coagulative necrosis.[5,6]

Cutaneous Injury

The classical three zones of burn injury to the skin include the central zone of coagulation or irreversible necrosis, the intermediate and potentially reversible zone of stasis or ischemia, and the peripheral reversible zone of hyperemia or inflammation.[5]

The exact cellular-level of pathophysiology in the different zones is not entirely known, however it involves mechanisms of necrosis or necroptosis that result in significant inflammatory responses as well as autophagy—which, may have a protective effect—and either early or

delayed apoptosis, that results in cellular loss, but with less inflammatory response.[5,7,8] All of these mechanisms result in immediate loss of skin tissue and play a role in burn injury progression if not managed both in the ED and throughout the three phases of wound healing: the *inflammatory phase*, the *proliferative phase*, and the *remodeling phase*.[5]

Thermal injury not only sets into motion a cascade of local events, but also results in systemic responses, especially in larger burns. Local processes include inflammation, activation, and aggregation of immune cells. Additionally, this causes microthrombosis with ischemia as a result of endothelial damage, vasoconstriction, dilation, edema, and reperfusion with production of reactive oxygen species and toxic cytokines.[8] Systemic processes not only include inflammatory, cytokine, and immunologic responses, but also metabolic and endocrine responses.[9]

Burn shock is characterized by macro- and microcirculatory impairment and cellular damage, both at the site of injury and throughout the body. The initial resuscitation phase (hypodynamic or ebb phase) occurs within the first 24 to 72 hours and involves cytokine and inflammatory pathway activation as well as systemic circulation of reactive oxygen species, leading to diffuse alterations of transmembrane potentials, plasma extravasation, and edema. This process has either a biphasic pattern—most severe in the first hour and then again at 12 to 24 hours post-burn—or single peak with the most significant manifestations in the first eight hours followed by a slow but steady reduction over the following 16 hours. Subsequently, there is increased vascular resistance, reduced cardiac output, and diffuse end-organ damage.[5,6,9,10] Given the resulting hypoproteinemia and capillary leak, an imbalance between oncotic and hydrostatic forces develop, making resuscitation essential at this stage. The second phase is the hyperdynamic or hypermetabolic flow phase that begins 24 to 72 hours post-injury. As vascular permeability and systemic vascular resistance drop, heart rate and cardiac output increase and metabolic rates can rise two- to three-fold.[5,6] Additional systemic effects include impaired immunity, insulin resistance, renal and hepatic dysfunction, increased serum triglycerides and free fatty acids, muscle wasting, bowel mucosa degradation with reduced absorptive capacity, and hormonal changes, including reductions in growth hormone, TSH, T3, T4, and testosterone.[5,6,9–11]

Inhalation Injury

The incidence of inhalation injury with thermal burns is approximately 6%, however incidences range from 2% in smaller burn injuries to nearly 60% in larger burn injuries and burns to the face.[12,13] It can occur with or without cutaneous burns, and, after age and TBSA, it is the most important predictive factor of mortality and is associated with a nearly threefold increase in mortality and a decrease in the LD-50 by 25% in certain population groups.[12,13]

Inhalational injury is caused by thermal injury to the upper airway and chemical injury to the lower airway. Additionally, systemic toxicity occurs from inhalation of substances such as carbon monoxide and cyanide.[13] Heat can stimulate the glottic closure reflex resulting in rapid asphyxiation and death. At the cellular level, the effect of thermal injury on the upper airway is similar to the pathophysiologic cutaneous response with inflammation, including activation and aggregation of immune cells as well as ischemia, followed by edema and reperfusion injury. Progressive airway edema after significant thermal injury is predictable and may threaten airway patency within hours of initial presentation. Additional complications can occur in the first 24 to 48 hours such as bronchoconstriction, ulceration and hemorrhage, pseudomembrane formation, loss of surfactant, and impaired ciliary transport. These can lead to ventilation/perfusion (V/Q) mismatch, decreased lung compliance, obstruction, barotrauma, increased dead space ventilation, and infection.[13]

CLINICAL FEATURES

Classification and Diagnosis of Burns

Accurate estimates of burn depth and size are difficult given the dynamic nature of burn injury in the first hours and even days. While the physical examination is the fastest way to initially gauge burn severity, this has been shown to be inaccurate and inconsistent among clinicians.[14] Estimation of depth is particularly challenging as most burn injuries are not uniform in depth, can have varied appearances based on the thickness of the skin, and have a tendency to progress over time.[14] Adequate diagnosis, however, is imperative as it affects clinical decision-making and can affect the timing of critical interventions and the appropriate treatment protocols.

Depth

Cutaneous burns are classified according to depth as superficial (previously first-degree), superficial partial-thickness and deep partial-thickness (previously second-degree), full-thickness (third-degree), deep full-thickness (fourth-degree), and fifth-degree (such tissue destruction resulting in amputation).[15] This classification was developed for its implications regarding surgical intervention and healing potential. Furthermore, a category of "indeterminate-depth" burns, a partial-thickness burn of unknown healing potential, has also been described in the literature and is a current focus of study.[16]

Superficial burns involve only the epidermis and are painful, erythematous, and blanch with pressure. They are dry, and the epithelium peels away by day three or four after the pain and erythema resolve. A sunburn is a common example. These injuries often heal within a week without scarring.[15] Superficial partial-thickness burns involve the superficial portion of the dermis (papillary dermis) and result in separation of the epidermis and dermis with blister formation. They are painful, erythematous, and blanch with pressure. They are wet, take one to three weeks to heal, and rarely result in significant scarring.[15] Deep partial-thickness burns involve the deeper layers of the dermis (reticular dermis) and result in damage to dermal structures such as hair follicles. They can blister, are painful to pressure, can be erythematous, mottled, or white, and may be wet or dry. They heal in two to nine weeks and can cause hypertrophic scarring.[15] Full-thickness burns involve the entire dermis and often some underlying adipose tissue and result in an inelastic burn eschar that is waxy and white, gray, or black without blisters. A burn eschar can compromise underlying tissues. Full-thickness burns are insensate and heal over the course of weeks once the eschar falls off and the bed of granulation tissue contracts and epithelializes from the wound margins.[15]

Deep full-thickness burns involve muscle, tendon, ligament, or bone and may result in amputation.[15]

These categories are summarized in Table 54.1 and typical examples of the appearance of some of the different burn depths are presented in Fig. 54.1 to 54.3.

Several techniques to help improve the accuracy of burn depth estimation beyond clinical examination have been studied, including laser Doppler flowmetry, laser Doppler imaging, thermography or thermal imaging, photoacoustic imaging, spectrophotometric intracutaneous analysis, dermoscopy, near-infrared spectroscopy, videomicroscopy, ultrasonography, and spatial frequency domain imaging.[14] Only a few of these have been studied in human investigations, and some require biopsy of the wound. While potentially effective inpatient tools, these are unlikely to be useful in the ED evaluation of burn injury depth.

Size

Determining the size, or TBSA, of a burn injury predicts mortality and is used to guide management decisions, including fluid resuscitation

TABLE 54.1 Clinical Estimation of Burn Depth

Depth	Appearance	Blanches With Pressure	Sensitivity to Pinprick	Pliability	Time to Healing	Need for Excision and Grafting
Superficial	Red, no blisters	+	++	Soft	1 week	–
Superficial partial thickness	Red, blisters	+	++	Soft	1–2 weeks	–
Deep partial thickness	Red or white, possible blisters	±	±	Slightly tense	2–9 weeks	±
Full thickness	Leather like, charred	–	–	Stiff, leather like	Variable; weeks to months	+
Deep full thickness	Exposed muscle, tendon, and/or bone	Not applicable	Not applicable	Not applicable	Variable; weeks to months	+
Fifth degree	Requires amputation	Not applicable	Not applicable	Not applicable	Variable; weeks to months	+

Fig. 54.1 Superficial Partial Thickness Burn, Which Is Pink and Glistening. Some of the blisters have sloughed off.

Fig. 54.2 Deep Partial Thickness Burn. The white appearing area over the dorsum of the hand is a deep partial thickness burn.

and burn center referral. TBSA does not include superficial burns. The Baux score, a sum of the patient's age and the percent TBSA burned, was originally described in the 1960s, but a revised score that includes inhalation injury that was published in 2010 is now more widely used, along with a simplified nomogram published in 2015.[17] Several other scores, including the Belgian Outcome in Burn Injury Score, Abbreviated Burn Severity Index, FLAMES Score, and the Ryan Score have also been used worldwide along with other mortality scores not specific to burn injuries (i.e., Sequential Organ Failure Assessment Score) to predict mortality.[18–22]

For larger (> 10% TBSA) burns in adults, the "Rule of Nines" is often used to estimate burn size. This method divides the body into areas

Fig. 54.3 Full-Thickness Burn Over Both Feet. The central area is depressed and has a yellowish color indicating it is a full-thickness burn.

that approximate 9% of the TBSA (Fig. 54.4).[21] In children, the Lund-Browder chart is recommended, which adjusts for age-related differences in the distribution of body parts and sizes (Fig. 54.5).[22] For small burns, the palmar surface area (PSA) of the entire palmar surface of the patient's hand and fingers can be used to estimate 1% of the TBSA, however studies have shown that PSA can represent 0.5% to 2.3% TBSA, depending on age, body habitus, and patient demographics.[21]

Given the increased incidence of obesity, the effect of bariatric-specific changes in body surface area (BSA) and physiological changes on burn care has yet to be fully explored. While it has been shown that these changes can affect treatment and outcomes, no reliable bariatric-specific BSA chart yet exists.[22,23]

Overestimation and underestimation of burn size is common, with ratios of overestimation to underestimation as high as 30:1 in the pre-hospital setting, and with variation as high as nearly 200% among clinicians, regardless of level of expertise.[21] Smaller burns are more likely to be overestimated than larger burns. A number of methods have been developed to increase the accuracy of burn size estimation. Computer software and other technologies can help improve burn size estimation.[21,24]

Inhalation Injury

Like burn size and depth, the diagnosis of inhalation injury is subjective and largely based on history and clinical findings. Pertinent historical features include exposure to flame, smoke, or super-heated air, presence in an enclosed space, duration of exposure, and loss of consciousness. Examination findings include facial burns; presence of carbonaceous material on the face, in the nose or oropharynx, or in sputum; singed facial or nasal hair; mucosal damage or edema; and

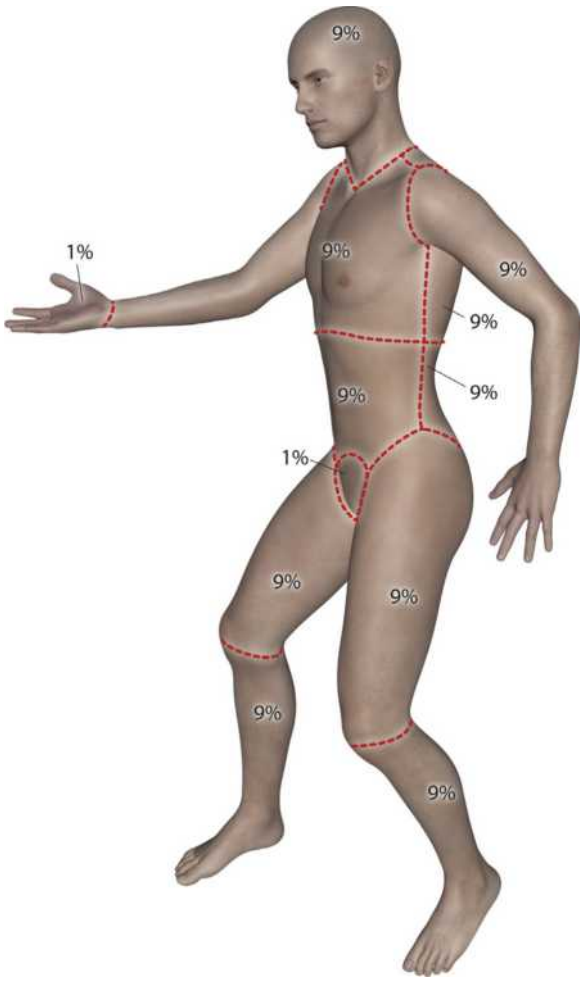

Fig. 54.4 The "Rule of Nines" for Estimating Burn Area in Adults.

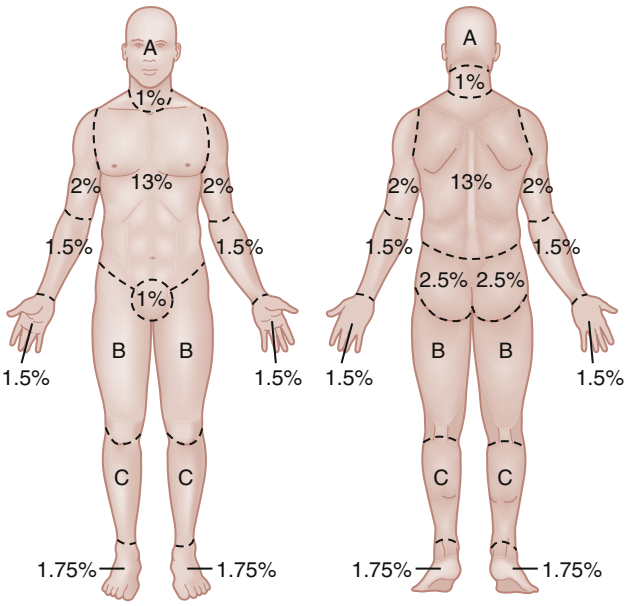

Relative percentages of areas affected by growth

Age	Half of head (A)	Half of one thigh (B)	Half of one leg (C)
Infant	9.5	2.75	2.5
1 yr	8.5	3.25	2.5
5 yr	6.5	4	2.75
10 yr	5.5	4.25	3
15 yr	4.5	4.5	3.25
Adult	3.5	4.75	3.5

Fig. 54.5 Lund-Browder Chart.

signs or symptoms of airway obstruction or respiratory compromise such as dyspnea, tachypnea, stridor, hoarseness, drooling, wheezing, accessory muscle use, tripoding, nasal flaring, and hypoxia. When clinical signs or symptoms of airway injury are indeterminant, methods for confirming inhalation injury include visualization via flexible or rigid video laryngoscopy. Computed tomography (CT), carboxyhemoglobin measurement, radionuclide imaging with Xenon, and pulmonary function testing can all be performed to assess lower airway or pulmonary involvement but are not the initial diagnostic tests for evaluation of upper airway injury.[13,25] For now, the gold standard remains flexible laryngoscopy. The Abbreviated Injury Score is a commonly used grading system to augment interpretation of visualized damage. The score and ranges from zero (no trauma) to five (mucosal sloughing, necrosis, and airway obstruction).[13] There is no current comprehensive standardized or validated method for diagnosing or scoring inhalational injury severity in the ED setting.

DIFFERENTIAL DIAGNOSES

The diagnosis and etiology of burns is generally elicited on history and examination. In patients who are unable to provide a history, some diseases with dermatological manifestations, such as erythema multiforme, Stevens-Johnson syndrome, drug-induced hypersensitivity syndrome, toxic epidermal necrolysis, staphylococcal scalded skin syndrome, subacute cutaneous lupus, necrotizing fasciitis, pemphigoid, and pemphigus, may be mistaken as burns. In fact, the clinical features and management of Stevens-Johnson syndrome and toxic epidermal necrolysis, which can cause life-threatening mucocutaneous eruptions including sloughing of large areas of the skin, are very similar to those of large burns.

In patients who can provide a history, it is important to ask patients about the etiology of the burn, duration of contact, if it was in an enclosed space, if a blast or blunt trauma occurred, presence or absence of any protective clothing or equipment, whether it was an intentional injury or accidental, and any initial first aid measures used. Child or elderly abuse must always be considered, especially when the history and pattern of burns are inconsistent with the physical findings.

DIAGNOSTIC TESTING

Routine laboratory testing is generally of little value in evaluating and managing patients with burns in the ED. Patients with suspected inhalation injury should have a chest radiograph, lactic acid level, and blood gas determination, including a carboxyhemoglobin level. Moreover, pulse oximetry, capnometry, capnography, and peak expiratory flow rates, either continuous or with serial measurements may be useful in monitoring respiratory status. Patients with large burns requiring admission should have an electrocardiogram and baseline laboratory testing, including a complete blood count, electrolyte panel, blood type and cross, lactic acid, and coagulation studies. Clinicians should perform a standard trauma assessment for blunt and penetrating injury if the burns occurred as a result of a blast or explosive event.

MANAGEMENT

Initial First Aid

Patients should be removed from the source of injury and any clothing and jewelry removed from the affected areas and burns cooled with room temperature water.[26] Direct exposure to ice or iced water is to be avoided to prevent further injury. Cover the burns with a clean dressing to minimize further trauma and reduce pain.

During transport, patients with large burns (greater than 20% TBSA in adults and greater than 10% in children) should have two large bore intravenous catheters placed followed by fluid resuscitation. The American Burn Association (ABA) recommends starting 125 mL/h lactated Ringers solution (LR) for patients 5 years old and younger, 250 mL/h LR for patients 6 to 13 years old, and 500 mL/h LR for patients 14 years and older, with the plan to adjust fluid rates to estimated TBSA on arrival to the ED (see later for more details on fluid resuscitation).[27] Place patients on supplemental oxygen to maintain oxygen saturation greater than 92%. Pain management using intravenous opiates, such as morphine (2 to 4 mg IV in adults, 0.05 mg/kg for children <50 kg) every 5 to 10 minutes until pain control is achieved is also recommended as per local emergency medical service (EMS) protocols in hemodynamically stable patients (see later for more details on pain management).

Airway Management

One of the most critical decisions in managing burn victims is the need for and optimal timing of endotracheal intubation since thermal injury predictably results in swelling of glottic and supraglottic structures. The degree of swelling is related to temperature and length of exposure. Occasionally, patients present needing immediate intubation. However, patients may arrive initially with a "sore throat" or a mildly raspy voice. Edema may worsen over the first several hours, especially as patients receive fluid resuscitation, therefore it is essential to closely monitor for progression of clinical signs and symptoms that suggest developing airway obstruction or delayed-onset respiratory compromise. Patients with a history of exposure in an enclosed space, suspected smoke inhalation, moderate to severe facial or oropharyngeal burns, circumferential neck burns, visible injury on laryngoscopy or bronchoscopy, cognitive impairment, hemodynamic stability, dysphagia, hoarseness, oropharyngeal soot, singed nasal or facial hair, larger burns (≥ 40% TBSA), stridor, or signs and symptoms of impaired oxygenation or ventilation should be intubated early, if not immediately.[13,28] No single feature can adequately predict the need for intubation, but patients without these criteria should generally not be intubated and undergo close observation. There are currently no consistent validated criteria or scoring systems to diagnose inhalation injury or predict airway compromise. Even initial direct visualization of the airway may not always accurately predict the need for intubation. When in doubt, early intubation is still encouraged; however, in cases where symptoms are mild and history is inconclusive, a strategy incorporating flexible laryngoscopy in lieu of early intubation can be used and may improve outcomes.[29] Unnecessary intubation and mechanical ventilation may lead to complications such as injury to the upper airway, pneumonia, and acute respiratory distress syndrome (ARDS). At present, the best way to confirm inhalation injury and the need for endotracheal intubation is by directly visualizing the airways with flexible or rigid laryngoscopy using topical anesthesia augmented by mild to moderate sedation when necessary. Repeat laryngoscopy or intubation should be performed if symptoms change (Fig. 54.6).[29] Awake intubation with generous amounts of topical anesthetics with or without supplemental sedation is the preferred intubation method in patients with inhalational burns with a predicted difficult airway and partial airway obstruction, however, rapid sequence intubation with video laryngoscopy is a reasonable approach if intubation is performed early and

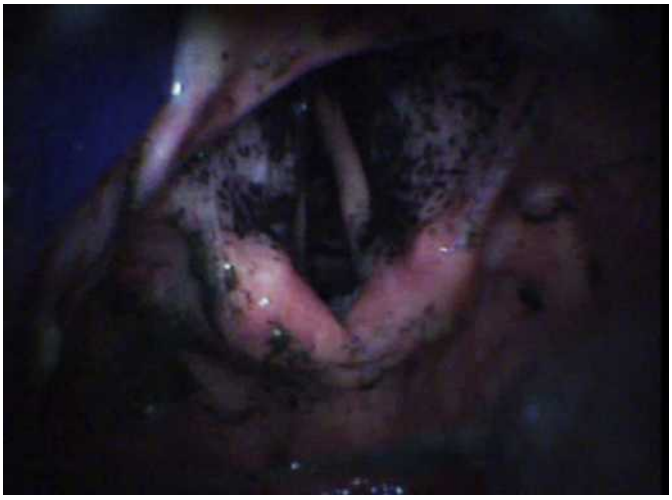

Fig. 54.6 Fiberoptic View of Inhalation Injury. (Courtesy Dr. Marvin Wayne.)

significant swelling is unlikely. If a "can't intubate and can't oxygenate" scenario develops during airway management, the failed airway algorithm (see Chapter 1) should be followed. Surgical airways are rarely needed but indicated if intubation is not successful and oxygenation cannot be maintained. The empirical use of corticosteroids in the management of inhalation injury is not recommended.[25]

Breathing Management

Although the chest radiograph and CT scans of the thorax may be helpful in some cases, there is no consensus as to the timing of these studies, and negative studies, especially in the initial period, should not be used to rule out inhalational injury.[25,30]

All patients with suspected inhalation injury should receive supplemental humidified oxygen to maintain oxygen saturation above 92%. Inhaled beta-agonists can be administered to reduce bronchoconstriction associated with inhalation injury. Non-invasive ventilation may be considered in awake, cooperative, spontaneously breathing, hemodynamically stable patients who can maintain their airway.[25]

For intubated patients, bronchoscopy is still the gold standard tool used to diagnose inhalation injury, determine severity, and remove airway debris and secretions that impede ventilation and enhance the inflammatory response. Furthermore, the presence of soluble urokinase plasminogen activator receptor (suPAR) in bronchial lavage fluid can help make the diagnosis and predict prognosis.[25]

It is well known that lung-protective ventilation strategies, including lower tidal volumes (6 mL/kg of predicted weight) and maintaining peak pressures below 35 mmHg, are imperative to avoid further lung injury during mechanical ventilation. This may lead to hypercapnia (permissive hypercapnia), which can be tolerated, especially in children. Addition of positive end-expiratory pressure (PEEP) may increase the functional residual capacity and improve oxygenation. Suggested initial ventilator settings are presented in Table 54.2. The best method of ventilation in patients with inhalation injury is subject to debate. In addition to traditional modalities (such as assist-control), some studies suggest that high frequency oscillatory ventilation or high frequency percussive ventilation may improve oxygenation in patients with inhalation injury when traditional methods are ineffective.[25,31] Prone positioning of the patient may also be considered in hypoxic patients. Extracorporeal membrane oxygenation (ECMO) has been studied for patients with burn injuries as they are prone to develop ARDS with or without inhalation injury. While initial results indicate good outcomes, more study is needed.[32]

TABLE 54.2 Recommended Initial Ventilator Settings

Tidal volume	6–8 mL/kg
Respiratory rate	8–12 in adults
	12–45 in children
Plateau pressures	<35 cm H_2O
I/E ratio	1 : 1 to 1 : 3
Flow rates	40–100 L/min
PEEP	8 cm H_2O

I/E, Inspiratory-expiratory; *PEEP,* positive end-expiratory pressure.

Nebulized heparin (5000 to 10,000 IU) in conjunction with beta agonists, n-acetylcysteine—an oxygen free radical scavenger and mucolytic—or other mucolytics have been shown to reduce the duration of mechanical ventilation.[25,33,34] Inhaled nitric oxide may also be helpful in some patients.[25] The empirical use of corticosteroids is not recommended. The use of exogenous surfactant may be helpful, but further study is required.[25]

Patients with smoke inhalation who are intubated are at high risk of developing pneumonia. Strategies such as use of silver-coated or hi-lo evac endotracheal tubes, restrictive blood transfusion, intensive insulin therapy, head elevation, frequent position changes, control of environmental infection (such as patient and staff cohorting, dedicated room equipment, contact barrier precautions, and hand hygiene), and good oral care should be used. Prophylactic antibiotics are not recommended. In the ICU, routine endotracheal surveillance cultures are performed to target early therapy in patients who develop pneumonia.[25,35]

Circulation Management and Fluid Resuscitation

Burn injuries result in significant fluids losses and shifts due to loss of the epidermal barrier and an increase in capillary permeability, respectively. Leakage of plasma proteins into the interstitial space during the early phases of a burn increases its oncotic pressure, further contributing to fluid shifts and tissue edema. As a result, a major focus of burn care is fluid resuscitation to restore tissue perfusion and prevent hypovolemic shock. Intravenous fluid resuscitation through large bore intravenous cannulas should be instituted for most burns greater than 20% TBSA in adults, and greater than 10% in children.[27] Avoid IV placement through burned tissue if at all possible. A number of formulas have been proposed for estimating the fluid requirements of burn patients (Table 54.3). The *Parkland formula* is the most common method used to calculate fluid requirements over the first 24 hours after injury and is based entirely on LR solution. Half of the fluids are given within the first 8 hours *from injury,* and the other half is given over the next 16 hours. However, patients managed with the **Parkland** formula have been shown to receive an average 4.6 to 6.3 mL/kg per percent of TBSA over the first 24 hours instead of the recommended 4 mL/kg per percent of TBSA, increasing the risk of over resuscitation.[36] The *Modified Brooke formula*, which calls for 2 mL/kg per percent of TBSA, may be a better starting point. The ABA recommends 3 mL/kg/% TBSA plus D5LR at maintenance for infants and young children ≤ 30 kg, 3 mL/kg/%TBSA for all other children < 14 years old and 2 mL/kg/%TBSA for all other individuals with thermal injuries.[27] The recommended fluid is LR for initial resuscitation. Studies evaluating other fluids, such as hypertonic saline, albumin, other colloids, and fresh frozen plasma (FFP), have shown conflicting results and any measured benefits were not noted in the initial stages of resuscitation.[27,36] Although these formulas are used as a general starting point, frequent readjustments based on patient response (such as monitoring vital signs, mental status, assessment of fluid status with ultrasound, and hourly urine output) are required to avoid both over and under resuscitation. A goal urine output of 0.5 to 1.0 mL/kg/h is recommended.[37]

TABLE 54.3 Burn Resuscitation Formulas

Formula	First 24 Hours
Parkland	LR solution 4 mL/kg per percent TBSA; half over the first 8 h
Modified Parkland	LR solution 3–4 mL/kg per percent TBSA; half over the first 8 h
Evans	Crystalloids in the amount of 1 mL/kg per percent TBSA and colloids at 1 mL/kg per percent TBSA; half over the first 8 h; plus 2000 mL glucose in water maintenance
Brooke	LR solution 1.5 mL/kg per percent TBSA and colloids at 0.5 mL/kg per percent TBSA; half over the first 8 h; plus 2000 mL glucose in water maintenance
Modified Brooke	LR solution 2 mL/kg per percent TBSA in adults and 3 mL/kg per percent TBSA in children; half over the first 8 h
Monafo	Solution containing 250 mEq Na, 150 mEq lactate, 100 mEq Cl; amount adjusted to urine output
Rule of Ten	LR solution at 10 mL per percent TBSA per hour for every 10 kg above 80 kg, 100 mL is added to this hourly rate
Cope and Moore	75 mL per percent TBSA oral electrolyte solution, 75 mL per percent TBSA FFP, 2000 mL fruit juice orally or 2000 mL 5% dextrose; half over the first 8 h
Gelin	Low molecular weight dextran: 2 mL/kg per percent TBSA for <30% TBSA; 2.5 mL/kg per percent TBSA for 30%–60% TBSA; 3 mL/kg per percent TBSA for >60% TBSA
Galveston (pediatric)	LR solution at 5000 mL/m^2 TBSA burned plus 2000 mL/m^2 TBSA, half over the first 8 h
Shriner's Cincinnati (pediatric)	Older children: LR 4 mL/kg per percent TBSA + 1500 mL/m^2 total; half over the first 8 h Younger children: 4 mL/kg per percent TBSA + 1500 mL/m^2 total; LR solution + 50 mEq $NaHCO_3$ in the first 8 h; LR solution in the second 8 h, and 5% albumin in LR in the third 8 h

LR, Lactated Ringers; *TBSA,* total body surface area; *Cl,* Chloride; *Na,* sodium; *FFP,* fresh frozen plasma; *$NaHCO_3$,* sodium bicarbonate.

Overly aggressive fluid resuscitation has been coined "fluid creep" and can have devastating results, including worsening local tissue edema with burn conversion, extremity compartment syndrome, abdominal compartment syndrome, and pulmonary edema.[36] Care should be taken to avoid hypothermia, which has been shown to worsen outcomes. Cold fluids as well as environmental and open-air exposure in the ED can inherently result in hypothermia, but patients with burns are particularly vulnerable given the impairment to their thermoregulatory function. Continuous monitoring of core temperature is recommended in patients with large burns.[38]

Escharotomy

With deep burns, a non-compliant and restrictive eschar forms, which, when circumferential or near-circumferential around an extremity or the abdomen, may compress the underlying tissues and structures

leading to a compartment syndrome. Similarly, an eschar involving the thorax may impede ventilation, eschar on the face may result in increased intraocular pressures, and eschar around the neck may compromise the airway. When this occurs, emergent release of the tissue pressure by making an incision through the eschar (escharotomy) is required. Escharotomy is rarely needed in the first few hours of burn injury, rather increased tissue edema as a result of resuscitation often leads to the need for the procedure at a later time.[39]

Specific indications for escharotomy include pain, pallor, paresthesia, paralysis, poikilothermia, pulselessness, decreased or absent oximetry signals, increased compartment pressures for eschar over limbs >30 mm Hg and increased intraocular pressures for peri-orbital eschar (>30 mmHg). Respiratory and hemodynamic dysfunction such as increased airway pressures, decreased tidal volumes, decreased preload, and tachycardia are indications for eschar over the chest. Poor respiratory compliance, hemodynamic instability, tube feed intolerance, decreased urine outpatient, or increased bladder pressure (>25 mm Hg) may indicate need for abdominal escharotomy.[39] Monitor bladder pressure in patients with concern for possible abdominal compartment syndrome.

Since the eschar is composed of necrotic tissue, escharotomy is generally associated with little pain or blood loss. The amount of blood loss can be further minimized by using electric cautery. To be effective, the incisions should be down to the subcutaneous level, allowing the stiff eschar to open. The incisions should also be slightly extended into normal tissue both proximally and distally. Along the extremities, the incisions are made over the medial and lateral aspects with care taken to avoid damage to underlying vital structures. With hand burns the incisions may need to be extended into the fingers. Proper escharotomy incisions are displayed in Fig. 54.7.[39]

Rarely, additional procedures, such as fasciotomy and nerve decompression may also be needed. Burns over the abdomen may require a decompressive laparotomy or a peritoneal catheter if escharotomy is not effective.[39]

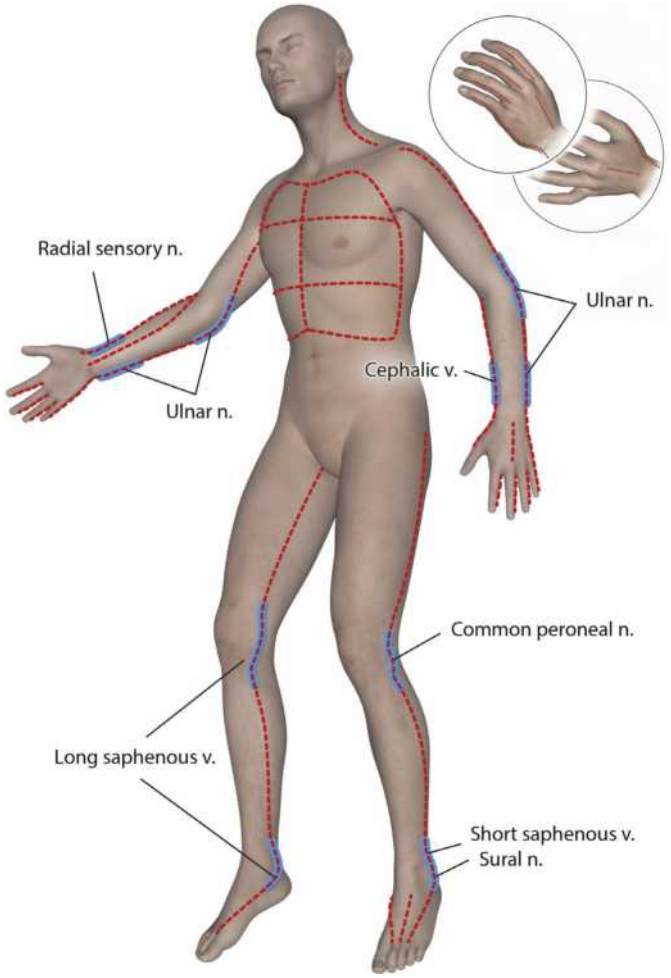

Fig. 54.7 Location of Escharotomy Incisions. Areas to avoid to prevent nerve injury are highlighted in blue.

Local Wound Therapies

Local wound therapies aimed at protecting the burn from further injury and infection and maintaining a moist wound environment that is most conducive to healing are paramount in burn injury care. Superficial burns do not require any local treatment. However, topical application of a nonsteroidal anti-inflammatory agent or aloe vera may reduce pain.

Burns should be cleaned gently with soap and water. Management of blisters is still a subject of debate. Intact blisters create a barrier, maintain a moist environment and contain some cells and signaling molecules that stimulate healing. On the other hand, they also contain substances that result in damage to the microcirculation, increased inflammatory response, and mechanical pressure over the wound. Practice varies by location, but in general, blisters should be left intact. Although there is no consensus, very large or tense blisters, as well as those located over joints, should be punctured to allow fluid to drain, but not fully deroofed.[40] Any already ruptured and non-adherent necrotic tissue should be gently removed manually or with topical agents. If a patient is to be transferred, wound therapy should generally be performed in the burn unit, and the burns should be covered with a clean, non-adherent dressing prior to transport.

Inpatient and outpatient dressings for patients who do not require skin grafting (partial-thickness burns, small full-thickness burns) is still a subject of considerable debate as evidenced by the large number of natural and synthetic agents and dressings available (Table 54.4). Dressing selection depends on depth and location of the injury; pain; condition of the wound and inherent amount of moisture, exudate, and drainage; risk of infection; ability for dressing changes; and cost. Dressings should prevent infection and contamination, maintain an appropriate amount of moisture but allow for gas exchange, provide comfort, and be cost-effective.[6,41,42]

Ointments are preferred over creams because they do not adhere to overlying dressings. Application of a topical generic antibacterial ointment is recommended. Petroleum jelly may also be used in wounds with low risk of contamination. Silver sulfadiazine cream was historically considered the standard therapy for the conservative management of burns. It has a wide antibacterial and antifungal spectrum and should be considered in heavily contaminated or infected burns however, it is no longer recommended for most other burns. Multiple systematic reviews have found that silver sulfadiazine was associated with poorer healing outcomes than other dressing types.[41,43] Moreover, other topical agents such as hyaluronic acid with or without zinc, or polyhexanide/betaine gel may also be effective.[44,45] Burn wounds should generally remain covered during the healing process.[46]

An alternative to topical agents is one of a number of commercially available occlusive dressings (see Table 54.4) in addition to other widely available dressings such as petrolatum gauze with or without other additives (such as tribromophenate). Although generally more expensive than topical agents and not as widely available, occlusive dressings require less frequent dressing changes and are associated with less pain and promote effective wound healing.[47–50] Many of the

TABLE 54.4 Representative Topical Agents and Dressings for Burns

Category	Examples	Advantages	Disadvantages
Non-Occlusive, Absorptive			
Gauze, nonadherent	Telfa (Kendall, Mansfield, MA)	Nonadherent, inexpensive	Requires daily dressing changes
Occlusive			
Foams	Mepilex (Mölnlycke, Gothenberg, Sweden); Curafoam (Kendall, Dublin, Ireland); Allevyn foam (Smith & Nephew, London, United Kingdom); Lyofoa (Molnycke, Gothenburg, Sweden)	Absorbs exudate, prevents surrounding maceration	Opaque, may dehydrate wounds with minimal exudate
Hydrocolloid	DuoDERM and Granuflex (ConvaTec, Bridgewater, NJ); Tegasorb (3M, St. Paul, MN)	Absorbs exudates, protective cushioning of wound	Opaque, no antimicrobial properties
Alginate	SeaSorb (Coloplast, Humlebaek, Denmark); Algiderm (Bard, Murray Hill, NJ); Melgisorb (Mölnlycke, Gothenberg, Sweden); Aquacel (ConvaTec, Bridgewater, NJ); Comfeel (Coloplast, Minneapolis, MN), or Sorbsan (Mylan, Morgantown, WV)	Absorptive	Frequent dressing changes
Nanocrystalline silver	Acticoat (Smith & Nephew, Largo, FL); Aquacel Ag (ConvaTec, Bridgewater, NJ); Silverlon (Argentum, Geneva, IL)	Antimicrobial, creates a moist environment, less frequent dressing changes	Need to keep dressing moist
Hydrogel	Curagel (Kendall, Mansfield, MA); Flexigel (Smith & Nephew, Largo, FL); Nu-Gel (Johnson & Johnson, Arlington, TX); Dermagel (Maximilian Zenho & Co, Brussels, Belgium), SilvaSorb (Medline, Mundelein, IL), or Skintegrity (Medline, Mundelein, IL)	Rehydrates dry wounds	Non-absorptive
Collagen	Fibracol (Johnson & Johnson, New Brunswick, NJ) or Puracol (Medline, Mundelein, IL)	Absorptive	Require secondary dressing
Transparent films	Tegaderm (3M, St. Paul, MN); OpSite (Smith & Nephew, Largo, FL)	Transparent, inexpensive	Non-absorptive

occlusive dressings may be left in place for up to one week unless obviously saturated or malodorous. Burns on the extremities should be elevated to reduce swelling and general care should be taken to avoid tight compressive dressings at any site. Emergency clinicians should know which products are available at their institution(s) and collaborate with clinicians in the inpatient and outpatient settings to determine the most appropriate and cost-effective protocols for burn wound treatment for patients at their institution.

For full thickness burns, the standard of care is early excision and grafting with autograft if possible. Patients with extensive burns may require temporary allograft, xenograft, skin substitutes, or dermal analogs, and, although beyond the scope of this chapter, there has been significant research in the surgical management of burns in the last couple of decades.[6]

A number of novel burn therapies have been investigated in preclinical and clinical studies but are not yet recommended in emergency settings. A systematic review of preclinical studies suggested that warm water, simvastatin, erythropoietin, or cerium nitrate may reduce the conversion of superficial to deep burns.[51] Ascorbic acid (vitamin C) is also being studied as a potential adjunctive therapy in burn resuscitation.[52,53] Finally, a systematic review and meta-analysis of growth factor use for partial thickness burns concluded that this therapy (fibroblast growth factor, epidermal growth factor, and granulocyte macrophage-colony stimulating factor) might be an effective and safe add-on to standard wound care for partial-thickness burns.[54] All patients with burn injuries should have their tetanus immunization status updated as appropriate.

Pain Management

Pain in patients who have sustained burn injuries is often undertreated, however routine monitoring of pain severity and the use of pain management protocols can improve pain management and avoid overuse of opioids. Pain in acute burn injury is predominantly due to three mechanisms: direct stimulation of nociceptors in the skin and the transmission of painful neural impulses via A-delta and C-fibers, inflammatory pain, and neuropathic pain (in chronic settings).

For pharmacological treatment, begin with acetaminophen (500 mg PO every 4 to 6 hours; 10–15 mg/kg/dose PO for children) or NSAIDs (such as ibuprofen 400 to 800 mg PO every 8 hours; 10 mg/kg/dose PO for children) for mild to moderate pain (although NSAIDs should be avoided in patients with severe burns or shock) and opioids (such as fentanyl at 1 to 2 mcg/kg IV for adults and children, morphine at 2 to 4 mg/kg IV for adults and 0.05 mg/kg IV for children <50 kg, and oxycodone 5–10 mg PO for adults and 0.1–0.2 mg/kg PO for children <50 kg) for more severe pain or breakthrough pain. Long-acting opioids, such as methadone, should be considered for patients suspected to need frequent or prolonged dosing of opioids. The addition of an anxiolytic, such as midazolam (1 to 2 mg IV for adults; 0.05–0.1 mg/kg IV depending on age for children) or lorazepam (0.5 to 1 mg IV for adults; 0.05 mg/kg IV for children), may be more effective than an opioid alone, particularly during wound management and procedures. Intravenous (0.15 to 0.3 mg/kg) ketamine has shown improvement in pain scores, particularly during debridement and dressing application, although more study is needed.[55,56] Ketamine infusion for background pain is used in some centers.[56] Intravenous lidocaine, dexmedetomidine, and nitrous oxide

may also be effective.[55,56] Finally, regional anesthesia may also be an effective substitute for systemic therapies when appropriate.[56] Avoid IM injections of medications (with the exception of tetanus immunization), particularly in large burns, given that changes in tissue fluid volume can make absorption less predictable.[27]

Although pharmacological agents are the cornerstone of burn pain management, non-pharmacological methods (such as cooling of the burn, covering the burn with a dressing) and cognitive-behavioral therapy (such as relaxation and distraction with mechanisms such as music, virtual reality, and aromatherapy) should be considered.[54,56]

DISPOSITION

Most superficial and small partial-thickness and even select small full thickness burns can be managed in the ED by an emergency clinician with close follow-up by a primary care physician comfortable handling burns (or a burn specialist for partial thickness and full-thickness burns) within the next 3 to 5 days. Patients with large or deep burns, burns involving sensitive areas, and those with significant comorbidities and trauma should be admitted. Criteria for referral and transfer to a burn center are presented in Box 54.1.[27]

The references for this chapter can be found online at ExpertConsult.com.

BOX 54.1 Criteria for Referral to a Burn Center

- Partial thickness burns greater than 10% TBSA
- Burns that involve the face, hands, genitalia, perineum, or major joints
- Full thickness burns in any age group
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
- Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality
- Burned children in hospitals without qualified personnel or equipment for the care of children
- Burn injury in patients who will require special social, emotional, or rehabilitative intervention

TBSA, Total body surface area.

CHAPTER 54: QUESTIONS AND ANSWERS

1. A 30-year-old man presents with a burn to both anterior aspects of his forearms after being burned by a radiator. He has severe pain and has deep (reticular) dermis extension of the burn. You call the consultant and describe the burn as which of the following?
- **a.** Superficial burn of 4.5% body surface area
- **b.** Superficial partial thickness burn of 9% body surface area
- **c.** Deep partial thickness burn of 4.5% body surface area
- **d.** Full thickness burn of 2.5% body surface area
- **e.** Deep full thickness burn of 9% body surface area

Answer: c. Deep partial thickness burns extend through the epidermis into the deep (reticular) dermis. Body surface area is determined by the rule of nines. Nine percent for each upper extremity means that the forearm is approximately one fourth of 9%. Two forearms burns are half of 9%. Partial thickness burns are often more painful than full thickness burns, in which all of the nerve endings are destroyed.

2. A 3-year-old boy presents with circumferential burns involving both upper extremities, including his hands, from pulling a boiling pot of water off the stove. The burns are mixed partial thickness and full thickness burns. Which of the following best describes the body surface area burned and the most appropriate disposition?
- **a.** 9% and admit to pediatrics with surgery consultation
- **b.** 9% and transfer to burn unit
- **c.** 18% and transfer to burn unit
- **d.** 18% and admit to pediatric surgery
- **e.** 20% and admit to pediatric intensive care unit

Answer: c. Children with burns over 10% total body surface area (TBSA) should be transferred to a burn unit. In addition, hand burns should be treated at a burn unit. Circumferential burns are not consistent with a splash injury, and child abuse should be suspected and reported.

3. A 55-year-old, 80-kg man presents with partial thickness burns of both his legs, front torso, and groin. What is the initial fluid resuscitation according to the Parkland formula?
- **a.** 500 mL LR solution in the first 4 hours
- **b.** 1100 mL normal saline in the first hour
- **c.** 1100 mL of LR solution in the first hour
- **d.** 2400 mL normal saline in the first hour
- **e.** 4200 mL LR solution in the first 4 hours

Answer: c. The amount of LR solution required for the first hour can be rapidly estimated with the Parkland formula by multiplying the estimated total body surface area (TBSA) of the partial and full thickness burn (55%) by body weight in kilograms (80 kg) and dividing by 4.

4. A 25-year-old woman presents with a partial thickness burn to her right forearm after a grilling accident. You note areas of gray discoloration with decreased blanching in the erythematous region of the burn. In addition to irrigation, debridement, and dressing with a nonadherent dressing, which of the following would be the most appropriate treatment?
- **a.** Apply silver sulfadiazine and follow-up with plastic surgery in 1 week
- **b.** Calculate the Parkland formula and administer fluids before discharge
- **c.** Educate the patient about daily dressing changes and have her follow-up with plastic surgery in 24 to 48 hours
- **d.** Immerse her forearm in ice water for pain control
- **e.** Unroof soft blisters and have the patient follow-up with her primary care physician in 1 week

Answer: c. The distinction between superficial and deep partial thickness burns is important in that deep partial thickness burns often do not heal within 2 or 3 weeks and may result in severe scarring and contractures, especially in children. As a result, deep partial thickness burns that do not heal within 21 days may require excision and skin grafting to minimize scarring. Deep partial thickness burns may also progress to full thickness burns during the course of several days after injury. Burns less than 20% TBSA can be treated with oral hydration. Although there are little data to guide treatment, blisters are generally left intact initially if possible unless tense or over a joint. They may later require debridement.

5. Which of the following is an indication for intubating a patient who was found in a burning house and requires transfer 2 hours away to a burn center?
- **a.** Soot in the airway and singed nasal hair
- **b.** Dyspnea and hypoxia
- **c.** Patient unable to handle own secretions
- **d.** Altered mental status
- **e.** All of the above

Answer: e. Traditionally, inhalation injury was diagnosed on the basis of clinical findings, such as facial burns, singed nasal vibrissae, carbonaceous sputum, and a history of injury within a closed space. However, these findings are neither highly sensitive nor highly specific. If the patient is at a burn center and symptoms are mild, then an approach involving flexible laryngoscopy and close observation in an ICU is reasonable. However, if the patient requires prolonged transport to a tertiary care center then intubation is recommended if signs or symptoms or airway involvement are present.

6. What is the most appropriate management for a superficial partial thickness burn on the forearm?
- **a.** A clean dry dressing, such as gauze
- **b.** Petroleum gauze
- **c.** Systemic antibiotics and silver sulfadiazine
- **d.** Topical antibiotic ointment
- **e.** B and D

Answer: e. Superficial partial thickness burns may be treated with a topical antibiotic ointment, petroleum gauze or one of several commercially available burn dressings. Silver sulfadiazine, as well as dry dressings, will slow re-epithelialization. Silver sulfadiazine is appropriate for infected or heavily contaminated burns. Systemic antibiotics are *not* indicated for non-infected burns.

55

Chemical Injuries

Michael D. Levine

KEY CONCEPTS

- For chemical injury, the degree of skin destruction is determined mainly by the properties of the toxic agent, its concentration, and the duration of its contact.
- Chemical injuries are commonly encountered after exposures to acids and alkalis.
- Hazardous materials (HazMat) are substances that can cause physical injury and damage the environment if improperly handled.
- In dealing with HazMat incidents, two distinct goals need to be achieved: (1) Containing the HazMat, extinguishing the fire and explosions, and eventually cleaning the site, and (2) evacuating victims exposed to the HazMat from the scene, decontaminating, and rapidly evaluating for treatment.
- Decontamination consists of removing contaminated clothing and hydrotherapy (i.e., washing of the skin) for the majority of exposures. For lithium, potassium, and sodium exposure, hydrotherapy is contraindicated because of the exothermic reaction upon contact with water.
- Alkali burns tend to penetrate deeper into tissue layers than acidic burns; and as a result, are associated with greater morbidity.
- Hydrofluoric acid burns can be associated with significant systemic hypocalcemia.
- Exposure to various toxic gases can occur from common industrial settings, and knowledge of these agents is necessary for proper treatment by the emergency clinician.
- Unconventional chemical weapons may be categorized into four major classifications: nerve agents, vesicants, choking agents, and cyanide agents.

GENERAL APPROACH TO A HAZMAT EVENT

Foundations

Background and Importance

During the past century, there has been a dramatic increase in the number of chemicals produced. Worldwide, there are more than 5 million known chemicals, with thousands of new chemicals developed annually. The chemical industry is a critical component to the US economy, producing more than 600,000 jobs. Large chemical incidents, such as the 1974 cyclohexane vapor leak and subsequent explosion in Flixborough, UK, and the 1984 methyl isocyanate release from a pesticide plant in Bhopal, India, have drawn large-scale media attention, and many smaller chemical spills occur daily.

It is estimated that 25,000 to 35,000 chemical incidents occur annually in the United States alone, with the majority resulting from either equipment failure or human error. Many individuals suffer injuries or deaths annually due to these chemical spills.[1] While these chemical incidents can occur in rural or urban environments, they are more common in rural areas.[1] Individuals living close to an industrial complex may be exposed to a chemical following inadvertent release from the industrial site. However, other individuals living far from any stored chemicals may be exposed due to accidents during transport.

It is estimated that half of all pesticide or agricultural chemical spills occur during transportation. The transport of hazardous materials occurs throughout the United States; it is estimated more than 1 million hazardous substances are shipped throughout the United States daily.[2] These chemicals, which include acids, alkalis, and other highly reactive substances, not only are found throughout industry but also are ingredients in many household products. Exposure to these substances can result in multi-system injuries.

A hazardous material (HazMat) is defined as a substance, including gases, solids, or liquids, that has the potential to cause harm to people or the environment. Historically, the Hazardous Substances Emergency Events Surveillance (HSEES) system collected information on chemical exposures, but this program concluded in 2009. The following year, the National Toxic Substances Incidents Program (NTSIP) was established, which compiles data from multiple sources to perform chemical surveillance. The most commonly released hazardous substances are volatile organic compounds, herbicides, acids, and ammonia. Various other products, such as cement, drain cleaners, and gasoline, are also hazardous, and exposure can result in severe disability or death.

Community Preparedness and HazMat Response

HazMats are found throughout society, including rural and urban settings. Furthermore, because these substances are often transported on highways and railroads, a HazMat exposure could potentially occur in any community. While industrial settings account for the largest percentage of chemical incidents, exposures in rural residential settings and agricultural settings occur.[3] First responders, paramedics, and members of the HazMat response team must work together to identify toxic chemicals and assess hazardous environments. Placards, shipping papers, United Nations chemical identification numbers, and markings on shipping containers help identify the offending agent. The Chemical Transportation Emergency Center (CHEMTREC) in Arlington, Virginia, maintains a 24-hour telephone hotline (Box 55.1) to assist in the rapid identification and management of hazards caused by chemical agents. Standardized placards have also been developed by the National Fire Protection Association (NFPA). These placards use four diamonds to identify specific hazards associated with this project. In addition, regional poison control centers (see Box 55.1) provide specific health information regarding individual chemicals.

Although placards can identify chemicals in the case of a known industrial exposure, it is not always clear an exposure has occurred. The challenges in identifying a HazMat scene are highlighted in Japan, where there has been an epidemic of chemical suicides with hydrogen sulfide gas inside locked cars. Following widespread internet awareness of this situation, there were a series of similar "copy-cat" incidents in the United States. Such exposures put first responders at particularly

BOX 55.1 Important Phone Numbers to Assist in the Identification and Management of Chemicals and Chemical Injuries

CHEMTREC: 1-800-424-9300
Poison Control: 1-800-222-1222

high risk of chemical injury, because they might have been unaware of any history of potential chemical exposure.

Contingency Plan

The contingency plan for HazMat management is comprised of two distinct parts: initiation of the site plan, and evacuation. Initiation of the site plan begins after the specific offending agent has been identified and the surrounding environment has been assessed. It is only after the substance has been identified that the risks to the public and the environment can be accurately identified. First responders should be trained to recognize the potential for a HazMat incident and establish a perimeter. During the evacuation phase, the HazMat technicians are specifically trained in the use of personal protective equipment (PPE), establishing entry into a HazMat scene, victim rescue, and determining the type and extent of a HazMat emergency. A central command post should be established in an area far enough from the incident to avoid direct contamination. Local geographic and environmental factors (e.g., wind direction and speed) may need to be considered when choosing a location for the command post, depending on the specific chemicals involved. The command post should coordinate the activities of the HazMat team with those of the emergency medical services personnel, firefighters, police officers, and other relevant personnel.

Anatomy, Physiology, and Pathophysiology

Most chemical agents cause skin damage by producing a chemical reaction rather than a hyperthermic injury. However, certain chemicals can generate significant heat production via an exothermic reaction after exposure to moisture. Nonetheless, the majority of dermal injuries result from direct damage to the skin rather than from a hyperthermic injury. The type of chemical reaction produced depends on the properties of the individual agent. In general, the degree of damage correlates directly with the toxic agent's concentration and duration of exposure. Several other factors contribute to the degree of injury—for example, areas of the body where the skin is particularly thin (e.g., face, scrotum) are more at risk than areas of the body where the skin is thicker (e.g., palms of hands and soles of feet). Skin that is thin or broken is at risk for more severe injury.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSES

Exposure to acidic compounds can produce protein denaturation and subsequent *coagulative necrosis*. In theory, the eschar limits the depth by which an acid can penetrate. Various acids produce eschars with characteristic colors. For example, nitric acid burns result in a yellow eschar, whereas sulfuric acid burns result in a black or brown eschar. Hydrochloric acid and phenol burns produce a white to gray-brown eschar. Despite the eschar formation, profound chemical burns can occur following exposure to an acid. Alkali agents, in contrast, produce a saponification and reactive *liquefactive necrosis*. Because there is no eschar to limit penetration, alkali burns tend to penetrate deeper into the tissues, which results in significant tissue damage.

Other infections (e.g., cutaneous anthrax), injury (e.g., full-thickness burn), or envenomation (e.g., Brown recluse spider bites or *Loxosceles* sp.) that result in eschar formation can be confused with chemical injury. However, history and physical findings differ, allowing for distinction from chemical injury. For example, a splash pattern may be seen following exposure to liquid chemicals. Ocular injection may be seen following exposure to chemical fumes that affect mucosal membranes. Wheezing may be heard following various inhalational injuries.

DIAGNOSTIC TESTING

Patients with significant burns or systemic toxicity are required to do a complete blood count, metabolic profile, including serum electrolytes, with hepatic and renal function tests. Monitor the urine output and check for infection or sepsis; an arterial or venous blood gas and serum lactic acid level is recommended. A chest radiograph is obtained following inhalational injuries.

MANAGEMENT

In dealing with a HazMat incident, two distinct processes occur simultaneously. First, the scene should be secured; this involves containing the substance, extinguishing fires, and controlling other environmental hazards. The second process involves treatment, which begins with decontamination. The exact decontamination depends on the specific agent and route of exposure. In general, all decontamination should be performed before arrival in the emergency department (ED). Individuals who are not exposed to the hazardous material are kept safely away from the scene to prevent subsequent exposure.

At the outset of any contamination event, the offending agent may not be known. Therefore, first responders and those having direct contact with exposed patients must wear appropriate PPE. Once the first responder is dressed appropriately, decontamination begins by removing the patient's contaminated clothes. It is critical that dry (anhydrous) chemicals can be brushed off the patient's skin, to the extent feasible, followed by copious irrigation with water delivered under low pressure. Ideally, the contaminated water will be contained on the scene for appropriate disposal. Liquid chemicals can be copiously irrigated directly. Decontaminate the patient before entering the ED if it was indicated but not performed on scene. The primary and secondary survey can occur simultaneously with decontamination.

Although the exact requirements for PPE among hospital personnel are somewhat controversial, at a minimum all personnel involved with decontamination should wear chemical-resistant clothing with a hood, boots, eyewear, at least two layers of gloves, and some form of respiratory protection.

The initial management of the chemically burned patient involves removing the individual from the hazardous environment. Because various chemicals will continue to destroy tissues until they are removed from the skin, the clothing should be removed, and prompt decontamination measures should be initiated at first chance.

Hydrotherapy involves the gentile irrigation of a large volume of water under low pressure for a prolonged time. Such therapy dilutes the toxic agent and washes it out of the skin. High-pressure irrigation should not be used, because it can drive the chemical deeper into the tissues, as well as produce splattering of the chemical into the eyes of the patient or rescuer.

Water should be used for irrigation after acid or alkali burns. Chemical neutralization may be more deleterious to victims with chemical burns. Additionally, it has been hypothesized that neutralizing agents produced additional heat, thereby augmenting the burn. Although the same effect may occur when certain chemicals come in

contact with water, large volumes of water tend to limit the exothermic reaction. More recently, scientists began to question the belief that neutralization of an alkaline burn of the skin with an acid increases tissue damage because of the exothermic nature of acid-base reactions. Nonetheless, at present, we recommend irrigation with water alone as the best method for decontamination. Not all agents are best decontaminated with irrigation or hydrotherapy. Dry chemical agents, such as lye or elemental metals (e.g., sodium), should be brushed away prior to instituting hydrotherapy. Elemental metals (e.g., sodium or potassium) may produce exothermic reactions when combined with water. To minimize the exothermic reaction from such compounds, mineral oil may be applied to the skin before water. However, copious irrigation should not be delayed while waiting for mineral oil. In addition to lye and elemental metals, some argue that phenol (carbolic acid) should not be irrigated with water owing to concern for enhanced skin penetration after exposure to water. The use of a substance that has both hydrophobic and hydrophilic properties for irrigation (i.e., polyethylene glycol [PEG]) has not been proven to exhibit clear benefit over water alone; therefore, hydrotherapy should not be delayed while waiting for PEG. If PEG solution is used for decontamination, a low-molecular-weight PEG solution (200 to 400 Da) is preferred. This solution is different than the PEG solution typically used for gastrointestinal procedures.

DISPOSITION

Treat patients in a similar manner as those with thermal burns, and criteria for transfer to a burn center are identical (see Chapter 54). Those with minor symptoms, in whom pain is controlled, and who lack systemic symptoms can be referred home. Admit patients with systemic toxicity, significant opioid analgesic requirements, and those requiring systemic administration of an antidote (e.g., intra-arterial calcium for hydrofluoric acid).

OCULAR INJURIES

Foundations

Background and Importance

Chemical burns to the eye require emergent management due to the potential for irreversible vision loss. Common causes include inadvertent handling of chemicals with resultant splash injury, exploding batteries, airbag deployment, and intentional assaults.

Anatomy, Physiology, and Pathophysiology

Alkali burns can initially appear trivial, but because of an interaction with lipids in the corneal epithelial cells, a liquefaction necrosis results, and deep penetration through the corneal stroma can ensue. The injury can occur rapidly; for example, anhydrous ammonia can penetrate the anterior chamber in less than 1 minute, resulting in complete blindness.

There are numerous grading systems that have been developed to describe ocular burns, including the Roper-Hall classification, which divides the injury into four grades based on the amount of corneal haze and perilimbal ischemia; and the Dua classification, which has six grades, and is based on the amount of limbal involvement (Table 55.1).[4] Exact classification systems are not particularly relevant for the emergency physician.

Clinical Features

Ocular chemical exposures can present with conjunctival injection, chemosis, cutaneous eyelid burns, subconjunctival hemorrhage and various degrees of vision impairment.

TABLE 55.1 Dua Classification

Grade	Prognosis	Clinical Findings	Conjunctival Involvement
I	Very good	0 clock hours of limbal involvement	0
II	Good	<3 clock hours of limbal involvement	<30%
III	Good	3 to 6 clock hours of limbal involvement	30%–50%
IV	Good to guarded	6 to 9 clock hours of limbal involvement	50%–75%
V	Guarded to poor	9 to 12 clock hours of limbal involvement	75%–100%
VI	Very poor	Complete limbal involvement	100%

Differential Diagnoses

The differential diagnosis for a red eye or vision loss is broad and is more fully discussed in Chapter 18. In the setting of trauma, the differential diagnosis includes subconjunctival hemorrhage, perforation, foreign body, and corneal abrasions. In the absence of trauma, the differential diagnosis includes benign etiologies (such as, subconjunctival hemorrhage or conjunctivitis) to more concerning etiologies (such as, iritis, uveitis, episcleritis, glaucoma, optic neuropathy, central retinal artery occlusion, or central retinal vein occlusion).

Diagnostic Testing

Perform a visual acuity test in all patients with ocular complaints. Check the ocular pH with litmus paper, ideally before and after irrigation. If the patient can tolerate the procedure, a comprehensive slit-lamp examination is preferred.

Management

The management of acute chemical burns to the eye involves several stages including removal of the offending substance, and administration of medications to decrease inflammation, avoid further tissue injury, and ultimately foster re-epithealization.[4] When a chemical injury to the eye is suspected, start copious irrigation immediately. In the pre-hospital setting, tap water irrigation is generally readily available and the ideal choice for irrigation. At the scene, it is recommended that the victim submerge the eyes in running tap water and continuously open and close the eyes with the head turned such that the affected eye is lower than the unaffected eye to minimize any contamination into the unaffected eye. In the ED, tap water irrigation can be continued in preparation for a more definitive irrigation system. However, because there is some concern for possible promotion of corneal edema, based on the hypotonicity of tap water, some advocate for use of other readily available solutions for ocular irrigation. Such solutions include either lactated Ringers, a balanced salt solution (BSS), or amphoteric solutions such as Diphoterine®.[4] The repeated application of topical anesthetics (such as, proparacaine) can decrease pain and facilitate irrigation. Hydrotherapy can also be accomplished by connecting intravenous tubing to a bag containing normal saline or lactated Ringers solution. The initial therapy consists of continual irrigation of the eye with 2 L of lactated Ringers during the first 30 minutes. A Morgan lens can be used for irrigation, although there is a theoretic risk of trapping the chemical between the conjunctiva and the Morgan lens, thereby increasing the burn. If a Morgan lens is used, we recommend replacing the lens between each liter. After 2 L has been infused, as described earlier, litmus paper is inserted into the conjunctiva

to determine the pH; irrigation is continued until the pH is at a near-physiologic level (pH of 7.4). Alkali burns are likely to require more irrigation than acidic burns. In either case, depending on the chemical's pH and amount of exposure, additional liters may be required to restore a near-neutral pH. Following irrigation, it is important that the emergency physician evert the upper eyelid and visually inspect the area for any lodged or hidden particulate matter. A slit-lamp examination with fluorescence staining is recommended to assess for any corneal abrasion. Although of undetermined benefit, ocular antibiotics are commonly used after appropriate decontamination if a corneal abrasion is present.

The use of topical or subconjunctival corticosteroids following alkali burns has been associated with reduced corneal opacity, vascularization, and inflammation. Topical corticosteroids, such as fluorometholone 1% or prednisolone 0.5% can reduce inflammation and should be continued for approximately 1 week. We recommend consulting an ophthalmologist prior to implementing corticosteroids.

Disposition

Emergent ophthalmologic consultation and close follow-up are indicated for all significant exposures. Most ocular burns, other than the mildest burns, are treated with a long-acting cycloplegic and a mydriatic. In addition, after consulting an ophthalmologist, a carbonic anhydrase inhibitor may be used for 2 weeks (or until the ocular pain subsides). These medications decrease the potential for pupillary constriction, increased intraocular pressure, and early glaucoma. Procedures such as amniotic membrane patching, anterior chamber paracentesis, and corneal transplant have been used for chemical injuries to the eye but should only be performed by an ophthalmologist.

Patients with lower grade ocular injuries can be managed as outpatients, but patients with higher-grade injuries should be admitted to the hospital for more intensive treatment.

SPECIFIC TOXINS

Hydrofluoric Acid

Foundations

Background and importance. Hydrofluoric acid is an acidic aqueous solution made from fluorine. It has a variety of industrial indications, including glass etching, the production of semiconductors, rust removal products, insecticides, tile-cleaning agents, and automobile wheel cleaning products.[5] It is available in many over-the-counter products in concentrations ranging from 6% to 12% but can be used in the industrial setting in concentrations exceeding 70%.

Anatomy, physiology, and pathophysiology. Absorption of hydrofluoric acid can occur upon exposure to the lung, skin, and eyes. In a 20-year review of all hydrofluoric acid deaths reported to the Taiwan Poison Control Center, dermal exposure accounted for 84% of all exposures, and the majority occurred in an occupational setting. Of these 324 subjects, the majority of subjects had mild toxicity. However, approximately 40% of subjects had moderate toxicity and 1% had severe toxicity. Two subjects died strictly from hydrofluoric acid-related dysrhythmias and shock. The timing of onset of pain after a hydrofluoric acid burn is inversely related to the concentration. For example, burns from a 20% hydrofluoric acid solution can have pain delayed for up to a day, whereas burns from a 50% hydrofluoric acid concentration will likely result in immediate pain.[5,6] Hydrofluoric acid is unique in its mechanism of action. Despite being an acid, it is capable of causing a liquefactive necrosis with subsequent deep tissue burn, similar to alkalis.[6] The free fluoride ion is responsible for most of the damage associated with hydrofluoric acid exposure. However, both the hydrogen ions as well as the fluoride ions cause tissue damage. In the setting of high concentrations of hydrofluoric acid (>50%), the hydrogen ion itself can cause damage to the skin, eyes, and mucosal membranes. Later, the fluoride ion causes both local and systemic toxicity, regardless of the concentration of hydrofluoric acid.[7] The free fluoride ion scavenges cations, such as calcium and magnesium, thereby resulting in systemic hypocalcemia and hypomagnesemia. In addition, free fluoride ions can inhibit sodium, potassium–ATPase (Na^+, K^+-ATPase), and the Krebs cycle. The combination of cellular destruction and inhibition of Na^+, K^+-ATPase can also result in hyperkalemia as a preterminal finding. As a result of the numerous electrolyte disturbances, QT prolongation, hypotension, and ventricular arrhythmias can occur. The severity of injury depends on the concentration of the substance and the duration of exposure.

Clinical Features

Inhalational Exposure

Inhalation of hydrofluoric acid is rare, and it almost always occurs in the industrial setting. Patient outcomes vary considerably depending on the concentration and duration of exposure to hydrofluoric acid. Inhalation and skin exposure to 70% hydrofluoric acid can result in pulmonary edema and death within hours. However, delayed pneumonitis and adult respiratory distress syndrome can occur, and the symptoms can be present for months. Pneumonitis can be severe and require ventilatory support.

Gastrointestinal Exposure

Gastrointestinal exposures are rare, except for cases of intentional ingestions. When such an exposure does occur, symptoms can include nausea, vomiting, and abdominal pain. Life-threatening fluoride toxicity can occur with large oral ingestions.

Ocular Exposure

Even though hydrofluoric acid is an acid, exposure of the eye to hydrofluoric acid can result in a severe burn with penetration and necrosis of the structures throughout the anterior chamber. As with other ocular injuries, immediate and copious irrigation of the eye is indicated. Systemic absorption is possible.

Dermal Exposure

Dermal exposure is the most common route of hydrofluoric acid injury. During handling of containers in which hydrofluoric acid is stored, contamination of inadequately protected fingers and hands often results in a chemical burn injury. The hydrofluoric acid skin burn has a distinct characteristic: the exposure causes progressive tissue destruction. Intense pain can occur; the onset of the pain is inversely related to the concentration of the hydrofluoric acid, such that the lower the concentration of hydrofluoric acid, the longer the time until symptoms may manifest. The pain may seem out of proportion the examination.[8] With larger exposures, the involved skin may develop a tough, coagulated appearance. If untreated, the burn can progress to an indurated, whitish appearance with vesicle formation. Within the digits, hydrofluoric acid has a predilection for subungual tissue. Severe untreated burns can progress to full thickness burns and can even result in loss of digits.

Differential Diagnoses

Because pain may seem out of proportion to the examination findings, shingles, neuropathy, and other chemical injuries are within the differential diagnosis. Numerous other gases causing respiratory compromise should also be included. In the presence of apparent burns, the differential diagnosis includes blistering disorders, toxic epidermal necrolysis, and infectious etiologies.

Diagnostic Testing

Test serum potassium, magnesium and ionized calcium levels in patients with hydrofluoric acid burns. With electrolyte abnormalities, an electrocardiogram (ECG) will assess for dysrhythmias or changes in the QTc or QRS intervals. Obtain a chest radiograph in individuals with inhalant or pulmonary symptoms. Finally, perform a detailed eye examination, including a slit-lamp examination, fluorescein staining, and visual acuities on individuals with ocular exposure.

Management

The initial treatment of hydrofluoric acid skin exposure is immediate irrigation with copious amounts of water for at least 15 to 30 minutes. Most exposures to dilute solutions of hydrofluoric acid respond favorably to immediate irrigation. Severe pain or any pain that persists after irrigation indicates a more severe burn that requires detoxification of the fluoride ion. Detoxification is accomplished when an insoluble calcium salt is formed. In the case of digital exposure, in which the fingertip is exposed, the fingernail should be removed.

In contrast to thermal burns, blisters are burst because necrotic tissue may harbor fluoride ions.[7] The fluoride ions can then be detoxified through topical treatment, local infiltrative therapy, or intra-arterial infusion of calcium. Calcium gluconate (2.5%) gel can be administered topically. Calcium chloride should not be used topically, as it is irritating to the dermis. Calcium gluconate gel is often not available in hospital pharmacies, but it can be made by mixing 3.5 g of calcium gluconate powder in 150 mL of a water-soluble lubricant (e.g., glycerin-hydroxyethyl cellulose lubricant [K-Y Jelly]). This gel is secured by an occlusive cover (e.g., powder-free latex glove). Because the skin is impermeable to calcium, topical treatment is effective only for mild, superficial burns.

Infiltration Therapy

Subcutaneous. Infiltrative therapy is necessary for treatment of deep, painful hydrofluoric acid burns. Calcium gluconate is the agent of choice and can be administered by either direct infiltration or intra-arterial injection. A common technique involves injecting 0.5 mL/cm^2 of 10% calcium gluconate subcutaneously through a 27- or 30-gauge needle. The use of an equal volume mixture of 5% calcium gluconate and 0.9% normal saline has been shown to reduce irritation of tissues and decrease subsequent scarring.

Despite its wide acceptance, the infiltration technique has disadvantages, especially in treating digits. A regional nerve block is recommended because the injections may be very painful. Removal of the nail to expose the nail bed is required if subungual tissue is involved. Vascular compromise can occur if excessive fluid is injected into the skin exposure sites, and unbound calcium ions have a direct toxic effect on tissue. Because of these disadvantages with subcutaneous infiltration in the hand, we recommend intra-arterial infusion in most instances.

Intravenous and intra-arterial. Patients with pain refractory to local or subcutaneous calcium administration may benefit from regional anesthesia, either intravenously (e.g., Bier block) or intra-arterially. Various dilute solutions of calcium have been used. Perhaps the simplest method involves the administration of a mixture of 10 mL of solution of 10% calcium gluconate in 40 to 50 mL of normal saline infused over 4 hours. Because of ease of administration, we recommend starting with this approach, although other approaches can be used in conjunction with this approach if pain persists. If more than 6 hours has elapsed since the time of hydrofluoric acid exposure, tissue necrosis cannot be prevented, even though pain relief can be achieved up to 24 hours after exposure. There is a direct correlation between the speed by which arterial infusion of calcium administration occurred and both the time of wound healing and the need for surgical intervention.

The intra-arterial infusion technique has potential disadvantages. Arterial spasm or thrombosis may result in significant skin loss. The intra-arterial procedure is more expensive, largely because it requires hospitalization for the use of the infusion pump and the monitoring of serum calcium concentrations if repeated infusions are used. Recently, the use of epidermal growth factor was found to be superior to saline, calcium gluconate, or magnesium sulfate.[9]

Respiratory Exposures

In the case of an inhalational exposure to hydrofluoric acid, prompt airway management is paramount, with endotracheal intubation occurring for the usual indications. Calcium gluconate can be nebulized as a 2.5% to 5% solution.[7] Racemic epinephrine or albuterol can be used for bronchospasm. Bronchoscopy can be performed to assess the degree of injury.

Ocular Exposures

The ocular use of calcium gluconate is somewhat controversial, because it has the potential to cause further damage to the eye. The use of ocular calcium gluconate is not routinely recommended. In the occupational setting, use of hexafluorine may be considered after copious irrigation of the eye with tap water or normal saline.[10]

Systemic Toxicity

Hydrofluoric acid binds calcium and magnesium ions with strong affinity. Systemic manifestations of fluoride toxicity are related to hypocalcemia and include abdominal pain, muscle fasciculations, nausea, seizures, ventricular dysrhythmias, and cardiovascular collapse. Burns as small as 2.5% of the total body surface area caused by concentrated hydrofluoric acid are fatal. Hypocalcemia can occur after significant exposure to hydrofluoric acid and is corrected with an intravenous 10% calcium gluconate infusion. Calcium chloride can be used, but its administration requires central venous access. In addition, fluoride ion toxicity has cardiac and neurotoxic effects.

Disposition

Patients treated with calcium therapy with continued refractory pain should be hospitalized for observation and should undergo a toxicological consultation. Patients with significant hydrofluoric acid exposure with systemic toxicity require hospitalization to monitor for cardiac dysrhythmias for 24 to 48 hours.

Formic Acid

Foundations

Background and importance. Formic acid is a caustic organic acid used in rubber, paper, tanning, agricultural, and electroplating industries. It has also been used to manufacture disinfectants and in various cosmetics.

Anatomy, physiology, and pathophysiology. Formic acid causes cutaneous injury by inducing a coagulative necrosis.

Clinical Features

Systemic toxicity occurs after absorption and is manifested by metabolic acidosis, gastrointestinal bleeding, bowel perforation, and aspiration. Because of its ability to induce oxidant stress, hemolysis may occur.

Differential Diagnoses

Similar to hydrofluoric acid, the differential diagnosis includes various other chemical burns, infectious etiologies, toxic epidermal necrolysis, and blistering disorders.

Diagnostic Testing

No specific diagnostic testing is indicated. If the patient shows any signs of systemic toxicity, obtain a complete blood count, serum electrolytes, and either an arterial or venous blood gas.

Management

Begin copious irrigation immediately. Acidosis (pH < 7.30) should be treated with sodium bicarbonate. Mannitol may be used to expand plasma volume and promote osmotic diuresis in patients with hemolysis. Folinic acid, which enhances the conversion of formic acid to carbon dioxide and water can be administered for severe toxicity. Hemodialysis may be required for patients with systemic toxicity, renal failure, and metabolic acidosis. Exchange transfusion may be indicated for those patients that are refractory to standard medical management, including hemodialysis.

Disposition

Treat patients according to local burn center referral guidelines and refer those who meet criteria for evaluation in a burn center. Other patients, including those without systemic manifestations and those not requiring significant doses of parenteral analgesics, can be discharged home with close outpatient follow-up. Specific treatment recommendations and disposition decisions can be discussed with a regional poison control center (see Box 55.1).

Anhydrous Ammonia

Foundation

Background and importance. Anhydrous ammonia is a colorless, pungent gas used extensively as a fertilizer in agriculture. It can also be used to manufacture explosives, petroleum, plastics, and synthetic fibers. In addition, the "dry cook" method of methamphetamine production uses anhydrous ammonia as an amphetamine precursor. This method was associated with numerous burns due to anhydrate ammonia. In recent years, due to changes in legislation, anhydrous ammonia has often been substituted with ammonium nitrate or ammonium sulfate-based products in a so-called "one pot" method. Nonetheless, it is used to produce methamphetamine. Anhydrous ammonia can be transported as a pressurized liquid. The sudden release of liquid ammonia can cause injury primarily through cutaneous (burn) and pulmonary injuries.

Anatomy, physiology, and pathophysiology. Anhydrous ammonia is generally stored at an extremely low temperature (−33°C). Consequently, exposure to liquid at this temperature can result in tissue necrosis and frost bite. The ammonia vapors readily dissolve in the moisture in skin, eyes, oropharynx, and lungs to form hydroxyl ions that cause chemical burns by liquefaction necrosis, which can result in full-tissue skin loss.

Clinical Features

Exposure to anhydrous ammonia results in dermal injury and chemical burns similar to other caustic agents. The severity of injury is directly related to the concentration and duration of ammonia exposure. In general, acute exposure to anhydrous ammonia produces the greatest injury to the proximal airway rather than the distal airway. However, following a recent large-scale release of anhydrous ammonia following an automotive accident, nearly 10% of the patients evaluated required intensive care unit admission. The majority of these patients required mechanical ventilation.[11]

Differential Diagnoses

The differential diagnosis includes chemical burns or frostbite injury from any other chemical (e.g., Freon), blistering disorder, infectious etiologies, and environmental exposures, such as frostbite and cold-related injuries.

Diagnostic Testing

Do a chest radiograph in patients with pulmonary complaints. Serum electrolytes and an arterial or venous blood gas are measured in symptomatic patients.

Management

Treatment consists of prompt irrigation of the eyes and skin with water and management of inhalation injury. If necessary, the airway should be secured through standard intubation methods with a large-diameter tube to prevent distal airway obstruction from sloughing of mucosa. After intubation, lower airway injury is managed with positive end-expiratory pressure ventilation.

Disposition

Patients with minor burns requiring admission or referral to a burn center, as per local guidelines can be discharged home, as long as there is no evidence of systemic toxicity or significant analgesic requirements. Patients with pulmonary complications should be admitted for further airway monitoring.

Cement

Cement is primarily composed of calcium oxide that combines with water to form calcium hydroxide. This compound is alkaline and can cause cutaneous injury following prolonged exposure.

There are three types of cement burns. The most common burn is a chemically abrasive form, and heat-related or blast-induced burns can also occur. Heat-related and blast-induced burns are more common in the industrial setting and are associated with severe burns, often involving the respiratory tract.

The treatment of cement burns attempts to eliminate the toxic component via copious irrigation, after all clothes have been removed. Early excision and grafting are often necessary, and referral to plastic surgery may be required for patients with extensive skin and degloving injuries.

Phenol and Derivatives

Foundations

Background and importance. Phenols are used industrially as starting materials for many organic polymers and plastics. They are widely used in the agricultural, cosmetic, and medical fields. Because of their antiseptic properties, they are also used in many commercial germicidal solutions. Dilute solutions of phenol have been used historically by plastic surgeons for chemical face peels. Phenols are usually mixed with water, soap, and croton oil. This solution can produce a partial thickness burn of a predictable depth in a controlled manner. The concentration is kept sufficiently low to reduce the occurrence of systemic complications. The physician performing phenol chemical peels should be concerned about the possibility of rapid phenol absorption. Even in a controlled setting, ventricular dysrhythmias occur as a result of the phenol application. A number of phenol derivatives (e.g., hexylresorcinol and resorcinol) are more bactericidal than phenol.

Anatomy, physiology, and pathophysiology. Phenol (carbolic acid) is an aromatic acidic alcohol with a characteristic odor. The concentration of phenol is inversely related to its depth of burn. Highly concentrated solutions result in coagulation of the keratin, thereby preventing deeper penetration. Histologic studies have demonstrated that 100% concentrations of phenol produce 35% to 50% less penetration than a 50% solution.

Both phenol and its derivatives are highly reactive, corrosive poisons that damage cells by inducing cell wall disruption, protein denaturation, and coagulative necrosis. After penetrating the dermis, phenols produce necrosis of the papillary dermis. This necrotic tissue may temporarily delay its absorption.

Clinical features. When the skin comes in contact with a phenol, treatment should be instituted immediately. The exposed area should be irrigated with large volumes of water delivered under low pressure. Because dilute phenol solutions are more rapidly absorbed through the skin than concentrated solutions, gentle swabbing of the skin surface with sponges soaked in water should be avoided. Any hair, including a beard or mustache, that has come in contact with a phenol should be removed as soon as possible, because the phenol can become trapped in the hair. Because of its lipophilic nature, it can easily penetrate the dermis, producing not only local findings, but systemic manifestations.

In animal studies, exposure to as little as 0.6 mg of phenol per kilogram can be lethal. Systemic toxicity of phenol primarily affects the central nervous system (CNS) and cardiovascular system. In the CNS, toxicity can manifest as stimulation, lethargy, seizures, or coma. Conduction disturbances can be either tachycardic or bradycardic in nature. Marked hypotension may occur as a result of central vasomotor depression, in addition to a direct toxic effect on the myocardial cells and small blood vessels. Hypothermia and metabolic acidosis can also occur.

Differential Diagnoses

The differential diagnosis includes burns from any other chemical or heat, blistering disorders, dermal infections, hydrofluoric acid exposure, methyl salicylate toxicity, and toxic epidermal necrolysis.

Diagnostic Testing

Perform an ECG, electrolytes and either an arterial or venous blood gas in patients with a phenol exposure.

Management

Experimental studies indicate that water alone is effective in reducing the severity of burns and preventing death in animals with skin exposed to phenol and its derivatives. The most effective treatment is undiluted PEG (molecular weight 200 to 400 Da) or isopropanol (isopropyl alcohol). Adequate supplies of either PEG or isopropanol should be stocked in hospitals located near areas where phenol is used and can often be found in the chemical section of hospital pharmacies. A quick wipe of the skin with PEG solutions reduces mortality and burn severity in experimental animals. These solutions can be used for facial phenol burns, because they are not irritating to the eyes. Decontamination with water should be performed until a PEG solution is obtained. Large amounts of water must be used, however, because small amounts enhance dermal absorption of phenols. Removal of phenol should be undertaken in a well-ventilated room so that the hospital personnel is not exposed to high concentrations of phenol fumes.

Treatment of Systemic Toxicity

The treatment of systemic symptoms is primarily supportive. Respiratory depression may require ventilatory support. Hypotension is best treated with an initial fluid bolus of 20 cc/kg of 0.9% normal saline or lactated Ringers solution. Vasopressors are recommended if shock and hypotension persist despite an adequate fluid challenge. Metabolic acidosis can be treated with sodium bicarbonate until the pH is near 7.40. The alkalization can also help prevent hemoglobin precipitation in the nephron as a result of hemolysis. Benzodiazepines, such as 2 mg intravenous lorazepam or 10 mg intravenous diazepam may be required to treat seizures caused by CNS stimulation. Intravenous lidocaine may be effective in treating ventricular dysrhythmia.

Disposition

Patients without systemic manifestations and not meeting local criteria for a burn center can be discharged after a period of 6 to 8 hours of cardiac monitoring, provided there are no arrhythmias or other manifestations of systemic toxicity. Admit patients with significant pain control requirements or vital sign abnormalities.

Phosphorus

Foundations

Background and importance. Phosphorus is a nonmetallic element that exists in three forms: elemental, white (yellow), and red. White phosphorus (also known as yellow phosphorus) is widely utilized for its explosive properties. It can be found in fireworks and munitions, but also in fertilizers and methamphetamine production. Historically, it has also been used as a rodenticide. The side of match boxes typically contains red phosphorus, a binder, and powdered glass. The heat generated by friction when the match is struck causes the red phosphorus to be converted to white phosphorus, which ignites spontaneously.

Anatomy, physiology, and pathophysiology. The autoignition temperature (the temperature at which spontaneous combustion can occur) is 30°C (86°F). When white phosphorus comes in contact with air at temperatures above the autoignition point, the phosphorus spontaneously oxidizes, forming phosphorus pentoxide. Phosphorus pentoxide can combine with small amounts of moisture in the air, forming phosphoric acid. In wounds, oxidation of phosphorus pentoxide will continue oxidizing until it is removed through debridement, neutralized, or consumed.

Clinical Features

Tissue injury from white phosphorus appears to have both thermal and chemical causes. The corrosive action of the phosphoric acid results in an exothermic reaction, thereby liberating heat and causing a thermal burn. The hygroscopic action of the phosphorus pentoxide is also responsible for causing a chemical burn, which may be partial or full thickness.

In cases of oral ingestion, white phosphorus toxicity classically occurs in three stages. The first stage can last 8 to 24 hours and is characterized by gastrointestinal tract irritation manifested as vomiting, diarrhea, abdominal pain, and gastrointestinal hemorrhage. The stool has a garlic-like odor and occasionally a luminescent or "smoking" appearance. Hypovolemic shock can result. Up to one third of patients who ingest significant quantities of white phosphorus will die during this stage. Following the first stage, a second, or latent phase ensues. During this period, which can last 1 to 3 days, symptoms appear to improve. However, the third stage is characterized by multisystem organ failure, including hepatic failure, renal failure, and CNS depression. Renal failure is usually present at days 1 to 4, whereas jaundice typically manifests at days 3 to 5. Red phosphorus can cause some gastrointestinal illness if consumed orally but is generally less toxic than white phosphorus.

Differential Diagnoses

The differential diagnosis depends on the type of phosphorous. For isolated burns, the differential diagnosis includes thermal or chemical burns (acids or alkali), infectious etiologies, and blistering disorders. For those with significant gastrointestinal illness, consider heavy metal toxicity (e.g., lead, mercury, thallium, arsenic, and iron), as well as ischemic bowel and common causes of gastrointestinal bleeding.

Diagnostic Testing

Regardless of the route of exposure, metabolic derangements including hypocalcemia and hyperphosphatemia can occur. Conduction system

disturbances, including bradycardia, QT prolongation, and ST and T wave abnormalities can occur and are partially explained by electrolyte derangements.[12] These ECG changes may explain the sudden early death that can occur in patients with relatively minor white phosphorus burns.

Management

The out-of-hospital management involves immediate removal of contaminated clothing, followed by submersion of the injured skin in cool water. Since white phosphorus becomes liquid at 44°C (111°F), avoid using warm or hot water. Remove visible phosphorus particles from the victim's skin and submerge in water. Cover burned skin with towels soaked in cool water during transport to the ED.

After the patient arrives the ED, the burned skin should be washed copiously with normal saline. In the past, some advocated for a suspension of 5% sodium bicarbonate, 3% copper sulfate, and 1% hydroxyethyl cellulose. Other similar solutions containing copper sulfate have also been described. The use of 0.9% normal saline solution, however, has demonstrated better effects than copper-containing solutions. Although there are some conflicting recommendations in the literature, given that saline is readily available and as efficacious as copper sulfate solutions with less associated toxicity, we recommend saline irrigation as the preferred irrigating solution.

Phosphorus particles can be identified with either ultraviolet light or copper-containing solutions. While the copper-containing solutions can convert phosphorus particles into cupric phosphide, which is black and thereby help facilitate removal, the use of copper solutions is associated with potential iatrogenic harm. Thus, we recommend a simple Wood's lamp be safely utilized, rather than copper solutions. Following copious irrigation with saline solution decontamination, and treatment of associated electrolyte disturbances, definitive management of the skin burns is accomplished as with any other burn wound. Monitor serum calcium and phosphate levels for 24 to 48 hours.

Disposition

Admit patients with significant phosphorus exposures to a monitored setting. As with all other caustic dermal burns, refer patients to a burn center as per local or regional guidelines.

Nitrates and Nitrites

Foundations

Background and importance. Both nitrates (NO_3^-) and nitrites (NO_2^-) are abundant in rural and industrial settings. Both sodium nitrate and sodium nitrite are used in food preservatives. Nitrites also have many medicinal uses secondary to their vasodilatory properties. Nitrates are commonly used in electroplating, engraving, and metal casting and as fertilizing agents. Exposure to either nitrates or nitrites has been associated with methemoglobinemia.

Anatomy, physiology, and pathophysiology. Reduced hemoglobin contains four heme groups, each with a ferrous (Fe^{2+}) ion. Methemoglobinemia results when the ferrous ion becomes oxidized to the ferric (Fe^{3+}) state. Under routine physiologic conditions, the body reduces the ferric valence back to the ferrous valence via cytochrome b5 reductase. At any given time, methemoglobin accounts for 1% to 2% of circulating hemoglobin. Cyanosis from methemoglobin occurs at concentrations above 1.5 g/dL.

Clinical Features

Methemoglobin toxicity exists along a spectrum. Many patients with low levels are asymptomatic. When methemoglobin concentrations in nonanemic individuals exceed 20%, headache, anxiety, dyspnea, and tachycardia can occur, although some individuals may be asymptomatic with levels exceeding 30%. Confusion, lethargy, and acidosis typically occur at methemoglobin levels approaching 40% to 50%. Coma, seizures, hypotension, dysrhythmias, and death occur when levels exceed 70%. Anemic patients may develop symptoms at lower levels. For example, a methemoglobin concentration of 1.5 g/dL in a patient with a baseline hemoglobin of 15 mg/dL will represent a methemoglobin level of 10%, whereas the presence of the same concentration of 1.5 g/dL of methemoglobin in an anemic patient with a baseline hemoglobin of 8 g/dL would represent a more concerning percentage of 18%. In addition, patients with profound methemoglobinemia and anemia (e.g., in the case of a drug-induced oxidant stress) may not develop cyanosis despite having a life-threatening methemoglobinemia.

Differential Diagnoses

The differential diagnosis includes exposure to any agent that can cause oxidant stress, including local anesthetics, phenazopyridine, dapsone, and arsine gas. In addition, hemolysis from non-oxidant stress should be included in the differential diagnosis. Consider other acquired hemoglobinopathies such as carboxyhemoglobinemia or sulfhemoglobinemia.

Diagnostic Testing

Consider the diagnosis of methemoglobinemia in any cyanotic patient whose pulse oximetry displays a saturation of 85% to 88% that is unresponsive to oxygen therapy and whose arterial blood appears "chocolate brown" in color. The methemoglobin level can be readily measured on a venous or arterial blood gas analyzed with standard co-oximetry.

Management

Asymptomatic patients are treated by rapidly removing the offending agent. For symptomatic patients without glucose-6-phosphate dehydrogenase (G6PD) deficiency, 1 to 2 mg/kg of a 1% methylene blue solution can be administered over 3 to 5 minutes. A repeat dose may be needed in cases of severe toxicity. Methylene blue acts via the enzyme nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, with which NADPH converts methylene blue to leukomethylene blue, which in turn donates an electron to reduce methemoglobin. For patients who fail to respond to methylene blue, or those with severe G6PD deficiency with concurrent severe toxicity from methemoglobinemia, exchange transfusion may be required.

Disposition

Patients without systemic toxicity and no evidence of methemoglobinemia can be discharged home after 6 hours, as long as the cutaneous burn is not too severe to warrant referral to a burn center as per local guidelines. Observe patients with methemoglobinemia in a monitored setting for 24 hours, even if the methemoglobinemia resolves after treatment with methylene blue.

Hydrocarbons

Foundations

Background and importance. Hydrocarbons are a heterogeneous group of organic compounds that are derived from carbon and hydrogen molecules. They are found in fuels, solvents, paints, paint and spot removers, dry cleaning solutions, lamp oil, rubber cement, and lubricants.

Hydrocarbons are primarily classified as aromatic or aliphatic, based on their shape. Halogenated hydrocarbons are a subgroup of aromatic hydrocarbons in which one of the hydrogen molecules is substituted with a halogen (e.g., fluoride, chloride).

Anatomy, physiology, and pathophysiology. The toxicity from hydrocarbons can affect many different organs, but the lungs are the most commonly affected. The toxicity of hydrocarbons is directly related to their volatility and inversely related to the viscosity and surface tension. The primary cause of hydrocarbon toxicity is aspiration, especially agents with high volatility, low viscosity, and low surface tension are most likely to be aspirated.

Clinical Features

The principal manifestation of hydrocarbon exposure is a pulmonary injury secondary to risk of accidental aspiration following ingestion. A chemical pneumonitis ensues with tachypnea, wheezing, hypoxia and respiratory failure. Systemic toxicity from dermal exposure to a hydrocarbon is relatively rare. Significant dermal exposures can occasionally cause local tissue irritation. Chronic dermal exposure can result in a dermatitis with pyoderma around the nose or mouth. This so-called "huffer's rash" is primarily seen with recreational abuse. The hydrocarbon inhalant can dry the skin, thereby causing microscopic cracks and allowing bacteria to enter, causing a bacterial superinfection.

Differential Diagnoses

The differential diagnosis includes exposure to any agent that can cause a chemical pneumonitis, as well as infectious pneumonia, acute exacerbation of a reactive airway disease, or pulmonary edema.

Diagnostic Testing

We recommend obtaining a chest radiograph 6 hours after ingestion, although no randomized study has demonstrated this approach to be superior to observing the patient for clinical manifestations of aspiration (e.g., coughing, gagging, vomiting, wheezing, tachypnea, or hypoxia).

Management

Treatment involves removal of the patient from the source of exposure and removal of any contaminated clothing. Copious irrigation with warm water should be performed and burns managed as are other thermal injuries.

Significant toxicity from inhaled (non-aspiration) exposure to hydrocarbons is also unlikely to produce serious effects. Some patients may develop mild headache, dizziness, nausea, or wheezing. These symptoms resolve after removal of the patient from the source of exposure.

Ingestion of hydrocarbons can result in aspiration and systemic toxicity. After ingestion of hydrocarbons, it is recommended that patients be monitored for 6 hours. There is no need for gastric decontamination. Beta-agonists can be administered for bronchospasm, and supplemental oxygen administered for hypoxia as needed. Endotracheal intubation is occasionally required for severe hypoxia and aspiration pneumonitis. Neither corticosteroids nor empirical antibiotic administration are indicated. Corticosteroids may be beneficial in the select group of individuals with underlying reactive airway disease, if it is felt that the hydrocarbon aspiration triggered an asthma exacerbation. Antibiotics may be warranted later in the clinical course if a superimposed bacterial infection develops. Such superinfections would typically manifest at least 24 hours post exposure.

Disposition

A patient can be discharged home after a 6-hour observation period, assuming no symptoms develop during the observation period and a chest radiograph (if obtained) is negative. All other patients warrant admission to observe for progression of symptoms and treatment of hydrocarbon-induced pneumonitis.

Tar

Foundations

Background and importance. There are two types of hot tar: coal tar pitches and petroleum-derived asphalts. Both products are heated to maintain a liquid form. Roofing tar needs to be heated to temperatures of at least 232°C to achieve desirable viscosities. Deeper burn injuries are associated with burns from roofing asphalt.

Clinical Features

When hot, liquefied tar comes in contact with skin, heat is transferred, and thermal injury results. The tar cools and solidifies on the skin, making removal difficult.

Management

Burns from hot tar present a treatment challenge. When hot tar touches skin, it rapidly cools, solidifies, and becomes enmeshed in the hair. It is important to facilitate this cooling process by adding cold water to the tar at the scene of the accident. Cooling tar with cold water limits the amount of tissue damage and prevents the spread. The tar is continually washed with water until it has cooled and hardened. After cooling, the skin is dried with towels to prevent systemic hypothermia. Adherent tar should not be removed at the scene of the accident. In the ED, definitive care of the burn injury involves early removal of tar, because it occludes injured skin and encourages bacterial growth. Tar adheres to skin because it is enmeshed in the hair, not because of a direct bond between epidermis and tar.

Solvents used to remove tar ideally should have a close structural affinity to tar. Both petroleum-based aromatic hydrocarbon solvents and surface-active agents, such as polyoxyethylene sorbitan (Tween 80) and petroleum-based (De-Solv-it), have been used to facilitate tar removal. In addition, the use of topical neomycin can enhance removal. Use of these surface-active agents is an effective, safe, and inexpensive means of removing tar from skin. Sunflower oil, NISA baby oil, mayonnaise, and butter have also been used to remove adherent tar from the skin, requiring 30 to 90 minutes for complete removal. Sunflower oil has proved effective and safe in removing tar without causing further skin damage.

Asphalts are susceptible to both aromatic (e.g., naphthalene) and aliphatic (e.g., hexane) hydrocarbon solvents, whereas coal tars are susceptible only to aromatic hydrocarbons. Broad-spectrum antibiotic ointments (e.g., neomycin, polymyxin B, or bacitracin) can be used both to help with removal and to help prevent infection. The ointment should be removed and a new coating applied every hour until all the tar has been removed. This process typically takes 12 to 48 hours. Antibiotic ointment can also be used to remove tar layered over the cornea and conjunctiva.

Disposition

Admit patients with significant burns or refractory pain requiring multiple doses of parenteral analgesics. Those who meet criteria for referral to a burn center should be transferred as per local guidelines. Other individuals can be discharged home with close, expedited out-patient follow-up and detailed wound care instructions.

Elemental Metals

The elemental metals, such as lithium, sodium, and potassium, are harmless unless they come in contact with water. When this happens, a violent exothermic reaction occurs that produces heat, hydrogen gas, and hydroxide. Explosions are possible. The evolved heat is sufficient to ignite the hydrogen gas, which results in further heat production and thermal burns. The formation of the hydroxide compound may also result in significant chemical injury to tissue.

The reaction occurs more rapidly with elemental potassium than with sodium. These deleterious effects of potassium have been attributed to trace amounts of potassium superoxide released on exposure to room air. Water lavage is therefore contraindicated in these circumstances.

Chromium

Chromium burns can produce systemic toxicity. Death may occur with burn surface areas exceeding 10%. In addition to local wound effects, systemic toxicity can result including hemolysis and renal failure. It has been suggested that early excision may reduce systemic complications, although there is no experimental evidence to support such a practice. Medical management of chromium toxicity remains the mainstay of therapy. Chelation therapy has not proven to be of clinical benefit.

Miscellaneous

Chlorine, Chloramine, Phosgene, Nitrogen Oxide and Phosphide

Foundations

Background and importance. Chlorine and phosgene gases were used in World War I as part of chemical warfare. Today, exposure to chlorine exposures can result from industrial sites, railroad accidents in which trains are transporting large amounts of chlorine or following exposure to pool chemicals. Cases involving release of large amounts of chlorine gas may result in injuries remote from the exposure, depending on wind conditions.

Zinc or aluminum phosphide pellets are often used as rodenticides. When the phosphide pellets come in contact with water, phosphine (PH_3) gas is formed. In addition, PH_3 gas can also be formed during the production of methamphetamine from red phosphorus.

Nitrogen oxides include nitrogen dioxide (NO_2), nitric oxide (NO), and nitrous oxide (N_2O). NO_2 toxicity can occur from the burning of nitrocellulose, from use of hockey and ice-skating arena Zamboni machines in poorly ventilated areas, and from silo filler's disease, in which the gas accumulates within a silo of decomposing grain.

Anatomy, physiology, and pathophysiology. Chlorine is a heavy greenish-yellow gas or liquid with a characteristic odor. The combination of bleach (sodium hypochlorite) with an acid produces chlorine gas, and the combination of bleach and ammonia produces chloramine gas. Both chlorine and chloramine gas produce similar toxicities. The clinical effects observed after chlorine or chloramine exposure are directly related to the time and concentration of the gas.

Phosgene reacts with water to form carbon dioxide and hydrochloric acid. Given that phosgene is relatively water insoluble, high concentrations are needed before enough hydrochloric acid can be produced to cause mucosal membrane irritation. Phosphide toxicity occurs via several mechanisms, including free radical formation, inhibition of cytochrome oxidase, and increased lipid peroxidation.[13]

NO_2 fumes can often be easily recognized because of their reddish-brown color. The nitrogen oxides can cause respiratory tract irritation. Toxicity varies somewhat depending on the oxide, but severe toxicity can result in delayed pulmonary edema, hypotension, hemoptysis, and methemoglobinemia.

Clinical Features. Mild exposure to chlorine or chloramine may simply cause mucosal membrane irritation, whereas more severe exposure will induce edema of both the upper airway and the lung parenchyma. Large acute exposure can induce wheezing, cough, and dyspnea. Acute lung injury or adult respiratory distress syndrome can result in severe cases. Because these gases are primarily reactive only at a local level, absorbed systemic effects are not commonly observed. Following large exposure, fatalities can occur.

Phosgene undergoes acetylation to produce lung injury, which can manifest as delayed pulmonary edema. The timing of the pulmonary edema is inversely related to the degree of exposure. Inhalation of PH_3 gas produces near instantaneous symptoms. Both pulmonary toxicity and gastrointestinal toxicity can result after exposure to PH_3 gas. Common pulmonary symptoms include cough, chest tightness, and dyspnea, followed later by pulmonary edema and acute lung injury. Vomiting, diarrhea, and abdominal pain are also commonly encountered. Coma, hypotension, renal failure, and various dysrhythmias have been described.

Management. The first step in treating an exposure to chlorine, chloramine, or phosgene gas is removal of the individual from the environment. Rapidly assess the patient's cardiopulmonary status after significant exposure. Endotracheal intubation may be required. Bronchospasm is treated with beta-agonists, such as albuterol. Irritation of the eyes is managed with copious irrigation with water or saline, followed by an assessment for corneal abrasions if persistent eye irritation is noted. Nebulized sodium bicarbonate (2 cc of 8.4% sodium bicarbonate mixed with 2 cc of sterile water) can be used for treatment of chlorine or chloramine gas exposure. There is limited evidence of the use of nebulized acetylcysteine (1 to 2 g; 5 to 10 mL of a 20% solution) following phosgene exposure. The use of corticosteroids has not been proven to be beneficial in the treatment of chlorine, chloramine, or phosgene toxicity. With phosphine gas toxicity, treatment is largely supportive. However, there is limited evidence suggesting beneficial effects of intravenous *N*-acetylcysteine, melatonin, vitamin E, and magnesium.[13] Given the potential toxicity of aluminum or zinc phosphide and the relatively minimal harm and cost associated with these therapies, the risk/benefit ratio probably favors treatment with these agents.

Disposition. Phosgene, phosphene, NO_2, nickel carbonyl, diborane, as well as zinc-based smoke bombs can cause delayed-onset pulmonary edema even when patients are initially asymptomatic. Therefore, patients exposed to these chemicals are best admitted for 24 hours of observation to the hospital of observation unit, even if asymptomatic early on in the clinical course. Chlorine and chloramine gases can also cause delayed pulmonary edema, however, unlike the former group of gases, with which patients can be asymptomatic for hours and then develop pulmonary edema, delayed pulmonary edema is unlikely with chlorine or chloramine. Therefore, asymptomatic individuals who have been exposed to these chemicals do not require prolonged observation.

Chemical Terrorism

In recent years, the public has become increasingly aware of chemical terrorism. Despite being banned by the 1925 Geneva Convention, chemical weapons have been used in both the military and the civilian arenas for many years. In the 1980s, chemical weapons were employed against Iraqi civilians. In 1995, Aum Shinrikyo, a Japanese cult, released sarin nerve gas in the Tokyo subway, causing 12 deaths and more than 5000 casualties. In 2013, sarin nerve gas was used by military forces in the Syrian civil war. A more complete discussion of chemical and biological weapons is found in Chapter e15. As terrorist organizations continue to use unconventional weapons such as chemical and biologic agents, the civilian medical community needs to better understand their characteristics and pathophysiology.

Response During a Chemical Attack

Triage of patients with exposure to nonconventional weapons remains a critical component of appropriate care. Triage should be performed by specially trained emergency medical personnel who are familiar

TABLE 55.2 Common Gases That Can Be Encountered as Weapons of Mass Destruction

Class	Example[a]	Treatment
Nerve agents	Tabun (GA) Sarin (GB) Soman (GD) Cyclosarin (GF) VX	Atropine and pralidoxime
Vesicants	Mustard agents Mustard, sulfur mustard (H) Distilled mustard, sulfur mustard (HD) Nitrogen mustard (HN1, HN2, HN3) Organic arsenical agents (e.g., lewisite; L) Halogenated oxime agents (e.g., phosgene oxime; CX)	Hydrotherapy Moist dressing on blisters Supportive care
Choking agents	Phosgene (CG) Chlorine (CL) Military smoke (HC) Chloropicrin (PS)	Supportive care
Cyanide agents	Hydrogen cyanide	Cyanide kit Amyl nitrite Sodium nitrite Sodium thiosulfate Hydroxocobalamin

[a]Chemical or common name (military chemical symbol).

with these agents and with the use of PPE. The ED could be quickly overwhelmed with masses of noncritically injured survivors. Ideally, triage would be conducted both at the scene of the attack and again at a second point before ED arrival. The greatest challenge for EDs in caring for these individuals is the sudden increase in patients requiring treatment in addition to the day-to-day surge capacity of the hospital.

Chemical Agents

Chemical agents are classified as (1) nerve agents, (2) vesicants, (3) choking agents, or (4) cyanide and related toxins (Table 55.2). Tabun (military symbol GA), the first nerve agent documented, was synthesized by the German chemist Gerhard Schrader in 1937, while researching new insecticides. The following year, sarin (GB) was created. Other important nerve agents include soman (GD) and VX.

Vesicants, also known as *blistering agents,* are a class of drugs that produce blisters at the site of contact. Despite their discovery in the 1800s, its introduction to warfare did not occur until the 20th century. Since World War I, however, sulfur mustard (also known as *mustard gas, mustard,* or *CAS No. 505-60-2*) has remained a constant threat in modern warfare. Other vesicants include lewisite (dichloro-2-chlorovinylarsine), which is an organic arsenical, and phosgene (dichloroformoxime), which is a halogenated oxime. Although phosgene is often considered a vesicant, it technically is not, as the urticarial lesions that develop following contact are not fluid-filled.

Choking agents have been used in both military and civilian settings. Although there are many different agents and uses, the collective term *choking agent* refers to a chemical that can potentially induce pulmonary edema. Phosgene and chlorine are two agents that were used extensively in World War I. The use of chlorine gas attacks has also been widely documented in the recent Syrian conflict. Zinc-containing smoke is another choking agent that is used in conventional warfare. Other agents are used for riot control. These agents were discussed previously in the Miscellaneous Gases section.

Cyanide agents, such as hydrogen cyanide or sodium azide, are cellular toxins. Cyanide was discovered in the 18th century by the Swedish chemist Carl Wilhelm Scheele. Today, hydrogen cyanide remains one of the most toxic chemicals known.

Nerve Agents

Foundations

Background and importance. The nerve agents are classified as either "G" agents or "V" agents and most recently include the Russian-based novice or "Novichok" binary agents. The nerve agents are all derived from phosphoric acid and are volatile liquids at room temperature. As such, they must be aerosolized or evaporated to be used as inhalational weapons. Because the vapors are heavier than air, they tend to remain close to the ground and will travel downwind and downhill.

Anatomy, physiology, and pathophysiology. The nerve agents function by affecting acetylcholine (ACh). Acetylcholine receptors are found on the postsynaptic membranes of cholinergic synapses. These receptors can be either nicotinic or muscarinic. Activation of the nicotinic receptors results in depolarization of the postsynaptic neuron or skeletal muscle cell, whereas activation of the muscarinic receptor affects exocrine glands and smooth muscle, primarily in the CNS. Under normal conditions, ACh is inactivated by the enzyme acetylcholinesterase. The primary mechanism of action of the nerve agents is to prevent acetylcholinesterase from hydrolyzing ACh. Consequently, because ACh is not degraded, an excess quantity of ACh accumulates in the synapse. The effects at the muscarinic receptors include excess secretions and smooth muscle contractions.

Clinical Features

The mnemonics *DUMBBELS* (diarrhea, urination, miosis, bronchoconstriction, bronchorrhea, emesis, lacrimation, and salivation) and *SLUDGE* (salivation, lacrimation, urination, defecation, and gastrointestinal emesis) are often used to describe these effects. The nicotinic manifestations include muscle fasciculations and weakness. The primary lethal clinical effects are respiratory related and treatment should be aimed at correcting these effects.

Differential Diagnoses

The differential diagnosis of a nerve gas exposure includes gastroenteritis, ischemic bowel, ketoacidosis, pulmonary edema, and reactive airway disease. Other cholinergic agents such as carbamate insecticides and herbicides (e.g., paraquat and diquat) as well as neostigmine, physostigmine are differential diagnosis considerations.

Diagnostic Testing

Patients should undergo a chest radiograph, ECG, arterial blood gas, and electrolytes performed. Plasma or RBC cholinesterase levels are not available in real time and, along with significant intra-individual and interindividual variation, make checking levels impractical for the emergency physician.

Management

Victims of dermal exposure should be undressed and thoroughly decontaminated with large-volume, low-pressure irrigation with water. After decontamination, the initial treatment is aimed at maintaining an airway and restoring adequate oxygenation and ventilation. If rapid

sequence intubation is desired for airway management, the paralytic succinylcholine should be used with caution because the duration of action will be significantly prolonged as normal degradation will be inhibited by the nerve agent. Atropine is a direct-acting antagonist of the muscarinic receptor. Because atropine does not bind to the nicotinic receptors, all nicotinic effects, including weakness or paralysis, will not be reversed. The initial recommended dose is 2 mg of atropine for adults, although much larger doses will likely be required (2 mg every 5 minutes until desired clinical effect). The endpoint for stopping atropine administration is not improvement in heart rate but, rather, drying of bronchial secretions. The oxime agent pralidoxime is also administered to patients with suspected or known ingestion with significant symptoms. The traditional dosage of pralidoxime is 30 mg/kg (2 g maximum) intravenously over 30 minutes, followed by a maintenance infusion of 8 to 10 mg/kg/h (650 mg maximum). Standard doses of benzodiazepines (diazepam 5 to 10 mg intravenous push [IVP] or lorazepam 1 to 2 mg IVP) are recommended to prevent and to treat seizure activity.

For pediatric patients, if accurate weight-based dosage cannot be achieved, children younger than 1 year old can receive 0.5 mg atropine, whereas children older than 1 year can receive the standard adult dose of 2 mg atropine as a starting dose. As with adults, the subsequent doses should double (e.g., 0.5 mg followed by 1 mg, followed by 2 mg) until respiratory secretions are dried.

Disposition

Patients who do not develop any sign of toxicity after a 6-hour observation period can be discharged home. Those with any signs of cholinergic toxicity, respiratory distress, or seizures should be admitted to an intensive care unit.

Vesicants

Foundations

Background and importance. At temperatures below 14°C, mustard exists in the solid form. Once in the liquid or gaseous form, mustard gas can be recognized by its unique garlic or fishlike odor. Mustard vapor is also much heavier than air and, as a result, tends to remain close to the ground. When stored as an oil-based liquid, it can be readily aerosolized and attached to a bomb device or shell. Because vaporization occurs slowly, the risk of injury is much greater in cool environments and closed spaces. Several minutes of exposure can result in skin and eye injury, and exposure for more than 30 minutes can lead to respiratory injury and death.

Anatomy, physiology, and pathophysiology. Mustard gas can enter the body after inhalational, dermal, or oral exposures. After entering the body, it functions as an alkylating agent. The altered molecules then interact with proteins and nucleic acids, forming covalent bonds. Mustard is the only vesicant that does not cause immediate pain.

Clinical Features

Manifestations of exposure occur several hours after exposure. After exposure to aerosolized mustard gas, cutaneous manifestations appear after a latent period of up to 24 hours. Initial dermal symptoms include burning, itching, and erythema, followed by hyperpigmentation, vesicle formation, and, later, bullae. Electrolyte depletion and secondary bacterial infection can occur if the affected body surface area is large. In addition, inhaled mustard gas can lead to vomiting and diarrhea. Myelosuppression can occur within 3 to 5 days of exposure, resulting in leukopenia and thrombocytopenia. Direct mucosal damage in the respiratory tract can occur, resulting in bronchiolar damage and hemorrhage. The systemic manifestations can occur with any route of exposure.

Differential Diagnoses

The primary differential diagnosis includes blistering diseases and cutaneous infections, such as toxic epidermal necrolysis. Burns from any chemical or thermal agent may present with similar dermatological findings.

Diagnostic Testing

Obtain a complete blood count and reassess daily for several days to assess for the development of myelosuppression. Those with pulmonary exposure should have a chest radiograph performed. Check electrolytes in individuals with gastrointestinal illness.

Management

Treatment consists first of removing the patient from the environment and decontaminating the vesicant. If available, water can be used for decontamination but may not be the preferred agent. Currently, the United States military recommends using an alkaline hypochlorite solution (pH 10 or 11) as the decontamination method of choice; a 0.5% hypochlorite solution (diluted household bleach [1:9]) is another alternative. However, these solutions should not be used on open abdominal or chest wounds. No specific antidote exists. British antilewisite (BAL; 2,3-dimercapto-1-propanol; dimercaprol) was originally developed as an antidote for lewisite. Although BAL is currently available as a chelator for other heavy-metal poisonings (e.g., mercury, arsenic), we do not recommend its use for mustard gas poisonings.

Disposition

Patients with extensive exposure to mustard gas should be admitted to the hospital for monitoring, dermal care, fluid resuscitation, and serial assessment for pancytopenia.

Cyanide

Foundations

Background and importance. Cyanide salts and hydrocyanic acid are commonly used for metal cleaning, precious metal extraction, photographic processes, electroplating, laboratory assays, and jewelry cleaning. In addition, cyanide gas is often liberated from the combustion of plastic-containing compounds. Iatrogenic cyanide toxicity can result from exposure to cyanogens, including plant or herbal cyanogenic glycosides (e.g., peach and cherry pits), nitriles, and nitroprusside. There is growing concern that cyanide may be used as terrorist weapon of mass destruction.

Anatomy, physiology, and pathophysiology. Cyanide is a cellular toxin. It binds to both Fe^{3+} and cobalt. By binding and inactivating the enzyme cytochrome oxidase, which is part of cytochrome a3 on the electron transport chain, cyanide inhibits oxidative phosphorylation. This inhibition results in profound cellular hypoxia and death.

Clinical Features

After ingestion of cyanide, patients experience sudden cardiovascular collapse, coma, and profound metabolic acidosis. A characteristic odor of "bitter almonds" is frequently discussed but only rarely clinically noted.

Differential Diagnoses

The primary differential diagnosis is hydrogen sulfide and azide gas exposure. Carbon monoxide should be included on the differential diagnosis, and these two conditions may occur simultaneously particularly in house or industrial fires.

Diagnostic Testing

Although cyanide levels are confirmatory, they are rarely immediately available. However, most patients with significant cyanide exposure

will have a profound lactic acidosis, typically exceeding 10 mmol/L. In addition, because the cellular utilization of oxygen is blocked, venous blood is highly oxygenated. Therefore, an elevated mixed venous oxygen saturation, or an elevated peripheral venous partial pressure of oxygen (PO_2) may be observed. Typically, with cyanide toxicity, the difference between the PO_2 from an arterial blood gas and that from a venous blood gas, obtained simultaneously, will be under 10 mmHg. Cyanide toxicity commonly results in shortening of the QT interval, with subsequent "T-on-R" phenomena. The pulse oximeter reading may be near normal in cyanide toxicity, despite significant cellular hypoxia.

Management

The initial treatment focuses on maintaining adequate oxygenation and vascular perfusion. Standard antiarrhythmic medications are appropriate for the treatment of cyanide-induced cardiac arrhythmias. Vasopressors such as norepinephrine may be required.

First responders must wear PPE when rescuing a patient unresponsive after cyanide gas exposure. Patients with cyanide salts on their skin must have the particulate matter brushed off, followed by topical irrigation; decontamination from other routes of exposure is rarely indicated. Currently, two specific types of antidotes can be used to treat known or suspected cyanide intoxication. One historic method of treatment involves the administration of amyl nitrite, sodium nitrite, and sodium thiosulfate. With this combination of medications, amyl nitrite pearls are broken open, and the patient is allowed to breathe a pearl for 30 seconds of each minute. A new pearl is needed every 3 or 4 minutes. Once intravenous access has been established, 300 mg of sodium nitrite (one 10-mL ampule of 3% solution for adults and 0.12 to 0.33 mL/kg for children) can be administered. Because sodium nitrite is a potent vasodilator, hypotension can ensue. Therefore, the sodium nitrite is administered over a minimum of 5 minutes. After sodium nitrite administration, sodium thiosulfate is administered at a dose of 12.5 g (one 50-mL ampule of a 25% solution for adults and 1.65 mL/kg for children). The function of the nitrites is to induce methemoglobinemia. Thiosulfate enhances transulfuration of hydrogen cyanide to thiocyanate via rhodanese, which is renally excreted. We recommend avoiding nitrites if coexisting carbon monoxide toxicity is suspected, as can occur with smoke inhalation.

Hydroxocobalamin (Cyanokit) is the most recently introduced and preferred antidote for cyanide intoxication, given at 5 g initial, additional 5 g if needed, up to maximum cumulative dose of 10 g. Hydroxocobalamin binds to cyanide to form cyanocobalamin, which subsequently undergoes renal excretion. Hydroxocobalamin appears to be safe for use in both the hospital and the out-of-hospital settings. The administration may result in a red discoloration of the skin and a deep purple discoloration of the urine, which is not a true allergic reaction. Its use is also associated with alteration in laboratory measurements of magnesium, iron, aspartate aminotransferase, total bilirubin, and creatinine. In treating a patient for known or suspected cyanide toxicity (even if in combination with carbon monoxide poisoning), both sodium thiosulfate and hydroxocobalamin can be safely administered.

Disposition

Patients with a brief exposure without any manifestations of toxicity can be discharged home after an observation period of 6 hours. One notable exception includes those with exposure to agents that get metabolized to cyanide (e.g., acetonitrile); individuals with exposure to these agents should be admitted to an intensive care unit for 24 hours. Additionally, admit any patient with metabolic acidosis, coma, or seizures to an intensive care unit.

CHAPTER 55: QUESTIONS AND ANSWERS

1. A 34-year-old man presents with burning, erythema, and blurred vision after cleaning liquid is splashed in his eye. Which of the following should you do?

a. Be concerned about acidic burn.
b. Be concerned about alkali burn.
c. Postpone irrigation until confirmation of the type of cleaning liquid.
d. Use a miotic agent.
e. Use copious irrigation until a pH of 7.4.

Answer: e. When a chemical injury to the eye is suspected, regardless of the offending agent, copious irrigation should be started immediately. Irrigation with water or normal saline should continue until the pH is at a physiologic level (approximate pH of 7.4). All but the mildest burns should be treated with a long-acting cycloplegic and mydriatic.

2. A patient presents to the emergency department (ED) complaining of severe burning of both hands since leaving her building this morning. In her history, you find out that the metal doors of her housing complex had just been cleaned of all rust. She has small blisters on her palms and a white appearance to the skin. What is the next step?

a. Consult plastics for an alkali burn.
b. Leave blisters, cover with bacitracin and gauze.
c. Mix calcium gluconate with KY jelly, apply to hands, and cover with gloves.
d. Obtain pain control and prescribe oral clindamycin.
e. Administer intravenous magnesium.

Answer: C. The rust cleaning and physical findings are descriptive of a hydrofluoric acid burn. It is also commonly used in the production of microelectronics, etching glass, for removing rust, and for cleaning cement and bricks. Calcium gluconate (2.5%) gel is the preferred topical agent. However, this gel is often not available in hospital pharmacies, but it can be made by mixing 3.5 g calcium gluconate powder in 150 mL of a water-soluble lubricant. The gel should be secured by an occlusive cover, such as a latex glove.

3. In a hydrofluoric burn, what electrolyte abnormality causes systemic manifestations contributing to this chemical's significant morbidity and mortality?

a. Hypercalcemia
b. Hypermagnesemia
c. Hypocalcemia
d. Hypokalemia
e. Hyponatremia

Answer: C. Hydrofluoric acid binds calcium and magnesium ions with strong affinity. Systemic manifestations of fluoride toxicity are at least partly related to hypocalcemia and include abdominal pain, muscle fasciculations, nausea, seizures, ventricular dysrhythmias, and cardiovascular collapse. Of note, hyperkalemia is often a terminal finding in fatal cases.

4. A 30-year-old female presents by emergency medical services confused and hypoxic. She has a history of depression, and was found with an empty bottle of fluoxetine, which she takes for her depression, and cefalexin and phenazopyridine, which she is currently taking for a urinary tract infection. She is noted to be hypoxic with a saturation of 83%, which does not improve with oxygen administration. She is speaking full sentences but is confused. The nurse informs you the arterial blood sample blood has a "chocolate brown" appearance. Which of the following represents the best management strategy?

a. Obtain a carboxyhemoglobin level and consider hyperbaric oxygen
b. Obtain a methemoglobin level, and consider administration of methylene blue
c. Determine if acidosis is present, and if present, administer sodium thiosulfate
d. Determine if the urine fluoresces with a Wood's lamp
e. Examine the urine for presence of crystals.

Answer: B. The patient is suffering from methemoglobinemia. For those symptomatic patients without glucose-6-phosphate dehydrogenase (G6PD) deficiency, 2 mL/kg of 1% methylene blue can be administered over 3 to 5 minutes. Symptoms typically improve within 20 minutes, although repeat doses may be needed. Severe cases can be treated with exchange transfusion. Candidates for exchange transfusion include those with G6PD with significant toxicity from methemoglobinemia or those patients who fail to respond to methylene blue.

5. A 21-year-old man presents to the emergency department (ED) with chronic shortness of breath and a "huffer's rash." The patient has dry, cracked skin with perioral pyoderma. The cause of these symptoms is most likely which of the following?

a. Anhydrous ammonia
b. Cyanide

c. Hydrocarbons
d. Nitrites
e. White phosphorous

Answer: C. The toxicity from hydrocarbons can affect many different organs, but the lungs are the most commonly affected organ. The toxicity is directly related to the volatility and inversely related to the viscosity and surface tension. Chronic dermal exposure to hydrocarbons can result in perioral or perinasal dermatitis with pyoderma. This so-called "huffer's rash" is primarily seen with recreational abuse.

6. Nerve agent poisoning may be rapidly fatal. Besides appropriate decontamination and atropinization, which of the following should be administered?
a. British anti-Lewisite 2 mg/kg intramuscularly
b. Methylene blue 2 mg/kg intravenously
c. *N*-acetylcysteine 140 mg/kg orally
d. Pralidoxime 600 mg intramuscularly
e. Pyridostigmine 1 mg intravenously

Answer: D. Nerve agents work by affecting acetylcholine (ACh) levels via inhibition of acetylcholinesterase. ACh receptors are found on the postsynaptic receptor of cholinergic synapses. These receptors can be either nicotinic or muscarinic. The effects at the muscarinic receptors include excess secretions and smooth muscle contractions. The initial recommended treatment is 2 mg of atropine for adults, although much larger doses will likely be required. Pralidoxime should also be administered to patients with suspected or known ingestion with significant symptoms. This agent potentially helps prevent irreversible inhibition of the acetylcholinesterase enzyme.

7. A 31-year-old man was found in his apartment after an apparent suicide attempt. He smells of bitter almonds. He is obtunded with hypotension, tachypnea, and normal oxygen saturation. After decontamination and resuscitation, what is the next step?
a. Atropine
b. Hydroxocobalamin
c. Methylene blue
d. Naloxone
e. Sodium thiosulfate

Answer: B. This patient likely has cyanide poisoning. One older method of treatment involves the administration of amyl nitrite, sodium nitrite, and sodium thiosulfate. The U.S. Food and Drug Administration (FDA) approved, and we recommend hydroxocobalamin (Cyanokit) to treat cyanide intoxication. Hydroxocobalamin binds to cyanide to form cyanocobalamin, which subsequently undergoes renal excretion.

56

Oral Medicine

Ryan Anthony Pedigo

KEY CONCEPTS

- Antibiotics do not have a role in the management of pulpitis, whether reversible or irreversible.
- Missing teeth must be accounted for. They may be hidden, left at the scene, aspirated, swallowed, or traumatically impacted.
- Avulsed permanent teeth should be stored in milk, saline, or a commercially available solution and reimplanted at the earliest possible opportunity. Primary teeth are not reimplanted.
- A localized periapical abscess that is successfully drained in an immunocompetent patient does not require antibiotics.
- Cover dental fractures that involve the dentin or pulp with a calcium hydroxide paste then promptly refer to a dentist.
- Periodontal splinting material can stabilize reimplanted teeth or luxated teeth once they have been put in the appropriate position.
- Advanced imaging for localized periapical abscess is unnecessary; however, contrast-enhanced CT of the face is necessary if signs or symptoms of a **deep neck infection** are present.
- Supraperiosteal nerve blocks can anesthetize individual teeth but are less effective for adult mandibular teeth since the surrounding bone is thicker.

INTRODUCTION

Dental concerns are common in the emergency department (ED). The spectrum of oral disease ranges from bothersome to emergently life-threatening.[1] This chapter covers disorders of the **tooth**, **gingiva**, and periodontium, dental procedure-related issues, odontogenic and deep infections of the head and neck, traumatic dental emergencies, as well as temporomandibular joint disorder (TMD) and dislocation.

DISORDERS OF THE TOOTH

Foundations

Anatomy, Physiology, and Pathophysiology

Humans have 20 deciduous (primary) teeth and 32 permanent (secondary) teeth, which are supported and maintained in the maxilla (upper teeth) and mandible (lower teeth) by the periodontium. The portion of the tooth that is normally visible in the mouth above the gingival margin is called the crown, whereas the lower portion is the root (Fig. 56.1).

The crown of the tooth has three layers; from outside to inside they are the enamel, dentin, and pulp. The enamel is the only part of the tooth that is visible in the absence of pathology (e.g., **fracture**s, caries) and is a hard coating that protects the tooth. The outermost layer of the root of the tooth is the cementum, which allows for attachment of the periodontal ligament to the adjacent alveolar bone. The next layer deep to the enamel (for the crown) or the cementum (for the root) is the dentin, which is an intermediate layer that is yellow in appearance. The dentin is comprised of porous microtubules that support the enamel and act as a cushion during mastication. If the dentin is exposed by caries or trauma, the patient will have sensitive teeth or pain. The deepest layer is the pulp cavity, which houses the tooth's neurovascular supply.

The deciduous dentition ("baby teeth") consists of 10 mandibular and 10 maxillary teeth (Fig. 56.2). The lower central incisor is the first tooth to erupt at approximately 6 months of age; all primary teeth should be present by age 3. The permanent dentition begins to erupt at approximately 6 years of age with the appearance of the first molar followed by the second molars by age 13 and ending with the third molars ("wisdom teeth") by age 17 to 21.

The permanent dentition consists of 32 teeth; there are 8 teeth per quadrant (e.g., right upper, right lower, left upper, left lower). From the midline outward, the names of the teeth in each quadrant are the central incisor, lateral incisor, canine, two premolars (also called *bicuspids*), and three molars (also called *tricuspids*). The permanent dentition is numbered from 1 to 32, starting with the upper right third molar (1) and moving to the upper left third molar (16), to the lower left third molar (17), and to the lower right third molar (32). The starting point for this numbering system can be recalled by the mnemonic "upright." It is often easier to name the tooth or teeth involved; for instance, if tooth 8 is injured, the clinician could describe the tooth as the "right maxillary central incisor" or the "right upper central incisor." If multiple teeth are involved, numbering is more concise.

Specific terminologies are also used to describe the various tooth surfaces in the mouth. The facial (also referred to as labial or buccal) surface faces outside the oral cavity; the oral (also referred to as palatal for upper teeth, or lingual for lower teeth) surface faces the tongue; the mesial surface is toward the midline; and the distal surface is toward the ramus of the mandible. The interproximal surface refers to the contacting area of adjacent teeth, and the occlusal surface refers to the biting area. Finally, *apical* is in the direction of the root, whereas *coronal* is toward the crown of the tooth.

Tooth decay, or dental caries or cavities, is caused by the breakdown of the teeth secondary to bacteria. Bacteria generate acid as a byproduct from cellular metabolism of food left on the tooth surface, subsequently demineralizing the enamel. Once the enamel is breached,

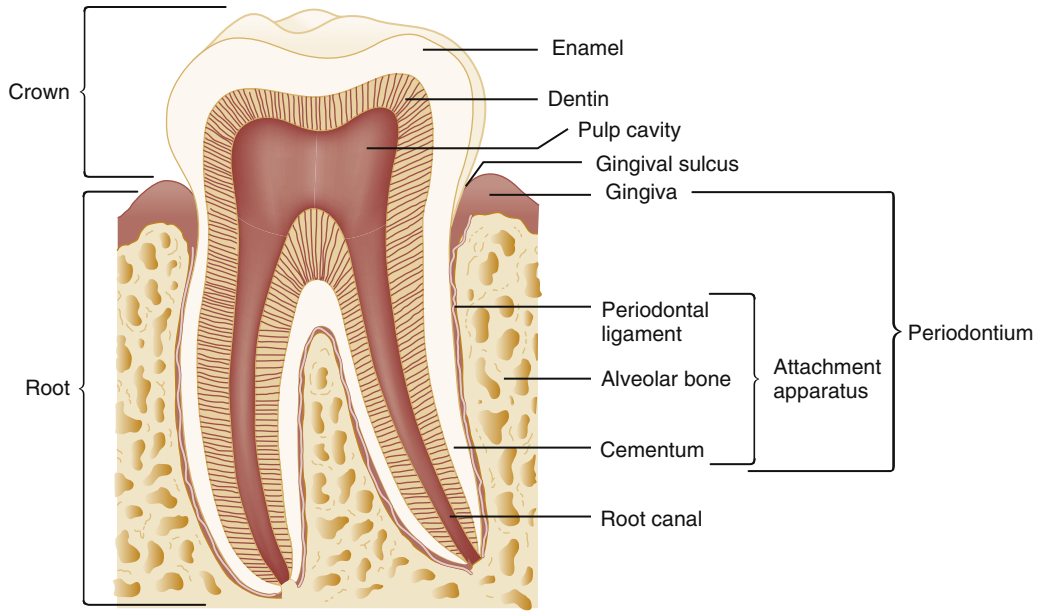

Fig. 56.1 The Anatomy of the Tooth and Associated Attachment Apparatus.

the microporous dentin can transmit saliva, byproducts of the bacteria, and the bacteria to the pulp. The pulp initially reacts with a hyperemic response, which proceeds to an inflammatory state termed pulpitis, which can be reversed. Untreated, pulpitis can further progress to total degeneration and necrosis (irreversible pulpitis).

Clinical Features

Dental caries are the most common cause of odontogenic pain. The patient may give a variable history of a sudden or gradual onset of a sharp to dull, throbbing pain. In most cases, the patient can indicate the specific tooth involved, but pain may be generalized. Early (reversible) pulpitis is sensitive to changes in temperature and pressure; irreversible pulpitis can show pain without any stimulus.

The physical examination described here is applicable to all sections of this chapter. Ideally the patient should be placed in a dental or ear, nose, and throat chair or on a bed at a 45-degree angle with adequate lighting. Pediatric patients often are examined while sitting on the parent's lap.

Pediatric patients may require distraction, familial assistance, anxiolysis, or sedation to permit adequate oral assessment and treatment of pain. Pediatric procedural sedation is described in Chapter 157.

A complete intraoral examination includes inspection of the oral cavity, gingiva, teeth, and surrounding structures (e.g., throat, neck, sinuses). Assess teeth for caries or fractures. Localization of the involved tooth may be accomplished by percussing the teeth or by having the patient bite on a tongue blade. Exquisite pain to percussion suggests an underlying periapical abscess (discussed in the section Odontogenic and Deep Neck Infections).

An extraoral examination includes evaluation of the nares and sinuses for discharge and pain, respectively, to evaluate for sinusitis. Facial asymmetry in the appropriate clinical context may indicate a deep neck infection. Palpate the temporomandibular joint (TMJ) with opening and closing of the jaw to assess for "clicks" or "pops," which may indicate the etiology of pain as TMJ disorder. In older individuals, palpate the temporal artery for tenderness and prominence.

Differential Diagnoses

Most dental pain is odontogenic, the most common cause being pulpitis due to caries. However, tooth pain is not always odontogenic. Unilateral upper tooth pain (usually the posterior teeth) can be related to maxillary sinusitis, dysbarism, or inflammation. Trigeminal neuralgia can present as tooth pain, but it is usually lancinating and may not be related to temperature changes or mastication. Atypical odontalgia is a centralized trigeminal neuropathy localized in a tooth or teeth. Frequently misdiagnosed, patients will often undergo multiple dental procedures with worsening of their pain. Atypical odontalgia causes persistent throbbing or burning pain that does not fulfill diagnostic criteria for another disorder and therefore is a diagnosis of exclusion. Elders with temporal (giant cell) arteritis may have pain with mastication because of jaw claudication.

Diagnostic Testing

Laboratory or radiographic testing are not routinely required. Panorex films, if available, can be obtained to assess for apical abscess if the diagnosis is not clinically apparent.

Management and Disposition

Management of dental caries with pulpitis consists in pain management and referral to a dentist for definitive care. Data are limited, but evidence suggests that antibiotics are not beneficial for the management of pulpitis, whether irreversible or not.[2]

Severe pain can be treated with supraperiosteal infiltration of local anesthetic to provide temporary relief (Fig. 56.3). To perform this, dry the area with gauze, apply a topical anesthetic to the gingiva (e.g., 20% benzocaine or 5% lidocaine) and allow it to sit for 5 minutes. Inject 1 to 2 mL of local anesthetic (e.g., 2% lidocaine) through the mucobuccal fold of the affected tooth with the bevel facing the tooth. Alternatively, an inferior alveolar nerve block may be used when multiple lower teeth are affected on one side. In adults, the supraperiosteal block is less effective for mandibular teeth due to the comparatively thicker bone surrounding the tooth compared to maxillary teeth.

The patient can be discharged with ibuprofen (400 to 600 mg every 6 to 8 hours). Nonsteroidal antiinflammatory drugs (NSAIDs) given at scheduled times (rather than as needed) are more effective than opioid analgesics.[3] However, for severe odontalgia, a short course of opioid analgesics in addition *to* scheduled NSAID administration is reasonable. Opioid analgesics should not be prescribed for long-standing dental problems, such as chronic caries. The patient with odontalgia from dental caries should follow-up with a dentist within one week.

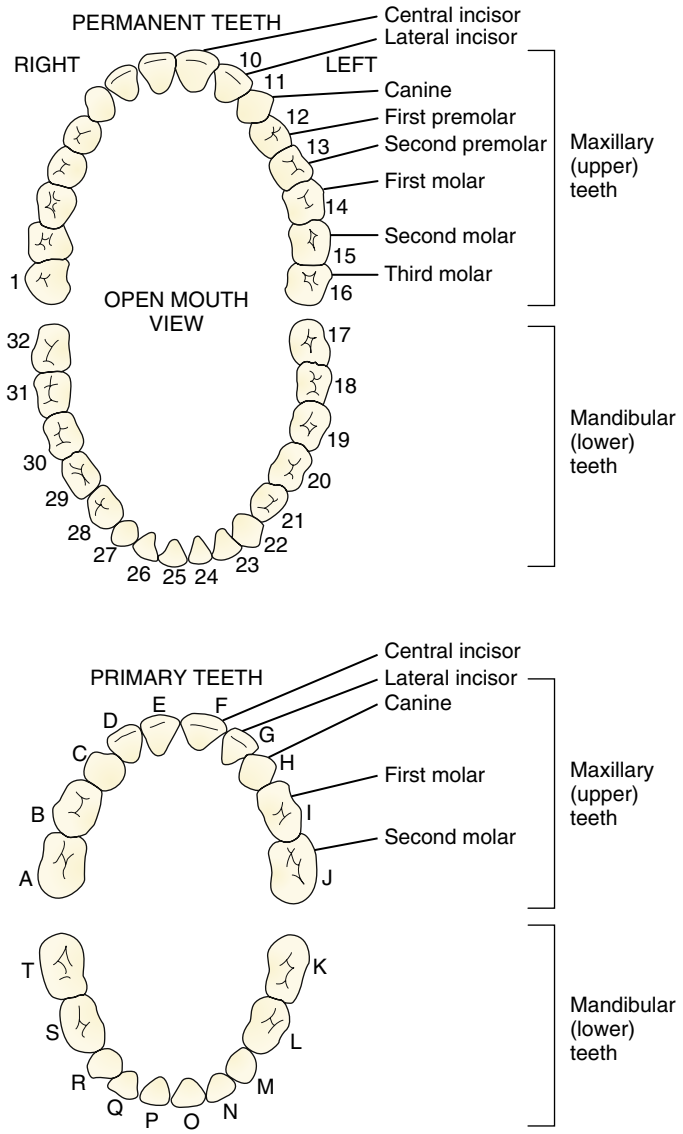

Fig. 56.2 **Identification of Teeth, Adult and Child.** Conventional numbering starts with the upper right third molar 1 to the upper left third molar 16; lower left third molar 17 to the lower right third molar 32. For the primary dentition, A to J and K to T. (Modified from Roberts J. *Roberts & Hedges' Clinical Procedures in Emergency Medicine*. 6th ed. Philadelphia, PA: Elsevier; 2014, Fig. 64.2, p. 1344.)

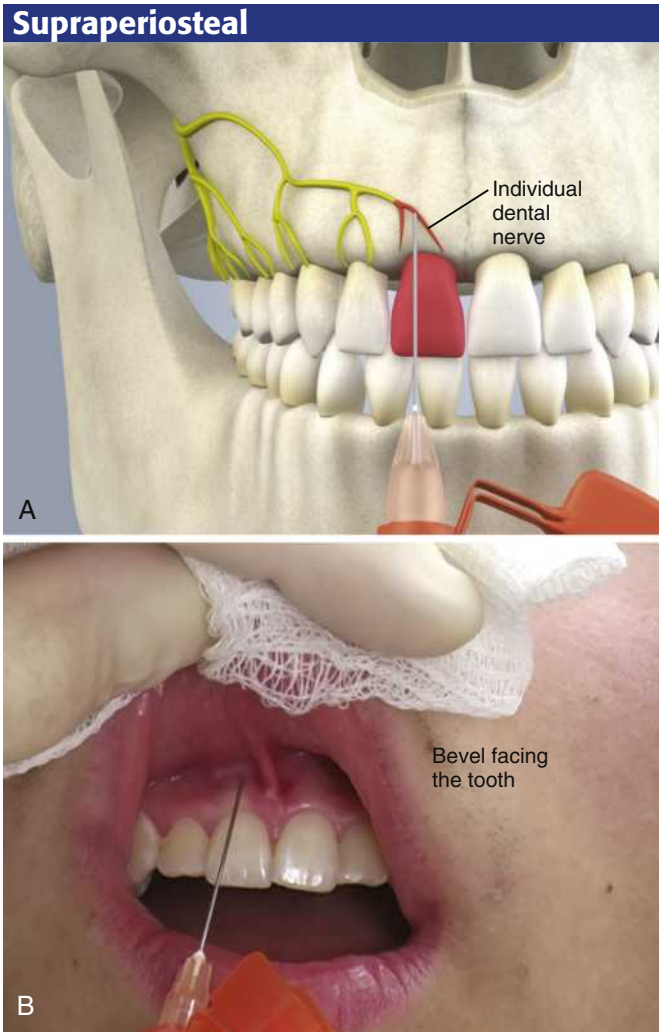

Fig. 56.3 (A and B) Supraperiosteal nerve block for anesthesia of individual teeth. (From Roberts J: Roberts J. *Roberts & Hedges' Clinical Procedures in Emergency Medicine*. 6th ed. Philadelphia, PA: Elsevier; 2014, Fig. 30.5.)

DISORDERS OF THE GINGIVA AND PERIODONTIUM

Foundations

Anatomy, Physiology, and Pathophysiology

The periodontium serves to hold the teeth in place and protect the root from bacteria. Collectively, the periodontal ligament, alveolar bone, and cementum comprise the attachment apparatus. The attachment apparatus plus the gingiva ("gums") is referred to as the *periodontium*. The gingiva consists of the mucosal tissue that overlies the mandible and maxilla inside the mouth and, in the normal state, acts as a barrier to infection and injury.

Gingivitis and Periodontitis. Periodontitis is inflammation of the supporting structures of the teeth (gingiva, alveolar bone, cementum, and periodontal ligament). Degradation of this support structure leads to loss of the alveolar bone and subsequent loosening or loss of teeth.

In necrotizing periodontal diseases, polymicrobial bacteria (with a predominance of *Fusobacterium* and spirochetes) invade the tissue and cause pain, bleeding, and destruction. These diseases include necrotizing gingivitis (acute necrotizing ulcerative gingivitis [ANUG], or "trench mouth") if the gingiva alone is involved, necrotizing periodontitis if the attachment apparatus in addition to the gingiva is involved, and necrotizing stomatitis if the disease extends to the surrounding oral mucosa (Fig. 56.4). Infection that further involves the tonsils and pharynx is termed *Vincent angina*. The most diffuse necrotizing disease is termed *noma* (cancrum oris, fusospirochetal gangrene) where the entire mouth is involved and is often fatal; this disease is most commonly encountered in young children in developing countries (Fig. 56.5).

Pericoronitis. The gingiva and surrounding tissue can also become inflamed leading to a condition known as *pericoronitis*. As teeth start to erupt, debris and bacteria can accumulate between the tooth and the surrounding soft tissue. The flap of gum overlying these teeth is called the operculum and is the source of pain and swelling during inflammation (Fig 56.6). This condition is exacerbated by trauma from mastication. The third molar ("wisdom tooth") is most commonly implicated, and symptoms typically occur in the second or third decade of life. This condition is more common with teeth that are malerupted or impacted.

Fig. 56.4 Necrotizing Stomatitis. The gingiva has classic papilla necrosis but the oral mucosa is also involved, making this condition necrotizing stomatitis and not simply necrotizing gingivitis. (From Smith J. HIV and AIDS in the adolescent and adult: an updated for the oral and maxillofacial surgeon. *Oral Maxillofac Surg Clin North Am.* 2008;20[4]:535–565, Fig. 8.)

Fig. 56.5 Noma (cancrum oris, fusospirochetal gangrene) is usually found in children in developing countries and can be disfiguring or even fatal. Noma represents the most severe end of the necrotizing periodontal disease spectrum. (From Farrar J, Hotez PJ, Junghanss T, et al., eds. *Manson's tropical diseases*. 23rd ed. London: Saunders/Elsevier; 2014, Fig. 29.1.)

Gingival Hyperplasia. Gingival hyperplasia is an overgrowth of the gum tissue surrounding the teeth. It can occur secondary to poor oral hygiene, dental plaque build-up or as an adverse reaction to medications. The most commonly associated drug classes are anticonvulsants, calcium channel blockers, and immunosuppressants (Table 56.1).

Clinical Features

The presentation of periodontitis is variable, depending on the severity of the disease. Simple gingivitis presents with swollen or tender gingiva, gingival bleeding after manipulation (e.g., brushing teeth, flossing), and halitosis from bacterial overgrowth. Periodontitis involves

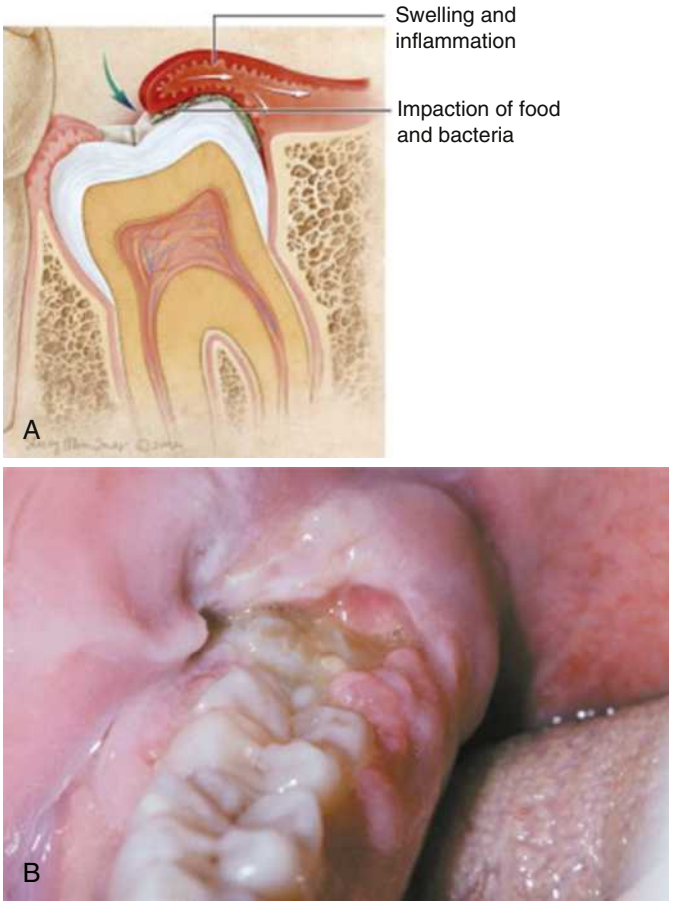

Fig. 56.6 Pericoronitis. (A) Illustration of pericoronitis with swollen and inflamed operculum. (B) Picture of pericoronitis of the third molar with erythema and inflammation of the surrounding tissue. (A, From Buttaravoli P, Leffler SM. *Minor Emergencies*. 3rd ed. St Louis: Elsevier; 2012, Fig. 46.1; B, From Neville BW, Damm DD, Allen CM, et al: *Oral and maxillofacial pathology*. 4th ed. St Louis, MO: Elsevier; 2016.)

the attachment apparatus as well and in more advanced cases, gingival recession from loss of alveolar bone and concomitant teeth loosening can be seen. Individuals with more severe periodontitis may also report fevers and malaise. Obtain a medication history to assess for drug-induced gingival overgrowth (see Table 56.1).

Inspect the gingiva for erythema, edema, and hyperplasia. The interdental papillae are normally pointed but, in necrotizing disease, the interdental papillae become blunted, "punched out," ulcerated, and covered with a whitish-yellow pseudomembrane of necrotic tissue and bacteria. The triad for necrotizing periodontal diseases includes papillary necrosis, gingival bleeding, and pain. More severe infection (e.g., necrotizing stomatitis) may also have an associated submandibular lymphadenopathy.

Mobile teeth suggest alveolar bone loss, where the disease has progressed deeper than the gingiva. Partially erupted teeth should be examined for evidence of pericoronitis. The overlying tissue (operculum) should be assessed for bleeding and inflammation.

Differential Diagnoses

Ulceration of the mucosa can be caused by necrotizing stomatitis and also by aphthous ulcers and other oral lesions. Aphthous ulcers are small (2 to 3 cm), superficial, and tender mucosal lesions that typically have a whitish center. They usually do not become infected. The neighboring gingiva should not be affected and appear healthy. Recurrent

TABLE 56.1 Medication Classes and Their Risk of Drug-Induced Gingival Overgrowth

Category	Pharmacologic Agent	Prevalence
Anticonvulsants	Phenytoin	50%
	Sodium valproate (valproic acid)	Rare
	Carbamazepine	None
Immunosuppressants	Cyclosporine	25%–30% (adults) 70% (children)
Calcium channel blockers	Nifedipine	6%–15%
	Felodipine	Rare
	Amlodipine	Rare
	Verapamil	<5%
	Diltiazem	5%–20%

From Song HJ. Periodontal considerations for children. *Dent Clin North Am.* 2013; 57(1):17–37, Table 1.

aphthous lesions can occur with Behçet disease and human immunodeficiency virus (HIV). Treatment is symptomatic with hydrogen peroxide rinses and topical anesthetics. Another consideration is acute herpetic gingivostomatitis, which is the most common manifestation of primary herpes simplex virus infection in children. In patients with gingival hyperplasia, an infiltrative process (such as leukemia) should be considered, especially if the patient has adequate oral hygiene or is not on medications associated with hyperplasia.

Diagnostic Testing

Gingivitis and Periodontitis

Necrotizing periodontal disease occurs most often in patients who are immunocompromised, such as patients with HIV, poorly controlled diabetes, or on long-term immunosuppressive therapy. Blood glucose and HIV testing may be initiated in the ED or as part of follow-up.

Pericoronitis

No laboratory or radiographic testing is routinely indicated for pericoronitis.

Management

Gingivitis and Periodontitis

Gingivitis responds to proper oral hygiene including twice daily flossing and brushing. Antibacterial mouth rinses, such as chlorhexidine rinses (preferred agent, 0.12% to 0.2%) or 3% hydrogen peroxide (diluted 1:1 with warm water) are recommended for more severe cases Necrotizing periodontal disease should be treated by a dentist, who will need to debride the necrotic tissue. Oral antimicrobials should be prescribed for patients with extensive disease, immunocompromise, or systemic symptoms; see Table 56.2 for more information.

All patients who smoke should be counseled on smoking cessation; this is the most common risk factor in HIV-negative patients. Analgesia using an NSAID such as ibuprofen (400 to 600 mg every 6 to 8 hours) or acetaminophen (650 mg every 6 hours) relieves pain and facilitates appropriate oral hygiene. Severe pain can be treated with opioid analgesic. Topical analgesics (e.g., viscous lidocaine) can also be effective but should be applied only to small areas to avoid ingestion or systemic toxicity.

Pericoronitis

Patients with pericoronitis should receive rinses as described previously; systemic antibiotics are not necessary unless the pericoronitis is severe. In such cases, penicillin 500 mg every 8 hours for 5 to 7 days is recommended. For patients with a penicillin allergy, clindamycin 150 to 300 mg every 6 hours is commonly used. Patients with pericoronitis should be referred to a dentist or an oral surgeon for local treatment of the operculum or, if impacted or malerupting, removal of the tooth. Adequate analgesia should be prescribed, as the pain in pericoronitis is often severe enough to affect the patients' quality of life.[4]

TABLE 56.2 Recommended Antibiotics for Severe Periodontal Disease, Severe Pericoronitis, and Simple Odontogenic Infections

Antibiotic	Dosage	Duration	Notes
Penicillin V	500 mg by mouth tid-qid	10 days	
Amoxicillin/clavulanate	500 mg/125 mg by mouth tid	10 days	875 mg/125 mg can be used
Metronidazole	500 mg by mouth bid	10 days	If allergic to penicillin
Clindamycin	300 mg by mouth qid	10 days	If allergic to penicillin
Nystatin	100,000 units/ml 5 ml swish/spit qid	10 days	If immunocompromised or suspect candidal infection

Disposition

Gingivitis and Periodontitis

Patients with gingivitis are discharged with dental follow-up in 1 to 2 weeks. Those with necrotizing gingivitis or mild necrotizing stomatitis should see a dentist within 24 to 72 hours, because they require frequent debridement until the infection is controlled. Patients with severe necrotizing gingivitis or stomatitis should have an emergency dental consultation (within 24 hours). Patients with significant systemic symptoms (especially fever or lymphadenopathy) or those who are immunocompromised with severe oral disease should receive antibiotic therapy and dental consultation.

Pericoronitis

Patients with pericoronitis should be referred for either extraction of the tooth or excision of the operculum.

DISORDERS INVOLING DENTAL PROCEDURES

Foundations

Anatomy, Physiology, and Pathophysiology

The most common dental procedures include fillings, crowns, root canals, and extractions. Fillings cover caries and protect the underlying tooth from further decay and infection. Crowns (or "caps") cover the portion of the tooth exposed above the gingiva and require an intact root for attachment. Root canals involve opening the pulp chamber, removing pulp tissue and root, sterilizing the canal, and sealing it to prevent ingress of saliva and contamination. Extractions are performed for non-salvageable teeth and involve removal of the entire tooth. All these procedures can have complications that may bring a patient to the ED.

Dislodgement of a filling or crown can expose the highly innervated pulp and lead to significant odontalgia. Similarly, the pulp can be irritated during procedures (e.g., root canal) because of residual gas bubbles that are inadvertently sealed into the cavity. In addition, any swelling that may elevate the tooth even minimally post-procedurally will cause premature and painful contact during mastication.

Fig. 56.7 Alveolar osteitis ("dry socket") with extraction site devoid of clot. (From Krakowiak PA. Alveolar osteitis and osteomyelitis of the jaws. *Oral Maxillofac Surg Clin North Am.* 2011;23[3]:401–413, Fig. 1.)

After an extraction, the patient will have an adherent clot in the fossa where the root of the tooth previously was. If this clot becomes dislodged (typically 3 to 4 days post-extraction) a condition called *alveolar osteitis* ("dry socket") can occur (Fig. 56.7). The incidence of alveolar osteitis is 2% after routine extraction but as high as 20% to 30% after removal of impacted mandibular third molars. The pain is secondary to localized inflammation of the exposed surrounding alveolar bone.

Clinical Features

Patients usually can provide the history of their dental procedures; dislodgement of a filling or crown can happen at any time but is more common early or after trauma. Post-root canal pain due to retained gas bubbles typically occurs immediately after the initial nerve block wears off.

Alveolar osteitis typically presents 3 to 4 days after an extraction with severe dull, aching pain at the site of extraction, often associated with halitosis and a foul taste in the mouth. Patients may have an antecedent of sucking through a straw or other activity that dislodged the clot.

Those with continued bleeding after an extraction should have their medical history and medications reviewed with specific attention to known or medication-associated coagulopathies and anti-platelet agents.

Patients with dislodged fillings or crowns will have an exposed dentin or pulp over the affected teeth. Post-extraction pain secondary to inflammation or retained gas bubbles may have a normal examination. Those with alveolar osteitis will have a tooth socket that has at least partial loss of the blood clot with exposed bone.

Differential Diagnoses

Differential diagnosis of alveolar osteitis after extraction includes a localized infection. In alveolar osteitis the extraction site is typically devoid of clot and should not have substantial surrounding edema, erythema or fluctuance, which is more typical of an infection.

Diagnostic Testing

An international normalized ratio (INR) is indicated for patients who are on warfarin and have post-extraction bleeding. A platelet count or hemoglobin may be helpful in selected cases where either thrombocytopenia or symptomatic anemia is considered.

Management

For teeth with exposed pulp, calcium hydroxide cement (Dycal) application to cover the exposed surface may provide symptomatic relief although analgesia with NSAIDs is generally enough. For those with severe pain, a short course (2 to 3 days) of an opioid (oxycodone 5 mg every 4 to 6 hours) is indicated. Patients with retained gas bubbles after a root canal have intense pressure-like pain, often refractory to analgesics and even nerve blocks, and they should be referred to an endodontist, preferably the clinician who performed the initial procedure.

Treat alveolar osteitis with NSAIDs and prompt (next working day) referral to their treating oral surgeon. If follow-up will be delayed, nerve block followed by gentle irrigation of the socket with sterile saline can be performed. The socket should not be curetted and the clot should not be removed if a residual clot exists, because this will expose more bone and lead to higher risk of continued pain and osteomyelitis. Medicated iodoform gauze with eugenol (an anesthetic) can be placed in the cavity and changed by the patient's surgeon within 24 to 48 hours with repeat irrigation. Chlorhexidine rinses have been shown to prevent alveolar osteitis yet its role in established alveolar osteitis is less clear.[5] No other treatment for alveolar osteitis has enough evidence to recommend use.

Extraction site bleeding should first be managed with direct pressure with the patient biting on dry gauze or gauze soaked with tranexamic acid.[6] If this fails, perform a supraperiosteal nerve block using lidocaine with epinephrine as this will decrease the blood supply and anesthetize the area so that more firm direct pressure can be applied. If bleeding continues after a second trial of pressure, the socket can be packed with absorbable gelatin sponge (Gelfoam) with or without topical thrombin. The gingiva can also be loosely closed with a 3-0 absorbable suture in a figure-of-eight fashion. With coagulopathy and significant ongoing hemorrhage, anticoagulation reversal may be required (see Chapter 111).

Disposition

In the absence of infection and with control of bleeding, patients with dental procedure-related complications can be discharged home with follow-up with the provider who performed the procedure.

ODONTOGENIC AND DEEP NECK INFECTIONS

Foundations

Anatomy, Physiology, and Pathophysiology

The anatomy of the neck is complex and comprises multiple true and potential spaces. There are fascial planes that normally act to contain infection. Aggressive organisms, an immunocompromised state, or surgical breech of these planes can result in deeper infections. For odontogenic infections, these spaces can be divided into those involved in maxillary infections and those involved in mandibular infections. More severe infections of the head and neck (such as those involving these spaces) are called deep neck infections (Fig. 56.8).

There are two primary spaces that can be involved in maxillary deep neck infections: the canine and buccal space. Infections of the root of the maxillary canine can lead to a canine space infection and often present with flattening of the ipsilateral nasolabial fold (Fig. 56.9). The major complication of this type of infection is cavernous sinus thrombosis. The buccal (buccinator) space can be involved with maxillary molars but also with mandibular molars (Fig. 56.10). Occasionally, the maxillary sinus itself can be involved.

The mandible has three associated primary spaces: submental, sublingual, and submandibular. The *submental* space is bound laterally by the digastric muscles and therefore causes a very discrete midline swelling when involved in a deep neck infection (Fig. 56.11); the mandibular incisors are the main culprits, because other teeth do not overly this space. The *sublingual* space is between the floor of the mouth and the mylohyoid muscle. It does not have a posterior border

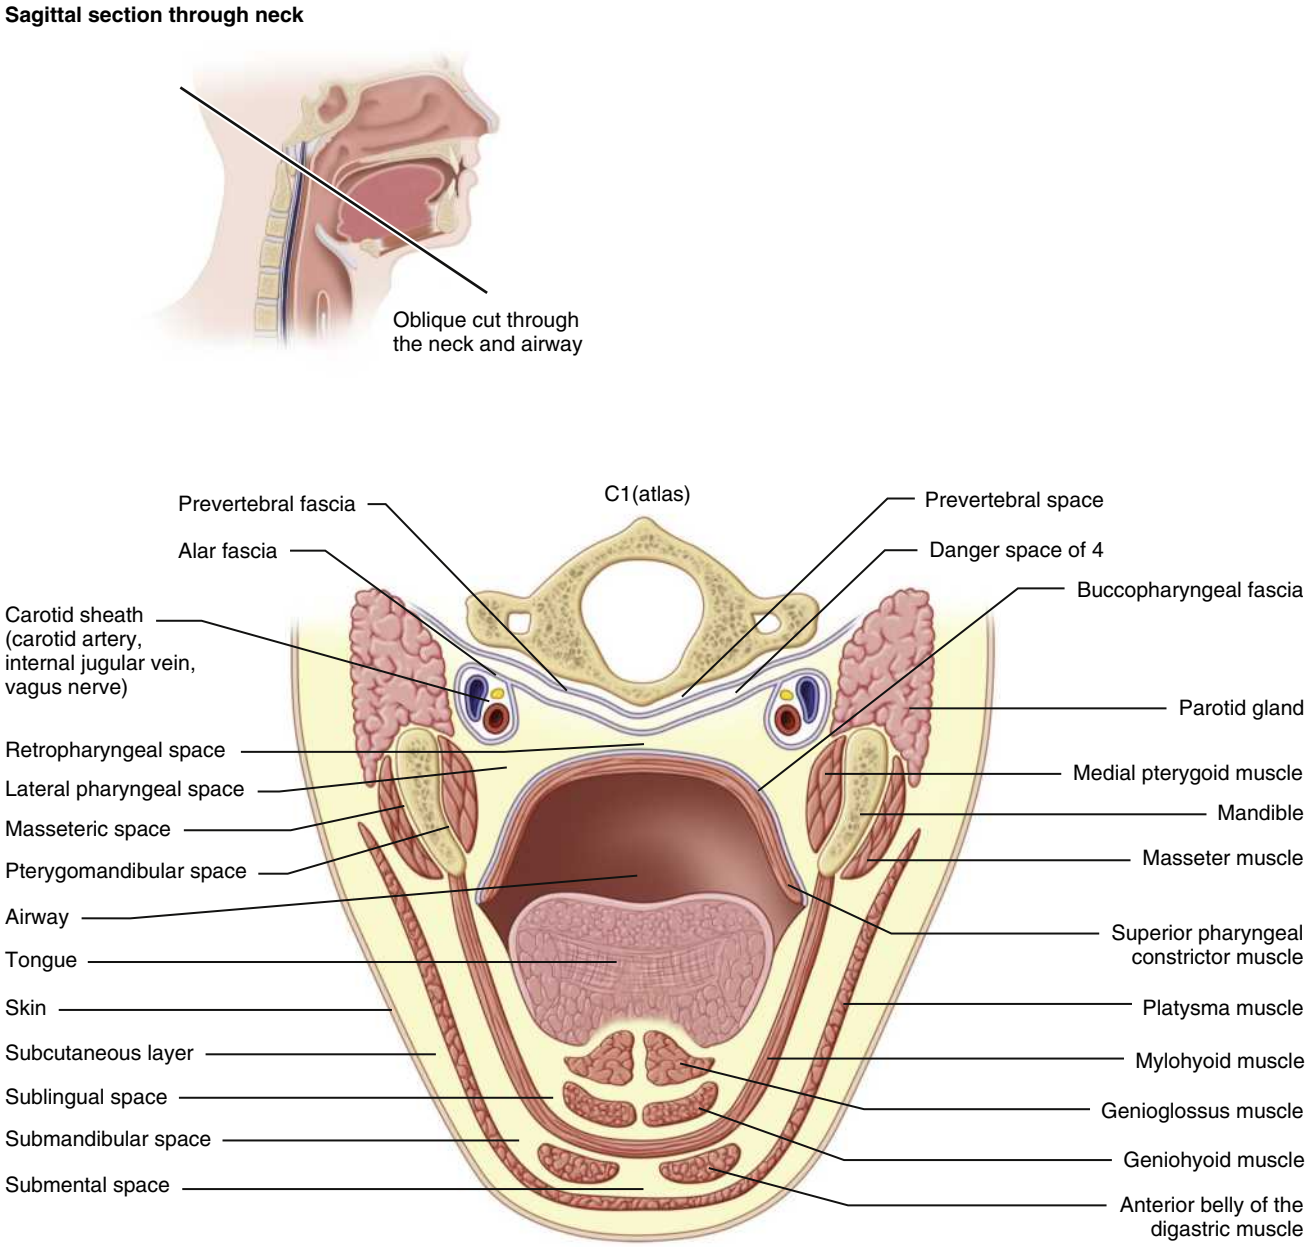

Fig. 56.8 Anatomy of Maxillofacial Space Infections. (From Bagheri SC. *Clinical Review of Oral and Maxillofacial Surgery*. 2nd ed. St Louis, MO: Elsevier/Mosby; 2013, Fig. 4.4.)

and therefore communicates with the submandibular space. Characteristically, infection of this space causes elevation of the tongue and firmness of the floor of the mouth (Fig. 56.12). Lastly, the *submandibular* space is usually involved as an extension of infection from a mandibular molar (Fig. 56.13). Although submandibular space infections have their medial border at the anterior belly of the digastric muscle, it can bypass this and enter the submental space and move to the contralateral submandibular space, and the sublingual space. This leads to infection of all three spaces termed *Ludwig angina.*

These primary space infections can progress to secondary spaces and lead to more wide-spread infection into the neck and mediastinum. A discussion of these spaces (e.g., retropharyngeal, parapharyngeal, prevertebral, and "danger" spaces) can be found in Chapter 58.

Oropharyngeal infections are the most common cause of deep neck infections in children (Fig. 56.14, Scenario 1 and 2). Acute tonsillitis can lead to peritonsillar abscesses and, if further invasion of the parapharyngeal space occurs, can spread into either the retropharyngeal (leading to a retropharyngeal abscess) or submandibular space (leading to Ludwig angina). Children can have retropharyngeal lymphadenopathy with pharyngeal and/or sinus infections, which may precipitate retropharyngeal cellulitis, lymphadenitis, or abscess. By age 4, there is spontaneous atrophy of these nodes; therefore, a retropharyngeal abscess in the absence of trauma (fish bone stuck in throat, etc.) in older children or adults is less common. Septic thrombophlebitis of the internal jugular vein, termed *Lemierre syndrome,* is caused by infection by *Fusobacterium necrophorum.*[7] Septic emboli dislodge from the internal jugular vein and lead to necrotic pleuropulmonary emboli, abscesses, and empyema. More distant embolic events can occur, leading to brain abscesses, meningitis, and septic joints.

Dental infections are the most common cause of deep neck infections in adults (see Fig. 56.14, Scenario 3). Pus leaks from the apex of an infected tooth root and forms a periapical abscess, confined within

the alveolar bone (Fig. 56.15). If the abscess erodes through the cortical plate of either the mandible or the maxilla, it can spread subperiosteally, extending into the previously described spaces. When the submental, submandibular, and sublingual spaces are involved in cellulitis with or without abscess, Ludwig angina occurs. Ludwig angina is a bilateral, board-like swelling involving the submandibular, submental, and sublingual spaces with elevation of the tongue (Fig. 56.16). The most serious sequela is airway obstruction. A characteristic brawny induration is present; there is often no fluctuance for incision and drainage. Hemolytic Streptococcus is usually responsible, although a mixed staphylococcal-streptococcal flora is common, and both may lead to an overgrowth of anaerobic gas-producing organisms, including *Bacteroides fragilis*.

Facial cellulitis is typically polymicrobial, which reflects the oropharyngeal flora. However, atypical organisms can also be present: *Actinomyces* can cause cervicofacial actinomycosis with draining sinus tracts, tuberculosis can cause cervical lymphadenopathy (scrofula) with secondary infection, and *Bartonella henselae* (the causative organism for cat scratch disease) can cause cervical lymphadenitis.

Clinical Features

Facial cellulitis and deep neck infections have many common historical features: in children, an antecedent of sinus or pharyngeal infection is common; in adults, a history of poor dentition is common. Frequently reported symptoms include pain at the affected site, fever, and malaise.

Recent dental work or trauma, recent upper airway manipulation or surgery, intravenous (IV) drug abuse, sinusitis, and otitis media are

all risk factors for infection. Patients who are immunosuppressed from HIV/acquired immunodeficiency syndrome (AIDS), cirrhosis, diabetes, chemotherapy, and/or steroid use are all at higher risk and should raise suspicion.

A complete head and neck examination is required, keeping in mind the aforementioned anatomy. Extraoral palpation can help assess whether there is deep space involvement indicated by the presence of tenderness, warmth, fluctuance, or crepitus. Percuss teeth to assess for tenderness which may indicate a periapical abscess. Involvement of the sublingual space is assessed by palpating the floor of the mouth looking for edema and tongue elevation.

Irritation of the internal pterygoid or masseter muscles causes trismus, which is the inability to open the mouth because of involuntary muscle spasm. Incomplete mouth opening secondary to phlegmon or edema will make oral examination challenging and intubation difficult because it is not relieved by neuromuscular blockade. A "hot potato" voice or difficulty swallowing or handling secretions suggests partial airway obstruction due to retropharyngeal or parapharyngeal infection. Respiratory distress may be apparent when obstruction is near-complete and may proceed rapidly to complete occlusion.

Differential Diagnoses

The main differential consideration is whether the infection is limited to superficial head and neck spaces or whether a deep neck infection is present.

Diagnostic Testing

A complete blood count usually shows leukocytosis, but the absence of such does not rule out a deep neck infection or significant cellulitis. Patients with localized periapical abscesses and associated cellulitis do not require an advanced imaging.[8] However, when there is concern for a deep neck infection, the imaging modality of choice is a contrast-enhanced computed tomography (CT) of the face and soft-tissue neck. CT imaging is recommended when a deep space infection is suspected as indicated by facial swelling (resulting in blunting of the mandibular margin), restricted mouth opening, voice changes, floor of mouth elevation, dyspnea, or odynophagia.[9,10] Patients with HIV or diabetes have an increased risk of deep neck infections, and testing may be helpful.

Management

Well-appearing patients with simple odontogenic infections (localized infection, no recent antibiotics, and an immunocompetent patient)

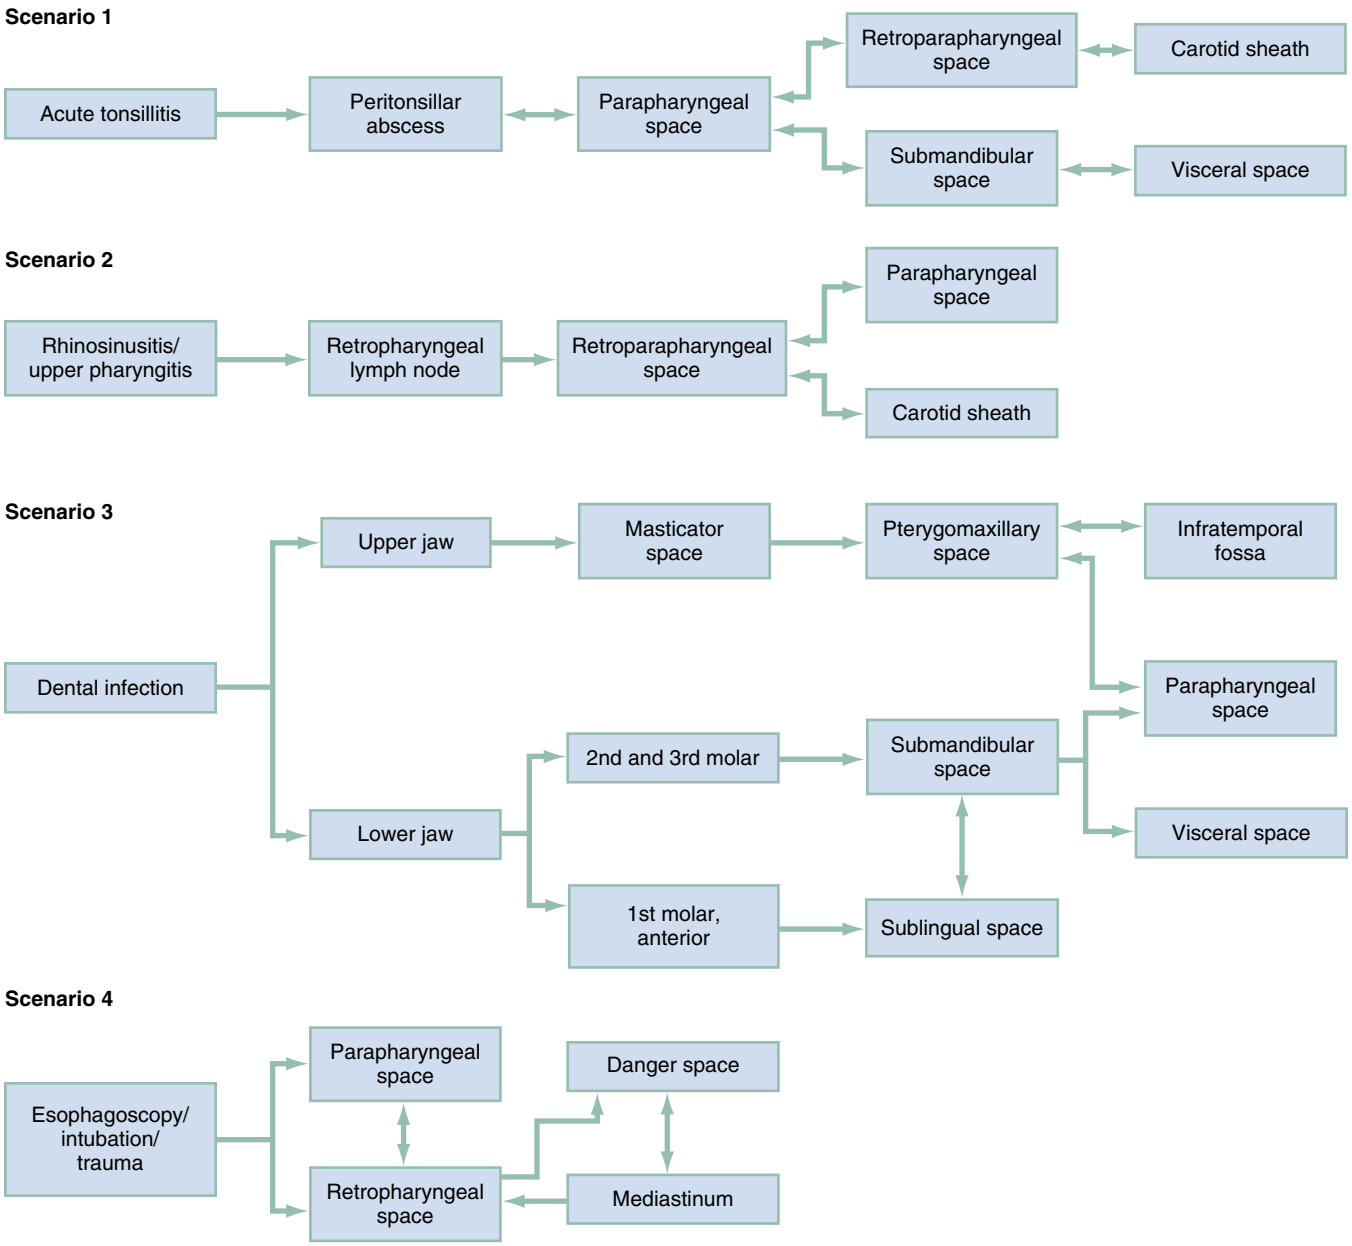

Fig. 56.14 Common Routes of Spread in Deep Neck Infections. (Modified from Cummings CW, Flint PW, Harker LA. *Cummings Otolaryngology Head & Neck Surgery*. 4th ed. St Louis, MO: Elsevier/Mosby; 2004, Fig. 10.2.)

can be managed with antibiotics as shown in Table 56.2. Simple tooth abscesses can be drained with local incision under local anesthesia if the clinician is skilled in the procedure. In the absence of systemic symptoms in the immunocompetent patient, routine antibiotics are unnecessary after successful drainage of a periapical abscess.[11,12]

Most deeper abscesses are drained by dentists or oral surgeons and tooth extraction may be required. Oral or oral maxillofacial surgery consultation is advisable before drainage of suspected deeply seated abscesses.

All serious deep neck infections should have broad-spectrum IV antibiotics administered. We recommend ampicillin-sulbactam with vancomycin or, if allergic to penicillin, clindamycin monotherapy in the immunocompetent host. See Table 56.3 for further details regarding antibiotic therapy in deep neck infection.

Ludwig angina management consists of antibiotics and airway management. Oral intubation may be difficult because of inability to displace the tongue with a laryngoscope. Intubation is not generally emergent and can be done in the operating room. Examination of the glottis and supraglottic airway by flexible endoscopy will ascertain the degree of airway compromise and, hence, the urgency of airway management. When emergent intubation is indicated, or a patient requires intubation before a prolonged transfer for care, we recommend use of a videolaryngoscope or flexible intubating endoscope (see Chapter 1). Consultation with an oral maxillofacial surgeon or otolaryngologist is indicated.

Disposition

Those with simple odontogenic infections can be discharged with close outpatient follow-up. Patients with severe odontogenic infections, deep neck infections, systemic toxicity, or immunocompromised patients should be hospitalized. Those with concern for airway compromise (e.g., Ludwig angina) or with extension into the neck or mediastinum should be admitted to the intensive care unit (ICU) after thorough evaluation of the airway by CT and flexible endoscopy.

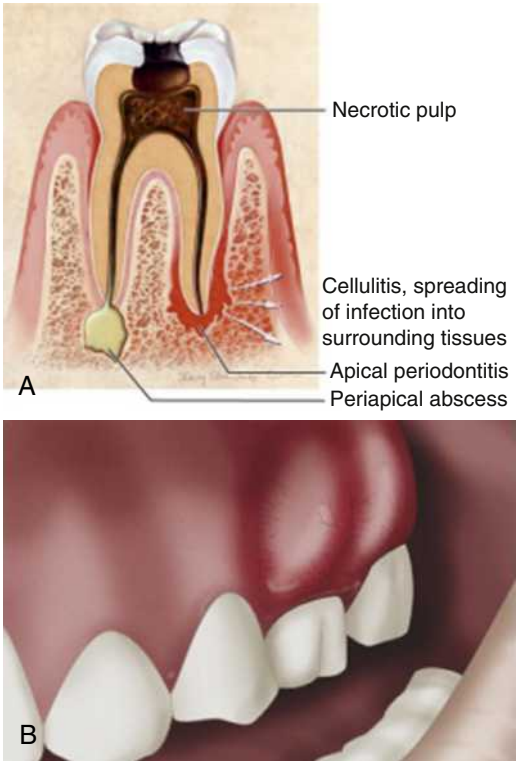

Fig. 56.15 (A) Periapical abscess diagram. (B) Physical examination findings of a periapical abscess. (From Buttaravoli P, Leffler SM. *Minor Emergencies*. 3rd ed. St Louis, MO: Elsevier; 2012, pp 178–180, Figs. 45.3 and 45.4.)

DENTOALVEOLAR TRAUMA

Foundations

Anatomy, Physiology, and Pathophysiology

Dentoalveolar trauma is common and can involve any tooth. The maxillary central incisors are commonly involved because many children have an anterior overbite, predisposing these teeth to injury. When teeth are subject to trauma, they can become concussed (with pain to percussion), subluxated (whereby teeth become more mobile, but are in their normal anatomic position), luxated (moved from their anatomic position), avulsed (out of the socket), have infraction (incomplete fracture of the enamel), or fractured. Refer to the first section of this chapter to review the relevant dental anatomy.

Forces that are applied to a tooth can lead to fractures. Classifying fractures is important because it guides management. Although some classification systems such as the Ellis system exist (Fig. 56.17), an anatomic description is always preferred. The following are types of fractures that can involve the crown of the tooth. An infraction is an incomplete fracture, or crack, of the enamel. An enamel fracture (Ellis I) is a complete fracture of the enamel, not involving any deeper layers. An enamel-dentin fracture (Ellis II) involves the dentin, which has a yellow tint. An enamel-dentin-pulp fracture (Ellis III) involves the pulp and will have a pinkish tinge or small amount of visible blood. In addition, fracture lines can extend into the root of the tooth which will often show tooth mobility. Fractures that extend into the root may additionally need stabilization as the attachment to the adjacent alveolar bone can be compromised.

Concussion occurs when the periodontal ligament sustains a mild injury, causing tooth pain but no mobility. More severe injuries include subluxation or luxation. If a tooth is mobile but is in the correct anatomic position, it is subluxated and will heal as long as no further trauma occurs. Luxation is where the tooth itself is moved in any direction that is no longer anatomic, and it can be further divided into four types: (1) extrusive luxation is where the tooth is forced partially out of the socket in an axial direction, (2) intrusive luxation occurs when a tooth moves apically (and can be mistaken for an avulsion if completely intrusively luxated), (3) laterally luxated, where the tooth is displaced laterally with potential surrounding alveolar bone injury, and (4) avulsion where the tooth is completely out of the socket (Fig. 56.18). A long-term sequela of blunt trauma or reimplantation of teeth is resorption of the root.

Dental trauma can also involve the surrounding alveolar bone. The alveolar bone usually breaks in segments, leading to malocclusion, pain, and a segment of teeth that are misaligned with respect to their uninvolved neighbors (Fig. 56.19). These injuries usually present in conjunction with injury to the tooth itself.

Clinical Features

Patients invariably will have a history of dentoalveolar trauma. Replantation of a pediatric tooth depends on whether the tooth is primary or secondary (Fig. 56.20) Primary dentition are not reimplanted as they will ankylose or fuse to the bone and interfere with the eruption of permanent teeth. Assessing the storage medium and timing of avulsion of a permanent tooth is important as it predicts success of reimplantation.

Inspect the teeth to evaluate for fractures, tenderness, and mobility. The diagnosis of subluxation can be made by gently tapping a tooth with two tongue blades: any perceptible mobility is evidence of subluxation. Mobility can also be seen when dental fractures extend into the root of the tooth.

Evaluate the oral mucosa and tongue for trauma. Small lacerations can usually be managed expectantly, but larger lacerations may require repair. Evaluate injuries for foreign bodies and to ensure injuries are not full thickness.

Differential Diagnoses

The extent of dentoalveolar trauma is typically apparent by the history and physical examination. The most important differential concerns the possible locations of missing teeth. If a tooth appears to be missing, ask the patient if the tooth was present before the trauma and, if so, whether any teeth were recovered at the scene. If no tooth is visualized, examine the socket to see if the tooth has been intrusively luxated. Evaluate surrounding soft tissue to ensure a tooth is not buried in in a mucosal laceration or other tissue defect. A tooth that cannot otherwise be accounted for may have been aspirated or swallowed.

Diagnostic Testing

Diagnosis of a tooth fracture or luxation is clinical, but CT of the face or Panorex x-rays can be ordered if CT is not available. Specialized views (e.g., maxillary anterior, periapical views) are used by dental professionals but are not regularly available in the ED. A chest or abdominal radiograph will help diagnose an aspirated or ingested tooth.

Management and Disposition

Prior to any manipulation of teeth, administer appropriate analgesia. Nerve blocks such as supraperiosteal nerve blocks (for isolated teeth) or inferior alveolar nerve blocks (for multiple traumatized mandibular teeth) are highly effective and easy to perform.

Check the patient's tetanus status and treat according to the standard for a non-tetanus-prone wound (10-year immunization update). Place all patients with dentoalveolar trauma (especially those who have splinting or calcium hydroxide paste applied) on a liquid diet for several days, advanced to a soft diet for 1 week.

TABLE 56.3 Recommended Antibiotics for Deep Neck Infections

Antibiotic	Dosage	Notes
Ampicillin/sulbactam **plus** vancomycin	3 g IV every 6 h 15–20 mg/kg q8–12 hours (2 g maximum)	
Clindamycin	600 mg IV every 8 h	If allergic to penicillin
Meropenem **plus** vancomycin	1 g IV every 8 h 20 mg/kg (2 g maximum)	If immunocompromised

IV, Intravenous.

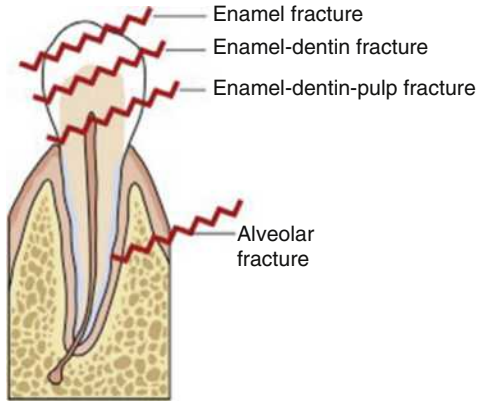

Fig. 56.17 **Ellis Fracture Classification.** *Ellis class I* fractures involve the enamel only; *Ellis class II* fractures involve the enamel and dentin; *Ellis class III* fractures involve the enamel, dentin, and pulp. (From Fowler GC. Management of dental injuries. In: Pfenninger JL, Fowler GC, ed. *Pfenniger and Fowler's Procedures for Primary Care*. Philadelphia, PA: Elsevier/Mosby; 2011:511–515, Fig. 81.2.)

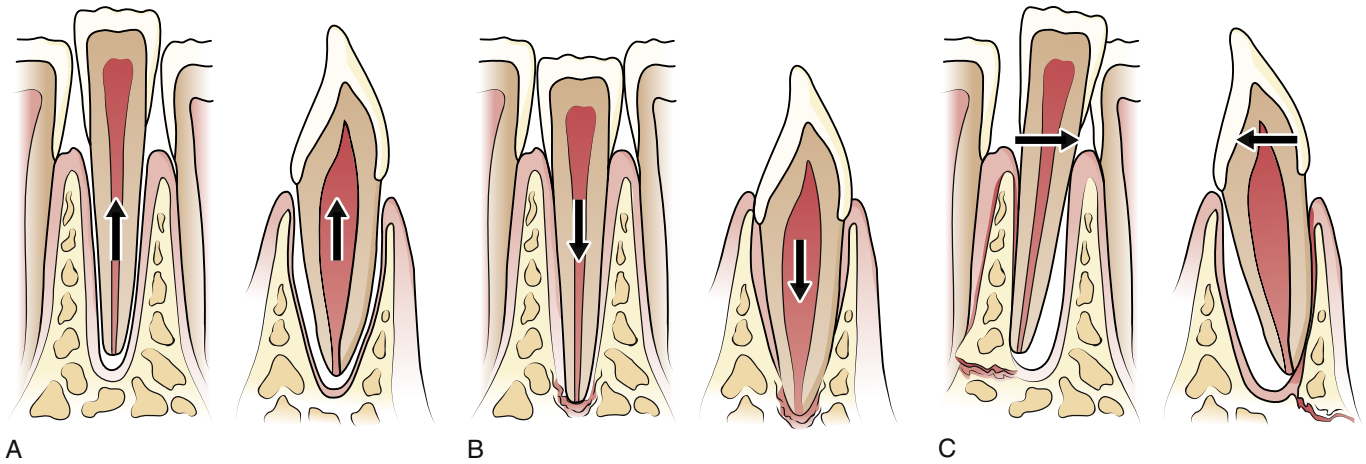

Fig. 56.18 Luxation of Teeth. (A) Extrusive luxation occurs when the tooth is forced partially out of the socket in an axial direction. (B) Intrusive luxation of a tooth compresses the periodontal ligament and vascular supply of the pulp. It may even crush the apical bone. (C) Lateral luxation occurs when the tooth is displaced in a lingual, mesial, distal, or facial direction. Fractures of the alveolar bone frequently accompany lateral luxation injuries. (From Roberts J. *Roberts & Hedges' Clinical Procedures in Emergency Medicine*. 6th ed. Philadelphia, PA: Elsevier; 2014, Fig. 64.9.)

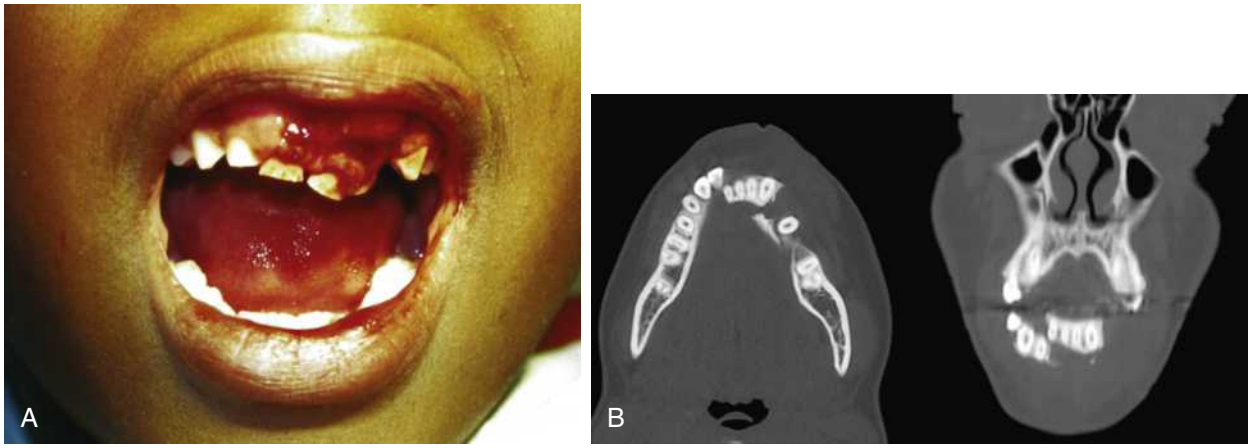

Fig. 56.19 (A) Alveolar ridge fracture involving the maxillary incisors with a segment of teeth misaligned with respect to their neighboring teeth. (B) Computed tomography (CT) demonstrating an alveolar ridge fracture in the axial and coronal planes, respectively. (From Roberts J. *Roberts & Hedges' Clinical Procedures in Emergency Medicine*. 6th ed. Philadelphia, PA: Elsevier; 2014, Figs. 64.14 and 64.15.)

Dental Fractures

Fractures of teeth involving the enamel only (Ellis I) need no emergent treatment. If available, an emery board can be used to file down any sharp edges to prevent intraoral trauma. Cover deeper fractures involving the dentin only (Ellis II) or both dentin and pulp (Ellis III) with a calcium hydroxide paste to protect the underlying structures from infection. Although dental trauma guidelines recommend sealing fractures involving the dentin with glass ionomer, this is not often available to the emergency clinician, so we believe it is reasonable to use calcium hydroxide paste instead. ED pulpotomy for enamel-dentin-pulp fractures to remove exposed pulp has been described, but it has a high complication rate and should not be attempted. We recommend follow up within 24 hours for all dental fractures that do not receive dental consultation in the ED, such as fractures involving the pulp or dentin.

To cover the tooth, first dry the affected tooth. Mix the catalyst and base of the calcium hydroxide product and directly apply it to the exposed tooth surface (Fig. 56.21). To keep the tooth dry, gauze rolls in the mucobuccal fold and a nasal cannula with air or oxygen directed at the anesthetized tooth surface is often helpful.

Tooth Avulsion

Avulsed *permanent* teeth should be reimplanted at the earliest opportunity as long as the tooth is still viable.[13,14] In general, teeth are likely to be nonviable if dry for over 60 minutes as the periodontal ligament cells die. There are some recommendations to reimplant the nonviable tooth to maintain contour of the alveolar bone, but the long-term viability of the tooth is unlikely as the periodontal ligament cells do not regenerate. Reimplantation of a nonviable tooth can be considered on a case-by-case basis and ideally in discussion with the provider that will follow the patient.

In the prehospital setting, the tooth can be reimplanted or stored in an appropriate medium to preserve periodontal ligament cell viability. Ideally, the tooth should be stored in either a commercially-available solution, such as Hank's balanced salt solution (e.g., Save-A-Tooth, EMT Toothsaver) or milk.[15] Saliva should only be used if no other storage media are available. Avoid water as its hypotonicity will cause the periodontal cells to swell and die. See Table 56.4 for the approximate length of viability of a tooth based on the solution in which it is stored. Do not soak the tooth in a doxycycline solution prior to reimplantation

Upper teeth	Primary erupt	Permanent erupt
Central incisor	8–12 months	7–8 years
Lateral incisor	9–13 months	8–9 years
Canine (cuspid)	16–22 months	11–12 years
First premolar		10–11 years
Second premolar		10–12 years
First molar	13–19 months	6–7 years
Second premolar	25–33 months	12–13 years
Third molar		17–21 years

Lower teeth	Primary erupt	Permanent erupt
Third molar		17–21 years
Second molar	23–31 months	11–13 years
First molar	14–18 months	6–7 years
Second premolar		11–12 years
First premolar		10–12 years
Canine (cuspid)	17–23 months	9–10 years
Lateral incisor	10–16 months	7–8 years
Central incisor	6–10 months	6–7 years

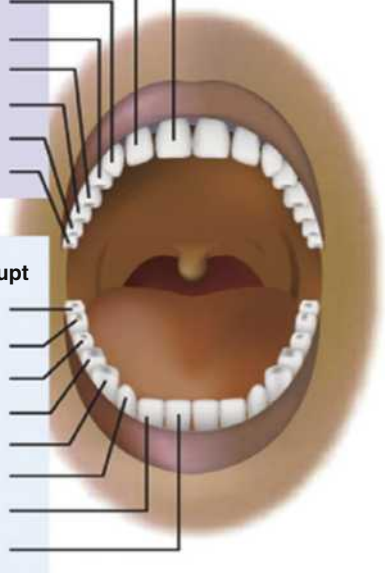

Fig. 56.20 Age of primary dentition and secondary (permanent) dentition of various teeth. (From Olynik CR, Gray A, Sinada GG. Dentoalveolar trauma. *Otolaryngol Clin North Am.* 2013;46[5]:807–823, Fig. 2.)

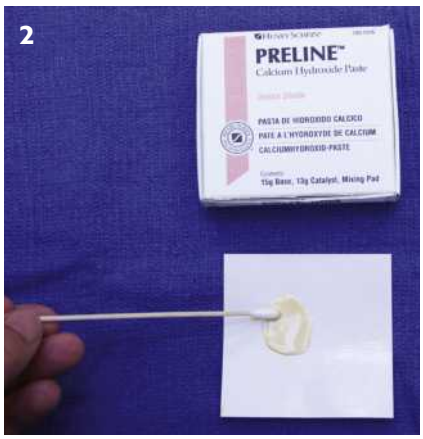
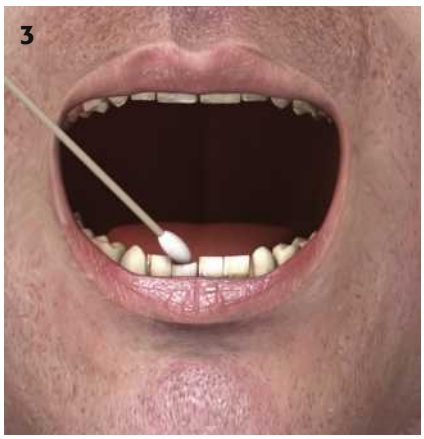
CALCIUM HYDROXIDE APPLICATION

Calcium hydroxide is used to treat dentin fractures and aids in prevention of infection and pain relief. It is supplied in separate tubes of catalyst and base.



Mix equal portions of catalyst and base on the mixing pad that is supplied with the product. A dental spatula is an ideal tool; however, a simple cotton applicator will suffice.



Dry the tooth surface prior to application by having the patient bite down on a gauze pad. Then place a small amount of the paste onto the exposed surface. It will dry within minutes.

Fig. 56.21 Calcium hydroxide application for the treatment of fractures involving the dentin (Ellis class II) and pulp (Ellis class III). (From Roberts J. *Roberts & Hedges' Clinical Procedures in Emergency Medicine.* 6th ed. Philadelphia PA,: Elsevier; 2014, Fig. 64.7.)

as there is no benefit to this practice.[16] There are no data to suggest other previously-proposed therapies such as hyperbaric oxygen and other specialized treatments provide benefit.[17] Implant-supported crowns have higher long-term success rates compared to reimplanted teeth, but it is still reasonable to attempt reimplantation as it is unclear which patients will have favorable outcomes with reimplantation and also unclear which patients would have access to implant-supported crowns.[18] Permanent teeth should be handled only by the crown to avoid injury to the periodontal ligament at the root.

In the awake patient not at risk for aspiration, provide analgesia (e.g., supraperiosteal nerve block), rinse the permanent tooth gently with saline while holding it by the crown if there are any visible debris, irrigate the socket to remove debris, and reimplant the tooth into the socket. Do not remove debris from the root that does not come off with saline,

because manual removal can damage the periodontal ligament cells. After replantation, a dental consultant can provide immobilization for the reimplanted tooth. If dental consultation is not available, use periodontal dressing material (Coe-Pak) to splint the tooth to the adjacent normal teeth to provide a 24- to 48-hour temporary splint. A resin and catalyst paste are mixed together in equal quantities to a firm consistency and molded over the anterior and posterior aspects of the involved tooth and two or three adjacent teeth on each side (Fig. 56.22). The gingiva and enamel must be completely dry; the provider's gloves should be wet or covered in lubricating jelly to allow for ease of handling of the paste. The positioning of the tooth does not need to be anatomically perfect, just approximate. Avoid getting the paste on the occlusal surface of the tooth. Advise the patient to have a soft diet (but avoid hot liquids that may soften the packing) and follow up with a dentist within 24 hours. Prescribe doxycycline 100 mg bid for 7 days for adults and penicillin 50 mg/kg/day divided qid (maximum 500 mg qid) for 7 days in children. Counsel patients about brushing gently with a soft toothbrush after each meal and utilizing chlorhexidine mouth rinses twice a day for 1 week.

TABLE 56.4 Periodontal Ligament Cell Viability by Storage Medium

Solution	Length of Preservation of Periodontal Ligament
None (dry)	Less than 60 min
Milk	3–8 h
HBSS	12–24 h
Oral rehydration solution	Similar to HBSS

HBSS, Hank's balanced salt solution.

Luxation and Alveolar Fractures

Teeth that are concussed or subluxated usually do not need specific treatment. Permanent teeth that have undergone extrusive or lateral luxation are gently placed into anatomic position and splinted in place.[20] Intrusive luxation does not have any ED-specific interventions

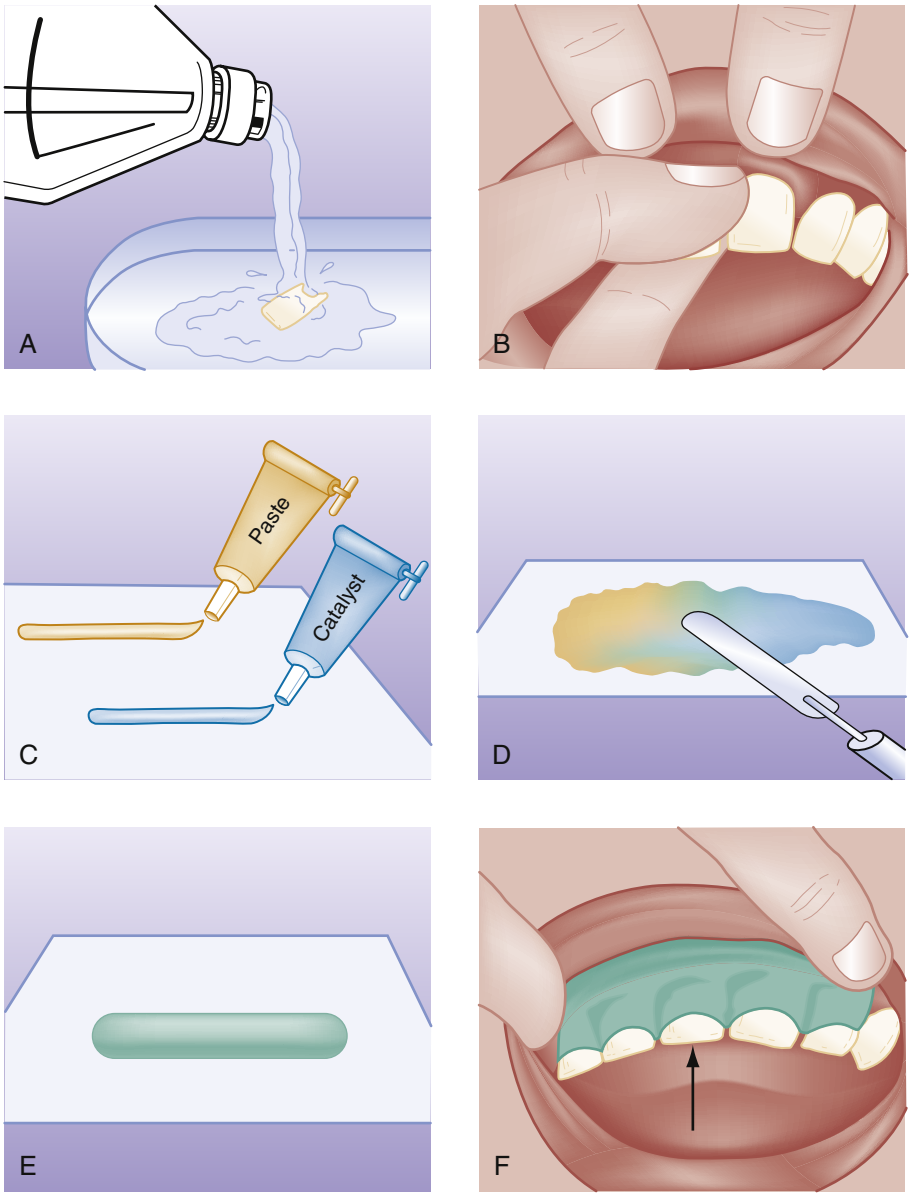


Fig. 56.22 Reimplantation and Stabilization of an Avulsed Tooth. (A) Tooth is rinsed. (B) Tooth is placed back into socket. (C and D) Periodontal pack is mixed. (E) Splint material is ready for application. (F) Packing is molded over reimplanted tooth and two adjacent teeth to either side.

except referral to a specialist, because the tooth cannot be easily retrieved. Pediatric teeth that have been extrusively luxated or laterally luxated and are close to shedding are gently removed.

Alveolar fractures may be apparent clinically from exposed pieces of bone or diagnosed radiographically. In massive facial trauma try to conserve as much of the alveolar bone as possible, unless there is a great danger of aspiration. Indiscriminate loss of alveolar bone results in tremendous cosmetic deformity that is difficult to restore with prosthetic devices or leaves no foundation for a dental implant, thus necessitating autologous bone grafting procedures. An alveolar fracture will eventually require 4 to 6 weeks of stabilization for adequate healing; if there is an associated subluxed or avulsed tooth, stabilization is maintained at the expense of possible ankylosis of the tooth.

Soft Tissue Injuries

Generally, lacerations to the buccal mucosa do not require repair if under 1 cm. A common rule is that if food can get stuck in the laceration, it should be considered for repair. In addition, lacerations to the gingiva that expose the base of the teeth should be repaired. This is a complex repair, however, and consultation or referral is indicated if the clinician is not experienced with the procedure. Frenulum injuries generally are not repaired but, in neonates and infants, should raise suspicion of child abuse.

Tongue lacerations usually heal well without intervention unless they are gaping, have a flap, involve the muscle, cause a bifid or grooved tongue, or if hemostasis cannot be achieved otherwise. After a lingual block or direct infiltration of anesthetic and irrigation, absorbable sutures such as 4-0 chromic, Vicryl, Dexon, or Vicryl Rapide can be used. Lacerations involving the muscular layer of the tongue are closed with one set of deep sutures that involve both the muscle and mucosa; a two-layer repair is not necessary. Full-thickness tongue lacerations can be closed either in three layers (e.g., mucosa inferiorly, muscle, mucosa superiorly) or one side of the mucosa can be repaired followed by a set of deep sutures that closes the muscular layer and opposing mucosa.

Disposition

Patients with dentoalveolar trauma usually do not need to be admitted, unless they have other concomitant trauma, uncontrolled pain, or have severe trismus preventing oral intake. All patients should have appropriate follow-up. Discharge includes adequate analgesia, antibiotics if indicated, and dental hygiene instructions.

TEMPOROMANDIBULAR JOINT DISORDER AND DISLOCATION

Foundations

Anatomy, Physiology, and Pathophysiology

The TMJ is the articulation between the squamous portion of the temporal bone and the condyle of the mandible. It is comprised of two types of synovial joints: hinge and sliding. The hinge joint action dominates during normal mouth opening, but with wide opening, translational movement occurs and the articular disc and condyle complex slide inferiorly (Fig. 56.23). When the condyle moves anterior to the articular eminence, dislocation occurs.

Temporomandibular Joint Disorder. The cause of TMD is debated, but jaw clenching and grinding associated with stress is thought to contribute. Tooth malocclusion was previously thought to be a common etiology, but this is rare unless there is an inciting event (e.g., if symptoms began after dental work with resultant malocclusion).

Temporomandibular Joint Dislocation. TMJ dislocation occurs when the condyle travels anteriorly along the eminence and becomes locked in the anterosuperior aspect of the eminence. The masseter, internal pterygoid, and temporalis go into spasm attempting to close the mandible; trismus results and the condyle cannot return to the temporal fossa. Mandibular dislocation is painful and frightening for the patient. Patients prone to mandibular dislocation include individuals with anatomic disharmonies between the fossa and articular eminence, weakness of the capsule and the temporomandibular ligaments, or torn ligaments. Dystonic reaction to drugs may result in mandibular dislocation. Patients who have had one episode of mandibular dislocation are predisposed to further dislocations. If a unilateral dislocation has occurred, the jaw deviates to the opposite side. More commonly, a symmetrical bilateral dislocation occurs.

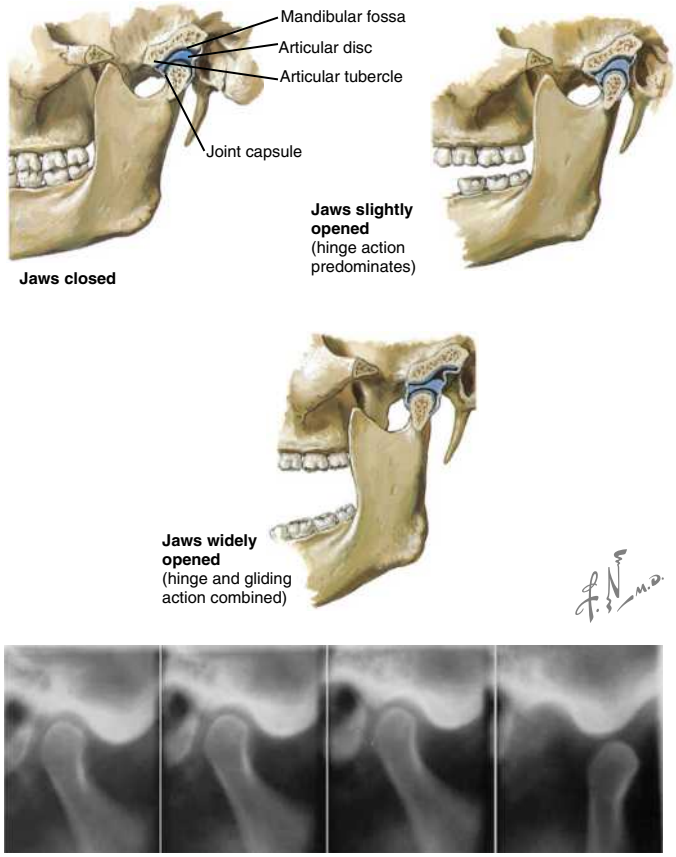

Fig. 56.23 The Temporomandibular Joint. With slight opening, the joint's function as a hinge predominates. With greater jaw opening, there is translational movement. (From Norton NS. Temporomandibular joint. In: *Netter's Head and Neck Anatomy for Dentistry*. 2nd ed. Philadelphia, PA: Elsevier/Saunders; 2012:2011.)

Clinical Features

Temporomandibular Joint Disorder

TMD is defined as "aching in the muscles of mastication, sometimes with occasional brief severe pain on chewing, often associated with restricted jaw movement and clicking or popping sounds." Patients may also report headache, facial pain, or even an earache. Pain is often precipitated by use of the muscles of mastication (e.g., chewing) or with increased ranging of the TMJ (e.g., laughing, yawning).

For TMDs, the main physical signs are related to three items: joint sounds, such as crepitus or a joint click upon range of motion; limitations of joint movements with pain during assisted maximum mouth opening; and muscle and joint pain and pain just anterior to the auricular canal. None of these findings alone has sufficient testing

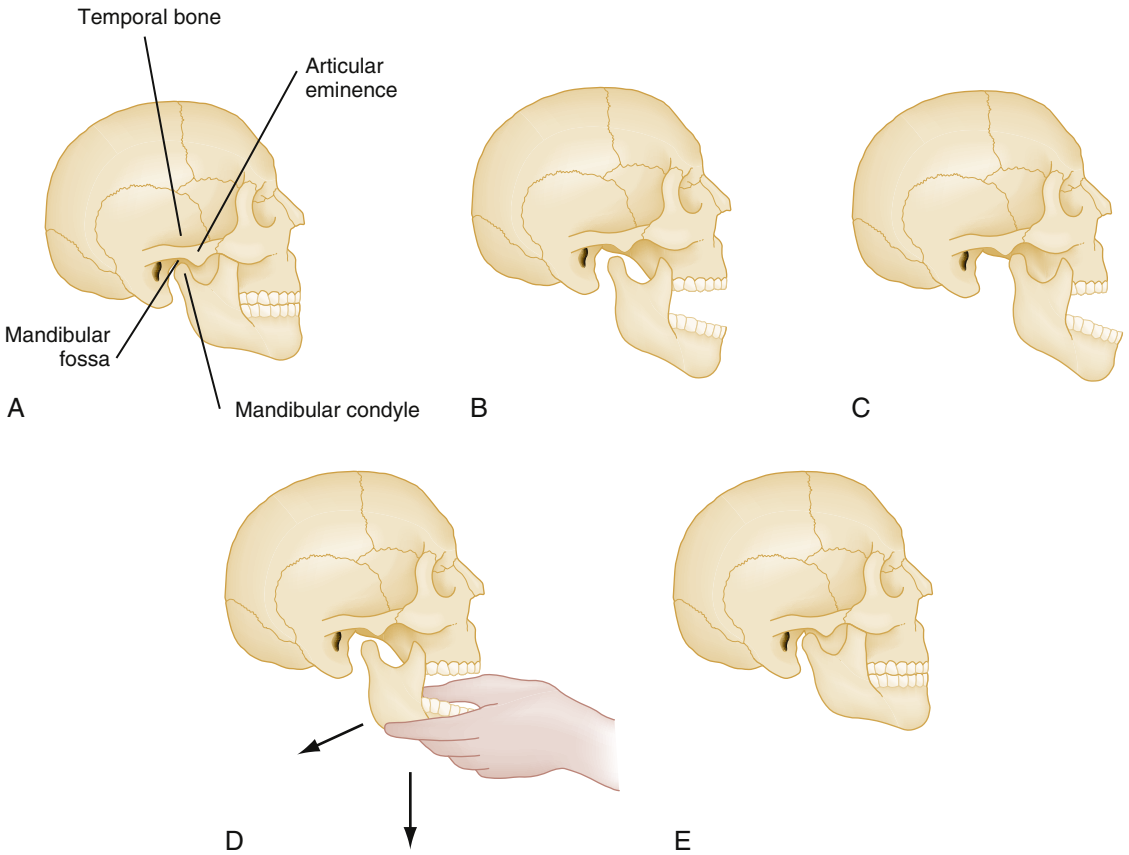

Fig. 56.24 Reduction of Temporomandibular Joint Dislocation. The temporomandibular joint is illustrated in normal and dislocated positions. (A) Closed position, with the mandibular condyle resting in the mandibular fossa behind the articular eminence. (B) In maximally open position, the mandibular condyle is just under and slightly behind the articular eminence. (C) In dislocated position, the mandibular condyle moves forward and upward slightly above the articular eminence; muscle spasm then occurs. (D) For reduction of dislocation, the thumbs are placed intraorally and lateral to the lower molars, and pressure is applied to the lower molar ridge area near the jaw angle in a downward and backward direction. (E) When the mandibular condyle has cleared the articular eminence, muscle contraction returns the jaw to a normal closed position. (Adapted from Rose LF, Hendler BH, Amsterdam JT. Temporomandibular disorders and odontic infections. *Consultant*. 1982;22:125.)

characteristics to rule TMD in or out, however. The diagnostic criteria of TMJ are outside the scope of this text.

Temporomandibular Joint Dislocation

The mandibular condyles may dislocate from trauma, but more often, dislocation follows extreme opening of the mandible, such as the case with yawning. Patients may have had prolonged jaw opening, such as in the case of dental procedures. They will report not being able to close the mouth. Recurrent dislocations are common, and patients may present knowing they have an anterior dislocation. Verbalization of their symptoms is often difficult because their mouth is stuck open.

On examination, jaw dislocations easy to recognize. The jaw will not be able to be closed, and a depression can be felt and seen in the preauricular area. There may be the appearance of an underbite as the mandible is anteriorly displaced. Asymmetry suggests a unilateral dislocation. If a traumatic mechanism is suspected, a secondary survey for trauma should be initiated.

Differential Diagnoses

The diagnosis of a TMJ dislocation is straightforward. However, TMD has many presenting complaints and therefore consideration for other etiologies is warranted. Pain can be secondary to pulpitis, an odontogenic infection, headache, otitis media, sinusitis, parotitis, and trigeminal neuralgia.

Diagnostic Testing

Radiographs are not indicated for straight-forward nontraumatic dislocation, unless the diagnosis is not certain. In cases of traumatic dislocation, obtain either a panoramic view of the mandible (Panorex) or CT scan of the facial to exclude fracture before manipulating.

Management

Temporomandibular Joint Disorder

Patients with TMD often have symptoms that fluctuate over time, and therefore initial therapy is conservative. NSAIDs, application of heat or cooling, and consideration of bite guards, if the patient has bruxism, are all reasonable first-line therapies. Heat therapy is typically 15 minutes at a time, four to six times daily. Refractory cases can also benefit from diazepam (2 to 5 mg by mouth every 8 hours as needed). If the symptoms are more severe, referral to a specialist is warranted because a multidisciplinary approach is often necessary to manage symptoms. Transcutaneous electrical nerve stimulation therapy or surgery may benefit patients with refractory cases.

Temporomandibular Joint Dislocation

Reduction of a dislocated mandible is often difficult, because masseter muscle contraction must be overcome. To relax the masseter, procedural sedation and analgesia is necessary. Either facing the patient or from behind, the emergency clinician grasps the mandible with both hands; the thumbs rest on the ridge of the mandible intraorally, posterior to the molars, and the fingers wrap around the outside of the jaw. It is best to have the patient sitting up, with a firm surface behind the head, so that posterior and inferior pressure can be exerted without accompanying movement of the patient's entire head. This method is effective and also prevents being inadvertently bitten by the patient since the reduction is extraoral.[19] Some physicians prefer an intraoral approach and place the thumbs on the occlusal surfaces of the teeth. In this case, the thumbs are wrapped with gauze and fortified with a piece of wooden tongue blade to protect them when reduction is accomplished, because the masseter muscles can contract with tremendous force.

Firm, progressive, downward pressure is applied on the mandible to free the condyles from the anterior aspect of the eminence; the mandible is guided caudally, then posteriorly and superiorly back into the temporal fossae (Fig. 56.24). If this maneuver is unsuccessful, both hands can be used on the affected side of the mandible. The patient is advised to avoid extreme opening of the mandible, such as occurs during laughing and yawning, to begin a soft diet for 1 week, and to apply warm compresses in the TMJ area. NSAIDs and muscle relaxants may be helpful. Patients with chronic dislocation may be helped initially with the application of a Barton bandage (elastic fabricated bandage that wraps around the top of the head and mandible).

A hands-free approach for reduction of acute nontraumatic TMJ dislocation using a "syringe" technique has also been described. With this technique, a 5- or 10-mL syringe is placed between the posterior upper and lower molars (or gums if edentulous) on the affected side. The patient then gently bites down and rolls the syringe back and forth; the syringe is a rolling fulcrum that helps the anteriorly-displaced condyle slip back into its normal position.

Disposition

Patients with TMD and with TMJ dislocation who have been relocated can be discharged home. Those with irreducible TMJ dislocation or those with TMJ dislocation in conjunction with a fracture are candidates for specialty consultation and may require admission for surgical reduction and fixation.

CHAPTER 56: QUESTIONS AND ANSWERS

1. A 27-year-old previously healthy man presents with dental pain, facial swelling, and a muffled voice. Physical examination is remarkable for trismus, poor dentition with diffuse periodontal disease, and an elevated floor of the mouth. You determine endotracheal intubation is necessary. Which of the following statements regarding the patient's management is *true?*

a. An awake intubation technique is indicated.
b. Pre-induction muscle relaxants will decrease the trismus.
c. Rapid sequence induction with rocuronium is indicated.
d. Succinylcholine will worsen the trismus.
e. Transtracheal retrograde wire intubation is indicated.

Answer: a. The trismus is mechanical (presence of a mass, abscess of phlegmon). Neuromuscular blockade, regardless of the choice between depolarizing or non-depolarizing agents, is not likely to help. Patients with anatomically difficult airway and symptoms of airway obstruction are optimally managed with an awake intubation, using a either a videolaryngoscope or flexible endoscope is indicated. Patients with limited oral access will be best managed with nasotracheal intubation over a flexible intubating bronchoscope. Transtracheal retrograde wire intubation is rarely, if ever, indicated in modern emergency practice. Traditional "muscle relaxants" are sedatives and have no direct muscle-relaxing properties.

2. A 21-year-old man presents with tooth pain. He underwent a left mandibular premolar extraction three days ago. Examination is remarkable for a painful but nonbleeding tooth socket. The face and mandible are not swollen. Which of the following statements regarding this patient's condition is *true?*

a. Analgesia is the main goal of emergency department (ED) therapy.
b. Antibiotics are indicated.
c. Dental consultation in the ED is indicated.
d. Opioids are the treatment of choice.
e. Provocation of socket bleeding is encouraged to form new clot.

Answer: a. A dry socket is an exquisitely painful post-extraction syndrome that typically occurs 3 or 4 days later. The pathophysiology is loss of the healing blood clot and localized bone infection. Treatment consists of pain control. Optionally, gentle irrigation, and packing with gauze soaked in eugenol can be performed. Opioids may be used, but this would be in addition to nonsteroidal antiinflammatory drugs (NSAIDs), which are excellent analgesics for dental pain and are preferred due to the inflammatory component.

3. A 2-year-old previously healthy toddler presents with an avulsed tooth after hitting his mouth on the ground after a trip and fall. Physical examination is remarkable for a non-toxic appearing child who is crying and has an open slightly oozing pocket at the maxillary central incisor. The mother has brought the tooth stored in milk and the event occurred one hour ago. Which of the following statements regarding the patient's management is *true?*

a. Set-up for conscious sedation should be arranged, because the replacement of the avulsed tooth may be painful.
b. The mother should store the tooth in the patient's mouth.
c. The tooth should be placed in Hank's balanced salt solution.
d. The tooth should be replaced in the socket as soon as possible.
e. The tooth should not be reimplanted.

Answer: e. Management of recovered avulsed teeth depends on the age of the patient and the length of time for which the tooth has been displaced. Avulsed primary teeth are not reimplanted. Reimplanted primary teeth ankylose or fuse to the bone, so although the dentofacial complex grows downward and forward, the reimplantation site does not. There also may be interference with the eruption of the permanent tooth. Cosmetic deformity results in either case. Thus, this patient should be referred to a specialist for consideration of a space maintainer or cosmetic appliance.

4. A 25-year-old previously healthy woman presents with recurrent pain from her temporomandibular joint disorder (TMD). The pain is described as being dull, and it worsens during the course of the day. Physical examination is remarkable for mild tenderness to palpation over the temporomandibular joint (TMJ) and some spasm noted over the masseter and internal pterygoid. Which of the following statements regarding the patient's management is *true?*
   a. A computed tomography (CT) scan of the face would be helpful.
   b. A Panorex should be obtained.
   c. Patient should be prescribed narcotic agents.
   d. Treatment consists of external application of heat for 15 minutes four to six times per day, soft diet, analgesics including nonsteroidal antiinflammatory drugs (NSAIDs).
   e. Ultrasound of the joint should be obtained.

Answer: d. TMJ radiographs are not helpful. Treatment consists of the external application of heat for 15 minutes four to six times per day, soft diet, analgesics including NSAIDs, and consideration of a muscle relaxant, such as diazepam (2 to 10 mg up to four times per day). Patients should be referred to a dentist specializing in TMD, such as a periodontist or a periodontal prosthodontist.

5. A 32-year-old previously healthy man presents with a fractured maxillary lateral incisor after a mechanical trip and fall. Physical examination is remarkable for a portion of the tooth that has an ivory-yellow appearance. You determine that he has a fractured tooth. Which of the following statements regarding the patient's management is *true?*
   a. A calcium hydroxide paste should be used to cover the exposed dentin.
   b. A dressing can be placed for comfort.
   c. An urgent pulpotomy is indicated.
   d. If this were a pediatric patient or an adolescent, it would be considered less serious, because children have more dentin than adults.
   e. The patient will likely need an emergent root canal.

Answer: a. This patient has a fracture involving the dentin, which has an ivory-yellow appearance. The pulp continually lays down dentin throughout the life of the tooth. In a child, the pulp is relatively large in size, and there is less dentin; the inverse is true in the adult. Because dentin is a microtubular tissue capable of preventing bacteria to percolate into the pulp chamber, fractures involving dentin are more serious in children and adolescents. In younger patients, the management of dentin fractures involves the immediate placement of a dressing of calcium hydroxide paste over the exposed dentin. Early intervention may prevent contamination of the pulp and avoid the need for subsequent root canal. In an adult, who has a greater thickness of dentin compared with pulpal tissue, there is less need for urgent referral to a dentist. A dressing can be placed on the tooth for comfort. Referral should be made to a dentist for the next working day.

Ophthalmology

Kama Guluma and Jeffrey E. Lee

KEY CONCEPTS

- Prophylactic topical antibiotics are not indicated for the treatment of corneal abrasions, and eye patches are not recommended because they can mask a worsening infection.
- Eyelid lacerations that may require referral to a plastic or ophthalmic surgeon include those with lid margin lacerations, a canalicular laceration, or levator or canthal tendon injuries.
- Alkaline burns to the cornea and conjunctiva need to be irrigated until a neutral pH is attained because they produce a liquefactive necrosis that penetrates and dissolves tissue.
- Admit hyphema patients with sickle cell trait, uncontrolled elevations in intraocular pressures (IOPs), hyphema of greater than 50%, and when there is concern for rebleeding.
- Avoid manipulation, palpation, or tonometry on a suspected globe rupture pending an ophthalmology consult.
- Scleritis, an autoimmune inflammatory process involving the sclera, can be confused with episcleritis caused by inflammation in the more superficial episcleral layer of the eye.
- Episcleritis, unlike scleritis, is associated with much less discomfort, a pinker and more pronounced peri-limbal injection from superficial episcleral vessels that—unlike the deeper injected scleral vessels in scleritis—will vasoconstrict and blanch with 10% phenylephrine. Treatment of both involves topical corticosteroid drops.
- Endophthalmitis is an infection of the eye itself, typically following intraocular surgery, that is treated with intravitreal antibiotics.
- Herpes zoster keratoconjunctivitis can complicate herpes zoster ophthalmicus. Emergent ophthalmologic consultation and treatment with systemic antiviral agents are required.
- Treatment of acute angle-closure glaucoma requires both a reduction in the production and an increase in the outflow of aqueous humor (see Box 57.1).
- With anisocoria, the following considerations help in determining which pupil—the larger or the smaller—is the pathological one: (1) parasympathetic innervation constricts a pupil in bright light, whereas sympathetic stimulation helps dilate a pupil in the dark; (2) an abnormally small pupil may therefore be due to either a decrease in sympathetic stimulation or an augmentation of parasympathetic stimulation—but likely the former (e.g., Horner syndrome); (3) an abnormally large pupil may therefore be due to either a decrease in parasympathetic stimulation or an augmentation of sympathetic stimulation—but likely the former (e.g., partial third-nerve palsy from compression, Adie's pupil, pharmacological mydriasis); or (4) the abnormally small pupil will usually look worse in the dark, whereas the abnormally large pupil will usually look worse in the light.

OVERVIEW

The emergent conditions that affect the eye, its surrounding tissues, and the act of seeing itself are myriad and broad in scope and include trauma, inflammatory conditions, infections, hydrostatic issues (such as glaucoma), vascular events, structural issues, optical derangements, and neurological developments (visual field cuts, anisocoria, nystagmus, diplopia). The evaluation of a chief complaint of "eye problem" may take the clinician in a variety of directions. Fig. 57.1 represents a general orientation to non-neurological and nontraumatic ophthalmological emergencies based on the four cardinal symptoms of pain, redness, altered vision, and swelling.

TRAUMATIC CONDITIONS

Foundations

The evaluation of a traumatic injury to the eye is framed around anatomic involvement including superficial (eyelids, conjunctival, corneal, and anterior segment) structures to deep (including ocular, retrobulbar, and periorbital) structures, keeping in mind that deep injuries may be present with minimal superficial manifestations. With facial trauma, many extraocular structures are damaged along with the eye (traumatic facial injury is discussed in more detail in Chapter 34). A detailed examination for additional injury is therefore important.

Periorbital Contusions and Eyelid Lacerations

Clinical Features and Differential Diagnoses

Periorbital contusions and eyelid lacerations present very evidently, but it is important to determine whether additional ocular injury such as a globe perforation, an orbital septal injury (suggested by prolapsed fat), a canalicular laceration (suggested by laterally displaced puncta) (Fig. 57.2), a levator or canthal tendon laceration, or an intraorbital foreign body is present because all require consultation in the emergency department (ED) with an ophthalmic surgeon. An eyelid or periorbital injury should not be a distraction from less visible underlying injuries to the eye itself (see sections on injuries to the anterior segment, posterior segment, and retrobulbar space).

Diagnostic Testing

The emergency clinician should undertake best attempts to thoroughly examine all ocular structures, even those hidden by swollen eyelids and periorbital tissue, and evaluate visual function. With delay, swelling can increase and limit visualization. Early examination, gentle pressure to avoid excessive tissue manipulation, or use of ice can improve the ability to open the eyelids, whereupon an assessment for deeper injuries

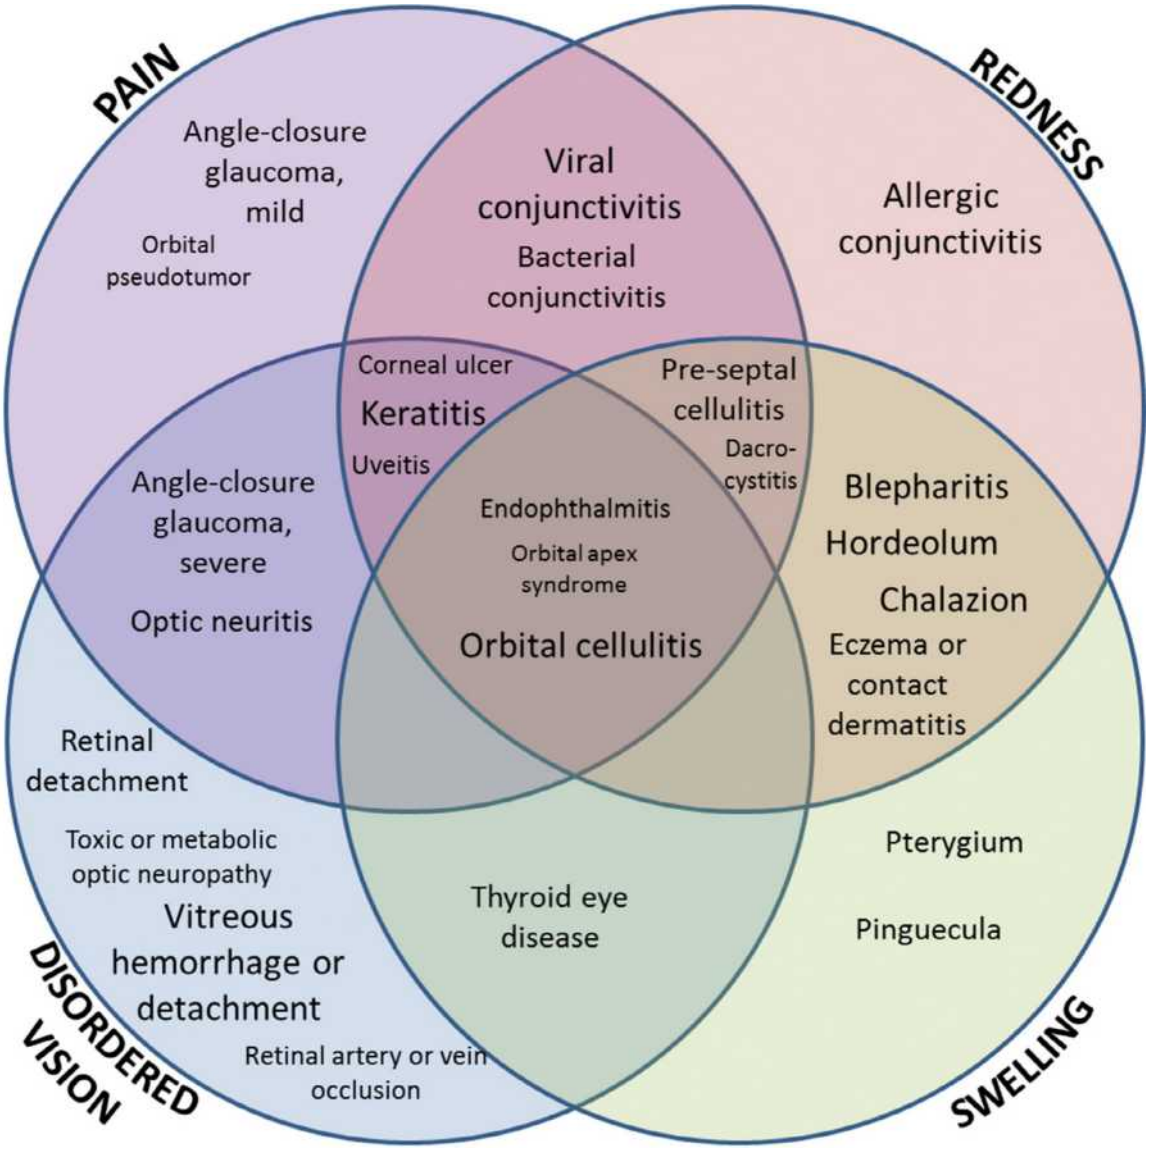

Fig. 57.1 An overview of nontraumatic, non-neurological ophthalmological conditions, arranged by primary presentation in the emergency department (ED). Relative text size is a general representation of the incidence or relatively likelihood of that entity in relation to others. (Note: The actual incidence or likelihood of the entity in any one ED will vary with the local disease patterns and patient population being treated in the department.)

can be made. The use of eyelid retractors, such as the Desmarres, can help avoid increasing intraocular pressure (IOP). However, if there is concern for a ruptured or perforated globe (with or without a foreign body present) and the globe cannot be safely and properly examined, computed tomography (CT) imaging, with or without consultation with an ophthalmologist, is advised (see Intraocular Foreign Bodies and Globe Rupture later in the chapter).

Management and Disposition

Isolated soft tissue injury to the eyelids and the surrounding area is treated with symptomatic management such as head elevation and cool compresses, as most will resolve. If there are no additional complications, one can manage simple lid lacerations that are parallel to relaxed skin tension lines (exceptions for damage to important structures noted earlier) with primary closure with 6-0 or 7-0 nylon or Prolene interrupted sutures, removed within a week. Patients are instructed to seek follow-up care for any increase in pain or swelling, decreased vision, double vision, or significant flashing lights or floaters, as these may be indications of retinal injury (see Posterior Segment/Ocular Injuries: Commotio Retinae, Retinal Detachment, Intraocular Foreign Body, and Perforated Globe later).

Conjunctival and Scleral Injuries: Subconjunctival Hemorrhage, Conjunctival Laceration, and Scleral Laceration

Clinical Features

Injuries to the conjunctiva include a subconjunctival hemorrhage (very common with blunt or penetrating injury) and conjunctival laceration. A subconjunctival hemorrhage develops when subconjunctival blood vessels bleed, either spontaneously or after a sudden acute venous congestion of the head, such as from a Valsalva maneuver or vigorous coughing. The hemorrhage smoothly and minimally raises the overlying conjunctiva, with no vessels visible behind the blood, and is

Fig. 57.2 Canalicular Laceration. (A) This patient experienced a laceration of the upper canaliculus. (B) Canalicular laceration extending from forehead and brow. (A, From Zitelli BJ, Davis HW, eds. *Atlas of Pediatric Physical diagnosis*. 5th ed. St Louis: Mosby; 2002. B, Courtesy Jeffrey Lee, MD, University of California San Diego.)

often discovered by the patient upon looking in the mirror (Fig. 57.3). Symptoms, if any are present, may include a very mild, diffuse foreign body sensation, due to the size and location of the hemorrhage, with no change in visual acuity. Subconjunctival hemorrhages from minor instigations are typically self-limited, but those from more direct trauma may be hiding an underlying injury. A 360-degree area of involvement associated with chemosis or pain, decreased visual acuity, or sensitivity to light should prompt an evaluation for globe perforation.

A conjunctival laceration will present with more discomfort than a subconjunctival hemorrhage, and if present, should prompt an evaluation for globe perforation and retained foreign body. A globe perforation from a related foreign body may present in an occult fashion, with only a mild-appearing conjunctival laceration or scleral "bruise," and should be suspected in the presence of a high-impact mechanism of injury (such as an injury from a compressed air tool or an object deflected by a hammer strike). A patient may also present with a scleral laceration, a laceration of the thick white envelope that provides the structural integrity of the globe, which should also prompt consideration of globe perforation.

Differential Diagnoses

Injury to the visible part of the anterior eye can be superficial or deep and largely can be distinguished based on the degree of pain, mechanism of injury, and depth of penetration on examination, as mentioned. The differential includes conjunctival abrasions or lacerations, scleral injury, and globe rupture. Inflammatory medical ocular conditions, such as scleritis or episcleritis, may have a similar appearance but will lack a history of trauma.

Diagnostic Testing

Examination for subconjunctival hemorrhage, conjunctival laceration, or scleral laceration is performed with a slit lamp and fluorescein dye. This is especially helpful in three ways: (1) identification of corneal abrasions, (2) screening for evidence of a globe perforation, and (3) identification of tarsal foreign bodies. A 10% fluorescein strip, applied using 2 to 3 drops of tetracaine or saline, will paint the conjunctival and corneal surface highlighting regions of lost or damaged epithelium with a bright greenish-yellow hue under a Wood's lamp. Intact epithelium will be spared. Fluorescein staining showing a pattern of repeated lines (Fig. 57.4) suggests the possibility of a retained tarsal foreign body hidden under the upper or lower lid. If the fluorescein

dye on the conjunctival surface is focally displaced by leakage of nonfluorescent aqueous fluid (called a *positive Seidel's test*), or if there is brownish-black uveal tissue visible in the scleral wound (Fig. 57.5), a globe perforation is present (see Intraocular Foreign Bodies and Globe Rupture). If no globe perforation is suspected, evert the eyelids and

inspect the conjunctival fornices for a hidden foreign body. In cases of spontaneous subconjunctival hemorrhage with no systemic signs of coagulopathy, the incidence of an underlying hemostatic disorder is low enough that a search for one is generally not warranted.[1]

Management and Disposition

Subconjunctival hemorrhages typically resolve spontaneously without treatment. Cool compresses are often recommended, but there is no evidence that they hasten recovery or improve outcome. There is no evidence to support the use of artificial tears or lubricants for treatment; however, it may help with normalizing the ocular surface and reduce any foreign body sensation the patient notices. Patients with simple subconjunctival hemorrhage are advised regarding the gradual resolution of their hemorrhage over 10 to 14 days, with the typical colorations associated with resolving hemorrhage. No follow-up is required unless the patient develops recurrent hemorrhages or new symptoms.

Although most conjunctival lacerations do not require repair, lacerations that are more than 1 cm need evaluation by an ophthalmologist in the ED for possible repair. Although there is no evidence to support the practice, topical antibiotic prophylaxis for 3 to 5 days (usually in ointment form; Table 57.1) is common practice. A deeper scleral

TABLE 57.1 Useful Topical Ophthalmic Medications and Their Dosages

Medication	Dosage
Topical Antibiotics	
Erythromycin 0.5% ointment	½-inch ribbon, four times per day for 7 days
Polymyxin B/trimethoprim solution	1 drop, four times per day for 7 days
Sulfacetamide 10% solution	1 to 2 drops, four times per day for 7 days
Azithromycin ophthalmic 1% solution	1 drop twice a day for 2 days, then daily for 5 days
Anti-Pseudomonal Topical Antibiotics	
Ciprofloxacin 0.3% ointment	½-inch ribbon, four times per day for 7 days
Ciprofloxacin 0.3% solution	1 to 2 drops, four times per day for 7 days
Moxifloxacin 0.5% solution	1 to 2 drops, three times per day for 7 days
Gentamicin 0.3% ointment	½-inch ribbon, two to three times per day for 7 days
Gentamicin 0.3% solution	1 to 2 drops, four times per day for 7 days
Ofloxacin 0.3% solution	1 to 2 drops, four times per day for 7 days
Topical Cycloplegics	
Cyclopentolate 1%	1 drop (may repeat in 5 min if needed), three times a day, for up to 4 days
Homatropine 5%	1 drop, four times per day, for up to 4 days
Topical Anesthetics[a]	
Tetracaine hydrochloride 0.5% or 1%	1 drop, every 30 min as needed, for 24 h only; up to 3 doses for minor procedures; up to 5 doses maximum for prolonged anesthesia
Proparacaine 0.05% (10 times dilution[b])	2–4 drops, every 30 min as needed, for 48 h only; up to 5 to 7 doses maximum
Topical Nonsteroidal Antiinflammatory Drugs	
Diclofenac 0.1%	1 drop, four times per day for 2–3 days
Ketorolac 0.4%	1 drop, four times per day for 2–3 days
Topical Antihistamines (Allergy)	
Azelastine 0.05%	1 drop twice a day
Emedastine 0.05%	1 drop up to four times per day
Topical Steroids	
Prednisolone acetate 1%	2 drops every 15–30 min four times, then four times per day for 2–3 days

[a]For corneal abrasions—use only in reliable patients who have been educated on use.
[b]Can use undiluted 0.5% for diagnostic purposes in emergency department (ED).

laceration requires emergent consultation with an ophthalmologist and may predispose to endophthalmitis. A full-thickness scleral laceration should be treated as a globe perforation.

Corneal Injuries: Corneal Abrasions, Foreign Bodies, and Lacerations

Clinical Features

Traumatic corneal injuries come in three varieties: (1) abrasions, (2) foreign bodies, and (3) lacerations (which may also go into the sclera). A corneal abrasion is typically sustained when an object or part of an object is dragged across the eye, such as seen with a fingernail injury to the eye or an attempt to pull off an adherent contact lens. A corneal foreign body is typically sustained when a small dense object traveling at high velocity impacts the cornea and becomes embedded, commonly seen with debris ejected from a grinding tool. A corneal laceration is typically sustained from a direct lancinating injury to the surface of the eye. Corneal injuries present with more symptom intensity than a conjunctival or isolated scleral injury, with significant foreign body sensation, pain, tearing, and a decrease in visual acuity if the abrasion, object, or laceration infringes upon the visual axis. Reactive conjunctival injection is often seen with primary corneal injuries either as a result of the primary process or secondary to patient manipulation and rubbing.

Differential Diagnoses

A foreign body may actually be conjunctival and not embedded in the cornea, presenting with more diffuse irritation, or a sensation of "something under the eyelid." Symptoms of a corneal abrasion can occur when the foreign object travels across the surface of the cornea by blinking or rubbing. As with a conjunctival and scleral injury, consider a perforated globe with any corneal injury, suggested by symptoms and signs (e.g., deep eye pain, decreased visual acuity, or photophobia) and injury mechanism.

Diagnostic Testing

With corneal abrasions and foreign bodies, the use of topical anesthesia (see Table 57.1) facilitates patient cooperation and helps localize the extent of the injury. Focal pain that is completely abolished by topical anesthesia, with no signs of deeper injury present, suggests the injury is confined to the superficial layers of the cornea. This does not obviate the need for a detailed examination with a slit lamp and fluorescein staining, with diagnostic goals as outlined with conjunctival injuries earlier. A corneal foreign body should be readily evident on slit-lamp evaluation (Fig. 57.6). If the foreign body spans the full thickness of the cornea, it should be considered a globe perforation requiring emergent ophthalmology consultation.

A corneal laceration may be difficult to characterize (or may even be hidden) on slit-lamp examination. The primary diagnostic goal is identifying it and determining whether or not it is through-and-through (i.e., representing an open-globe injury). Signs suggesting the latter are loss of anterior chamber depth, prolapsed iris (Fig. 57.7A), an irregular or teardrop-shaped pupil (see Fig. 57.7B), blood in the anterior chamber (Fig. 57.8), and a 360-degree subconjunctival hemorrhage. Looking for a positive Seidel's test with fluorescein, as described for conjunctival injuries earlier, can be used to confirm (but not exclude) an open globe. A critical point is that corneal perforation is a form of an open globe, and once this is found, the examination ends (so as to prevent the additional extrusion of globe contents, worsening visual outcome) until the patient can be further examined under controlled conditions by an ophthalmologist (see Intraocular Foreign Bodies and Globe Rupture later).

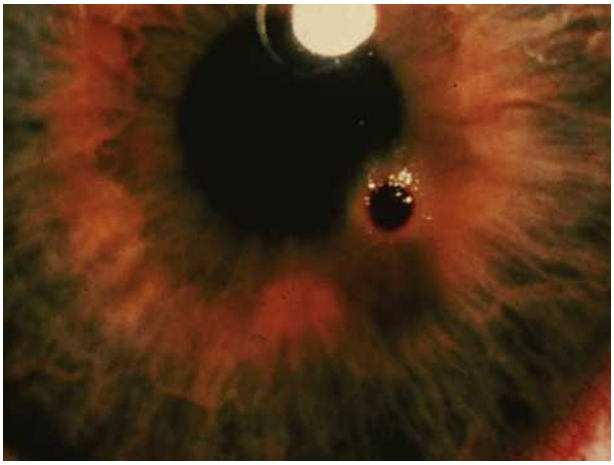

Fig. 57.6 Corneal Foreign Body Seen on Slit-Lamp Examination. (Courtesy www.tedmontgomery.com.)

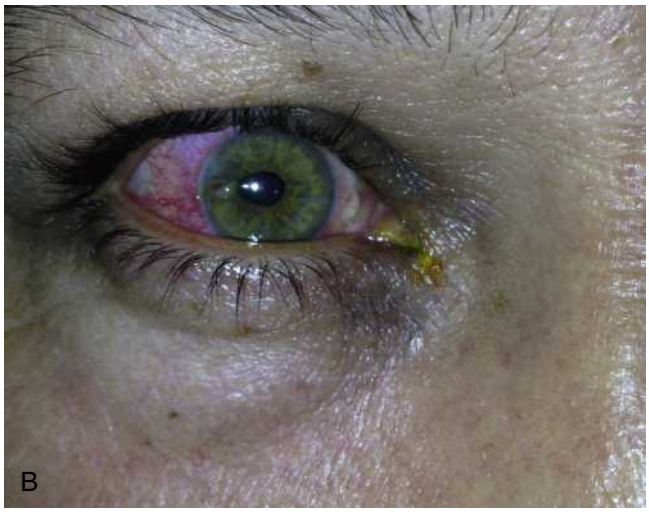

Fig. 57.7 Corneal Laceration With Prolapse of the Iris. (A) The pupil is irregular and teardrop-shaped, pointing toward the laceration. (B) Corneal laceration with teardrop pupil, pointing toward the laceration. (A, From Roberts JR, Hedges JR, eds. *Clinical Procedures in Emergency Medicine*. 5th ed. Philadelphia, PA: Saunders; 2010. B, Courtesy Jeffrey Lee MD, University of California San Diego.)

If the mechanism of injury involves a high-velocity projectile and no foreign body is seen on slit-lamp examination but is suspected, initiate an evaluation for an intraocular foreign body (see Intraocular Foreign Bodies and Globe Rupture).

Fig. 57.8 Hyphema in the Anterior Chamber. (Courtesy Steve Chalfin, MD, University of Texas Health Science Center, San Antonio, TX.)

Management and Disposition

Corneal abrasions. There is no evidence that the treatment of corneal abrasions with topical antibiotics, as often recommended, has any beneficial effect. Furthermore, the infection rate of untreated corneal abrasions is low—at 0.7%—and prophylactic antibiotic use is not warranted. Indiscriminate use can introduce the risk of toxic and allergic reactions. We do not recommend routine topical antibiotics for uncomplicated, superficial corneal abrasions. They are reasonable to prescribe when abrasions are deep, caused by a heavily contaminated object, or present in a high-risk patient. Additionally, empiric treatment of a corneal abrasion with an anti-pseudomonal agent such as tobramycin, ciprofloxacin, or ofloxacin is warranted in a contact lens wearer or immunocompromised patient (see Table 57.1). Abrasions from organic material or any slowly healing abrasions may warrant additional treatment and ophthalmic consultation.

Pain control with a corneal abrasion is paramount. Topical nonsteroidal antiinflammatory drugs (NSAIDs), such as ketorolac or diclofenac (see Table 57.1), have been shown to decrease the need for rescue analgesia.[2] Prospective trials and observational studies suggest that topical anesthetics self-administered as needed for a short duration of time by ED patients for corneal abrasion pain provide significant pain relief without complications.[3] Meta-analyses incorporating these trials as well as postoperative ophthalmology literature support this finding.[4–6] Therefore, a patient with a corneal abrasion can be provided a limited 24- to 48-hour course of a topical anesthetic (see Table 57.1), as the most intense pain occurs in the first 24 hours.

Uninformed patients using over-the-counter topical anesthetics for otherwise simple corneal injuries can develop an erosive keratopathy, perhaps by masking the pain of an emerging infection or due to a direct toxic effect from a misused anesthetic. It is therefore important to counsel patients regarding the correct, limited use of these agents. Eye patches are not recommended as they can also mask a worsening infection. Urgent ophthalmologic consultation is warranted with signs of active infection, such as a corneal infiltrate (whitening of the cornea) or ulceration (see Corneal Ulcers and Infiltrates later); otherwise, the patient can follow-up with an ophthalmologist in 24 to 48 hours.

Corneal foreign bodies. Foreign bodies of the cornea and conjunctiva, especially those containing iron (given the risk of rust deposition over time), should be removed in the ED if possible, using a topical anesthetic for comfort (see Table 57.1). Corneal foreign bodies can be removed by a moist cotton-tipped applicator or, if needed, by using a 25-gauge or 27-gauge needle carefully applied in a plane tangential to the surface of the cornea, under slit-lamp visualization. Non-corneal conjunctival foreign bodies can be removed by irrigation, a wet cotton-tipped applicator, or fine forceps. For metallic foreign bodies, residual rust rings can be removed 24 to 48 hours later because the rust will migrate toward the corneal surface and be more accessible. Ophthalmologic consultation is recommended for deep and large corneal foreign bodies or if the central area of the visual axis is involved. Indications for topical antibiotic prophylaxis are the same as for corneal abrasions.

Corneal lacerations. Large but partial corneal lacerations should be evaluated by ophthalmology for potential closure in the operating room versus observation with medical therapy (topical cycloplegics and antibiotics; see Table 57.1), pressure patch, and possible tissue grafts. Smaller corneal lacerations can be evaluated and treated as corneal abrasions; however, topical antibiotics are routinely indicated given the depth of injury. A complication of a corneal laceration or abrasion is an infected corneal ulcer (see Corneal Ulcers and Infiltrates), which may develop days to weeks later.

Anterior Segment Injuries: Traumatic Hyphema, Iritis, Cyclodialysis, and Lens Dislocation

Clinical Features

Any blunt or penetrating injury of the eye may result in injury to the underlying anterior chamber, iris, lens, and associated anterior segment structures of the eye. A traumatic hyphema (blood in the anterior chamber from ruptured vessels in the ciliary body or iris) can present with a spectrum of severity, from microhyphema (where red blood cells suspended in the anterior chamber aqueous are only visible by slit-lamp examination), to a layered hyphema (where a layer of blood may be observed grossly in the lower anterior chamber), to a full or total hyphema (in which the entire anterior chamber is filled with blood). A microhyphema may not be visible to the naked eye but will be associated with peri-limbal conjunctival injection (ciliary flush) and either an abnormal or dilated pupil size, the latter known as traumatic mydriasis (Fig. 57.9). Patients may experience blurry vision and photophobia (ciliary spasm) from a simultaneous traumatic iritis (iridocyclitis). A traumatic hyphema from a blunt injury may also be associated with a cyclodialysis, a tear in which the ciliary muscle is avulsed from a scleral spur.[7]A blunt injury to the eye can also weaken the lens zonule complex, resulting in a lens dislocation (Fig. 57.10A). Predisposing factors for lens dislocation include Marfan's syndrome, homocystinuria, and myopia. Patients may complain of monocular diplopia, distorted images, and blurred vision, and have other signs related to the trauma, such as traumatic mydriasis, iridocyclitis, and hyphema.

Differential Diagnoses

Acute glaucoma may present with similar symptoms but only rarely occurs as a result of trauma. As with any eye injury, globe penetration is a concern and is best evaluated using fluorescein dye and a slit lamp examination.

Diagnostic Testing

A diagnosis of a traumatic hyphema can often be missed without the illumination and magnification with a slit lamp. One sequela is increased IOP and, as long there are no signs of globe rupture, the pressure should be measured. An elevated IOP occurs up to 3 days after the initial injury in approximately one-fourth of patients; it is typically self-limited, but in certain instances, it can persist and lead to optic nerve injury and vision loss. Photophobia in the injured eye, especially if occurring on the illumination of the opposite eye, strongly suggests traumatic iritis. A cyclodialysis will be evident on slit-lamp examination as a separation of the edge of the iris away from the limbal margin.

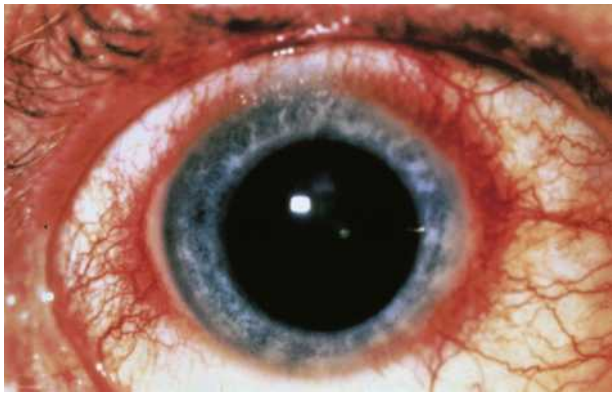

Fig. 57.9 Ciliary Flush. Note that conjunctival injection is most prominent immediately around the limbus. (Courtesy Douglas Brunette, MD.)

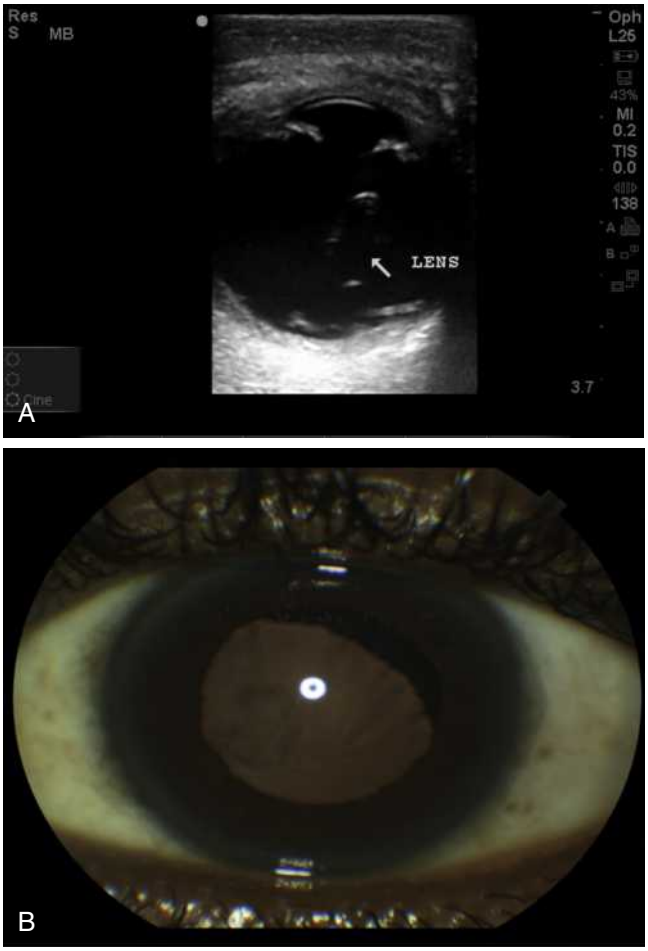

Fig. 57.10 (A) Ocular ultrasound showing lens dislocation. (B) Dislocated lens with edge visible. (A, Courtesy Douglas Brunette, MD. B, Courtesy Jeffrey Lee, MD, University of California San Diego.)

A lens dislocation may be evident on slit-lamp examination; one may see the edge of the natural lens (which is normally not visible whether or not the patient is dilated) (see Fig. 57.10B), phacodonesis (shimmering of the lens with eye movement), and iridodonesis (shimmering of the iris with eye movements), which are evidence that the lens zonules have been compromised. A displaced crystalline lens may also be visible on ultrasound (see Fig. 57.10A). Using a large amount of gel will minimize pressure from the higher resolution ultrasound probe on the eye.[8,9] Depending on the lens location, additional findings including increased IOP, corneal swelling, and intraocular inflammation may be present.

Management and Disposition

Traumatic iritis, hyphema, and cyclodialysis. With isolated traumatic iritis, the primary goals of treatment are minimizing scarring, decreasing inflammation, and pain relief. This is often best achieved with a paralytic agent for the iris and ciliary body (e.g., homatropine or cyclopentolate; see Table 57.1). Topical ophthalmic steroid drops (e.g., prednisolone acetate; see Table 57.1) are considered in cases where significant posttraumatic inflammation is present; however, use caution in cases of corneal abrasions. Close follow-up with ophthalmology within 48 hours is warranted to ensure the injury does not result in other ocular issues, such as glaucoma, corneal damage, and hypotony.

Both easily visible (see Fig. 57.8) and subtle traumatic hyphema deserve attention in follow-up to help minimize the likelihood of long-term complications. These complications include corneal staining and elevated IOP, which should be monitored to ensure proper resolution. In the past, recommended treatments for hyphema included strict bedrest with the head of the bed elevated at least 30 degrees, which presumably allows blood to settle and filter out inferiorly, and restriction of work requiring near-vision since accommodation may stress already injured blood vessels. However, there is no evidence that strict bedrest has any effect on outcome or that the head of the bed position affects resorption rate in a consistent manner, so a patient with an uncomplicated hyphema can be discharged home with gentle ambulation allowed, with the head of the bed elevation recommended with large hyphemas to prevent clotting in the visual axis and to help rehabilitate vision more effectively.[10,11] The recommendations for pediatric patients with small, uncomplicated traumatic hyphema are identical. In these cases, hospital admission is not warranted.[12] Admission is recommended, however, for patients with hyphema greater than 50% as large volumes of blood can lead to severely high IOP and permanent corneal damage. Additionally, patients with sickle cell trait, in whom sickling of red cells in the naturally hypoxic and acidotic anterior chamber prevents egress of aqueous humor and blood products, should also be observed in the hospital. Finally, patients who are poorly compliant, take anticoagulants, or likely to be lost to follow-up should initially be managed as inpatients. Topical and oral agents to lower IOP are appropriate, but carbonic anhydrase inhibitors should be avoided in sickle cell patients. Guidance on the use of antifibrinolytics is not clear. On the one hand, systemic or topical aminocaproic acid and tranexamic acid have been shown to reduce the rate of recurrent bleeding; however, they have not been shown to affect final visual acuity and may reduce the rate of clearance of the hyphema.[10] Initiation of these treatments is best done in consultation with an ophthalmologist.

For patients discharged with a traumatic hyphema, next-day follow-up with an ophthalmologist is recommended to assess IOP and to evaluate for indications for urgent paracentesis and washout of the anterior chamber or an emergent trabeculectomy or shunting surgery. Inability to clear the hyphema, uncontrolled IOP, or rebleeding (which occurs in 6% to 33% of patients within 2 to 5 days) typically require intervention.[10,13] Patients with 20/200 vision or less in whom a rebleed might go unnoticed or with elevated IOP should be followed for 3 days to identify these developments. Patents with underlying traumatic iritis may be prescribed cycloplegics (homatropine; see Table 57.1), but there is little evidence to support their use for hyphema alone. Eye patching is postulated to prevent photosensitization of the corneal endothelium by protoporphyrin, a blood product, but it has not been shown to improve outcome and is not routinely recommended.[10]

The patient with a cyclodialysis can be treated with topical cycloplegics (see Table 57.1) to relax the iris and ciliary body and be referred to an ophthalmologist for routine outpatient follow-up. Small tears tend to resolve spontaneously and can be managed conservatively, whereas large ones may be permanent or require surgery to correct.

Lens subluxation and dislocation. Lens subluxations or dislocations can be vision-threatening emergencies and should be evaluated by an ophthalmologist in the ED for potential medical or surgical treatment.

Posterior Segment/Ocular Injuries: Commotio Retinae, Retinal Detachment, Intraocular Foreign Body, and Perforated Globe

Clinical Features

A more significant mechanism increases the possibility of a deeper ocular injury including commotio retinae, a retinal or vitreous hemorrhage, a retinal detachment or tear, an intraocular foreign body, and a perforated globe.

Commotio retinae, also known as *Berlin's edema,* most often occurs after ocular trauma that results in bony injury to the orbit. In one series, it was diagnosed in approximately 6% to 13% of patients who had surgically treated orbital blowout fractures.[14] With a retinal or vitreous hemorrhage, patients can experience variable vision compromise ranging from dark floaters to vision blackout. A retinal detachment can present with floaters, flashes of light (photopsia), or both and may progress to a curtain-like blocking of the patient's vision as it evolves into a retinal detachment. The retina has no pain receptors and patients are usually pain-free.

An important evaluation after blunt trauma to the orbit is to determine if a globe perforation or intraocular foreign body is present. Besides pain and decrease in vision, other signs (loss of anterior chamber depth, irregular or tear drop-shaped pupil, blood in the anterior chamber, 360 degrees subconjunctival hemorrhage, or prolapse of uveal tissue) should be noted. When traumatic vector forces are not enough to blow out the orbit, they are typically re-directed to the globe itself. Muscle insertion sites and the limbus are the most common sites of scleral rupture because these are the thinnest areas (see Fig. 57.5). Significant collateral damage to adjacent structures such as the lens, retina, uvea, and optic nerve can also occur. The patient with a globe injury may develop sympathetic ophthalmia, a vision-threatening autoimmune response to the remaining healthy eye triggered by the exposure of the previously naïve immune system to intraocular contents from the ruptured eye.

Differential Diagnoses

In addition to retinal detachment, sudden painless alterations in vision or vision loss can stem from primary medical conditions such as central retinal artery and central retinal vein thrombosis. Embolic carotid artery disease and retinal arteritis, as seen with giant cell (temporal) arteritis, are additional considerations.

Diagnostic Testing

Test visual acuity in all patients with traumatic eye injuries. In some cases of retinal injury, visual acuity testing can be normal. Commotio retinae may appear as whitening of the retina on fundoscopy. The diagnostic approach to retinal detachment is discussed in more detail later in this chapter. In instances of a penetrating injury to the globe or orbit, careful evaluation for a retained foreign body is important. Initially, it may not be clear if a foreign body is intraocular or just intraorbital. If the suspicion for an intraocular foreign body or ruptured globe is high but the examination cannot be performed with minimal manipulation, an orbital CT scan can provide information about the structural integrity of the globe and orbit as well as the location of foreign bodies; however, because it has a sensitivity of between 56% to 75% for open-globe injury, CT cannot be relied upon alone, and formal surgical exploration may be needed.

Management and Disposition

Retinal injuries. A traumatic retinal detachment, if detected and treated early before the macula is involved, carries a good prognosis. Approximately 10% of all retinal detachments are caused by blunt trauma. The management of retinal detachment and vitreous hemorrhage is discussed in more detail later in this chapter. The decreased visual acuity from commotio retinae is self-limited and resolves in a few weeks. Evaluation by an ophthalmologist in the ED is recommended, however, because the commotio can mask a retinal tear.

Intraocular foreign bodies and globe rupture. For patients with a possible globe perforation (open globe) with or without an intraocular foreign body, examine the eye with as little manipulation as possible and, once diagnosed, stop the examination, cover the eye, and consult an ophthalmologist emergently. Any additional examination is only performed in the operating room. In anticipation of potential surgery, place a protective shield over the affected eye, administer a tetanus booster, and provide medications to control pain and nausea. The incidence of endophthalmitis (an infection of the globe; see Infectious Conditions later) following open-globe injury ranges from 2.6% to 30%. Administer systemic antibiotics that are active against *Staphylococcus aureus, Bacillus* species, *Pseudomonas* species, gram-negative organisms, and anaerobes, keeping in mind that *Staphylococcus* species are most common.[15] Cefazolin 1 g IV or vancomycin (dosed based on weight and renal function as per pharmaceutical guidelines) and a fourth-generation fluoroquinolone are good first-line agents. Foreign bodies, especially non-metallic foreign bodies, pose the highest risk of infection.[15]

In general, intraocular foreign bodies need to be removed. For intraorbital foreign bodies, the type and location of the material influence the necessity to remove them. Removal of inert plastic, glass, and metals may cause more damage than their permanent presence, whereas organic foreign bodies typically need to be removed because of their propensity to cause infection. Siderous oxidation of ocular tissues is a late complication of iron-containing intraocular foreign bodies and can lead to visual loss. Chalcosis, a sterile inflammatory reaction to copper-containing compounds, may occur, necessitating removal of the offending object.

It is controversial whether succinylcholine is contraindicated during rapid sequence intubation in a patient with a suspected open-globe injury because of the theoretical possibility of a rise in IOP from succinylcholine causing further extrusion of globe contents.[16,17] Where time and circumstances permit, we recommend rocuronium over succinylcholine for intubation of patients with open-globe injuries; however, there is no compelling evidence that succinylcholine causes harm.

Retrobulbar and Peribulbar Injuries: Orbital Wall Fracture, Retrobulbar Hemorrhage, and Optic Nerve Injury

Clinical Features

Trauma to the eye can result in disruption to tissue around the globe and should be suspected based on the mechanism and recognition of specific clinical features. Clinical signs that may indicate an acute orbital wall fracture include ecchymoses, tissue swelling, hypesthesia of the trigeminal nerve, double or blurry vision, enophthalmos (posterior displacement of the eyeball within the orbit), and ptosis. In an orbital floor fracture, a medially hinged bony "trapdoor" fragment may have transiently displaced inferiorly, allowing herniation of orbital contents

into the maxillary sinus. Associated globe injuries occur in 10% to 25% of patients with orbital floor fractures.

The triad of proptosis, ophthalmoplegia, and altered vision suggests a retrobulbar hemorrhage, which can threaten the patient's vision and be present without an orbital wall fracture. The orbit is essentially a continuous cone-shaped fascial envelope with rigid bony walls on all sides (except anteriorly where the orbital septum forms an inflexible boundary), in which there is little room to accommodate an increase in volume.[18] A retrobulbar hemorrhage from a ruptured infraorbital or ethmoidal artery occurring with intact orbit walls will increase intraorbital pressure and cause an orbital compartment syndrome, resulting in ischemia of the optic nerve and retina. Blunt trauma can also cause a direct optic nerve injury, causing decreased visual acuity or vision loss.

A rare complication of an orbital fracture or retrobulbar injury is an oculocardiac reflex from pressure exerted on the periorbital soft tissues. An afferent signal via the trigeminal nerve and efferent signal via the vagus nerve can trigger bradycardia, junctional rhythm, or even asystole, with nausea and vomiting, and is potentially fatal if unresolved.[19,20]

Differential Diagnoses

Orbital cellulitis, an infectious process involving the orbital compartment posterior to the septum may present in a similar fashion causing pain, swelling and pain with globe movement. Fever and lack of a blunt trauma will distinguish it from traumatic etiologies. An orbital CT scan, along with clinical features, can confirm the diagnosis.

Diagnostic Testing

The diagnostic evaluation of a possible retrobulbar or orbital injury requires a thorough examination, paying particular attention to extraocular eye movements, assessing for an afferent pupillary defect (APD; Fig. 57.11), and checking facial sensation. An orbital wall fracture is most readily diagnosed with an orbital CT scan with axial and coronal fine (minimum 1.5 mm) cuts (Fig. 57.12). Less sensitive diagnostic screening tools include plain x-ray, in which suggestive signs are a bulge extending from the orbit into the maxillary sinus ("teardrop" sign) and an air-fluid level in the maxillary sinus. Bedside ultrasound can suggest a retrobulbar process when bright acoustic shadowing or subcutaneous air is seen, although sensitivity is marginal between 56% and 92%).

Clinical signs strongly suggesting a retrobulbar hematoma include the presence of three or more of the following: pain, decreased vision, proptosis with resistance to retropulsion, chemosis, limited extraocular motility, diplopia, diffuse subconjunctival hemorrhage, increased IOP, and an APD.[18] fundoscopy may reveal edema of the optic disc or retina or retinal venous congestion. A CT scan of the orbit can provide

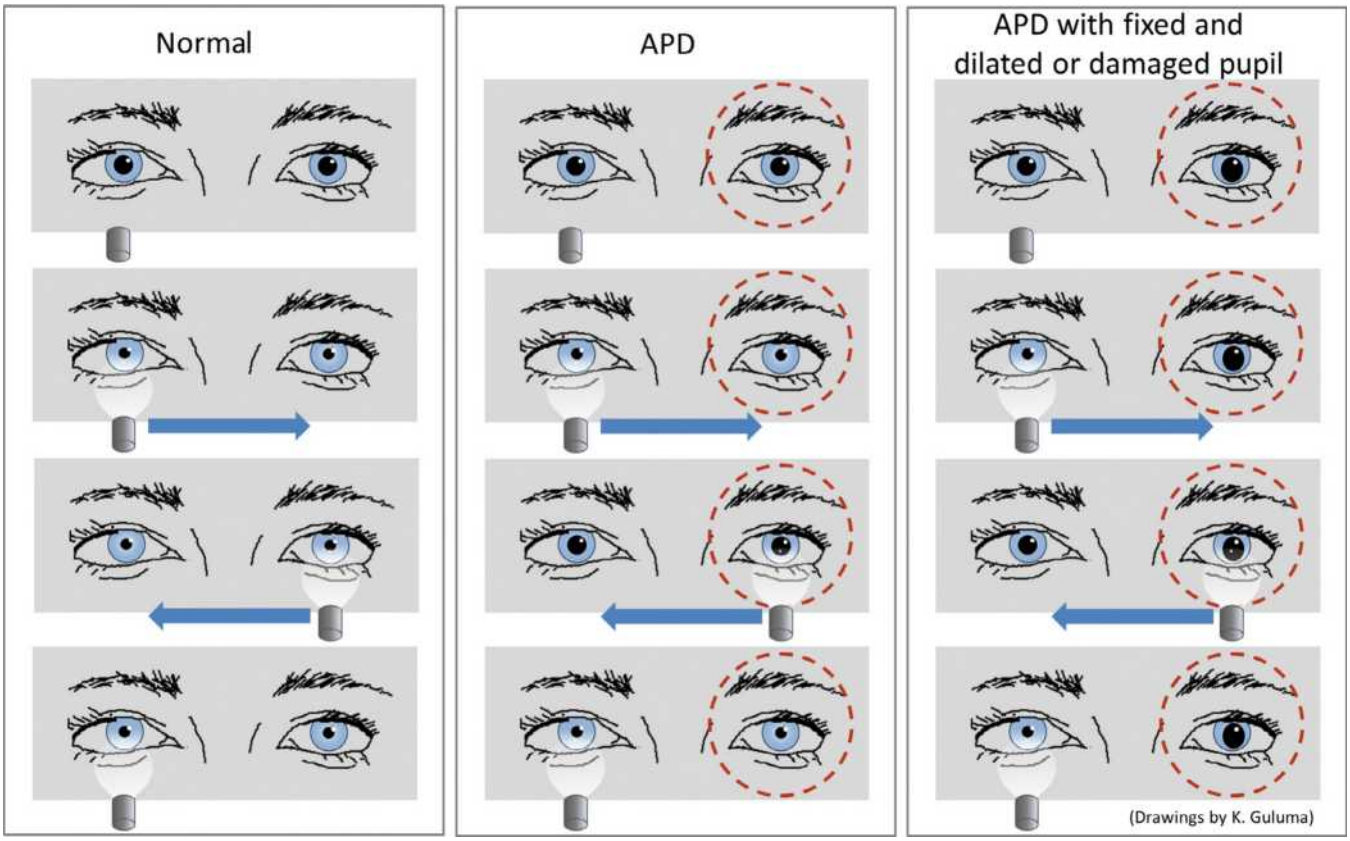

Fig. 57.11 The "swinging flashlight test" for an afferent pupillary defect *(APD),* which is otherwise known as a *Marcus Gunn pupil*. Normally *(panel on left),* both pupils constrict regardless of which eye is illuminated due to intact afferent stimulus into the direct and consensual pupillary light reflexes. With an APD *(panel in the middle),* the pupils dilate upon "swinging" the flashlight to the pathological eye with dysfunction in the retina or optic nerve *(dashed circle)* because of a sudden loss of afferent stimulus into light reflexes. With a fixed and dilated or damaged pupil *(panel on the right),* the same will hold true, except that the damaged pupil may not react due to an intrinsic problem, regardless of the presence of an APD. In each condition, whether normal or with an APD, the pupillary findings will reverse on swinging the flashlight back across to the other eye. The flashlight should be held over each eye for at least 3 seconds to ensure time for a response.

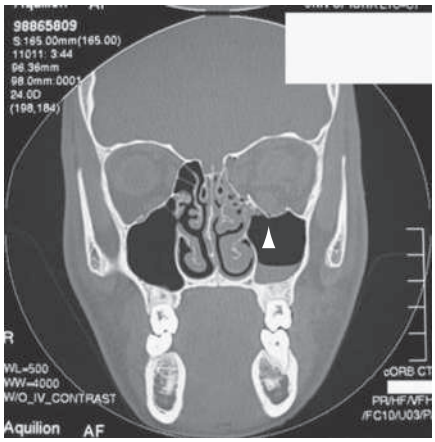

Fig. 57.12 Facial computed tomography (CT) scan showing left inferior orbital fracture with blood in the maxillary sinus. (Courtesy University of Iowa Department of Ophthalmology, http://webeye.ophth.uiowa.edu/eyeforum/Images/floorfx_08232004.jpg.)

additional evidence if clinical findings are inconclusive. However, if there is significant suspicion, treatment should not be delayed because vision loss can be permanent.

An optic nerve injury can coexist with a retrobulbar hematoma, and clinical findings may not necessarily differentiate whether there is compression or transection. Optic nerve injury may manifest as a decrease in visual acuity, visual field deficit, a relative APD (Marcus Gunn pupil), or a change in the appearance of the optic nerve. The optic disc can appear normal or swollen. A CT scan can help determine the nature and degree of optic nerve injury.

Management and Disposition

Orbital wall fractures. Prophylactic antibiotics are commonly administered for orbital wall fractures that extend into an adjacent sinus, although there is no scientific evidence supporting their use outside of intra-operative administration.[21] Antibiotic prophylaxis is warranted in patients with coincident sinusitis seen on CT scan because this increases the risk of developing orbital cellulitis. The patient should be instructed to avoid exerting Valsalva maneuvers and nose blowing and should be prescribed nasal decongestants, such as pseudoephedrine 30 mg every 6 hours, to decrease the risk of orbital emphysema. Lastly, to improve healing and decrease swelling, ice packs to the orbit for at least 48 hours is recommended.

Some ophthalmologists use steroids to reduce swelling; however, this is a case-by-case decision. Clinical findings that warrant urgent surgical exploration include pediatric trapdoor fractures, CT evidence of entrapment with associated diplopia, gaze restriction, or a non-resolving oculocardiac reflex. Early enophthalmos greater than 2 mm; large (>2 cm^2) defects of the orbital floor or medial wall may indicate urgent exploration, but recent evidence suggests delayed management is reasonable.[22] Outside of these indications, persistent diplopia and cosmetic concerns (such as, enophthalmos) are generally not addressed until the swelling subsides after 7 to 10 days. Patients can be discharged for reevaluation by an ophthalmologist in 1 to 2 weeks. Children with orbital wall fractures are a special consideration because they are more predisposed to buckling "green-stick" fractures of the orbital wall and develop fibrosis and shortening of the affected muscle within a couple of days, affecting ocular function; thus, refer children with orbital wall fractures to an ophthalmologist within 1 to 2 days.

Retrobulbar hemorrhage. The loss of vision associated with a retrobulbar hematoma is thought to be irreversible within 60 to 100 minutes after the onset of ischemia. Emergent ophthalmologic consultation for decompression is required. The time interval for decompression does not start with the injury but at the time at which the intraorbital compartment pressure from the hematoma reaches a pressure critical enough to start to cause vision loss. Use IOP-lowering agents to temporize compartment pressure until surgical decompression can occur. These include intravenous (IV) carbonic anhydrase inhibitors, topical beta-blockers, alpha agonists, and in some cases 1 to 2 g of IV mannitol per kilogram. Once ischemia and vision loss sets in, time is of the essence. A lateral canthotomy may need to be performed by the emergency clinician as a temporizing, vision-saving measure if definitive decompression is going to be delayed (Fig. 57.13).[23–26]

Optic nerve injury. Once the determination of the type and degree of optic neuropathy is determined, treatment options can be considered. There is not a clear benefit from surgical decompression of orbital canal fractures that impinge on the nerve, or from steroids for traumatic optic neuropathy. Both are options to consider in conjunction with an ophthalmologist.[27]

Chemical Exposures and Glues

Clinical Features and Differential Diagnoses

Chemical burns can lead to devastating vision loss. Alkaline burns are more severe because they produce a liquefactive necrosis in which damaged tissues secrete proteolytic enzymes as part of an inflammatory response leading to cataract formation, damage to the ciliary body and trabecular meshwork, and irreversible intraocular damage in as little as 5 to 15 minutes. Acid burns are usually less severe because they cause coagulative necrosis, in which the precipitation of tissue proteins limits the depth of the injury. The one exception to this is hydrofluoric acid, which may rapidly pass through cell membranes and enter the anterior chamber.

Superglue is another chemical exposure that may present in the ED. Cyanoacrylate is often used in ophthalmological surgical procedures and is relatively nontoxic to the eye.[28] The main issues arising from superglue exposure are adhesion of eyelashes, which is difficult to reverse, and concurrent conjunctival and corneal abrasion.

Certain substances, such as detergents and solvents, can lead to epithelial injury and anterior chamber inflammation, which are treated based on examination findings (e.g., abrasion or iritis). Signs of potent chemical exposure include periorbital edema and erythema, de-epithelialized skin, and loss of eyelashes and eyebrows, corneal and conjunctival epithelial defects, chemosis, corneal cloudiness, sterile ulceration, edema, and perforation. Elevated IOP may result from damage or inflammation of the trabecular meshwork. Although a determination of the pH of the solution involved is the most important consideration, other factors in the exposure, such as temperature, amount, impact force, concentration, osmolarity, and redox potential, can greatly influence the pathophysiology of chemical tissue damage. Accessing the material safety data sheet (MSDS) of the agent involved or consulting with a Poison Center can greatly facilitate identification of the offending agent and guide the appropriate treatment. If the exposure occurred as a result of an explosion, penetrating globe injury may also be present.

Diagnostic Testing

Treatment of a chemical exposure should begin as soon as possible with copious irrigation, even prior to arrival to the ED. During the initial ophthalmic examination pay attention to the inspection of the fornices to ensure that there is no remaining chemical gel or solid material. Screen for ocular trauma facilitated by a topical anesthetic for patient comfort. With known chemical exposures, irrigation should be

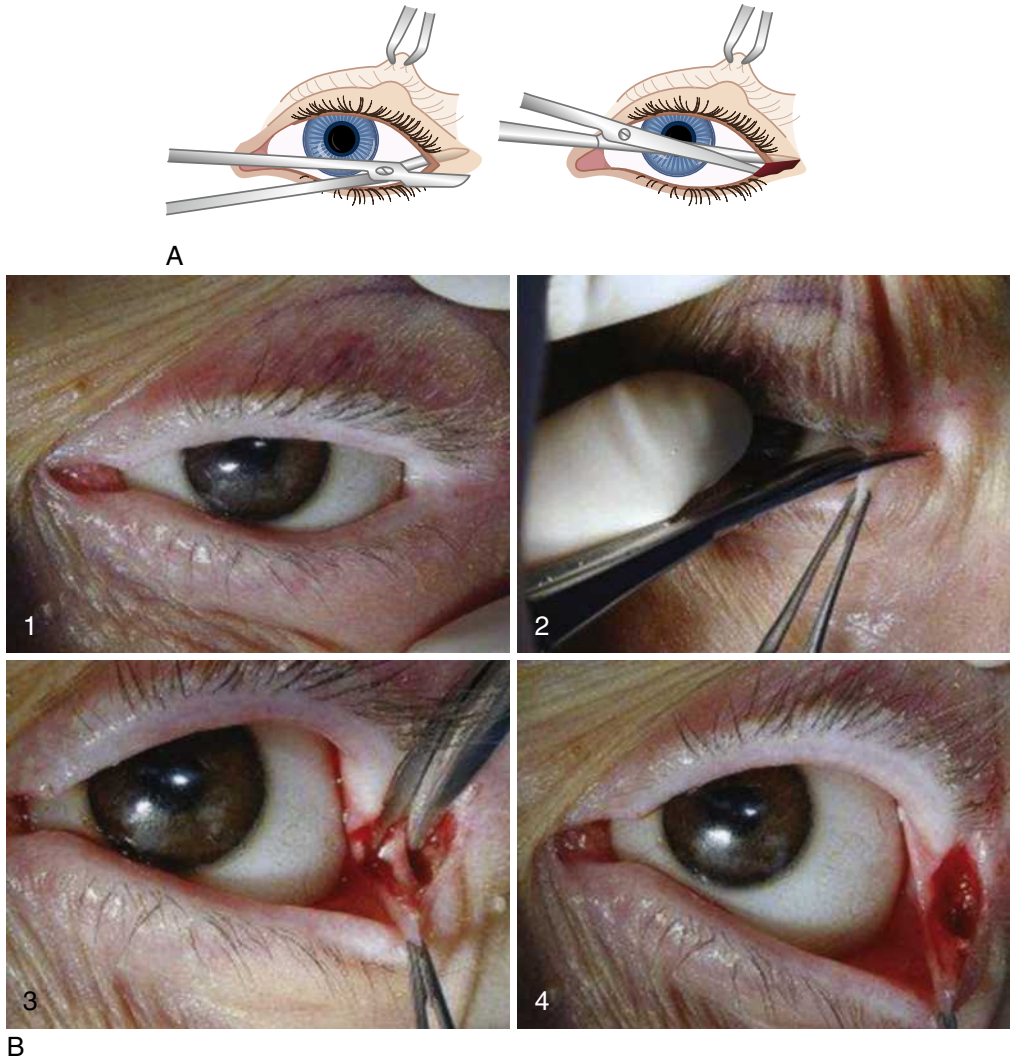

Fig. 57.13 (A) Lateral canthotomy. (B) *1,* Preoperative view of orbit. *2,* Incision for lateral canthotomy. *3,* Identification and incision of inferior canthal tendon, completing cantholysis. *4,* View after lateral canthotomy and inferior cantholysis, creating maximal immediate decompression by allowing eyeball and orbital contents to move anteriorly. (B, From Ramakrishnan VR, Palmer JN. Prevention and management of orbital hematoma. *Otolaryngol Clin North Am.* 2010;43:789–800.)

continued for a minimum of 10 minutes until a quick evaluation can be performed. This includes a pH measurement (Nitrazine paper dipped in lower lid fornix) to evaluate for acidity or alkalinity. Continue irrigation until the pH is in the neutral (7 to 7.5) range. Superglue exposure represents a special circumstance, and there are two main principles in the evaluation: (1) to separate the lids so that a detailed eye examination can be performed to remove residual superglue, and (2) to identify any corneal abrasion with fluorescein staining.

Management and Disposition

For acid or alkaline burns, perform immediate irrigation. The longer irrigation is delayed, the more irrigant will be required because the chemical can deposit within the tissue and be harder to wash away. It may take up to 20 L or more to change the pH to a physiologic level (a goal pH of 7 to 7.5). Based on animal studies, isotonic saline irrigation solutions may be ineffective at neutralizing a significant exposure to an alkaline agent (such as, sodium hydroxide) within the 20-minute time frame required to reduce injury, and buffered irrigation products specially designed for the task are significantly more effective.[29,30] This being said, initiation of irrigation with whatever solution is most readily available should not be delayed while such a solution is being obtained. Time to initiation of irrigation is the key determinant in patient outcome.[30] Ringer's lactate solution and tap water are options.[30] Tap water is more effective than saline at normalizing pH, specifically for alkali burns, and is also better tolerated than saline. It is therefore recommended in situations in which a buffered product is not available; however, since there is a concern for corneal edema due to the hypotonicity of water, Ringer's lactate is preferable if it is available.[30] The use of topical anesthesia (see Table 57.1) and assistive devices, such as a Morgan lens and an eyelid retractor, can aid in delivering the irrigation more effectively. Emergent ophthalmological consultation is warranted in significant acid burns and all alkaline burns. In chemical exposures deemed to have a low risk of significant injury (an assessment aided by contact with a local poison center) and with no signs of immediate ocular injury, the patient can be treated and referred for follow-up with an ophthalmologist in 24 to 48 hours.

For more significant chemical injuries, cycloplegics, antibiotic ointments, and occasionally steroid drops are indicated (see Table 57.1

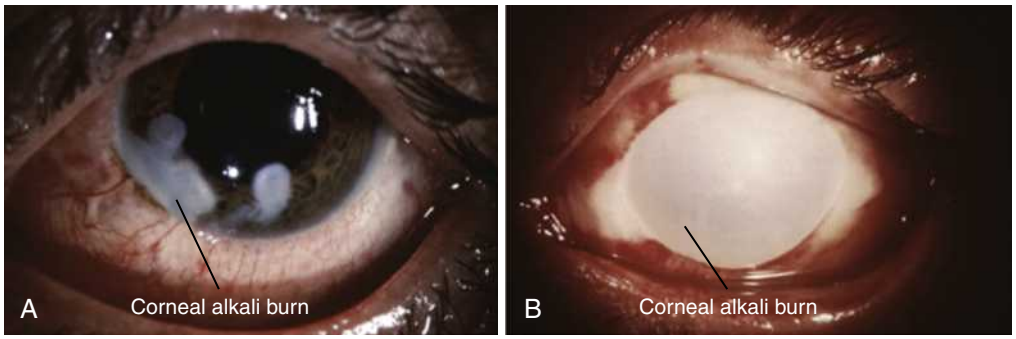

Fig. 57.14 (A) Alkali burn demonstrating corneal burns and conjunctival injection on the day of the accident. (B) Complete corneal tissue destruction 7 days after alkali burn. (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

for agents and dosing). After the acute treatment has been completed, obtaining additional history about the offending chemical can be useful in determining prognosis. Substances with a pH ranging from 2 to 12 with limited contact time tend to have a better prognosis. However, at the time of presentation, the severity and complications of the injury may not be completely known because the full extent of the injury has not yet occurred. These complications can include permanent corneal injury (Fig. 57.14), glaucoma, palpebral and conjunctival adhesions, cataracts, and retinal injury.

In the case of superglue, cyanoacrylate does not bond well to wet surfaces, and an exposure into the eye typically results in a forceful blink and extrusion of the glue onto the dry surfaces of the lid margins. Gentle traction will often separate glued eyelashes; if not, carefully trim them with Westcott scissors. Slit-lamp examination can help determine which lashes can be more readily separated. Time will help loosen the adhesions and allow for removal of the glue. If there is eyelid malposition, cutting the lashes can often allow for normalization of the eyelid position. Avoid attempts to dissolve the glue with other substances, such as acetone, because they may cause ocular damage. Ophthalmology consultation in the ED is recommended for cases in which the above measures fail to separate the lids to enable an examination, if there is residual eyelid mal-positioning, or if there is a suspected corneal abrasion from the hardened glue. If separating eyelids reveals no evidence of subsequent lid malalignment and no sign of conjunctival involvement or injury, the patient can be referred to an ophthalmologist for follow-up as an outpatient the next day.

INFLAMMATORY CONDITIONS

Foundations

Inflammatory conditions of the eye tend to present as a "red eye," which is a general term that encompasses a variety of etiologies in the conjunctiva, cornea, globe, and surrounding orbit. The clinical approach to the red eye in general, including inflammatory and infectious processes, is described in detail in Chapter 18.

The Conjunctiva and Cornea: Keratitis, Pterygium, and Pinguecula

Clinical Features

Conjunctival and corneal inflammatory conditions include allergic conjunctivitis, superficial punctate keratitis, ultraviolet (UV) keratitis (radiation keratitis), and pterygium and pinguecula. Allergic conjunctivitis, although technically an inflammatory process, is similar enough in presentation to infectious conjunctivitis that it is considered together with the infectious processes outlined later in this chapter.

Superficial punctate keratitis presents with pain or foreign body sensation, photophobia, and redness due to poor lubrication of the corneal surface from any one of several etiologies, including dry eyes, drug toxicity, and contact lens overuse. UV keratitis is a specific form of keratitis that presents when prolonged exposure to UV light results in a direct oxidative photodegradation injury to the corneal epithelium, at times severe enough to cause ulceration.[31] Sources of UV overexposure include tanning booths, reflection from snow or water, or a welder's arc. There is a latency of 6 to 10 hours before symptoms arise, at which point patients have a significant degree of pain and discomfort, photophobia, and mild conjunctival injection.

Another set of conjunctival inflammatory conditions, somewhat similar in appearance to one another, are pterygium and pinguecula. A *pterygium* is a chronic inflammatory fibrovascular hypertrophy of conjunctiva in the palpebral fissure triggered by chronic exposure to UV light. It typically grows temporally from the nasal side of the eye (or vice versa), eventually covering the cornea.[32] A pterygium can become acutely inflamed, whereupon patients experience foreign body sensation, dry eyes, and redness, but they typically do not have significant loss of vision unless the process starts to infringe upon the visual axis or becomes large enough to distort the shape of the cornea (both are very gradual and chronic processes). A *pinguecula* is of similar pathology and pathophysiology to a pterygium, resulting in similar symptoms, except that it stops at the limbus and does not enter the cornea or visual axis.

Differential Diagnoses

Squamous cell carcinoma of the conjunctiva can appear deceptively like hypertrophic conjunctiva and will be impossible to distinguish from more benign etiologies during an ED evaluation. While inflammatory conjunctival processes can occur in any age group, cancer tends to occur in elder Caucasian populations. Refer elders with new conjunctival growths to an ophthalmologist for definitive workup and management.

Diagnostic Testing

Slit-lamp examination is an integral part of the diagnostic evaluation of conjunctival and corneal inflammatory conditions. With superficial punctate keratitis and UV keratitis, multiple punctate epithelial erosions are seen upon fluorescein staining. A patient with a pterygium or pinguecula will have a visible, opaque conjunctival overgrowth on the conjunctiva of one or both eyes, typically triangular or pie-shaped, with the apex of the triangle pointing toward the pupil.

Management

Superficial punctate keratitis and radiation keratitis. Superficial punctate keratitis and UV keratitis are treated the same as corneal abrasions because all entail injury to the corneal epithelium and superficial cornea and include limited use of topical anesthetics and topical antibiotics administered for 3 to 5 days if infection is a concern (see Table 57.1). UV keratitis will typically resolve in about 24 hours or so, and given the nature of the injury, patients should be instructed to avoid damaging UV rays.[31]

Pterygium and pinguecula. Treatment of pterygium and pinguecula are similar, and it includes UV protection, lubrication, and treatment of acute inflammation with topical NSAIDs (see Table 57.1). The inflammation of a pterygium or pinguecula is usually self-limited, and encroachment into the visual axis from a pterygium is typically very gradual.

Disposition

For UV keratitis, ophthalmologic follow-up in 24 hours is recommended if symptoms have not resolved. With pterygium and pinguecula, non-emergent referral to an ophthalmologist is recommended for surgical treatment of severe cases and for evaluation of the rare coexistence of an ocular surface squamous neoplasia.

The Globe: Uveitis, Scleritis, and Episcleritis

Clinical Features

The globe can be afflicted by a variety of autoimmune conditions typically involving the uvea as a uveitis, sclera as a scleritis, or the superficial layers of the outer sclera, called episcleritis.

Uveitis is an autoimmune inflammation of the uvea, the part of the middle layer of the eye that includes the highly vascularized and pigmented iris, ciliary body, and choroid.[33] The iris and ciliary body are most commonly involved, a condition called *iritis* or *anterior uveitis,* but uveitis may rarely involve the intermediate and posterior chambers as a panuveitis. No cause is identified in 60% to 80% of people, although uveitis is one of the most frequent extra-articular features in seronegative arthritides (including ankylosing spondylitis, psoriatic arthropathy, arthritis from inflammatory bowel disease, and reactive arthritis). The typical patient with acute anterior uveitis will present with a very painful red eye, often with photophobia, and occasionally with decreased visual acuity.[34]

Scleritis is a similar autoimmune inflammatory process but involves the sclera (the tough connective tissue layer that begins at the limbus and surrounds the eye) instead of the uvea.[35] It is divided into anterior scleritis and the less frequent posterior scleritis, inflammation of the sclera posterior to the insertion of the rectus muscles. Scleritis can also be infectious but is difficult to treat and requires both systemic and local therapies.

Episcleritis, which can be confused with scleritis, is caused by inflammation in the episcleral layer of the eye rather than the deeper scleral layer. Episcleritis, unlike scleritis, is not vision-threatening and is not associated with as much discomfort.

Differential Diagnoses

Traumatic and infectious causes, specifically conjunctivitis, are the main differential considerations. Conjunctivitis has significant clinical overlap with more sinister inflammatory processes; however, more intense pain, photophobia and altered vision, as well as a history of autoimmune disease, will help distinguish a garden-variety conjunctival process from inflammation involving deeper ocular structures.

Diagnostic Testing

On slit-lamp examination, uveitis will typically reveal conjunctival injection, ciliary flush in the peri-limbal area, and cells and flare in the anterior chamber. Episcleritis can be distinguished from scleritis in that it is associated with more peri-limbal injection and has a redness that can be described as salmon pink, rather than the deeper purple hue seen in scleritis; instillation of 10% phenylephrine drops will constrict and blanch injected superficial episcleral vessels in episcleritis but will not do so to the injected deeper vessels involved in scleritis.[35] Scleritis is often more severe than episcleritis and has a much higher association with systemic diseases, such as Wegener granulomatosis, rheumatoid arthritis, and connective tissue disease. Further evaluation can be deferred to outpatient follow-up if there are no significant systemic findings.

Management

The treatment of uveitis and scleritis begins with topical corticosteroids and cycloplegics for symptoms of iridospasm (especially for anterior uveitis and scleritis; see Table 57.1). With treatment failures or severe cases, treatment is escalated to oral prednisone or IV corticosteroids followed by systemic immunomodulators (such as T-cell inhibitors or antimetabolites) and biologics (such as adalimumab or infliximab) in refractory cases.[33,34] Decisions about treatment are typically made in concert with an ophthalmologist.

Disposition

Patients with uveitis and scleritis should be referred to an ophthalmologist for close follow-up in 24 to 48 hours as scleritis has a strong association with ocular complications, including keratitis, increased IOP, and vision loss.

The Orbit: Orbital Pseudotumor, Orbital Apex Syndrome, and Thyroid Orbitopathy

Clinical Features

The orbit may be affected by idiopathic, noninfectious inflammatory processes that lead to diffuse eye pain, redness, swelling, and potentially disordered vision. These include orbital inflammatory pseudotumor and orbital apex syndrome (which are unilateral), as well as thyroid myopathy (which is usually bilateral but asymmetric).

Orbital inflammatory pseudotumor (also known as *idiopathic orbital inflammation syndrome, orbital pseudotumor,* or *orbital inflammatory syndrome*) presents as an acute to subacute tumor-like inflammation consisting of a pleomorphic cellular response and a fibrovascular tissue reaction. It is associated with various rheumatologic disorders, including Wegener granulomatosis, giant cell arteritis, systemic lupus erythematosus, dermatomyositis, and rheumatoid arthritis. In orbital apex syndrome, the apex of the orbit (through which the optic nerve, superior ophthalmic vein, and cranial nerves [CNs] III, IV, V, and VI travel) may be selectively affected similarly to cavernous sinus syndrome and superior orbital fissure syndrome. Etiologies include infection, carotid-cavernous fistula, inflammatory vasculitides (such as giant cell arteritis or Tolosa-Hunt syndrome), tumor, or infiltration as may be seen with sarcoidosis. Both orbital inflammatory pseudotumor and orbital apex syndrome may result in proptosis, chemosis, and/or conjunctival injection.[35] With orbital apex syndrome, there may be dysfunction of CNs II, III, IV, V, and VI (see Chapter 18).

Inflammatory thyroid orbitopathy from Graves disease is the most common cause of ocular myopathy in elders. It presents with oculomotor muscle swelling and restriction that is bilateral in 85% of cases. It classically affects the inferior and medial recti muscles first, leading to restriction of elevation and abduction of the eye with orbital muscle dysfunction and misalignment of the visual axes. The examination may reveal stigmata of the underlying disease process, such as lid lag or

periorbital swelling or proptosis, as well as diffuse conjunctival edema and vascular injection near the insertions of the rectus muscles.

Differential Diagnoses

Any visual disturbance coupled with periorbital pain and an ophthalmoplegia should raise concern about cavernous sinus thrombosis or an intracranial process. A history of hypercoagulable conditions, use of oral contraceptives, or any other focal neurologic finding will suggest one of these conditions. If suspected, a CT venogram is indicated, along with orbital imaging to better assess.

Diagnostic Testing

The diagnostic evaluation of a suspected orbital inflammatory process primarily involves imaging of the orbit. The optimal test is magnetic resonance imaging (MRI) of the orbits with gadolinium, which allows an assessment for enlargement or enhancement in extraocular muscles and orbital structures. Contrast-enhanced orbital CT, with fine cuts through the orbit, is a more readily available second-line option.[36]

Management

The mainstay of therapy (assuming infection is excluded) for orbital pseudotumor is systemic corticosteroid therapy, although there is increasing use of antimetabolites, cytotoxic agents, and other immunosuppressive agents.[37] Treatment of orbital apex syndrome includes management of underlying etiology (infection, neoplasm, or inflammation). These treatment choices will typically be made in concert with an ophthalmologist. For thyroid orbitopathy, the treatment of the underlying Graves disease will address many of the ophthalmological issues but may involve immunosuppressive medications, radiation, or even surgery (including orbital surgery).

Disposition

After consultation with an ophthalmologist, it is appropriate to discharge for outpatient follow-up in 24 to 48 hours.

INFECTIOUS CONDITIONS

Foundations

A critical determination in a patient with a red, irritated, or painful eye is whether or not there is an infectious process at play. This is based on clinical features, keeping in mind that the globe of the eye and the encompassing tissues of the orbit represent a pristinely organized and functional arrangement of tissue planes and glandular structures and that any disruption to these structures, whether from minor trauma, prior surgery, or inflammation, can present similarly and also predispose the patient to an infectious process.

The Conjunctiva: Allergic, Viral and Bacterial Conjunctivitis, and Ophthalmia Neonatorum

Clinical Features and Differential Diagnoses

Symptoms of conjunctivitis, whether it be allergic, toxic, or infectious, include redness, discharge, foreign body sensation, photophobia, and blurry vision.

The most common form of conjunctivitis is thought to be allergic conjunctivitis. This is not infectious per se, but it is considered in the differential diagnosis here because it often a challenge to distinguish it from a viral conjunctivitis. Allergic conjunctivitis is a type 1 histaminergic hypersensitivity reaction with red itchy eyes and clear discharge and is classically bilateral, associated with pollen and dust, and can be seasonal. In more severe cases, moderate-to-severe injection with glassy chemosis is observed. A toxic conjunctivitis, typically from topical ocular medications, may appear similar to allergic conjunctivitis; a contact dermatitis (from a trigger like eye makeup) should be suspected if there is an associated lichenified, eczematous periorbital dermatitis and edema.

Of the infectious etiologies, viral causes are most common. Viral conjunctivitis is classically preceded by a viral infection with upper respiratory symptoms, with sequential involvement of both eyes; however, many episodes of viral conjunctivitis have no preceding symptoms. Adenovirus is the most common cause and is highly infectious and easily spread by contact with fomites. The conjunctival discharge with viral infections tends to be watery and less purulent than that in bacterial conjunctivitis, although the quality of discharge cannot accurately separate viral from bacterial causes. Preauricular lymphadenopathy and follicular changes of the conjunctiva can be seen (Fig. 57.15). Viral conjunctivitis and keratoconjunctivitis can present with purulence, including having the eyelids stuck shut when awakening from sleep. Viral infections typically last 1 to 3 weeks. Epidemic keratoconjunctivitis is a highly contagious and more virulent viral conjunctivitis often presenting in epidemics, with which the patient may also complain of foreign body sensation and have mild keratitis.

Bacterial conjunctivitis is significantly less common than viral. The organisms involved include Staphylococcus species, as well as *Moraxella catarrhalis, Streptococcus pneumoniae, Haemophilus influenzae,* and rarely *Neisseria gonorrhoeae,* with an increased prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) conjunctivitis over the last decade. Conjunctivitis from gonorrhea classically presents with copious purulent discharge (Fig. 57.16) and carries a high risk for corneal involvement and subsequent corneal perforation.[38]

Distinguishing viral from bacterial conjunctivitis can sometimes be a challenge in the ED. A systematic review found that redness of the conjunctival membrane that is intense enough to obscure the tarsal vessels, physician-observed purulent discharge, and matting of both eyes in the morning increase the likelihood [LRs 3 to 4] of a bacterial cause, whereas inability to discern that the patient's eye is red from 20 feet away and absence of morning matting of either eye decrease the probability of a bacterial cause.[39]

What appears to be an infection of the conjunctiva may actually represent an infection of the cornea, and therefore, a slit-lamp examination is important; if signs of corneal involvement are present, a keratitis is likely (see Diagnostic Evaluation in The Conjunctiva and Cornea: Keratitis). Epidemic keratoconjunctivitis may have some mild punctate keratitis on fluorescein staining.

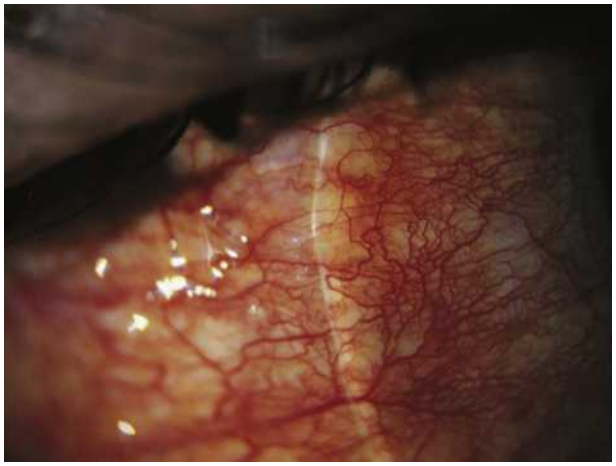

Fig. 57.15 Conjunctival Injection Resulting From Viral Conjunctivitis. (Courtesy www.tedmontgomery.com.)

Ophthalmia neonatorum is neonatal conjunctivitis that develops during the first 30 days of life. While it can be caused by allergy or chemicals, the most concerning causes are bacterial and viral infections, which present with tearing and discharge followed by scarring and blindness. The evaluation involves gram stain and cultures geared to infections such as *N. gonorrhoeae*, *Chlamydia,* and herpes simplex virus (HSV) that are transmitted from mother to infant through the birth canal. HSV may have associated corneal dendrites and lid edema. Infection with *N. gonorrhoeae* manifests within 2 to 4 days after birth (but may take up to 20 days). Examine the infant for evidence of systemic gonococcal infection.

Diagnostic Testing

Most cases of conjunctivitis are diagnosed clinically and do not require testing from the ED. In cases where *Neisseria* is highly suspected, a gram stain and culture (or a polymerase chain reaction [PCR] test as done for genital samples) can aid in the diagnosis.[40]

Management and Disposition

Allergic and viral conjunctivitis. Allergic conjunctivitis and viral conjunctivitis are usually self-limited and can be treated with supportive measures such as cool compresses. Topical antibiotics should be avoided unless there is concern for a bacterial superinfection; however, prescribe topical antibiotic ointment (erythromycin 0.5% applied two to three times daily until symptoms resolve) if there is diagnostic uncertainty. For allergic conjunctivitis, the patient should be counseled to avoid the offending agent and can be prescribed topical and systemic anti-allergy medications (see Table 57.1 for choices and dosing of topical options). Avoid medications with preservatives because they may exacerbate symptoms. Consider other etiologies if symptoms worsen after 2 to 3 days.

If inflammation is severe (with pseudomembranes or bleeding), then an ophthalmology evaluation in the ED for steroid treatment is recommended; otherwise, patients can be discharged with a referral to an ophthalmologist if they worsen or if they do not improve by 7 to 10 days. Keep children with viral conjunctivitis out of school until symptoms have resolved, which will be 3 to 5 days, keeping in mind that communicability can potentially last up to 10 to 14 days from onset of symptoms.[38]

Bacterial conjunctivitis. Although bacterial conjunctivitis is typically self-limited, most resolving in 1 to 2 weeks without treatment, topical antibiotics shorten the time to resolution.[38] Ointment is preferred given the smoothing effect on the eye and easy instillation. The prescribed antibiotics (see Table 57.1 for options) should cover the organisms mentioned previously and be taken for at least 1 week; those with the highest level of evidence for the treatment of bacterial conjunctivitis are tobramycin, ciprofloxacin, moxifloxacin, ofloxacin, azithromycin, and trimethoprim/polymixin B. Avoid gentamicin and neomycin due to toxicity. Prescribe ointment effective against *Pseudomonas* for contact lens wearers (see Table 57.1). For suspected *N. gonorrhoeae* conjunctivitis treatment involves ceftriaxone 1 g intramuscularly once or azithromycin 1 g orally if cephalosporin allergic. Saline irrigation of the affected eye(s), with concomitant empirical treatment for *Chlamydia trachomatis* infection is recommended (either doxycycline 100 mg orally bid for 7 days [preferred] or 1 gm of azithromycin orally once).[38]

Ophthalmia neonatorum. Hospitalization of neonates with blood and cerebrospinal fluid (CSF) examination may be indicated for ophthalmia neonatorum. *N. gonorrhoeae* conjunctivitis in a neonate is typically treated with a single dose of ceftriaxone 25 to 50 mg/kg up to a total dose of 250 mg intramuscularly (IM) or IV, topical erythromycin or polymyxin B–bacitracin ointment, and saline washes of the affected eye. Potential ocular chlamydial infection is simultaneously treated with topical erythromycin ointment and oral erythromycin syrup 50 mg/kg/day divided into four doses per day for 14 days. Treat suspected HSV with acyclovir IV 20 mg/kg every 8 hours plus vidarabine 3% ointment five times per day for 14 to 21 days. Evaluation for systemic involvement is indicated and ophthalmology consultation in the ED is warranted.

The Cornea: Corneal Ulcers, Herpes Simplex Keratitis, and Herpes Zoster Keratitis

Clinical Features

What appears to be conjunctivitis may actually represent an infection of the cornea. A *corneal ulcer*, also known as "ulcerative keratitis," (Fig. 57.17) is an infectious or inflammatory erosion of both the outer epithelial cell layer and the underlying stromal layer (which is the bulk of the cornea). Corneal ulcers present with pain and redness of the eye, tearing, sensitivity to light, and blurred, hazy, or otherwise decreased vision. There can also be a discharge or foreign body sensation. A corneal abrasion can become an ulcer if secondarily infected, which in turn can lead to corneal perforation if severe and untreated. Although corneal ulcers are due to infection, most of the resulting corneal injury is due to the secondary inflammation. The most common bacterial

Fig. 57.16 Purulent Discharge and Conjunctival Hyperemia Suggest Bacterial Conjunctivitis. (From Goldman L, Schaefer AI, eds. *Goldman's Cecil Medicine*. 24th ed. Philadelphia, PA: Saunders; 2012.)

Fig. 57.17 This corneal ulcer caused by *Pseudomonas aeruginosa* occurred in a young man who wore decorative contact lenses without professional supervision. (From Yanoff M, Duker JS, eds. *Ophthalmology*. 3rd ed. Philadelphia, PA: Mosby; 2008.)

pathogens are *Staphylococcus, Streptococcus, Mycobacterium,* and *Pseudomonas*, with the latter associated with contact lens wear. Fungal pathogens are typically seen in users of corticosteroid drops and in agricultural workers who are at risk of contaminating their eyes with vegetable matter or soil.

The cornea can also be infected by viruses. Herpes simplex keratitis, one of the most common causes of viral keratitis, can produce recurrent corneal ulcers similar to herpes infections in other areas. Herpes simplex infection may be either primary or reactivation of preexisting disease. Symptoms are similar to corneal ulcers. Herpes zoster keratitis can occur in the setting of herpes zoster ophthalmicus. Herpes zoster is re-activated along the ophthalmic division of the trigeminal nerve, and eye involvement is possible. Patients will typically present with a dermatomal rash over the forehead and upper eyelid and sometimes along the nose (branch of the nasociliary nerve "*Hutchinson sign*") or even have a unilateral Horner syndrome.

Differential Diagnoses

Distinguishing a corneal from the conjunctival process is paramount but can be difficult based on symptoms alone, as both will present with pain, foreign body sensation, and conjunctival injection. Slit and Wood's lamp examinations, after fluorescein dye, will help reveal corneal defects suggestive of keratitis.

Diagnostic Testing

The foundation of the diagnostic evaluation of corneal lesions is a careful examination and biomicroscopy with the slit lamp and fluorescein staining to evaluate corneal epithelial surface disruptions. On slit-lamp examination, a corneal ulcer may appear to have more "heaped up" edges (seen with tangential lighting) than those seen with a corneal abrasion; this finding, combined with stromal edema or infiltration (whitening of the underlying or surrounding cornea), helps identify the process as an ulcer instead of an uncomplicated abrasion.

A corneal ulcer from herpes simplex keratitis may present with classic "dendritic" lesions on slit-lamp examination (Fig. 57.18), an amoeba-shaped ulceration, or have nonspecific findings such as punctate epithelial erosions, stromal whitening, and thinning of the cornea. Herpetic vesicles may be seen on the lids or conjunctiva. Herpes zoster keratitis can appear similar but will have signs of a dermatomal vesicular rash and is frequently associated with iritis, uveitis, and choroiditis. Viral cultures can help direct therapy.

Fig. 57.18 Herpes Simplex Keratitis Infection. Note the typical dendritic pattern on the cornea. (Courtesy www.tedmontgomery.com.)

Management

Corneal ulcers and infiltrates. Topical anti-microbial therapy for corneal ulcers and infiltrates is appropriate initial therapy, although systemic antibiotics are warranted for severe infections. The fluoroquinolones (see Table 57.1) have particularly good ocular penetration; doxycycline and other tetracyclines have good anti-collagenase properties that help preserve corneal integrity. Steroids may be used to decrease inflammation but must be used with caution because they may exacerbate the clinical situation. Ophthalmology consultation in the ED is important for the management of corneal ulcers because they can rapidly progress to permanent vision loss.

Herpes simplex keratitis. Herpes simplex keratitis is the most common cause for corneal transplants in the United States. Emergent ophthalmologic consultation is recommended, and the severity of the disease will dictate treatment. Herpes simplex keratitis is treated with topical antiviral agents, such as topical acyclovir trifluridine 1% nine times a day for 14 days, ganciclovir 0.15% gel three to five times per day, or trifluridine 1% solution five to eight times per day for 14 days.[38] Topical prophylactic antibiotics, such as erythromycin ointment, and a cycloplegic agent are given if there are symptoms of iritis (see Table 57.1). Avoid topical steroids because they worsen infection. Consider systemic therapy (acyclovir 200 to 400 mg five times per day, valacyclovir 500 to 1000 mg two or three times per day, or famciclovir 250 mg twice a day for 7 to 10 days) if topical treatment is not available or if the process is severe.[38]

Herpes zoster keratitis. Herpes zoster ophthalmicus accounts for approximately 10% to 20% of all zoster cases and necessitates emergent ophthalmologic consultation. If not treated and recognized immediately, herpes zoster ophthalmicus may result in permanent vision loss. Systemic therapy is the standard of care (unlike HSV, topical antivirals have little effect). If retinal involvement occurs or the patient is immunocompromised, inpatient treatment is recommended. Higher dose antiviral agents (acyclovir 800 mg five times daily, valacyclovir 1000 mg three times daily, or famciclovir 500 mg three times daily, all for 7 to 10 days[38]) are used, and occasionally, topical steroid agents and systemic antibiotics may be added. Topical antibiotics are used to prevent bacterial superinfection of skin and lid lesions. Early treatment with antiviral therapy within 72 hours of the onset of the rash has been shown to reduce acute pain and ocular complications. Additional consideration for therapy includes pain management and aggressive lubrication to maintain a healthy ocular surface.

Disposition

Treatment of corneal infections is most often done as an outpatient with either topical or systemic anti-infective medications after consultation with ophthalmology. If ED consultation is unavailable, referral to be seen in 24 hours is recommended. Admission or transfer will typically not be needed but should be considered for severe symptoms or for patients with an inability to follow-up urgently.[41]

The Eyelids and Periorbital Area: Hordeolum, Chalazion, Dacryocystitis, Blepharitis, and Cellulitis

Clinical Features

The tissues of the eyelids and periorbital area are susceptible to any of a number of types of infections, which include those related to glandular or ductal structures, such as a hordeolum, chalazion, or dacryocystitis, or more diffuse involvement of tissue, such as blepharitis or periorbital cellulitis. Hordeola and chalazia, also known as *styes of the eyelid,* are inflamed oil glands of the eye. A *hordeolum* is caused by acute inflammation of an oil (Zeiss or meibomian) gland or hair follicle. It is typically painfully tender, erythematous, associated with swelling, and

can be infected. On the other hand, a *chalazion* is a chronic sterile, granulomatous inflammation of a meibomian gland (and may evolve from a hordeolum), which results in localized swelling that is usually not acutely painful (Fig. 57.19).

Dacryocystitis is an infection of the lacrimal sac, usually resulting from a nasolacrimal duct obstruction. It is more common in females. Symptoms and signs include pain, tenderness, swelling, and erythema over the lacrimal sac medial to the eye (Fig. 57.20). Pressure over the sac may express purulent material from the puncta. The lacrimal gland itself can also become infected, appearing as a focal area of periorbital erythema, swelling, and tenderness lateral to and above the upper eyelid.

Patients with blepharitis typically describe itching and burning of the eyelids with associated tearing and crusting. The eyelids become diffusely inflamed and thickened, with erythematous margins, and telangiectasias surrounding the eyelid margin. Blepharitis can be distinguished from a pre-septal cellulitis in that it is isolated to just the eyelid margin. Blepharitis has an association with atopic dermatitis, rosacea, and eczema.

Any one of the aforementioned focal infections, but especially dacryocystitis and blepharitis, may be complicated by a more diffuse cellulitis. Cellulitis frequently presents, however, as an individual entity, and it must be carefully distinguished as either pre-septal (also called *periorbital*) or post-septal (also called *orbital*). *Pre-septal* and *post-septal* are the most useful terms because they incorporate the most impactful clinical distinction in the ED and remove any chance of confusion as to what is being referred to in communications with consultants. Pre-septal cellulitis is limited to the tissue anterior to the orbital septum, whereas post-septal cellulitis implies the spread of the infection beyond the septum, which is concerning because it can lead to the involvement of valuable orbital structures. Pre-septal cellulitis will present with lid erythema, warmth, tenderness, swelling, and even a low-grade fever. Post-septal cellulitis will present similarly but will often have more sinister symptoms including proptosis, ophthalmoplegia, pain with eye movement, chemosis, and systemic signs of infection. In severe cases, visual loss can occur. In children, pre-septal cellulitis is often more difficult to differentiate from post-septal cellulitis because of an incompletely formed orbital septum.

Differential Diagnoses

The periorbital tissue can be swollen, erythematous, and even exhibit skin changes in a variety of conditions that are non-infectious. Renal disease leading to nephrotic syndrome may result in periorbital edema, although it is generally nontender and lacks erythema. Cutaneous allergic reactions and dermatitis commonly afflict the skin around the eyes as well as the eyelids. The skin will appear swollen and red, and the patient may even describe the areas as being painful. The most common offenders are makeup, facial moisturizers, and cleansers that are enriched with dye and perfumes.

Diagnostic Testing

For hordeolum, chalazion, dacryocystitis, blepharitis, and a cellulitis that is clearly pre-septal, the diagnosis is established on the clinical examination alone, and no additional diagnostic tests are needed. CT imaging is indicated in cases concerning an orbital abscess or when localization of an infection (pre-septal or post-septal) is difficult. In such cases, a complete blood count (CBC) may also be helpful. The primary diagnostic decision for the ED patient with a cellulitis around the eye is deciding who needs further evaluation with a CT scan. Proptosis, ophthalmoplegia, pain with eye movement, and chemosis suggest the possibility of post-septal cellulitis[42], but upward of 50% of confirmed cases may not exhibit these symptoms.[42] In these "no orbital symptom" cases, a peripheral absolute neutrophil count (ANC) of greater than 10 000 cells/μL, moderate-to-severe periorbital edema (extending beyond the eyelid margins), absence of conjunctivitis as the presenting symptom, age greater than 3 years, and recent antibiotic use have been shown to be predictors of an orbital abscess, specifically in the pediatric population. In addition, a sudden onset is more typical of post-septal orbital cellulitis. The absence or presence of a fever has little

Fig. 57.19 Chalazion of the Upper Eyelid. (Courtesy www.tedmontgomery.com.)

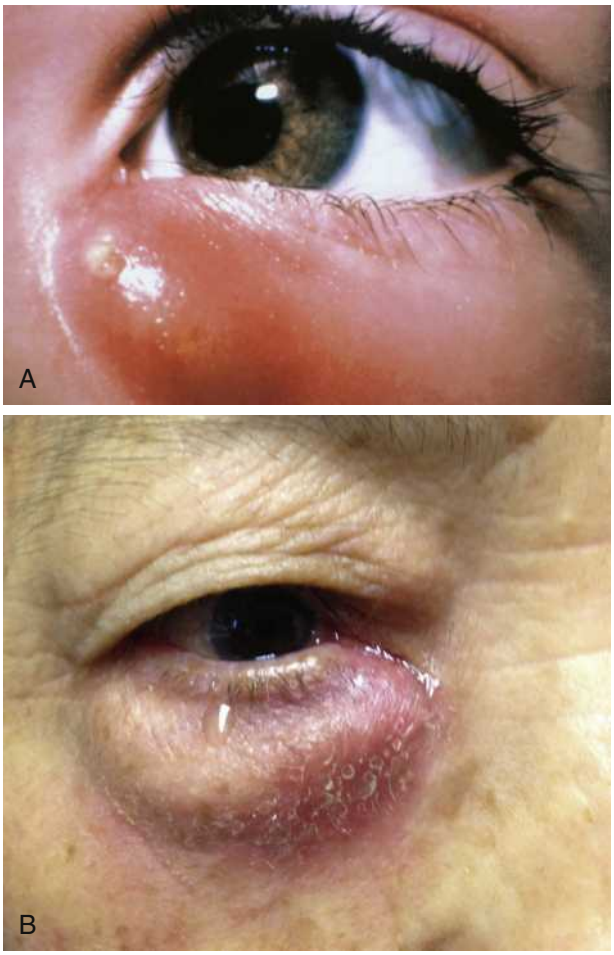

Fig. 57.20 (A and B) Dacryocystitis. (Courtesy Jeffrey Lee, MD, University of California San Diego.)

discriminatory utility. Cultures obtained from swabs of the eyes are discouraged due to the risk of misleading results from inoculation with commensal organisms, and blood cultures have little diagnostic utility.

Management

Hordeolum and chalazion. Hordeola and chalazia are typically self-limited and can resolve on their own when the glands become unobstructed. Conservative treatment to normalize the flow of the obstructed oil glands is the primary goal. This includes warm compresses for 10 to 15 minutes, three to five times a day. Treatment of an underlying blepharitis may be indicated. Referral to an ophthalmologist is recommended for incision and drainage or additional management and evaluation in nonresponsive cases. Progression to an infected oil gland may indicate the need for antibiotics, depending upon whether the process takes the form of a blepharitis or a cellulitis (see the treatment of each in the following sections).

Dacryocystitis. The most common causative organisms in dacryocystitis are *S. aureus, S. pneumoniae*, *H. influenzae*, *Serratia marcescens*, and *Pseudomonas aeruginosa*, with an emerging prevalence of MRSA. Treatment consists of massage, warm compresses, and systemic antibiotics selected so as to include coverage of MRSA. Obtain a culture by applying gentle pressure to the nasal lacrimal duct and expressing fluid. In infants, acute dacryocystitis represents a medical emergency because it can lead to complications including orbital cellulitis. Admission is warranted for severe cases. Occasionally, drainage of the sac is required; however, this can lead to fistula formation. Dacryocystorhinostomy is the definitive treatment. The optimal time for surgery is when the infection is controlled, so arrange for patients to follow-up with an ophthalmologist in 24 to 48 hours.

Blepharitis. The initial treatment of blepharitis is conservative, designed to remove residual oils and scurf, and entails warm massage with a moist washcloth about for 10 to 15 minutes three to five times a day and cleaning the lid margins twice a day with a cotton swab soaked in mild baby shampoo. Because blepharitis arises as a result of an inflammatory process, there is potential for bacterial overgrowth and superinfection (*Staphylococcus epidermidis* primarily, but also *Propionibacterium acnes,* and corynebacteria), and—if there is a concern for infection—topical azithromycin, erythromycin, or levofloxacin (see Table 57.1) can be considered.

Periorbital cellulitis. If pre-septal cellulitis in a patient with no other underlying medical conditions is diagnosed with certainty, the patient can be discharged on oral antibiotics directed toward the most common organisms, *Streptococcus* and *Staphylococcus,* keeping in mind that orbital cellulitis tends to be polymicrobial. The incidence of MRSA, although still relatively low in children, is rising. It is prudent to tailor antibiotic therapy so it includes this species, especially in adults.[43,44] A treatment option is a beta-lactam antibiotic, such as oral amoxicillin-clavulanate, 875 mg two times daily for 10 to 14 days for adults (or 45 mg/kg/day divided in two doses for 10 to 14 days for children), and in considering MRSA, adding clindamycin or trimethoprim-sulfamethoxazole (TMP-SMX). In children, the diagnostic uncertainty between pre-septal and orbital cellulitis dictates more aggressive management of any periorbital infection.[45] An IV second- or third-generation cephalosporin, such as cefuroxime or ceftriaxone, is recommended. Other IV antibiotic options include ampicillin/sulbactam (Unasyn) or a combination of a first-generation cephalosporin with metronidazole.

Disposition

Patients with hordeola and chalazia can be discharged to follow-up with an ophthalmologist if symptoms persist. Dacryocystitis, pre-septal cellulitis, and blepharitis are generally treated as outpatients with either referral to ophthalmology or an evaluation by the patient's primary care provider in 24 to 48 hours. In severe cases of pre-septal cellulitis, or with any concern of post-septal cellulitis, hospitalization with IV antibiotics is indicated to avoid complications, such as subperiosteal abscess, orbital abscess, meningitis, osteomyelitis, and cavernous sinus thrombosis.

The Globe: Endophthalmitis

Clinical Features

Endophthalmitis is an infection involving the globe itself. Pain and decreased vision are the primary symptoms. Examination findings include decreased visual acuity, chemosis, hyperemia of the conjunctiva, and intraocular inflammation (evidenced by hypopyon) (Fig. 57.21). The most common etiology of endophthalmitis is recent intraocular surgery. Other etiologies include previous perforated globe and endogenous infection. Early diagnosis and management are paramount to improve outcome.

Differential Diagnoses

Endophthalmitis and uveitis have significant clinical overlap. Recent ocular surgery or risk factors predisposing the patient to endocarditis suggest globe infection in contrast to autoimmune inflammation.

Diagnostic Testing

Endophthalmitis can be difficult to distinguish from uveitis, and the two have vastly different treatments and acuity. An ultrasound of the eye (done in much the same way as to evaluate for retinal detachment) can be performed. Endophthalmitis is suggested by numerous heterogeneous strands and membranes in a vitreous that would otherwise be uniformly hypoechoic.

Fig. 57.21 Eye with endophthalmitis, illustrating a hypopyon (pus in the anterior chamber). (Courtesy Kama Guluma, MD, University of California San Diego.)

Management

Endophthalmitis is a medical emergency that must be promptly treated. Systemic antibiotics are not effective (although commonly administered), and intravitreal antibiotics should be given.[46] The evaluation and treatment should be done in consultation with an ophthalmologist who can administer the intravitreal antibiotics at the bedside and perform a vitrectomy (removal of infected vitreous akin to draining an abscess) in the operating room if needed. Gram-positive pathogens, especially coagulase-negative staphylococci, are most common in post-cataract endophthalmitis; *Candida* followed by streptococci and staphylococci are most common in post-keratoplasty cases; coagulase-negative staphylococci, Bacillus species, streptococci, gram-negative bacilli (e.g., Pseudomonas and Klebsiella) are prominent in post-traumatic endophthalmitis; and *S. aureus*, streptococci (viridans, *S. pneumoniae*, and group A and B streptococci), and gram-negative bacilli (*Escherichia coli* and *Klebsiella pneumoniae*) are found in endogenous endophthalmitis associated with endocarditis.[46]

Disposition

Patients with endophthalmitis should be admitted to the hospital for continued treatment, infectious disease consultation, and continued antibiotic therapy.

ACUTE ANGLE-CLOSURE GLAUCOMA

Foundations

Aqueous humor provides structural support to the eye and delivers oxygen and nutrients to the avascular lens and cornea. It is produced by the ciliary processes, passes from the posterior chamber to the anterior chamber through the pupillary aperture, and then is transported into the trabecular meshwork located at the anterior chamber angle formed by the junction of the root of the iris and the peripheral cornea. This trabecular meshwork serves as a one-way valve and filter for the aqueous humor as it enters into the canal of Schlemm, which in turn drains into episcleral veins. IOP is normally between 10 and 20 mmHg and is determined by the rate of aqueous humor production relative to its outflow and removal.

Clinical Features

Glaucoma is the most common optic neuropathy in adulthood. It is characterized by visual field loss and death of retinal nerve fibers. Glaucoma usually, but not always, is associated with elevated IOP. The two most common and important forms of glaucoma are primary open-angle glaucoma and acute angle-closure glaucoma.

Primary open-angle glaucoma is a chronic condition characterized by asymptomatic elevated IOP (but IOP may not always be elevated), and an enlarged ratio of the diameter of the optic cup to the diameter of the optic disc (termed *cupping*) and peripheral visual field loss. Patients may be on topical ophthalmic medications designed to improve aqueous outflow. It is not typically a condition that results in an ED visit, although it can lead to complete blindness over time.

Acute angle-closure glaucoma is an ocular emergency and may present in a patient with no prior knowledge or history of glaucoma. A variety of rare conditions, such as tumors or neovascular processes, can predispose a patient to this, but the more common etiology is an anatomically shallow anterior chamber that further narrows with aging as the lens enlarges. Acute symptoms are often precipitated by pupillary dilation from being in a low-light environment or taking an anticholinergic or sympathomimetic medication. This transient contraction of the iris crowds the angle ("pupillary block") and continued formation of aqueous without adequate drainage leads to a sudden increased IOP. This causes the iris to bulge forward, further inhibiting outflow, and eventually compromising arterial flow into the eye.

The patient with acute angle-closure glaucoma typically presents with severe unilateral eye pain, redness, and blurred vision with "halos," as well as nausea, vomiting, and headache. On examination, the pupil may be moderately dilated and unreactive to light. The anterior chamber is shallow, often visualized with illumination from the side by a penlight, the conjunctiva injected, and the cornea cloudy. (Fig. 57.22). The IOP is significantly elevated which can lead to ischemia of the optic nerve, retinal nerve fiber layer, and even the avascular anterior portion of the lens. Sustained elevation in IOP can cause permanent corneal and optic nerve damage and cause the peripheral iris to adhere to the trabecular meshwork, forming anterior synechiae and an irreversible occlusion that only can be corrected by surgery.

Differential Diagnoses

Cataracts will also result in corneal clouding and a multitude of traumatic and infectious conditions will result in a painful red eye, often with reduced vision. Cataracts are generally painless. The suddenness of symptom onset and the conditions under which the symptoms began will help distinguish acute angle-closure glaucoma from other conditions. Primary headache conditions such as paroxysmal hemicrania may present with autonomic symptoms and sometimes with eye symptoms, such as tearing. A thorough eye examination is required to ensure acute glaucoma is not missed.

Diagnostic Testing

IOP measurement, using a tonopen, can confirm the diagnosis. In acute angle-closure glaucoma, IOP is typically higher than 30 mm Hg, although patients may be symptomatic at lower pressures.

Management

Treatment of acute angle-closure glaucoma begins with medications used to lower the IOP by reducing the production and increasing the outflow of aqueous humor (Box 57.1) and then proceeds to definitive treatment of the anatomical abnormalities that predisposed the patient to elevated IOP. Emergent ophthalmology consultation is necessary.

Definitive treatment for anatomic abnormalities includes laser peripheral iridotomy. This is undertaken within 24 to 48 hours for persistent symptoms despite medical management.

Disposition

Obtain ophthalmology consultation for acute angle-closure glaucoma. Patients will often need to be observed in the ED or hospital in order to

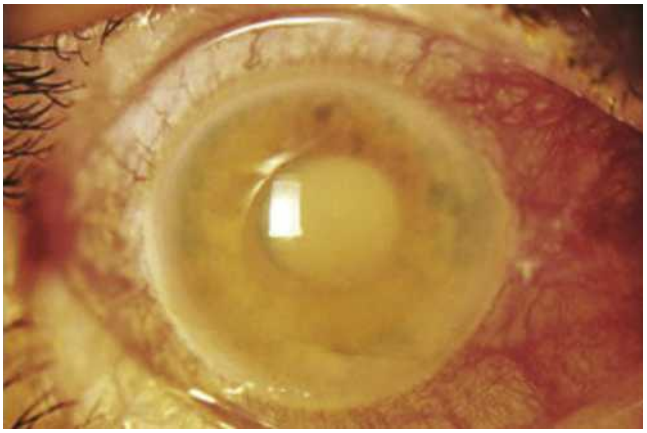

Fig. 57.22 Acute Angle-Closure Glaucoma. (From Yanoff M, Duker JS, eds. *Ophthalmology*. 3rd ed. Philadelphia, PA: Mosby; 2008.)

BOX 57.1 Drugs Used to Treat Acute Glaucoma

Drugs that reduce the production of aqueous humor
- Prostaglandins (latanoprost 0.005%—1 gtt)
- Topical beta-blocker (timolol 0.5%—1 to 2 gtt)
- Carbonic anhydrase inhibitor (acetazolamide 500 mg IV or orally)
- Systemic osmotic agent (mannitol 1–2 g/kg IV over 45 min, to minimize cerebral effects, and typically reserved if topical medications and acetazolamide do not work within 1 hour)

Drugs used to increase the outflow of aqueous humor
- Topical selective alpha agonists (like alphagan-alpha 2 specific-1 gtt)
- Miotics (pilocarpine 1%–2%)
- Topical steroid (prednisolone acetate 1%—1 gtt every 15–30 min four times, then every hour)

track IOPs. Final disposition is made in conjunction with an ophthalmology specialist.

PRIMARY DISORDERS OF VISION

Foundations

The process of visual perception is an orchestration of light refraction by the cornea and lens, signal transduction by the retina to generate electrical impulses, and transmission of those impulses through the optic nerve to be processed in each occipital cortex, being split and crossed at the chiasm along the way (Fig. 57.23). Primary disorders of vision can be caused by a derangement anywhere in this process and may present as blurred vision, a focal disturbance in the visual field (dark objects, floaters, flashing lights), a visual field cut, or frank vision loss. Double vision has a very distinct presentation and is addressed in Chapter 17.

The history enables a tailored approach to the evaluation of an atraumatic visual disturbance but may be fraught with challenges. It is

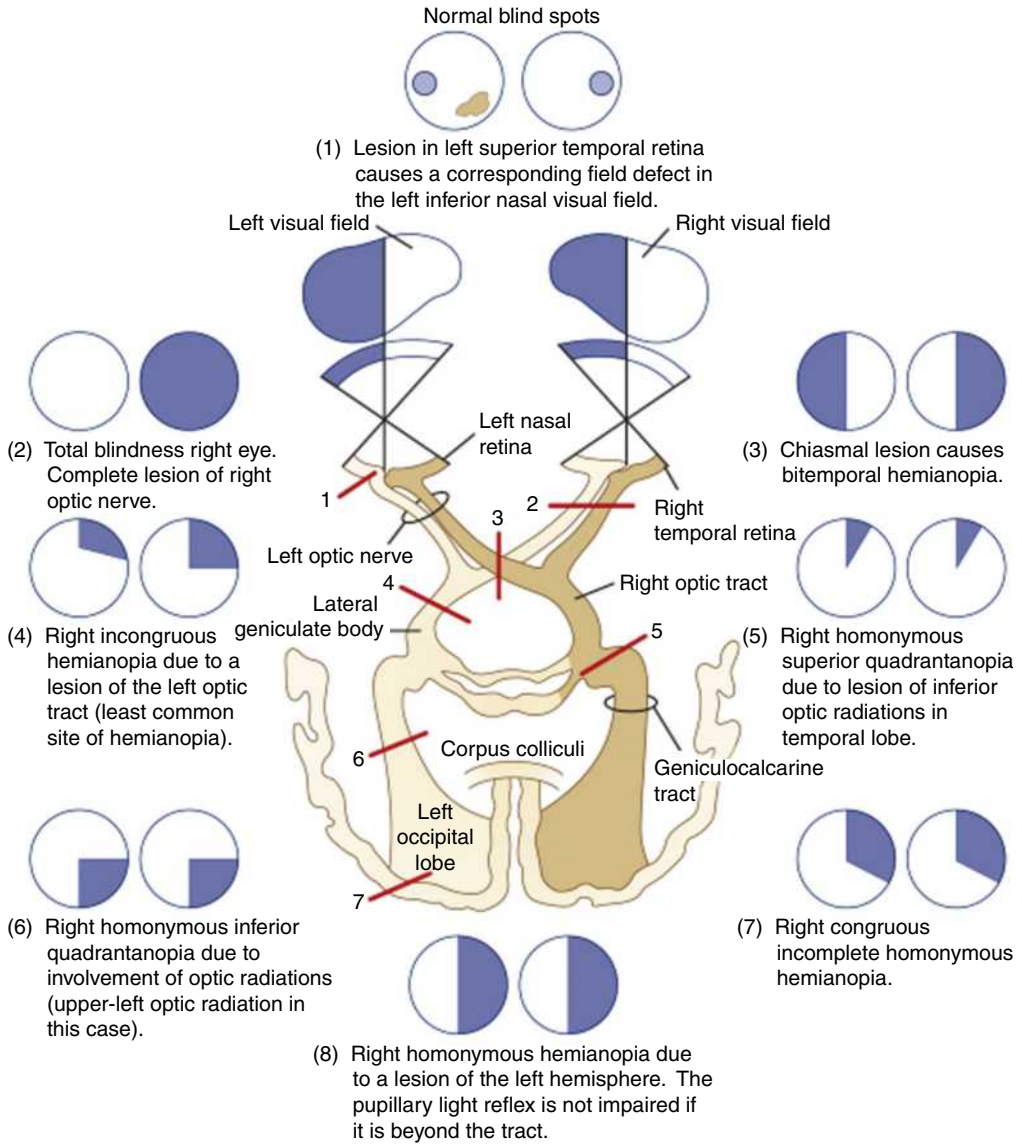

Fig. 57.23 Topographic Diagnosis of Visual Field Defects. (From Bradley WG, Duroff RB, Fenichel GM, et al: *Neurology in Clinical Practice*. 5th ed. Oxford: Butterworth-Heinemann; 2007.)

paramount to accurately catalog the symptoms. Patients may use the term *blurred vision* to actually describe double vision, and vice versa. A visual field deficit can be inadvertently ignored leading to a patient being "blind to the blind spot." In addition, a patient may not notice a chronic problem in one eye until it eventually develops in the remaining functioning eye. Finally, a patient may report what is actually a binocular defect of both visual fields on one side as a monocular issue in a single eye. This discrimination is lost if the visual disturbance was transient or not confirmed by checking both eyes.

Vision loss occurring beyond the retina can be considered *neuro-ophthalmologic* and divided, anatomically, into prechiasmal, chiasmal, and post-chiasmal (see Fig. 57.23). Patients with prechiasmal visual loss have monocular decreased visual acuity or visual field loss, typically from dysfunction of the optic nerve on that side, with an APD on the side involved in the swinging flashlight test (see Fig. 57.11). This finding will not cross the midline and involves only a single eye. Patients with chiasmal and post-chiasmal visual loss will typically have preserved visual acuity and a visual field loss in both eyes that respects the midline (see Fig. 57.23).

An ischemic event may occur anywhere from the retina to the occipital cortex depending on the vessel involved. The retina has a dual blood supply. The inner layers are supplied by a solitary central retinal artery, while the outer retinal layers are supplied by a choroidal circulation of ciliary arteries. The central fovea, within the macula, is also fed by choroidal vessels. In a central retinal artery occlusion (CRAO), the relative pallor of the surrounding retina, results in the pathognomonic "cherry-red spot" as the fovea continues to be perfused. About 15% to 30% of humans have a cilioretinal artery that also supplies the inner retina, which might preserve some residual blood flow to the macula in an acute CRAO. The blood supply to the optic nerve is complex and involves posterior ciliary and choroidal artery branches near the head and branches from the central retinal and ophthalmic arteries more proximally.

Blurred Vision: Optic Neuritis, Toxic and Metabolic Disturbances, and Papilledema

Clinical Features

Any disturbance in the refraction of light may cause blurred vision. These include corneal infiltrates (from infections), pupillary dilation (which results in an increase in the scatter of light rays reaching the lens), and changes in the refractive properties of the lens or vitreous, which can be seen with corneal edema from rapid osmotic changes. Blurred vision may also result from transductive dysfunction due to retinal or optic nerve inflammation or edema.

Typical optic neuritis is a primary, autoimmune inflammatory process of the optic nerve, affecting mostly young patients (range, 15 to 45 years old). It is the presenting symptom in 25% of cases of multiple sclerosis and may also be seen with other inflammatory, infectious, or autoimmune disorders.[47] The patient with optic neuritis typically presents with monocular blurring or fogginess of vision evolving over hours or days associated with variable degrees of pain with movement of the involved eye if the lesion is within the orbit. Patients may report fleeting flashes of light with eye movement, as well as worsening of vision with small increases in body temperature (from exercise, hot baths, or hot weather). Autoimmune optic neuritis often fluctuates with visual acuity reaching its poorest within 1 week and then slowly improving over the next several weeks. Approximately 30% of patients with acute optic neuritis develop multiple sclerosis within 5 years, and another 30% will have a recurrence within 10 years as the result of other causes. The natural history of atypical infectious and paraneoplastic etiologies of optic neuritis is concordant with the causative disease process.

Toxic visual disturbances are uncommon but may be seen with certain ingestions, such as methanol toxicity.[48] Orally ingested methanol is metabolized to formic acid, which accumulates in the optic nerve and leads to edema and compromised axoplasmic flow. In addition, it leads to widespread electrophysiological dysfunction that also affects photoreceptors in the retina, leading to visual loss. Other potential causes of a toxic visual disturbance are barbiturates, chloramphenicol, emetine, ethambutol, ethylene glycol, hypervitaminosis A, isoniazid, and heavy metals.

Metabolic visual disturbances, often from rapid osmolar shifts in the cornea, lens, or retina, have the potential to cause visual changes. This is most commonly seen with acute hyperglycemia. A rapid elevation in blood glucose (or a rapid correction of severe hyperglycemia), as seen in poorly controlled diabetics, may cause acute hyperopia (farsightedness), presumably due to changes in refraction in the lens.[49] It may alternatively cause acute myopia when the rise in intracellular glucose levels in the lens overwhelms the normal glucose metabolic pathway such that it is converted to less absorbable sorbitol and fructose, generating an acute hyperosmolar state and stromal swelling. This may be followed by acute bilateral cataract formation within a matter of hours to days. Metabolic visual disturbances can also result from a nutrition-related optic neuropathy from causes such as thiamine deficiency.

Papilledema may be seen on examination and refers to the changes in the optic disc from increased intracranial pressure. The subarachnoid space of the brain is continuous with the optic nerve sheath. Increases in the CSF pressure caused by idiopathic intracranial hypertension, cryptococcal meningitis in HIV/AIDS patients, hydrocephalus, or an intracranial mass can be transmitted to the optic nerve, resulting in swelling of the optic nerve head. Although visual symptoms may be isolated, patients often present to ED with a headache. A small percentage of patients with idiopathic intracranial hypertension present with isolated subjective visual loss, blurred vision, or enlargement of the physiologic blind spot as the initial presenting symptom of the disease, and rapid deterioration may occur over days in severe cases. Swelling of the optic disc and blurring of the disc margins, hyperemia, and loss of physiologic cupping are present (Fig. 57.24A). There may be the obliteration of spontaneous venous pulsations. Flame-shaped hemorrhages and yellow exudates may appear near the disc margins as the edema progresses (see Fig. 57.24B). Visual acuity will be affected as the swelling becomes severe. Papilledema is typically bilateral but may be asymmetrical. Conditions with optic nerve swelling (such as, ischemic optic neuropathy, optic disk vasculitis, and diabetic papillitis) may mimic papilledema.

Differential Diagnoses

As described, the differential diagnosis of "blurry vision" is broad and includes optic neuritis (which is usually monocular), toxic and metabolic visual disturbances (usually binocular), and papilledema from raised intracranial pressure (also usually binocular).

Diagnostic Testing

In the diagnostic evaluation of blurred vision, a standard ophthalmological assessment including visual acuity and a slit-lamp examination is important, but fundoscopy and an assessment of visual fields are critical.

Optic neuritis. With optic neuritis, visual acuity will usually be abnormal, and the patient may have variable visual field defects with central defects being most common. An APD is usually present, and direct ophthalmoscopic examination reveals a normal or swollen disk (Fig. 57.25). MRI of the optic nerves with gadolinium is used to confirm the diagnosis in most cases, as it reveals optic nerve lesions

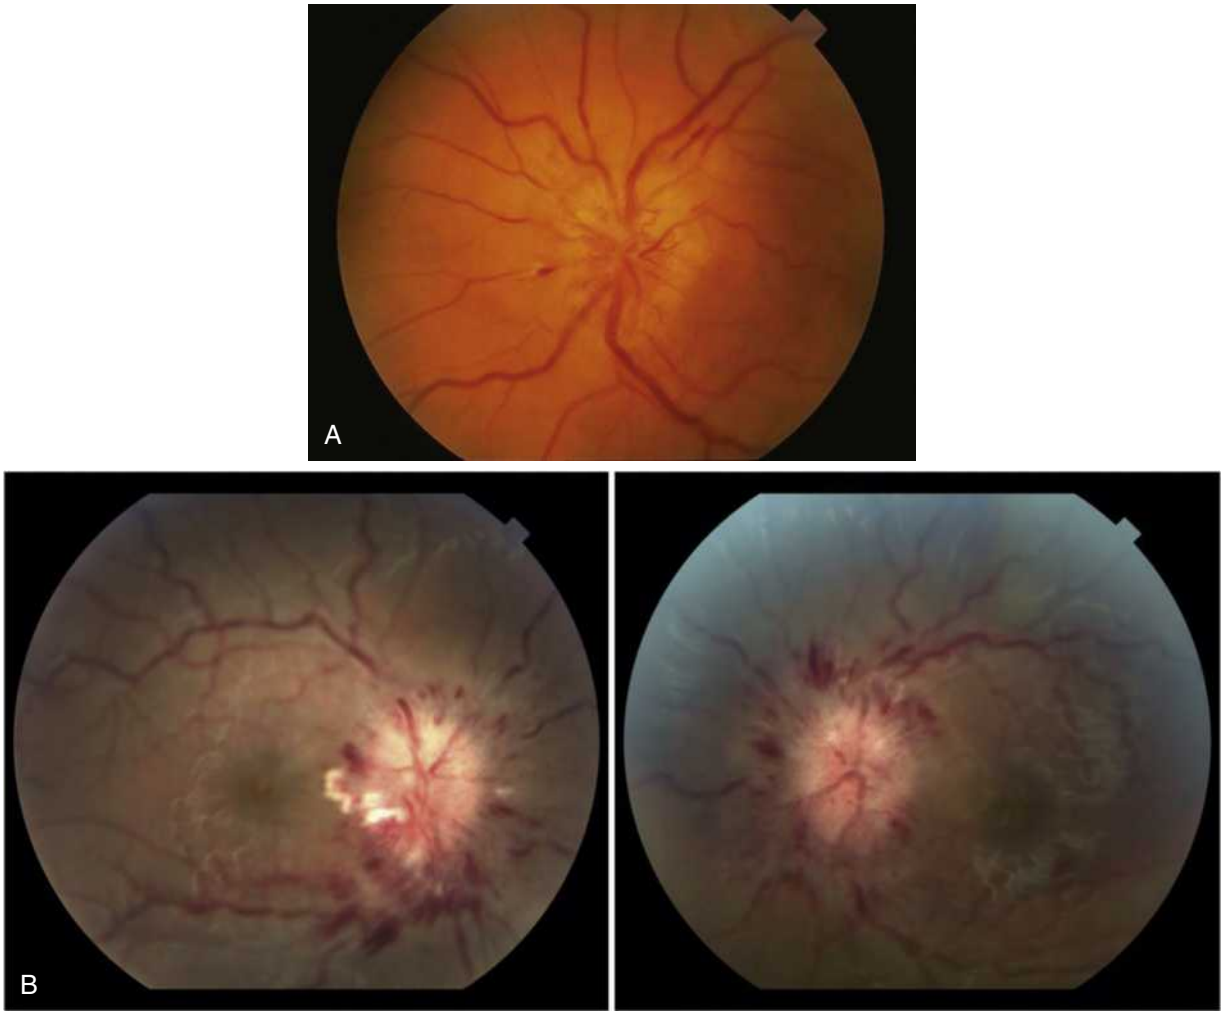

Fig. 57.24 (A) Papilledema. Note the blurred disk margins. (B) Papilledema. Note the blurred disk margins, exudates, and hemorrhages. (B, Courtesy Jeffrey Lee, MD.)

in the majority of cases.[50,51] CSF analysis from lumbar puncture, which may show pleocytosis and a raised protein concentration, can be performed if MRI is nondiagnostic or unavailable. Infectious and autoimmune serologies and optical coherence tomography may be utilized by consultants downstream in the workup.[52] Optic neuritis may be associated with autoimmune, infectious (syphilis, Lyme, HIV, varicella zoster virus, and cat-scratch disease) and non-infectious disorders such as sarcoidosis. The exact autoimmune etiology often requires antibody testing directed by specialists.[52,53] The ED workup for new-onset optic neuritis is to help exclude infectious causes that might need time-dependent antimicrobial therapy. Infectious etiologies of optic neuritis are frequently associated with uveitis, retinitis, and chorioretinitis; therefore, the presence of any of these features, or ocular inflammation, an optic nerve granuloma, or severe optic disc edema, should raise concern for infection.[52]

Toxic and metabolic visual disturbances. These processes are bilateral, progressive, and symmetrical and may manifest with a significant drop in visual acuity along with haziness in the lenses or retinal edema on fundoscopy. Blurred vision due to hyperglycemia typically reverses when hyperglycemia is treated, although cataracts may be permanent. Hyperglycemia and diabetic ketoacidosis have also been implicated in cortical blindness from posterior reversible encephalopathy syndrome lesions in the occipital lobes.[54,55]

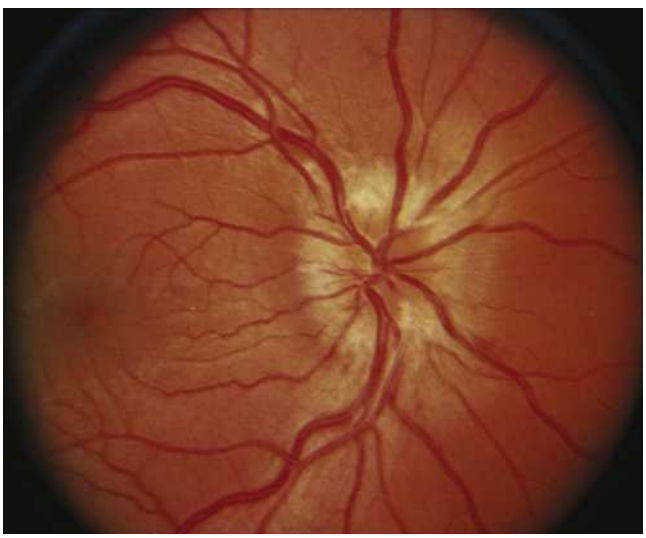

Fig. 57.25 Optic disk swelling (papillitis) associated with acute optic neuritis. (From Yanoff M, Duker JS, eds. *Ophthalmology*. 3rd ed. Philadelphia, PA: Mosby; 2008.)

Papilledema. Early or mild papilledema may be difficult to detect with the direct ophthalmoscope. When clinical suspicion is high, consultation with an ophthalmologist for stereoscopic viewing of the optic discs with indirect ophthalmoscopy is recommended. In cases in which idiopathic intracranial hypertension is suspected but there is still a question, patients can undergo neuroimaging with MRI.[56]

Management

For autoimmune optic neuritis, steroids are used for acute symptoms but lack proven benefit on long-term visual outcomes.[57] High-dose methylprednisolone, either 500 mg/day orally for 5 days, or 1 g/day IV for 3 days followed by oral prednisone (1 mg/kg/day for 11 days), is a common approach. Recent studies have shown no difference in efficacy between oral and IV administration.[58,59] Plasmapheresis, plasma exchange, and IV immunoglobulins are also options and are typically reserved for cases in which there is concern for a poor visual prognosis or a lack of response to steroids.[52,60] In toxic or metabolic causes, the treatment is aimed at the underlying toxin, metabolite, or deficiency involved. The management of papilledema is aimed at the underlying cause.

Disposition

Obtain neurology consultation for patients with presumed or diagnosed acute optic neuritis. Many patients will need admission for IV steroid treatment. Patients with toxic or metabolic visual disturbances will typically require admission for treatment of the underlying toxin or metabolic derangement. Patients with altered (but not loss of) vision due to simple hyperglycemia, without diabetic ketoacidosis, who have an improvement in symptoms after glycemic correction in the ED may be discharged with 24 to 48-hour follow-up.

Floaters, Flashes, and Field Deficits: Vitreous and Retinal Disorders

Clinical Features

Visual field disturbances may take the form of floaters, photopsia, or field deficits. Floaters are due to objects in the field of vision caused by material obstructing the light path. Photopsia (flashing lights) is from aberrant stimulation of the retina and can be unilateral or bilateral. The most common causes of unilateral photopsia are vitreous or retinal detachment (discussed later in this chapter), conditions in which abnormal mechanical stimulation of the retinal photoreceptors leads to a cascade of action potentials that the visual system interprets as flashes of light. A less common cause of unilateral photopsia is uveitis involving the choroid.

Vitreous hemorrhage results from bleeding into the pre-retinal space or the vitreous cavity. The most common causes are diabetic retinopathy and retinal tears. Additional causes include neovascularization associated with a variety of intraocular pathologies. Symptoms begin with dark floaters or "cobwebs" in one's vision that may progress over a few hours to painless visual loss. Floaters, described by the patient as dark or black dots or strands moving in the visual field in the direction of the preceding eye movement, are caused by vitreous blood.

Vitreous detachment is most common in patients older than 60 years. With aging, the vitreous gel desiccates, shrinks, and pulls away from the retina, leading to symptoms similar to those of vitreous hemorrhage and retinal detachment.

Three mechanisms cause retinal detachment: (1) rhegmatogenous, (2) exudative, and (3) tractional. The retina has two layers—the inner neuronal retina layer and the outer retinal pigment epithelial layer—that can be separated by fluid accumulation. A tear in the retinal membranes may lead to retinal detachment. A rhegmatogenous retinal detachment occurs as a result of a tear in the neuronal layer, allowing fluid from the vitreous cavity to leak between and separate the two retinal layers. It occurs in patients older than 45 years, is more common in men, and is associated with degenerative myopia. Trauma can cause this type of detachment at any age, with patients with severe myopia being at greater risk. An exudative retinal detachment occurs as a result of fluid or blood leakage from vessels within the retina and is associated with hypertension, pre-eclampsia, central retinal venous occlusion, glomerulonephritis, papilledema, vasculitis, and choroidal tumor. Finally, tractional retinal detachment is a consequence of contraction of a fibrous band that has formed in the vitreous. With retinal detachment, patients typically note flashes of light related to the traction on the retina, floaters from blood or pigmented debris in the vitreous, and visual loss. The visual loss is painless and commonly described as filmy, cloudy, or curtain-like in appearance.

If a visual field disturbance is binocular, then a chiasmal or cortical disorder should be considered. Chiasmal disease is most commonly caused by compression from nearby tumors. Visual loss is gradual and progressive. Post-chiasmal symptoms depend on the location of the tumor and can be located anywhere from the immediate post-chiasmal optic tract to the occipital cortex.

Differential Diagnoses

The differential diagnosis of visual field disturbances is broad and includes intraocular (monocular) entities such as vitreous hemorrhage, vitreous and retinal detachment, and extraocular (binocular) entities at the optic chiasm and beyond. The most common cause of bilateral (and homonymous) photopsia is migraines, although scintillating scotomas are much more frequent. Less common causes of bilateral homonymous photopsia include lesions of the visual cortex with release hallucinations or epileptic seizures. Perichiasmal disorders include pituitary tumors, craniopharyngiomas, and meningiomas. Beyond the chiasm, the list of culprits includes infarctions, tumors, arteriovenous malformations, and posterior reversible encephalopathy syndrome.

Diagnostic Testing

In the diagnostic evaluation of visual field disturbances, the history should be specific enough to ascertain if the problem is an issue of an absence of vision (i.e., a "blind spot,") or visual field deficit, or of an obstruction of vision (i.e., a "floater," as seen in vitreous detachment or hemorrhage, or retinal detachment). Perform a visual acuity assessment in all patients with a visual disturbance. In addition, complete a visual field examination to determine if the disturbance is monocular or binocular and whether it crosses the midline. Fundoscopy is especially important to enable an assessment of the vitreous and retina, and ocular ultrasound is a helpful adjunct. With this approach, the considerations outlined earlier can be differentiated and addressed.

Vitreous hemorrhage and detachment. With a vitreous hemorrhage, direct ophthalmoscopy reveals a reddish haze in mild cases and a black reflex in severe cases. Details of the fundus are usually difficult to visualize. There is a diminished red reflex and an inability to visualize the fundus clearly with the direct ophthalmoscope. Ocular ultrasound will reveal echogenic debris in the vitreous (Fig. 57.26A). A vitreous hemorrhage or detachment usually does not cause an APD by itself, and if an APD is present, an occult retinal detachment may be present. A hemorrhage may be evenly distributed throughout the vitreous, or—if trapped in the subhyaloid space as a pre-retinal hemorrhage—may be focal, with a boat shape (see Fig. 57.26B).

Retinal detachment. With a retinal detachment, visual acuity can range from minimally changed to severely decreased. Visual field

deficits relate to the location of the retinal detachment, and an APD occurs if the detachment is large. When the detachment is visible on ophthalmoscopy, the retina appears out of focus at the site of the detachment. In large retinal detachments with large fluid accumulation, a bullous detachment with retinal folds can be seen (Fig. 57.27A). Retinal detachment cannot be ruled out by direct fundoscopy. Indirect ophthalmoscopy is needed to visualize the more anterior portions of the retina. Bedside ultrasonography can be a useful tool in screening for a retinal detachment (see Fig. 57.27B).[61] It will reveal a billowing hyperechoic line that may undulate with side-to-side movements of the eye and generally has very high sensitivity and specificity, both greater than 90%.[61] Point-of-care ultrasound is operator-dependent, however, and a recent study revealed that false negatives occurred when retinal detachment was mistaken for a vitreous detachment or hemorrhage, often due to improper technique or inadequate gain on ultrasound.[62] This being said, even though a retinal tear could still be present, the absence of any echogenicity in the posterior pole of the eye in a properly performed ultrasound scan makes a significant retinal detachment unlikely.

Chiasmal and cortical disturbances. A chiasmic or cortical cause of a visual field disturbance can usually be made by confrontation visual field testing. The classic defect for a lesion in or compression of the optic chiasm (chiasmal) is a bitemporal hemianopsia; however, tumors can compress the chiasm and optic nerves asymmetrically, resulting in combined central and temporal defects. When a visual field defect respects the vertical midline, the lesion is outside the globe and likely either chiasmal or post-chiasmal (see Fig. 57.23).

The classic visual field defect in post-chiasmal (cerebral or cortical) disease is a homonymous hemianopsia, a visual field loss on the same side of both eyes (see Fig. 57.23). Patients with such lesions need to be evaluated and treated based on underlying neurological conditions such as occipital infarction, neoplasm, an inflammatory or infectious process, or posterior reversible encephalopathy syndrome. The diagnostic workup involves imaging. Noncontrasted CT of the brain is easily and quickly obtained and the initial test of choice. CT angiography is obtained if intervenable cerebrovascular disease is possible. Obtain a brain MRI if initial CT imaging is normal or non-diagnostic.

Management

Ophthalmologic consultation in the ED, or a same-day evaluation by an ophthalmologist, is required to characterize the extent and complications of any suspected vitreous hemorrhage or detachment and to manage vision-threatening complications. Symptoms of photopsia with floaters are associated with a higher incidence of concurrent retinal tears.[63] The management of a vitreous hemorrhage is otherwise largely expectant, with limitation of activity, avoidance of anticoagulants, and sleeping with the head of the bed elevated to allow blood to settle and optimize visualization of the retina on subsequent examinations. Surgery is often required if there is an associated retinal detachment. The same consideration applies for a posterior vitreous detachment, for

which no specific emergent treatment is indicated unless accompanied by a retinal tear, vitreous hemorrhage, or retinal detachment.

For patients who are highly symptomatic from floaters, treatment options include laser vitreolysis (using laser energy to fragment the vitreous opacities) or vitrectomy which involves surgical replacement of the patient's vitreous with an inert and translucent balanced salt solution.[64] Any patient suspected of having a retinal tear or detachment requires immediate ophthalmologic consultation as treatment with tamponade or retinopexy can prevent a retinal detachment from progressing to involve the macula. Loss of central vision indicates macular involvement and the duration of macular detachment, measured from the reported time of the loss of central visual acuity, is inversely related to final visual acuity.

Disposition

Final disposition is determined in conjunction with an ophthalmologist. If a retinal disorder is likely, emergent consultation or transfer is required.

Sudden Monocular Vision Loss: Retinal Artery and Vein Occlusion, and Ischemic Optic Neuropathy

Clinical Features

Sudden onset of atraumatic, vision loss is usually due to a vascular process resulting in retinal ischemia or infarction. Binocular processes include a sudden homonymous hemianopia from an infarction of the visual pathways in the temporal, parietal, or occipital lobes; and sudden total blindness in both eyes due to a basilar artery territory infarction of both occipital lobes.

In a CRAO, acute retinal ischemia develops from a sudden embolic, thrombotic, vasculitic, or vasospastic occlusion of a branch of the retinal artery (a branch retinal artery occlusion [BRAO]) or the central retinal artery itself. The examination reveals a markedly reduced visual acuity with a prominent APD and an edematous with a pale gray-white retina with a cherry-red spot representing the fovea seen on fundoscopy (Fig. 57.28). A CRAO may be (1) non-arteritic and permanent (constituting over two-thirds of all CRAO cases), such as an ischemic stroke of the retina, (2) non-arteritic and transient, which may be seen with a transient ischemic attack [TIA] of the retina related to vasospasm, or (3) arteritic due to a systemic inflammatory condition like temporal arteritis.[65] CRAO has a poor prognosis with spontaneous resolution occurring in only 1% to 8% of cases. It most commonly occurs in patients 50 to 70 years old, with vascular risk factors or a history of collagen vascular disease, vasculitis, cardiac valvular abnormality, or sickle cell disease. Patients with increased orbital pressure from acute glaucoma, retrobulbar hemorrhage, and endocrine exophthalmos are also at risk.

A central retinal vein occlusion (CRVO) leads to congestion of venous blood and fluid in the intraretinal space that may lead to secondary retinal ischemia. A CRVO is differentiated from CRAO based on findings on funduscopic examination. Appearance can vary but classically includes dilated and tortuous veins, retinal hemorrhages, and disk edema (Fig. 57.29). Branch retinal vein occlusion is an incomplete CRVO and carries about better prognosis. Neovascular glaucoma and macular edema are the major complications of ischemic CRVO. It is characterized as either non-ischemic or ischemic; a non-ischemic CRVO is associated with dilatation of retinal vessels and edema only, whereas an ischemic CRVO presents with the sudden onset of painless vision loss in one eye. Predisposing factors include hypertension, hyperlipidemia, diabetes mellitus, vasculitides, hyperviscosity, and smoking.

Ischemic optic neuritis (ION) falls into two primary types, anterior ischemic optic neuropathy (AION; involving the optic nerve head) and posterior ischemic optic neuropathy (PION; involving the rest of the optic nerve). AION can further be divided into arteritic anterior ischemic optic neuropathy (A-AION) due to temporal arteritis and, more commonly, non-arteritic anterior ischemic optic neuropathy (NA-AION) from noninflammatory vascular causes.[66]

Examination findings are similar in A-AION and NA-AION and include a large APD, visual loss, and a visual field defect that may respect the horizontal (as opposed to vertical) midline, with a pale and swollen optic disc on fundoscopy. Patients with A-AION may have concurrent symptoms of temporal arteritis, such as weight loss, malaise, jaw pain,

headache, scalp tenderness, polymyalgia rheumatica, and low-grade fever; in up to 25%, however, acute vision loss is the only symptom. Vision loss can be preceded by episodes of amaurosis fugax. Untreated, it may progress to involve both eyes. Temporal arteritis is extremely rare in people younger than 50 years, and the incidence rises with each subsequent decade. Vision loss is unilateral in 46%, sequential in 37%, and simultaneously bilateral in 17%.

Patients with the much more common NA-AION lack the classic symptoms of temporal arteritis and tend to be younger with systemic vascular disease, diabetes, or hypertension. This is an acute ischemic event affecting the anterior optic nerve that typically occurs in patients over the age of 50 years and may be precipitated by anemia, hypovolemia, dehydration, systemic hypotension, or fluctuations in blood pressure, especially in patients undergoing dialysis.[66]

A sudden complete monocular vision loss due to a vascular event can be transient *(amaurosis fugax)* and can herald a more significant or permanent loss of vision in any of the aforementioned processes. It has been reported in 2% of CRAO, 14% of BRAO, 5% of CRVO, just over 3% in NA-AION, and in 32% of patients with temporal arteritis who have ocular involvement.

Differential Diagnoses

Distinguishing cortical from retinal vascular causes of vision loss is accomplished by history alone in most cases. Cataracts and glaucoma typically cause gradual onset loss of vision, although sudden decreases in vision can occur. A cloudy or steamy lens will be visible. Acute angle-closure glaucoma can present with sudden monocular vision loss, but pain is universally present.

Diagnostic Testing

Diagnostic testing for monocular vision loss begins with a fundoscopic examination to look for the typical clinical features detailed previously. Along with the history, this is often enough to make a presumptive diagnosis. If there is diagnostic uncertainty, obtain CT or MRI to evaluate for structural causes. If inflammatory arteritis is a concern, check a sedimentation rate (ESR) or C-reactive protein (CRP) level.

Management

Central retinal artery occlusion. Like acute ischemic stroke, CRAO is a time-sensitive process. Animal models suggest that the retina will likely make a full recovery with an occlusion that lasts less than 90 minutes but will be irreversibly damaged with one lasting longer than 4 hours and will have variable degrees of recovery with times in between. A number of interventions have been proposed geared toward dislodgement of the embolus (via direct digital pressure through closed eyelids for 10 to 15 seconds and followed by a sudden release), dilation of the artery to promote forward blood flow (by increasing intra-arterial carbon dioxide level [pCO_2] with an inhaled mixture of 95% oxygen and 5% carbon dioxide [carbogen]), and reduction of IOP through anterior chamber paracentesis to increase the perfusion gradient.[67] Unfortunately, none of the presented therapies have been shown to improve visual acuity outcomes after CRAO.[65] A potential option is hyperbaric oxygen (HBO), which affords a theoretical benefit of direct oxygenation of the retina, but current evidence is limited to retrospective data.[68–71] There are no robust prospective, randomized controlled trials confirming the efficacy of HBO as a treatment for CRAO, likely because implementing such trials is limited by logistics.[68]

A non-arteritic CRAO may be amenable to the use of thrombolytic agents.[67] Available studies are heterogeneous, using different agents, dosing regimens, and time windows in largely retrospective case series with different findings, but it appears that intra-arterial thrombolytic therapy might be effective if given less than 6 hours from onset. IV thrombolysis might be effective if given less than 4.5 hours from the onset, with a post-thrombolysis major hemorrhage rate significantly lower than that seen with ischemic stroke.[72] Until a large randomized controlled trial of the safety and efficacy of thrombolysis for CRAO is performed, management should be tailored to individual patient circumstances in consultation with an ophthalmologist.

There are no national guidelines for the treatment of CRAO, and a survey of university-associated teaching hospitals offering vascular neurology, neuro-ophthalmology, or retina fellowships in the United States found significant heterogeneity in approaches.[73] Adding to the complexity of care is the variable time available for intervention. This depends on the extent of vascular disease and collateral flow from ciliary vessels.[74,75]

Begin a hypercoagulable workup in patients younger than 50 years. There is a strong association between non-arteritic retinal artery occlusion and subsequent risk of an acute ischemic stroke. An expedited workup for cerebrovascular disease and assessment of stroke risk is recommended.[76–80].

Central retinal vein occlusion. An ultimate visual acuity better than 20/200 is seen in over 80% of patients with a non-ischemic CRVO but in less than 10% of patients with ischemic CRVO. Treatment of CRVO includes treating the underlying etiology and monitoring for potential sequelae. Consult ophthalmology in the ED to secure timely initiation of therapy, which largely centers around treating the macular edema associated with the occlusion. Potential treatments include anti-vascular endothelial growth factor pharmacotherapies, intravitreal injections of corticosteroids or antiangiogenic monoclonal antibodies (ranibizumab, bevacizumab), retinal photocoagulation, and cyclocryotherapy.[81–83] The use of antithrombotic therapy, in particular, the use of low-molecular-weight heparin, has also shown promise.[84] Underlying medical disease should be managed; the prognosis depends on the degree of obstruction and resultant complications.

Ischemic optic neuropathy. Temporal arteritis with evolving vision loss or amaurosis fugax from A-AION represents a distinct clinical emergency. Untreated, vision loss becomes bilateral in days to weeks in at least 50% of cases.[66] Admit patients for high-dose IV methylprednisolone (typically 500 mg to 1 g daily for 3 days) before transitioning to oral medications. Patients treated with high-dose IV methylprednisolone are more likely to have visual improvement (a 34% chance of improvement) and are less likely to develop fellow eye involvement than those receiving oral prednisone.

The visual loss in NA-AION is less severe than with temporal arteritis, and improvement occurs in one-third of patients. There is no known treatment (intravitreal and systemic steroids have been tried without success, as have anti-VEGFs). Emergent ophthalmological consultation is warranted for any apparent ION to aid with differentiation of the type and extent of the process and management.

Disposition

All patients with sudden monocular vision loss require emergent ophthalmologic evaluation. Most will be admitted for further workup and management. Final disposition is done in conjunction with ophthalmology or neuro-ophthalmology specialists.

Functional Vision Loss

Functional (or factitious) vision loss may be due to a conversion reaction or malingering. Distinguishing organic from psychiatric causes of visual disturbances can be challenging and may require consultation with an ophthalmologist, a neurologist, and a psychiatrist. Some tests can be performed in the ED that will suggest a functional overlay, given that the most common presentation of functional vision loss is a decreased visual acuity. They include (1) rotating an optokinetic drum

or rocking a mirror slowly back and forth in front of the patient (which will induce nystagmus or eye movements in the functional patient, but not in the truly blind patient), (2) rapidly moving the examiner's hand toward the eye in question (which will induce a blink to a visual threat in the functional patient, but not in the truly blind patient), (3) checking for an APD as in Fig. 57.11 (which will be absent in the functional patient but not in the truly blind patient with an optic nerve problem), (4) having the patient raise his or her arms and touch both index fingers together. A functional patient will feign inability to approximate the fingers, but a truly blind patient will be able to do, given that the test is actually one of proprioception and not vision.

Another presentation of functional visual loss is a defect in the visual field, typically with a central scotoma. This can be identified as functional by having the patient sit in front of a picture and describe the extent of a visual field defect vis-à-vis what is missing and then moving him or her further away and asking for another description of what is missing. The functional patient may describe the same missing elements in the picture in an effort to convince the examiner that the defect is stable, whereas the patient will a real visual field deficit will notice that more elements in the picture are missing.

DIPLOPIA

Chapter 17 provides a comprehensive overview of the approach to diplopia. The approach is based on whether binocular diplopia is due to (1) a simple restrictive, mechanical orbitopathy from inflammatory or infectious mass-effect directly restricting of the movement of the eye, (2) a palsy of one or more of the oculomotor CNs, (3) a more proximal neuro-axial process involving the brainstem and related CNs, or (4) a systemic neuromuscular process.

ANISOCORIA

Foundations

Anisocoria, a difference in pupil size, is present normally in 20% of the population but can also result from a process affecting the nuclei or the innervation pathways or from pharmacological interference at the neural endplates in the pupillary muscles.

Dilation (mydriasis) of the pupil is controlled by the dilator muscle, innervated by sympathetic nerves that exit the spinal cord at the level of C8, T1, and T2, and then travel back up under the subclavian artery and over apices of the lungs, enter the superior cervical ganglion, then the internal carotid plexus, and finally the ophthalmic division of the trigeminal nerve (CN V), whereupon they reach the eye through the superior orbital fissure. This sympathetic innervation serves a largely inhibitory role, facilitating pupillary dilation in darkness.

Constriction (or miosis) of the pupil is controlled by the pupillary sphincter muscle, innervated by parasympathetic nerves that originate in the nuclei of CN III. This parasympathetic innervation is the primary means of regulating pupillary size in response to different intensities of light. Afferent input from the retina of each eye bifurcates to innervate the Edinger Westphal nuclei of each CN III, and each nucleus in turn provides efferent output to its pupillary constrictor muscle, underlying the direct and consensual pupillary light reflexes.

Clinical Features

Anisocoria may be a pupillary variant in neurologically normal patients. It can also be seen in pathologic conditions, as a post-surgical finding or after pharmacologic application. These include an Adie's or Argyll Robertson pupil, pharmacologic mydriasis and miosis, a third-nerve palsy, Horner syndrome, and a physiologic or headache-associated anisocoria.

Adie's and Argyll Robertson Pupils

An Adie's tonic pupil results from dysfunction or lesion of the ciliary ganglion or short ciliary nerves and may be idiopathic or the result of local ocular or orbital damage from surgery, trauma, procedures, infection, inflammation, or ischemia. An Adie's tonic pupil may also be part of a condition causing systemic autonomic dysfunction, such as diabetes, dysautonomia, neurosyphilis, amyloidosis, or sarcoidosis. These patients present with a large pupil on one side. They may be asymptomatic or report sensitivity to light in that eye and blurred vision when looking at things near them.

The Argyll Robertson pupil is typically smaller than an Adie's and similarly constricts poorly to direct light, but it briskly constricts when a target within reading distance is viewed. It is attributable to a dorsal midbrain lesion that interrupts the pupillary light reflex pathway but spares the more ventral pupillary near the reflex pathway.

Pharmacologic Mydriasis and Miosis

Anisocoria can be caused by a variety of accidental medication and plant exposures. Parasympathomimetic miosis may be induced by exposures to organophosphate esters, pilocarpine drops, or dust-containing cholinesterase inhibitors from a dog's flea collar. Parasympatholytic mydriasis may be seen with anticholinergic medications (such as, transdermal scopolamine), aerosolized ipratropium administered through nebulizer masks, cycloplegics (such as, homatropine, cyclopentolate, or tropicamide), and plants containing anticholinergic agents, such as Jimsonweed *(Datura stramonium)* and Angel's trumpet *(Datura suaveolens)*. *Sympathomimetic mydriasis* may occur from sprays containing phenylephrine (Neo-Synephrine), cocaine, and apraclonidine (a glaucoma medication).[85–87]

Third-Nerve Palsy

CN III innervates the medial, inferior, and superior recti muscles, the inferior oblique muscle, and the levator palpebrae superioris muscle, which lifts the upper eyelid. It also provides parasympathetic innervation to two intrinsic ocular muscles, the ciliary and constrictor pupillae muscles, which constrict the pupil. A CN III palsy, therefore, results in an eye that appears deviated "down and out" with a dilated pupil and ptosis. The parasympathetic fibers that affect pupillomotor constriction are located peripherally and on the superomedial surface of CN III, where compression from an aneurysm or other source may cause pupillary involvement before other oculomotor signs, such as ptosis or diplopia, develop.

Horner Syndrome

Horner syndrome presents with ptosis, miosis, and facial anhidrosis resulting from a disruption of sympathetic innervation anywhere along the chain of sympathetic innervation. The presence of associated symptoms may help localize the etiology, as outlined in Table 57.2.[88] In children, the most common cause of acquired Horner syndrome is a neuroblastoma of the paravertebral sympathetic chain, although it may be from a mediastinal tumor. Horner syndrome can also be congenital, suggested by heterochromia or hypopigmentation of the ipsilateral iris.

Physiologic and Headache-Associated Anisocoria

In physiological anisocoria, the difference in pupil size will typically be 1 mm or less. A more prominent transient mydriasis (benign episodic unilateral mydriasis) may occasionally accompany a migraine headache, either from sympathetic hyperactivity, or—with an ophthalmoplegic migraine—parasympathetic hypoactivity from CN III dysfunction.[89,90] A non-migrainous benign episodic unilateral mydriasis can occur without headache, ptosis, or ocular motility disorder, in episodes lasting minutes, hours, or even days and is also thought

TABLE 57.2 Potential Locations of Lesion Causing a Horner Syndrome, Based on Symptoms and Signs

Symptoms and Signs	Potential Lesion Location	Potential Lesion Type
Brainstem symptoms (vertigo, ataxia, diplopia, and focal sensory and motor deficits)	Pontine or midbrain	Infarction or neoplasm
Myelopathic symptoms (paraparesis, sensory deficit, bowel or bladder symptoms, or hyperreflexia)	High spinal cord	Neoplastic or demyelinating process
Arm pain, weakness or numbness, neck lymphadenopathy (especially with hoarseness from recurrent laryngeal nerve compression)	Brachial plexus or cupula of the lung	Neoplastic process, such as a Pancoast tumor
Ipsilateral ear or neck pain (especially with symptoms of phrenic or vagus nerve involvement)	Carotid sheath	Carotid dissection; inadvertent injection of an anesthetic into the sheath during dental or line-placement procedures
Hearing loss and ear pain; trigeminal nerve dysautonomia (ipsilateral facial pain, rhinorrhea, conjunctival injection, and tearing)	Skull base	Neoplasm; inflammatory or infectious mass effect

Flaherty PM, Flynn JM: Horner syndrome due to carotid dissection. *J Emerg Med* 2011; 41(1):43–46. Horner syndrome: clinical perspectives. *Eye Brain.* 2015;7:35–46.

to be caused by over-activity of sympathetic innervation to the pupil. Patients are typically young females, and episodes last a median duration of 12 hours.

Patients can also present with a "tadpole pupil," in which the pupil becomes distorted and pulled in one direction like the tail of a tadpole, possibly occurring several times a day for several days and then resolving. This is likely the result of a sectoral spasm of the dilator muscle, thought to be benign, and has been associated with strenuous exercise. If, on the other hand, the patient has a baseline anisocoria and the tadpole pupil manifests in the smaller of the pupils, testing for Horner syndrome is recommended.

Diagnostic Testing, Management, and Disposition

The evaluation of new anisocoria is outlined in Fig. 57.30. Assuming no damage to the iris (implying a purely structural problem) is evident on slit-lamp examination, the strategy is to differentiate a benign cause of anisocoria (e.g., physiological or pharmacological) from one that requires additional neuro-ophthalmological consultation (e.g., Horner syndrome) or emergent neuroimaging (e.g., CN III compression potentially due to an aneurysm). The first step is to determine which pupil—the larger or the smaller—is the pathological one, keeping in mind that that parasympathetic innervation constricts a pupil in bright light, whereas sympathetic stimulation helps dilate a pupil in the dark. The subsequent steps incorporate the principles that an abnormally large pupil may be due to either a decrease in parasympathetic stimulation or an augmentation of sympathetic stimulation, and an abnormally small pupil may be due to either a decrease in sympathetic stimulation or an augmentation of parasympathetic stimulation.

Medications such as hydroxyamphetamine (an indirect-acting adrenergic mydriatic that causes endogenous norepinephrine to be released from sympathetic nerve endings without directly stimulating the effector cells), as well as direct adrenergic agonists, such as a phenylephrine or 1% apraclonidine, can be used with ophthalmological consultation to perform a secondary evaluation of a Horner's pupil. Pilocarpine is a direct cholinergic receptor agonist and is used to differentiate hypo-parasympathetic conditions (see Fig. 57.30).

Once one of the typical presentations of anisocoria is identified, the evaluation progresses based on the clinical indications. Examination of an Adie's tonic pupil typically reveals poor reaction to light with sectoral palsy of the iris sphincter and a lack of (or slow) constriction with near accommodation. Slit-lamp examination may reveal sectoral palsies of the iris, and a weak cholinergic agent (pilocarpine 0.1%) causes an intense pupillary constriction (compared to the patient's normal pupil) as a result of the cholinergic supersensitivity in the affected pupil. These patients should be referred non-emergently to an ophthalmologist for further evaluation.

The Argyll Robertson pupil, like the Adie's pupil, will demonstrate segmental, slow, or little iris sphincter constriction with light, but normal constriction with near accommodation ("light-near dissociation," which distinguishes it from an acute Adie's pupil). Screen a patient with bilateral Argyll Robertson pupils for neurosyphilis (please refer to entries dedicated to syphilis elsewhere in this text).

Evaluate a patient with a new-onset Horner syndrome, based on associated signs and symptoms, as outlined in Table 57.2. An MRI is best for disorders of the brain, skull-base, and spinal cord lesions, while computed tomography angiography (CTA) is best for chest and neck/carotid pathology. The cadence of the evaluation (and which components are done in the ED) will be dictated by the acuity of the primary considerations in the differential diagnosis, with aneurysm, dissection, brainstem stroke, and a rapidly progressive myelopathic process evaluated emergently in the ED, and a more subacute or chronic process (such as a tumor) often worked up as an outpatient.

The diagnostic evaluation and management of a third-nerve palsy are covered in Chapter 17 and Chapter 91. With regards to pharmacologic mydriasis and miosis, most of the exposures and their effects will be self-limited and transient, and the specific management will be dictated by the severity of symptoms.

The first-time clinical presentation of physiological and headache-associated anisocoria (mydriasis) may provoke a neuro-imaging evaluation for the presence of aneurysmal or mass compression of CN III; although this is being excluded, treatment can be rendered along lines that are standard for migraine headache. Physiological and headache-associated anisocoria is otherwise self-limited and will not typically require urgent ophthalmology referral unless persistent.

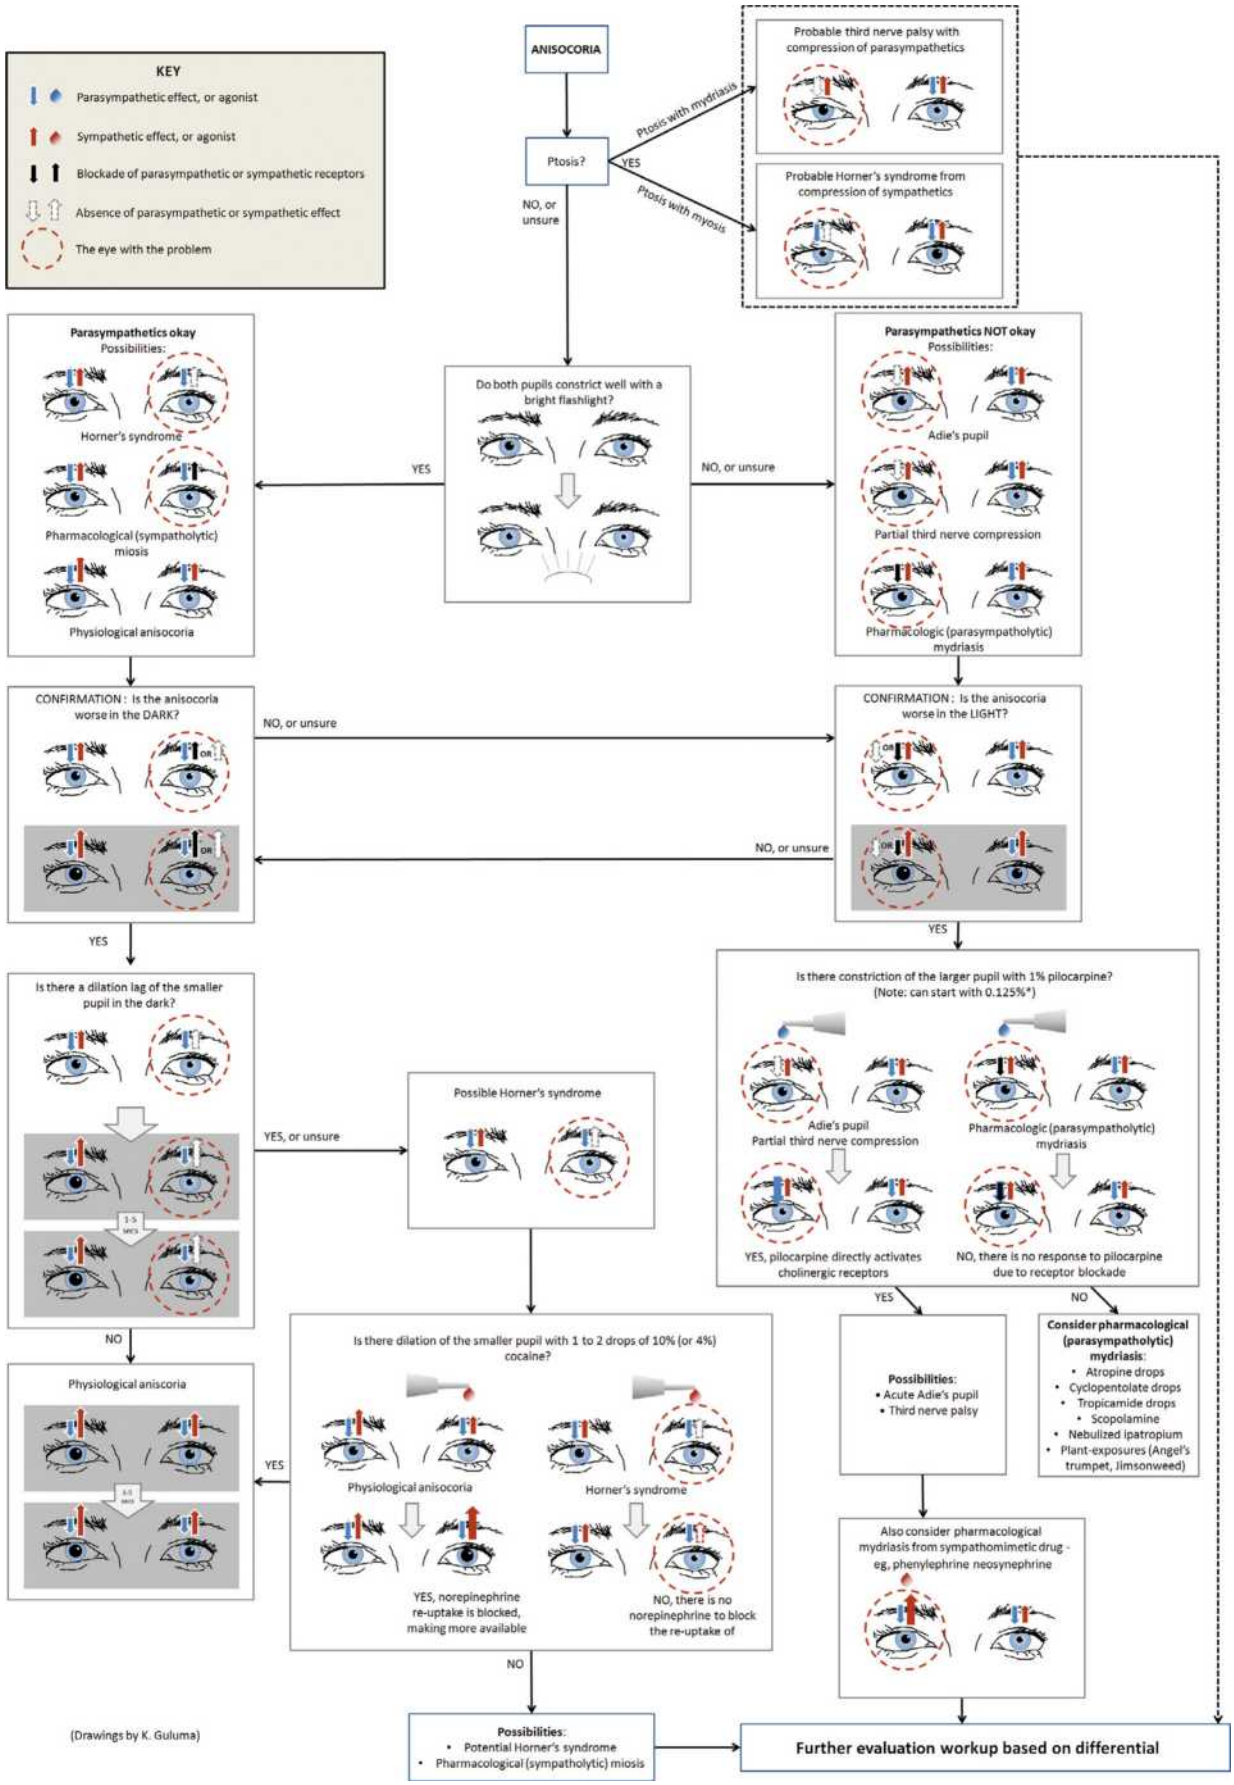

Fig. 57.30 The approach to anisocoria in the emergency department (ED), an explanatory algorithm. *Some authors advocate that a marked response to low concentration (0.1% or 0.125%) pilocarpine is more consistent with an Adie's pupil and can be used to differentiate it from an acute third-nerve palsy (which may require the more concentrated 1% to elicit a reaction). This approach may be impractical, however, as a sole means to rule out a third-nerve palsy from something like an aneurysm.

NYSTAGMUS

Foundations

Three specific mechanisms keep an object of visual interest on the fovea: (1) fixation, wherein the visual system detects retinal drifts and programs corrective eye movements; (2) the vestibulo-ocular reflex (VOR), which keeps the eyes on target despite head movements; and (3) eccentric gaze-holding, which requires ongoing signals from the brainstem and cerebellum to overcome the natural elastic pull of orbital tissues when the eyes are deviated away from the mid-position to fixate on a target.

Clinical Features

Dysfunction in any of these three mechanisms removes the visual target from the fovea and may result in nystagmus and oscillopsia (a subjective sense of movement of the visual field).[91,92] Nystagmus is a repetitive horizontal, vertical, or torsional back and forth movement of the eyes that may appear as an equal "to and fro" motion (pendular nystagmus) or demonstrate an alternating, slow phase followed by a corrective fast phase (jerk nystagmus). In jerk nystagmus, although the slow phase is the abnormal one, the directionality of the nystagmus is described as that of the fast phase. Gaze-evoked nystagmus is an inability to hold the eyes in a fixed position at the eccentric extremes of gaze. Drug-induced gaze-evoked nystagmus is symmetric with a larger amplitude and slower velocity and beats in the direction of the gaze (i.e., upbeat nystagmus with the patient looking up, rightward nystagmus with the patient looking to the right, and so on). GEN from a focal cerebellar or brainstem lesion may look similar to that which is drug-induced, but it is characterized by a sustained asymmetric and rebound nystagmus in which, although the slow phase is directed toward a primary position where the eyes deviate, a few slow phases may be directed toward the prior gaze direction after the eyes return to the primary position.

Nystagmus can be physiologic or pathologic and congenital or acquired. It may be a variety of characteristics that included differences in amplitude, sustainability, and direction and may present with or without cerebellar findings. A patient may also have congenital nystagmus, typically identified as chronic or present since birth. The focus in the ED is therefore on acquired pathological nystagmus, of which the etiologies can be classified as either (1) peripheral (such as, seen with benign peripheral vertigo or vestibular neuronitis), (2) central, indicating an ischemic stroke or CNS mass lesions, or (3) toxic and metabolic which can be seen with certain medications, alcohol, or illicit drugs. The key findings for these various forms of nystagmus are outlined in Table 57.3.

TABLE 57.3 Forms and Causes of Nystagmus

Type of Nystagmus	Presumed Area of Dysfunction	Character/ Primary Direction	Triggered by Head Movements?	Suppresses on Visual Fixation on an Object?	Changes Direction With Gaze?	Sustained?
Peripheral Nystagmus						
Labyrinthitis or vestibular neuronitis	Labyrinthine dysfunction or viral infection of the superior portion of the vestibular nerve trunk	Horizonto-rotatory, one direction only, slow phase toward dysfunctional nerve	Yes	Yes	No, just gets more pronounced the further the patient looks away from dysfunctional nerve	Yes
Benign paroxysmal positional vertigo (BPPV)	Otolithic, posterior canal (most common)	Torsional combined with vertical, one direction only	Yes, raising the head from horizontal to vertical	Yes	No	No
Benign paroxysmal positional vertigo (BPPV)	Otolithic, other canals	Horizonto-rotatory, one direction only, slow phase toward dysfunctional canal	Yes, turning head side-to-side	Yes	No, just gets more pronounced the further the patient looks away from dysfunctional canal	No
Central Nystagmus						
Downbeat nystagmus	Vestibulocerebellum Drugs: Lithium, phenytoin, carbamazepine, alcohol, toluene, felbamate, lamotrigine, phencyclidine (PCP), ketamine Nutritional deficiencies: magnesium, vitamin B_{12} or thiamine	Pure vertical, with fast component downward	No	No	No, just more pronounced on looking down	Yes
Upbeat nystagmus	Pontomesencephalic or pontomedullary junction, or the superior vestibular nucleus and tracts Nutritional deficiencies: Thiamine (Wernicke's)	Pure vertical, with fast component upward	No	No	No, just more pronounced on looking up	Yes
Torsional	Cerebellum or brainstem Drugs: PCP, ketamine	Pure rotary, with bi-directional fast component	No	No	Yes	Yes

TABLE 57.3 Forms and Causes of Nystagmus—cont'd.

Type of Nystagmus	Presumed Area of Dysfunction	Character/ Primary Direction	Triggered by Head Movements?	Suppresses on Visual Fixation on an Object?	Changes Direction With Gaze?	Sustained?
Horizontal	Cerebellum or brainstem Drugs: PCP, ketamine	Bi-directional	No	No	Yes, fast component beats in direction of gaze, and gets worse with more extreme deviation	Yes
Gaze-evoked nystagmus (GEN)	Cerebellum or brainstem Drugs: Phenytoin, alcohol	Multi-directional, but asymmetric intensity	No	No; in fact worsens on eccentric fixation	Yes, fast component beats in direction of gaze, and gets worse with more extreme deviation	Yes, specifically if vision is eccentrically fixated on an object
Other Miscellaneous Central Nystagmus Presentations						
Acquired pendular nystagmus	Paramedian pontine tract (seen in multiple sclerosis) Drugs: Phenytoin	Oblique or elliptical movements, can even be monocular	No	No	No	Yes
Periodic alternating nystagmus	Nodulus and ventral uvula of the vestibulocerebellum Drugs: Phenytoin	Horizontal nystagmus with a slow phase that changes direction every 1–2 min	No	No	No	Yes
Superior oblique myokymia	Possible cranial nerve (CN) disorder	Torsional oscillopsia, in one eye	No	No	No	Yes
See-saw nystagmus	Parasellar mass, or stroke to mesodiencephalic regions	Elevation with intorsion of one eye, with simultaneous depression and extorsion of the other eye	No	No	No	Yes
Oculopalatal myoclonus	Dentate, red, and inferior olivary nuclei in the brainstem	Vertical-torsional or pure vertical (with one eye being more prominent), associated with palatal myoclonus	No	No	No	Yes

Differential Diagnoses

Peripheral nystagmus may be seen in vertiginous middle ear disorders such as benign paroxysmal positional vertigo or viral vestibular neuritis. Central causes include stroke, vestibular schwannoma, and cerebellar pathology. Toxin-induced nystagmus can be seen with anticonvulsants, ethanol, lithium, ketamine, dextromethorphan, and recreational drugs such as phencyclidine and lysergic acid diethylamide (LSD).

Diagnostic Testing

Both peripheral and central nystagmus (e.g., from otoconia, vestibular neuronitis, posterior circulation stroke, brain tumor, and so on) present with prominent vertigo, and a detailed discussion of these entities is deferred to the entries on vertigo and dizziness in Chapter 15. The goal in the ED is differentiating more subtle presentations of central causes from benign peripheral ones. This can be determined by assessing (1) the direction of the nystagmus, (2) its intensity with extremes of gaze, and (3) how it is affected by visual fixation, as outlined in Table 57.3. Peripheral nystagmus, associated with vertigo and a presumed middle ear etiology, does not require an ED workup. For central causes or when the diagnosis is unclear, neuroimaging, typically MRI and MRA, is indicated. Nystagmus thought to be from medication or recreational drug toxicity is suggested by a concurrent toxidrome and lack of prominent vertigo or ataxia and will require toxicologic studies or specific drug levels to confirm the diagnosis may be suggested by a concurrent toxidrome and lack of prominent vertigo or ataxia.

Management

The management of nystagmus is targeted toward the underlying etiology. Peripheral nystagmus associated with vertigo and a peripheral etiology is symptomatic. Management of drug-induced nystagmus starts by holding the offending agent and targeted therapies for drug toxicity.

CHAPTER 57: QUESTIONS AND ANSWERS

1. A 23-year-old male presents with left periorbital pain after being struck with a fist. On examination, there are no globe injuries but marked periorbital swelling is noted. Computed tomography (CT) of the face reveals an orbital floor fracture. Which of the following would be the most likely physical findings?
   - **a.** Cheek anesthesia, enophthalmos, and limitation of upward gaze
   - **b.** Cheek anesthesia, ptosis, and limitation of inferior gaze
   - **c.** Forehead anesthesia and afferent papillary defect
   - **d.** Forehead anesthesia, diplopia, and limitation of lateral gaze
   - **e.** Ptosis, miosis, and ipsilateral anhydrosis

Answer: a. An orbital floor fracture may entrap the inferior rectus and inferior oblique muscles, resulting in diminished upward gaze. Other findings may include ptosis, enophthalmos, ipsilateral cheek/lip anesthesia, and orbital emphysema. As many as 25% of such patients have associated globe injuries. Option E describes Horner syndrome, which is not a typical finding.

2. A 20-year-old male presents with periorbital pain and swelling after a blow to the eye by a softball. Physical examination reveals proptosis with significant decline in vision and limitation of ocular motion in all planes. Tonometry reveals an intraocular pressure (IOP) of 45 mm Hg. Which of the following should be the first indicated maneuver?
   - **a.** Acetazolamide 500 mg IV, mannitol 20 g IV, and topical timolol
   - **b.** Computed tomography (CT) scan of the head and face
   - **c.** Endotracheal intubation and hyperventilation
   - **d.** Immediate lateral canthotomy and cantholysis
   - **e.** Ophthalmologic consultation

Answer: d. These findings should make one suspect retrobulbar hemorrhage. All of these interventions are likely indicated. Intraocular hypertension may compromise central retinal artery flow. Although immediate ophthalmologic consultation and pressure-lowering maneuvers are indicated, lateral canthotomy and cantholysis will provide the most rapid temporizing measure to preserve vision.

3. A 43-year-old male presents with acute ocular pain after a splash injury from drain cleaner. What should be the sequence of interventions?
   - **a.** Copious irrigation for 10 minutes, pH testing, cyclopentolate cycloplegia, topical antibiotics/intraocular pressure (IOP) measurement
   - **b.** Intravenous (IV) analgesia, cyclopentolate cycloplegia, IOP measurement, isotonic irrigation
   - **c.** IOP measurement, analgesia, head-up position, cycloplegia
   - **d.** Phenylephrine cycloplegia, isotonic irrigation for 10 minutes, pH testing, slit-lamp examination for foreign bodies
   - **e.** Phenylephrine cycloplegia, slit-lamp examination for foreign bodies, isotonic irrigation for 10 minutes, pH testing

Answer: a. Copious irrigation, ideally beginning at the scene, is the cornerstone of management. Nitrazine pH testing after 10 minutes should guide the need for continued irrigation. Cycloplegia, IOP measurement, and topical antibiotics come after pH normalization. Phenylephrine is contraindicated for cycloplegia in these cases because of its vasoconstrictive properties.

4. A 17-year-old girl who wears contact lenses presents with a 24-hour history of right eye pain. Physical examination reveals a right corneal abrasion at the 6-o'clock position of the limbus. Appropriate treatment consists of which of the following?
   - **a.** Cessation of contact lens wear, eye irrigation (qid) with isotonic saline solution, followed by instillation of undiluted topical tetracaine for 5 days
   - **b.** Emergent ophthalmology consultation
   - **c.** Tetanus prophylaxis, eye patching for 48 hours, antibiotic ointment, and a 24-hour recheck
   - **d.** Tetanus prophylaxis, topical nonsteroidal antiinflammatory drugs (NSAIDs), cessation of contact lens wear, and a 24-hour recheck
   - **e.** Topical nonsteroidal medications, topical anti-pseudomonal antibiotic, and a 24-hour recheck

Answer: e. Tetanus prophylaxis is not indicated for corneal abrasion unless there is corneal perforation or contamination with organic material. Topical NSAIDs reduce corneal abrasion pain. Antipseudomonas coverage with cessation of contact lens wear is appropriate. Eye patching is not indicated. Administration of undiluted topical anesthetics for more than 24 hours is untested and may be dangerous. Oral analgesics may be needed.

5. How do patients with subconjunctival hemorrhage most commonly present?
   - **a.** Asymptomatic blood in the eye, noticed in the mirror or by a friend
   - **b.** Decreased visual acuity
   - **c.** Foreign body sensation
   - **d.** Modest pain
   - **e.** Photophobia

Answer: a. Any significant symptoms, such as pain, decreased vision, foreign body sensation, or photophobia, should spark the search for more serious pathology. Bilateral hemorrhage in the absence of a clear cause (e.g., severe vomiting) should raise suspicion for coagulation issues.

6. A 38-year-old man presents with unilateral left-sided visual loss after a motor vehicle collision (MVC). The only clinical finding is a left-sided hyphema rising to 50% of the height of the anterior chamber. Intraocular pressure (IOP) is 17 mm Hg in the unaffected eye and 29 mm Hg in the affected eye. Appropriate management should include which of the following?
   - **a.** Cycloplegia, intravenous (IV) mannitol, ophthalmology consultation
   - **b.** IV analgesia and antibiotic, immediate ophthalmologic consultation for decompression resulting from intraocular hypertension
   - **c.** Oral acetazolamide, shield, antiemetics, 24-hour recheck
   - **d.** Topical beta-blocker, shield, modest analgesia, admission
   - **e.** Topical beta-blocker, topical nonsteroidal antiinflammatory drugs (NSAIDs) for pain, shield, 24-hour recheck

Answer: d. Significant hyphema is an indication for admission. The presence of elevated IOP requires urgent treatment (which might also include topical alpha agonists or IV acetazolamide, and so on), shield, elevation of the head, and cautious use of systemic analgesics. Any form of platelet inhibition would be contraindicated.

7. What is the major complication of hyphema?
   - **a.** Detached retina
   - **b.** Glaucoma
   - **c.** Horner syndrome
   - **d.** Rebleeding
   - **e.** Vitreous hemorrhage

Answer: d. Rebleeding typically occurs 2 to 5 days later as the clot retracts. It is most common in patients with elevated intraocular pressures (IOPs), hyphema greater than 30% of the anterior chamber, and with delayed presentation. Rebleeding may lead to glaucoma and synechia formation.

CHAPTER 57: QUESTIONS AND ANSWERS—cont'd

8. A 48-year-old woman presents with right eye pain, photophobia, and decreased vision after a motor vehicle collision (MVC). Physical examination reveals an irregularly shaped pupil and a small hyphema. Photophobia, decreased acuity, minimal pupil reactivity, and bloody chemosis are seen on examination. What is the most likely diagnosis?

a. Acute angle-closure glaucoma
b. Blunt ciliary injury
c. Iridodialysis
d. Scleral rupture
e. Traumatic miosis

Answer: d. Scleral rupture occurs either at the insertion of the extraocular muscles or at the limbus, where the sclera is the thinnest. A "teardrop" pupil is often seen and may be accompanied by bloody chemosis or severe subconjunctival hemorrhage. Brownish-black pigment prolapse may also be seen. Intraocular pressure (IOP) may be low, but tonometry is generally contraindicated in cases of suspected globe injury.

9. A 26-year-old man presents with a 3-day history of right eye pain, decreased vision, and photophobia. He reports a history of left eye trauma 6 weeks prior, with hyphema, traumatic iritis, and persistent decreased vision. He is otherwise healthy. Physical examination reveals photophobia in the right eye with bilateral decreased vision. Before the past 3 days, the vision in the right eye had been perfect. What is the most likely explanation for his right eye symptom?

a. Collagen vascular disease
b. Post-traumatic conjunctivitis
c. Post-traumatic retinal tear
d. Spontaneous vitreal hemorrhage
e. Sympathetic ophthalmia

Answer: e. Sympathetic ophthalmia is an autoimmune inflammatory response in the unaffected eye, days to months after uveal trauma in the opposite eye. Pain, photophobia, and decreased vision are common. This patient had no findings consistent with conjunctivitis or collagen vascular disease, and a retinal tear would not typically be painful.

10. Oral antibiotics are indicated for which of the following?

a. Blepharitis
b. Chalazion
c. Dacryocystitis
d. Endophthalmitis
e. Hordeolum

Answer: c. Dacryocystitis is an infection of the lacrimal sac from nasociliary duct obstruction. Warm compresses are also recommended and may be helpful, although evidence is lacking. Warm compresses and topical antibiotics are appropriate for the other conditions. Intravitreal antibiotics are indicated for endophthalmitis.

11. Bedside ocular ultrasonography can provide useful information for which of the following conditions?

a. Lens dislocation
b. Retinal detachment
c. Vitreous hemorrhage
d. All of the above

Answer: d. A displaced lens can be seen in the relatively hypoechoic vitreous. Vitreous hemorrhage and retinal detachment can both be diagnosed with emergency department bedside ultrasonography.

Otolaryngology

Aaron G. Matlock and James A. Pfaff

KEY CONCEPTS

Otitis Media

- Otitis media is caused by eustachian tube inflammation and dysfunction leading to fluid accumulation in the middle ear and proliferation of nasopharyngeal bacteria, most commonly *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.*
- Diagnosis of acute otitis media (AOM) is made based on the presence of a middle ear effusion and signs of inflammation, including ear pain, tympanic membrane erythema and bulging, and fever.
- Bullae may be seen in some cases of AOM. This is known as bullous myringitis and treatment for this condition does not differ from non-bullous AOM.
- Mastoiditis is the most common suppurative complication of AOM though is rare in the modern era.
- Most cases of AOM resolve spontaneously, and observation for 2 to 3 days may be offered instead of immediate antibiotics in appropriately selected pediatric patients. Observation strategies are not validated in adult patients.
- Amoxicillin is the recommended initial antibiotic treatment of choice for most patients with AOM. Recurrent otitis media or treatment failures warrant selection of an alternate antibiotic regimen.
- Antibiotics alone do not provide improvement in pain in the first 24 hours of AOM, and pain should be addressed with the use of over-the-counter analgesics, such as acetaminophen or ibuprofen.
- Otitis media with otorrhea from an acute perforation is treated in the same manner as AOM without perforation. These perforations are typically small and resolve spontaneously.
- In patients with tympanostomy tubes presenting with acutely increased otorrhea, treatment with ototopical fluoroquinolone drops is recommended.

Otitis Externa

- Otitis externa (OE) is most commonly seen in warm climates and summer months. *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most common causative pathogens.
- Patients with immunocompromised states (diabetes) and persistent OE despite treatment should be evaluated for necrotizing OE, a severe, life-threatening infection of the outer ear and surrounding structures.
- Topical antibiotic drops are effective for most cases of OE. Systemic antibiotics are not indicated in immunocompetent patients with infection limited to the external ear canal.
- Fluoroquinolone drops are effective in most cases of OE, and they may be used in patients with a non-intact tympanic membrane. Aminoglycoside ear drops are ototoxic and should not be used in patients with a tympanic membrane (TM) perforation.

Necrotizing (Malignant) External Otitis

- Necrotizing external otitis is an aggressive from of OE with high associated mortality. Patients with diabetes mellitus, immunocompromise, and advanced age are at particular risk.
- Necrotizing otitis media should be considered in at-risk patients with progressive OE unresponsive to treatment.
- CT scanning can aid in diagnosis of necrotizing otitis media by demonstrating bony erosion and characteristic soft-tissue abnormalities.
- Necrotizing otitis media is treated with systemic antibiotics with activity against *Pseudomonas aeruginosa.* Ciprofloxacin is an appropriate initial antibiotic treatment.
- Patients with necrotizing otitis media should be managed in coordination with an otolaryngologist. Surgical intervention may be needed in refractory cases.

Mastoiditis

- Mastoiditis is the most common suppurative complication of otitis media, though it is a relatively rare condition. It may occur in patients without known preceding otitis media.
- The most common physical findings with mastoiditis are postauricular erythema and tenderness, protrusion of the auricle, and an abnormal TM.
- CT scanning is indicated in patients with suspected intracranial involvement from mastoiditis.
- Mastoiditis is treated with vancomycin (15 mg/kg IV), and an agent active against *Pseudomonas aeruoginosa* is added in those who have previously received antibiotics.
- Consultation with an otolaryngologist is advised to assist in management of mastoiditis.

Sudden Hearing Loss

- Sudden sensorineural hearing loss (SSNHL) is defined as acute hearing loss over a period less than 3 days and is often misdiagnosed.
- SSNHL is idiopathic in 70% of cases. It may also be secondary to infection, otologic disease, trauma, vascular disease, hematologic disorders, or neoplasm.
- Imaging is not warranted in the ED for SSNHL unless a space-occupying lesion is suspected.
- SSNHL is treated with steroids (prednisone 1 mg/kg/day up to 60 mg, tapered over 10 to 14 days), and prompt surgical follow up for further evaluation.

Epistaxis

- Epistaxis is distressing to patients but rarely life-threatening. Most nosebleeds arise from an anterior locus.
- A causative link between hypertension and epistaxis has not been clearly established; however, patients are often hypertensive upon presentation, which may be associated with persistent bleeding.

Continued

KEY CONCEPTS—CONT'D

- Most cases of anterior epistaxis can be managed in the ED with a combination of direct pressure, topical vasoconstrictive drugs, chemical cautery and packing, as needed. Tranexamic acid is an effective adjunct to these treatments that decreases immediate and delayed bleeding.
- Posterior epistaxis requires specialized packing techniques and monitoring in an inpatient setting.
- Refractory cases of epistaxis may require embolization or surgical treatment
- Routine use of prophylactic antibiotics in patients treated with anterior packing for epistaxis is not recommended.

Sialolithiasis

- Sialolithiasis is most commonly seen in the submandibular salivary gland. Risk factors include dehydration, anticholinergic and diuretic medications and smoking.
- Sialolithiasis may be treated with manual massage of the gland, sialogogues and anti-inflammatory pain medications.
- CT scan is the preferred imaging modality for suspected sialolithiasis and can identify stones and evidence of infection.
- Sialadenitis is an associated infection of the salivary glands, and antibiotics such as amoxicillin/clavulanate or clindamycin should be added to the treatment regimen.

Neck Masses

- Neck masses in children are likely inflammatory or benign congenital abnormalities. In adults, neck masses commonly represent malignancies.
- Physical examination findings such as stridor, dysphagia, voice changes and referred pain can help localize symptoms and guide diagnostic approach.
- CT scan with contrast is the preferred initial imaging modality to characterize the neck mass and involvement of surrounding structures.
- Patients with airway compromise secondary to a neck mass warrant emergent airway management and ENT evaluation.
- Patients with hoarseness lasting greater than 2 weeks and patients with neck masses unresolved within 2 weeks should be evaluated in follow-up by an otolaryngologist.

OTITIS MEDIA

Foundations

Background and Importance

Otitis media is broadly defined as inflammation of the middle ear and is a continuum of disease. Acute otitis media (AOM) is characterized by the presence of a middle ear effusion with signs and symptoms of an acute infection. This has also been called acute suppurative or purulent otitis media. Otitis media with effusion (OME) describes a middle ear effusion without signs or symptoms of an acute infection. Chronic otitis media refers to prolonged discharge from the ear through perforation of the tympanic membrane (TM). Recurrent otitis media is defined by three or more episodes of AOM in 6 months or four episodes within 1 year.

AOM is one of the most common diseases affecting preschool children in the United States (US) and is the primary driver of pediatric antibiotic use in the outpatient setting.[1] The peak incidence is between 6 and 15 months of age.[2] Risk factors for the development of otitis media include male sex, non-Hispanic white race, daycare attendance and family history of recurrent otitis media.[3] Additional modifiable risk factors include parental smoking and pacifier and bottle use. Breastfeeding is shown to be protective.[4]

Children with anatomic abnormalities, such as cleft palate and Down syndrome, have a higher rate of OM, likely due to eustachian tube abnormalities. Pneumococcal vaccination in childhood has significantly decreased the incidence of both pneumococcal and non-pneumococcal cases of AOM.[4,5] AOM is less common in adults but the diagnostic and treatment approach is overall similar to that in children. OME is also less commonly seen in adults and is associated with head neck malignancy.

Anatomy and Pathophysiology

The eustachian tube, which lies between the middle ear cavity and nasopharynx, ventilates the middle ear to equilibrate pressure, allows for middle ear drainage, and provides protection from regurgitated nasopharyngeal secretions. The eustachian tube may become mechanically or functionally obstructed due to inflammation from an upper respiratory infection or due to anatomic factors, decreasing middle ear ventilation. This results in a negative middle ear cavity pressure, and fluid accumulates in the middle ear space. Colonized bacteria and respiratory viruses from the nasopharynx enter the middle ear cavity, leading to inflammation, further fluid accumulation and increased pressure; the signs and symptoms of AOM then follow.[6]

AOM is commonly a co-infection of viral and bacterial pathogens, and viruses have been isolated from middle ear aspirates in children in 70% of cases.[6] The most commonly isolated bacterial pathogens in AOM are *Streptococcus pneumoniae, Haemophilus influenzae* (primarily non-typeable), and *Moraxella catarrhalis*. The widespread use of the pneumococcal vaccination has changed the frequency of these common organisms, with *H. influenzae* increasing in frequency in some settings, particularly in persistent AOM and treatment failures. *H. influenzae* is also a common pathogen identified in cases of acute otitis media with TM perforation.[7] Rarer causative pathogens include *Streptococcus pyogenes, Staphylococcus aureus, Mycobacterium tuberculosis*, *Chlamydia trachomatis*, and gram-negative species.

In young infants with AOM, the associated bacterial pathogens are typically the same as in older children; however, in neonates, Group B *Streptococcus*, *S. aureus*, and gram-negative bacteria are also possible.[8]

Clinical Features

Ear pain, unilateral or bilateral, is the most important symptom for making the diagnosis of AOM. Patients with AOM may present with a multitude of symptoms, such as cough, upper respiratory tract symptoms, poor appetite, vomiting, fever, and pulling at the ears, all of which are nonspecific. In fact, there is no constellation of symptoms or scoring systems that reliably predict AOM, and examination of the tympanic membrane is essential to make the diagnosis.

During the physical examination, the auricle and external canal are inspected for signs of erythema, discharge, or tenderness. If the canal is occluded with cerumen, curettage or gentle irrigation may clear the canal to improve visibility. The TM in an uninfected ear may be pearly gray, pink, amber or blue. The presence of erythema, in itself, does not indicate infection since crying or fever may cause TM hyperemia. However, a TM that is distinctly or strongly erythematous suggests AOM. The presence of opacification, bubbles, air fluid levels, retraction of the TM, or lack of movement with pneumatic otoscopy are suggestive of a middle ear effusion. A moderate to severely bulging tympanic membrane is highly predictive of acute otitis media and represents the most important diagnostic characteristic.[4] A comparison examination of the other ear may help in confirming suspected infection.

Bullae may be seen on the TM in up to 5% of cases of AOM in children younger than 2 years. This condition is called bullous myringitis,

and while it was previously thought to be caused by *Mycoplasma pneumoniae,* cultures of middle ear aspirates in children with this condition generally yield the typical AOM pathogens. Thus, bullous myringitis is not treated differently than non-bullous cases of otitis media.

Children with purulent conjunctivitis may have concomitant AOM, a symptom complex known as otitis-conjunctivitis syndrome, which is predominantly caused by *H. influenza.*

In neonates, the TM is in a highly oblique position and normally appears thickened and opaque in the first few weeks of life. With tympanostomy tubes, even in the absence of infection, the TM may have decreased mobility, altered landmarks, opacity, or dullness. If the tube is patent, erythema and discharge indicate infection. If the tube is not patent, typical erythema, bulging of the TM, and immobility indicate AOM.

Severe complications of otitis media are categorized anatomically as intratemporal or intracranial, and they are both rare (less than 1% incidence) in the era of antibiotic treatment. Intratemporal complications include mastoiditis, facial nerve paralysis and conductive and perceptive hearing loss. Intracranial complications include meningitis and intracranial abscesses.[9] The development of each these complications may occur through direct extension of infection through diseased bone and blood vessels or extension of infection along existing pathways, such as the round or oval windows.

Spontaneous perforation of the tympanic membrane occurs in between 5% and 30% of cases of AOM and occurs more commonly in children with frequent episodes of OM and in those with a history of TM perforation. Perforation occurs most commonly anteriorly and inferiorly at the pars tensa and resolves rapidly and spontaneously, generally without residual clinical problems.[7] However, AOM with perforation can result in a persistent TM defect, chronic otitis media, or both.

Chronic otitis media (COM) refers to inflammation of the middle ear that persists for 6 weeks or longer, accompanied by discharge through a perforated membrane. Chronic TM perforation may allow keratin-producing squamous epithelium to migrate into and accumulate in the middle ear, resulting in cholesteatoma. More commonly, cholesteatoma results from chronic OME in which retraction of the TM results trapped pockets of keratin-producing epithelial cells behind the tympanic membrane. Cholesteatoma may result in hearing loss, temporal bone destruction and cranial invasion.[10]

Differential Diagnoses

AOM is uncommon in children younger than 6 months as a result of the protection of maternal antibodies. Other sources of infection should be investigated in a febrile, ill-appearing infant. In addition to AOM, other causes of otalgia include OME, trauma, foreign bodies, and complications of OM, such as mastoiditis and referred pain from the teeth, sinuses, throat, or temporomandibular joint (Box 58.1).

Diagnostic Testing

The primary diagnostic modality for AOM is direct visualization with pneumatic otoscopy to confirm bulging and immobility of the TM.

BOX 58.1 Differential Diagnosis of Acute Otitis Media

Otitis media with effusion
Trauma
Otic foreign bodies
Mastoiditis
Otitis externa
Referred pain from teeth, sinuses, throat or temporomandibular joint

Management

The American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) published updated guidelines for the diagnosis and management of AOM in children in 2013 and reaffirmed in 2019.[4] These guidelines address diagnosis, pain management, observation, and antibiotic recommendations and apply to healthy children, not those with anatomic conditions that put them at risk for infection. The guidelines were developed by a multispecialty panel, and we believe are both reasonable and applicable to emergency medicine practice.

AOM can cause substantial pain, which should be appropriately addressed. Antibiotic treatment does not reduce the patient's pain during the first 24 hours of treatment, so analgesics are usually required.[2,4] Acetaminophen and ibuprofen are safe and available over the counter and are first-line analgesics in most cases. Each agent has been shown to be more effective than placebo at reducing pain, and the adverse events do not appear to differ between these analgesics for this indication. There is insufficient evidence to recommend combination therapy with ibuprofen and acetaminophen over monotherapy.[11] Topical therapies, such as lidocaine drops have been shown to demonstrate a brief improvement in pain, however, the dose is not well-established.[4] Antiyprene-benzocaine and other benzocaine-containing topical otic analgesics used have been removed from the US market by the Food and Drug Administration (FDA), as many of these medications were not evaluated or approved by the FDA for efficacy or safety.[12]

Children younger than 2 years, those with bilateral disease, or those with associated otorrhea gain the greatest benefit from antibiotic treatment for AOM. However, approximately 80% of cases of AOM resolve spontaneously, and the use of observation in lieu of immediate antibiotics has been advocated.[2] In appropriate cases (see following), antibiotics can be deferred, and parents can be instructed to follow-up in 48 to 72 hours there is no improvement or if clinical worsening develops. Alternately, an antibiotic prescription may be given with the instruction to fill it if there is no improvement (or worsening) within 48 to 72 hours. This is sometimes referred to as the "wait-and-see" or "safety net" prescription. Observation for AOM has been demonstrated to reduce antibiotic exposure and healthcare costs, and has not been shown to increase the risk of complications.[2,13–15]

Observation in lieu of immediate antibiotics can be considered in healthy children older than 6 months if certain criteria are met. In children between 6 months to 2 years of age, observation can be offered as an alternative to antibiotics if the infection is unilateral and the patient is absent severe signs and symptoms or otorrhea. Severe signs and symptoms are defined as moderate-to-severe otalgia of greater than 48 hours duration and temperature greater than 39°C. In children older than 2 years, observation may be offered in the absence of severe illness or otorrhea. Observation decisions must also take into account the reliability of the caregivers and ability to ensure close follow-up, and shared decision with caregivers should be used. Table 58.1 summarizes the AAP recommendations.

Antibiotics are modestly more effective than placebo for AOM in reducing pain after 24 hours, but treatment benefits should be weighed against adverse effects from the treatment itself. Diarrhea and rash occur more commonly in patients treated with antibiotics compared to those treated with placebo or observation.[2,4,16] Rates of serious complications of AOM have not been shown to differ between antibiotic treatment and observation or placebo.[2,14] Observation in appropriately selected patients remains a safe practice, and we recommend the continued use of this strategy. It is important to note the lack of data supporting the use of observation in adult patients, and antibiotics are recommended as a first-line treatment for AOM in adults.

Amoxicillin is the most cost-effective treatment for AOM, has a favorable side effect profile, and is generally palatable to children.[17,18] We

TABLE 58.1 Recommendations for Initial Management for Uncomplicated Acute Otitis Media

Age	Otorrhea With AOM	Unilateral or Bilateral AOM With Severe Symptoms[a]	Bilateral AOM Without Otorrhea	Unilateral AOM Without Otorrhea
6 months to 2 years	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation[b]
≥2 years	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation [b]	Antibiotic therapy or additional observation [b]

[a]Toxic-appearing child, persistent otalgia >48 h, temperature >39°C (102.2°F) in the past 48 h, or if there is uncertain access to follow-up after the visit.
[b]Should be a shared decision with caregivers, and a mechanism must be in place to ensure follow-up and antibiotics if the child worsens or fails to improve within 48–72 h of AOM onset.
AOM, Acute otitis media.
Adapted from Lieberthal AS, Carroll AE, Chonmaitree T, et al. Clinical practice guideline: the diagnosis and management of acute otitis media. *Pediatrics.* 2013;131:e964–e999.

recommend amoxicillin as the first-line antibiotic in the non–penicillin-allergic pediatric patient. It is dosed at 80 to 90 mg/kg/day in two divided doses. This dose is preferred because it is effective against susceptible and intermediately resistant strains of *S. pneumonia*, and because only 15% to 20% of children have poor gastrointestinal absorption of amoxicillin.

In patients with reported penicillin allergies, it is important to ascertain the specifics and severity of prior reactions. There is only minimal cross-reactivity to cephalosporins for patients with a penicillin allergy, and the use of a second- or third-generation cephalosporin is generally considered safe in this setting, unless the child has a previous adverse reaction to cephalosporins or has a history of severe allergic reaction to penicillin. In patients with non-severe penicillin allergy history, alternate treatment options include cefdinir (14 mg/kg/day in one or two divided doses), cefuroxime (30 mg/kg/day in two divided doses), cefpodoxime (10 mg/kg per day in 2 divided doses), and ceftriaxone (50 mg/kg once daily for 3 days, max 1000 mg/day) IM or IV for 3 days.

In pediatric patients with cephalosporin allergy, or in those with history of severe penicillin allergy, alternate outpatient choices are limited, but macrolides and clindamycin are possible options. However, these agents have less favorable spectra of coverage for AOM pathogens. Macrolides have limited activity against *S. pneumoniae* and *H. influenzae*, and clindamycin has limited coverage of *H. influenzae*. Despite these limitations, these agents are preferred in patients with severe penicillin allergy. Clindamycin is dosed at 30 to 40 mg/kg/day divided TID, and azithromycin is given at 10 mg/kg for an initial dose, followed by 5 mg/kg for days 2 through 5.

Children who have taken amoxicillin in the previous 30 days, or those with concurrent conjunctivitis, or those in whom coverage of β-lactamase–positive *H. influenzae* and *M. catarrhalis* is desired should be initially treated with amoxicillin-clavulanic acid (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate, divided TID).

Patients should be reevaluated in 3 days if there is no improvement. Treatment failure is defined by a lack of improvement in signs and symptoms. The reasons for treatment failure may include an incorrect initial diagnosis or antibiotic resistance. In these cases, antibiotic agents effective against the β-lactamase–producing organisms *H. influenzae* and *M. catarrhalis* should be utilized. Recommended antibiotics include amoxicillin-clavulanate (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate) or IM or IV ceftriaxone (50 mg/kg IV or IM once daily for 3 days). Table 58.2 summarizes the AAP/AAFP guidelines for antibiotic treatment.

Patients with AOM for whom treatment with appropriate β-lactam antibiotics has failed, or in patients with cephalosporin or severe penicillin allergies for whom macrolide or clindamycin therapy has failed should be referred to a pediatric infectious disease specialist or otolaryngologist.

AOM treatment historically involved a 10-day course of oral antibiotics, but studies have demonstrated similar efficacy for shorter courses of treatment with less side effects for non-severe cases of AOM.[4,19] Patients younger than 2 years, those with TM perforations, or those with chronic or recurrent infections should be treated with a 10-day course. Children older than 2 years with a first-time infection, non-severe signs and symptoms and an intact TM can be treated with a 7-day course. Antibiotic treatment choices for AOM in adults mirror those used in children. The use of antihistamines, decongestants, or steroids are not recommended for the treatment of an acute episode of otitis media.

Patients with AOM associated with otorrhea secondary to acute TM perforation are treated with an oral antibiotic, following the same recommendations as for AOM with an intact membrane. There is no advantage to adding topical antibiotic therapy in this situation.

Tympanostomy tubes may be used in cases of recurrent or complicated AOM, and this represents one of the most common operative procedures for children in the United States. Such patients may present with otorrhea, and in general, increased drainage from a tympanostomy tube represents an acute infection. The organisms involved are usually the same that cause AOM, particularly in children younger than 2 years. *Pseudomonas aeruginosa, S. aureus, and Staphylococcus epidermidis* may also be seen. In the acute setting, topical antibiotic administration with ofloxacin (5 drops to the affected ear bid for 10 days) or ciprofloxacin-dexamethasone (four drops to affected ear bid for 7 days) is the preferred treatment, as these medications may be used in patients with a non-intact TM. Systemic treatment should be reserved for patients showing signs of complicated or invasive infections or signs of systemic disease.

Chronic suppurative otitis media is characterized by chronic middle ear inflammation and otorrhea associated with a TM perforation. It is one of the most common childhood infectious diseases worldwide and a leading cause of hearing impairment in resource limited settings. *P. aeruginosa and S. aureus* are common etiologic pathogens. Topical ofloxacin or ciprofloxacin are the recommended antibiotic treatments.

After a 10-day course of antibiotics, patients may demonstrate a middle ear effusion, but the majority of these cases resolve spontaneously. Patients with OME are generally observed with serial follow-up to reassess for significant hearing loss or structural abnormalities. Antibiotics, antihistamines, decongestants and steroids offer little or no benefit and are not recommended. Tympanostomy tubes may be beneficial in children with persistent OME with hearing loss, those with structural damage to the TM and middle ear, and in children at risk for speech, language, or hearing problems. Adenoidectomy may also be offered in specific cases.[20–22]

Disposition

Patients with acute otitis media should be seen in 48 to 72 hours if there is no improvement in symptoms. Children who improve can

TABLE 58.2 Recommended Antibiotics for Initial Treatment of Pediatric Patients With Acute Otitis Media and in Those Who Have Failed Initial Antibiotic Treatment

INITIAL ANTIBIOTIC TREATMENT		IF FAILURE OF INITIAL ANTIBIOTIC TREATMENT	
First Line	**Alternate[a]**	**First Line**	**Alternate**
Amoxicillin (80–90 mg/kg/day in two divided doses)	Cefdinir 14 mg/kg/day in one or two doses	Amoxicillin-clavulanate 90 mg/kg/day of amoxicillin, with 6.4 mg/kg/day of clavulanate in 2 to 3 divided doses	Ceftriaxone 50 mg/kg IM or IV once daily for 3 days
Amoxicillin-clavulanate[b] (90 mg/kg/day of amoxicillin, with 6.4 mg/kg/day of clavulanate in 2 to 3 divided doses)	Cefuroxime 30 mg/kg/day in two divided doses	Ceftriaxone 50 mg/kg IM or IV once daily for 3 days	Clindamycin 30–40 mg/kg/day in three divided doses with third-generation cephalosporin[c]
	Cefpodoxime (10 mg/kg/day in two divided doses)		Tympanocentesis Consult specialist[d]
	Ceftriaxone 50 mg/kg IM or IV once daily for 1 or 3 days		

[a]Consider in penicillin allergy. Cefdinir, cefuroxime, and ceftriaxone are highly unlikely to be associated with cross-reactivity with penicillin allergy on the basis of their distinct chemical structures.
[b]May be considered initially for patients who have received amoxicillin in the previous 30 days or who have otitis-conjunctivitis syndrome.
[c]If failure of second antibiotic.
[d]Perform tympanocentesis and drainage if skilled in the procedure or seek a consultation from an otolaryngologist for tympanocentesis and drainage. If the tympanocentesis reveals multidrug-resistant bacteria, seek and infectious disease specialist consultation.

be followed up in 8 to 12 weeks to ensure resolution of any residual effusion. Children with complications of AOM warrant referral to an otolaryngologist. Adults who have persistent OME warrant otolaryngology referral to rule out nasopharyngeal carcinoma.

OTITIS EXTERNA

Foundations

Otitis externa (OE) is inflammation of the external auditory canal. The external auditory canal is lined with squamous epithelial cells and cerumen glands that provide a protective lipid layer. This protective layer may be disrupted by high humidity, increased temperature, maceration of the skin after prolonged exposure to moisture, and local trauma (cotton swabs or the use of hearing aids), resulting in the introduction of bacteria. Otitis externa (OE) is most commonly caused by *P. aeruginosa* and *S. aureus,* including methicillin-resistant *S. aureus*.[23,24] It occurs most often in the summer and in tropical climates and is also referred to as swimmer's ear or tropical ear.

Clinical Features

The diagnosis of OE is made clinically. The external auditory canal (EAC) may initially be pruritic and progress to ear pain. Additional symptoms include ear fullness, discharge, hearing loss or jaw pain. On otoscopy, the EAC will often appear erythematous and edematous. Manipulation of the auricle or tragus classically reproduces the discomfort. Debris or cerumen visible within the EAC may be yellow, brown, white, or gray. There may be associated lymphadenitis, TM erythema, or local cellulitis. Clinical assessment should include history related to immunocompromise, diabetes mellitus, TM tubes or non-intact TM, as these factors may modify management of OE.[25]

Differential Diagnoses

It may be difficult to distinguish OE from AOM with perforation and otorrhea, particularly in children. The TM may be erythematous in both conditions, and a TM perforation may be small and difficult to visualize in AOM with otorrhea. EAC edema may preclude a full view of the TM, and EAC discharge may appear similar in each condition. EAC pain with traction of the pinna and severe pain with otoscopy points more towards a primary external otitis. In equivocal cases, it is reasonable to treat for both conditions.

Otomycosis is a fungal infection of the ear canal and can occur as a primary or secondary infection and accounts for 10% of cases of OE. Itching is the prominent symptom, often with minimal pain or otorrhea. *Aspergillosis* and *Candida* are the causative organisms in most cases. Otomycosis usually affects individuals in tropical climates, those with diabetes, and immunocompromised patients.

Furunculosis is a small, erythematous, and well-circumscribed infection of the cartilaginous portions of the external canal, usually caused by *S. aureus.* Auricular cellulitis may cause erythema, induration, and other systemic infectious signs.

Skin conditions such as eczema, seborrhea, and contact dermatitis can all mimic OE. A careful dermatologic history, as well as medication and exposure history, should be elicited. Exposure to reactive metals from devices such as hearing aids, chemicals from cosmetics and shampoos are also differential considerations.

Herpes zoster oticus, also known as Ramsay-Hunt syndrome, is a manifestation of varicella zoster reactivation affecting the auricle, with resulting facial paralysis that may involve multiple cranial nerves. It initially causes pain, erythema, and swelling, with vesicles developing approximately 3 to 7 days later (Box 58.2).

Diagnostic Testing

OE is a clinical diagnosis. Generally, additional diagnostic testing is not indicated.

Management

Treating OE involves cleaning the canal and treating the infection. The external canal may be cleaned with a small cotton swab or combination of gentle suctioning and irrigation, depending on the degree of obstructing exudate and whether there is an intact TM.

Contact dermatitis
Herpes zoster oticus
Necrotizing external otitis

Topical antibiotics are highly effective for treatment of OE, and they remain the mainstay of therapy for uncomplicated cases, with clinical cure rates of 65% to 90% within 10 days. The addition of systemic antibiotics to topical therapy does not improve cure rate in uncomplicated OE and is not indicated in most immunocompetent hosts with infection localized to the EAC. Co-administration of topical and systemic antimicrobials are reserved for cases in which the infection extends beyond the ear canal, or in patients with significant immunocompromise, including those with poorly controlled diabetes.[25] In situations where systemic antibiotics are indicated, ciprofloxacin (adult dosage, 500 mg BID for 7 to 10 days) is recommended, in combination with topical antibiotic drops.

Many effective FDA-approved ototopical antibiotics are available, and cost and side-effect profile should be considered when choosing a drug. While there is not strong evidence for the superiority of any one agent, fluoroquinolone-containing drops may have a modest advantage in bacteriologic cure rates.[25] Otic corticosteroids can reduce inflammation and the duration of ear pain in OE, and several otic drops are available as a combination corticosteroid and antibiotic. However, the addition of a steroid formulation to antibiotics alone has not been shown to change clinical cure rate.

Fluoroquinolone otic drops are effective against common OE pathogens, including *P. aeruginosa* and *S. aureus*, and demonstrates adequate activity against MRSA at the high concentrations delivered by topical therapy.[26] Quinolone drops may also be used in the setting of a non-intact TM, in contrast to otic aminoglycosides, which are contraindicated in this situation due to their ototoxicity. We recommend ofloxacin otic at a dose of 5 drops in the affected ear(s) QD for 7 days in children less than 13 years and 10 drops in the affected ear(s) QD for 7 days in those older than 13 years. A reasonable alternative is ciprofloxacin plus dexamethasone (Ciprodex), at a dose of 4 drops in the affected ear(s) BID for 7 days.

Fluoroquinolone otic drops are relatively costly, and polymyxin B, neomycin, and hydrocortisone (Cortisporin) suspension is an effective and less expensive alternative, dosed as 3 drops to the affected ear TID or QID. This medication should not be given in patients with a TM perforation due to ototoxicity, and some patients to may develop cutaneous sensitivity to the neomycin component.

Having the patient lie down for 5 minutes after the otic solution has been placed can improve drug delivery. Commercially available wicks made of compressed cotton or hydroxycellulose can also be placed to facilitate medication delivery. If available, these should be inserted when EAC swelling is significant enough that drops could encounter difficulty entering the ear canal. The wick is inserted 10 to 12 mm into the canal, moistened with antibiotic drops, and left in place for 2 to 3 days pending follow-up. OE is often painful, and analgesia should be appropriately addressed.

Disposition

Patients with OE rarely require admission. Patients should be followed for symptom improvement within 2 to 3 days. If there is clinical worsening or no response to therapy, resistant organisms or other conditions such as necrotizing external otitis should be considered. Patients who have a wick placed should be evaluated in 2 to 3 days to reassess and to ensure removal of the wick.

NECROTIZING (MALIGNANT) EXTERNAL OTITIS

Foundations

Necrotizing external otitis (NEO) is an aggressive form of OE, also known as malignant OE, due to its relatively high rate of morbidity and mortality. This disease is most commonly seen in patients with advanced age, immunocompromise, and in particular, diabetes mellitus. In a recent national inpatient database review, diabetes was a comorbidity in 55% of cases of NEO.[27] *P. aeroginosa* is the predominant pathogen, identified in the majority of cases.[28–33] *S. aureus, S. epidermidis, Proteus mirabilis,* and *Aspergillus* have also been described as causative organisms. The infection begins in the external canal and progresses through the periauricular tissue and cartilaginous bony junction of the external auditory meatus. It may spread to the base of the skull at the temporal bone, with a resultant osteomyelitis of the skull base. The facial nerve is the first cranial nerve affected, but other nerves may also be involved.[34] The pathogenesis is uncertain but may be related to vascular insufficiency or immune dysfunction.

Clinical Features

Patients may have persistent otorrhea unresponsive to topical medications, severe otalgia, headache, and periauricular pain and swelling. The diagnosis should be considered for at-risk patients who have a prolonged course of OE. The characteristic clinical finding is granulation tissue on the floor of the ear canal at the bony cartilaginous junction. Cranial nerve VII is most commonly involved, and this manifests as facial paralysis. Further extension can result in involvement of the additional cranial nerves. Cranial nerve involvement is not associated with increased mortality from NEO.[31] Additional complications include meningitis, brain abscess, and thrombosis of the sigmoid sinus.

Differential Diagnoses

Differential considerations include severe OE, otitis media, mastoiditis, trauma, and referred pain from the teeth, sinuses, throat or temporal mandibular joint (Box 58.3).

Diagnostic Testing

There is no single diagnostic criterion for necrotizing external otitis. The diagnosis is made from a range of clinical, laboratory, and radiographic findings. The C-reactive protein level and erythrocyte sedimentation rate may be elevated, but they are nonspecific markers. In the ED, computed tomography is the initial study of choice and, in most cases, will identify bony erosion and soft tissue abnormalities. Magnetic resonance imaging can be helpful in determining the full extent of disease and evaluating for intracranial complications, and gallium nuclear medicine scans are helpful in evaluating treatment response.[35]

Management and Disposition

If NEO is suspected, systemic antibiotic therapy should be initiated, and consultation should be made with an otolaryngologist. Ciprofloxacin 400 mg IV every 12 hours can be given as monotherapy, or in combination with an antipseudomonal β-lactam depending on the severity of illness and local *Pseudomonas* resistance to fluoroquinolones. Piperacillin-tazobactam (4.5 g IV every 6 hours) or cefepime (2 g IV every 6 hours or 2 g extended infusion every 8 hours) are appropriate options for combination therapy with ciprofloxacin. Treatment may be required for 6 to 8 weeks. Although extensive surgical treatment was previously required, surgical intervention

is now used in a minority of cases, particularly to obtain cultures, debride necrotic tissue or if medical management is failing.[27,31]

Patients are generally managed initially in an in-patient setting in consultation with an otolaryngologist.

MASTOIDITIS

Foundations

Mastoiditis is the most common suppurative complication of otitis media, although the incidence of acute and chronic mastoiditis has decreased significantly since the advent of antibiotics, and it is rare in the modern era.[36–38] Acute mastoiditis may occur with or without known preceding acute otitis media, and may occur as a complication of leukemia, mononucleosis, sarcoma of the temporal bone, and Kawasaki disease. It has also been described as a complication of cochlear implant placement.[39]

The middle ear and mastoid air cells are connected by the aditus ad antrum. If this narrow connection becomes obstructed, a closed space is formed with the potential for mastoid abscess development and bone destruction. Infection may spread from the mastoid air cells by venous channels, resulting in inflammation of the overlying periosteum. Progression results in the destruction of the mastoid bone trabeculae and coalescence of the cells, resulting in acute mastoid osteitis or coalescent mastoiditis.

Data are conflicting as to whether the incidence of mastoiditis has decreased in the post-pneumococcal vaccine era, and *S. pneumoniae* continues to be a leading cause of acute mastoiditis. Group A streptococcus is another commonly isolated pathogen. *P. aeruginosa*, *S. aureus* and *Fusobacterium necrophorum* are important emerging pathogens, particularly in patients who have recently received antibiotics.[37,40–42]

Clinical Features

Clinical findings in acute mastoiditis include fever, headache, otalgia, and erythema. Pain is nearly always present. There are no specific diagnostic criteria, but the most common physical findings are postauricular erythema and tenderness, protrusion of the auricle, and an abnormal TM. The TM is similar to that seen in AOM—erythema, bulging, and decreased mobility—but may be normal in 10% of cases. Suspicion should be heightened if symptoms of AOM have lasted longer than 2 weeks.

Differential Diagnoses

The differential diagnosis of mastoiditis includes severe otitis media, external otitis, skull fracture, posterior auricular lymphadenopathy or lymphadenitis, and deep space neck infections (Box 58.4).

Diagnostic Testing

Although the diagnosis of mastoiditis can be made clinically in patients with typical findings, a CT scan is indicated in patients with neurologic symptoms suggestive of intracranial extension or when there is failure to improve with conservative therapy.[43] Fig. 58.1 is a CT scan demonstrating acute mastoiditis.

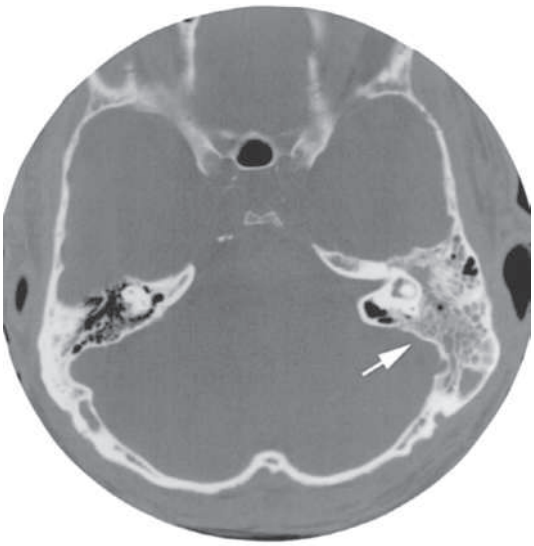

Fig. 58.1 CT Scan of Mastoiditis. (From McWhorter AJ, Limb CJ, Niparko JK. Otologic and skull base emergencies. In: Eisele DW, McQuone SJ, eds. *Emergencies of the Head and Neck*. St. Louis: Mosby; 2000:384.)

Management and Disposition

Parenteral antibiotics should be administered to patients with suspected mastoiditis. In patients without recurrent acute otitis media or recent antibiotic use, vancomycin at a dose of 15 mg/kg IV is recommended. In patients who have had an episode of acute otitis media within the past 6 months, or in patients with recent antibiotic use, we recommend the addition of an antibiotic with activity against *P. aeruginosa*, such as cefepime, at a dose of 50 mg/kg IV (max 2 g) in pediatric patients, or 2 g IV in adults. Patients may be managed with or without surgical procedures which may range from myringotomy and tympanostomy tube placement to mastoidectomy.[44]

Hospitalization is usually necessary for the administration of IV antibiotics. Early otolaryngologic referral is also advised for possible aspiration and drainage of the middle ear, as well as the management of any potential complications.

SUDDEN HEARING LOSS

Foundations

Sudden sensorineural hearing loss (SSNHL), defined as the idiopathic loss of hearing of 30 dB over at least three test frequencies, occurring over a period of less than 3 days, is considered an otolaryngologic emergency. Any age group can be affected, but the peak incidence occurs in the fifth or sixth decade of life, with an equal gender distribution. Its severity ranges from difficulty with conversation to complete hearing loss.

SSNHL is idiopathic in 70% of cases. It may also be secondary to infection, otologic disease, trauma, vascular disease, hematologic disorders, or neoplasm. A delay in diagnosis is common because the patient may report ear fullness that is often attributed to cerumen impaction or congestion from upper respiratory infections. Tinnitus is a common finding. The likelihood of recovery is related to the severity of the hearing loss, age of the patient, and associated vestibular symptoms.[45] A history should include the time of onset, history of trauma or recent illnesses, medications, and presence of otologic and neurologic symptoms.

Clinical Features

The physical examination includes a thorough inspection of the external canal and TM integrity. Weber's test for hearing and Rinne's test may help in distinguishing conductive versus sensorineural deficits. A comprehensive neurologic examination, including cranial nerve and cerebellar testing, may localize brainstem involvement.

Differential Diagnoses

The differential diagnosis for hearing loss is broad and can be differentiated into causes that involve the outer, middle, or inner ear. Outer ear causes include cerumen impaction and OE. Middle ear causes include otitis media and tympanic membrane perforation. Inner ear causes include medications, barotrauma, and autoimmune disease (Box 58.5).

Diagnostic Testing

Laboratory testing and imaging are not indicated in the ED evaluation unless the physical examination points to a space-occupying lesion (i.e., focal neurologic deficits not referable to the ear). MRI with gadolinium is the study of choice to identify retrocochlear pathology and is more likely diagnostic when the patient has associated vertigo.[46]

Management and Disposition

A tapered dose of oral steroids is the most common treatment, ideally given within the first 14 days but may have benefit up to weeks after the onset.[47] The usual dose and the one we recommend is prednisone 1 mg/kg/day, up to 60 mg, tapered over 10 to 14 days. Additional treatments include hyperbaric oxygen therapy and steroids, intratympanic steroids or a combination of both oral and intratympanic steroids by providers who can offer them.[48] Patients should be counselled on the limitations of these treatments and the possibility that the hearing may not recover, though some improvement is observed in 32% to 65% of patients.[49]

Patients should receive expeditious ENT referral on discharge from the ED.

EPISTAXIS

Foundations

Epistaxis is a common otolaryngologic problem, although only a minority of patients experiencing a nosebleed will require emergency care, and death from epistaxis is exceedingly rare. Epistaxis has a bimodal distribution, with peaks in childhood and in elders.[50] Incidence is higher in winter months and in colder geographic locations. This effect may be attributable to dry air from indoor heating, which desiccates nasal mucosa, and the effect of cold temperature on coagulation.[51] Epistaxis can be quite distressing to patients, and a thorough understanding of nasal anatomy, pathophysiology and treatment allow for prompt and efficient management of the disorder.

Anterior epistaxis accounts for 90% of all nosebleeds and usually involves Kiesselbach's plexus on the anteroinferior nasal septum. Anterior epistaxis is typically unilateral. Posterior epistaxis accounts for about 10% of cases and differs from anterior bleeding in that it is more severe and occurs mostly in older adults with multiple comorbidities.

Three arteries with anastomoses between them supply the nasal area (Fig. 58.2). The sphenopalatine artery supplies the turbinates and meatus laterally and the posterior and inferior septum medially. This artery is identified in a majority of cases of severe posterior epistaxis.[52] The anterior and posterior ethmoidal arteries from the ophthalmic branch of the internal carotid artery supply the superior mucosa medially and laterally. The superior labial branch of the facial artery provides circulation to the anterior mucosal septum and anterior lateral mucosa.

Clinical Features

Initial evaluation of epistaxis focuses on airway patency, tissue perfusion and hemodynamics, and abnormalities should be addressed immediately if identified. History should specify the timing, frequency, and severity of bleeding. Additional pertinent history with regard to trauma, comorbidities, and medications should be elicited. Bleeding disorders and use of anticoagulant and antiplatelet medications are a significant risk factor for epistaxis and are associated with bleeding recurrence.[53-58] Patients often are anxious, and an elevated blood pressure is commonly seen in individuals presenting with epistaxis; however, studies have not established a causal relationship between hypertension and epistaxis. When elevated blood pressure is present, however, it may be associated with persistent epistaxis.[59,60]

During physical examination, efforts should be made to identify the source of bleeding, as this allows for application of chemical cautery in appropriate patients, which decreases risk of recurrent bleeding. To optimize physical examination of the nares in an actively bleeding patient, instruct the patient to blow their nose, and then apply bilateral pressure on the nasal septum by compressing the cartilaginous part of the nose for 10 to 15 minutes.

A nose clip can be used, and this technique has been shown to be superior to manual pressure alone.[61] Administering two sprays of 0.05% oxymetazoline into the affected naris before applying pressure will optimize hemostasis and facilitate inspection after the pressure is released.

BOX 58.5 Differential Diagnosis of Sudden Sensorineural Hearing Loss

- Cerumen impaction
- Otitis externa
- Otitis media
- Tympanic membrane perforation
- Medication side effects or toxicity
- Barotrauma
- Autoimmune disease

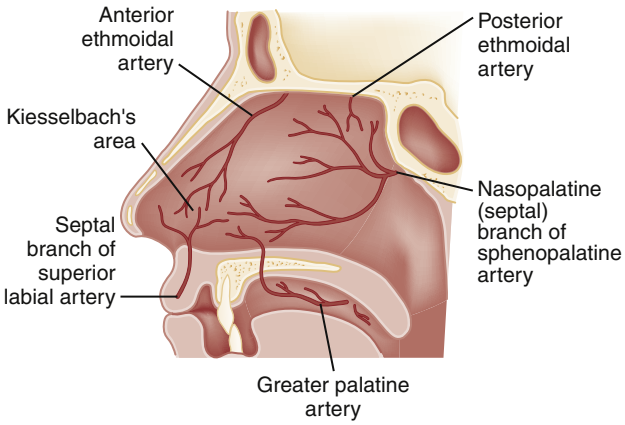

Fig. 58.2 Arterial Supply to the Medial Wall of the Nose.

This simple maneuver also educates the patient on how to self-manage further episodes. While pressure is being applied, materials for illumination, suction, visualization, and treatment should be assembled.

Upon examination, the floor of the nose should be parallel to the room floor. If the head is tilted, only the anterior and upper aspect of the nares can be visualized. A nasal speculum, if used, should be opened in a vertical direction rather than side to side in the nares, so as not to obscure the septum.

Differential Diagnoses

There are many etiologies of epistaxis, but the most common are an upper respiratory infection with associated mucosal vasodilation and trauma, either accidental or iatrogenic.

The differential diagnosis also includes nasal foreign bodies and clotting and vascular disorders. In children less than the age of 2, epistaxis is rare, and special consideration should be given to non-accidental trauma and bleeding disorders (Box 58.6).[62,63]

Diagnostic Testing

In most cases of epistaxis, diagnosis is made clinically, and diagnostic imaging and laboratory studies are not routinely indicated. Consideration of laboratory testing, including coagulation studies, should be reserved for patients on anticoagulant medications, those with severe hemorrhage or significant underlying medical conditions, such as advanced liver disease or hematologic malignancy that may contribute to coagulopathy or thrombocytopenia.

Management

Identifying and treating the source of epistaxis bleeding is important, as failure to identify the locus of hemorrhage is a significant risk factor for recurrent bleeding. Ahead of further intervention, a topical anesthetic agent, such as 2% aqueous lidocaine, should be applied via mucosal atomization or soaked gauze. When combined with a vasoconstrictive agent, this facilitates additional examination and hemostatic treatments.[64] If the bleeding site is identified, chemical cautery with silver nitrate should be considered, as it has been shown to be effective, with a low rate of re-bleeding compared with other treatment modalities.[58] Silver nitrate cautery is likely to be unsuccessful during active bleeding, so hemostasis is secured first. The area is cauterized from the periphery to the center and superiorly to inferiorly to avoid blood, which renders the silver nitrate sticks ineffective. Contact with mucosa should not be maintained longer than 15 seconds because septal damage may occur. Bilateral application of silver nitrate to the septum is not advised because it may deprive the septum of a blood supply and theoretically could lead to necrosis. If cautery is unsuccessful, apply topical thrombogenic agents, such as absorbable gelatin sponge (Gelfoam) and absorbable knitted fabric (Surgicel).

If bleeding persists, proceed to tamponade with an anterior nasal packing device. Options include polyvinyl acetal nasal tampons, such as the Merocel device (Medtronic, Inc, Minneapolis, MN) or inflatable nasal balloons, such as the Rapid Rhino device (Smith & Nephew, Austin, TX), which are coated in a procoagulant material. Such nasal balloon devices are self-lubricating once moistened; application of additional lubricant is unnecessary. They are inserted along the floor of the nose and inflated with air. For uncontrolled bleeding despite the presence of an adequately applied anterior tampon, a second anterior tampon should be inserted into the opposite naris.[65]

Topical tranexamic acid may also be used in the treatment of acute epistaxis, either as an adjunct to, or in place of packing or other hemostatic agents. Tranexamic acid functions by inhibiting fibrinolysis and has demonstrated effectiveness in a number of other clinical bleeding scenarios. A recent systematic review and meta-analysis evaluating topical tranexamic acid in the treatment of epistaxis found moderate quality evidence to support the benefit of topical tranexamic acid in reducing bleeding at 10 minutes and re-bleeding at 7 to 10 days when combined with standard care alone. There was no significant increase in adverse events among patients treated with tranexamic acid.[66-68] In one trial included in this meta-analysis, topical tranexamic acid was demonstrated to be superior to anterior nasal packing specifically in patients taking antiplatelet drugs.[69] While the dosing of topical tranexamic acid has not been standard across trials, several trials have used a dose of 500 mg of the intravenous tranexamic acid solution applied to a nasal pledget or atomized into the nose.[69–71]

Posterior epistaxis is suggested when bleeding persists in the setting of properly placed anterior nasal packing. In this case, placement of a posterior pack is necessary with a commercially available double balloon catheter device.[65] Double balloon catheters generally consist of a separately inflatable anterior and posterior portion. They are inserted along the floor of the nose after adequate topical anesthesia has been achieved. The posterior balloon is then inflated, and the device is gently seated by pulling anteriorly. The anterior balloon is then slowly inflated to a degree tolerable by the patient.

If a commercial double balloon catheter device is unavailable, a standard Foley catheter may be inserted into the nasopharynx, partially inflated with 5 to 7 mL of water, and then pulled anteriorly with an additional 5 to 7 mL of water added to the balloon if needed, but caution should be exercised to avoid pressure necrosis. Fig. 58.3 illustrates treatment of posterior epistaxis.

If these techniques do not provide successful hemorrhage control, otolaryngologic consultation is necessary. Surgical ligation has been the treatment of choice for intractable bleeding, but endovascular embolization has emerged as a treatment alternative and has a reported success rate of greater than 80%.[72] The decision to choose embolization over surgery is influenced by factors such as patient comorbidity, presence of anticoagulation, institutional experience, patient preference, and health care costs. Embolization is preferred in patients with chronic coagulation disorders and those being treated with antiplatelet/anticoagulation therapy that cannot be interrupted.[73,74]

Prophylactic antibiotics remain in common use following nasal packing, given concerns for toxic shock syndrome from *S. aureus* as well as otitis media and sinusitis. However, there are no published reports

BOX 58.6 Causes of Epistaxis

- Nasal or facial trauma
- Upper respiratory tract infections
- Nose picking
- Allergies
- Low home humidity
- Nasal polyps
- Foreign body in the nose
- Environmental irritants
- Neoplasms
- Surgery (postoperative epistaxis)
- Anticoagulant or antiplatelet therapy
- Barotrauma
- Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease)
- Blood dyscrasias
- Hepatic disease
- Alcoholism
- Vitamin K deficiency
- Folic acid deficiency
- Chemotherapy
- Chronic use of nasal vasoconstrictors
- Cocaine use

EPISTAXIS MANAGEMENT: POSTERIOR PACKING WITH INFLATABLE DEVICES

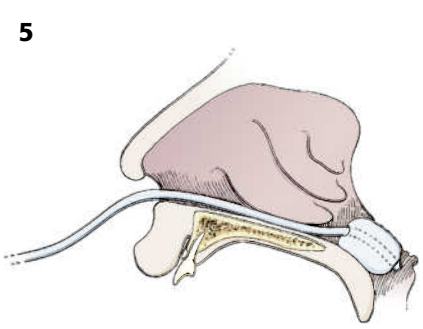
A

Insert a 12-Fr Foley catheter through the naris and into the posterior pharynx.

Look into the mouth to confirm that the catheter is properly positioned.

Inflate the balloon halfway with about 5–7 mL of water.

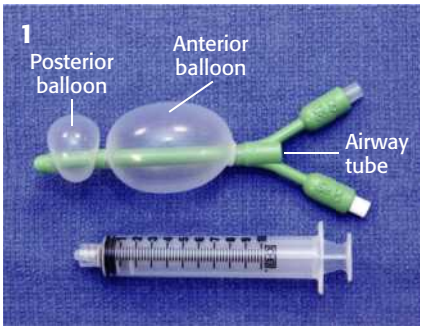
Slowly pull the catheter into the posterior nasopharynx up against the posterior aspect of the middle turbinate.



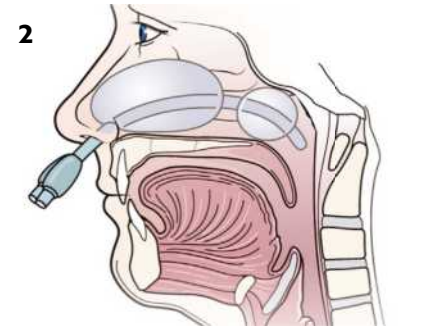
Foley catheter in proper position in the posterior nasopharynx. Inflate the balloon with another 5–7 mL of water.

While maintaining traction, place anterior packing with layered gauze. Packing of the opposite side may be required to prevent septal deviation. Place a piece of gauze on the exposed catheter and secure with an umbilical clamp.

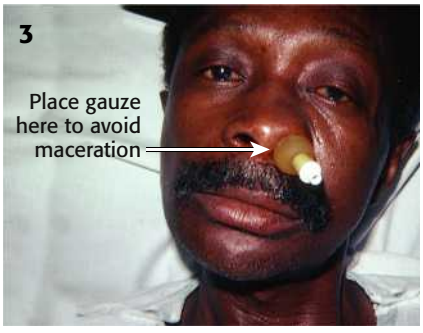
B



Double-balloon epistaxis catheters have both an anterior and posterior balloon, and some have an integral airway tube. These devices serve as an anterior and posterior pack. They are easily inserted and are often successful in the temporary control of posterior epistaxis in the ED.



Insert the lubricated device along the nasal floor as far back as possible. Inflate the posterior balloon halfway with air, apply traction to pull the balloon up against the middle turbinate, and then complete the inflation. Maintain the position of the balloon and then inflate the anterior balloon with 30 mL of air.



This patient with posterior epistaxis was successfully treated in the ED and discharged. Historically, most patients with posterior packs were admitted to the hospital; however, the ease and safety of balloon devices allow selected patients to be treated as outpatients. Consider admission for older adults and those with pulmonary or cardiovascular disease.

Fig. 58.3 Management of Epistaxis—Posterior Packing With Inflatable Devices. (A) Foley catheter technique. (B) Dual-balloon tamponade catheter. (Adapted from Riviello RJ. Otolaryngologic procedures. In: Roberts JR, ed. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*. Philadelphia: Elsevier/Saunders; 2013:1330.)

of toxic shock syndrome associated with anterior nasal packing. Similarly, no studies have documented toxic shock syndrome, otitis media or sinusitis when patients were not given prophylactic antibiotics with nasal packing in place for less than 24 to 48 hours.[65,75,76] We do not recommend routine antibiotic prophylaxis after anterior nasal packing. However, antibiotics may be considered in patients with immune compromise or valvular disease, or in patients whose packing is left in place for greater than 48 hours.[65]

Disposition

Most patients with anterior epistaxis may be discharged with follow-up within 24 to 48 hours. Nasal packing is generally removed within 48 hours to avoid tissue necrosis associated with prolonged placement. Nasal packing is uncomfortable, and analgesia should be appropriately addressed at discharge.

Patients with posterior epistaxis and packing often warrant hospital admission. There has been concern that patients with posterior nasal packs may develop hypoxia as a result of a theoretical "nasopulmonary reflex." However, there is little evidence to support this theory. Adverse respiratory events are due to a combination of factors such as sedation, underlying cardiovascular or pulmonary disease, and obstructive sleep apnea. Most patients with posterior nasal packing can be admitted to a setting with continuous pulse oximetry, but patients with serious comorbidities such as heart disease or obstructive sleep apnea may require a higher level of care.

SIALOLITHIASIS

Foundations

Stones of the salivary glands occur in 1% of the population, most commonly in patients between 30 and 50 years of age. The most common gland affected is the submandibular (submaxillary) gland, accounting for 80% to 95% of cases. Stones are found less commonly in the parotid and sublingual glands. Sialolithiasis is uncommonly seen in children.

The exact causative mechanism is unclear, but sialolithiasis is thought to be due to increased viscosity of the saliva and the long upward curvature of the submandibular (Wharton's) duct. Stasis and inflammation result in precipitation of calcified stones after a nidus of a complex glycoprotein combines with calcium and phosphate. Risk factors include dehydration, diuretic or anticholinergic medications, trauma, gout, and a history of smoking.

Clinical Features

Pain from sialolith obstruction is usually associated with mealtime, when salivary secretion is increased. Patients generally present with pain, swelling, and tenderness of the gland. If the gland is infected, the patient may have systemic symptoms, such as fever or chills. The area may be erythematous, with purulence coming from the duct, a condition termed sialadenitis. *S. aureus, H. influenzae, Strep* species and anaerobes predominate in bacterial infections. Children differ in that they have a shorter duration of symptoms, and their stones present more distally in ducts than those found in adults.

Differential Diagnoses

The differential diagnosis of sialolithiasis includes other salivary gland pathology, lymph node disease, granulomatous processes, soft tissue masses, and neoplasms (Box 58.7).

BOX 58.7 Differential Diagnosis of Sialolithiasis

- Salivary gland pathology
- Lymph node disease
- Granulomatous process
- Soft tissue masses
- Neoplasms

Diagnostic Testing

CT scanning is very sensitive for salivary gland calculi of all sizes and remains the study of choice. Although there have been reports of ultrasonography recognizing up to 90% of stones larger than 2 mm, it does not allow reliable exclusion of small salivary calculi. Both modalities may help identify other causes of inflammation, such as an abscess or cellulitis.

Management and Disposition

If the salivary stone is palpable, gently massage the gland in an attempt to extract the stone. Additional measures include sialogogues (tart candies to promote glandular secretions) and analgesics. When infection is present, antibiotics with effective coverage of commonly implicated pathogens, such as amoxicillin/clavulanate (875/125 mg BID) or clindamycin (300 mg TID) are appropriate.

Stones larger than 5 mm and stones located within the gland or in the proximal duct are often resistant to conservative measures. These may require surgical or minimal invasive treatment by an otolaryngologist or oral surgeon.

NECK MASSES

Foundations

Neck masses are a relatively common clinical finding, with a multitude of causes. Children and young adults are more likely to have benign disorders, such as inflammatory or congenital abnormalities, including thyroglossal or branchial cleft cysts. Adult neck masses are more likely to be neoplastic. In general, 80% of non-thyroid neck masses in adults are neoplastic, of which 80% are malignant. In children, however, more than 80% of neck masses are benign. This is often referred to as the rule of 80, or the 80% rule. Risk factors that may predispose patients to ENT malignancies include alcohol and tobacco use, viruses such as herpes, genetics, diet, and excessive exposures to ultraviolet sunlight, dust, or chemicals.

Identifying the parotid and submandibular glands, thyroid cartilage, thyroid gland, and lymph nodes can help distinguish normal structures from other masses (Fig. 58.4). The neck is divided into cervical triangles, with the sternocleidomastoid muscle as the common boundary. The anterior portion is bordered by the midline of the neck, inferior aspect of the mandible superiorly, and anterior border of the neck posteriorly. Lesions of the skin, scalp, oral cavity, oropharynx, hypopharynx, larynx, and tongue may manifest here. The posterior triangle is bordered by the sternocleidomastoid anteriorly, posteriorly by the trapezius muscle, and inferiorly by the clavicle. Lesions in this area may include those from the nasopharynx and metastatic lesions from the lung, gastrointestinal, and genitourinary tracts.

Clinical Features

Important associated symptoms in patients with neck masses include dysphagia, odynophagia, otalgia, stridor, speech disorders, and globus phenomena. Dysphagia, or difficulty swallowing, may be caused by physical obstruction or neurologic disorders. Odynophagia is pain on swallowing and can have a number of causes, such as tonsillitis or carcinoma of the pharynx. In an adult, a sore throat that lasts for several weeks should raise the suspicion of a neoplastic process. Otalgia is pain felt in the ear that may be referred from the larynx, pharynx, or cranial

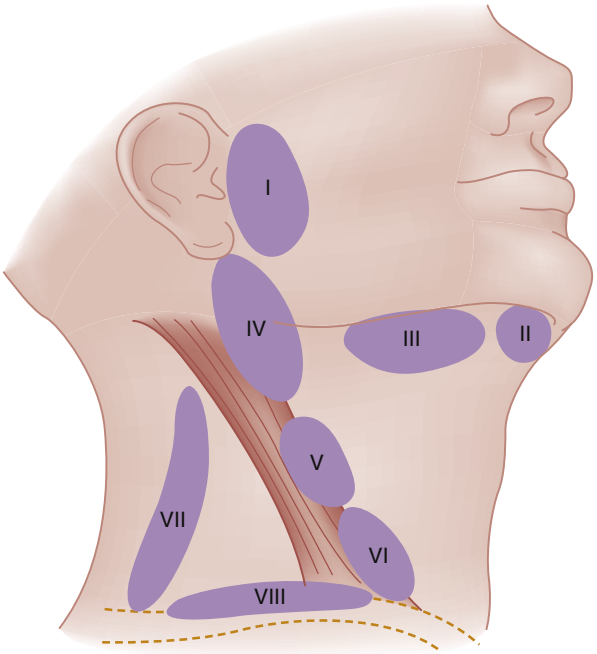


Fig. 58.4 Major Lymph Node Groups in the Head and Neck. *I,* Parotid nodes; *II,* submental nodes; *III,* submandibular nodes; *IV,* jugulodigastric nodes (superior jugular nodes); *V,* midjugular nodes; *VI,* lower jugular nodes; *VII,* spinal accessory nodes; *VIII,* subclavian nodes. Groups VI and VII are often termed *scalene nodes.* (Adapted from Moloy PJ. How to [and how not to] manage the patient with lump in the neck. In: American Academy of Otolaryngology–Head and Neck Surgery Foundation, ed. *Common Problems of the Head and Neck Region.* Philadelphia: WB Saunders; 1995:134.)

nerves V, IX, or X. Referred ear pain is an ominous sign in adults and should be presumed to be cancer until proved otherwise. Similarly, unilateral otitis media with effusion in adults should be considered nasopharyngeal carcinoma until proven otherwise.

Stridor, specifically inspiratory stridor, is diagnostic of upper airway obstruction. It localizes a lesion to above or at the level of the larynx. In adults, the presence of stridor with a neck mass increases the possibility of carcinoma. Speech disorders, particularly so-called hot potato speech, are suggestive of space-occupying lesions above the oropharynx, such as a peritonsillar abscess. Globus is the symptom of perceiving a lump in the throat. It is a commonly reported symptom, is often a functional complaint. Hoarseness is also a common complaint, with many varied descriptions, and causes range from viral pharyngitis to laryngeal cancer. Hoarseness lasting longer than 2 weeks should be investigated further. Additional history about alcohol or tobacco use, the location of the mass, rate of growth, presence of pain, and constitutional symptoms, such as fever, night sweats, and weight loss, are also helpful.

The head and neck examination may identify masses, lesions, mucosal ulcerations or discolorations, and cranial nerve abnormalities. The mass itself should be palpated for location, size, and consistency. Benign lymph nodes are generally mobile, soft, fleshy, and smaller than 1 to 1.5 cm, so any hard nodes larger than 1.5 cm with decreased mobility should be considered abnormal and as warning signs of malignancy.

Differential Diagnoses

The differential diagnosis of neck masses can generally be broken down into three categories—inflammatory, congenital, or neoplastic (Box 58.8).

Diagnostic Testing

The diagnostic strategy is tailored to findings elicited by history and physical examination. CT of the neck with contrast is the initial study of choice to evaluate the character of the mass and involvement of surrounding structures. Patients with hoarseness lasting longer than 2 weeks should be referred to an otolaryngologist for a flexible endoscopic examination unless they have developed acute stridor, dyspnea, or acute deterioration. These patients should have emergent otolaryngologic consultation for endoscopic examination of the upper airway.

BOX 58.8 Differential Diagnosis of Neck Masses

Inflammatory
Adenitis
Bacterial (*Streptococcus, Staphylococcus*)
Viral (HIV, EBV, HSV)
Fungal (coccidioidomycosis)
Parasitic (toxoplasmosis)
Cat scratch disease
Tularemia
Local cutaneous infections
Sialoadenitis (parotid and submaxillary glands)
Thyroiditis
Mycobacterium avium-intracellulare
Mycobacterium tuberculosis

Congenital or Developmental
Brachial cleft cyst
Thyroglossal duct cyst
Dermoid cyst
Cystic hygromas
Torticollis
Thymic masses
Teratomas
Ranula
Lymphangioma
Laryngocele

Neoplastic
Benign
Mesenchymal tumors (e.g., lipoma, fibroma, neural tumor)
Salivary gland masses
Vascular abnormalities (e.g., hemangioma, AVM, lymphangioma, aneurysm)

Malignant
Primary tumors
Sarcoma
Salivary gland tumor
Thyroid or parathyroid tumors
Lymphoma

Metastasis
From primary head and neck tumors
From infraclavicular primary tumors (e.g., lung or esophageal cancer)

AVM, Arteriovenous malformation; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus.

Management and Disposition

Most masses in children are inflammatory, and it is reasonable to treat them with antibiotics. Amoxicillin/clavulanate or clindamycin are appropriate choices. Follow-up within 2 weeks should be advised. In adults, antibiotics should only be given if there is concern for a bacterial infection.[77] Adults warrant ENT referral if the mass does not resolve in 2 weeks, is enlarging or fixed, is associated with matted cervical lymph nodes, or if the masses are found in the parotid or thyroid gland.

CHAPTER 58: QUESTIONS AND ANSWERS

1. *Bullous myringitis* is most commonly caused by which of the following bacterial pathogens?
   - **a.** *Streptococcus pneumoniae*
   - **b.** *Pseudomonas aeruginosa*
   - **c.** *Mycoplasma pneumoniae*
   - **d.** *Staphylococcus aureus*

Answer: a. Bullae may be seen on the TM in up to 5% of cases of AOM in young children. While this finding has been historically associated with *M. Pneumoniae*, the bacterial pathogenesis of bullous myringitis is similar to that of non-bullous AOM and is treated similarly.

2. Which of the following patients with acute otitis media would be appropriate candidates for observation in lieu of immediate antibiotic treatment?
   - **a.** A 6-month-old female with bilateral middle ear effusions with red bulging tympanic membranes and fever to 103.5°F
   - **b.** A 6-year-old male with three days of ear pain, fever to 101.5°F and an erythematous, bulging TM with purulent material seen in the external ear canal
   - **c.** A 2-year-old male without significant medical history presenting with 1 day of right ear pain and fever to 100.5°F. His exam reveals an erythematous TM with a middle ear effusion. There is no otorrhea or TM perforation noted.
   - **d.** A 5-month-old female with fever to 101.2°F with an erythematous, bulging left TM seen on otoscopy.

Answer: c. Observation for 48 to 72 hours can be considered in lieu of immediate antibiotics in pediatric patients aged 6 months to 2 years with unilateral AOM of <48 hours duration, in the absence of severe symptoms (including temperature <102.2°F) or otorrhea. Patients older than 2 years with unilateral or bilateral AOM without otorrhea or severe symptoms can be appropriate for an observation strategy. Patients with otorrhea and those younger than 6 months should be treated with antibiotic therapy and are not appropriate for an observation approach. This decision should be made in conjunction with caregivers, and reliable follow-up must be in place. This approach is not validated in adult patients.

3. A 72-year-old female with a history of poorly controlled diabetes mellitus presents to the ED with severe left ear pain of 2 weeks duration. On ear examination, granulation tissue is noted in the external auditory canal. The patient has facial asymmetry, which her family states developed 2 days ago. What is the most appropriate imaging modality for this patient in the ED?
   - **a.** MRI with contrast
   - **b.** CT with contrast
   - **c.** Skull x-ray
   - **d.** Transcranial doppler ultrasound

Answer: b. This patient is presenting with findings consistent with necrotizing external otitis: granulation tissue in the EAC and facial paralysis. CT scan is the most appropriate choice for imaging in the ED and will demonstrate bony erosion and associated soft-tissue abnormalities. MRI and nuclear medicine studies may be helpful later in the patient's course.

4. Routine use of prophylactic antibiotics in patients treated with anterior packing for epistaxis has clearly demonstrated which of the following benefits?
   - **a.** Prevention of toxic shock syndrome
   - **b.** Reduction in incidence of acute otitis media
   - **c.** Prevention of acute sinusitis
   - **d.** None of the above

Answer: d. Administration of prophylactic antibiotics in patients discharged with anterior nasal packing has not been shown to prevent the listed infectious complications and is not recommended in patients without immunocompromise, valvular disorders, or in those whose packing will be left in place for less than 48 hours.

5. Neck masses in pediatric patients are more likely to represent an _____ process, while neck masses in adult patients are most likely secondary to a _____ process.
   - **a.** inflammatory, inflammatory
   - **b.** neoplastic, inflammatory
   - **c.** inflammatory, neoplastic
   - **d.** neoplastic, neoplastic

Answer: c. In adults, neck masses should raise concern for malignancy, as 80% of non-thyroid neck masses in adults are neoplastic in etiology. In children, the majority of neck masses are inflammatory in nature or secondary to benign congenital abnormalities.

59

Asthma

Taher T. Vohra and Richard M. Nowak

KEY CONCEPTS

- Inhaled and systemic steroid medications are effective in controlling airway inflammation and have important roles in the management of asthma exacerbations.
- Inhaled bronchodilators and systemic corticosteroids remain the mainstays of management for most acute asthma exacerbations.
- Acute severe asthma requires rapid identification. Treatment may use strategies not used in mild-to-moderate exacerbations, such as infusion of magnesium sulfate, use of non-invasive ventilation, and endotracheal intubation.
- Ventilator management in the intubated asthmatic is critical and includes lower tidal volumes (6 to 8 mL/kg) and low respiratory rates, often less than 10 per minute.
- A normal partial pressure of carbon dioxide (P_{CO_2}) in a pregnant patient represents hypercarbia.
- Elevated lactic acid levels are common in critically ill asthmatics and do not reflect deterioration or a poor prognosis.
- ED management of acute asthma is expanding (up to 24 hours) as more non-critically ill asthmatics are treated in observation units.
- Integration of discharged patients with acute asthma into chronic management strategies to prevent relapse requires physicians be familiar with controlling medications, such as inhaled corticosteroids and long-acting beta agonists.

FOUNDATIONS

Background and Importance

The word *asthma*, derived from the Greek ασυμα, signifies panting and was used initially as a synonym for "breathlessness." In 1698, Floyer published *A Treatise of the Asthma,* in which he attempted to differentiate asthma more clearly from other pulmonary disorders. Subsequent definitions of asthma highlight concepts of airway hyperresponsiveness, bronchospasm, reversible airway obstruction, and inflammation, emphasizing the many facets of this complex disease.

In 2017, it was estimated that 42.6 million Americans had been diagnosed with asthma by a health professional within their lifetime.[1] Asthma is more prevalent in children than adults, in females than males, and in African Americans and Puerto Ricans than whites or other Hispanics (Fig. 59.1). Asthma is also more prevalent in impoverished individuals and in the northeastern region of the United States (Fig 59.2).

African American adults had an ED visit rate for asthma nearly four times that of whites.[2] Over 3500 deaths due to asthma were reported in 2017 in the United States.[3,4] The female death rate from asthma was 1.3 times higher than males. African Americans were 2.5 to 3 times more likely to die from asthma than whites, Hispanics, and other races. Decreases in asthma death rates were noted from 2001 to 2007 but have remained steady from 2007 to 2017 (Fig. 59.3).[3] The highest death rate is reported among adults 65 years old and older, and the lowest among children 0 to 4 years old.

Industrialized nations have higher rates of asthma suggesting that urbanization and westernization correlate with increased asthma prevalence. Migrants who move from an area of low asthma prevalence to that of high prevalence assume increased asthma prevalence, suggesting that environmental factors play a role. Urban areas in the United States have high mortality rates associated with asthma, indicating that poverty and lack of access to medical care may also be major determinants of asthma complications.

Factors that contribute to asthma morbidity and mortality include under-treatment of acute episodes by emergency clinicians; overuse of prescribed or over-the-counter medications leading to delays in seeking treatment; failure of emergency clinicians to consider previous ED visits, hospitalizations, or life-threatening episodes of asthma; and failure to initiate corticosteroid therapy early in the course of an exacerbation. The cost of asthma care is a barrier to asthma management. African American and Hispanic adults identify costs related to seeking asthma care with a physician and the cost of asthma medications as significant impediments. Over-reliance on emergency facilities for all asthma care and lack of access or compliance with ongoing asthma care are other important factors contributing to morbidity and mortality from asthma.

Anatomy and Physiology

Asthma is a complex, immunologically mediated condition involving a variety of cellular and airway alterations. Airway inflammation and remodeling are the final common pathways that result in bronchospasm and limitation of airflow.

Asthma is a chronic respiratory disease characterized by periods of variable and recurring symptoms, airflow obstruction, and bronchial hyperresponsiveness that manifests clinically as attacks of impaired breathing. Asthma is an inflammatory disease. Repetitive episodes of acute superimposed on chronic airway inflammation are responsible for alterations in airway function and result in irreversible structural airway changes. Control of asthma symptoms ultimately depends on

ameliorating airway inflammation. Genetic, social, physiologic, and environmental factors influence the expression and control of asthma symptoms. Asthma is thus a complex interaction of the immune system, the environment, and genetic predispositions, which combine to alter airway structure and function. Successful emergency department (ED) management of asthma must address the multiple factors that result in airway dysfunction.

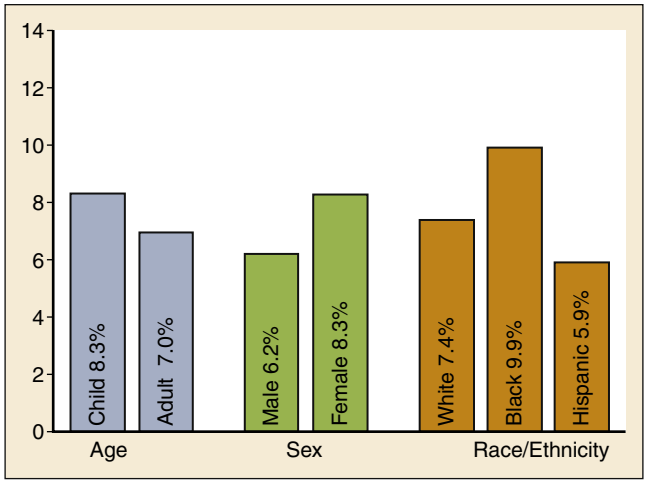

Fig. 59.1 Asthma Prevalence Percentages in 2017 by Age, Sex, and Race/Ethnicity in the United States. (From Centers for Disease Control and Prevention. Asthma: data, statistics, and surveillance. Available at: https://www.cdc.gov/asthma/data-visualizations/prevalence.htm.)

Compared with healthy individuals, patients with asthma show bronchial hyperreactivity (hyperresponsiveness) in response to various environmental and infectious stimuli (e.g., methacholine). Allergens (e.g., environmental, viruses, occupational) and non-allergic stimuli (e.g., exercise, aspirin-induced and menstrual-related asthma) induce bronchoconstriction via release of mediators and metabolites from inflammatory cells. Edema, inflammation, mucus production, and airway smooth muscle hypertrophy result in bronchoconstriction, airway obstruction, and airflow limitation. Recurrent episodes of airway inflammation result in permanent structural airway remodeling contributing to airway obstruction and hyperresponsiveness and decreases in response to therapy.

Autopsies of patients with fatal asthma reveal grossly inflated lungs that may fail to collapse on opening of the pleural cavities. Histologic examination reveals luminal plugs consisting of inflammatory cells, desquamated epithelial cells, and mucus. Marked thickening of the airway basement membrane, submucosal inflammatory cells, increased deposition of connective tissue, mucous gland hyperplasia, and hypertrophy of airway smooth muscle are also observed. Reports of slow-onset asthma fatalities reveal greater bronchial eosinophilia and basement membrane thickening when compared with rapid-onset fatal asthma. Reports of rapid-onset fatal asthma describe a greater number of degranulated mast cells and less mucus in the airway lumens, suggesting that terminal events may be dominated by bronchoconstriction without excessive luminal plugging.

Pathophysiology

Evidence that inflammation is a component of asthma physiology was initially derived from autopsy findings in patients with fatal asthma.

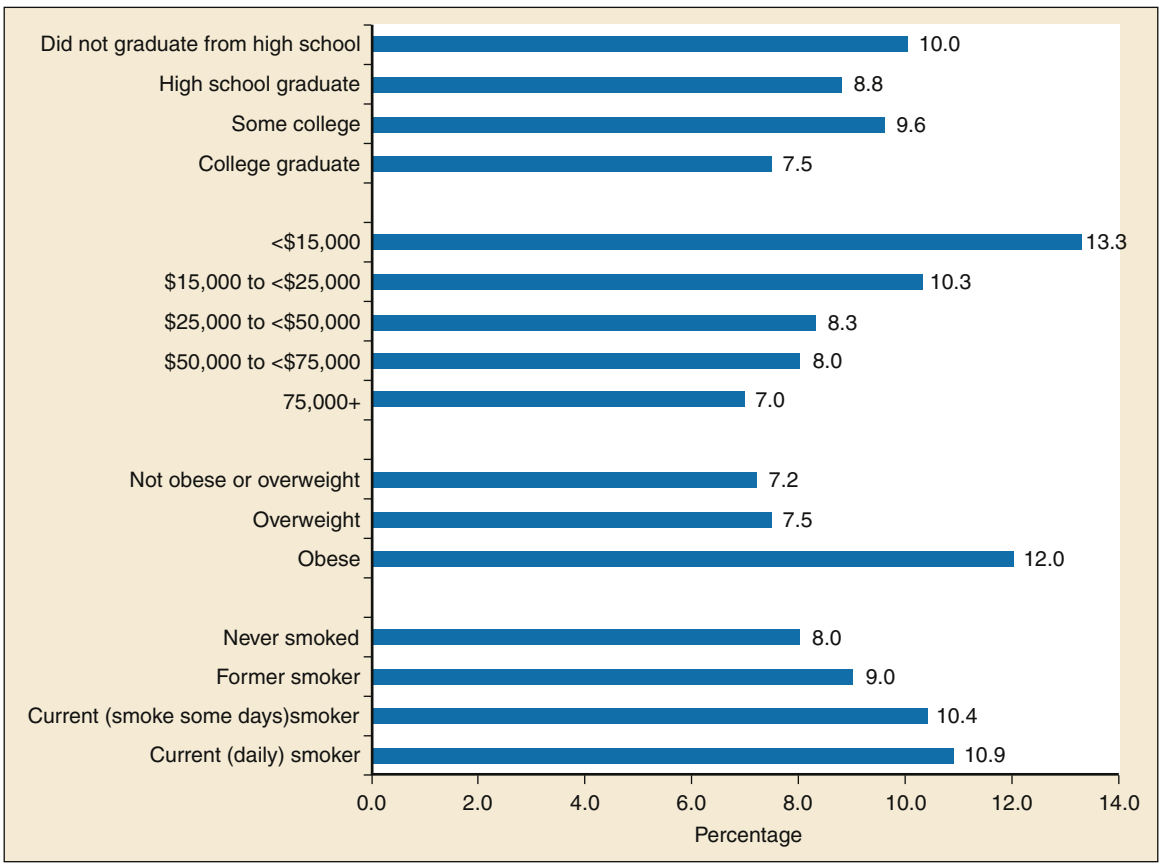

Fig. 59.2 Adult Asthma Prevalence Percent in 2017 by Education, Income, and Behavioral Risk Factors. (From Centers for Disease Control and Prevention. Asthma facts: CDC's National Asthma Control Program Grantees. Available at: https://www.cdc.gov/asthma/data-visualizations/prevalence.htm.)

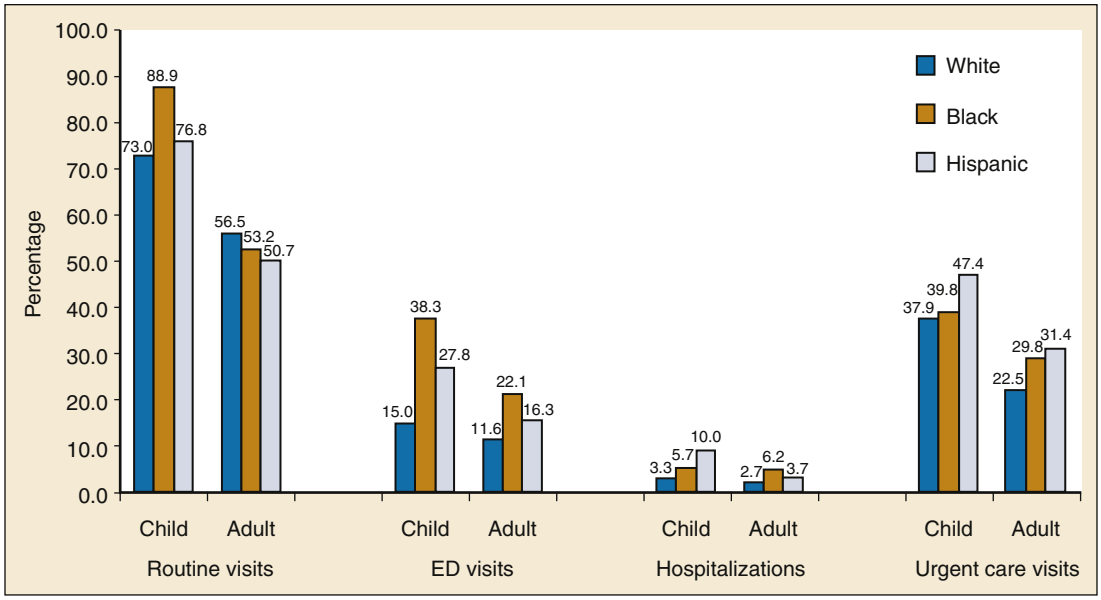

Fig. 59.3 Asthma Death Rates and Number of Deaths From 2007 to 2017. Thirty-five National Asthma Control Program (NACP) grantees. (Puerto Rico is excluded.) *Age-adjusted rate per million population. (From Centers for Disease Control and Prevention. Asthma facts: CDC's National Asthma Control Program Grantees. Available at: https://www.cdc.gov/asthma/data-visualizations/mortality-data.htm#anchor_1569599940376.)

The airways revealed infiltration by neutrophils, eosinophils, and mast cells and the presence of subbasement membrane thickening, loss of epithelial cell integrity, goblet cell hyperplasia, and mucous plugs. Bronchial biopsy findings in patients with even mild degrees of asthma also demonstrate inflammatory changes in the central and peripheral airways that correlate with disease severity. Inflammatory and chemotactic cytokines produced by both resident airway and recruited inflammatory cells are identified in bronchoalveolar lavage washings and pulmonary secretions.

Asthma has been divided into allergic and non-allergic types based on the presence or absence of immunoglobulin E (IgE) antibodies to common environmental antigens (pollen, dander, mites) and microbiologic antigens (bacteria, viruses). Exposure to microbes and allergens during childbirth, infancy, and childhood may confer a protective effect against atopy and suppress expression of the asthma phenotype later in life (known as the *hygiene hypothesis*). Regardless of the asthma type, a common feature is the presence of airway T-helper cells that release cytokines (e.g., interleukin [IL]-4, IL-5, and IL-13) that stimulate basophil, eosinophil, mast cell, and leukocyte migration to the airways and enhance IgE production. The result is amplification of the airway inflammatory response and, over time, irreversible airway remodeling. These complex cellular interactions clinically manifest as bronchospasm, mucus production, airway edema, and limitation of airflow.

Mast cells and eosinophils contain and release intracellular mediators and cytokines (histamine, prostaglandins, leukotrienes, tumor necrosis factor alpha [TNF-α]) that contribute to prolonged bronchial smooth muscle spasm, edema, and mucus production (Fig. 59.4). Airway epithelial cells are more than a passive barrier and produce pro-inflammatory mediators. Abnormal repair processes may further airway obstruction and contribute to airway remodeling.

Airway remodeling refers to the persistent structural changes in airways caused by repetitive or chronic airway inflammation. Microscopic remodeling features include epithelial thickening, subepithelial fibrosis, mucous gland metaplasia, increases in airway smooth muscle, angiogenesis, and loss of cartilage integrity. Airway remodeling occurs very early in asthma (childhood) and may precede clinical symptoms. Remodeling features are prominent in patients with severe asthma. Basement membrane thickening may be protective by preventing inflammatory cells and proteins from entering the airway submucosa through a damaged epithelium. Simultaneously, this process may be counterproductive by reducing the elasticity of the small airways. Airway remodeling induced by chronic inflammation may lead to the development of chronic irreversible airflow limitation and increased asthma mortality.

Genetics is playing an ever-increasing role in the understanding of asthma pathophysiology.[5] Heritability estimates vary between 35% and 95% for asthma and 30% and 66% for bronchial hyperresponsiveness. The first Genome Wide Association Study (GWAS) identified a novel asthma susceptibility locus on chromosome 17q21 and two large meta-analyses of asthma GWASs identified four gene loci considered robustly associated asthma susceptibility genes. Environmental influences (e.g., allergens, pollutants, tobacco, and occupational exposures) are associated with asthma, and the interaction of genetic variability and environmental factors may allow prediction of future disease risk, expression, and severity and response to therapies.[6]

CLINICAL FEATURES

Signs and Symptoms

Most patients with acute asthma have a constellation of symptoms, including cough, dyspnea, and wheezing. Slow-onset asthma with progressive deterioration over at least 6 hours (usually days) occurs in over 80% of cases. This type has a female predominance, is triggered by upper respiratory tract infections, and has an airflow inflammation mechanism that results in a slower response to treatment. Sudden-onset asthma with rapid deterioration in less than 6 hours occurs in less than 20% of cases. This type has a male predominance, is triggered by respiratory allergens, exercise, and psychosocial stress, and has a bronchospastic cause resulting in more severe airway obstruction with a faster response to therapy.

On initial history, questions should include possible triggers, onset of symptoms, and severity of symptoms, especially as compared with

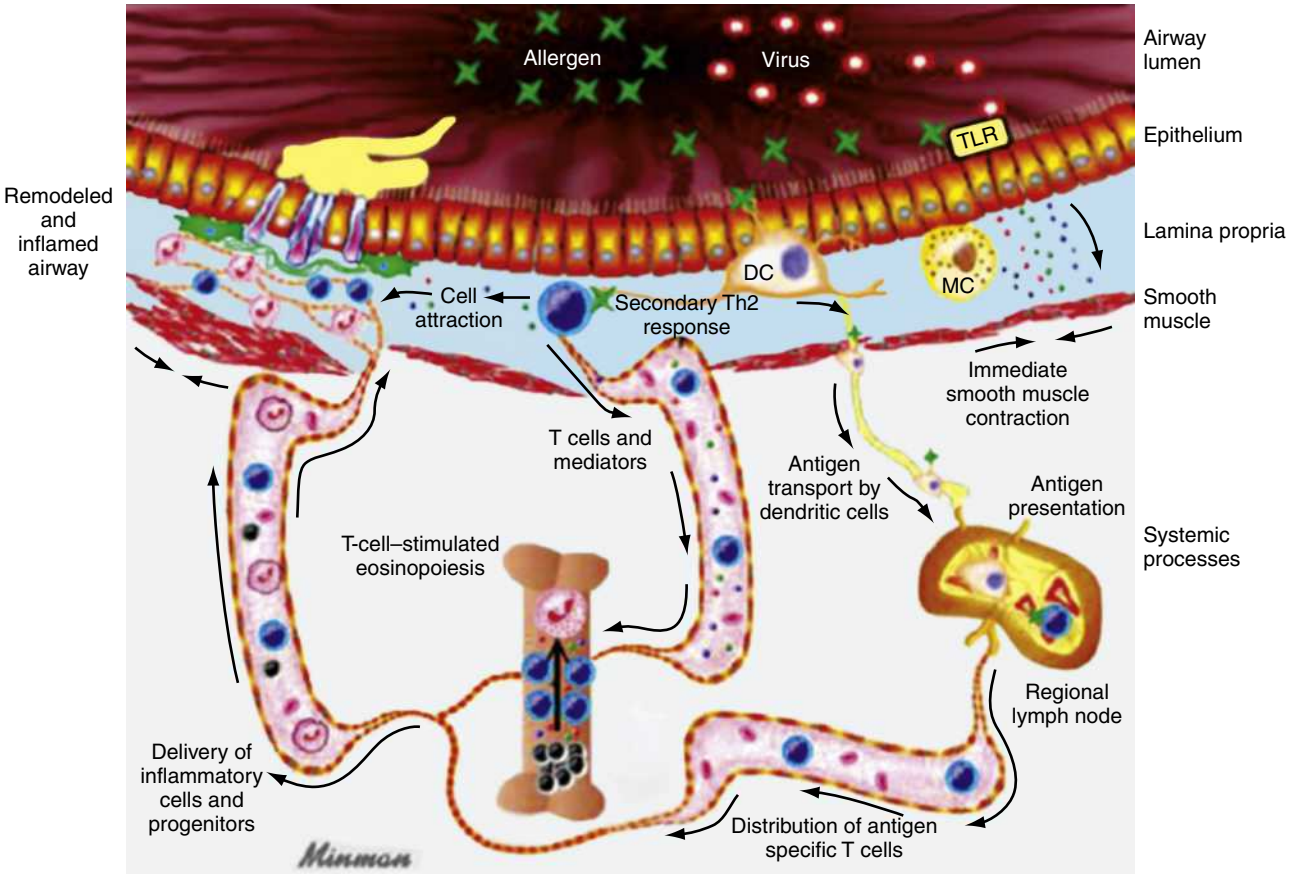

Fig. 59.4 The Physiologic Mechanism of Asthma. *DC,* Dendritic cell; *MC,* mast cell; *Th2,* T-helper 2; *TLR,* toll-like receptor. (From Murphy DM, O'Byrne PM. Recent advances in the pathophysiology of asthma. *Chest.* 2010;137:1417.)

previous exacerbations. Comorbidities should be identified, especially those that may be worsened by systemic corticosteroids such as diabetes, peptic ulcer disease, hypertension, and psychosis.[7] All current asthma medications should be noted, including times and amounts recently used, and any potential asthma aggravators, such as aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), beta-blockers (including topical agents used for glaucoma), and angiotensin-converting enzyme inhibitors. Cardioselective and nonselective beta-blocker use increases hospitalizations and ED visits. There are inter-individual differences in the dyspnea perceived by asthmatic patients for the same level of airway narrowing. Patients with a blunted perception of dyspnea ("poor perceivers") have more ED visits, hospitalizations, and near-fatal and fatal asthma attacks.

Patients with mild or moderate acute asthma usually speak in sentences or phrases and may have a normal or slightly elevated pulse and respiratory rates. They also will usually have a normal oxygen saturation. Patients with severe acute asthma typically speak only one to two words at a time, may be agitated or restless and hunched forward, may be tachypneic or tachycardic, and may be hypoxic. Patients with altered level of consciousness such as confusion or drowsiness, silent chest on exam, poor respiratory effort or elevated paCO2 have life-threatening or near-fatal asthma.[7,8]

Wheezing does not define the presence, severity, or duration of asthma. It correlates poorly with the degree of functional derangement and may be absent when maximal effort produces minimal airflow. Physical examination may help to identify such complications of asthma as pneumonia, pneumothorax, or pneumomediastinum.

BOX 59.1 Risk Factors for Death From Asthma

Asthma History

A history of near-fatal asthma requiring intubation and mechanical ventilation
Hospitalization or ED visit for asthma in the past year
Currently using of having recently stopped using oral corticosteroids (a marker of event severity)
Not currently using inhaled corticosteroids
Over-use of SABAs, especially use of more than one cannister monthly
Poor adherence with asthma medications and/or poor adherence with (or lack of) a written asthma action plan

Other Factors

Psychosocial problems
Psychiatric disease
Food allergy in a patient with asthma

Risk Factors

Asthma exacerbations are more common in females. Additionally, specific risk factors for exacerbations include a history of one or more exacerbations in the past year, poor adherence to a plan or uncontrolled symptoms, incorrect inhaler use, chronic sinusitis, or smoking. Ethnicity and socioeconomic status are also predictors of exacerbations with African Americans having higher rates of ED visits and hospitalizations than Caucasians or Hispanics.[2] Risk factors for death from asthma are also important to determine and are listed in Box 59.1.[7,8]

Specific Contexts

The following conditions are particularly challenging due to their overlap and contribution to asthma.

Cough Variant

Chronic cough may be the sole manifestation of the disease in cough-variant asthma. It is associated with airway hyperresponsiveness and may be present more often at night. Other conditions of chronic cough to consider would be angiotensin converting enzyme (ACE) inhibitors, gastroesophageal reflux disease (GERD), chronic sinusitis, postnasal drip, and inducible laryngeal obstruction.

Cigarette Smokers

One-third of patients who come to the ED with acute asthma are current cigarette smokers, and these patients have poorer asthma control and greater acute care needs than lifelong nonsmokers or former smokers. They may also have chronic obstructive pulmonary disease (COPD) which makes diagnosis and treatment more challenging. Ambiguity between COPD and asthma should prompt referral due to the worse outcomes of patients with asthma and COPD overlap.[8]

Athletes

Exercise-induced bronchoconstriction has been recognized since the first modern Olympic Games. The key stimulus is felt to be airway dehydration resulting from increased ventilation, increasing the osmolarity of the airway lining fluid. The increased osmolarity may trigger release of mediators (histamine, leukotrienes, prostaglandins) from airway inflammatory cells, resulting in smooth muscle contraction and airway edema.[9]

Prophylaxis for exercise-induced asthma includes environmental measures (face mask or nasal breathing to allow warming and humidification of cool dry air, pre-exercise warm-up, and avoidance of known allergens) and medications. Inhaled glucocorticoids are strongly recommended, and a short-acting inhaled beta-2 agonist used 5 to 10 minutes before exercise is effective in preventing exercise induced bronchoconstriction.[9] Long-acting beta agonists (LABAs) in combination with inhaled glucocorticoids are useful when low doses of inhaled glucocorticoids are ineffective. Pretreatment with cromolyn, leukotriene antagonists (montelukast), or an inhaled parasympatholytic (ipratropium) is also effective.

Perimenstrual Asthma

Perimenstrual asthma affects up to 40% of asthmatic women yet receives little emphasis in asthma treatment guidelines. The ratio of female-to-male asthma prevalence increases dramatically after puberty, and health care for asthma increases in the perimenstrual phase.

Elderly

Asthma can appear at any age, including the ninth decade, wheezing and dyspnea may be mis-ascribed by patients and physicians to heart failure, bronchitis, COPD, occupational lung disease, or poor exercise capacity. Older asthmatic patients (>55 years old) have higher morbidity and mortality.

Obesity

Due to respiratory symptoms associated with obesity overlapping with asthma, there may be misdiagnosis or underdiagnosis. Objective testing is important to diagnose asthma in this patient population accurately. Overweight (body mass index [BMI] of 25 kg/m^2 or more) asthmatics have poorer asthma control, higher admission rates, and a greater risk of complications, possibly secondary to a difference in the perception of dyspnea or response to asthma controller agents. However, obesity does not adversely influence the severity or the resolution of an acute exacerbation.

Aspirin-Exacerbated Respiratory Disease

Aspirin-exacerbated respiratory disease (AERD) was first described more than 100 years ago. Clinically, AERD includes the tetrad of nasal polyps, eosinophilic sinusitis, asthma, and sensitivity to cyclooxygenase (COX)-1 inhibitor drugs (e.g., aspirin). A detailed mechanism is shown in Fig. 59.5. NSAIDs also precipitate AERD. AERD is a common precipitant of life-threatening asthma; one survey notes that 25% of asthmatics who require mechanical ventilation have AERD. Patients with AERD should avoid aspirin and NSAIDs. ICS are the primary therapy in AERD. Oral corticosteroids may be needed, and leukotriene antagonists may be useful. Desensitization with aspirin can significantly improve symptoms. There is little evidence to justify managing patients with AERD differently than other patients with acute asthma except for avoidance of aspirin and NSAIDs.

DIFFERENTIAL DIAGNOSES

See Box 59.2.

Diagnostic Testing

Peak Expiratory Flow

The severity of airflow obstruction cannot be accurately assessed from symptoms and physical examination alone. Because physicians initially tend to underestimate the degree of airway obstruction in acute asthma, routine measurement of the peak expiratory flow (PEF) in liters per second should be part of ED assessment and monitoring. Any patient not able to perform peak flow measurement should be considered to have severe airway obstruction.

The same device should be used to assess an individual patient, and different portable meters should not be used interchangeably. PEF assessed as a percentage of previous personal best is the most useful measurement. PEF as a percentage of predicted values (available online) gives a reasonable estimate if personal best values are unknown. PEF < 50% is often used to categorize an acute severe asthma exacerbation, and less than 33% may signify life-threatening or near-fatal asthma.[7]

Pulse Oximetry

Oxygen saturation (SpO_2) should be measured using pulse oximetry to determine the efficacy of oxygen supplementation, especially in children that cannot perform PEF. SpO_2 should be maintained between 94% and 98%. If SpO_2 falls below 90%, it may signal the need for more aggressive therapy.[7]

Capnography

Capnography is an alternative technique to monitor for hypercapnia and respiratory failure and is effective in asthma. Capnographic waveform analysis can indicate improvements in airway diameter in acute asthma and has the advantage of being effort independent and providing continuous monitoring.

Blood Gas

Initially, in acute asthma exacerbations, stimulated hyperventilation leads to a fall in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$). As airway obstruction increases, patients develop hypoventilation. With hypoventilation, the $PaCO_2$ normalizes and then increases with resulting hypercapnia and respiratory acidosis. Routine arterial blood gas (ABG) analysis is not indicated in acute asthma exacerbations. An ABG should be considered to identify hypercapnia if the SpO2 is <92% or the PEF is <50% of personal best or predicted value.

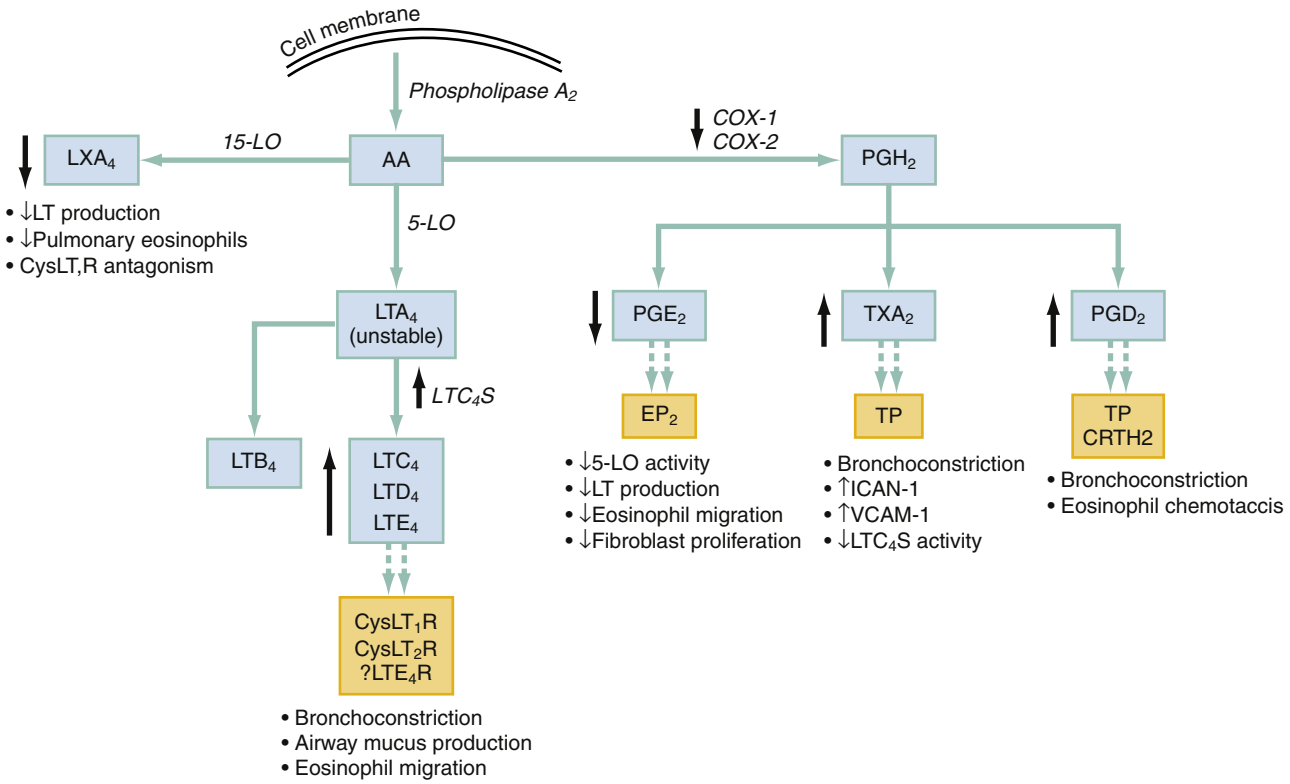

Fig. 59.5 Mechanism of aspirin-exacerbated respiratory disease (AERD). Inhibition of the enzyme cyclooxygenase *(COX)* decreases production of prostaglandin E_2 *(PGE_2).* PGE_2's inhibitory effect on 5-lipoxygenase *(5-LO)* is diminished resulting in increased production of leukotrienes (*LTC_4, LTD_4,* and *LTE_4)* causing bronchoconstriction, mucus production, and airway eosinophil migration. *5-LO,* 5 Lipoxygenase; *15-LO,* 15 lipoxygenase; *AA,* arachidonic acid; *COX-1,* cyclooxygenase 1; *COX-2,* cyclooxygenase 2; *CRTH2,* chemokine receptor-homologous Th2 lymphocytes; *$CysLT_1R$,* cysteinyl leukotriene T1R; *$CysLT_2R$,* cysteinyl leukotriene T2R; *EP_2,* E prostanoid 2 receptor; *LTA_4,* leukotriene A4; *LTB_4,* leukotriene B4; *LTC_4S,* leukotriene C4 synthetase; *LTC_4,* leukotriene C4; *LTD_4,* leukotriene D4; *LTE_4,* leukotriene E4; *LTE_4R,* leukotriene E4R; LXA_4, lipoxin A4; *PGD_2,* prostaglandin D2; *PGE_2,* prostaglandin E2; *PGH_2,* prostaglandin H2; *TP,* T prostanoid receptor; *TXA_2,* thromboxane A2. BOX 59.2 The Differential Diagnosis of Asthma

- Cardiac conditions
  - Valvular heart disease
  - Congestive heart failure
- COPD exacerbation
- Pulmonary infection
  - Pneumonia
  - Allergic bronchopulmonary aspergillosis
  - Löffler syndrome
  - Chronic eosinophilic pneumonia
- Upper airway obstruction
  - Laryngeal edema
  - Laryngeal neoplasm
  - Foreign body
  - Vocal cord dysfunction
- Endobronchial disease
  - Neoplasm
  - Foreign body
  - Bronchial stenosis
- Pulmonary embolus
- Cystic fibrosis
- Carcinoid tumor
- Allergic/anaphylactic reaction
- Adverse drug reaction (ACE inhibitors)
- Miscellaneous conditions
  - Churg-Strauss syndrome
  - GERD
  - Hyperventilation with panic attack
  - Noncardiogenic pulmonary edema
  - Addison's disease
  - Invasive worm infection

ACE, Angiotensin-converting enzyme; *COPD,* chronic obstructive pulmonary disease; *GERD,* gastroesophageal reflux disease.

This will help identify possible respiratory acidosis and the need for airway management and ventilatory support. A venous blood gas (VBG) may also be considered as a screening tool for hypercapnia. A $PaCO_2$ on a VBG of less than 40 mm Hg likely excludes hypercapnia, however for an accurate measurement, one should obtain an ABG.[10]

Other Blood Testing

Leukocytosis is common with acute asthma exacerbation and does not necessarily indicate an acute superimposed pulmonary infection. Corticosteroids and catecholamines demarginate polymorphonuclear leukocytes after 1 to 2 hours, and patients on chronic steroid therapy may have normal or significantly elevated white blood cell counts.

Serum electrolytes are not altered unless the patient takes corticosteroids or diuretics or has cardiovascular disease and is receiving beta-2 agonist therapy. Frequent albuterol treatments can cause transient hypokalemia, hypomagnesemia, and hypophosphatemia, but this is rarely of clinical significance. The rare asthmatic on chronic theophylline therapy should have a level measured for possible toxicity. In the older asthmatic with cardiovascular comorbidities, measurement of the B-type natriuretic peptide (BNP) level may reveal unrecognized congestive heart failure. Hyperlactatemia is common in acute asthma and is thought to be secondary to albuterol therapy or the increased work of breathing. It is not associated with worse pulmonary function tests,

more hospitalizations, or relapse at one week. Overall, routine testing of the blood in an acute asthma exacerbation is not recommended.

Radiology

A chest radiograph (CXR) is of little value in most acute asthma exacerbations and should be restricted to patients with a suspected complicating cardiopulmonary process, such as pneumonia, pneumothorax, pneumomediastinum, subcutaneous emphysema, or congestive heart failure. Patients who do not respond to optimal therapy and require hospital admission have a higher likelihood of radiographically identifiable, unsuspected, clinically significant pulmonary complications of asthma.

Point of Care Ultrasound

The finding of an ultrasound comet-tail sign has high diagnostic accuracy in differentiating acute heart failure from COPD/asthma-related causes of acute dyspnea.

Electrocardiogram

The electrocardiogram (ECG) is selectively helpful in assessing patients with chest pain or a history of significant cardiovascular disease, in whom the asthma attack may be a physiologic stress test. In patients with severe asthma, the ECG may show a right ventricular strain pattern that reverses with improvement in airflow. All patients with severe hypoxemia should also receive cardiac monitoring.

In summary, the severity of airflow obstruction cannot be accurately judged by patients' symptoms, physical examination findings, and laboratory test results. Serial measurements of airflow obstruction with PEF is key for disease assessment and response to therapy (Table 59.1).

MANAGEMENT

Subacute lack of asthma control, defined as more than four outpatient visits or more than five short-acting beta-2 agonist prescriptions per year, is associated with an increased risk of acute asthma exacerbation. The ability to gauge the severity of an attack and present to the ED promptly is important, because patients who wait longer have worse asthma on presentation, more functional limitations, and are more likely to be admitted. Emergency medical services providers should provide albuterol inhalation therapy by protocol, and basic emergency medical technicians can be authorized to administer the patient's own inhaler. Further studies are needed to determine whether paramedics should be trained to administer continuous positive airway pressure ventilation in asthmatics with severe respiratory failure to decrease tracheal intubation and mortality rates.

The rapidity of the reversal of the acute airflow obstruction is directly predictive of the outcome. Effective bronchodilation often results in a decreased need for hospitalization with significant cost savings. As outlined in Tables 59.2 and 59.3, the severity of an attack as measured by peak flow measurement determines the aggressiveness of the therapy.

TABLE 59.1 Objective Findings in Asthma Assessment

Factor	Severe Asthma
Pulse rate (beats/min)	≥120
Respiratory rate (breaths/min)	≥30
Use of accessory muscles of respiration	If present, may indicate severe asthma; if absent, may have equally severe asthma in 50% of cases
ABG analysis (mm Hg)	Pa_{O_2} ≤ 60 or Pa_{CO_2} ≥ 42 indicates severe asthma; all other values difficult to interpret unless PEF known
Pulmonary function studies	PEF measures the degree of airflow obstruction; most useful in assessing severity and guiding treatment decisions

ABG, Arterial blood gas; Pa_{CO_2}, partial pressure of carbon dioxide in arterial blood; Pa_{O_2}, partial pressure of oxygen in arterial blood; *PEF,* peak expiratory flow rate.

Oxygen Administration

All patients should receive supplemental oxygen titrated to maintain arterial oxygen saturation between 94% and 98%, as titrated oxygen is associated with better physiologic outcomes than empiric high flow 100% oxygen therapy.[7]

Adrenergic Medications

Inhaled Beta2 Agonists

Inhaled short-acting beta-2 agonist (SABA) such as albuterol should be used in patients that present with acute asthma exacerbations. For patients with mild to moderate asthma, albuterol can be administered with a pressurized metered-dose inhaler (pMDI) with a spacer and is

TABLE 59.2 Initial Severity Assessments and Therapies in the Emergency Department

	Mild to Moderate	Severe
PEF (percentage predicted/personal best)	≥40%	Unable or <40%
Oxygen therapy	Maintain Sa_{O_2} ≥90%	Maintain Sa_{O_2} ≥90%
Nebulized Albuterol Solution		
Albuterol	2.5 mg every 20 min for up to three doses	5.0 mg every 20 min for three doses Continuous for 1 h if severe
Albuterol Metered-Dose Inhaler With Spacer		
Albuterol (90 µg/puff)	6–12 puffs every 20 min for up to three doses with supervision	Same for three doses (if able to do) with supervision
Ipratropium Therapy		
Nebulized solution	0.5 mg every 20 min for three doses (may mix with albuterol solution)	0.5 mg every 20 min for three doses (may mix with albuterol solution)
MDI (18 µg/puff) with spacer	8 puffs every 20 min for three doses	8 puffs every 20 min for three doses
Systemic Corticosteroids		
Oral (preferred)	40–50 mg of prednisone or prednisolone per day if no immediate response to albuterol	40 to 50 mg of prednisone or prednisolone per day
IV (unable to take orally or absorb)	125 mg of methylprednisolone per day	125 mg of methylprednisolone per day
IV magnesium sulfate	Not indicated	2 g over 20 min (or at rates of up to 1 g/min) if PEF ≤ 25% predicted

IV, Intravenous; *MDI,* metered-dose inhaler; *PEF,* peak expiratory flow rate; Sa_{O_2}, oxygen saturation in arterial blood.

TABLE 59.3 Response After 1 Hour of Initial Treatment

	Moderate Exacerbation	Severe Exacerbation
PEF (percentage predicted)	40%–69%	<40%
Oxygen therapy	Maintain Sa_{O_2} ≥90%	Maintain Sa_{O_2} ≥90%
Albuterol Therapy		
Racemic albuterol	Every 1–3 h, admit decision in <4 h	Every 1 h or continuous
Ipratropium therapy	Every 1 h or continuous	Every 1 h or continuous
Corticosteroids	Every 6–8 h	Every 6–8 h

PEF, Peak expiratory flow rate; *Sa_{O_2},* oxygen saturation in arterial blood.

more efficient and cost-effective than nebulization. However, for severe or near-fatal asthma, nebulization of beta-agonist is recommended over pMDI to allow for continuous administration, although there is a paucity of data to guide this recommendation. (see Table 59.2).

Long-Acting Beta-2 Agonists

Inhaled long-acting beta-2 agonists are medications used as the initial additional therapy to manage symptoms not adequately controlled by ICS alone. Salmeterol is a LABA with an onset of action of 20 minutes and thus is not a rescue medication. Formoterol is also a LABA that has an onset of action within minutes (similar to albuterol) and maximal effect within 2 hours. There is no difference in the efficacy of combination LABA/ICS inhalers compared to both medications in separate inhalers with good adherence. Regular use of LABAs without concomitant use of ICSs results in greater hospitalizations and asthma-related deaths, resulting in a black box warning on the package insert. There is no role for the use of LABA without the concomitant use of ICS.[7] In practice, combination inhalers are preferred to ensure LABAs and ICS are taken together. Due to the rapid onset of the medication, combination formoterol and ICS inhalers may be used as both controller and rescue medications. However, the role of these medications in the ED is limited amidst other readily available options.

Intravenous Beta2 Agonists

There is no evidence to support the routine use of intravenous beta-2 agonists.[8] There may be a limited role in ventilated patients or those in extremis, however, there is little evidence to support this.[7]

Subcutaneous Beta2 Agents

Terbutaline is a beta-2 adrenergic receptor agonist, administered subcutaneously. While terbutaline was previously used regularly for severe asthma, no evidence supports the use of subcutaneous adrenergic agents over aerosol delivery. It may be considered in patients who cannot adequately inhale albuterol or with severe bronchospasm unresponsive to other treatments.

Epinephrine

Epinephrine 0.3 mg given intramuscularly in addition to standard asthma therapy is recommended for patients with anaphylaxis or angioedema.

Corticosteroids

Steroids are an important part of acute and chronic asthma management. They reduce mortality, relapses, subsequent hospitalization, and the requirement for beta-2 agonist therapy.[7] They should be given as early as possible in an acute asthma exacerbation. There is no benefit to adding ICS to systemic steroids.

Systemic Corticosteroids

Corticosteroids are indicated for all patients with an acute asthma exacerbation. Early systemic corticosteroids are particularly important for patients who fail to achieve lasting improvement with the initial administration of SABA, were taking OCS when they developed the exacerbation, or have required OCS with past exacerbations.[8] Steroid effects begin within hours in acute asthma and peak at about 24 hours.

As studies have demonstrated that oral corticosteroids are equivalent to IV therapy, oral steroids are preferred unless the patient is very ill, is unable to swallow or is vomiting, or is thought to have impaired gastrointestinal transit or absorption. The recommended initial oral dose is usually 50 mg of prednisone.[7,8] If IV methylprednisolone is used, the dose is 125 mg/day in one or two divided doses until the switch to oral therapy or until PEF reaches 70% of predicted or personal best. Oral dexamethasone can alternatively be prescribed at a dose of 16 mg per day for 2 days.[11] Side effects of short-term (hours or days) steroid use include reversible increases in serum glucose (important in diabetics) and decreases in potassium, fluid retention with weight gain, mood alterations including psychosis, hypertension, peptic ulcers, aseptic necrosis of the femur, and rare allergic reactions.

Inhaled Corticosteroids

Use of high-dose ICS within 1 hour of arrival for acute asthma without systemic steroids reduces the need for hospitalization.[8] However, there is conflicting evidence regarding the role of ICS in addition to OCS in the setting of an acute exacerbation, and there is no known benefit to using ICS instead of OCS. ICS have an additional cost and no established dose and duration of treatment for patients in the ED. Therefore, we do not recommend routinely adding ICS to systemic steroids for the ED treatment of acute asthma exacerbations.

Corticosteroids and Discharged Patients

Discharged patients who receive systemic corticosteroids should continue oral out-patient therapy to control disease and prevent relapse. Any need for additional steroids should be determined at follow-up. An acceptable regimen is 40 to 50 mg of prednisone (or equivalent) in single daily dose for 5 to 7 days. Dose tapering to prevent asthma rebound or adrenal suppression is unnecessary unless the patient was already receiving systemic steroids or a prolonged course of therapy of more than 2 weeks is necessary. An alternative approach, if compliance or inability to obtain oral corticosteroids is an issue, is to give a single intramuscular dose of dexamethasone 10 mg, triamcinolone diacetate 40 mg, or methylprednisolone 160 mg before discharge.[12]

Patients with acute exacerbations of asthma may be on insufficient chronic controller medications. If the patient is not taking oral corticosteroids or ICS, the addition of ICS to the patient's regular asthma medications on discharge as a controller medication significantly reduces the risk of asthma-related death or hospitalization.[8] Patients with a moderate or severe exacerbation not taking any ICS should be given a prescription for an ICS containing medication. Patients already on ICS therapy should continue this home medication in addition to the prescribed short course of oral steroids.

Anticholinergic Medications

Anticholinergic drugs available for inhalation therapy are bronchodilators that override the smooth muscle constrictor and secretory effects of the parasympathetic nervous system, blocking reflex bronchoconstriction and reversing acute airway obstruction. Ipratropium bromide,

a quaternary derivative of atropine, is the preferred anticholinergic agent for acute asthma exacerbations. The maximum effect with inhaled ipratropium is 30 to 120 minutes after administration, lasting up to 6 hours. Its bronchodilatory potency is lower and onset of action slower than those of the beta-2 agonists and should not be used alone for acute attacks. For patients with moderate to severe exacerbations, emergency department treatment with a SABA and ipratropium was associated with fewer hospitalizations and greater improvement in PEF compared with SABA alone.[13] Treatment recommendations (see Table 59.2) include adding ipratropium (0.5 mg) with the first three albuterol treatments in severe acute asthma (PEF < 40% predicted). The equivalent MDI dose is approximately eight puffs (18 μg/puff) every 20 minutes for three doses.

Inhaled tiotropium bromide is a long-acting (>24 hours) anticholinergic agent. There is inconclusive evidence about the benefit of adding tiotropium for patients not responding to ICS plus LABA therapy as an outpatient. It is also unclear if there is any benefit to adding tiotropium to ICS compared to increasing the dose of ICS. There is no clear role for use of tiotropium for patients presenting to the emergency department with acute asthma exacerbations.[7]

Magnesium

Magnesium relaxes bronchial smooth muscle and dilates asthmatic airways in vitro. Mechanisms include calcium channel-blocking properties, inhibition of cholinergic neuromuscular transmission, stabilization of mast cells and T-lymphocytes, and stimulation of nitric oxide and prostacyclin. Intracellular magnesium levels are lower in acute asthma, and the level correlates with airway reactivity in chronic disease.

For adults with severe asthma attacks (PEF < 25%, predicted), adults and children with persistent hypoxia after initial treatment, and children with PEF < 60% after 1 hour of care, the addition of magnesium decreases the need for hospital admission.[14] The optimal dose and rates of infusion are unclear, but it is reasonable to administer 2 g of IV magnesium sulfate over 20 minutes to adult patients with severe refractory asthma while continuing aggressive inhalation therapy. For pediatric patients, a dose of 40 mg/kg/day (max of 2 g) of IV magnesium sulfate is recommended. Studies that excluded patients with severe asthma showed no benefit with use of IV or nebulized magnesium. Side effects of magnesium infusion are dose-related and include warmth, flushing, sweating, nausea and emesis, muscle weakness, loss of deep tendon reflexes, hypotension, and respiratory depression.

Methylxanthines

Theophylline is the main oral methylxanthine used to treat asthma, and a small subset of ambulatory patients may benefit from its chronic administration. IV methylxanthines are not recommended for acute disease as there is no demonstrated efficacy and increased adverse events.[8] However, there may be a limited role in patients with near-fatal asthma with a poor response to initial therapy.[7]

Leukotriene Modifiers

The cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4) are highly potent mediators of inflammation that play a large role in the pathogenesis of asthma. Leukotriene receptor antagonists (LTRAs) are used as controller medications. There is limited data regarding their efficacy in acute asthma management. Current recommendations do not support their use in the treatment of acute asthma in the emergency department.

Antibiotics

Bacterial, chlamydial, and mycoplasmal respiratory tract infections infrequently contribute to acute asthma. Antibiotics should generally be reserved for patients with clear objective evidence of infection. There may be a future role for procalcitonin to guide antibiotic use, but more studies are needed.[15]

Sedatives

Sedatives are contraindicated in acute disease because of their respiratory depression.

Ketamine

Ketamine is an IV dissociative anesthetic with potent bronchodilator effects. Studies suggest possible benefit when used in acute asthma, but no statistically significant findings have been reported. Further prospective work is needed. At present, ketamine is not recommended for acute asthma in the non-intubated patient.[7]

Heliox

Helium is an inert gas with one-eighth the density of nitrogen. When 60% to 80% helium is blended with 20% to 40% oxygen, the resulting gas mixture (heliox) has a threefold reduction in density compared with air. Heliox reduces the resistance associated with gas flow through airways with non-laminar flow and reduces respiratory muscle work; it also increases the diffusion of carbon dioxide and may improve alveolar ventilation. Heliox may decrease the work of breathing long enough to stop intubation by carrying bronchodilators to the distal airways and allowing anti-inflammatory agents time to achieve their effects. When heliox was compared to oxygen to drive nebulized delivery of beta-agonist therapies, an increase in PEF and a lower rate of hospitalization were observed. Patients with severe asthma receiving heliox nebulization of beta-2 agonists have more significant increases in PEF compared to those with mild to moderate asthma. Heliox has not been demonstrated to decrease the need for intubation in severe and resistant asthma, however. It is administered by nonrebreather mask and can also be used with mechanical ventilation. Emergency clinicians can consider heliox in cases of severe airflow obstruction (PEF < 30% predicted and a rapid onset of symptoms within 24 hours), a history of labile asthma or previous intubation, and inability to be adequately mechanically ventilated.

High-Flow Nasal Canula

Oxygen delivered via high-flow nasal canula (HFNC) can be used with hypoxemic patients. HFNC, with flow rates up to 60 L/min of warmed and humidified oxygen, provides high concentrations of oxygen, decreases respiratory work and may provide continuous positive airway pressure. The role in asthmatic adults is unknown, however, small studies have shown it reduces respiratory distress in children.[16] Further studies are warranted to determine overall efficacy.

Noninvasive Ventilation

Noninvasive ventilation (NIV) may benefit carefully selected patients with severe and resistant asthma. Continuous positive airway pressure improves oxygenation and reduces respiratory muscle fatigue by increasing functional residual capacity and lung compliance and supplying some of the inflating pressure required during inspiration. Biphasic positive airway pressure (BiPAP) provides continuous positive airway pressure but delivers higher pressure during inspiration than expiration. BiPAP allows speech and reduces the need for sedation as compared to intubation. Nebulized bronchodilators can be delivered through the BiPAP circuitry. BiPAP is well tolerated by children with status asthmaticus and may decrease the need for intubation and mechanical ventilation.[17] BiPAP may decrease the need for hospitalization, intubation, and ICU and hospital length of stay in adults with status asthmaticus.[18] There is limited evidence to routinely recommend NIV in patients with respiratory failure from severe asthma exacerbations.

NIV is not a substitute for endotracheal intubation and mechanical ventilation. A trial of NIV before intubation and mechanical ventilation can be considered in select patients by providers familiar with the use of NIV. Patients should have an alert mental status, intact airway reflexes, and ICU admission is mandatory. Intermittent ABG

monitoring to assess for worsening hypercapnia or respiratory acidosis during NIV identifies nonresponders that may need intubation.

Mechanical Ventilation

Endotracheal intubation and mechanical ventilation are required in 2% of all asthma exacerbations and 10% to 30% of those requiring ICU admission. Indications for intubation include coma, altered consciousness, cardiac or respiratory arrest, paradoxical breathing pattern, refractory hypoxemia, and failure of NIV. Some authors recommend threshold levels for intubation based on ABG results, but there is no evidence that ABG results provide better guidance regarding the need for intubation than overall clinical assessment.

Orotracheal rapid sequence intubation (RSI) with induction agents and muscle paralysis is preferred. A large endotracheal tube (≥8.0 mm for adults) facilitates airway suctioning, mucous plug removal, and bronchoscopy if needed later in the course. Ketamine (1 to 2 mg/kg) is the preferred agent for induction in RSI of the asthmatic patient because of its bronchodilatory and sympathetic stimulatory properties. Alternatively, propofol (1.5 to 2 mg/kg) offers rapid-onset deep sedation and possesses bronchodilatory properties, but its vasodilatory effects may cause hypotension, especially in the volume-depleted asthmatic. Succinylcholine (1.5 mg/kg) or a competitive neuromuscular blocking agent, such as rocuronium (1 mg/kg), can be used for intubation. Continued deep sedation with propofol, a long-acting benzodiazepine (e.g., lorazepam) or an opioid that does not release histamine (e.g., fentanyl) usually avoids the need for muscle paralysis. When bagging the patient after intubation, care must be taken to avoid hyperventilation.

A ventilator strategy providing adequate oxygenation and ventilation while minimizing hyperinflation, high airway pressure, barotrauma, and systemic hypotension must be instituted. Decreasing hyperinflation is the priority, rather than correcting hypercarbia and respiratory acidosis. Permissive hypercapnia is an appropriate technique. Low tidal volumes (6 to 8 mL/kg) keep airway pressures lower, thus reducing the risk of intrinsic positive end-expiratory pressure ("auto-PEEP"), stacking of ventilations, and barotrauma. Low ventilation rates (below 10 breaths/min) and high inspiratory flow rates (above 60 L/min) provide prolonged time for expiration. Oxygenation is maintained by titrating the fraction of inspired oxygen (Fio_2) as needed to maintain Spo_2 > 92%. Therapies such as IV hydration, inline beta-2 agonists and anticholinergics, IV corticosteroids, and magnesium to decrease airway pressure and airway obstruction are delivered simultaneously.

Continuous capnography is advisable. Moderate levels of hypercapnia are well tolerated and have few deleterious effects. Elevated carbon dioxide levels have vasodilatory effects on cerebral vessels. Cerebral blood flow reaches its maximum at a $Paco_2$ level of 120 mm Hg, which may increase intracranial pressure. Although there is no consensus on what constitutes a safe level of hypercapnia, $Paco_2$ levels above 100 mm Hg should be avoided.

Complications of mechanical ventilation in the asthmatic patient include hypoxemia, hypotension, nosocomial infections, and barotrauma. Hypotension is almost uniformly secondary to increased intrathoracic pressure with a subsequent decrease in venous return and cardiac output. Slowing the rate of mechanical ventilation or removing the patient from the ventilator for a short time (20 to 30 seconds) allows more time for expiration, thereby decreasing intrathoracic pressure. Volume depletion and medication effects (e.g., narcotic sedative agents) are other potential explanations for hypotension. Pneumothorax should be considered whenever sudden deterioration occurs or when hypotension is accompanied by a significant rise in peak inspiratory pressures on the ventilator. Although complications may occur, the use of mechanical ventilation in critically ill asthmatics is associated with low morbidity and mortality.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an invasive therapy that uses an artificial membrane to oxygenate and remove carbon dioxide. ECMO allows for gas exchange while using lung-protective ventilation strategies. Currently, there are no studies showing a clear indication for the use of ECMO in the asthmatic patient, however, registry data and case reports suggest a role in treating near fatal asthma in ventilated patients. If available, ECMO may be considered in asthmatic patients that are refractory to conventional ventilator management.[7]

Other and Future Therapies

In patients without dehydration or hypovolemia, the administration of fluids does not clear airway secretions. Mucolytics may worsen cough or airflow obstruction, and chest physical therapy is not beneficial. Infused enoximone (a phosphodiesterase III inhibitor) can cause significant bronchodilation. Specific cytokine antagonists, agonists, inhibitors of T-cell function, selective inducible nitric oxide synthetase inhibitors, and possibly gene-directed therapies may become novel treatments. Dexmedetomidine is a unique sedative that induces sleep but preserves respiratory drive and does not cause respiratory depression or change in airway patency. There may be a future role for the use of intravenous or intranasal dexmedetomidine for anxiolysis in asthma. Further studies are needed.[19]

There are currently biologic therapies available for the management of chronic asthma. Omalizumab, a recombinant humanized monoclonal anti-IgE antibody, is indicated for the treatment of severe allergic asthma. It has been shown to control symptoms in severe chronic asthmatic and may be an alternative for patients with poor compliance to ICS therapy.[20,21] Benralizumab, an antiinterleukin 5 receptor α monoclonal antibody, when given in the ED to severe nonresponding patients decreases future hospitalizations.[21]

SPECIAL SITUATIONS

Pregnancy

Asthma during pregnancy is extremely variable. During pregnancy, approximately one third of women have their asthma worsen, a third have their asthma improve, and a third have no change in their asthma symptoms. Approximately 11% to 18% of pregnant women will present to the emergency department with an asthma exacerbation and 62% of these will be admitted. Asthma exacerbation rates and hospitalizations are directly proportional to the degree of asthma control and baseline severity of disease. Maternal and neonatal outcome are excellent in patients with mild or moderate asthma. Severe asthma during pregnancy is associated with gestational diabetes and delivery before 37 weeks.[22]

The least amount of medication needed to maintain the pregnant asthmatic in the mild severity range is recommended. Acute exacerbations should be treated as in any nonpregnant patient. Pregnant asthmatics are less likely to receive systemic corticosteroids than nonpregnant asthmatics in the ED. Oral and IV steroids are safe during pregnancy and should be administered in a manner similar to nonpregnant patients. ICSs are not associated with adverse perinatal outcomes and are recommended for all pregnant patients with asthma (budesonide is preferred). Inhaled beta-2 agonists, ipratropium, magnesium sulfate, cromolyn, theophylline, and leukotriene antagonists are safe.[7] Acute asthma attacks are rare in labor likely due to endogenous steroid production. There are no contraindications to any asthma medication in the breast-feeding patient.

Near Fatal Asthma

Near fatal or life-threating asthma is used to describe acute severe asthma with clinical features such as altered consciousness level, exhaustion, poor respiratory effort, silent chest, hypotension, cyanosis,

a PEF <33% or hypoxia with a SpO_2 <92% or PaO_2 <60 mm Hg.[22a] Acute severe asthma does not require the patient to have severe asthma; rather it refers to acute episodes requiring immediate multimodal therapies to prevent progression to irreversible hypoxia and cardiopulmonary arrest. The terms status asthmaticus, near fatal asthma, and life-threatening asthma are all used to describe patients with different severity of acute severe asthma.

Risk factors for death from asthma have been identified (see Box 59.1). Other risk factors linked to near-fatal and fatal asthma include frequent use of inhaled beta-2 agonists, decreased use of corticosteroids, hospital admission for asthma treatment within the previous 12 months, low socioeconomic status, environmental exposures (air pollution, cigarette smoking), and psychosocial problems. Patients with near-fatal asthma are likely to depend on EDs for asthma management. Patients with fatal asthma commonly tend to be African American, live in inner-city areas, and are 15 to 34 years old. Less than 1% of asthmatics in the ICU die from their disease. Most deaths occur at home or on the way to the hospital, at night, and within 24 hours of the onset of symptoms.

Clinical Approach to Acute Severe Asthma

The patient with life-threatening or near fatal asthma appears agitated (hypoxemic), assumes an upright position, and appears to be in severe respiratory distress. Tachypnea, diaphoresis, and accessory muscle use are evident. Speech is fragmented into single or short bursts of syllables or words. Absence of wheezing indicates severe expiratory obstruction and minimal air movement. Peak expiratory testing is difficult for the patient to perform but when possible indicates severe expiratory obstruction. Alterations in consciousness and bradypnea indicate hypercarbia and impending respiratory arrest. No laboratory markers identify near fatal asthma.

Attempts to abort the episode include continuously nebulized beta-2 and anticholinergic agents (see Table 59.2). If parenteral adrenergic therapy is desired, terbutaline is preferred because of its beta-2 selectivity. IV magnesium sulfate may be of benefit. Oral prednisone 50 mg or IV methylprednisolone 125 mg should be administered. The use of additional therapies such as noninvasive or mechanical ventilation as described above may be necessary.

The American Heart Association recommendations for cardiopulmonary resuscitation in asthmatics indicate no difference from other cardiac arrest situations. Unrecognized barotrauma may cause cardiac arrest. Bedside ultrasound should be used to identify occult pneumothorax and to reveal nonpalpable cardiac contractions. Empirical bilateral tube thoracostomy should be performed if unexplained cardiac arrest occurs, especially in the context of dramatic increases in peak inspiratory pressure. ECMO may be indicated for severe asthma refractory to conventional therapies.

DISPOSITION

Asthmatic patients discharged from the ED have rates of relapse that vary from 11% over 3 days to 45% at 8 weeks. The relapse risk increases in those with numerous asthma-related ED visits within the previous year, more outpatient medications, and longer duration of symptoms before the ED visit. Other studies have also shown that insufficient improvement in peak flow measurements with hospital-based treatment is a risk factor for relapse.

Patients requiring extended care who are without life-threatening exacerbations, pregnancy, or complications of asthma can generally be treated in an observation unit with 8-week outcomes equal to those admitted to the hospital. Table 59.4 summarizes disposition guidelines based on PEF and other potential factors.

TABLE 59.4 Emergency Department Disposition Decision-Making Guidelines

	Good Response	Incomplete Response	Poor Response
PEF (% predicted/ personal best)	≥60%	40%–60%	<40%
Disposition Site			
Home	Yes	Consider based on risk factors (see Box 59.1)	No, continue therapy
Hospitalization	No	Consider based on risk factors (see Box 59.1)	Yes, if available and appropriate

Additional Factors With Increased Likelihood of Admission

- Female sex, older age, and non-white race
- Use of more than 8 beta agonist puffs in previous 24 h
- Severity of exacerbation (need for rapid medical intervention on arrival, respiratory rate >22, oxygen saturation <95%, final PEF <50% predicted
- Past history of intubations or asthma admissions
- Previous use of OCS

OCS, Oral corticosteroids; *PEF,* peak expiratory flow rate.

Asthma exacerbation does not end on discharge; airway inflammation and peripheral obstruction may take hours to days to resolve. Patients are likely to need continued beta-2 agonist therapy for a short time after the ED, and they should demonstrate the correct use of their inhalers. However, guidelines for the chronic use of inhaled beta-2 agonists recommend limited daily use only as a rescue therapy. A spacer should be used with any MDI. A patient using a portable, preloaded, multidose dry powder inhaler must be able to inhale from the mouthpiece in a rapid and forceful inhalation to total lung capacity.

Patients receiving systemic corticosteroids in the ED should continue these orally for 5 to 7 days. For patients with asthma symptoms less than twice per month, ED clinicians should consider discharging them with a low dose ICS-formoterol inhaler or having them take a low dose ICS whenever SABA is taken. If patients have asthma symptoms more than twice per month, they should be discharged with a low dose ICS-formoterol inhaler or taking a low dose ICS whenever SABA is taken. If the patient was not using controller medications before the acute visit and has characteristics of persistent asthma (symptoms or rescue therapy more than twice per week, interference with sleep more than twice per month, activity limitation caused by asthma or exacerbations requiring oral corticosteroids more than once in the past year), moderate-dose ICSs or a combination ICS and LABA should be started.[8]

Patients should contact their physician for asthma-related problems within the following 3 to 5 days and should make a follow-up medical appointment within 1 to 4 weeks. Interventions that include free medications, transportation vouchers, and appointment assistance significantly increase the likelihood that discharged asthma patients will obtain primary care follow-up. This assistance, however, may not affect long-term outcomes.

Patients managed by asthma specialists have fewer symptoms, less beta-agonist use, improved quality of life, reduced ED visits, and fewer hospitalizations than those managed by generalists. Patients

with severe persistent asthma or prior severe exacerbations should be referred to an asthma specialist.

The asthma patient should be provided with written education about discharge medications, medication adjustment if the condition is not improving (such action plans are not often created and when done are often inadequate), and a peak flow meter for daily measurements, especially for those who have difficulty perceiving airflow obstruction or who have symptoms of worsening asthma. At a minimum, focused education should address the difference between controller and rescue medications and the need for follow-up. Intervening in the ED during an acute asthma exacerbation with a web-based education tool may reduce future ED visits.[23] Smoking asthmatics have more respiratory symptoms, lower lung function, and more parenchymal abnormalities noted on chest computed tomography, so smoking cessation should be discussed.

CHAPTER 59: QUESTIONS AND ANSWERS

1. Which of the following is a risk factor for sudden death from asthma?

- **a.** A hospitalization for asthma in the past year but not within the past 30 days
- **b.** An emergency department (ED) visit for asthma in the past year but not within the past 30 days
- **c.** Current use of systemic corticosteroids
- **d.** Patient perception that the current exacerbation is very severe

Answer: c. Risk factors for sudden death are current or recent corticosteroid use, ED or hospitalization within the past 30 days, more than two hospitalizations for asthma in the past year, more than three ED visits for asthma in the past year, using more than two beta-agonist canisters per month, previous intubation or intensive care unit (ICU) visit, and difficulty perceiving symptoms or their severity.

2. A 23-year-old man with known severe asthma presents with an acute asthma flare over 2 hours. Physical examination reveals a well-developed man in marked respiratory distress. Heart rate is 120 beats/min, oxygen saturation is 90%, respiratory rate is 26 breaths/min, blood pressure is 140/92 mm Hg, and oral temperature is 98.7°F (37.2°C). Current medications are albuterol metered-dose inhaler (MDI) and fluticasone inhaler 500 µg twice daily. What therapy is recommended for this acute flare?

- **a.** Albuterol 2.5 mg nebulized, Ipratropium 0.5 mg, methylprednisolone 125 mg intravenously, and magnesium sulfate 2 g intravenously
- **b.** Epinephrine infusion at 5 µg/min
- **c.** Ipratropium 500 µg nebulized × three doses with methylprednisolone 125 mg intravenously
- **d.** Methylprednisolone 125 mg intravenously with salmeterol nebulized via continuous nebulization

Answer: a. Short-acting inhaled beta-agonists with ipratropium are the cornerstone of acute asthma management. Corticosteroids are indicated in any moderate or severe flare. Oral steroids are as efficacious as intravenous (IV) steroids if the patient can take oral medications. Magnesium sulfate may obviate the need for intubation or decrease hospital length of stay in severe cases. Salmeterol is a slow-onset, long-acting beta-2 agonist (LABA) not indicated in acute asthma management.

3. What is the medication combination of choice for the rapid sequence induction of an asthmatic?

- **a.** Etomidate/succinylcholine
- **b.** Ketamine/succinylcholine
- **c.** Midazolam/pancuronium
- **d.** Propofol/rocuronium

Answer: b. No choice is contraindicated. Ketamine is the sedative of choice because of its bronchodilatory effect. Propofol may have the same benefit, although less profoundly. Thiopental releases histamine, and etomidate does not bronchodilate. Succinylcholine releases trace amounts of histamine, but this is not known to cause any adverse effect. Rocuronium has an onset time similar to that of succinylcholine, no

histamine release, and a prolonged duration of action. Either succinylcholine or rocuronium is acceptable for rapid sequence intubation (RSI) in acute asthma.

4. Which of the following is a risk factor for death in patients presenting with an asthma attack?
   a. Currently taking theophylline
   b. Family history of asthma
   c. Presence of symptoms for 1 week
   d. Use of three albuterol metered-dose inhalers (MDIs) per month

Answer: d. The following are risk factors for death from asthma:

- Past history of sudden severe exacerbations
- Prior intubation for asthma
- Prior asthma admission to an intensive care unit (ICU)
- Two or more hospitalizations for asthma in the past year
- Three or more emergency department (ED) care visits for asthma in the past year
- Hospitalization or an ED care visit for asthma within the past month
- Use of more than two MDI short-acting beta-2 agonist canisters per month
- Current use of or recent withdrawal from systemic corticosteroids
- Difficulty perceiving severity of airflow obstruction
- Comorbidities such as cardiovascular diseases or other systemic problems
- Serious psychiatric disease or psychosocial problems
- Illicit drug use, especially inhaled cocaine and heroin

5. A 25-year-old woman presents with wheezing and shortness of breath from asthma. She was recently exposed to cigarette smoke. She denies cough and fever. You cannot get much more of a history from her at this time because she finds it difficult to speak in complete sentences. Her vital signs are blood pressure, 136/85 mm Hg; heart rate, 110 beats/min; respiratory rate, 32 breaths/min; and temperature, 99°F (37.2°C). Her oxygen saturation is 92%. Her PEF is 50% of predicted. On physical examination, you note bilateral wheezing, regular tachycardia, and accessory muscle use. The remainder of her examination is normal. Over the course of 1 hour, she receives supplemental oxygen, three doses of nebulized albuterol (5 mg) mixed with ipratropium (0.5 mg), and oral prednisone 50 mg. She now reports feeling somewhat better. She speaks in longer sentences but still cannot speak in complete sentences. A repeat peak flow measurement is now 60% of predicted. Otherwise, there are no changes on a repeat physical examination. You plan to admit her to your ED observation unit. What is an appropriate next step in the management of this patient?
   a. Additional nebulized albuterol
   b. Intravenous (IV) magnesium sulfate
   c. IV methylprednisolone (Solu-Medrol)
   d. Oral montelukast

Answer: a. This patient presents with a moderate-to-severe asthma exacerbation. She has responded to initial therapy but continues to have moderate symptoms. Additional adrenergic medications are indicated. Because she is tolerating nebulized medications and is responding, there is no need for IV or subcutaneous adrenergic agents, such as terbutaline. IV magnesium sulfate is a smooth muscle relaxant, but it is generally reserved for more severe asthma exacerbations. Oral and IV steroids have the same efficacy, and regardless of the route, only need to be administered every 6 to 8 hours. Montelukast is a leukotriene-modifying drug that is used in chronic management.

60

Chronic Obstructive Pulmonary Disease

Patricia Ruth Atchinson and Matthew A. Roginski

KEY CONCEPTS

- Chronic obstructive pulmonary disease (COPD) is "a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway or alveolar abnormalities usually caused by significant exposure to noxious particles or gases."
- COPD exacerbation is a worsening of symptoms from baseline beyond day-to-day variation and requiring additional treatment. It is most commonly caused by viral infections, bacterial infections, environmental pollutants, particulate matter, thrombotic disease, or temperature changes.
- Dyspnea, cough, increased sputum production, and sputum purulence are the most common symptoms of COPD exacerbations. They are a result of airway inflammation, increased mucus production, and air trapping.
- Treatment includes nebulized short-acting beta-agonists such as albuterol, short-acting anticholinergics such as ipratropium, and glucocorticoids such as prednisone.
- Antibiotics should be given to patients with COPD exacerbations who have signs of lower respiratory tract infection, increased purulence of their sputum, or who have respiratory failure. Antibiotics should be provided empirically based on local resistance patterns to *Streptococcus pneumoniae, Moraxella catarrhalis,* and *Haemophilus influenzae* with common regimens including amoxicillin/clavulanate, macrolides, or tetracyclines.
- Patients with COPD are at increased risk for thromboembolic disease due to a sedentary lifestyle and chronic inflammation. Patients admitted for COPD exacerbation presenting a pleuritic chest pain or signs of heart failure without an infectious precipitant should be screened for pulmonary embolism.
- Patients with COPD exacerbations commonly present with tachyarrhythmias including atrial fibrillation, atrial flutter, and multifocal atrial tachycardia.
- Oxygen supplementation should be administered with a saturation goal of 88% to 92%.
- In severe exacerbations, patients develop a rapid, shallow breathing pattern which decreases the exhalation time, causes hyperinflation, increases the proportion of dead space ventilation, and causes respiratory muscle fatigue.
- Bi-level noninvasive ventilation is the first-line therapy for patients with hypercapnic respiratory failure and acute COPD exacerbations without hemodynamic instability, severe agitation, or respiratory arrest. Implementing noninvasive ventilation decreases the mortality, intubation rates, and hospital length of stay.
- If intubation is required, ventilation priorities are decreasing the patient work of breathing and limiting dynamic hyperinflation primarily using a low respiratory rate of 10 to 14 breaths/min and tidal volume of ≤8 mL/kg predicted by body weight. Respiratory acidosis with a pH greater than 7.2 should be tolerated without manipulating the minute ventilation.
- All patients being discharged from the emergency department should be counseled on smoking cessation, adequate inhaler techniques, and offered pneumococcal and influenza vaccination if not current.

FOUNDATIONS

Background

Chronic obstructive pulmonary disease (COPD) is a leading cause of death in the United States and worldwide[1] with a high financial burden to the healthcare system and frequent presentation to the emergency department (ED). The prevalence of COPD is likely underrecognized.[2,3] A large multinational collaboration called the Global Initiative for Chronic Obstructive Lung Disease (GOLD) was created to develop guidelines worldwide to improve prevention and treatment of COPD. GOLD defines COPD as "a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway or alveolar abnormalities usually caused by significant exposure to noxious particles or gases."[1] COPD is caused by both environmental and genetic factors. Cigarette smoking is the most important risk factor for developing COPD, but fewer than half of smokers will develop COPD. Other risk factors include an age greater than 40 years, male gender, occupational exposures, indoor air pollution, and genetic factors such as alpha-1 antitrypsin deficiency.

Airflow limitation diagnosed by spirometry determines the disease severity. Symptom burden and exacerbation risk are also incorporated into the diagnostic criteria. Treatment recommendations of the stable patient incorporate both the airflow obstruction and symptom burden. Patients with COPD have a high prevalence of concomitant comorbid conditions, including ischemic heart disease, atrial fibrillation, heart failure, metabolic syndrome, musculoskeletal disease, anxiety, depression, and lung cancer.[4]

Anatomy/Physiology/Pathophysiology

The tracheobronchial tree is composed of large conducting airways that divide into smaller bronchi and bronchioles terminating in a functional lung unit called a pulmonary acinus. The acinus is supplied by a first order respiratory bronchiole and includes alveolar ducts and alveolar sacs (Fig. 60.1). The larger bronchi are in close proximity to pulmonary arteries and lymphatics and not directly connected to the lung parenchyma. They remain patent because of their cartilaginous structure and the pressure gradient from the alveolar to the intrathoracic space. Smaller bronchioles (<1 to 2 mm) are embedded in lung parenchyma and do not have a cartilaginous structure; they remain patent because of the elastic recoil of the lung parenchyma. Collectively, the total cross-sectional area of the bronchioles is approximately 100 times greater than that of the large proximal airways and, under normal circumstances, do not contribute to flow resistance. In COPD, progressive changes within the bronchial tree and the lung parenchyma cause airflow resistance.

Frequent exposure to noxious stimuli (e.g., cigarette smoke or small particles) induces inflammation in the airways and pulmonary parenchyma. Lymphocytes, macrophages, and neutrophils infiltrate inflamed tissues. Over time, a chronic inflammatory response leads

to remodeling and destruction of the normal tissue by oxidative stress and protease activity. Inflammation in the bronchi and bronchioles results in increased mucus production with submucosal gland enlargement and goblet cell metaplasia, decreased mucociliary clearance, and increased permeability of the airspace epithelial border. Sustained inflammation can result in the remodeling of smooth muscle and connective tissue, epithelial hypertrophy, and fixed obstruction in small airways from fibrosis.

Inflammation in the lung parenchyma destroys the connective tissue matrix of alveolar walls and septae. The balance of protease/antiprotease activity has an essential role in disease progression. Activated neutrophils are the primary producer of elastase in the lungs, and neutrophil elastase destroys the matrix of lung parenchyma. The action of neutrophil elastase is inhibited by alpha 1-antitrypsin. Patients who are deficient in alpha 1-antitrypsin, as well as patients who are chronically exposed to noxious stimuli, leading to the activation of neutrophils in the pulmonary parenchyma, have significant parenchymal damage.

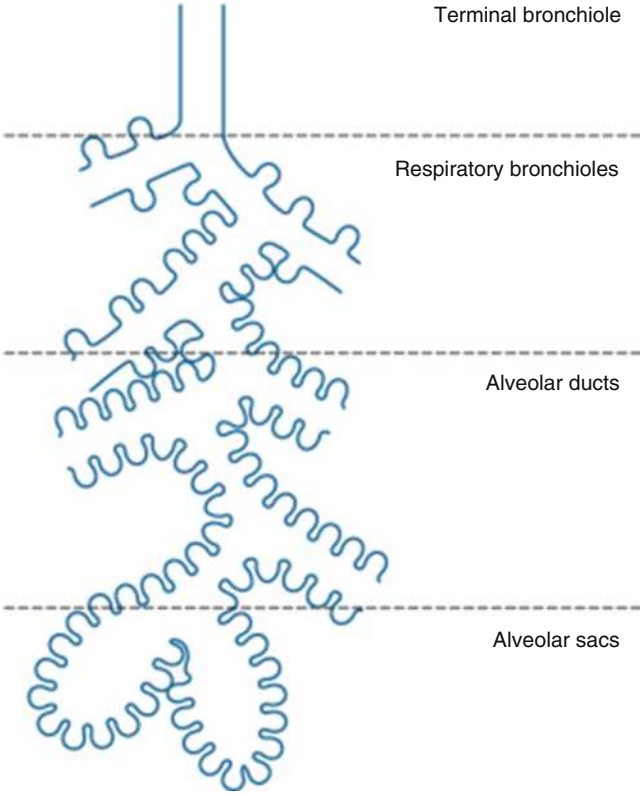

Fig. 60.1 Diagram of a single pulmonary acinus displaying the generations between terminal bronchiole and alveolar sacs. (From Nunn's Applied Respiratory Physiology. Lumb, Andrew B, MB BS FRCA. Published January 1, 2017. Pages 3–16.e1. © 2017. Figure 1.6.)

COPD is a multifactorial and heterogeneous disease with different aspects of the disease progressing independently of the another. Patients are no longer categorized as having primarily emphysematous or chronic bronchitis phenotypes because both often coexist. Emphysema is a pathological diagnosis referring to the destruction of the lung parenchyma. Pulmonary parenchymal destruction results in gas trapping and airflow obstruction. The pattern and location of damage can vary based on precipitating factors. Patients with alpha 1-antitrypsin deficiency usually have panacinar emphysema predominantly in the lower lung zones, whereas chronic smokers typically have central acinar emphysema predominantly in the upper lung zones (Fig. 60.2). Severity of airflow obstruction and air trapping are proportional to the amount of parenchymal destruction. Decreased and damaged lung parenchyma provide less traction on the small bronchioles (<1 to 2 mm) embedded in the parenchyma and requiring an intact architecture for patency. As airflow obstruction and parenchymal destruction worsen, the total number of terminal bronchioles is also reduced.[5] This combination of events leads to decreased gas exchange, decreased pressure gradient from the alveoli to the conducting airways during exhalation, and collapse of the bronchioles leading to gas trapping (Fig. 60.3). Fig. 60.4 shows evidence of parenchymal destruction in a patient with COPD and emphysema on contrast enhanced chest CT.

Chronic bronchitis is diagnosed in the presence of cough and sputum production for most days over 3 months for at least 2 consecutive years. These patients have increased mucus production, decreased ciliary clearance and chronic bronchial inflammation. They are likely to have central hypoxemia because of these changes. There are efforts to clarify different endotypes of COPD to develop targeted treatments. For example, alpha 1-antitrypsin deficiency and inflammation that has an eosinophilic predominance may be more amenable to steroids.[4] Asthma-COPD overlap syndrome has clinical features of both asthma and COPD regarding bronchial hyperresponsiveness and etiology of inflammation.[6] Differentiation is of limited clinical utility in the ED.

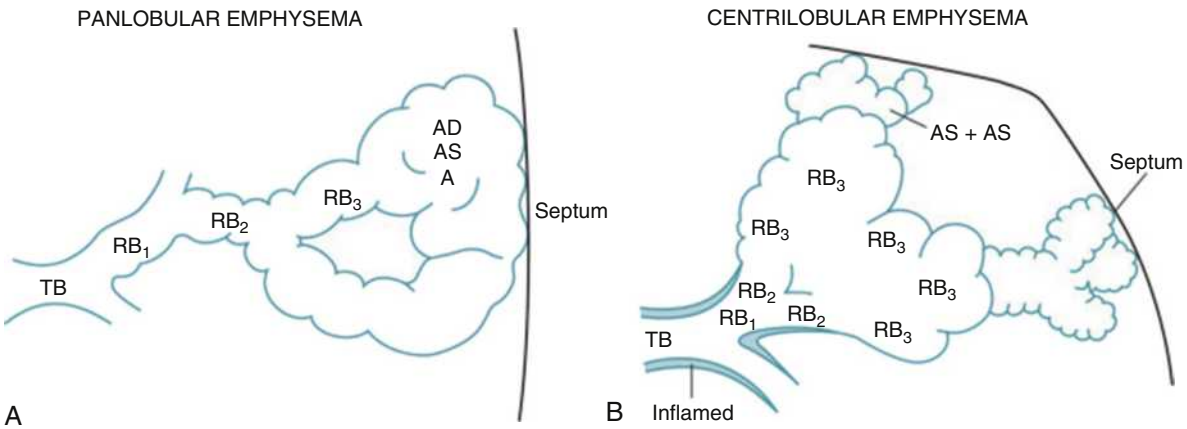

Fig. 60.2 Diagram of panacinar (A) and centriacinar (B) emphysema. Panacinar emphysema (A) has uniform enlargement of the acinus. Centriacinar emphysema the enlargement is primarily at the level of the respiratory bronchiole and not alveolar sacs. *A*, Alveolus; *AD*, alveolar duct; *AS*, alveolar sac; *RB 1, 2, 3*, three generations of respiratory bronchioles; *TB*, terminal bronchiole. Fig. 60.4 (A and B) Coronal contrast enhanced CT images in a patient with emphysematous chronic obstructive pulmonary disease. Decreased attenuation in the right and left upper lung zones represents the parenchymal destruction and loss.

Pulmonary hypertension may be present in patients with severe COPD because of changes in the pulmonary vasculature and surrounding structures. Late in the course of COPD, there is often chronic hypoxia secondary to lung parenchyma destruction. Hypoxic vasoconstriction in the small vessels of the pulmonary arterial bed and loss of pulmonary capillaries result in vascular remodeling, intimal hyperplasia, smooth muscle hyperplasia, and hypertrophy. Hypoxic vasoconstriction may be reversible, but vascular remodeling may not be. As the disease progresses, pulmonary hypertension (cor pulmonale), and right ventricular remodeling may result. These progressive changes are also associated with a patient's clinical course. For example, a large pulmonary artery to aorta ratio on CT scan is associated with an increased risk of COPD exacerbation.

As airflow obstruction and increasing air trapping develop on the microscopic pulmonary acinus level, there are associated changes in the macroscopic lung physiology. COPD patients have increased residual volume, functional residual capacity (FRC), and total lung capacity due to hyperinflation. This contributes to the increase in dead space and decline of forced expiratory volume in one second (FEV_1) because of the loss of lung tissue and loss of elastic recoil of the lungs. Over time these changes cause the diaphragm to flatten with a decreased zone of opposition causing a decrease in mechanical efficiency. The rib cage also changes with an increase in the antero-posterior diameter (Fig. 60.5). These changes are associated with decreased respiratory efficiency and increased energy consumption to maintain an adequate minute ventilation. Patients with these underlying changes have a decreased respiratory reserve in the setting of a COPD exacerbation, pneumonia, or metabolic acidosis that requires respiratory compensation.

Clinical Features

The diagnosis of COPD should be considered in patients who have progressive dyspnea, chronic cough or sputum production, recurrent

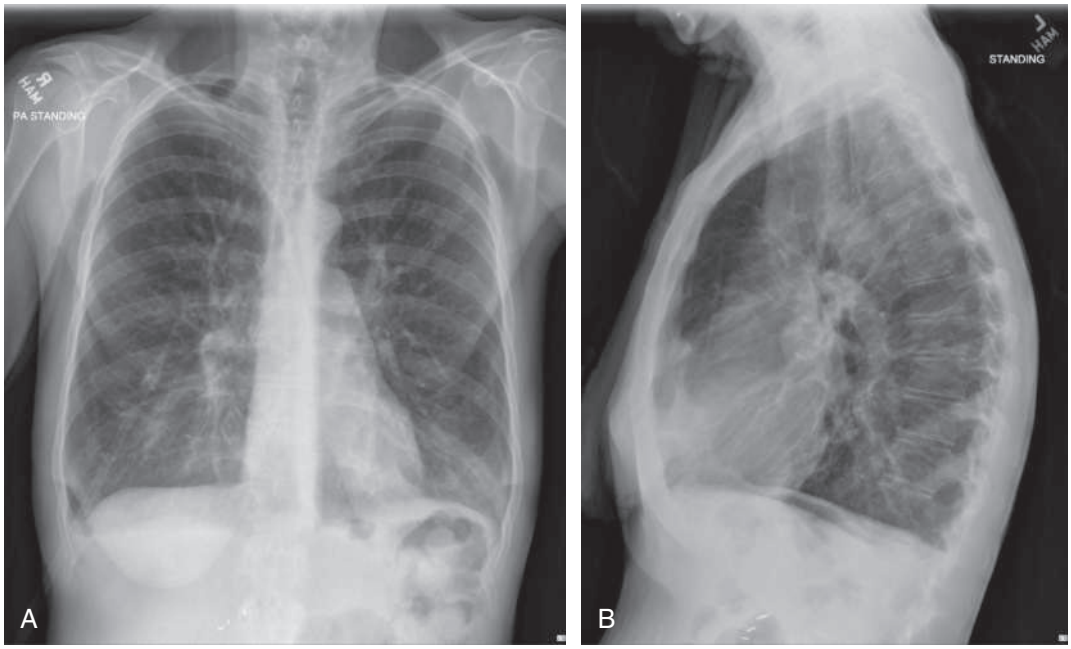

Fig. 60.5 (A and B) Chest x-rays displaying typical changes seen in chronic obstructive pulmonary disease. A is a posterior-anterior chest x-ray showing hyperinflated lungs and a flattened diaphragm. B is a lateral chest x-ray showing hyperinflated lungs and a flattened diaphragm and with an increased antero-posterior diameter.

lower respiratory tract infections or have multiple risk factors.[1] The diagnosis of COPD requires spirometry-proven airflow limitation defined as the ratio of FEV_1 divided by forced vital capacity (FVC) after bronchodilators of less than 0.7. Patients who have normal spirometry with chronic symptoms and possible emphysema on CT scan are not considered to have COPD.[7] Airflow limitation may worsen over time, especially in the setting of continued exposure to noxious stimuli, and is frequently associated with escalating patterns of worsening exacerbations. However, it is difficult to predict the progression of airflow limitation for an individual, because a small subset of patients get stable or improve over time.[8,9]

The GOLD classification of COPD incorporates the severity of spirometric abnormalities, nature and magnitude of the symptoms, history of moderate to severe exacerbations, and comorbid conditions because the health status and spirometric abnormalities have a weak correlation. The severity of COPD is graded by the degree of airflow obstruction (FEV_1) after bronchodilation (Table 60.1). In addition to the grade, the "ABCD" assessment tool incorporates symptomatic assessment and risk of exacerbations to better assess patients and guide therapy. The letter group is determined by the Modified British Medical Research Council (mMRC) Questionnaire[10] or COPD Assessment Test (CAT)[11] as well as the exacerbation history (Table 60.2). While emergency physicians are not tasked with diagnosing COPD, understanding the spirometric and letter grading provides a more complete understanding of the disease severity, symptom burden, medication regimen, and risk for hospitalization and decompensation.

Acute Exacerbations

A COPD exacerbation is an acute worsening of respiratory symptoms from baseline day-to-day variations that require additional therapy.[1,12] Exacerbations can be triggered by respiratory infection, environmental pollutants, particulate matter, thrombotic disease, or temperature changes. Respiratory infections are more commonly viral, with bacterial infections implicated in 30% to 50% of exacerbations. The most commonly implicated bacterial causes include *Haemophilus influenzae,*

TABLE 60.1 Severity Classification of Airflow Limitation in Patients With COPD (FEV_1/FVC <0.7)

GOLD Classification of Airflow Limitation Severity in COPD (based on post-bronchodilator FEV_1)		
GOLD 1	Mild	FEV_1 ≥80% predicted
GOLD 2	Moderate	50% ≤FEV_1 <80% predicted
GOLD 3	Severe	30% ≤FEV_1 <50% predicted
GOLD 4	Very Severe	FEV_1 <30% predicted

Streptococcus pneumoniae, and *Moraxella catarrhalis*. The most commonly isolated virus is rhinovirus, and viral infections may have a longer and more severe course. Patients presenting with a COPD exacerbation without a clear exposure or infectious risk should be screened for pulmonary embolism, especially if pleuritic chest pain or signs of heart failure are present.[13,14]

Exacerbations are considered mild when only worsening of symptoms are reported, moderate when the patient receives antibiotics or systemic glucocorticoids, and severe when the patient requires an ED visit.[1,4,15] Exacerbations are commonly associated with dyspnea, cough, increased sputum production, and sputum purulence. Depending on the severity, dyspnea and respiratory symptoms may occur at rest or with exertion. Coughing spells may be associated with chest pain from irritation of the intercostal muscles or atraumatic rib fractures in severe cases. Severe coughing episodes may precipitate syncope because of the increase in intrathoracic pressure and decrease in cardiac preload. Inflammation and mucous production increase air trapping, combined with chronic changes to pulmonary mechanics and impaired ability to compensate; this ultimately leads to decreased respiratory efficiency, increased dead space ventilation, and dynamic hyperinflation. As the work of breathing increases, the proportion of cardiac output required by the respiratory musculature increases, further limiting the patient's ability to compensate, and predisposing the patient to progressive respiratory failure.

Respiratory Failure

Patients with a declining respiratory status have a breathing pattern marked by small, frequent breaths through pursed lips. This change in breathing pattern decreases the exhalation time, increases the proportion of dead space ventilation, and has a high energy cost. Many of these patients experience expiratory flow limitation (EFL), in which expiratory flow does not increase despite an increase in the gradient from alveolar pressure to ambient air pressure.[16] In patients with EFL, exhalation to passive FRC (complete exhalation) depends on the expiratory time and not the patient effort. Increased patient effort and pleural pressure do not result in faster expiratory airflow. EFL predisposes patients to dynamic hyperinflation and alveolar overdistension with tachypnea.

Dynamic hyperinflation occurs when inhalation occurs prior to complete exhalation because of truncated expiratory time. Dynamic hyperinflation increases the end-expiratory lung volume, with alveolar overdistension, increased intrathoracic pressure, and decreased lung compliance. These factors subsequently result in an elevated work of breathing, increased dead space ventilation, respiratory muscle fatigue, and hypercapnia culminating in respiratory failure. Clinical definitions of respiratory failure consider respiratory rate, accessory muscle use, increases in the arterial partial pressure of carbon dioxide ($PaCO_2$), and hypoxemia. Definitions of respiratory failure are displayed in Box 60.1.

Differential Diagnosis for the Emergency Presentation

The differential diagnosis for a COPD exacerbation, displayed in Box 60.2, includes pulmonary, cardiac, and metabolic conditions. Respiratory decompensation may be from pneumonia, bleb rupture and pneumothorax, or pleural fluid collection. Pulmonary embolism should be considered in patients without an infectious prodrome, unexplained pleuritic chest pain, signs of new heart failure, or in those whose vital sign abnormalities are out of proportion to the clinical exam. Traumatic or pathologic rib fractures from coughing can cause chest pain and dyspnea. Chest pain may also be related to hyperinflation and overdistention of the respiratory muscles causing discomfort. Patients with COPD have increased risk of coronary artery disease, arrhythmias, and heart failure. Acute cardiogenic pulmonary edema may also present as dyspnea and wheezing. Progressing pitting edema may represent cor pulmonale. Patients at risk for lung cancer may present with dyspnea in the setting of malignant pulmonary or pericardial effusions. Metabolic acidosis or sepsis may present as dyspnea and tachypnea because changes in the respiratory system in severe COPD limit respiratory compensation of a metabolic process.

BOX 60.1 Classification of Respiratory Failure in COPD Exacerbation

No respiratory failure
- Mild tachypnea with rate of 20–30 breaths per minute
- Normal work of breathing
- Baseline mental status
- Mild hypoxemia responsive to oxygen by nasal cannula
- No hypercapnia

Acute respiratory failure
- Significant tachypnea with rate >30 breaths per minute
- Increased work of breathing with accessory muscle use
- Baseline mental status
- Hypoxemia responsive to supplementation with <35% FiO_2
- Hypercapnia with $PaCO_2$ 50–60 mmHg and pH >7.25

Severe respiratory failure
- Altered mental status
- Hypoxemia requiring supplementation with >35% FiO_2
- $PaCO_2$ >60 mm Hg or pH ≤7.25

BOX 60.2 Differential Diagnosis of an Acute Chronic Obstructive Pulmonary Disease Exacerbation

Differential Diagnosis for COPD and COPD Exacerbation

Pneumonia
Pneumothorax
Pleural effusion
Pulmonary embolism
Pulmonary edema
Cardiac arrhythmia
Malignancy
Pericardial effusion
Heart failure
Metabolic acidosis with compensatory tachypnea

COPD, Chronic obstructive pulmonary disease.

Diagnostic Testing

In the outpatient setting, the diagnosis of COPD relies upon spirometry. Patients with symptoms and risk factors suggestive of COPD should be referred for formal evaluation. The diagnosis of COPD exacerbation is clinical and based on a worsening of the patient's baseline symptoms including increased dyspnea, changes in sputum production or increased sputum purulence, and cough.

Chest Radiography

A chest x-ray should be obtained for patients to evaluate a new alveolar process such as a lobar pneumonia, pneumothorax, pulmonary

edema, lobar atelectasis, effusion, or malignancy. Typical findings in a COPD exacerbation without the aforementioned pathology include hyperinflated lung fields, decreased vascular markings, increased antero-posterior diameter, and flattening of the diaphragms (see Fig. 60.5). Bullae may be present and can mimic pneumothorax on chest x-ray and pulmonary ultrasound. If there is diagnostic uncertainty for bullae versus pneumothorax, a CT scan should be performed given its greater sensitivity.

Pulse Oximetry

Continuous pulse oximetry should be used to identify hypoxemia and titrate oxygen therapy.

Blood Gas Analysis

We recommend an initial blood gas in patients presenting with acute respiratory failure. A venous blood gas provides an accurate determination of both pH and hypercapnia. A normal $PaCO_2$ on a venous blood gas can exclude hypercapnic respiratory failure.[17] If there is severe hypercapnia or hypoxia, correlation with an arterial blood gas is recommended. An arterial or venous $PaCO_2$ is recommended if end-tidal capnography is being used because of a possible $PaCO_2$ to end-tidal CO_2 discrepancy in the setting of an increased dead space fraction.

Electrocardiogram

An electrocardiogram should be performed in all patients presenting with acute dyspnea. Tachycardia and tachyarrhythmias, including atrial fibrillation, atrial flutter, multifocal atrial tachycardia, and ventricular arrhythmias, occur in up to 35% of patients presenting with COPD exacerbations.[17] Patients with COPD are at increased risk for ventricular tachycardia when compared to the general public, independent of their left ventricular ejection fraction.[18,19] Patients with COPD commonly exhibit P pulmonale, large (>2.5 mm) peaked P waves in leads II, III, and aVF, and >1.5 mm in V1 and V2, low QRS voltage (due to hyperinflated lung between the chest wall and the heart), and poor R wave progression (≤3 mm in V3) in the precordium.

Laboratory Tests

The utility of C-reactive protein (CRP) in COPD management is a developing area of research. Some studies describe that a low CRP decreases the prescription of antibiotics in COPD exacerbations without increasing the proportion of treatment failure.[20–22] We do not think there is sufficient evidence at this time to support using CRP to guide antibiotic prescribing.

Procalcitonin (PCT) has also been considered as a screening test to guide the use of antibiotics, with some studies suggesting that a low PCT can safely be used to decrease antibiotic prescriptions in COPD exacerbation.[23] However, in patients admitted to intensive care units, PCT-guided therapy was associated with worse mortality at 3 months, suggesting that in the critically ill, the prompt administration of antibiotics outweighs the need for judicious antibiotic prescribing.[24]

We also recommend a complete blood count to screen for anemia and a metabolic profile to screen for metabolic acidosis or hyperglycemia. A troponin should be obtained if there is concern for myocardial ischemia. A D-dimer should only be obtained to screen for an acute pulmonary embolism after prior appropriate risk stratification.

Management

Short-Acting Beta Agonists

Short-acting beta agonists (SABAs) with or without short-acting anticholinergics are the cornerstone of COPD exacerbation management. SABAs work through relaxing airway smooth muscle by stimulating beta-2 adrenergic receptors, increasing cyclic adenosine monophosphate (AMP) and producing a functional antagonism to bronchoconstriction. Short-acting anticholinergics prevent the bronchoconstrictive effects of acetylcholine on M2 muscarinic receptors expressed by smooth muscles. In an acute exacerbation, data do not support the use of nebulizers over metered dose inhalers to deliver these medications.[25,26] In the emergency setting, we recommend the use of nebulized medications instead of devices that require adequate inspiratory flow, breath holding, muscle coordination, and proper technique to promote adequate medication disbursement.[26,27] We recommend air-driven nebulizers rather than oxygen-driven nebulizers if available.[28] Patients may receive SABAs hourly for 1 to 3 hours then every 2 to 4 hours based on response. Continuous nebulization not indicated.

Glucocorticoids

Glucocorticoids act as potent anti-inflammatory mediators by inhibiting cytokine expression and eosinophils via induction of eosinophil apoptosis. They are recommended in COPD exacerbation because they decrease the recovery time, improve oxygenation, improve lung function, and decrease hospital length of stay. These benefits outweigh the risks, including infection, thromboembolism, osteoporosis, diabetes, and hypertension. Bioavailability is similar between oral and parenteral corticosteroids; thus we recommend oral glucocorticoids for patients able to tolerate oral medications or with enteral access. We recommend 40 mg oral prednisone for 5 days, because 5 day courses are as effective as longer courses.[29] Eosinophilia-guided therapy may be as effective as the standard 5-day course of steroids in patients ≥40 years old and hospitalized for COPD[30] but this is not part of the standard treatment recommendations at this time.

Antibiotics

The role of antibiotics in COPD exacerbation remains controversial. There is no clear mortality benefit of using antibiotics in patients who are to be discharged from the ED without signs of lower respiratory infection on chest imaging. The GOLD collaborators recommend the administration of antibiotics to patients with COPD exacerbation who note increased sputum purulence as well as increased dyspnea or increased sputum volume. Antibiotics should be provided empirically based on local resistance patterns to *S. pneumoniae, M. catarrhalis,* and *H. influenzae* with common regimens including amoxicillin/clavulanate, macrolides, and tetracyclines. Patients with chronic severe airflow limitations, known bronchiectasis, and or those that require mechanical ventilation should receive antibiotic coverage that includes pseudomonas. Data does not suggest a specific duration of treatment with antibiotics in those patients who are discharged from the ED. We recommend a 5-day course of macrolides or a 7-day course of amoxicillin/clavulanate or tetracyclines as initial antibiotic therapy, along with follow up with their primary care physician or pulmonologist within 10 days of discharge with attention to decreased sputum purulence as a marker of improvement. Any patient requiring ventilatory support via either noninvasive ventilation (NIV) or endotracheal intubation should receive antibiotics as there is a clear mortality benefit in these patients.

Adjunctive Treatments

All actively smoking patients who present a COPD exacerbation should be counseled on smoking cessation. Inhaler technique should be assessed, and counseling provided in case of inadequate techniques. Patients should be up to date on influenza and pneumococcal vaccinations unless contraindicated. There is no conclusive role for antitussive therapy. Patients being hospitalized should have vitamin D level checked and supplemented if below 25 nmol/L or above 10 ng/mL.[31]

Methylxanthines are not recommended. Heliox is not recommended as a treatment adjunct.[32–34]

Respiratory Support

Oxygenation

Hypoxemia is a common finding in patients with severe COPD and during a COPD exacerbation. The precipitating factors of hypoxemia are multifactorial, including changes in the ventilation and perfusion ratios because of hyperinflation and bronchospasm, mucous plugging, alveolar infiltration, disproportionate blood flow in under-ventilated areas, and increased oxygen consumption leading to decrease venous oxygen tension. Both hypoxemia and hyperoxemia should be avoided. Supplemental oxygen should be titrated to maintain an arterial partial pressure of oxygen (PaO_2) greater than 60 mm Hg and peripheral oxygen saturation between 88% and 92%. Prolonged exposure to high concentrations of inspired oxygen may result in increasing hypercapnia. The primary mechanism is thought to be from a change in the ventilation and perfusion ratios by altering hypoxic vasoconstriction to under-ventilated lung zones. The hypoxic respiratory drive does not appear to be a major contributor in most hypercapnic patients in respiratory distress, but there does appear to be a subset of patients in whom $PaCO_2$ increases in the setting of hyperoxia. The Haldane effect (high oxygen tension induces right shift in the CO_2 dissociation curve and increases the $PaCO_2$) may also contribute to hypercapnia. Normally, this is compensated for by an increase in minute ventilation, but if the patient cannot increase their minute ventilation, $PaCO_2$ will increase.

Non-Invasive Ventilation

Bi-level NIV is the first-line therapy for patients with an acute COPD exacerbation with respiratory failure (see Table 60.3 for indications and contraindications). NIV decreases the mortality, intubation rates, and hospital length of stay.[1,15,35,36] The inspiratory positive airway pressure (IPAP) of NIV helps offload respiratory muscles and aid in the work necessary to overcome the intrinsic positive end expiratory pressure (iPEEP). Initiating NIV changes the patient's breathing pattern; the respiratory rate decreases, allowing a more effective emptying of the lungs, and the patient can take breaths with larger tidal volumes, improving alveolar ventilation. If possible, a chest x-ray, blood gas, and respiratory assessment are recommended prior to the initiation of NIV to evaluate for pneumothorax, tachypnea, accessory muscle use, pH, and $PaCO_2$.

We recommend initial settings of an IPAP of 12 to 15 cm H_2O and an expiratory positive airway pressure (EPAP) of 5 cm H_2O through a facemask tightened to minimize air leaks. Inspired oxygen should be quickly titrated to an oxygen saturation of 88% to 92%. While fitting the mask on the patient, a nurse, respiratory therapist, or physician should explain the process to the patient because of the associated anxiety during mask placement while in respiratory distress. An adjunctive fan directed at the patient's face or adjunctive low dose morphine may relieve the sensation of breathlessness.[37–39] Should the patient have increased work of breathing on these initial settings, we recommend increasing the IPAP by increments of 2 to 3 cm H_2O every 2 to 3 minutes to a maximum IPAP of 25 cm H_2O. Improvement in pH and respiratory rate predict treatment success and are usually seen in the first 1 to 4 hours after initiation.[40]

Failure of NIV may occur because of the severity of the underlying disease, severity of comorbidities, or inability to tolerate therapy. The overall failure rate is approximately 10% to 15%[41] but increases with a lower presenting pH and severity of illness. In general, patients initiated on NIV should be reassessed for the same indications they were started on NIV (tachypnea, accessory muscle use, pH, and $PaCO_2$) and if there is no improvement after initiation of therapy, patients should have their NIV settings adjusted or be intubated.

TABLE 60.3 Indications and Contraindications for Noninvasive Positive Pressure Ventilation and Invasive Mechanical Ventilation

	RESPIRATORY SUPPORT INDICATIONS	
	Bi-Level Noninvasive Ventilation	**Invasive Mechanical Ventilation**
Indications	• Respiratory acidosis ($PaCO_2$ ≥45 mm Hg and pH ≤7.35) • Severe dyspnea with signs of respiratory muscle fatigue and accessory muscle use • Persistent hypoxemia despite supplemental oxygen therapy	• Unable to tolerate NIV • NIV failure • Persistent diminished consciousness • Respiratory or cardiac arrest • Persistent inability to remove secretions • Hemodynamic instability without response to fluids and vasoactive medications • Life-threatening hypoxemia not corrected by less invasive interventions
Contraindications	• Active vomiting/high-risk aspiration • Respiratory arrest • Facial trauma • Depressed mental status not related to high $PaCO_2$	• Appropriate for NIV • Patient wishes (e.g., advanced directive, do not resuscitate or do not intubate order)

NIV, Noninvasive ventilation.

High-Flow Nasal Cannula

While high-flow nasal cannula (HFNC) oxygen therapy is primarily used in hypoxic respiratory failure,[41] it is increasingly being used in patients with COPD. Multiple small studies show an increase in oxygenation, reduction in hypercapnia, and comfort in stable patients with COPD.[42–44] While NIV remains the first-line therapy in hypercapnic respiratory failure in COPD, HFNC is a viable support modality for patients with mild to moderate respiratory acidosis who do not tolerate or need breaks from NIV[45–47] and do not require intubation and invasive ventilation. The same monitoring parameters as NIV apply to HFNC.

Invasive Ventilation

The decision to intubate a patient during a COPD exacerbation depends on the patient's condition (not laboratory values), failure of first-line therapy, and patient's wish. Indications for intubation and mechanical ventilation are outlined in Table 60.4. The mortality rate of patients with respiratory failure secondary to COPD exacerbation is high, but it is important to note that the mortality rate in COPD exacerbation patients is lower than in all comers with respiratory failure to the intensive care unit. Treatment recommendations should be based on the patient's values and disease burden. We advise against prognostication in the very early phase of the resuscitation. An immediate response to intubation and continued treatment is often not seen in the ED. Inaccurate prognostication may have downstream repercussions in the care of the patient later in the hospital admission or subsequent admissions.

The goals of mechanical ventilation are to decrease the patient distress and work of breathing, minimize dynamic hyperinflation and intrinsic PEEP, and to lessen hypercapnia and hypoxemia without exposing the patient to iatrogenic complications. No mode of

ventilation is superior to achieve these goals. Focus during the initial ventilation phase should be directed towards maintaining normoxia and preventing dynamic hyperinflation. Severe respiratory acidosis is common, and hypercapnia should be tolerated without adjusting the minute ventilation if the pH is greater than 7.2.

After the patient is initially intubated and while still sedated and paralyzed, an assist control mode of ventilation is required. We recommend volume assist control with an initial respiratory rate of 10 to 14 breaths/min, tidal volume of ≤8 mL/kg of predicted body weight, a square flow inspiratory waveform, inspiratory time of 0.8 to 1 seconds, PEEP of 5, and titration of inspired oxygen to a saturation of 88% to 92%. These patients commonly have long time constants and EFL and require a longer exhalation time to reach FRC. Dynamic hyperinflation risk is proportionally related to a high minute ventilation. Setting a respiratory rate of 10 to 14 breaths/min is the most effective way to decrease the minute ventilation and duty cycle time to prevent dynamic hyperinflation. Respiratory rates less than 10 breaths/min are not recommended. They allow for longer emptying, but may decrease the minute ventilation to an undesirable level causing a severe hypercapnic respiratory acidosis without a significant benefit in lowering end-expiratory lung volumes and pressures (Fig. 60.6).[16] Soon after

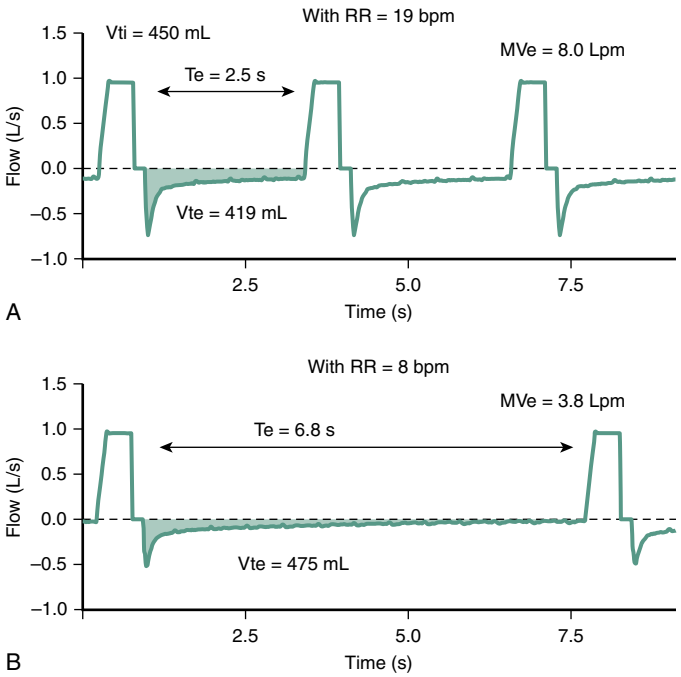

Fig. 60.6 Flow-time curves from a patient with chronic obstructive pulmonary disease with tidal expiratory flow limitation showing the result of prolonging expiration time. (A) Original ventilator settings in volume-controlled mode with a respiratory rate of 19 breaths/min, expiratory time *(Te)* of 2.5 seconds and the exhaled tidal volume *(Vte)* (area between the expiratory flow tracings and the x-axis) of 419 mL. This approach resulted in a total minute ventilation *(Mve)* of 8.0 liters per minute (Lpm) and the intrinsic positive end-expiratory pressure of 7.3 cm H_2O (not shown here). (B) The same patient with the respiratory rate reduced to 8 breaths/min while keeping the other parameters unchanged. This approach resulted in a Te of 6.8 seconds, more complete lung emptying (an end-expiratory flow virtually reached zero), and the intrinsic positive end-expiratory pressure decreased to less than 1 cm H_2O (not shown here). However, the additional Vte gained was less than 60 mL compared with the original settings, and the total MVe was decreased to 3.8 Lpm, which was clinically undesirable. (From Junhasavasdikul D, Telias I, Grieco DL, et al. Expiratory flow limitation during mechanical ventilation. *Chest*. 2018;154(4):948–962. https://doi.org/10.1016/j.chest.2018.01.046 https://doi.org/10.1016/j.chest.2018.01.046)

intubation, peak pressure, total PEEP, and plateau pressure should be measured. High peak pressures are expected because of high resistance in the airways. When there is an elevated peak pressure, greater than 40 to 45 cm H_2O, it is important to confirm that there are no quickly reversible causes of airway resistance such as a mucous plug, kinked or malpositioned endotracheal tube, or tension pneumothorax. Plateau pressures should also be measured at this time to evaluate pulmonary compliance, with a goal of less than 30 cm H_2O. High peak pressures and low plateau pressures reflect increased resistance with normal compliance of the respiratory system. In this scenario, peak pressures do not represent pressures at the alveoli. If the peak airway pressures are consistently above 40 to 45 cm H_2O without a reversible cause, and plateau pressures are low, we recommend adjusting the peak pressure alarm profile so the patient is not under-ventilated (if the peak pressure limit is reached, the flow will terminate resulting in a small tidal volume with a high dead space to alveolar ventilation ratio) and continue medical management while mechanically ventilated.

Dynamic hyperinflation occurs when the patient receives a breath before the respiratory system returns to FRC (i.e., completely exhales), which increases end-expiratory lung volumes and intrathoracic pressure. Signs of dynamic hyperinflation can be detected by evaluating the flow versus time waveform, the end-expiratory velocity, or measuring the total PEEP. The flow versus time waveform (Fig. 60.7) graphically displays inspiratory and expiratory flow throughout the respiratory cycle. If the expiratory flow limb does not reach zero prior to the next delivered breath, there will be dynamic hyperinflation because exhalation was not complete. Some ventilators display the end-expiratory velocity in liters/min, and a positive velocity at the end of the breath means they are exhaling at the time of the next breath.

Checking the total PEEP screens for dynamic hyperinflation and intrinsic or auto-PEEP (iPEEP). Total PEEP is measured after a 3 to 5-second end-expiratory hold on a passively breathing patient. The pressure reflects the externally applied (ventilator set) PEEP and the iPEEP (Fig. 60.8). For example, if the ventilator prescribed external PEEP is 5 cm H_2O and the total PEEP is 17 cm H_2O, the iPEEP or auto-PEEP is 12 cm H_2O. This increased pressure results from increased end-expiratory lung volumes and alveolar overdistension within the fixed thoracic space. Patients who are intubated during a COPD exacerbation without multiple pulmonary infiltrates should have a normal plateau pressure despite an increase in peak pressure. A high plateau pressure in the setting of an increase in iPEEP represents decreased compliance of an over distended lung. Increased expiratory lung volumes and iPEEP may cause hypotension from decreased preload. This

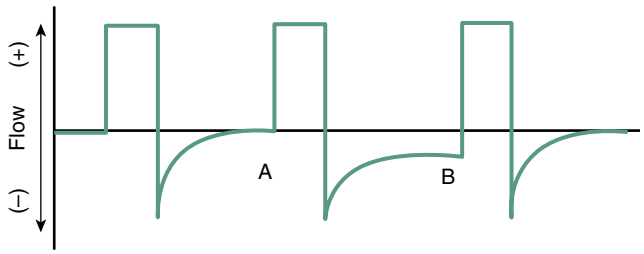

Fig. 60.7 **Flow Versus Time Ventilator Waveform.** Positive flow on the y-axis is the ventilator delivering a breath into the patient. Negative flow is the patient's passive exhalation. (A) depicts an expiratory flow limb returning to zero at the end of exhalation. The represents complete exhalation of the tidal volume and a return to the passive functional residual capacity. The curve and slope of the expiratory flow limb is determined by the passive recoil of the chest wall. (B) depicts an expiratory flow limb that does not return to zero prior to the next ventilator delivered breath. This represents the patient's continued and incomplete exhalation prior to the next delivered breath.

response is exaggerated in COPD because highly compliant lungs readily transmit the increased pulmonary pressures to the heart and great vessels. In the example above the total pressure in the chest transmitted to the great vessels is 17 cm H_2O (12.5 mm Hg).

Pressure assist control may also be used as an initial ventilator setting when a patient is sedated and paralyzed (also see Ventilatory Support, Chapter 2). We recommend starting with a pressure of 15 cm H_2O above PEEP and an inspiratory cycling time of 0.8 to 1 seconds. Inspiratory pressure and cycling time targets may be adjusted to deliver a tidal volume of approximately 8 mL/kg predicted body weight. Some patients may be more comfortable in a pressure-controlled mode because of an increased inspiratory flow, but there is no significant outcome difference among ventilation modes. When ventilating a patient in pressure assist control mode, it is essential to monitor tidal volumes to assure adequate ventilation because tidal volumes will vary depending on the resistance and compliance of the respiratory system.

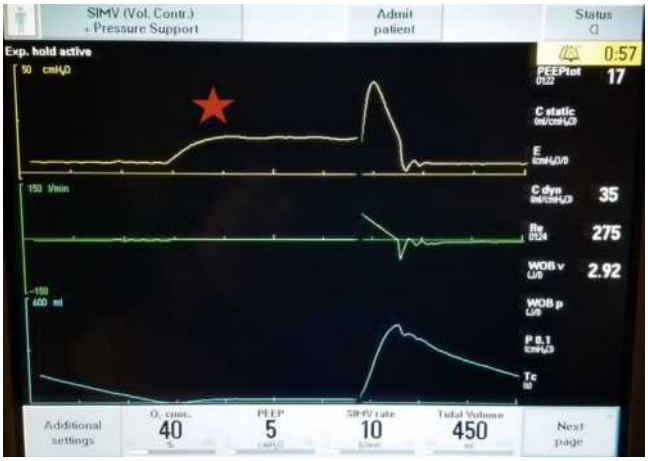

Fig. 60.8 Ventilator screen displaying an end expiratory hold with an elevated intrinsic positive end expiratory pressure (PEEP). The star marks an elevation in the pressure waveform with a corresponding total PEEP of 17 cm H_2O and set PEEP of 5 cm H_2O. The iPEEP in this case is 12 cm H_2O (total PEEP minus set PEEP). (Image courtesy of Dr. Skyler Lentz.)

Spontaneously breathing patients may be transitioned to pressure support ventilation. Many patients are comfortable in this mode of ventilation because they control inspiratory time and flow. We recommend an initial pressure support of 15 cm H_2O above PEEP titrated based on tidal volume and patient comfort. In any mode of ventilation, some patients may ineffectively trigger or cycle a mechanical breath causing ventilator dyssynchronies. If patients appear to be attempting to inhale or exhale in asynchrony with the ventilator, we recommend consulting an intensivist or pulmonologist. Ventilator troubleshooting steps are displayed in Table 60.4.

PEEP can be safely set to 5 cm H_2O for all patients with a COPD exacerbation. There is no significant benefit of decreasing the PEEP to 0 cm H_2O or increasing the PEEP in the early care of sedated and paralyzed patients. Further PEEP titration depends on individual patient's physiology. In most cases of patients with COPD who are intubated, EFL is present and PEEP may be increased to between 50% and 80% of the total PEEP. Increasing the PEEP does not decrease the expiratory flow because it is no longer determined by the absolute pressure

TABLE 60.4 Troubleshooting for Commonly Encountered Problems in Intubated Chronic Obstructive Pulmonary Disease Patients With Mechanical Ventilation

TROUBLESHOOTING VENTILATION DIFFICULTIES

Problem	Suggestion
Elevated end-tidal CO_2 or $PaCO_2$	Tolerate respiratory acidosis if the pH is >7.2 without adjusting the respiratory rate or tidal volume. Respiratory acidosis will improve with medical treatment and time while ventilated.
Elevated end-tidal CO_2 or $PaCO_2$ AND pH <7.2	1. If there is minimal iPEEP, increase the respiratory rate slowly and frequently check for iPEEP. 2. Should iPEEP develop, increase the tidal volume and keep the rate low. COPD does not require acute respiratory distress syndrome (ARDS) ventilation strategy. While the goal tidal volume is ≤8 mL/kg predicted body weight, if severe respiratory acidosis and obstructive shock from dynamic hyperinflation is a life threat start increasing the tidal volume.
High peak pressures	This is a reflection of increased airway resistance. Check a plateau pressure to evaluate compliance of the respiratory system. If the plateau pressure is low: 2. Evaluate for common causes of elevated peak pressures including kinked tubing, pneumothorax, mucous plugging, and mainstem intubation. 3. Continue bronchodilator therapy and tolerate high peak pressures. Increase peak pressure alarms to prevent hypoventilation.
High plateau pressures	If the patient does not have a reason to have a low compliance (e.g., multifocal pneumonia) this likely represents alveolar over distention from dynamic hyperinflation. Check a total PEEP and decrease the minute ventilation.
Elevated total PEEP or iPEEP	This represents dynamic hyperinflation. If hypotension is present remove the patient from the ventilator for approximately 10–15 s to allow adequate exhalation. Reduce the minute ventilation by decreasing the respiratory rate between 10 and 14 breaths/min.
Awakens from sedation or paralysis wears off	Clinical decision of transition to a pressure supported mode of breathing or increasing sedation. • If stable, patients will often tolerate pressure support ventilation with an initial setting of pressure support of 15 cm H_2O over a PEEP of 5 cm H_2O. The patient will determine their respiratory rate. Monitor for triggering or cycling dyssynchronies such as the patient trying to inhale or exhale and the ventilator not responding. • If a patient is unstable or has severe air trapping, increase sedation so the patient is synchronous with the ventilator. Reattempt sedation wean at a later time.

COPD, Chronic obstructive pulmonary disease; *iPEEP*, intrinsic positive end expiratory pressure.

gradient between the alveoli and ventilator and may improve expiratory flow by stenting open small collapsing airways. If any PEEP changes are made, it is important to follow the associated changes in peak pressure, total PEEP, and plateau pressure.

Disposition

Disposition decisions are based on a multitude of factors including severity of symptoms, presence of respiratory failure, response to treatment in the ED, presence of serious comorbidities, failure of outpatient treatment, and home resources/support. Patients who have significant symptom improvement in the ED with no signs of respiratory failure, no new oxygen needs, a normal laboratory evaluation, and no evidence of hemodynamic instability or cardiac ischemia, with adequate home support and a follow-up plan with a primary care or pulmonology provider are suitable for discharge home. We recommend education about inhaler or nebulizer use and close coordination with their primary care provider or pulmonologist. Patients with severe symptoms, including resting dyspnea, worsened hypoxia, tachypnea, drowsiness and confusion, or symptoms significantly worse than their baseline should be admitted to the hospital. If there are signs of respiratory failure and need for NIV, consultation with the intensive care unit is recommended (Box 60.3).

ED observation units (sometimes called short-stay units or clinical decision units) can provide short term care for COPD exacerbations in patients with non-severe symptoms who fail to improve significantly with initial treatment but are expected to improve within 48 hours. Observation units help decrease the number of patients requiring inpatient hospital admission.[48] Through protocolized care and the coordination of discharge services, observation unit stays can decrease the 30-day ED revisit rate without decreasing the number of patients discharged directly from the ED.[49] Patients with underlying severe disease, frequent recent hospitalizations, severe symptoms including new oxygen requirement, and abnormal chest x-ray findings suggestive of lobar pneumonia are unlikely to respond to treatment within a timeframe appropriate for an ED observation admission.[50]

BOX 60.3 General Guidelines for Admission of the Patient With Chronic Obstructive Pulmonary Disease

1. Significant worsening of symptoms from baseline
2. Inadequate response of symptoms to emergency department (ED) management
3. Significant comorbid conditions (e.g., pneumonia, heart failure)
4. Worsening hypoxia or hypercarbia (from baseline)
5. Inability to cope at home or insufficient home resources

CHAPTER 60: QUESTIONS AND ANSWERS

1. A patient presents to the emergency department with 8 months of progressive dyspnea. There is no recent change in the patient's symptoms. On exam, there is a prolonged expiratory phase without wheezing, no rales, no pedal edema. The electrocardiogram is normal. The chest x-ray revealed hyperinflation with a flattened diaphragm. The diagnosis of chronic obstructive pulmonary disease (COPD):

a. Can be made clinically in this patient
b. Can be made radiographically with demonstration flattening of the diaphragms and hyperinflation on chest x-ray
c. Requires demonstration of spirometry-proven airflow limitation with the ratio of forced expiratory volume in one second (FEV_1) to forced vital capacity (FVC) after bronchodilators less than or equal to 0.7
d. Requires genetic testing and historical features including increased cough, sputum production, noxious stimuli, and dyspnea

Answer: c. The diagnosis of COPD requires spirometry-proven airflow limitation defined as a ratio of FEV_1 divided by FVC after bronchodilators of less than 0.7. Patients who have normal spirometry with chronic symptoms and possible emphysema on CT scan are not considered to have COPD.

2. In a patient with a diagnosis of chronic obstructive pulmonary disease (COPD), increased dyspnea, sputum production, and sputum purulence worse than baseline day-to-day variations for the past three days requiring evaluation in the emergency department is defined as:

a. Chronic bronchitis
b. COPD exacerbation
c. Emphysema
d. Progression of underlying disease

Answer: b. COPD exacerbation can be defined as a worsening of symptoms from baseline day-to-day variations that requires treatment. The most common symptoms include increased dyspnea, cough, increased sputum production and increased sputum purulence.

3. A 64-year old male with a history of severe chronic obstructive pulmonary disease (COPD) with baseline 3 L/min oxygen requirement presents to the emergency department with complaint of dyspnea. On physical exam, he is taking rapid shallow breaths with a respiratory rate of 50, requiring 8 L/min by nasal cannula to maintain a SpO_2 of 88%, but is awake and following commands. A blood gas reveals a pH of 7.25 and a pCO_2 of 70 mm Hg. Chest x-ray reveals hyperinflated lungs without evidence of pneumothorax or infiltrate. Antibiotics, nebulized short-acting beta-agonists, and glucocorticoids are initiated. The next step in management is:

a. Continue medical management
b. Intubate the patient for anticipated clinical decline
c. Start noninvasive bi-level positive pressure ventilation
d. Trial high flow nasal cannula

Answer: c. This patient is presenting with respiratory failure without clear contraindications to noninvasive ventilation. The patient should be trialed on noninvasive ventilation and receive inhaled bronchodilators including albuterol and ipratropium, glucocorticoids, and antibiotics. Glucocorticoids have similar bioavailability and efficacy when given PO or IV, however in patients with respiratory distress we recommend avoiding oral medications.

CHAPTER 60: QUESTIONS AND ANSWERS—cont'd

4. The rapid, shallow breathing pattern that develops in a chronic obstructive pulmonary disease (COPD) exacerbation _____ exhalation time causing hyperinflation, and _____ the proportion of dead space ventilation causing hypercapnia and respiratory muscle fatigue.

a. Decreases, decreases
b. Decreases, increases
c. Increases, decreases
d. Increases, Increases

Answer: b. The rapid, shallow breathing pattern that develops in a COPD exacerbation decreases exhalation time causing hyperinflation and increases the proportion of dead space ventilation causing hypercapnia and respiratory muscle fatigue. If untreated, this will progress to respiratory failure.

5. When treating a patient with a chronic obstructive pulmonary disease (COPD) exacerbation who requires invasive mechanical ventilation, setting the initial tidal volume to 8 mL/kg predicted body weight and the respiratory rate to 10 to 14 breaths/min helps prevent the development of:

a. Acidosis
b. Dynamic hyperinflation
c. Hypercapnia
d. Expiratory flow limitation

Answer: b. Decreasing the respiratory rate in an intubated patient with COPD allows for complete emptying and return to FRC, decreasing the development of dynamic hyperinflation and auto-positive end expiratory pressure (PEEP).

61

Upper Respiratory Tract Infections

Matthew A. Roginski and Patricia Ruth Atchinson

KEY CONCEPTS

- Viral infections cause most cases of pharyngitis. Patients should not be treated with antibiotics based on symptoms and exam alone. Patients with a Centor criteria score of 0 or 1 do not require further testing or treatment. Those with a score of 2 or greater should undergo rapid antigen testing with treatment decisions based on results. Throat cultures are recommended in children but are not necessary in adults.
- Antibiotics for group A *Streptococcus* pharyngitis are aimed at symptom reduction, decreasing transmission, and decreasing suppurative complications. Rheumatic fever is very rare and likely from a shift in streptococcal M proteins rather than antibiotic use.
- Infectious pharyngitis presents with an acute onset and resolves within days. In subacute and chronic cases of pharyngitis, consider abscess formation, neoplastic causes, HIV, and autoimmune disease.
- In streptococcal pharyngitis, a single high dose of corticosteroids, such as 10 mg dexamethasone, is safe and reduces symptom severity.
- Consider deep space infection and epiglottitis in patients who present with neck pain, hoarseness, and have a benign oropharyngeal exam.
- Airway edema from palatine or lingual tonsillitis, epiglottitis, or deep space infection is rare, but life-threatening.
- Deep space infections such as retropharyngeal and parapharyngeal abscesses are difficult to diagnose clinically, and contrast-enhanced CT is recommended.
- Transcervical or intraoral ultrasound is useful in the diagnosis and treatment of peritonsillar abscess.
- Acute rhinosinusitis is likely viral and will resolve with supportive care, including nasal irrigation with hypertonic saline.
- Although rarely needed, first-line antibiotic treatment for acute rhinosinusitis is amoxicillin or amoxicillin-clavulanate for 5 days.

PHARYNGITIS

Foundations

Tonsillopharyngitis (pharyngitis) is generally a benign, self-limited inflammatory syndrome of the oropharynx. Although most cases are mild, severe cases may lead to airway swelling, dehydration from decreased oral intake, and suppurative complications, including peritonsillar abscess, deep space infection, and hematogenous spread. A majority of cases are viral and caused by common cold viruses. Bacterial infection is responsible for approximately 5% to 10% of adult and 20% to 30% of pediatric cases. Common bacterial causes of pharyngitis include group A beta-hemolytic *Streptococcus* (GAS), non–group A *Streptococcus*, *Fusobacterium*, and mixed aerobes and anaerobes (Table 61.1). Transmission occurs through direct person-to-person contact or via aerosolized respiratory secretions. Although fomite transmission is rare, crowded conditions such as in schools, daycare, and military training facilities increase transmission rates.

Tonsils are lymphoid tissue covered with respiratory epithelial tissue. Waldeyer ring refers to the lymphoid tissue in the pharynx consisting of the palatine tonsils (commonly referred to as tonsils), pharyngeal tonsils (adenoids), tubal tonsils (surrounding eustachian tubes), and lingual tonsils at the base of the tongue. Tonsillar infection, inflammation, and hypertrophy may occur in any of these locations (Fig. 61.1). Although rare, lingual tonsillitis predominantly occurs in patients who had their palatine tonsils removed.

Clinical Features

Symptom chronicity, associated complaints, patient comorbidities, and patient risk factors are important considerations. Acute presentations are more likely to be infectious, whereas more chronic presentations raise concern for noninfectious or neoplastic etiologies. Sore throat, odynophagia, fever, malaise, and tender anterior cervical adenopathy are the most common symptoms. Although presentation differs by the disease process, erythema, edema, and petechiae of the oropharynx (Fig. 61.2), as well as palatine tonsillar plaques (Fig. 61.3), are common findings.

Viruses that cause the common cold are responsible for 30% to 60% of pharyngitis cases (see Table 61.1). Symptoms may overlap with GAS but are unlikely to be as severe and are associated with rhinorrhea, cough, conjunctivitis, congestion, and headache. Viral symptoms usually precede symptoms of a sore throat. Inflammation and hypertrophy of tissue in the Waldeyer ring without exudate is common.

Infectious mononucleosis, caused by the Epstein-Barr virus (EBV), classically presents with the triad of fever, tonsillar pharyngitis, and posterior cervical lymphadenopathy. The incubation period is 3 to 7 weeks, and patients experience a prodrome of fever, chills, and malaise. Most patients have exudative pharyngitis with tonsillar hypertrophy (see Fig. 61.3). Petechiae are intermittently present at the junction of the hard and soft palate (see Fig. 61.2). In severe cases, upper airway swelling may lead to difficulty managing secretions, stridor, and dyspnea. Splenomegaly is present in approximately half the cases. A pruritic morbilliform rash may occur regardless of contact with beta-lactam antibiotics. Jaundice is rare.

Influenza may present with nonexudative pharyngitis and sore throat along with generalized fever, chills, myalgia, and headaches. Human immunodeficiency virus (HIV) and cytomegalovirus can present as a mononucleosis-like illness. Pharyngitis and hypertrophy of tissue in the Waldeyer ring may also occur. The acute retroviral syndrome of primary HIV infection includes fever, sore throat, nontender lymphadenopathy, diffuse maculopapular rash, arthralgias, mucocutaneous ulcerations, and diarrhea. Spread by sexual contact, herpes simplex pharyngitis presents with painful vesicles or ulcerations on an erythematous base on the lips, tongue, palate, or mucosa (Fig. 61.4). Patients with oropharyngeal herpes have palatal hyperemia with sore throat, odynophagia, stomatitis, and tender cervical adenopathy. Immunosuppressed patients with oropharyngeal herpes may present with large ulcerations, and bacterial superinfection is possible. Coxsackie virus may also cause herpangina

TABLE 61.1 Infectious and Noninfectious Causes of Pharyngitis

INFECTIOUS ETIOLOGIES				NONINFECTIOUS ETIOLOGIES
Bacterial	**Viral**	**Fungal**	**Adjacent Infections**	
Group A β-hemolytic strep	Rhinovirus	Candida	Retropharyngeal abscess	Tumor
Groups C and B β-hemolytic strep	Coronavirus		Parapharyngeal abscess	Autoimmune disease
Fusobacterium	Parainfluenza		Epiglottitis	Neurogenic pain
Neisseria gonorrhoeae	Adenovirus		Ludwig angina	Foreign body
Corynebacterium diphtheriae	Influenza			Trauma
Chlamydia	Human immunodeficiency virus			Medication induced
Mycoplasma pneumoniae	Epstein-Barr virus			Stevens-Johnson syndrome
Arcanobacterium haemolyticum	Herpes virus			Allergic reaction
	Cytomegalovirus			Esophageal reflux
				Environmental exposure

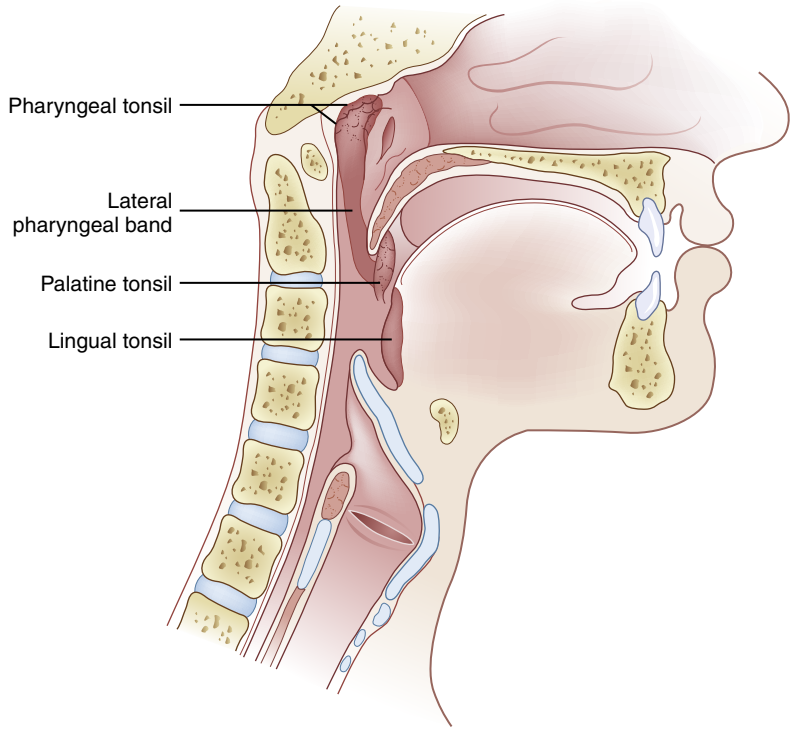

Fig. 61.1 Sagittal anatomic illustration of locations of tonsils in Waldeyer ring. Note the lingual tonsils on the posterior tongue. (From Embryology, anatomy, and histology of the pharynx. In: Wenig, BM. *Atlas of Head and Neck Pathology*. Philadelphia: Elsevier; 2016: 399-406. Fig. 8-2.)

with oral and pharyngeal erythematous papulo-vascular ulcerations. Coxsackie virus also causes small tender, nonpruritic, cutaneous lesions on the palms, soles, and buttocks.

Group A beta-hemolytic *Streptococcus* is a gram-positive coccus that grows in chains and is the most frequent cause of bacterial pharyngitis, most commonly in children ages 5 to 15 years. Humans are the only carrier of GAS, and asymptomatic carrier status is uncommon. The incubation period is typically 2 to 5 days. Virulence factors of GAS include host inflammatory mediators, bacterial cell wall, and secreted enzymes and exotoxins. Infection is most common in the fall and winter. Untreated, symptoms last 3 to 7 days, and patients are contagious up to one week after symptom resolution. Treated, symptoms resolve approximately 16 hours sooner than in untreated patients, and the contagious period decreases to 24 hours after the start of antibiotics. Rapid onset of sore throat, odynophagia, cervical adenopathy, fevers, chills, and neck stiffness are characteristic. Headache, abdominal pain,

Fig. 61.3 Photograph of enlarged palatine tonsils. (A) shows nonexudative pharyngitis. The diffuse tonsillar and pharyngeal erythema seen here is a nonspecific finding that can be produced by a variety of pathogens. (B) shows exudative pharyngitis with white plaques on the tonsils and hyperemia, most commonly seen in either group A streptococcal or Epstein-Barr virus infection. (From Wetmore RF. Tonsils and adenoids. In: *Nelson Textbook of Pediatrics*. 2019. Pages 2198-2202.e.1. 2020.)

Fig. 61.4 Photograph of oral ulcerations from recurrent oropharyngeal herpes infection. (From Hellstein JW, Fielding CG, Castle JT. *Vesiculobullous Diseases. Oral and Maxillofacial Surgery*. Elsevier. Published January 1, 2018. Pages 550-574. © 2018. Figure 24-4 Recurrent herpes of palate.)

nausea, and vomiting may be present. GAS does not present with trismus, cough, conjunctivitis, diarrhea, rhinorrhea, or oral ulcerations.[1]

Exam findings include symmetric erythema and edema of the oropharynx, gray/white tonsillar exudates (see Fig. 61.3), palatal petechiae (see Fig. 61.2), and tender cervical adenopathy. GAS pharyngitis associated with a desquamating, fine, sandpaper-like rash is called *scarlet fever* and is related to an exotoxin-producing strain of GAS. Suppurative complications of GAS include acute otitis media, mastoiditis, meningitis, peritonsillar and retropharyngeal abscess, and rarely, necrotizing fasciitis or hematogenous spread to distant sites.[2] Acute rheumatic fever and post-streptococcal glomerulonephritis are rare in the general population. The decrease in the frequency of acute rheumatic fever is likely due to a shift in the streptococcal M protein types leading to decreased rheumatogenicity rather than due to the increased use of antibiotics.[2]

Non–group A *Streptococcus* also causes acute pharyngitis with a similar presentation to GAS, but acute infection is difficult to distinguish from normal upper respiratory flora on respiratory culture. *Fusobacterium necrophorum* is an anaerobic gram-negative rod that is part of the normal oral flora and causes pharyngitis in patients 15 to 45 years old with a similar presentation to GAS. *Fusobacterium* is the primary causative agent in septic jugular vein thrombophlebitis (Lemierre syndrome). The early identification and treatment (Table 61.2) of *Fusobacterium* in pharyngitis remains unclear; *Fusobacterium* should be considered in young adults with ongoing severe symptoms.[3-5]

Arcanobacterium haemolyticum is a nonmotile beta-hemolytic gram-positive bacillus that is not part of the upper respiratory flora and is associated with a minority of pharyngitis cases with peak prevalence in the late teens. It is associated with deep space infections such as retropharyngeal abscesses. Along with pharyngitis, patients may also experience an urticarial, maculopapular rash that spares the face, palms, and soles. *Francisella tularensis* is a zoonotic gram-negative bacillus that may cause a false-positive monospot test and has atypical lymphocytes on peripheral smear. It can present as pharyngitis and a flu-like illness in patients with a contaminated food or water source.[3,4] *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* pharyngitis may occur as part of an outbreak in crowded conditions. Lower respiratory tract infection and rhinosinusitis may occur.

Neisseria gonorrhoeae is an intracellular gram-negative diplococcus that is transmitted through sexual contact. Patients are usually symptomatic with tonsillitis and found to have enlarged tonsils with a white-yellow exudate in the tonsillar crypts. *Chlamydia trachomatis* pharyngitis has a similar presentation to gonococcal pharyngitis and is transmitted through sexual contact. *Treponema pallidum* is the spirochete that causes syphilis. Primary infection can present with painless oral ulceration. Secondary syphilis may have associated pharyngitis with localized adenopathy that can be mistaken for carcinoma. Patients with atypical presentations, risk factors for sexually transmitted infections, or no other apparent cause should have a focused sexual history and appropriate testing based on their response.

Diphtheria is caused by the gram-positive bacillus *Corynebacterium diphtheriae*. Although the incidence has decreased because of vaccination, diphtheria should be considered in patients who traveled to endemic areas or who are not vaccinated. The incubation period is 2 to 5 days. Early symptoms are typical of generalized pharyngitis with sore throat, cervical adenopathy, and fever. Toxin-producing strains may create a pseudomembrane that is grayish-green to black (if bleeding occurs) that tightly adheres to mucosal tissue and is friable. Severe forms may obstruct the airway and may be associated with extensive swelling of the tonsils, uvula, and anterior neck. Toxins produced can affect distant sites causing myocarditis, neuritis, and acute tubular necrosis. Non–toxin producing strains cause moderate to severe pharyngitis without pseudomembrane formation.

TABLE 61.2 Treatment Recommendations for Pharyngitis[a]

Organism	Treatment
Group A *Streptococcus*	Penicillin V, Oral • Children 250 mg two or three times daily for 10 days • Adolescents and adults 500 mg twice daily for 10 days Penicillin VK • Children <27 kg: 250 mg two or three times daily • Children ≥27 kg or adults: 500 mg two or three times daily Penicillin G, IM • <27 kg: 600,000 units; >27 kg 1.2 million U once Amoxicillin • 50 mg/kg once daily (max 1000 mg) or 25 mg/kg (max 500 mg) twice daily for 10 days Single-dose corticosteroids • Dexamethasone 0.6 mg/kg up to 10 mg PO Penicillin Allergic Cephalosporins • Cephalexin 20 mg/kg/dose (max 500 mg/dose) twice daily for 10 days Clindamycin • 7 mg/kg/dose (max 300 mg/dose) three times daily for 10 days Azithromycin • 12 mg/kg (max 500 mg/dose) for 5 days
Fusobacterium and anaerobic infections	Metronidazole • Adults 500 mg IV every 8 hours; children 10 to 15 mg/kg (max 500 mg/dose) IV every 8 hours AND Ceftriaxone • Adults 2 g IV every 24 hours; children 50 mg/kg (max 2 g/dose) IV every 24 hours OR Piperacillin-tazobactam • Adult 3.375 g IV every 6 hours, children 100 mg/kg of piperacillin (max 4.5 g/dose) IV every 6 to 8 hours
Diphtheria	Antitoxin (request from CDC) AND penicillin • Adults: Penicillin 2 to 3 million units/day IV in divided doses every 4 to 6 hours Children: Penicillin 150,000 to 250,000 units/kg/day IV in divided doses every 6 hours. The AAP recommends 14 days of treatment
Gonococcal	Ceftriaxone 500 mg IM ×1 (1g IM x1 if weight >150 kg) and doxycycline 100 mg twice daily for seven days (doxycycline is needed until chlamydia is ruled out)
Herpes	Acyclovir 200 mg 5 times/day for 7 days OR Valacyclovir 1 gm twice daily for 7 days OR Famciclovir 250 mg three times/day
Candida	Mild: Clotrimazole troches or nystatin swish/swallow Moderate to severe: adults, fluconazole 200 mg on day one and 100 to 200 mg once daily for 7 days; children, fluconazole 6 to 12 mg/kg (max 200 mg/dose) daily

[a]Renally dose antibiotics, antivirals, and antifungals.

Oral candidiasis presents with a white pseudomembrane over the tongue, buccal mucosa, palate, and oropharynx that can be scraped off with a tongue depressor. It occurs most commonly in immunocompromised patients, the elderly, patients with recent antibiotic exposure, and those on chronic steroids. Chronic hyperplastic candidiasis may present as elevated white plaques that cannot be scraped off of the buccal mucosa.

BOX 61.1 Centor Criteria for Determining Group A Beta-Hemolytic Streptococcal Pharyngitis

Swollen tonsils and exudates
Tender anterior cervical adenopathy
Absent cough
Fever

Differential Diagnosis for Emergency Presentation

A focused differential for pharyngitis is largely guided by the history and physical exam with attention to systemic signs and symptoms. Table 61.1 lists the infectious and noninfectious causes of pharyngitis.

Diagnostic Testing

Diagnostic testing is not required if features strongly suggest a viral etiology: associated with rhinorrhea, cough, conjunctivitis, congestion, and headache which usually precede symptoms of a sore throat. Testing for Epstein-Barr virus (EBV) can be considered in patients with splenomegaly, posterior cervical adenopathy, palatal petechiae, and those patients with persistent symptoms despite adequate treatment for GAS pharyngitis. The initial testing for infectious mononucleosis is a heterophile antibody test (Monospot). The Monospot has high specificity but variable sensitivity, with false-negative results in children and early in the infection. If the antibody test is negative and the patient remains symptomatic, we recommend follow-up with their primary care physician and retesting in 7 to 10 days or checking an EBV viral capsid antigen IgM. Viral load is not validated for infectious mononucleosis. Mononucleosis causes an absolute lymphocytosis with greater than 10% atypical lymphocyte count due to EBV's effect on B lymphocytes and the cytotoxic T-cell response. Influenza is tested with a PCR nasal or oral pharyngeal swab. Influenza testing should occur in patients with fevers, myalgia, headache, and sore throat occurring when influenza viruses are circulating in the community, when the patient is being admitted to the hospital, or when testing will influence management. HIV testing is performed with a fourth-generation combination assay. It should be performed in patients with risk factors and persistent pharyngitis symptoms without any other etiology. Herpes is diagnosed with PCR testing of a viral swab from an ulcer or unroofed vesicle or HSV IgG and IgM serology.

Rapid antigen testing is recommended as a first-line diagnostic test for GAS pharyngitis. These patients present with sore throat, fever, exudative pharyngitis, and cervical lymphadenopathy without associated cough or rhinorrhea. Scoring systems such as the Centor criteria (Box 61.1) should be used to identify adults who do not require further testing or treatment. The score should not be used in patients who are immunocompromised, have complicated comorbid conditions, or have symptoms for greater than 5 days. Patients with zero or one Centor criterion should not be tested or treated. Empiric treatment is not recommended for any patient.[1,5] Rapid antigen tests are highly sensitive and specific when performed correctly (swabbing the bilateral tonsils and the posterior pharynx, avoiding the buccal mucosa and tongue). A positive test indicates the presence of GAS and does not require follow-up testing. If the antigen testing is negative, a confirmatory culture on sheep blood agar is recommended in children, can be considered in adolescents, and is not necessary in adults. There is no role for antistreptolysin O titers.

Patients with persistent symptoms and unknown etiology should undergo throat culture. *Arcanobacterium haemolyticum* is performed on human blood agar. Diphtheria requires culture on Loeffler medium. The laboratory should be notified if there is concern for *Arcanobacterium* or diphtheria, which would be indicated in patients with severe pharyngitis or the appearance of gray pseudomembrane in the posterior oropharynx. Candida is diagnosed when budding yeast with or without pseudohyphae is seen on the Gram stain or potassium hydroxide stain. A throat swab with a nucleic acid amplification test is recommended for *Chlamydia trachomatis* and *Neisseria gonorrhoeae.*

Management

For a majority of cases, supportive care alone with nonsteroidal antiinflammatory medications or acetaminophen will be sufficient. There is no direct evidence of benefit from warm salt gargles, lozenges, soft or cold foods, or humidified topical analgesics. Viscous lidocaine should be avoided due to the potential for suppression of cough and gag and risk for aspiration. Treatment for infectious mononucleosis is supportive. Corticosteroids are not recommended for infectious mononucleosis,[6] except in the cases of significant oropharyngeal edema with stridor or change in phonation. Treatment of influenza should be started as soon as possible on documented or suspected influenza cases in hospitalized patients, children less than 2 years old, adults 65 years and older, pregnant women and within 2 weeks postpartum, patients with immunosuppression, and patients with chronic cardiac, pulmonary, hepatic, renal or hematologic disorders. Clinicians can consider antiviral treatment in patients not at high risk for complications and outpatients with symptom onset less than 2 days before presentation, and in those symptomatic with household contact with those at high risk for compilations of influenza, or health care workers with contact with those at high risk for complications.[7] Treatment consists of antiviral medication (oral oseltamivir, inhaled zanamivir, or intravenous peramivir.) HIV requires referral to appropriate providers for the initiation of antiretroviral medications.

The rationale for the treatment of GAS is to decrease the length of symptoms, suppurative complications, and the infectious period. Prophylactic antibiotics to close contacts of infected patients is not recommended. Retesting after treatment is not required unless there are recurrent symptoms. Treatment failures may be related to carrier status, lack of compliance, recurrent exposure, resistant bacteria, or eradication of protective flora. Treatments of pharyngitis are listed on Table 61.2. We recommend steroid administration for GAS. A single dose of corticosteroids such as dexamethasone appears to be safe and leads to a decrease in symptom duration.[8-10] Patients with recurrent episodes of GAS should be referred to an otolaryngologist for consideration of tonsillectomy.[11] Diphtheria is treated with diphtheria antitoxin (DAT) and penicillin or erythromycin. Mild candidal pharyngitis treatment is topical with clotrimazole troches or nystatin swish and swallow, whereas moderate to severe forms require systemic therapy with fluconazole.

Disposition

Patients with uncomplicated pharyngitis may be discharged and treated as outpatients. Patients with evidence of upper airway obstruction including stridor, difficulty managing secretions, and changes in phonation or severe systemic symptoms such as hypotension or altered mental status require consultation with an otolaryngologist and admission to the hospital.

LARYNGITIS

Foundations

Acute laryngitis is an inflammation of the larynx which is predominantly caused by viral infections. Chronic laryngitis is diagnosed after three weeks of continuous symptoms and may be due to gastroesophageal reflux, overuse of the voice, trauma, thermal and chemical burns, irritants, and allergic reactions.

Diffuse inflammation of the larynx caused predominantly by viral infection results in mucosal edema and laryngeal obstruction. It occurs most commonly in children ages 1 to 5 years and is more frequently seen in the winter and spring.[12] Immunocompromised patients can develop laryngitis caused by opportunistic fungal and viral infections. Patients with frequent use of inhaled corticosteroids are also at increased risk for fungal laryngitis.

Clinical Features

Laryngeal inflammation and edema cause sore throat, hoarse voice, inspiratory stridor, fever, and barking cough. Chronic laryngitis may additionally present with globus sensation and excessive throat clearing. Laryngitis may exist on its own or be part of a constellation of symptoms of upper airway infection including epiglottitis. Epiglottitis generally includes inflammation of the arytenoids and aryepiglottic folds and is sometimes referred to as supraglottitis. Inflammation of the glottis, arytenoids, and aryepiglottic folds increases the potential for acute upper airway obstruction, though the majority of cases of laryngitis are self-limited.

Differential Diagnosis for Emergency Presentation

The etiologies of laryngitis are similar to pharyngitis displayed in Table 61.1, with the majority being caused by the viruses that cause the common cold. The differential diagnosis includes infectious etiologies such as retropharyngeal abscess and noninfectious etiologies such as anaphylaxis, angioedema, tumor, thyroiditis, chemical or thermal injury, and foreign body.

Diagnostic Testing

There is no specific diagnostic testing for laryngitis, and the majority of cases will resolve within two weeks. Routine viral testing or bacterial cultures are not recommended.

Management

The majority of patients with laryngitis will improve without intervention. Systemic steroids have been shown to decrease symptom severity in pediatric patients; we recommend dexamethasone 0.6 mg/kg given via intramuscular, intravenous, or oral route depending on patient ability to tolerate oral intake and intravenous access availability with a maximum dose of 10 mg. Immunocompromised patients and patients with symptoms persisting for greater than two weeks should be referred to otolaryngology.

Disposition

Laryngitis can be treated on an outpatient basis. Exceptions occur when symptoms of laryngitis are occurring concomitantly with symptoms of supraglottitis/epiglottitis.

EPIGLOTTITIS

Foundations

Acute epiglottitis is an inflammation of the epiglottis and commonly the supraglottic region, including the arytenoids, base of the tongue, and vallecula. It is sometimes referred to as supraglottitis, but we will use the term epiglottitis. It is a rare but potentially life-threatening disease because of rapidly occurring airway obstruction and asphyxiation. Since the widespread adoption of the *Haemophilus influenzae* type B conjugate vaccine, epiglottitis is more common in adults than children.[13] Patients with diabetes, immunosuppression, and substance abuse issues, including tobacco and alcohol, are at increased risk for its

Fig. 61.5 Lateral neck x-ray with an edematous epiglottis: "thumb print sign."

development.[14,15] The majority of cases are caused by bacterial infection, including *Haemophilus influenzae* (type B and non-typeable), *Streptococcus pneumoniae,* and *Staphylococcus* subspecies. Noninfectious causes of epiglottitis include burns, trauma, and inhalational injury.[16]

Clinical Features

Symptoms are on a spectrum from sore throat, dysphagia, odynophagia, fever, hoarseness, and foreign body sensation in early stages to stridor, inability to manage secretions, and breathlessness with signs of airway compromise. Patients may sit forward in a sniffing position to maintain airway patency if there is sufficient swelling.

Differential Diagnosis

The differential diagnosis for epiglottitis includes infectious etiologies such as retropharyngeal abscess and noninfectious etiologies such as anaphylaxis, angioedema, tumor, thyroiditis, chemical or thermal injury, and foreign body.

Diagnostic Testing

Flexible laryngoscopy is the gold standard for diagnosis of epiglottitis and should be performed in patients presenting with symptoms of epiglottitis including sore throat, voice changes, and stridor. Lateral neck radiographs with an epiglottis width greater than 5.5 mm ("thumb sign" Fig. 61.5) have moderate sensitivity[17] but cannot be used to rule out epiglottitis.[18] We recommend against an initial diagnostic CT scan of the neck because of the need for supine positioning and potential for airway obstruction. Do not swab the posterior throat or use a tongue depressor because this may exacerbate the edema.

Management

All patients with epiglottitis should receive early airway evaluation assessing for voice changes, ability to manage secretions, position of comfort, and intravenous antibiotics. Antibiotic recommendations are outlined in Table 61.3. Corticosteroids can decrease supraglottic edema and may decrease the need for airway intervention we recommend dexamethasone 0.6 mg/kg with a maximum dose of 10 mg, though there is a paucity of randomized trials to guide steroid dosing.[10] Nebulized 2.25% racemic epinephrine diluted in normal saline and administered via jet nebulizer every 3 to 4 hours may decrease edema. Although oral or nasotracheal intubation is frequently unnecessary, the swelling typical of the epiglottitis (Fig. 61.6) can cause significant difficulty with intubation attempts and require an emergent surgical airway.[14] Given the high risk for failure to obtain an airway, we recommend early consultation with otolaryngology and anesthesia for intubation in the operating room. The need for emergency intubation increases in patients exhibiting dyspnea, stridor, drooling, tachypnea, and with the mouth held open or sitting forward in the sniffing position. If emergency intubation is required, we recommend awake fiberoptic intubation without the use of paralytics.

Disposition

Patients with epiglottitis require admission due to the risk for rapid airway obstruction. Patients who require emergency airway intervention or who are at high risk for deterioration should be admitted to the intensive care unit.

PERITONSILLITIS: PERITONSILLAR CELLULITIS AND ABSCESS

Foundations

Peritonsillar cellulitis is an infection of the peritonsillar tissue not associated with a collection of purulent material. Peritonsillar abscess is a collection of pus between the palatine tonsillar capsule and the superior constrictor muscle of the palatopharyngeus muscle. Fibrous septae in the peritonsillar space are responsible for directing the infection anteriorly and superiorly. Intratonsillar abscess refers to a collection of pus within the tonsillar parenchyma.

Peritonsillar abscess is most frequently seen in adults younger than 40 years old. Risk factors for developing a peritonsillar abscess include recent streptococcal tonsillitis, mononucleosis, obstruction or infection of the Weber glands, smoking, and dental or periodontal disease. There is an association with antiinflammatory medication use.[19,20] Infections are usually polymicrobial, but *Streptococcus pyogenes* is most frequently isolated. Recurrent peritonsillar abscesses have a high incidence of *Fusobacterium.*[21] Complications of peritonsillar abscess include abscess rupture into the airway and spread into the adjacent peritonsillar space.

Clinical Features

Symptoms include unilateral sore throat, odynophagia, dysphagia, fever, malaise, drooling, muffled voice, trismus, and ipsilateral otalgia. There is usually a delay between the time of symptom onset to abscess formation. Once an abscess has formed, the most common physical exam finding is a tense, erythematous, and edematous anterior tonsillar pillar with displacement of the infected tonsil and uvula towards the contralateral tonsil (Fig. 61.7). The tonsils and oral mucosa are usually erythematous with an exudate. Peritonsillar cellulitis may have a similar appearance without displacement of the tonsil and uvula. Associated findings are tonsillar edema, trismus, drooling, and tender cervical adenopathy. Peritonsillar abscess is usually unilateral, but bilateral abscesses occasionally occur.

TABLE 61.3 Microbiology[46] and Recommended Antimicrobials for Epiglottitis, Peritonsillar Abscess, Parapharyngeal Abscess, and Retropharyngeal Abscess

Condition	Organisms	Antimicrobial[a]
Epiglottitis/Supraglottitis	Normal Host: • Haemophilus influenzae • Streptococcus pneumoniae • Beta-hemolytic streptococci • Staphylococcus aureus • Neisseria meningitidis	• Ampicillin-sulbactam OR ceftriaxone AND • Vancomycin OR clindamycin (if low MRSA suspicion)
	Immunocompromised: • Above infection and • Pasteurella mul*tocida* • *Aspergillus* spp.	• Cefepime or piperacillin tazobactam AND Vancomycin
Parapharyngeal abscess Retropharyngeal abscess Peritonsillar abscess Ludwig angina	Community: • Streptococcus pyogenes • Staphylococcus aureus • Streptococcus milleri group • Arcanobacterium hemolyticum • Mixed oral flora	Ampicillin-sulbactam OR ceftriaxone and metronidazole OR Clindamycin and levofloxacin
	Immunocompromised	Cefepime and metronidazole OR Piperacillin tazobactam AND Vancomycin
	MRSA risk (eg, IVDA, diabetes)	Add vancomycin or linezolid

MRSA, methicillin-resistant *staphylococcus aureus*; *IVDA,* intravenous drug abuse.
[a]Renally dose antibiotics.

Differential Diagnosis for Emergency Presentation

The differential diagnosis for peritonsillitis is similar to retropharyngeal abscess displayed in Box 61.2. This includes infectious and noninfectious inflammation or infiltration of any of the surrounding structures including peritonsillar cellulitis, benign hypertrophy, lymphoma or tumor, pharyngitis, deep neck infection, carotid aneurysm, epiglottitis, and mononucleosis.

Diagnostic Testing

Although the diagnosis may be made clinically, ultrasound and contrast-enhanced CT aid in differentiation from cellulitis, characterization of the abscess, and identification of deep space infections. Transcervical ultrasound is useful in children.[22-24] While operator dependent,[25] a linear probe under the mandible can identify peritonsillar fluid collections. In pediatric patients, an ultrasound first approach can decrease the length of stay without increasing the frequency of return visits.[11,26-28] In older patients without trismus, intraoral ultrasound is a useful tool in the identification of an abscess (Fig. 61.8). In both transcervical and intraoral modalities the limitations of ultrasound include misinterpretation of a parapharyngeal abscess as a peritonsillar abscesses. Contrast-enhanced CT is recommended in patients in whom ultrasound is not technically possible or limited, swelling is significantly greater than anticipated in a patient with an otherwise mild presentation, or when there is a concern for a deep space infection (Fig. 61.9A and B).

Management

Peritonsillar cellulitis and intratonsillar abscess require medical therapy alone. Antibiotic options are listed in Table 61.3. Adjunctive treatment with a single dose of corticosteroids, such as dexamethasone 0.6 mg/kg with a maximum dose of 10 mg appears to be safe and effective, decreasing pain, edema, trismus, and leads to a faster recovery without deleterious effects.[11,26-28] In cases of a small peritonsillar abscess (<1 cm) antibiotics and steroids alone may be sufficient.

Larger abscesses benefit from drainage.[29] Needle aspiration or surgical incision and drainage can usually be accomplished in an awake patient with the use of topical lidocaine or benzocaine for anesthesia. Ultrasound guidance can increase diagnostic yield and identify the carotid artery during the procedure. Although needle aspiration is less painful and can be easier to perform, recurrence rates in needle aspiration may be higher compared with surgical incision and drainage.[30] Routine culture of purulent material is not indicated unless the patient is diabetic or immunocompromised, or if there are recurrent infections.

Disposition

Most patients are successfully managed as outpatients with a course of antibiotics after treatment in the emergency department. Hospital admission should be considered in patients who are toxic appearing, require intravenous hydration and analgesia, show signs of parapharyngeal extension on CT scan, or who are immunocompromised with multiple comorbidities.

LUDWIG ANGINA

Foundations

Ludwig angina is a rapidly progressive, bilateral, gangrenous cellulitis of all submandibular spaces that can rapidly lead to death within hours. Ludwig angina is a bilateral process because of the communication among the open posterior aspect of the submandibular spaces. Dental

origin from the mandibular molars is the most common cause of Ludwig angina. Mandibular molar roots insert below the mylohyoid muscle on the mandible, and the lingual aspect of the mandible is a thin osseous structure. Additional causes of Ludwig angina are mandibular fracture, oral trauma (tongue piercing, lingual laceration, iatrogenic lacerations from intubation), secondary infection of oral malignancy, suppurative parotitis, and adjacent head and neck infections. Infection may spread posteriorly between the submandibular and parapharyngeal spaces via the styloglossus muscle leading to deep neck infections. Ludwig angina occurs more frequently in immunocompromised and diabetic patients.

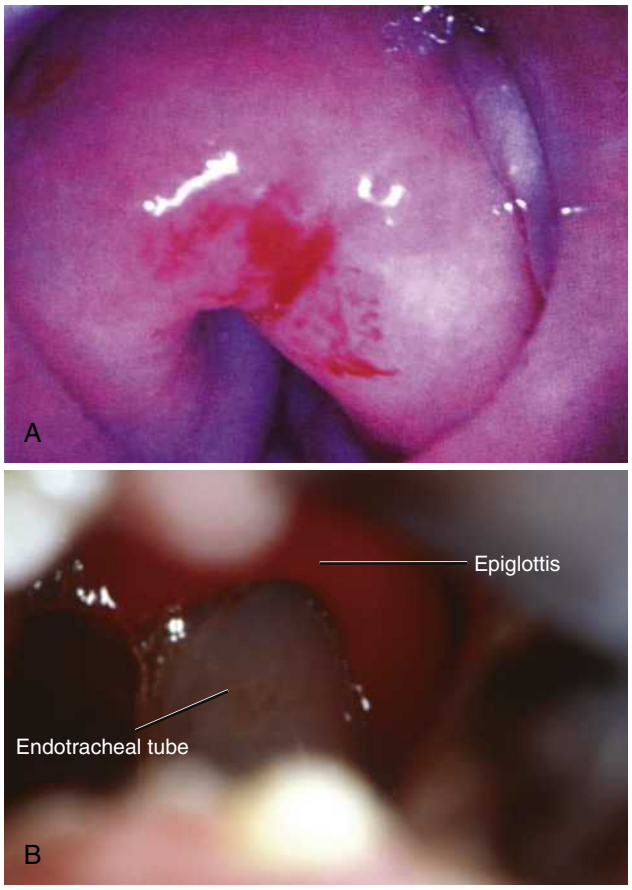

Fig. 61.6 Epiglottitis. Image A shows an enlarged and swollen epiglottis without visible vocal chords. Image B shows an enlarged epiglottis over an endotracheal tube. (From Hannallah RS, Brown KA, Verghese ST. Otorhinolaryngologic procedures. In: Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*, 6th edition. Philadelphia: Elsevier; 2019: Figure 33.23)

Clinical Features

Patients may report recent dental infection, dental procedure, or dental caries with progressive pain and swelling. Patients present with dysphagia, odynophagia, drooling, swelling of the floor of the mouth, tongue displacement, muffled voice, fever, and neck stiffness. The most common physical exam findings are submental and submandibular swelling with protrusion of the tongue. There may be elevation of the floor of the mouth with a woody consistency on palpation. The patient's neck may have tense brawny edema from the submandibular region to the hyoid, commonly described as a bull neck. As the cellulitis progresses, the patient may have trismus, inability to manage secretions, dyspnea, a hoarse voice, and progressive anxiety secondary to airway impingement. Cervical adenopathy and palpable fluctuance are usually absent.

Differential Diagnosis for Emergency Presentation

The differential diagnosis includes viral and bacterial infections of the oropharyngeal region including deep space infections such as pharyngeal or retropharyngeal abscess, parotid or submandibular gland abscess, oropharyngeal tumors, sublingual hematomas, glossal and posterior oropharyngeal angioedema, and laryngeal diphtheria.

Diagnostic Testing

The diagnosis of Ludwig angina is made clinically. Contrast-enhanced CT scan may aid in the identification of deep neck structures involved and the extent of infection.

Management

Asphyxia from progressive edema is the leading cause of death in Ludwig's angina. Airway management is essential when there are any signs of airway compromise, including dyspnea, tachypnea, inability to manage secretions, agitation, stridor, and progressive edema. An awake fiberoptic nasal or oral intubation with a flexible bronchoscope after adequate topicalization is recommended. Oral laryngoscopy may be difficult because of edema and tongue displacement. Paralysis prior to securing the airway is not advised.

A surgical airway may be required if endotracheal intubation cannot be accomplished. Surgical airways can be more challenging

in Ludwig angina due to anterior neck distortion from edema and the risk of spreading infection from dissecting tissue planes (Fig. 61.10). Intravenous antibiotics are of paramount importance once the patency of the airway is ensured (see Table 61.3.) There usually is not a role for surgical intervention with the exception of an infected tooth extraction, débridement of necrotizing infection, or drainage of purulent collections.

Disposition

Patients with Ludwig angina should be admitted to the intensive care unit.

RETROPHARYNGEAL ABSCESS

Foundations

Retropharyngeal abscess is an infection of the deep neck spaces that can lead to life-threatening complications, including airway compromise and mediastinal spread of infection. The retropharyngeal space is posterior to the hypopharynx and esophagus in the midline neck, immediately anterior to the danger and prevertebral spaces that extend to the diaphragm and coccyx, respectively (Fig. 61.11). It is bordered laterally by the carotid sheath/parapharyngeal space. Infections may spread from one deep space to another and involve the carotid sheath, mediastinum, and chest.

Retropharyngeal abscesses most commonly occur in children younger than 5 years old with a male predominance.[31] Children have lymph nodes present in the retropharyngeal space that are the lymphatic drainage of the nasal cavity, paranasal sinuses, oropharynx, hypopharyngeal space, middle ear, and eustachian tubes but atrophy prior to puberty. Upper respiratory tract infections, otitis media, and sinusitis can lead to suppurative lymphadenitis and abscess formation.[31] A minority of children with Kawasaki disease also have a deep neck infection.[32,33] In adults, retropharyngeal abscess formation can be caused by penetrating trauma, foreign body (fish or chicken bones) or iatrogenic instrumentation (feeding tube, laryngoscope, suctioning),

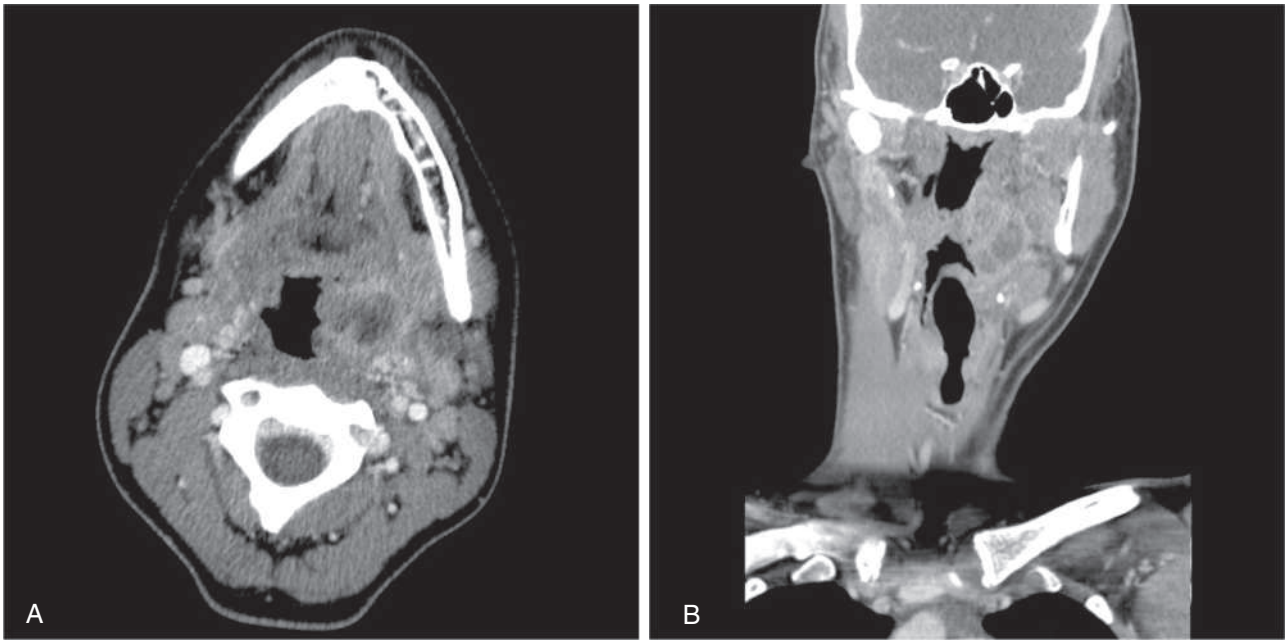

Fig. 61.9 Contrast-enhanced axial (A) and coronal (B) CT image of a left-sided peripherally enhancing and centrally hypoattenuating peritonsillar abscess. There is mild mass effect on the oropharyngeal airway and mild inflammation of the fat in the left parapharyngeal space.

Fig. 61.10 Anterior neck swelling and erythema in Ludwig angina. (From Bernardoni B, Grosso R, Powell E, et al. Case study in critical care transport: a 51-year-old male with Ludwig angina. *Air Med J* 2017;36(2):45-48.)

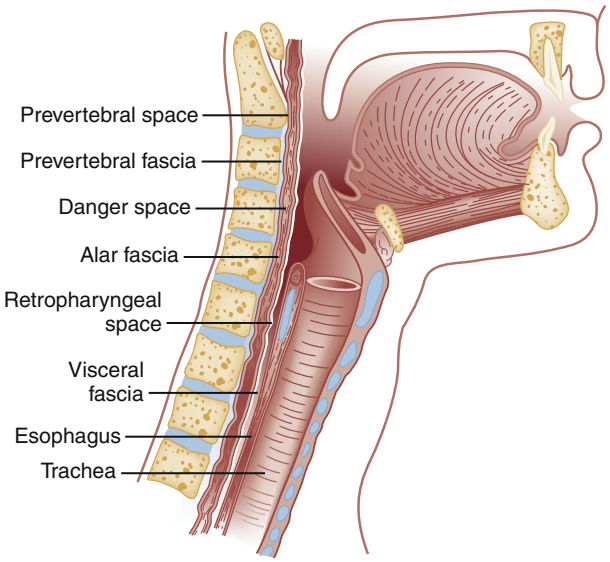

Fig. 61.11 Anatomic illustration of the lateral view of the neck showing of the prevertebral space, danger space, and retropharyngeal space.

spread from adjacent infections (dental or peritonsillar), hematologic spread of infections, and infections of the spine communicating with the prevertebral space. Risk factors include immunosuppression, chronic steroid use, diabetes, and human immunodeficiency virus. Diabetic patients have a higher prevalence of multispace spread of infection.[34] Adolescents and adults with a prior tonsillectomy also have an increased risk of deep neck infections.[35]

Microbiology of retropharyngeal abscesses is polymicrobial with a mixture of aerobes and anaerobes as described in Table 61.3. Intravenous drug abuse increases the frequency of methicillin-resistant *Staphylococcus aureus* infections.[36] A history of immunocompromise or prior nosocomial infection increases the risk of drug-resistant organisms as well as the risk for tuberculous or fungal infection. Complications from

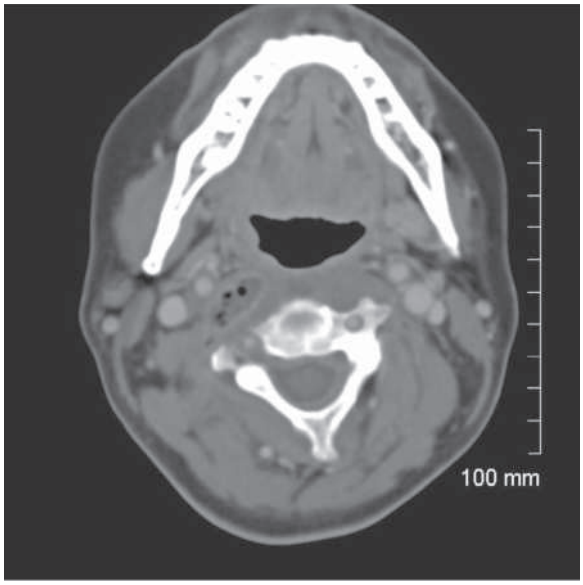

Fig. 61.12 Axial CT scan image demonstrating right sided retropharyngeal abscess.

retropharyngeal abscess include airway compromise, abscess rupture leading to aspiration of pus, and involvement of the carotid sheath. The carotid sheath is surrounded by deep fascia and includes the carotid artery, internal jugular vein, and vagus nerve, and thus infection can result in compromise of any of these structures including arterial erosion, aneurysm, Lemierre syndrome, palsy of cranial nerves IX–XII, and mediastinitis.

Clinical Features

Patients with a retropharyngeal abscess may present with fever, sore throat, dysphagia, odynophagia, drooling, pain, hoarseness, trismus, and neck stiffness. As the abscess and inflammation become more severe, patients may appear toxic and hold their heads in a sniffing position while sitting upright. Advanced cases can cause ligamentous and osseous destruction, resulting in torticollis and severe pain. The patient may experience referred pain to the posterior neck and shoulder when swallowing.

Physical examination findings of tender cervical lymphadenopathy, neck swelling, torticollis, and fever are common. Retropharyngeal cellulitis or early abscess present with diffuse edema and erythema of the posterior pharynx. Depending on the structures involved, patients may present with trismus, making intraoral physical examination difficult and not advised. Tenderness with external laryngeal and tracheal manipulation is commonly present.

Differential Diagnosis for Emergency Presentation

The differential diagnosis for retropharyngeal abscess is similar to peritonsillar abscess and parapharyngeal abscess displayed in Box 61.2.

Diagnostic Testing

Contrast-enhanced CT scan is the preferred diagnostic test for the identification of retropharyngeal abscess. CT findings are characterized by a fluid collection with central hypodensity and complete ring enhancement with scalloping (Figs. 61.12 and 61.13). Fat stranding and edema characterized by low-density thickening without peripheral enhancement may represent an early phase of infection before an abscess develops. If contrast-enhanced CT imaging is not possible, additional studies may include non-contrast-enhanced CT scan and ultrasound imaging. Lateral neck radiographs taken during inspiration

while the neck is extended will suggest a pathologic process if there is swelling but are unlikely to differentiate abscess from edema and the structures involved. On lateral neck radiographs, a retropharyngeal space measured from the anteroinferior aspect of the second vertebral body to the posterior pharyngeal wall that is wider than 7 mm (children and adults) or a retrotracheal space measured at the sixth vertebral body more than 14 mm in children and 22 mm in adults is abnormal and suggests an inflammatory process.

Management

Initial management should focus on airway stabilization and broad-spectrum intravenous antibiotics. Intravenous antibiotic selection is displayed in Table 61.3. Short-term, high-dose, adjunctive corticosteroids such as dexamethasone 0.6 mg/kg with maximum dose of 10 mg are often used with antibiotics and may be associated with a decreased need for surgical drainage.[11,34,37] In cases of a retropharyngeal abscess less than 2 cm, medical management alone may be sufficient. In immunosuppressed patients and those living in areas with high rates of tuberculosis with insidious onset of symptoms and a high suspicion for tuberculous or fungal infection, consultation with an infectious disease specialist along with an otolaryngologist is recommended. In cases with evidence of ligamentous and osseous destruction, neck immobilization and further dedicated cervical spine imaging may be required.

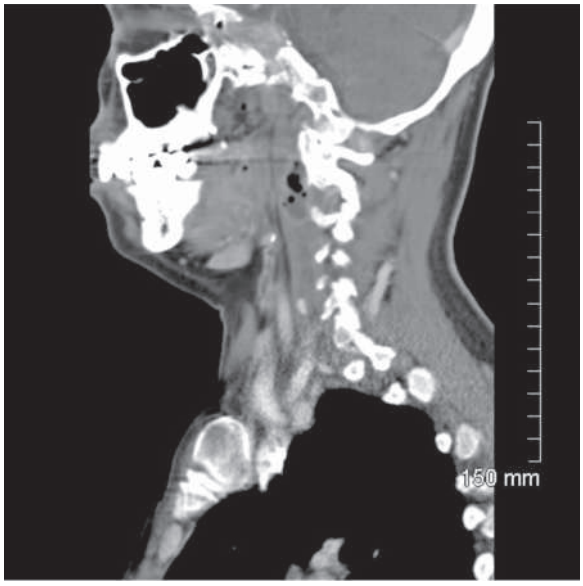

Fig. 61.13 Sagittal CT scan demonstrating right sided retropharyngeal abscess.

Disposition

Patients with a retropharyngeal abscess should be admitted to the hospital after otolaryngology consultation in the emergency department. In general, these patients are at high risk for airway compromise and should be admitted to an intensive care unit. If the patient has early, mild disease with a stable airway exam they may be suitable for admission to a floor bed.

PARAPHARYNGEAL ABSCESS

Foundations

Parapharyngeal abscess is a serious infection with close proximity to the airway, carotid sheath, and mediastinum. Seen in Figure 61.14, the parapharyngeal space is found on either side of the neck and extends from the skull base to the styloglossus muscle at the angle of the mandible. The posterior aspect of the parapharyngeal space is separated from the midline retropharyngeal space and danger space by a fascial plane. The carotid sheath is found in the retrostyloid compartment of the parapharyngeal space and contains the common carotid artery, internal jugular vein, the sympathetic plexus, cranial nerves IX through XII, and lymph nodes. Parapharyngeal space abscesses usually emanate from dental or peritonsillar infections with similar organisms. Spread from adjacent infections, suppurative lymphadenitis, iatrogenic via

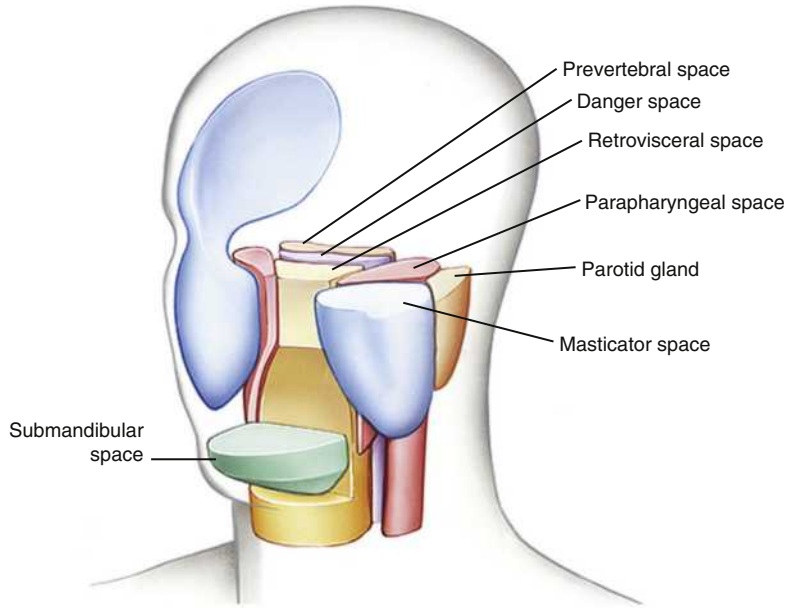

Fig. 61.14 Block diagram of the deep spaces in the neck showing the relationship of the parapharyngeal space, danger space, and prevertebral space. (From Som PM, Curtin HD. Parapharyngeal and masticator space lesions. In: Som PM, Curtin HD, eds. *Head and Neck Imaging*, 5th edition. St. Louis: Mosby, Inc.; 2011.)

local infiltration for surgical procedures or nerve blocks, infected neck tumors or cysts, parotitis, and sinusitis are rare causes.

Complications of a parapharyngeal abscess range from airway obstruction secondary to edema, neck or mediastinal spread, vascular involvement, and nerve compromise. Abscess rupture with pus into the airway can result in pneumonia, lung abscess or empyema. Mediastinal spread is possible through connection with the retropharyngeal space and danger space. Involvement of the carotid sheath has the potential to affect the sympathetic chain ganglia causing an ipsilateral Horner syndrome and neuropathies of cranial nerves IX–XII. Communication with the carotid artery may cause erosion, aneurysm, and rupture. Any signs of bleeding should be investigated with CT or MR angiography. Lemierre syndrome should be considered when sore throat or tonsillitis is followed by sepsis and multisystem involvement. Proptosis, impaired extraocular movement, or pupillary changes should prompt consideration of cavernous sinus thrombosis, a life-threatening complication with spread of infection through the ophthalmic venous system. Parapharyngeal abscess may have local spread causing mandibular osteonecrosis and parotid abscess.

Clinical Features

Symptoms include pain and swelling of the neck, odynophagia, pain with mastication, and torticollis if the sternocleidomastoid muscle is involved. Physical exam findings vary depending on the extent of the infection. The sternocleidomastoid muscle may obscure exam findings of an abscess. Fever, trismus, edema, and pain with movement of the sternocleidomastoid muscle may be observed. Patients with infection involving the anterior aspect of the parapharyngeal space may have medial tonsillar displacement and pharyngeal edema.

Differential Diagnosis for Emergency Presentation

The differential diagnosis for parapharyngeal abscess is similar to peritonsillar abscess and retropharyngeal abscess displayed in Box 61.2.

Diagnostic Testing

Contrast-enhanced CT is the preferred diagnostic study (Fig. 61.15). External ultrasound can provide useful information but may be limited in parapharyngeal abscess. Dedicated CT angiography or Doppler assessment are recommended if vascular complications are suspected.

Management

Initial management is focused on airway management, early treatment with broad-spectrum antibiotics listed in Table 61.3, dexamethasone 0.6 mg/kg intravenous or intramuscular with maximum dose 10 mg, and consultation with an otolaryngologist. Airway management is essential when there are any signs of airway compromise, including dyspnea, tachypnea, and inability to manage secretions, agitation, or stridor. An awake fiberoptic nasal or oral intubation with a flexible bronchoscope after adequate topicalization is recommended. Paralysis prior to securing the airway is not advised.

Disposition

Consultation with an otolaryngologist and admission to the hospital are recommended. Admission to the ICU is recommended should there be signs of airway or vascular compromise.

RHINOSINUSITIS

Foundations

Rhinosinusitis is inflammation of the upper airways and paranasal sinuses associated with nasal discharge, facial pain or pressure, nasal blockade, and a sense of fullness mostly associated with an infectious source (viral, bacterial, fungal.) Acute rhinosinusitis is classified as having symptoms for fewer than 4 weeks. Viral etiologies tend to have symptoms that peak and resolve in a few days, whereas bacterial etiologies tend to last longer than 10 days with persistent symptoms or will worsen after a period of improving symptoms. Rhinovirus, adenovirus, influenza or parainfluenza virus are the most common precipitants.[38] *Streptococcus pneumoniae*, non-typable *Haemophilus influenzae*, and *Moraxella catarrhalis* are the most common bacterial causes of maxillary sinusitis.[32,39] *Staphylococcus aureus*, gram-negative bacilli, and *Streptococcus* spp. are associated with subacute, chronic, and health care–associated sinusitis.

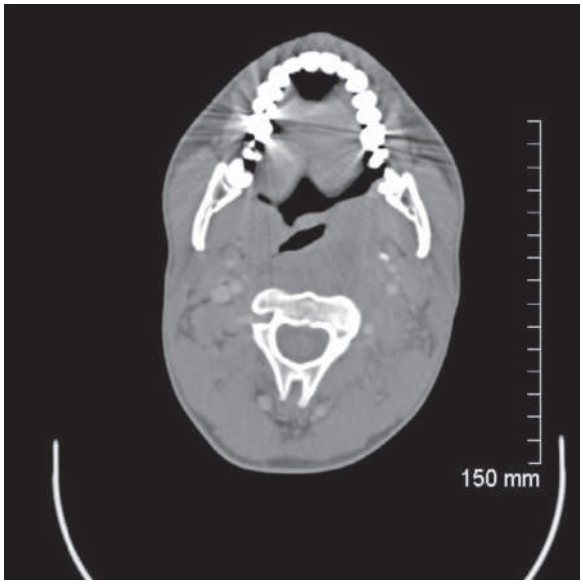

Fig. 61.15 CT scan showing a left-sided parapharyngeal abscess.

Structural abnormalities that predispose patients to acute rhinosinusitis include nasal septal deviation, infraorbital ethmoid air cells larger than 3 mm, accessory ostia in the common drainage pathway, conchae bullosa, oroantral fistula, and maxillary dental disease. Viral infection may be antecedent to bacterial infection because mucosal swelling and inflammation impair drainage and promote ciliary dyskinesia providing an environment for bacterial growth.[32] This may be the etiology of the double sickening phenomenon when patients report improvement of symptoms followed by worsening. It is impossible to differentiate between the viral and bacterial etiologies based on symptoms alone, and thus it is difficult to characterize the preponderance of antecedent infection. Rarely, acute rhinosinusitis may be attributed to periapical infection of the maxillary molars with direct extension into the sinus space.[38] Chronic rhinosinusitis causes symptoms for greater than twelve weeks. Chronic rhinosinusitis is not associated with structural abnormalities and is more commonly related to inflammatory disorders. Noninfectious etiologies of rhinosinusitis include allergic etiologies and vascular engorgement associated with pregnancy mimicking rhinosinusitis.

Complications from rhinosinusitis are extremely rare, but include cellulitis, meningitis, and orbital or intracranial abscess. Patients with poorly controlled diabetes and immunosuppression are at increased risk of invasive fungal species including *Aspergillus* spp., mucormycosis, and *Fusarium* spp.

Clinical Features

Symptoms of rhinosinusitis include purulent nasal discharge, facial pain or pressure, posterior nasal drip, and decreased sense of smell. These symptoms may be associated with sore throat, hoarseness,

cough, headache, fatigue, malaise, and fever. Differentiation between viral and bacterial rhinosinusitis is not possible based on any one symptom and relies mostly upon the time course of symptoms. Bacterial causes are more likely to be associated with prolonged symptoms lasting longer than 10 days, frequently with a worsening of symptoms after initial improvement, severe symptoms for greater than 3 to 4 days, and unilateral maxillary tooth or cheek pain. Allergic rhinosinusitis is more likely to be associated with watery rhinorrhea, ocular itching with watery discharge, and sneezing.[38,40] On exam, patients have purulent nasal discharge and may have pain with percussion of sinuses or maxillary teeth. High fever, nasal crusting or severe facial pain in immunocompromised patients is concerning for invasive infection.

Differential Diagnosis for Emergency Presentation

Differential diagnosis includes allergic rhinitis, dental infection, headache syndromes (including cluster headache, tension headache, and vascular headache), tumor, and intracranial abscess.

Diagnostic Testing

The diagnosis of acute rhinosinusitis is clinical. The diagnosis of bacterial rhinosinusitis requires one of the three criteria[5,41]: at least 10 days of persistent symptoms without improvement, three to four days of severe symptoms including a fever greater than 39 degrees Celsius with nasal discharge or facial pain without improvement, or onset of progressive symptoms with worsening symptoms after initial improvement. Visual examination of the nares directly or via nasal endoscopy may reveal swelling of the turbinates and purulent appearing discharge. Routine CT imaging is not indicated. However, if performed for other reasons, CT may reveal thickening of the walls of both nasal passages, engorgement of inferior turbinates, obstruction of the ethmoid infundibulum, and abnormalities of maxillary, sphenoid, and frontal sinuses.

The gold standard for diagnosis of bacterial rhinosinusitis is culture of secretions obtained via sinus puncture. This is not recommended in the emergency department. Culture taken via sinus puncture in patients with radiographic features of rhinosinusitis or with purulence of discharge has been found to correlate with positive cultures 50% of the time and the sinus puncture is painful and carries potential risks to the patient.[32]

Management

The vast majority of acute rhinosinusitis is self-resolving and management should focus on symptom management and patient education. We recommend symptom management with acetaminophen 650 mg (15 mg/kg for children) every 6 to 8 hours and ibuprofen 800 mg (10 mg/kg for children) every 8 hours, nasal irrigation with saline 1 to 2 sprays each nostril every 4 hours, and intranasal corticosteroids such as fluticasone propionate or mometasone furoate 2 sprays in each nostril once daily.[38,42,43] Data on the efficacy of decongestants and mucolytics are lacking and they are not recommended. Systemic corticosteroids for acute rhinosinusitis are not recommended. Routine use of antihistamines is not recommended unless there are additional allergic symptoms.

Given the risks and lack of benefit of routine antibiotic use in rhinosinusitis, antibiotics should only be used for patients who meet the definition of bacterial rhinosinusitis.[44] Overall, the use of antibiotics is contested, and the benefits are small, with cure rates at 7 to 15 days slightly higher in patients treated with antibiotics than in those treated with placebo.[38] In bacterial rhinosinusitis there is controversy as to when antibiotics should be initiated. Some guidelines propose initiation at the time of diagnosis[41] while others advocate for a watchful waiting approach for well appearing patients and initiation of antibiotics if symptoms do not improve within 7 days of diagnosis.[45] For ED patients we recommend starting the antibiotics at the time of ED presentation. Antibiotics should be given to patients with multiple comorbidities, immunosuppression, prior sinus surgery, or symptoms not isolated to the maxillary sinus. Amoxicillin 500 mg three times daily or amoxicillin-clavulanate 875 mg/125 mg twice daily for 5 days are first-line antibiotics. Amoxicillin-clavulanate should be used if the patient smokes, has diabetes, has had recent antibiotics, is older than 65 years, or is a health care worker. Doxycycline 100 mg twice daily may be given for penicillin allergic patients. Levofloxacin and moxifloxacin are also second-line agents but should be reserved for patients without other options because of the side effect profile. Avoid macrolides (azithromycin), trimethoprim-sulfamethoxazole, and second- and third-generation cephalosporins because of increasing *S. pneumoniae* resistance.

The length of antibiotic treatment is also controversial with ranges of 5 to 14 days. We recommend the initial treatment course of 5 days because there are similar treatment effects with reduced exposure to antibiotics. Children should be treated for 10 days. For adults with recurrent episodes of rhinosinusitis or prior antibiotic exposure the treatment course should be 10 days. Chronic sinusitis is not likely to be from an infectious etiology and should be managed with saline rinses and intranasal corticosteroids. If there is concern for an invasive fungal infection typified by severe rapidly progressive symptoms in patients with immunosuppression, patients should have emergent consultation with an otolaryngologist and begin empiric therapy with intravenous antifungal.

Disposition

Uncomplicated rhinosinusitis can be discharged home. Admission should be considered in patients presenting with systemic evidence of illness, immunosuppression, or complications. Referral to an otolaryngologist is indicated in patients presenting with recurrent acute rhinosinusitis (greater than 4 distinct episodes of rhinosinusitis within a calendar year).[46]

CHAPTER 61: QUESTIONS AND ANSWERS

1. A previously well 18-year-old male presents with throat pain and fever to 39 °C for the past 2 days. He denies vomiting, diarrhea, cough, or rhinorrhea. He is not sexually active. Physical exam is notable for tender anterior cervical lymphadenopathy and symmetrically swollen and erythematous palatine tonsils with a gray-white tonsillar exudate. The remainder of his neck and physical exam is benign. What is the most appropriate next step?

a. Empirically prescribe amoxicillin for 10 days
b. Obtain a complete blood count with differential
c. Obtain an intraoral tonsillar ultrasound
d. Perform a rapid strep antigen test and prescribe antibiotics only if there is a positive result

Answer: D. This patient is presenting with pharyngitis, with sore throat, fever, exudative pharyngitis, and cervical lymphadenopathy without associated cough or rhinorrhea. A majority of cases are viral and caused by common cold viruses. Bacterial infection is only responsible for approximately 5% to 10% of adult and 20% to 30% of pediatric cases. Rapid antigen testing is recommended as a first-line diagnostic test for GAS pharyngitis, because it is highly sensitive and specific when performed correctly. A positive test indicates the presence of GAS and does not require follow up testing.

2. A 19-year-old female patient presents to the emergency department with vision changes and headaches. She reports a sore throat 10 days ago started to improve, but never completely resolved. For the past 3 days she noted increasing left-sided neck pain and fevers. On exam she appears uncomfortable with a fever and mild tachycardia. She is warm and diaphoretic with a dry forehead on the left. Her left eyelid is slightly lower than the right and her left pupil is 3 mm smaller than the right. Her extraocular movements are intact, and her intraoral exam shows symmetric tonsils with mild erythema and a midline uvula. She has mild trismus. What is most likely causing her symptoms?

a. Parapharyngeal abscess with invasion of the carotid sheath
b. Peritonsillar abscess with compression of the carotid sheath
c. Spread of infection into the cavernous sinus causing thrombosis and intracranial abscess
d. Submandibular space infection and spread into retropharynx

Answer: A. Complications from retropharyngeal or parapharyngeal abscess include airway compromise, abscess rupture leading to aspiration of pus, and involvement of the carotid sheath. The carotid sheath is surrounded by deep fascia and includes the carotid artery, internal jugular vein, and vagus nerve, and thus infection can result in compromise of any of these structures including arterial erosion, aneurysm, Lemierre syndrome, palsy of cranial nerves IX–XII, and mediastinitis.

3. A 34-year-old male presents with complaints of high fever, left-sided face pain, and purulent nasal discharge for 10 days. He has been attempting symptom management with nasal saline irrigation and intranasal corticosteroids, but after initial improvement reports worsening symptoms. What is the next step in treatment?

a. CT scan of his face to evaluate for complications of rhinosinusitis
b. Obtain bacterial culture via sinus puncture
c. Prescribe a 5-day course of amoxicillin
d. Supportive care with antiinflammatory medications, rest, and continued nasal saline irrigation

Answer: C. The diagnosis of acute rhinosinusitis is clinical. The diagnosis of bacterial rhinosinusitis requires one of the three criteria: at least 10 days of persistent symptoms without improvement, three to four days of severe symptoms including a fever greater than 39 degrees Celsius with nasal discharge or facial pain without improvement, or onset of progressive symptoms with worsening symptoms after initial improvement. Given the risks and lack of benefit of routine antibiotic use in rhinosinusitis, antibiotics should only be used for patients who meet the definition of bacterial rhinosinusitis with these criteria.

4. Patients presenting with symptoms concerning for a retropharyngeal abscess are best evaluated using what modality?

a. Contrast-enhanced CT
b. Intraoral ultrasound
c. Lateral neck x-ray
d. Visualization with a fiberoptic scope

Answer: A. Contrast-enhanced CT scan is the preferred diagnostic test for the identification of retropharyngeal abscess. CT findings are characterized by a fluid collection with central hypodensity and complete ring enhancement with scalloping. Fat stranding and edema characterized by low-density thickening without peripheral enhancement may represent an early phase of infection before an abscess develops.

CHAPTER 61: QUESTIONS AND ANSWERS—cont'd

5. This bacterium is frequently implicated in non-GAS pharyngitis and is also most commonly implicated in suppurative jugular thrombophlebitis:

a. *Arcanobacterium haemolyticum*
b. *Fusobacterium necrophorum*
c. *Haemophilus influenzae* type B
d. Methicillin-resistant *Staphylococcus aureus*

Answer: B. *Fusobacterium necrophorum* is an anaerobic gram-negative rod that is part of the normal oral flora and causes pharyngitis in patients 15 to 45 years old with a similar presentation to GAS. *Fusobacterium* is the primary causative agent in septic jugular vein thrombophlebitis (Lemierre syndrome). *Fusobacterium* should be considered in young adults with ongoing severe symptoms.

62

Pneumonia

Matthew A. Waxman and Gregory J. Moran

KEY CONCEPTS

- Empirical antimicrobial therapy should be started in the emergency department (ED) for patients admitted with pneumonia.
- *Streptococcus pneumoniae* is the most commonly encountered pathogen in hospitalized patients, especially those requiring the intensive care unit.
- No characteristic radiographic pattern is pathognomonic for a specific pneumonia pathogen.
- *Legionella* should be suspected in patients with gastrointestinal or neurologic symptoms presenting with pneumonia.
- As part of the evaluation of patients with pneumonia, the patient's immune status should be considered. Patients with HIV and other immunosuppressive conditions are at risk for opportunistic infections, such as *Pneumocystis jiroveci.*
- Empirical therapy should treat the most likely pathogens for the clinical situation, such as *S. pneumoniae, Haemophilus influenzae, Mycoplasma pneumoniae,* and *Chlamydia pneumoniae,* and should be consistent with current national treatment guidelines, such as those from the American Thoracic Society/Infectious Disease Society of America (ATS/IDSA).
- Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is an uncommon cause of community-acquired pneumonia (CAP), but empirical coverage of MRSA should be strongly considered for patients with severe pneumonia and sepsis, with concomitant influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia.
- Patients with prior use of intravenous antibiotics, neutropenia, or underlying bronchiectasis are at increased risk of infection with *Pseudomonas aeruginosa.* Empirical therapy for high-risk or critically ill patients should cover for *P. aeruginosa.*
- Disposition is dictated by the patient's underlying medical conditions, severity of illness, likelihood of clinical deterioration, and feasibility of home care and outpatient follow-up.

PRINCIPLES

Background and Importance

Pneumonia is the leading infectious cause of death worldwide, with over 3.1 million deaths annually. In the United States, there are over 4 million adult cases of community-acquired pneumonia (CAP) annually. The economic burden associated with CAP annually in the United States is over 17 billion dollars. Most cases of CAP are managed in the outpatient setting, and the mortality is low. Pneumonia necessitating hospitalization is associated with a mortality rate as high as 20%. Pneumonia remains challenging because of an expanding spectrum of pathogens including SARS-CoV-2, changing antibiotic resistance patterns, continued introduction of newer antimicrobial agents, and increasing emphasis on cost-effectiveness and outpatient management.

As the percentage of the population older than 65 years continues to increase, the incidence of pneumonia is expected to increase. An increasing number of patients are taking immunosuppressive drugs related to the treatment of malignancy, transplantation, or autoimmune disease, resulting in more cases of pneumonia from opportunistic pathogens. *Streptococcus pneumoniae* is the most frequently identified pathogen and is also associated with increasing antimicrobial resistance. In addition, the threat exists of respiratory infections caused by biologic terrorism or newly recognized pathogens such as COVID-19 that have the potential to spread globally through international travel.

Anatomy and Physiology

Despite the constant presence of potential pathogens in the respiratory tract, the lungs are remarkably resistant to infection. The alveolar surface of the lungs covers an area of approximately 140 m^2, about 10,000 L of air passes through the respiratory tract each day, and typical ambient air can contain hundreds to thousands of microorganisms per cubic meter. Although the cough and laryngeal reflexes prevent most large particulate matter from entering the lower respiratory tract, aspiration of oropharyngeal contents may be a common occurrence during normal sleep. Despite these hazards, the lower airway tract is a virtually sterile environment.

Pathophysiology

The development of clinical pneumonia requires a defect in host defenses, presence of a particularly virulent organism, or introduction of a large inoculum of organisms. Pneumonia commonly results from microaspiration of upper respiratory pathogens into the sterile lower respiratory tract. If the challenge of invading organisms overwhelms host defenses, microbial proliferation leads to inflammation, an immune response, and clinical pneumonia. If host defenses are weak, a minimal challenge may lead to the development of pneumonia. The challenge with pneumonia is identifying the causative agent rather than making the diagnosis. A careful history, including foreign travel, recent antibiotic use, and exposure to the health care system, such as dialysis or living in a nursing home, can help inform empiric therapy. Empiric therapy should be chosen with activity against the spectrum of likely pathogens based on the patient's overall clinical presentation.

In the emergency department (ED), it is often difficult to determine the specific cause of pneumonia because routine microbiologic and serologic testing is not available in the time frame of ED evaluation, although rapid polymerase chain reaction (PCR) testing to determine the pathogen is increasingly available. Even in hospitalized patients, the specific microbiologic cause of pneumonia is usually not identified. When identified, *S. pneumoniae* is the most commonly encountered pathogen in hospitalized patients, with *Haemophilus influenzae* a distant second.[1,2] *Legionella, Mycoplasma,* and *Chlamydophila* spp., referred to as atypical pathogens, are also prevalent in hospitalized

patients. Improved molecular testing has shown that viral pathogens such as rhinoviruses, influenza, parainfluenza, and adenoviruses account for up to one-quarter of etiologies in hospitalized patients.[3,4]

Among adults requiring intensive care unit (ICU) admission, *S. pneumoniae* is the most common pathogen, with even higher prevalence among fatal cases. *Legionella* spp., *Staphylococcus aureus* (including methicillin-resistant *S. aureus* [MRSA]), and aerobic gram-negative bacilli also appear to be relatively more common among adults with severe CAP.[4] Atypical organisms, such as *Mycoplasma* species or viruses, account for a higher proportion of pneumonia in patients with milder illness amenable to outpatient therapy. Atypical organisms can also occur with significant frequency in patients with severe illness requiring hospitalization, particularly because of *Legionella* infection. Coinfection, such as with *Chlamydophila pneumoniae* and *S. pneumoniae,* is also well recognized.

S. pneumoniae is a gram-positive coccus that colonizes the nasopharynx in 40% of healthy adults. Although this organism can cause pneumonia in healthy people, patients with a history of diabetes, cardiovascular disease, alcoholism, sickle cell disease, splenectomy, and malignancy or other immunosuppressive illness are at increased risk. A vaccine containing the capsular polysaccharides of 23 pneumococcal types most commonly associated with pneumonia reduces the likelihood of serious pneumococcal infection. It is recommended for adults at increased risk because of underlying illness or age older than 65 years and others who smoke or have comorbidities such as chronic lung disease.[5] Despite this recommendation, many ED patients have not received the pneumococcal vaccine, and vaccinating eligible patients in this setting seems to be feasible and effective. A 13-valent protein-conjugate pneumococcal vaccine effectively reduces invasive pneumococcal disease and pneumonia in infants and young children. Although underutilized in the adult population, the vaccine has resulted in a marked decrease in the incidence of pneumococcal pneumonia.[6]

H. influenzae, the second most frequently isolated organism in CAP among adults, is a pleomorphic gram-negative rod. It is a common pathogen in adults with chronic obstructive pulmonary disease (COPD), alcoholism, malnutrition, malignancy, or diabetes.

S. aureus may be emerging as a more common cause of CAP and has been found more frequently than *H. influenzae* in some series. Community-associated strains of methicillin-resistant *S. aureus* (CA-MRSA) are uncommon in CAP but are more likely to cause severe disease. Often associated with influenza, staphylococcal pneumonias are often necrotizing, with cavitation and pneumatocele formation. Intravenous (IV) drug users may develop hematogenous spread of *S. aureus* that involves both lungs, with multiple small infiltrates or abscesses (e.g., tricuspid endocarditis resulting in septic pulmonary emboli).

Klebsiella pneumoniae is a gram-negative rod that rarely causes disease in a normal host and accounts for a small percentage of cases of CAP. It may cause severe pneumonia in debilitated patients with alcoholism, diabetes, or other chronic illness. There is a high incidence of antibiotic resistance because the organism is often hospital-acquired.

Mycoplasma pneumoniae is one of the most common causes of CAP in previously healthy patients younger than 40 years. Another important organism in CAP is *C. pneumoniae,* an intracellular parasite transmitted between humans by respiratory secretions or aerosols. Seroprevalence studies have indicated that virtually everyone is infected with *C. pneumoniae* at some time and that reinfection is common, particularly in older adults. It accounts for at least 10% of outpatient CAP cases, although this is underestimated due to difficulty in diagnosing infection with this organism.

At least 30 species of *Legionella* have been isolated since the 1976 convention-related outbreak in Philadelphia, from which the organism derives its name. *Legionella* is an intracellular organism that lives in aquatic or soil environments. There is no person-to-person transmission. Although it is implicated in point outbreaks related to cooling towers and similar aquatic sources, the organism also lives in ordinary tap water and is underdiagnosed as a cause of CAP. *Legionella* prevalence seems to vary greatly by geographic region with a high prevalence in Australia.

Lower respiratory infections caused by anaerobic organisms generally result from the aspiration of oropharyngeal contents with large amounts of bacteria. These infections are typically polymicrobial with oral flora such as *Peptostreptococcus, Bacteroides, Fusobacterium,* and *Prevotella* spp. Presentation is often subacute or chronic and may be difficult to distinguish clinically from other causes of pneumonia. Clinical factors that suggest an anaerobic infection include risk factors for aspiration, such as central nervous system depression or swallowing dysfunction, severe periodontal disease, fetid sputum, and presence of a pulmonary abscess or empyema.

Viral pneumonias are common in infants and young children and are recognized as an important cause of pneumonia in adults. Respiratory syncytial virus and parainfluenza viruses are the most common causes of pneumonia in infants and small children, occurring mostly during autumn and winter. Influenza viruses are historically the most common cause of viral pneumonia in adults. Winter influenza outbreaks, usually of influenza type A, may cause up to 40,000 deaths annually in the United States. More than 90% occur in people aged 65 years or older. Updated influenza epidemiology is available from the United States Centers for Disease Control (CDC).[7] Metapneumovirus is a paramyxovirus that is an important cause of viral pneumonia in children and adults. SARS-CoV2 is now the most common viral pneumonia requiring hospitalization. During epidemics, clinicians should suspect a viral agent in patients with hypoxia, fever, and cough.

Fungal infections caused by organisms such as *Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides immitis* commonly manifest as pulmonary disease. These organisms are present in the soil in various US geographic areas—*H. capsulatum* in the Mississippi and Ohio River valleys, *C. immitis* in desert areas of the Southwest, and *B. dermatitidis* in a poorly defined area extending beyond that of *H. capsulatum*. These infections should be considered in people in appropriate geographic areas, especially in those who are near activities that disturb the soil, such as construction or dirt bike riding, and in patients who do not respond to antibacterial antibiotics. The clinical presentation varies from an acute or chronic pneumonia to asymptomatic granulomas and hilar adenopathy.

Pneumocystis pneumonia (PCP) occurs in immunocompromised hosts, principally those with acquired immunodeficiency syndrome (AIDS) or malignancy. *Pneumocystis jiroveci* is one of the most common opportunistic infections leading to a diagnosis of HIV infection (see Chapter 121). Patients with pulmonary complaints should be questioned about HIV risk factors, and emergency clinicians should search for signs of HIV-related immunosuppression, such as weight loss, lymphadenopathy, and oral thrush. PCP typically manifests subacutely with fatigue, exertional dyspnea, nonproductive cough, pleuritic chest pain, and fever.

Mycobacterium tuberculosis is a slow-growing bacterium transmitted between people by droplet nuclei produced from coughing and sneezing. *M. tuberculosis* survives within macrophages as a facultative intracellular parasite and may remain dormant in the body for many years. Active tuberculosis (TB) develops within 2 years of infection in approximately 5% of patients, and another 5% develop reactivation disease at some later time. Reactivation is more likely to occur in people with impaired cell-mediated immunity, such as patients with diabetes, renal failure, immunosuppressive therapy, malnutrition, or HIV. Approximately one-third of the world's population is infected with

M. tuberculosis. About 9 million new cases of active disease develop annually, resulting in 1.5 million deaths worldwide. Approximately 2.7 per 100,000 individuals in the United States develop TB each year.[8] Multidrug-resistant strains of *M. tuberculosis* have been found in increasing numbers, especially among patients with HIV and in immigrants from Southeast Asia.

Clinical Features

The ED evaluation should focus on establishing the diagnosis of pneumonia and determining the presence of epidemiologic and clinical features that would influence decisions regarding hospitalization and antibiotics. Fundamental components of the history include character of symptoms, setting in which the pneumonia is acquired, geographic or animal exposures, and host factors that predispose to certain types of infections.

Pneumonia generally manifests as a cough productive of purulent sputum, shortness of breath, and fever. In most healthy older children and adults, the diagnosis can be reasonably excluded on the basis of history and physical examination, with suspected cases confirmed by chest radiography. The absence of any abnormalities in vital signs or chest auscultation substantially reduces the likelihood of pneumonia as demonstrated by radiography. No single isolated clinical finding, however, is highly reliable in establishing or excluding a diagnosis of pneumonia.[6]

Older or debilitated patients with pneumonia often have nonspecific complaints, such as acute confusion or a deterioration of baseline function, without classic symptoms. Similarly, older patients may not present with a well-defined infiltrate on radiography. Older patients are more likely to have advanced illness at the time of presentation and may have sepsis in the absence of a previous syndrome suggestive of pneumonia. Occasionally, patients with lower lobe pneumonia have abdominal or back pain as a presenting symptom.

Classic teaching divides pneumonia based on clinical patterns into typical pneumonia caused by pyogenic bacteria, such as *S. pneumoniae* or *H. influenzae,* and atypical pneumonia caused by organisms such as *Mycoplasma* and *Chlamydophila* spp. This classic teaching is artificial, and a clear differentiation between these two types of pneumonia on clinical grounds alone is impossible. Clinical factors, including timing of onset, viral prodrome, absence of rigors, nonproductive cough, lower degree of fever, absence of pleurisy or consolidation, normal leukocyte count, and an ill-defined infiltrate on a chest radiograph, cannot reliably differentiate atypical pneumonias from those with pyogenic bacterial causes. Although it is impossible to determine the specific cause of pneumonia with certainty without microbiologic or serologic tests, certain clinical factors can suggest that a specific pathogen should be considered.

Clinical factors suggesting pneumococcal pneumonia include the abrupt onset of a single shaking chill, followed by fever, cough productive of rust-colored sputum, and pleuritic chest pain. Patients with a history of asplenia, sickle cell disease, HIV, multiple myeloma, or agammaglobulinemia are at increased risk of pneumococcal bacteremia and sepsis, with high mortality rates. Adults with chronic lung disease who develop pneumonia caused by *H. influenzae* typically demonstrate an insidious worsening of baseline cough and sputum production, and bacteremia is rare. *K. pneumoniae* may cause severe pneumonia in older or debilitated patients with so-called currant jelly sputum from the necrotizing nature of the infection. Abscess formation, empyema, and bacteremia are common with this organism, and mortality is high.

Mycoplasmal infection usually begins as a flulike illness with headache, malaise, fever, and nonproductive cough. Skin lesions, including maculopapular, vesicular, urticarial, or erythema multiforme–type rashes, are common, especially in younger patients. Although bullous myringitis is described as a classic finding, it is not specific for mycoplasmal infection and is seldom encountered. Patients generally do not have a toxic appearance, and most can be treated on an outpatient basis. Although mucopurulent sputum generally indicates the presence of pyogenic bacterial pneumonia or bronchitis, it may also be present with mycoplasmal or viral pneumonia. Viral pneumonia in adults is often preceded by symptoms of upper respiratory infection, such as rhinitis or sore throat. Most *C. pneumoniae* infections in young adults cause a minor, self-limited, upper respiratory illness that is subacute in onset. This organism is also associated with bronchitis, wheezing, sinusitis, and pharyngitis. Development of radiographically evident pneumonia is more common in older adults with C. *pneumoniae*. Some patients with *Legionella* infection have a mild, self-limited atypical pneumonia presentation. Older patients, smokers, and those with chronic disease or immunosuppression are more prone to develop the more acute and severe systemic illness of Legionnaires disease. Gastrointestinal symptoms, such as diarrhea and abdominal cramping, confusion, and muscle aches are sometimes prominent.

In addition to age, the presence of underlying illness, and presenting symptoms, the setting of acquisition of pneumonia may provide clues to likely causes. CAP that occurs in otherwise healthy individuals is likely to be caused by viruses, *Mycoplasma* spp., or *S. pneumoniae. S. aureus,* including MRSA, can cause severe pneumonia associated with influenza. Recently hospitalized and long-term care patients may develop pneumonia from agents that are uncommon in CAP, such as Enterobacteriaceae, *Pseudomonas aeruginosa,* and *S. aureus.* Healthy patients in an institutional setting, such as a dormitory or military barracks, are more likely to have pneumonia caused by *Mycoplasma* spp. or viruses.

Patients with underlying lung disease, especially COPD, constitute an important group likely to develop pneumonia. The lower respiratory tract of these patients is commonly colonized with organisms such as *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis.* Cystic fibrosis patients are prone to pneumonia caused by *P. aeruginosa* or *S. aureus*. Defective mucociliary clearance in both these groups makes them highly susceptible to repeated episodes of pneumonia.

Patients with immunosuppression as a result of hematologic malignancy, patients receiving chemotherapy for malignancy, and transplant recipients are prone to pulmonary infections with a wide variety of organisms. In addition to the usual pathogens, these patients may develop pneumonia secondary to viruses such as cytomegalovirus (CMV), varicella, or herpes simplex virus. They are also more likely to develop pneumonia caused by aerobic gram-negative bacilli, *Aspergillus* and geographic fungi, and *P. jiroveci.*

Although the use of highly active antiretroviral therapy has decreased the incidence of opportunistic infections among HIV-infected patients, emergency physicians are likely to encounter patients presenting with opportunistic infections who are undiagnosed or not under regular HIV care. In addition to *P. jiroveci*, there is also an increased incidence of *M. tuberculosis* and common bacterial pathogens such as *S. pneumoniae. S. pneumoniae* and *S. aureus* pneumonia remain the most common pathogens in HIV-infected patients. Other less common causes of pneumonia in HIV-infected patients include *Mycobacterium avium* complex, CMV, aerobic gram-negative bacilli, and *Cryptococcus neoformans.* PCP usually has a gradual presentation characterized by malaise, nonproductive cough, exertional dyspnea, and weight loss. Hypoxemia, hypocapnia, and absence of pulmonary effusions are common with PCP pneumonia. PCP pneumonia often presents in the ED with a decreased oxygen saturation with ambulation in the setting of HIV disease or risk factors.

The potential for opportunistic pulmonary infection can be predicted by a recent absolute CD4 lymphocyte count less than 200/mm^3.

Patients with recognized HIV infection often know their CD4 count. A total lymphocyte count less than 1000/mm^3 on a complete blood count is also suggestive and can be used as a guide for patients in which a CD4 count is not known. In patients who do not know their HIV status, the presence of findings such as weight loss, oral hairy leukoplakia, oral candidiasis, and diffuse tinea infections strongly suggests immunosuppression.

SARS-CoV-2 is a novel beta-coronavirus that emerged in 2019 causing a pandemic (see Chapter 120). Patients with COVID-19, which refers to the disease, have a variable presentation with pulmonary symptoms predominating. COVID-19 causes a range of severity from asymptomatic or minimally symptomatic respiratory infection to severe pneumonia with hypoxemia in up to 20% of patients. The route of transmission is primarily respiratory droplets and is easily spread between close contacts. Risk factors for severe disease include obesity, advanced age, hypertension, and other comorbid conditions.[9]

Patients in nursing homes and extended-care facilities are at increased risk for infection with resistant organisms such as *P. aeruginosa, K. pneumoniae* (including strains producing extended-spectrum β-lactamases), *Acinetobacter* spp., and hospital-associated strains of MRSA. In 2019, the American Thoracic Society/Infectious Disease Society of America (ATS/IDSA) issued revised guidelines for the management of patients who may be at risk for multidrug resistance based on recent exposure to the health care system.[10] These guidelines for the treatment of CAP abandoned the use of a prior categorization of health care–associated pneumonia (HCAP) which indicated risk of drug resistant pathogens and suggested broad spectrum antibiotics. The guidelines now recommend using local data on resistance patterns and individual patient risk factors to decide when to cover for pathogens such as MRSA or *Pseudomonas*. Critical illness at time of presentation to the ED, living in a nursing home, and immunosuppression are risk factors for drug-resistant pathogens.

Differential Diagnoses

Differentiation between upper and lower respiratory tract infections may be difficult. A chest radiograph helps differentiate between upper respiratory tract infection or bronchitis and pneumonia. Many noninfectious conditions may result in inflammatory lung processes, including exposure to mineral dusts (e.g., silicosis), chemical fumes (e.g., chlorine and ammonia), toxic drugs (e.g., bleomycin), radiation, thermal injury, or oxygen toxicity. Immunologic disease (e.g., sarcoidosis, anti-glomerular basement membrane disease, and collagen vascular disease) or hypersensitivity to environmental agents (e.g., farmer's lung disease) may also result in pneumonia. Tumors may be confused radiographically with pneumonia or may appear initially as a postobstructive infection or adenopathy with peripheral infiltrates. The lymphangitic spread of lung malignancy may resemble that of interstitial pneumonia.

It is important to distinguish between the acute aspiration of gastric contents or other liquids and bacterial pneumonia that may develop later as a complication of aspiration. Aspiration of liquids into the lung disrupts surfactant and causes an inflammatory response that may lead to hypoxia and respiratory failure. The aspiration of acidic gastric contents is particularly damaging to the lungs and is common in patients who are unconscious from intoxication or anesthesia or who have neurologic deficits. Patients may initially have coughing or shortness of breath or may appear well initially and then develop respiratory dysfunction during the next several hours.

Acute aspiration of acidic fluid into the lungs causes a chemical pneumonitis. This may produce fever, leukocytosis, purulent sputum, and radiographic infiltrates that mimic those of bacterial pneumonia. Although some patients go on to develop bacterial pneumonia, prophylactic administration of antibiotics is not recommended, and anaerobic coverage should be avoided. Antibiotics should be initiated if the patient develops signs of bacterial pneumonia, including new fever, expanding infiltrate appearing more than 36 hours after aspiration, or unexplained deterioration.[11]

Diagnostic Testing

Although many chest radiographs are obtained unnecessarily for patients with upper respiratory tract infections or bronchitis, it is difficult to identify a set of specific criteria to direct test ordering that is better than the clinical judgment of an experienced physician. A routine chest radiograph for all patients with cough is not necessary. Computed tomography (CT) of the chest is more sensitive than plain radiography for detecting the presence of pulmonary consolidation, although the natural history of CT-positive, plain radiograph–negative pneumonia is not clear. CT of the chest should be considered in patients such as older adults or those with significant comorbidities, for whom identification of a subtle infiltrate would change management. Young healthy adults with a presumptive diagnosis of pneumonia who will be treated as outpatients may have a chest radiograph deferred unless there is a suspicion of immunocompromise or other unusual features of disease. A chest radiograph should be obtained subsequently if there is a poor initial response to treatment. Routine performance of chest radiography for patients with exacerbation of chronic bronchitis, asthma, or COPD is of low yield and may be limited to patients with other signs of infection or congestive heart failure.

Although the causative agent cannot be determined solely by the results of chest radiography, certain radiographic patterns may suggest the possibility of specific pathogens. In pyogenic bacterial pneumonias, radiographs usually show an area of segmental or subsegmental infiltration and air bronchograms (Fig. 62.1). Lobar consolidation is present in a few cases of bacterial pneumonia, often caused by pneumococci or *Klebsiella.* A dense lobar infiltrate with a bulging fissure appearance on a chest radiograph is often described with pneumonia caused by *Klebsiella,* but this finding is nonspecific, and most cases manifest as a more subtle bronchopneumonia. Pneumonia resulting from the spread of infection along the intralobular airway results in fluffy or patchy infiltrates in the involved areas of the lung. A wide variety of bacteria and agents such as *Chlamydophila*, *Mycoplasma*, and *Legionella* spp., viruses, and fungi may cause this pattern.

An interstitial pattern on a chest radiograph (Fig. 62.2) typically is caused by *Mycoplasma* spp., viruses, or *P. jiroveci*. The classic radiographic findings in PCP are bilateral interstitial infiltrates that begin in the perihilar region (Fig. 62.3). Radiographic manifestations of PCP can vary considerably, including normal appearance and lobar infiltrates, pleural effusions, hilar adenopathy, parenchymal nodules, and cavitary disease. Tiny nodules disseminated throughout both lungs represent a miliary pattern typical of granulomatous pneumonias, such as TB or fungal disease. The location of infiltrates may also suggest the cause. Aspiration pneumonia occurs in dependent areas of the lung, usually the superior segments of the lower lobes or posterior segments of the upper lobes. Infiltrates from pneumonias produced by hematogenous spread (e.g., *S. aureus*) tend to be multiple and peripheral. Apical infiltrates suggest TB.

The presence of additional radiographic features in association with infiltrates may suggest a specific cause. An infiltrate associated with hilar or mediastinal adenopathy suggests the presence of TB or fungal disease or may indicate pneumonia associated with a neoplasm. Bacteria most likely associated with cavitation (Fig. 62.4) are anaerobes, aerobic gram-negative bacilli, and *S. aureus.* Cavitation also may be

Fig. 62.1 Posteroanterior Chest Radiograph Reveals Left Upper Lobe Pneumonia. A variety of organisms can produce this pattern, usually *Streptococcus pneumoniae*, *Haemophilus influenzae*, or gram-negative bacilli, but also *Chlamydophila pneumoniae, Mycoplasma,* or *Legionella* spp.

present in fungal disease or TB and with noninfectious processes (e.g., malignancy and pulmonary vascular disease). Pneumatoceles or spontaneous pneumothorax may be seen in HIV patients with PCP. Pleural effusions occur with a wide variety of organisms, including many types of pyogenic bacterial pneumonias, *Chlamydophila* and *Legionella* spp., and TB. Anaerobic infections associated with an effusion are especially prone to the development of empyema. The diagnosis and aspiration of pleural effusions can be aided by bedside ultrasonography in the ED.

Lung ultrasonography is an emerging modality in the differentiation of respiratory complaints in the ED. The use of lung ultrasound has been shown to effectively differentiate pneumonia, congestive heart failure, and COPD/asthma in the acutely dyspneic patient.[12] Ultrasonography has been shown to be highly sensitive and specific for the diagnosis of pneumonia when compared to CT.[13] Normally air-filled alveoli in pneumonia are surrounded by fluid and on ultrasound appear as B lines which are a form of reverberation artifact. (Fig. 62.5)

Radiographic findings are nonspecific for predicting a specific infectious organism in pneumonia. *Mycoplasma* pneumonia may manifest as a dense infiltrate, or pneumococcal pneumonia may manifest as a diffuse interstitial infiltrate. Immunocompromised patients are particularly prone to having atypical radiographic appearances. Patients with a clinical picture strongly suggestive of pneumonia may have a normal initial chest radiograph and develop a radiographic infiltrate in the next 2 days. A chest radiograph is not required for the diagnosis of pneumonia. The absence of findings on a chest radiograph should not preclude the use of antimicrobial therapy in patients with clinical signs and symptoms of pneumonia. Immunocompromised patients, older adults, and patients with significant comorbidities may be treated with empirical antibiotics in the setting of signs and symptoms indicating pneumonia, even with a negative chest radiograph.

Laboratory studies also are nonspecific for identifying the cause of pneumonia. Although the finding of a white blood cell (WBC) count greater than 15,000/mm^3 increases the probability of the patient having a pyogenic bacterial cause rather than a viral or atypical cause, the predictive value of this finding depends on the stage of the illness and

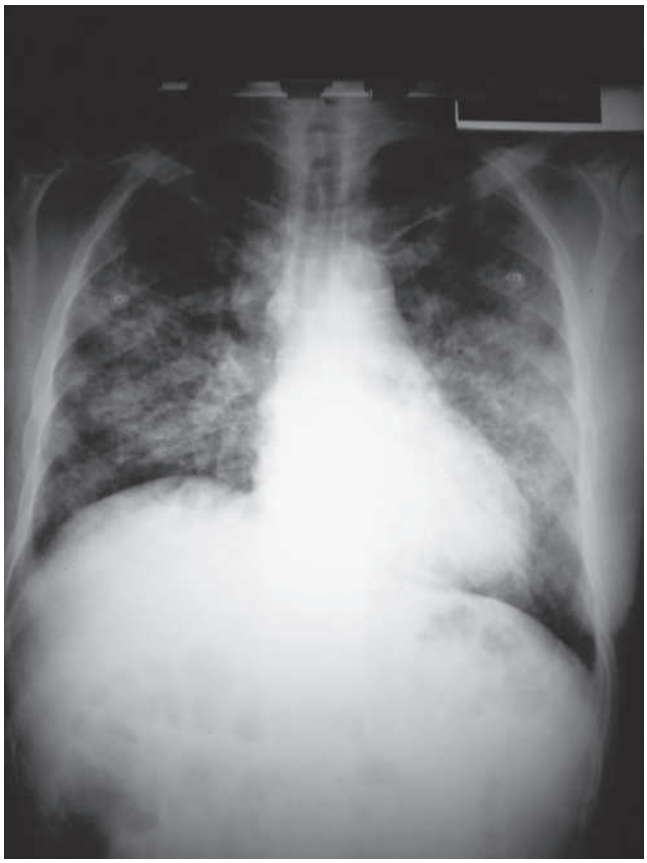

Fig. 62.2 Posteroanterior Chest Radiograph Reveals Patchy Interstitial Infiltrates. Viruses and *Mycoplasma* are the most likely causes in an otherwise healthy patient, but many bacterial organisms may also produce this pattern.

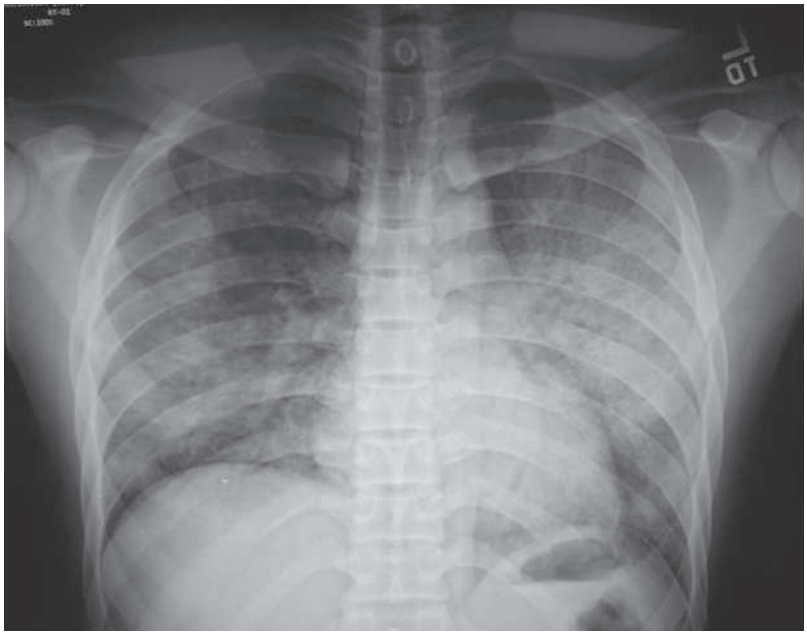

Fig. 62.3 Posteroanterior chest radiograph of a human immunodeficiency virus (HIV)–infected patient reveals interstitial disease mixed with patchy alveolar infiltrates. *Pneumocystis jiroveci* is the most common cause, but bacterial pathogens and tuberculosis also are considered.

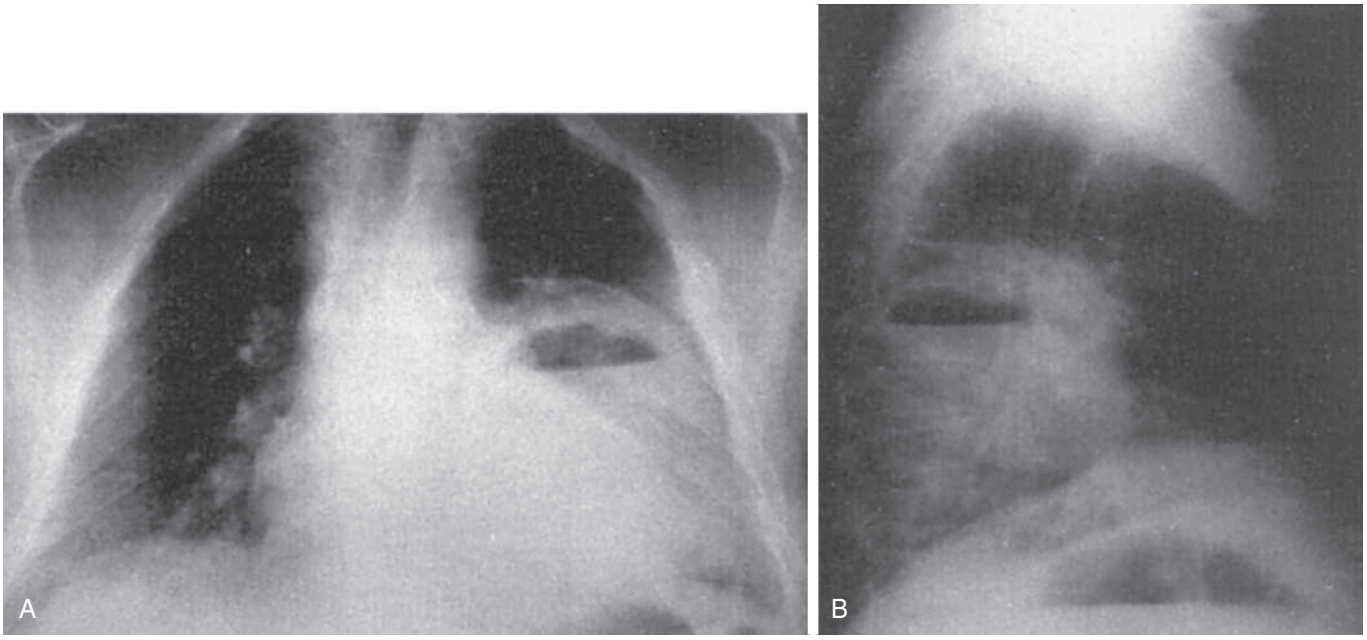

Fig. 62.4 Posteroanterior (A) and lateral (B) chest radiographs reveal a lung abscess in the left lower lobe, with a distinct air-fluid level.

likely prevalence of various causes. This is neither sensitive nor specific enough to aid decisions regarding therapy in an individual patient. A WBC count may be helpful if it yields evidence of immunosuppression, such as neutropenia, or if it reveals lymphopenia that may indicate immunosuppression from HIV. Basic metabolic panels may help identify patients with renal or hepatic dysfunction or metabolic acidosis associated with sepsis. These findings predict a complicated course and influence decisions regarding disposition, choice of antimicrobial agents, and dosages. The serum lactate dehydrogenase level is significantly elevated in patients with PCP compared with patients with non-PCP pneumonia. Inflammatory markers such as the erythrocyte sedimentation rate and C-reactive protein levels are not helpful in clinical decision making regarding pneumonia. The procalcitonin level has been suggested to assess the likelihood of a bacterial cause, response to antimicrobial therapy, and prognosis. A recent study of hospitalized patients with CAP failed to find a procalcitonin threshold that discriminated between viral and bacterial pathogens.[14] Empiric antibiotic therapy should be initiated in patients with suspected pneumonia regardless of procalcitonin level.[11]

Assessment of respiratory function with pulse oximetry is important in the evaluation of patients with pneumonia because the clinical assessment of oxygenation can be inaccurate. Pulse oximetry should be

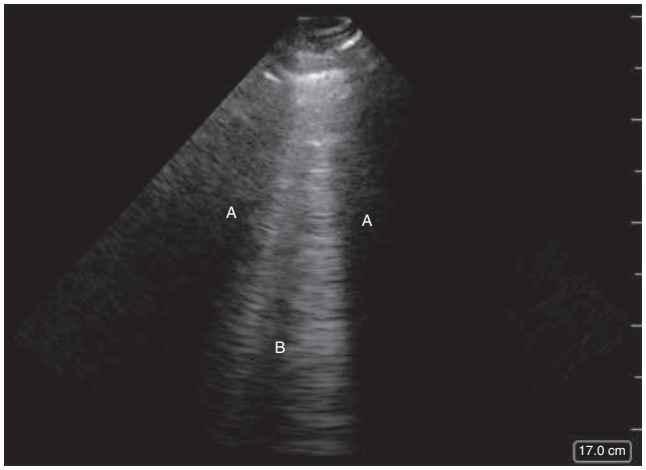

Fig. 62.5 Ultrasound image of the lung showing (A) hypoechoic rib shadows and (B) "comet tailing" or B-lines caused by reverberation artifact in lung tissue. B-lines when present anteriorly to posteriorly from the pleural line to the bottom of the image represent pneumonia or consolidation. (Image courtesy of Jackie Shibata and Alan Chiem.)

performed in any patient suspected to have pneumonia, and pneumonia should be considered in patients with low oxygen saturation.

Sputum gram staining rarely results in a change in therapy or outcome. Correlation between the identification of pneumococcus on Gram staining and sputum culture results is poor, even when commonly used criteria for an adequate sputum specimen are applied (<5 squamous epithelial cells and >25 WBCs/high-power field). Gram staining is even less likely to show gram-negative pathogens, such as *H. influenzae,* and should not be relied on to rule out a gram-negative cause. Empirical antimicrobial agents are usually highly clinically effective if chosen based on clinical information without sputum analysis. ATS/IDSA guidelines for the management of CAP support limiting sputum Gram staining and culture to patients with severe disease or risk factors for unusual pathogens.[10] Confirmation of the diagnosis of PCP requires sputum induction and staining and, in some cases, further invasive procedures, such as bronchoscopy with bronchoalveolar lavage or biopsy.

Routine blood cultures are of essentially no value in immunocompetent adults with pneumonia, in whom there is a very low prevalence of bacteremia, and management is rarely changed based on the results. Follow-up of false-positive blood cultures is costly and labor-intensive and may lead to the unnecessary use of antibiotics, such as vancomycin or linezolid, when contaminant growth is initially reported as gram-positive cocci. Blood samples for culturing should be obtained from immunocompromised patients, those with severe sepsis or requiring ICU admission, or those with risk factors for endovascular infection (e.g., prosthetic valves, IV drug use, cavitary infiltrates).[11] When culture specimens are drawn, they should ideally be obtained before the initiation of antibiotics, although antibiotics should not be delayed more than 60 minutes for this reason.

Patients with pneumonia and a large pleural effusion should undergo diagnostic thoracentesis. Fluid should be sent for cell count, differential, pH (pH <7.2 predicts the need for a thoracostomy tube), Gram staining, and culture. For most patients, thoracentesis can be safely deferred until after hospital admission. Patients in significant respiratory distress, or with evidence of tension and mediastinal shift, should undergo emergent diagnostic and therapeutic thoracentesis in the ED.

Serologic tests are widely available for the diagnosis of many organisms, including *C. pneumoniae, Legionella* spp., and fungi. The use of serologic tests to determine the cause of pneumonia may be helpful retrospectively, but these have traditionally required acute and convalescent serum titers and are of little use in the ED. Urine antigen tests for *S. pneumoniae* and *Legionella* are available and may be obtained within the time frame of an ED evaluation.

Rapid diagnostic testing using PCR such as the BioFire have increasingly become available for rapid identification of a wide variety of respiratory bacterial and viral pathogens. The use of a rapid diagnostic respiratory panel has been associated with a potential positive impact on hospital antibiotic stewardship.[15] The role and cost-effectiveness of rapid diagnostic respiratory pathogen testing in the ED is unclear. Rapid PCR testing may be especially useful in outbreak settings such as the SARS-CoV-2 pandemic to assist in isolating or cohorting patients with highly transmissible pathogens.

MANAGEMENT

The possibility of communicable disease should prompt consideration for early isolation. Patients with a history of TB exposure or suggestive symptoms (e.g., persistent cough, weight loss, night sweats, hemoptysis) or who belong to a group at high risk for TB (e.g., undomiciled, history of IV drug use or alcoholism, HIV risk, immigrant from high-risk area) should be given a mask and placed in respiratory isolation before evaluation, including chest radiography.[16] Because pulmonary TB cannot be distinguished reliably from other pulmonary infections at presentation in patients with advanced HIV, TB should be considered in all HIV-infected patients with respiratory complaints, and respiratory isolation should be initiated. The chest radiograph cannot exclude TB in this population because it may not have a typical appearance of TB. EDs that frequently care for patients at risk for TB should consider triage protocols to identify these individuals rapidly before patients, visitors, or staff are unnecessarily exposed. Suspected infection with organisms transmitted by respiratory droplet during seasonal transmission (e.g., influenza or SARS-CoV-2) should prompt infection control precautions, such as a mask being placed on the patient and proper personal protective equipment (PPE) worn by the provider.

Antimicrobials should be administered in the ED for patients who are being admitted to the hospital with suspected pneumonia. The timely administration of antimicrobials is associated with improved outcomes for hospitalized pneumonia patients, although confounding factors limit a full understanding of this relationship. Any presumed benefit of early antibiotic administration should be weighed against the risk of inappropriate use for patients in which the diagnosis is unclear. The antibiotics selected should cover the likely causes based on clinical, laboratory, radiologic, and epidemiologic information. The regimen should also be as selective as possible to avoid drug toxicity, emergence of resistance to broad-spectrum agents, and excessive cost.

The prevalence of drug-resistant *S. pneumoniae* (DRSP) has been increasing. In the United States more than 30% of isolates of *S. pneumoniae* are resistant to one or more antibiotic.[17] DRSP that is resistant to penicillin is usually resistant to other β-lactams, macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX). Extended-spectrum (or respiratory) fluoroquinolones, such as levofloxacin, are active against DRSP and other typical and atypical bacterial pathogens. Because the oral bioavailability of fluoroquinolones is high, oral therapy provides serum and tissue levels essentially equivalent to parenteral therapy. It is not clear, however, the extent to which in vitro resistance is related to adverse clinical outcome. Most cephalosporins achieve adequate levels in serum and tissues to treat *S. pneumoniae* respiratory tract infections successfully.

TABLE 62.1 Community-Acquired Pneumonia in Adolescents and Adults: Outpatient Treatment

Clinical Setting	Antibiotic Regimen[a]	Comments
Previously healthy, no antimicrobials in last 3 months	Doxycycline 100 mg PO bid for 7 days. or Centered between doxycyline and amoxicillin	Preferred for adolescent or young adult when likelihood of *Mycoplasma* is high; variable activity vs. *Streptococcus pneumoniae*
	Amoxicillin 1000 mg PO tid for 7 days.	Macrolide monotherapy no longer recommended unless local pneumococcal resistance is <25%.
Comorbidities or antimicrobials in last 3 months	Amoxicillin/clavulanate 875 mg/125 mg tid or Cefpodoxime 200 mg PO bid or Cefuroxime 500 mg PO bid for 7 days + azithromycin 500 mg PO on first day and then 250 mg daily for 4 days.	Especially preferable if fluoroquinolones recently received
	Levofloxacin 750 mg PO daily for 5 days	Can substitute moxifloxacin 400 mg daily for 7–14 days; active against DRSP; consider fluoroquinolone if recently received β-lactam.

DRSP, Drug-resistant Streptococcus pneumoniae; *PO,* orally.
[a]Renally dose antibiotics.

CA-MRSA remains an uncommon cause of CAP, but empirical coverage of MRSA should be strongly considered for patients with severe pneumonia associated with sepsis, especially in children or healthy young adults with likely influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia. Antimicrobials with consistent in vitro activity against CA-MRSA isolates include vancomycin, TMP-SMX, tigecycline, linezolid, and ceftaroline. Although vancomycin is used most often for documented MRSA infections, vancomycin may be losing efficacy in light of increasing minimum inhibitory concentrations.[18]

Appropriate agents for the outpatient treatment of adults with CAP include amoxicillin, doxycycline, and fluoroquinolones with enhanced activity against *S. pneumoniae* (Table 62.1). Macrolide monotherapy is no longer routinely recommended for CAP unless local pneumococcal resistance is less than 25%.[11] Few places in the United States currently meet that criterion. In patients properly identified as being at low risk for complications with careful outpatient follow-up, use of amoxicillin 1 g PO three times daily or doxycycline 100 mg PO twice daily for 1 week is recommended. For patients at higher risk of DRSP because of recent antibiotic use or comorbidities such as chronic heart, lung, liver, or renal disease, treatment choices include monotherapy with a respiratory fluoroquinolone or combination therapy with amoxicillin/clavulanate and a macrolide, or a cephalosporin such as cefpodoxime and a macrolide. Patients who have received a fluoroquinolone in the past few months, or are at high risk of a fluoroquinolone adverse effect (e.g., QTc prolongation, tendon rupture, *Clostridioides difficile,* aortic dissection, aortic aneurysm, myasthenia gravis exacerbation), should be treated with a combination macrolide and beta lactam agent (see Table 62.1).

For patients whose illness is severe enough to require hospital admission and parenteral antibiotics, current guidelines use major and minor criteria to distinguish between non-severe and severe pneumonia (Box 62.1). For patients with a non-severe pneumonia needing admission to the hospital, a combination of a β-lactam agent such as ceftriaxone (or ceftaroline, ampicillin-sulbactam, or ertapenem) plus a macrolide such as azithromycin is the regimen recommended in ATS/IDSA guidelines (Table 62.2). Alternatively, an extended-spectrum fluoroquinolone (e.g., levofloxacin, moxifloxacin) can be given as monotherapy, but this regimen may be more likely to promote antimicrobial resistance and predispose the patient to adverse effects. These regimens treat the most common bacterial pathogens, such as *S. pneumoniae*, and *H. influenzae*, and atypical pathogens, such as *Mycoplasma, Chlamydophila,* and *Legionella* spp. β-Lactam monotherapy has been found to be noninferior to β-lactam–macrolide combination therapy or fluoroquinolone monotherapy in nonsevere CAP; it is a reasonable choice for patients without a specific reason to suspect atypical organisms.

Fluoroquinolones have some activity against TB and are important second-line agents. They should be avoided as a primary treatment for CAP in patients for whom TB is a possible diagnosis to avoid partial treatment and selecting for resistant strains. While anaerobic coverage should not be provided routinely for suspected aspiration pneumonia, if lung abscess or empyema is suspected, clindamycin or metronidazole

BOX 62.1 Criteria for Severe Community-Acquired Pneumonia

Minor Criteria[a]

- Respiratory rate ≥30 breaths/min
- Pao_2/Fio_2 ratio ≤250[b]
- Multilobar infiltrates
- Confusion, disorientation
- Uremia (BUN level ≥20 mg/dL)
- Leukopenia[c] (WBC count <4000 cells/mm^3)
- Thrombocytopenia (platelet count <100,000 cells/mm^3)
- Hypothermia (core temperature <36°C [96.8°F])
- Hypotension requiring aggressive fluid resuscitation

Major Criteria

- Invasive mechanical ventilation
- Septic shock with the need for vasopressors

[a]Other criteria to consider include hypoglycemia (in patients who do not have diabetes), acute alcoholism or alcoholic withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.
[b]A need for noninvasive ventilation can substitute for a respiratory rate higher than 30 breaths/min or a Pao_2/Fio_2 ratio below 250.
[c]As a result of infection alone.
BUN, Blood urea nitrogen; *Pao_2/Fio_2,* arterial oxygen pressure/fraction of inspired oxygen; *WBC,* white blood cell.
Adapted from Mandell LA, Wunderink RG, Anzueto A, et al; Infectious Diseases Society of America; American Thoracic Society. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis.* 2007;44:S27–S72.

TABLE 62.2 Community-Acquired Pneumonia in Older Children and Adults: Inpatient Antimicrobial Treatment[a]

Clinical Setting	Antibiotic Regimen	Comments
Community-acquired, immunocompetent patient	Ceftriaxone 1 g q24h ± azithromycin 500 mg q24h IV or PO	Can substitute ceftaroline, ampicillin-sulbactam, or ertapenem for ceftriaxone.
	Respiratory fluoroquinolone (levofloxacin 750 mg IV q24h, or moxifloxacin 400 mg IV q24h)	Treats most common bacterial and atypical pathogens; active against DRSP
Severe pneumonia (ICU)	Ceftriaxone 1 g IV q24h + levofloxacin 750 mg IV q24h + vancomycin 15 mg/kg IV q12h	Can substitute cefepime, ceftaroline, ertapenem, or β-lactam or β-lactamase inhibitor for ceftriaxone; can substitute moxifloxacin for levofloxacin; can substitute linezolid for vancomycin
Increased risk of resistant pathogens with IV antibiotics within the last 90 days or severe pneumonia with neutropenia, bronchiectasis (risk for MRSA, *Pseudomonas*)	Cefepime 2g IV q12h + levofloxacin 750 mg IV q24h + vancomycin 15 mg/kg IV q12h	Can substitute other antipseudomonal β-lactams, such as piperacillin-tazobactam, aztreonam, imipenem, meropenem, or doripenem, for cefepime; can substitute aminoglycoside plus macrolide for ciprofloxacin
Presumed PCP	TMP-SMX component 5 mg/kg	Add ceftriaxone to TMP-SMX if severe, until PCP confirmed; alternatives for sulfa allergy include clindamycin + primaquine

DRSP, Drug-resistant Streptococcus pneumoniae; *ICU*, intensive care unit; *IV*, intravenously; *PCP*, Pneumocystis pneumonia; *PO*, orally; *TMP-SMX*, trimethoprim-sulfamethoxazole.
[a]Renally dose antibiotics.

should be added, or the regimen can include an antibiotic with anaerobic activity, such as ertapenem, ampicillin-sulbactam, piperacillin-tazobactam, tigecycline, or moxifloxacin (see Table 62.2).

Severely ill and compromised patients are at relatively greater risk of infection with *S. pneumoniae,* aerobic gram-negative bacilli, *S. aureus* (including MRSA) and, in some areas, *Legionella* spp. For pneumonia patients admitted to an ICU, adequate activity against DRSP may be more important. Outcomes with severe pneumonia may be better with combination therapy.[11] A third-generation cephalosporin or β-lactam or β-lactamase inhibitor can be combined with a macrolide or fluoroquinolone, and addition of vancomycin or linezolid should be considered for MRSA activity.

Patients with prior use of IV antibiotics, neutropenia, or underlying bronchiectasis are at increased risk of infection with *P. aeruginosa.* Empirical therapy for high-risk patients or critically ill patients should include two agents with extended gram-negative activity, including *P. aeruginosa.* Empirical regimens include cefepime, imipenem, meropenem, doripenem, or piperacillin-tazobactam, plus ciprofloxacin (high dose) or an aztreonam and macrolide. For life-threatening pneumonia in populations at risk for MRSA, vancomycin or linezolid should be added to empiric coverage.

Because hospital-acquired pneumonia is associated with higher mortality and a greater likelihood of unusual pathogens, the use of broader spectrum empirical therapy is often appropriate, usually with a combination of antimicrobials to increase the chance that at least one antibiotic will be active against the causative pathogen. Patients admitted to the hospital for pneumonia should be tested for influenza in the appropriate season and treated with oseltamivir if positive. The use of corticosteroids to treat influenza pneumonia is associated with increased mortality, and only recommended for patients in refractory septic shock.[19]

For patients with HIV, it is important to treat *P. jiroveci* and bacterial pathogens such as *S. pneumoniae.* TMP-SMX is the treatment of choice; the usual regimen is 15 to 20 mg/kg of TMP to be continued for 21 days, in addition to a regimen to cover CAP organisms.[20] For patients allergic to sulfa, options include clindamycin 600 mg IV q6h, plus primaquine, 30 mg (base) PO daily. The addition of corticosteroids (prednisone 40 mg PO bid) reduces mortality and clinical deterioration in patients with hypoxemia. Traditionally, this has been defined as a PaO_2 less than 70 mm Hg or alveolar-arterial gradient greater than 35 mm Hg. In practice, pulse oximetry with an SaO_2 ≤92% on room air or desaturation with exercise should warrant the initiation of corticosteroids. *Mycoplasma, Legionella,* and *Chlamydophila* spp. are uncommon causes of severe pneumonia in HIV patients, so empirical therapy with erythromycin or doxycycline is not routinely recommended.

DISPOSITION

There is tremendous variability among emergency clinicians in deciding whom to admit for pneumonia. It is a common tendency to overestimate disease severity, leading to hospitalization of patients at low risk for death or serious complications. The decision to hospitalize a patient with pneumonia does not necessarily mean that a prolonged inpatient stay is required. Observation for 12 to 24 hours in the ED observation unit or hospital may allow the early discharge of certain moderate-risk patients and help support patients with complex social issues. Inpatient treatment of pneumonia is 15 to 20 times more expensive per patient than outpatient treatment, and most patients are more comfortable in a home environment.

Although no firm guidelines exist regarding hospital admission, scoring systems may assist with hospitalization decisions. One commonly used system is the Pneumonia Severity Index (PSI), a prospectively validated predictive rule for mortality among immunocompetent adults with CAP. This model suggests a two-step approach to assess risk. Patients are assessed as low risk for outpatient management if age is less than 50 years, have normal vital signs and lack of comorbid conditions. High-risk patients are stratified by a scoring system to determine if they need admission (Table 62.3). Hospitalization is recommended for patients with a score greater than 91, and brief admission or observation may be considered for patients with a score of 71 to 90. The PSI may underestimate disease severity in younger patients and oversimplify how clinicians interpret continuous variables such as blood pressure.[11] Clinical judgment should supersede a strict

TABLE 62.3 Scoring System for Pneumonia Mortality Prediction

Patient Characteristics	Points
Demographic Factor	
Age	
• Male	Age (yr)
• Female	Age (yr)—10
Nursing home resident	10
Comorbid Illness	
Neoplastic disease	30
Liver disease	20
Congestive heart failure	10

Tachycardia	1 point
Confusion	1 point
Hypoxia	2 points
Low arterial pH	2 points

interpretation of this scoring system. When emergency clinicians are provided with the patient's risk score, use of the decision rule results in a significantly lower overall admission rate, cost savings, and similar quality of life scores compared with those for patients conventionally managed by their physicians. The ability to take oral medications, access to follow-up, a stable living environment with adequate supportive services, and ambulatory pulse oximetry greater than 90% are important for successful discharge home from the ED.

A simpler tool is the CURB-65 rule. This mnemonic uses five simple criteria to determine patients at lower risk for adverse events—***c***onfusion, ***u***remia (blood urea nitrogen >20 mg/dL), ***r***espiratory rate greater than 30 breaths/min, ***b***lood pressure less than 90 systolic or less than 60 mm Hg diastolic, and age ***65*** years or older. The risk of 30-day mortality increases with more of these factors present: 0.7% with zero factors, 9.2% with two factors, and 57% with five factors. Patients with zero or one feature can receive outpatient care, those with two should be admitted, and ICU care should be considered for those with three or more factors. No randomized trials of hospital admission strategies have directly compared the PSI with the CURB-65 score. CURB-65 is the preferred clinical decision instrument given its simplicity and ability to risk stratify rapidly with readily available clinical information in the ED.

The decision to admit a patient to the ICU is straightforward when patients are intubated or require vasopressors. It is more difficult to identify patients who do not require these interventions initially but may be at greater risk for deterioration and require a level of monitoring beyond that available on the typical hospital ward. Objective criteria using the PSI (class V) and CURB-65 have been proposed but have not been prospectively validated for the ICU admission decision. When similar criteria were retrospectively studied in a cohort of CAP patients, they did not perform better than actual emergency clinician decisions. ATS/IDSA guidelines include criteria for defining severe CAP (see Box 62.1), but these have not been validated.[11] An ICU risk stratification score is abbreviated as SMART COP; intensive respiratory or vasodepressor support is predicted by clinical features such as hypoxia and hypotension (Table 62.4). A SMART-COP score above 3 points has identified 92% of patients who received intensive respiratory or vasodepressor support, including 84% of patients who did not need immediate admission to the ICU.[2] The decision to admit a patient to the hospital largely reflects the potential for acute deterioration, and some rate of floor to ICU transfer is inevitable. The Sequential Organ Assessment Score (SOFA) was found to be superior in identifying a severe state of disease compared to other CURB-65, PSI, and SMART-COP in patients admitted to the ICU with pneumonia.[21] The SOFA score is widely used in predicting mortality in patients admitted to the ICU. The SOFA score does not help differentiate lower-risk patients identified for discharge by the CURB-65 score.

Most patients with CAP do not need respiratory isolation. Patients who could pose a threat of transmission to other patients (e.g., influenza, varicella, TB, SARS-CoV-2) should be isolated. Neutropenic patients generally are placed in respiratory isolation. HIV-infected patients with pneumonia should be isolated until their TB status can be evaluated via sputum acid-fast bacilli smears; this is particularly true for patients with other risk factors for TB. Isolation should be strongly considered for others at high risk for TB.

CHAPTER 62: QUESTIONS AND ANSWERS

1. Which of the following statements is true regarding the treatment of community-acquired pneumonia (CAP)?

a. Amoxicillin monotherapy is not an option as it does not effectively cover atypical pneumonia.

b. Macrolide resistance almost always prohibits azithromycin monotherapy for CAP.

c. The most common atypical pneumonia in CAP is *Chlamydophila.*

d. Clinical history and prodrome often lead to the identification of the causative organism.

Answer: b. The 2020 American Thoracic Society/Infectious Disease Society of America (ATS/IDSA) guidelines no longer recommend macrolide monotherapy as *Streptococcus pneumoniae* resistance is greater than 30% in most settings in the United States. Amoxicillin is now recommended as a first-line agent in the treatment of CAP in healthy patients without comorbidities.

2. A 92-year-old male nursing home resident presents to the emergency department (ED) with a history of hypertension and nonproductive cough. He has a SaO_2 at triage of 82% but is speaking full sentences and with supplemental oxygen his saturation increases to 95%. Chest x-ray reveals diffuse infiltrates. Which of the following viral causes of pneumonia is this patient likely to have?

a. COVID-19

b. Respiratory syncytial virus (RSV)

c. Parainfluenza virus

d. Metapneumovirus

Answer: a. The novel coronavirus causing a worldwide pandemic is more likely to cause severe disease in patients with comorbidities and those living in nursing homes. SARS-CoV-2 often causes profound hypoxia that corrects with supplemental oxygen and causes diffuse infiltrates.

3. Which of the following causative organisms would be an indication for respiratory isolation?

a. *Histoplasma capsulatum*

b. *Herpes simplex virus* (HSV)

c. *Mycobacterium tuberculosis*

d. *Pneumocystis jiroveci*

Answer: c. Any patient with suspected tuberculosis (TB) infection should be placed in respiratory isolation and all staff should take appropriate personal protective precautions. None of the other causative agents require isolation.

4. A 60-year-old man with a past medical history of diabetes controlled with insulin and diagnosis of influenza 7 days prior presents with cough, weakness, and purulent sputum production. Vital signs are temperature 38.3°C (101°F) oral, heart rate, 130 beats/min, blood pressure, 80/50 mm Hg, respiratory rate, 30 breaths/min, and oxygen saturation, 92%. The chest radiograph reveals consolidation in the left lower lung (LLL). What is the most appropriate antibiotic therapy?

a. Ceftriaxone plus levofloxacin plus vancomycin

b. Ceftriaxone with a macrolide

c. Fluoroquinolone only

d. Trimethoprim-sulfamethoxazole (TMP-SMX)

e. Vancomycin only

Answer: a. In patients requiring hospitalization for community-acquired pneumonia (CAP), coverage for CAP would typically be with a combination of a macrolide with a β-lactam. Because this patient has signs of septic shock, consideration should be given to the addition of an agent for methicillin-resistant *Staphylococcus aureus* (MRSA; vancomycin) in addition to CAP coverage.

5. Which of the following is true regarding the use of procalcitonin in emergency department (ED) patients with pneumonia?

a. Procalcitonin is not useful in determining if a pneumonia is bacterial or viral.
b. Procalcitonin predicts mortality in ED patients.
c. It is helpful is predicting who can be discharged from the ED.
d. Procalcitonin is useful in guiding antimicrobial therapy.

Answer: a. While sometimes requested by hospitalist colleagues, the ED use of procalcitonin has not been shown to be useful in determining mortality, viral versus bacterial etiology, mortality, or prognosis.

63

Pleural Disease

Alysa S. Davis and Nicholas M. Mohr

KEY CONCEPTS

- Point of care thoracic ultrasound can be used to rule out pneumothorax with high sensitivity.
- For healthy young patients with a small primary spontaneous pneumothorax, observation with supplemental oxygen is an appropriate treatment option. For larger symptomatic primary spontaneous pneumothorax, simple aspiration with a catheter is often successful.
- In most cases of secondary pneumothorax, tube thoracostomy should be considered because less invasive approaches are associated with treatment failure.
- The most common causes of pleural effusion in the United States are congestive heart failure, malignancy, and bacterial pneumonia. Pulmonary embolism is an uncommon cause of pleural effusion.
- Thoracentesis should be performed under ultrasound guidance to minimize the risk of complications.
- On a frontal (anteroposterior or posteroanterior) projection, a volume of at least 200 mL of pleural fluid is required to detect a pleural effusion. Ultrasound can detect as little as 50 mL of pleural fluid and can be easily preformed at bedside.

INTRODUCTION

Emergent pleural disease presentations range in severity from asymptomatic pleural effusion to life-threatening tension pneumothorax. This chapter reviews the two most common nontraumatic pleural conditions: spontaneous pneumothorax and pleural effusion. Traumatic pleural diseases are covered in Chapter 37.

SPONTANEOUS PNEUMOTHORAX

Foundations

Background and Importance

Pneumothorax is defined as an abnormal collection of air in the pleural space between the parietal and visceral pleura and can range from benign to life-threatening. A spontaneous pneumothorax occurs in the absence of any precipitating external factors, such as trauma or thoracic procedures. A spontaneous pneumothorax can be either a primary spontaneous pneumothorax with no clinically apparent underlying pulmonary disease or a secondary spontaneous pneumothorax in patients with underlying pulmonary disease. Tension pneumothorax is a pneumothorax that leads to a life-threatening increase in pleural pressure associated with displacement of mediastinal structures and hemodynamic compromise.

Primary spontaneous pneumothorax most commonly occurs in healthy young men of above average height and is three times more likely to occur in men than in women. Marfan syndrome and mitral valve prolapse are associated with increased risk for primary spontaneous pneumothorax. Environmental risk factors include smoking and changes in ambient atmospheric pressure. Genetic factors also predispose to primary spontaneous pneumothorax, although this is a rare cause.

As with primary spontaneous pneumothorax, the incidence of secondary spontaneous pneumothorax is three times higher in men. Secondary spontaneous pneumothorax occurs in the setting of chronic pulmonary disease, with chronic obstructive pulmonary disease (COPD) being the most common cause in the United States (Box 63.1). Pneumothorax is also a known complication of *Pneumocystis jirovecci* pneumonia in patients with HIV. In developing countries, tuberculosis and lung abscess are the leading causes of secondary spontaneous pneumothorax.

Both primary and secondary spontaneous pneumothorax are relatively rare in children. Causes of secondary spontaneous pneumothorax include asthma, cystic fibrosis, foreign body aspiration, and connective tissue disease, such as juvenile idiopathic arthritis. The principles associated with the diagnosis, treatment, and surgical management of spontaneous pneumothorax in children are similar to those in adults.

Anatomy and Physiology

Anatomically, the visceral and parietal pleura lie in close approximation with only potential space between them. Normally, the intrapleural pressure remains negative during inspiration, meaning that it is slightly less than atmospheric pressure. The alveolar walls and visceral pleura form a barrier that separates the intrapleural and intraalveolar space and maintains the transpulmonary pressure gradient. When this barrier is disrupted, air enters the pleural space until either the pleural defect is sealed or until the intraalveolar and the intrapleural pressures equalize. In primary spontaneous pneumothorax, the alveolar-pleural barrier is disrupted when a subpleural bleb or bulla ruptures into the pleura space. Blebs are small subpleural thin-walled air-containing pockets that can easily rupture. Increased intrabronchial pressures and intraalveolar pressures generated by bronchospasm and intrinsic positive end expiratory pressure (PEEP) can play a role in the rupture of these blebs. In secondary spontaneous pneumothorax, underlying lung disease and chronic inflammation can also weaken the alveolar-pleural barrier and lead to rupture of blebs.

When negative intrapleural pressure is lost, the ipsilateral lung collapses. A large pneumothorax can result in a restrictive ventilation impairment with reduced vital capacity, functional residual capacity,

Connective Tissue Diseases
Marfan syndrome
Ehlers-Danlos syndrome
Scleroderma
Rheumatoid arthritis

Miscellaneous
Pulmonary infarction
Endometriosis, catamenial pneumothorax

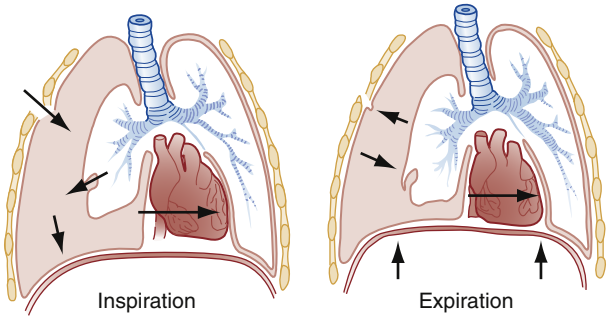

Fig. 63.1 Tension pneumothorax with total collapse of the right lung and shift of mediastinal structures to the left. Air is forced into the pleural space during inspiration and cannot escape during expiration.

and total lung capacity. Shunting of blood through poorly ventilated atelectatic lung tissue may lead to acute hypoxemia, but this effect is a late finding because it is mitigated by compensatory hypoxic vasoconstriction in the collapsed lung.

In tension pneumothorax, the alveolar-pleural defect acts as a one-way valve, allowing air to pass into the intrapleural space during inspiration and trapping the air in the pleural space during expiration (Fig. 63.1). This leads to progressive accumulation of intrapleural air and increasing intrapleural pressure, causing mediastinal shift and compression of the mediastinal venous structures and the contralateral lung. This leads to worsening hypoxemia and can impair venous return to the heart. Untreated, tension pneumothorax progresses to cardiovascular collapse and death.

Clinical Features

Symptoms of primary spontaneous pneumothorax are similar in adults and children. Symptoms often begin suddenly with ipsilateral pleuritic chest pain and dyspnea. Over time, the pain may evolve to a dull steady ache. Although dyspnea is common, it may not be severe in the absence of underlying lung disease or tension pneumothorax. Symptoms are often mild, and patients may wait several days before seeking medical attention. Without treatment, symptoms may spontaneously resolve within 24 to 72 hours, even though the pneumothorax may still be present.

Physical exam findings often correlate with the degree of symptoms. Sinus tachycardia is the most common early physical exam finding. With a large pneumothorax, hypoxia and decreased breath sounds with hyperresonance to percussion may be present. In children, breath sounds are distributed throughout the thorax, which makes unilateral breath sounds more challenging to identify. Other classic physical exam findings include unilateral hemithorax enlargement, unequal chest wall movement with exhalation, absent tactile fremitus, and inferior displacement of the liver or spleen (on the affected side). Absence of these findings does not exclude pneumothorax, and imaging should be obtained when pneumothorax is suspected. In children, routine chest radiography is not recommended in all cases of chest pain, but it should be performed if history or physical examination findings suggest that pneumothorax may be present.

Symptoms of tension pneumothorax include hypoxia, increased work of breathing, and tachycardia. Hypotension is a late finding. Distention of the jugular veins is common but may be difficult to detect. Displacement of the trachea is also a classically described sign but is usually a late finding. Absence of tracheal deviation does not rule out tension. Complete cardiovascular collapse, including cardiac arrest, may occur in tension pneumothorax if intervention is delayed.

In secondary spontaneous pneumothorax, the severity of signs and symptoms are related to both the size of the pneumothorax and the degree of underlying lung disease. Because of poor pulmonary reserve, dyspnea is nearly universal, even in the setting of a small pneumothorax. Symptoms are unlikely to resolve on their own. Physical exam findings such as hyperexpansion and distant breath sounds often overlap considerably with the findings of underlying lung disease, which makes clinical diagnosis difficult. The diagnosis of pneumothorax should be considered whenever a patient with COPD or other significant underlying lung disease has increasing dyspnea, and for this reason chest radiography is recommended in all patients with exacerbations of chronic lung disease.

Differential Diagnosis

The differential diagnosis of spontaneous pneumothorax includes many conditions that also manifest with chest pain and dyspnea. Among the most important is pulmonary embolism (PE), which has similar symptoms of pleuritic chest pain and dyspnea. Other pleural-based diseases such as pneumonia, tumor, and pleural effusion have characteristic radiographic findings that can help to make the diagnosis. Rarely, pneumothorax may mimic acute myocardial infarction or pericarditis with corresponding electrocardiographic changes. Pericardial effusion with or without tamponade can also present with chest pain, dyspnea, and tachycardia, but can be easily diagnosed with bedside ultrasound.

Spontaneous pneumomediastinum is a closely related clinical entity with similar symptoms, and it is diagnosed by the presence of subcutaneous or mediastinal emphysema on chest radiograph. Most cases of spontaneous pneumomediastinum occur in the absence of underlying disease and have a benign course. Secondary causes of pneumomediastinum (e.g., Boerhaave syndrome) are more serious, and treatment focuses on the underlying disorder.

Spontaneous hemopneumothorax is a rare but potentially serious condition that occurs when collapse of the lung is associated with the rupture of a vessel in a parieto-pleural adhesion. The clinical presentation is similar to spontaneous pneumothorax alone but may be accompanied by signs of hemorrhagic shock and effusion on chest imaging. Treatment entails tube thoracostomy to evacuate the pleural space, reexpand the lung, and limit ongoing bleeding.

Diagnostic Testing

Although the history and physical exam may suggest the diagnosis of spontaneous pneumothorax, the diagnosis is made with chest imaging, which may include chest radiography, ultrasound, or computed tomography (CT).[1] The classic radiographic finding is a thin visceral pleural line lying parallel to the chest wall, separated by a radiolucent band devoid of lung markings (Fig. 63.2). The average width of this band can be used to estimate the size of the pneumothorax, such as with the Rhea method which estimates the size of the pneumothorax by plotting the average of three different distances on a nomogram (Fig. 63.3). However, precise quantification is often inaccurate and, in general, it is more practical to characterize the pneumothorax using a semiquantitative approach as small, moderate, or large. The British Thoracic Society guidelines define size based on the measurement of the intrapleural distance at the level of the hilum: small, less than 1 cm; moderate, 1 to 2 cm; and large, more than 2 cm. The American College of Chest Physicians recommends measuring from the apex to the cupola with small being defined as less than 3 cm and large as greater than 3 cm. The estimated size, the patient's clinical status, and associated comorbidities are all useful in guiding management decisions.

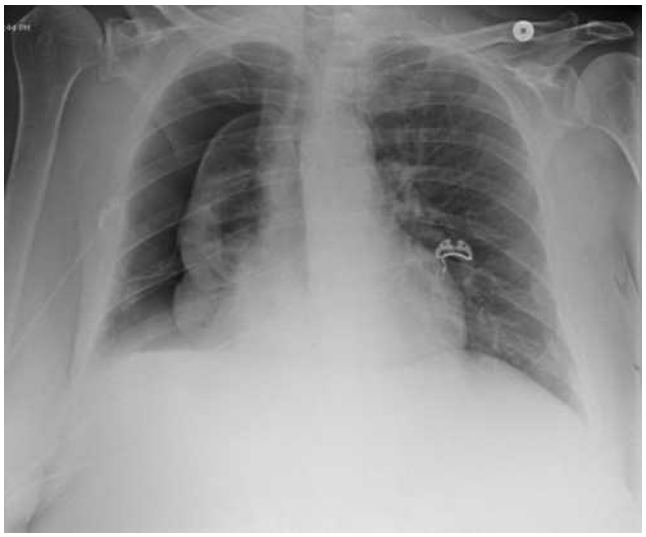

Fig. 63.2 Classic radiographic finding of a pneumothorax showing a thin visceral pleural line lying parallel to the chest wall, separated by a radiolucent band devoid of lung markings.

Tension pneumothorax is a clinical diagnosis, and there should be no delay in treatment for radiographic confirmation. When the diagnosis of tension pneumothorax is not clinically apparent and a chest x-ray is obtained, the classic appearance is one of complete lung collapse with gross distention of the thoracic cavity on the affected side and shift of the mediastinal structures across the midline. In critically ill patients for whom only a supine chest x-ray can be obtained, the finding of a deep sulcus (i.e., a deep lateral costophrenic angle) can suggest the presence of a pneumothorax on that side. Small to moderate pneumothoraces may be difficult to detect in the supine position.

Special care should be taken when viewing chest radiographs of patients with underlying lung disease, especially COPD. In patients with COPD, the relative paucity of lung markings throughout the lung makes pneumothorax more difficult to detect. In addition, large bullae may mimic the radiographic appearance of pneumothorax. A clue to differentiating pneumothorax from a giant bulla is that pneumothorax often shows a pleural line that runs parallel to the chest wall, whereas bullae usually have a more concave appearance. When the diagnosis is unclear, a CT scan can differentiate between the two and evaluate for underlying pathology. Chest CT should be obtained in patients with significant underlying lung disease who present with new-onset dyspnea or hypoxia with a nondiagnostic chest x-ray. Chest CT pulmonary angiography with intravenous contrast is necessary to rule out PE, but a noncontrast chest CT can identify occult pneumonia, pneumothorax, or progression of underlying chronic lung disease. CT can also be used in primary spontaneous pneumothorax to identify bullae, predict the likelihood of recurrence, and guide intervention decisions. Given the increasing use of CT, occult pneumothorax is an increasingly

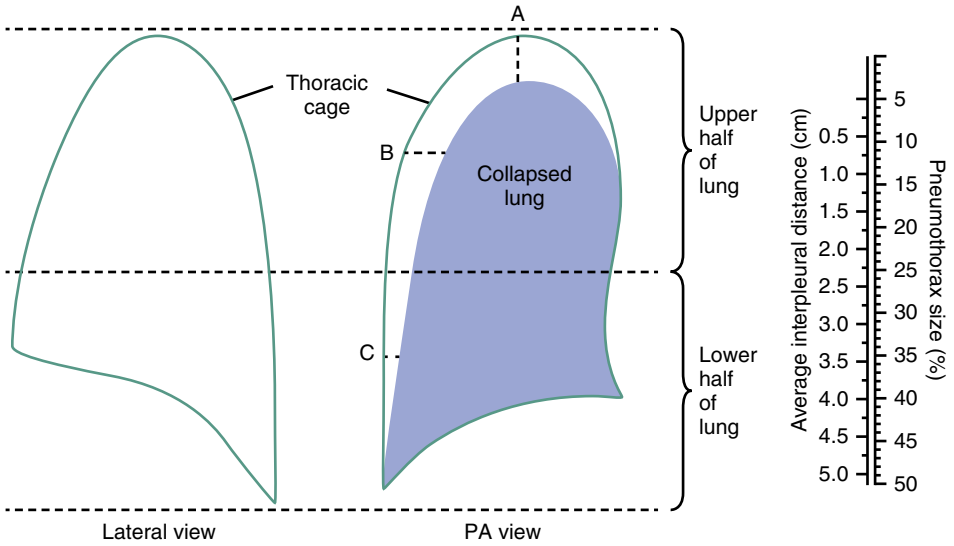

Fig. 63.3 Rhea method of calculating pneumothorax size involves taking the average of the maximal apical intrapleural distance (A), the intrapleural distance of the midpoint of the upper half of the lung (B), and the intrapleural distance of the midpoint of the lower half of the lung (C) and plotting that average distance on the nomogram to get the pneumothorax size (%).

common diagnosis. Typically, an occult pneumothorax not apparent on chest -ray can be managed conservatively in stable patients. Ventilated patients with an occult pneumothorax require close monitoring or early intervention due to the potential for expansion of the pneumothorax with positive-pressure ventilation.

Point of Care Ultrasound

Point of care ultrasound (POCUS) is increasingly being used to diagnose pneumothorax.[1] Bedside thoracic ultrasound is a very sensitive test for the diagnosis of pneumothorax. Sensitivity of chest radiographs in the diagnosis of pneumothorax is 28% to 52% whereas the sensitivity of ultrasound is 79% to 98%. The specificity of chest radiograph (99%) in the diagnosis of pneumothorax is similar to that of ultrasound (98%). In addition to using ultrasound for the diagnosis of spontaneous pneumothorax, it can also be used for screening of postprocedural pneumothorax (e.g., after central line placement). Ultrasound assessment for pneumothorax is best done with a high-frequency linear transducer. A phased array transducer or curvilinear transducer may also be used when set to a shallow depth. There are three features on two-dimensional ultrasound that have been described to be consistent with pneumothorax: lung sliding, B-lines, and a lung point. M-mode may also be used to clarify the ultrasound interpretation in the assessment of pneumothorax.[2]

In the absence of pneumothorax, the visceral and parietal pleura are closely approximated, and they create a characteristic shimmery or sliding appearance with respiratory variation (Fig. 63.4A). Visualization of lung sliding rules out pneumothorax in the area of examination. Visualization of lung sliding throughout the lung rules out pneumothorax, while absence of pleural sliding is suggestive of a pneumothorax. Because lung sliding only rules out pneumothorax in a local region, it is critical to obtain multiple views to rule out pneumothorax. Air generally goes to the most anterior portion in a supine patient and ultrasound should include the most nondependent portion of the patient when assessing for pneumothorax. Identification of a lung point, or the boundary between normal lung sliding and the absence of lung sliding, is highly specific for the detection of pneumothorax and can give clues about its size.

M-mode may be used to better capture the appearance of pneumothorax in a still image: normal lung sliding in M-mode creates a "seashore" sign while the absence of lung sliding creates a "barcode" appearance (Fig. 63.4B). Recent studies have shown that the addition of M-mode helps add to the diagnostic accuracy of lung sliding and is especially useful in less experienced sonographers.[2]

B-lines are long, wide bands of hyperechoic artifact of the visceral pleura that extend vertically through the entire image. If B-lines are present, the visceral pleura is visible by ultrasound, so no pneumothorax separates the two pleural layers. The presence of B-lines rules out pneumothorax in that area. The presence of B-lines can help rule out pneumothorax in patients with pleural disease that would otherwise cause poor lung sliding, such as blebs, fibrosis, or history of pleurodesis or pneumonectomy. In addition, mainstem intubation may lead to the absence of lung sliding in the contralateral hemithorax strictly because ventilation is not applied to the affected side, but B-lines will still be present.

Management

The management of spontaneous pneumothorax has two goals: (1) to evacuate air from the pleural space; and (2) to prevent recurrence. Therapeutic options for treatment of spontaneous pneumothorax include simple observation, aspiration with a catheter, tube thoracostomy, video-assisted thoracoscopic surgery, and thoracotomy. Treatment decisions should be individualized, with considerations for the size of the pneumothorax, severity of the signs/symptoms, presence of underlying pulmonary disease, other comorbidities, history of previous pneumothorax, patient reliability, availability of follow-up, and degree of persistent air leak.

Primary Spontaneous Pneumothorax

For young, healthy patients with a small primary spontaneous pneumothorax and minimal symptoms, supplement oxygen and observation are appropriate. The intrinsic resorption rate is 1-2% per day and the rate of absorption can be accelerated with the administration of 100% oxygen via nonrebreather mask. If observation is selected as the treatment of choice, the patient should be observed for at least 4 hours with supplemental oxygen in the emergency department (ED). Repeat chest radiography prior to discharge should confirm that there is no interval worsening. The patient should follow up with a primary care provider or return to the ED in 24 to 48 hours for reevaluation.

For a primary spontaneous pneumothorax that is larger in size (i.e., >2–3 cm) or a smaller pneumothorax that causes significant symptoms or expands during observation, therapeutic options include needle aspiration, placement of a small-bore (8–14 Fr) pleural catheter, or observation alone. Optimal treatment for those with a first episode of primary spontaneous pneumothorax has been controversial and no available treatment options have been demonstrated to be clearly superior. Advantages of a simple needle aspiration include low morbidity, less invasiveness than chest tube placement, fewer follow-up visits, and overall cost savings. Recent data suggest that conservative management (observation alone) in patients with uncomplicated moderate to large spontaneous pneumothorax is noninferior to drainage with a lower rate of serious adverse events.[3] Currently, either observation alone or simple aspiration is a reasonable approach, and symptoms and patient shared decision-making may be used to select an appropriate treatment option.

Needle aspiration is often performed with a thoracentesis kit, which typically contains an 8 French catheter over an 18-gauge needle and a three-way stopcock. In the needle aspiration technique, the small catheter is placed into either the second anterior intercostal space at the midclavicular line or laterally at the fourth or fifth intercostal space at the anterior axillary line after prepping and sterile draping of the patient and local anesthesia infiltration. A three-way stopcock is then attached, and a large syringe is used to aspirate aliquots of air until resistance is met. The catheter is then removed. If a repeat chest radiograph after the observation period shows no reaccumulation of the pneumothorax, the patient may be discharged home with return precautions and close follow-up. Success of a catheter aspiration is more likely when a patient is younger than 50 years or when the volume of air aspirated is less than 2.5 L. Aspiration of larger volumes of air suggests a continuing air leak. If aspiration fails to reexpand the lung fully, a small-bore chest tube (8–14 Fr) should be placed.

For most patients with primary spontaneous pneumothorax requiring ongoing pleural drainage, placement of a small-bore tube or pigtail catheter is sufficient, because air leak is usually minimal. Small-caliber tubes are easy to insert, are well tolerated by patients, and leave only a small scar after removal. Complications with small-caliber tubes include kinking, malposition, inadvertent removal, occlusion by pleural fluid or clotted blood, and failure due to large persistent air leak. Pigtail catheters have similar outcomes to small-bore chest tubes and are easily placed using the Seldinger technique. Traditionally, patients with indwelling chest tubes or catheters were managed in the hospital, but those with access to close outpatient follow-up can also be managed at home with a one-way Heimlich valve, which consists of a one-way flutter valve covered in transparent plastic.

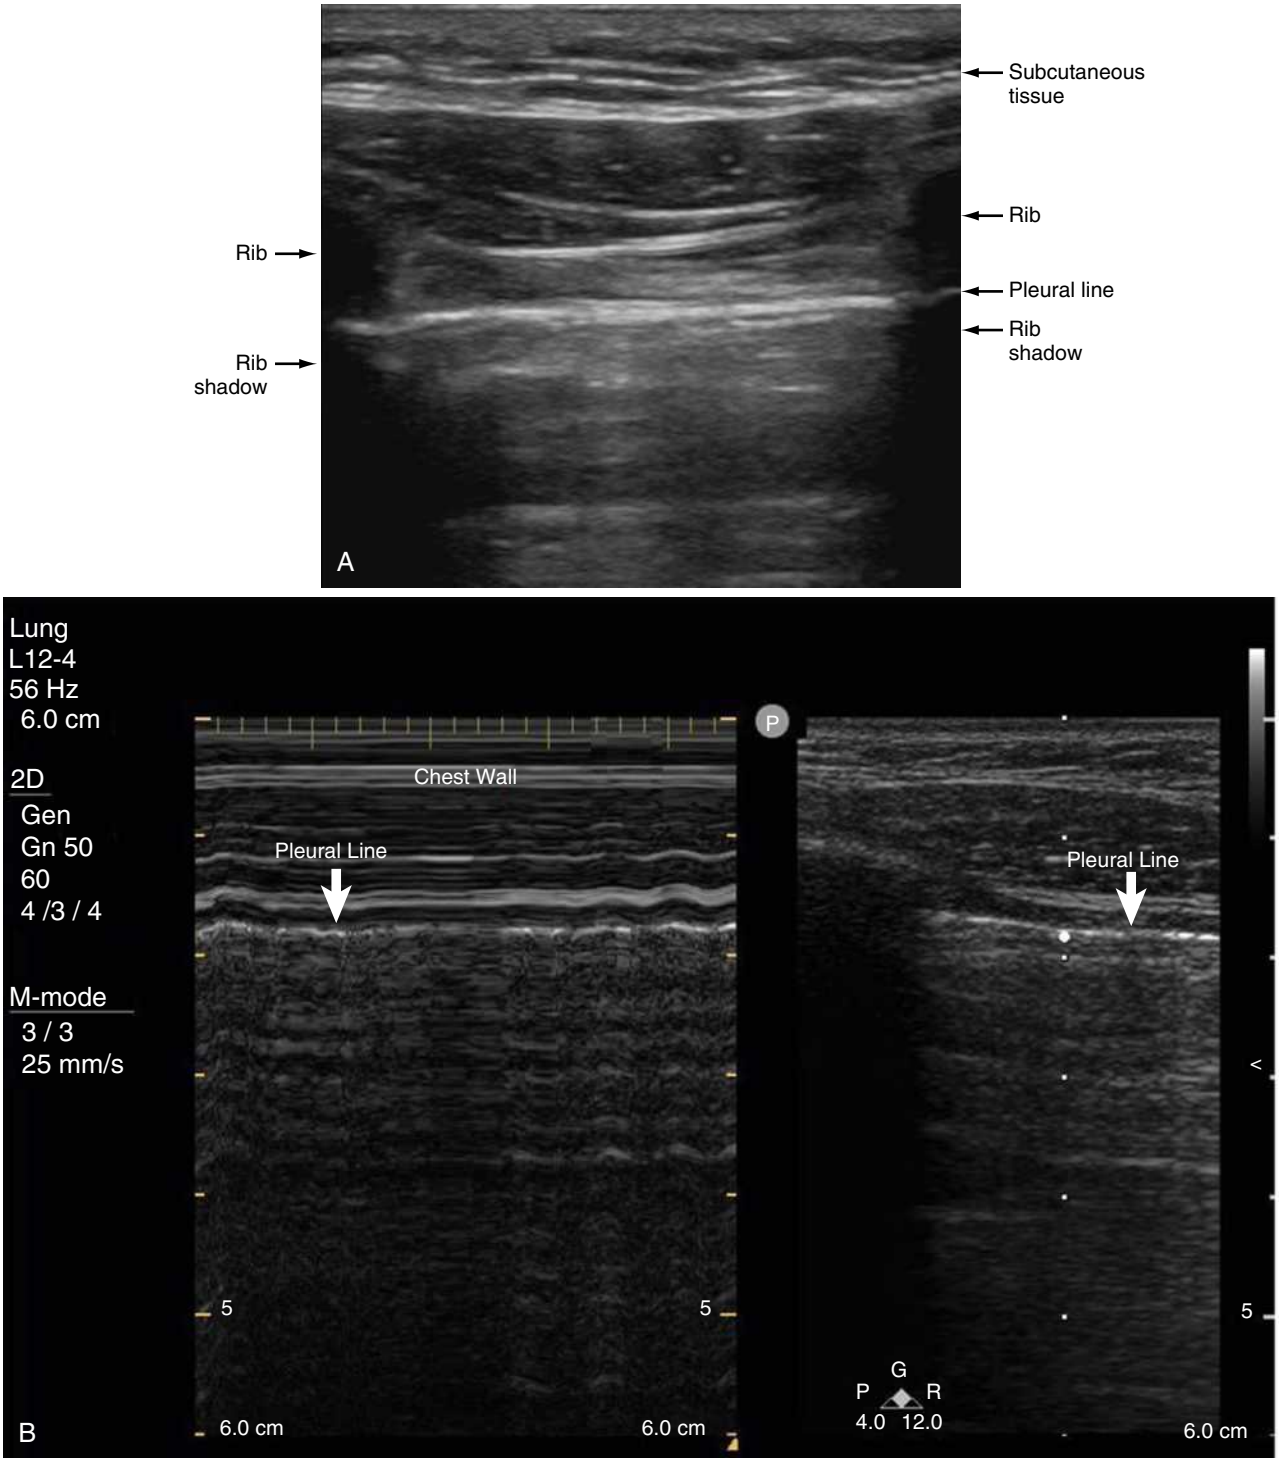

Fig. 63.4 (A) Ultrasound demonstrating location of pleural line. Lung sliding is dynamic and visualized in real time as shimmering or sliding of the pleural line. (B) The use of M-mode creates a "seashore" sign with normal lung sliding.

Secondary Spontaneous Pneumothorax

For patients with secondary spontaneous pneumothorax that is small (<1 cm), admission or placement in an ED observation unit for oxygen therapy and at least 24 hours of observation is appropriate. Secondary spontaneous pneumothorax has a higher likelihood of failing observation, which is why admission is recommended. In patients with secondary spontaneous pneumothoraces of moderate size (1–2 cm), a trial of simple needle aspiration is appropriate. If aspiration is successful and the pneumothorax is resolved or less than 1 cm in size, the patient should be admitted or placed in an ED observation unit for 24 hours of observation. If the pneumothorax is larger (>2 cm) or fails simple aspiration, then a tube thoracostomy is recommended with a small size chest tube or pigtail catheter (8–14 F).

Patients with respiratory distress, those with tension pneumothorax, those likely to require mechanical ventilation, and those with associated hemothorax or pleural effusion may require tube thoracostomy to definitively reexpand the lung with a moderate-sized chest tube (14–28 Fr). Larger-bore tubes (>28 Fr) may be required for patients with hemothorax or a large air leak, but typically are unnecessary in spontaneous pneumothorax.

After insertion, a chest tube is attached to a water seal device and left in place until the lung has fully reexpanded and the air leak has ceased. The routine use of suction neither increases the rate at which the lung reexpands nor improves patient outcomes and is no longer recommended. The use of suction (with a pressure of 20 cm H_20) is reserved for situations where the lung fails to reexpand after drainage through a water seal device or Heimlich valve for 24 to 48 hours.

Complications from chest tube placement include tube malposition, pleural space infection, and pain at the chest tube site. Reexpansion pulmonary edema and reexpansion hypotension are rare occurrences after evacuation of a large pneumothorax. Chest x-ray is routinely obtained after chest tube placement to assess for adequacy of placement and complications.

Tension Pneumothorax

If the clinical circumstances suggest a tension pneumothorax, treatment should be initiated prior to definitive diagnostic testing. Emergency management of tension pneumothorax includes rapid pleural decompression. This decompression may be accomplished by inserting a large bore intravenous catheter followed by tube thoracostomy or by immediate finger or tube thoracostomy. The determination of which procedure to perform should be guided by the setting, training of the care team, and available equipment.

Needle decompression is a temporizing procedure that releases high pressure air from the pleural space and restores hemodynamic stability. Definitive management is still required with a prompt tube thoracostomy. Needle decompression is completed by inserting a large bore IV catheter (14–16 gauge in adults, 18 gauge in children) of adequate length (at least 3–5 cm in adults) into the pleural space via the second intercostal space anteriorly at the midclavicular line or via the 4th/5th intercostal space at the midaxillary line. The diagnosis is confirmed by air escaping under positive pressure as the needle or chest tube enters the pleural space or by rapid hemodynamic improvement. The needle can then be removed, and the IV catheter remains in the chest wall open to air until definitive tube thoracostomy is completed. After tube thoracostomy, the catheter can be removed. In obese patients, a standard IV catheter may be of insufficient length to reach the pleural space and a longer needle or immediate finger or tube thoracostomy is required.

Disposition

Disposition decisions should consider the type and size of pneumothorax, underlying comorbidities, hemodynamic stability, and availability of follow-up. Admission to the hospital is generally not required for young, otherwise healthy patients with a small pneumothorax and no hypoxemia or hemodynamic abnormalities. After a period of observation (4–6 hours), these patients can be discharged home. Discharged patients should have the capability to return to an ED if their condition worsens and should undergo follow-up with a primary care provider or in the ED in 24 to 48 hours. Air travel and underwater diving must be strictly avoided until the pneumothorax has completely resolved, to prevent pressure-related pneumothorax expansion.

In most cases, chest tube management requires hospital admission although outpatient management of primary spontaneous pneumothorax with a small-caliber tube and Heimlich device is possible with good outpatient follow-up. Those with secondary spontaneous pneumothorax require either 24 hours of observation or admission for ongoing chest tube management.

Spontaneous pneumothorax usually resolves within 7 days of tube thoracostomy. Air leaks that persist beyond 2 days are less likely to resolve on their own. If the air leak persists beyond 4 to 7 days, tube thoracostomy is considered to have failed and surgical intervention is generally recommended. Failure of tube thoracostomy is more common in secondary spontaneous and recurrent pneumothorax because they tend to be associated with larger and more persistent air leaks.

Recurrence of spontaneous pneumothorax is common (approximately 30%). Younger age, lower weight/height ratio, and ongoing smoking are associated with increased risk of recurrence. There are a variety of operative and nonoperative interventions aimed at decreasing the rate of recurrence. Pleurodesis involves pleural instillation of a sclerosing agent or mechanical pleural abrasion to promote scarring of the parietal and visceral pleura, which obliterates the pleural potential space. Another strategy involves resection of apical bullae or other lesions at risk for causing recurrences. Often the two strategies are combined. Minimally invasive procedures, such as video-assisted thoracoscopic surgery (VATS), allow for resection of bullae and pleurodesis. Patients with extensive bullae may require thoracotomy for wider visualization of lesions.

Recurrence may be life-threatening for patients with serious underlying lung disease, and intervention may be used to prevent recurrence as part of the initial approach to secondary spontaneous pneumothorax. In contrast, for patients with primary spontaneous pneumothorax, interventions typically are not considered until after a second ipsilateral pneumothorax. However, those with a first episode of primary spontaneous pneumothorax with bullae greater than 2 cm have less recurrence when they undergo surgical resection after the first episode.[4] Preventive treatment is also recommended for patients who plan to continue activities that increase the risk of severe complications if a pneumothorax recurs, such as flying or diving.

PLEURAL EFFUSION

Foundations

Background and Importance

Pleural effusion is an abnormal collection of fluid in the pleural space. The most common causes of pleural effusion in the United States are congestive heart failure, malignancy, bacterial pneumonia, and pulmonary embolism. Tuberculosis remains a leading cause of pleural effusion in endemic areas. Other conditions commonly associated with pleural effusion include viral infections, cirrhosis, nephrotic syndrome, uremia, ovarian hyperstimulation syndrome, collagen vascular disease, myxedema, and intraabdominal inflammation. Esophageal perforation is a rare and uniquely morbid cause of pleural effusion (Box 63.2).

A pleural effusion that is associated with bacterial pneumonia or lung abscess is termed a *parapneumonic effusion*. The term *pleural empyema* (or pyothorax) implies the presence of pus within the pleural space. Fluid in the pleural space that is anatomically confined and is not free flowing within the pleural space is termed a *loculated effusion*. Loculated effusions occur when there are adhesions between the visceral and parietal pleurae. Traumatic hemothorax is a distinct type of pleural effusion that is approached in Chapter 37.

Anatomy and Physiology

Under normal circumstances, a thin layer of fluid lies between the visceral and parietal pleura. Pleural fluid is produced from systemic capillaries at the parietal pleural surface and absorbed into the pulmonary capillaries at the visceral pleural surface. Although lymphatics play an

Chylothorax

essential role in removing pleural fluid, the direction of pleural fluid flow is generally governed by the difference in hydrostatic pressures between the systemic and pulmonary circulations (Fig. 63.5). Under normal circumstances, pleural fluid exists in a dynamic equilibrium with approximately 1 L of fluid traversing the pleural space every 24 hours. The net accumulation of fluid in the pleural space is small (approximately 0.1–0.2 mL/kg body weight) and clinically insignificant. Pleural effusions develop when the influx of fluid into the pleural space exceeds the efflux.

Pathophysiology

Pleural effusions are classically divided into two groups according to the composition of the pleural fluid: transudates and exudates. Transudative effusions are ultrafiltrates of the plasma and contain very little protein. A transudative effusion develops due to an increase in hydrostatic pressure or decrease in oncotic pressure within the pleural microvessels. The most common cause of transudative effusion is congestive heart failure with an associated increase in hydrostatic pressure. Patients with severe malnutrition also develop transudative effusions because of profound hypoalbuminemia and loss of plasma oncotic pressure. Other conditions such as cirrhosis and nephrotic syndrome are also associated with an increase in hydrostatic pressure and loss of plasma oncotic pressure.

In contrast, exudative effusions contain a relatively high amount of protein, reflecting an intrinsic abnormality of the pleura. Any pleural or pulmonary disease associated with inflammation can result in an exudative effusion. The most common cause of exudative effusion is a parapneumonic effusion. Malignant effusions are another common form of exudative effusion and often reflect alteration in pleural permeability and altered lymphatic drainage. Exudative effusions may also arise from inflammatory abdominal conditions, such as pancreatitis. As an exudative effusion is resorbed, the fibrinous tissue left behind can give rise to ongoing inflammation and pleural adhesions.

Some pleural effusions have characteristics of both transudative and exudative pleural effusions. For example, in the case of PE, the pathogenesis of pleural effusion is multifactorial and involves increased pulmonary vascular pressure (leading to a transudative effusion) and ischemia and inflammation of the pleural membrane (leading to an exudative effusion).

Massive pleural effusions (>1.5–2 L) are usually associated with malignancy but can also arise in the setting of heart failure and in other conditions of volume overload. Massive effusions can restrict respiratory movement, compress the lung parenchyma, and result in intrapulmonary shunting. In extremely rare cases, tension hydrothorax can develop with mediastinal shift and circulatory compromise.

Clinical Features

Pleural inflammation, with or without effusion, is associated with pleuritic pain (i.e., sharp and worse with deep breathing) or with pain referred to the ipsilateral shoulder. Symptoms generally depend on the size of the effusion and underlying cause. Small pleural effusions are typically asymptomatic, and generally dyspnea does not develop until the volume of pleural fluid in adults reaches at least 500 mL.

Physical findings also depend on the size of the effusion. A pleural friction rub may be the only finding in a patient with isolated pleurisy, whereas patients with massive pleural effusions can have hemodynamic compromise. Classical physical signs of pleural effusion include diminished or distant breath sounds, dullness to percussion, and decreased tactile fremitus. The technique of auscultatory percussion (i.e., percussing the chest while listening for dullness with the stethoscope) may be more sensitive and specific for the physical diagnosis of pleural effusion. Egophony and enhanced breath sounds are often appreciated at the superior border of the effusion because of the underlying atelectatic lung disease.

Differential Diagnosis

The differential diagnosis of pleural effusion includes a wide variety of diseases characterized by dyspnea or chest pain and ranges from congestive heart failure and volume overload, pneumonia, pulmonary embolism, and pericardial effusion. Of note, many of these conditions may coexist with pleural effusions. The presence of a pleural effusion requires thoughtful consideration of the underlying cause. Specifically, an unexplained pleural effusion should raise concern for malignancy and requires follow-up.

Diagnostic Testing

The diagnosis of pleural effusion should be confirmed by chest X-ray, CT, or bedside ultrasound. A volume of approximately 200 mL is required before a pleural effusion can be demonstrated on an upright,

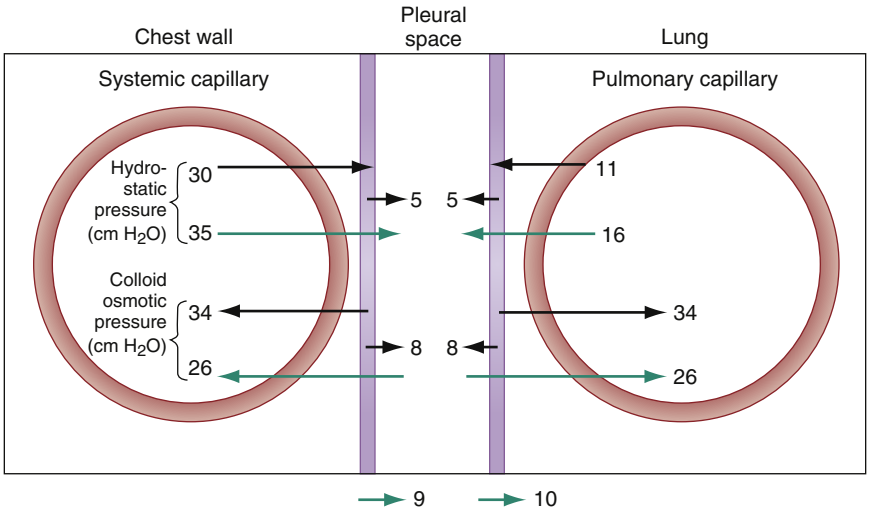

Fig. 63.5 Diagrammatic representation of the pressures involved in the formation and absorption of pleural fluid. (Adapted from Robert G, Fraser GA, Paré PD, et al. *Diagnosis of Diseases of the Chest*, ed 3, Philadelphia: WB Saunders; 1989.)

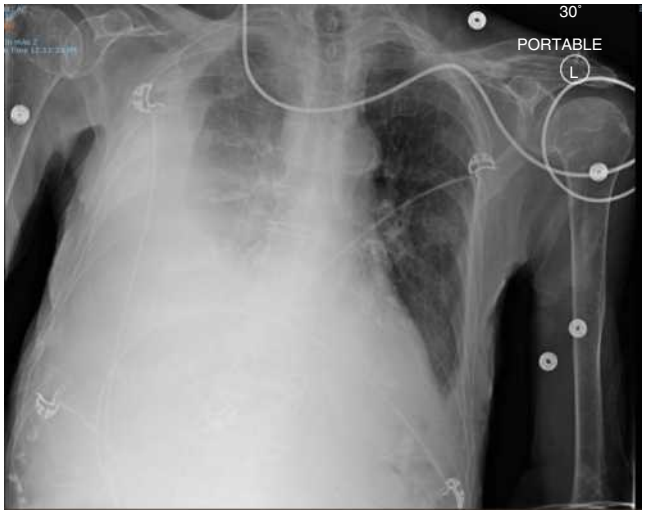

Fig. 63.6 Radiograph of a right-sided pleural effusion.

frontal chest x-ray. A smaller amount of fluid may be demonstrated in the posterior costophrenic gutter on the lateral projection. The classic radiographic appearance of a pleural effusion is blunting of the costophrenic angle. With larger pleural effusions, the hemidiaphragm may be obscured entirely, typically with an upward concave appearance because pleural fluid tends to layer higher laterally than centrally (Fig. 63.6). Pleural fluid can also extend up a major fissure and appear as a homogenous density in the lower portion of the lung field. Massive pleural effusions can completely opacify the hemithorax.

Pleural effusions are more difficult to diagnose on a supine radiograph. In the recumbent position, free pleural fluid gravitates superiorly, laterally, and posteriorly and thus, pleural effusions may not be clearly discernable. If the effusion is large enough, diffuse haziness or partial opacification of a hemithorax may be seen. Other findings on the supine radiograph may include apical capping, obscuring of the hemidiaphragm, or a widened minor fissure. Loculated fluid in a pleural fissure may assume a fusiform appearance and can simulate a mass. The lateral recumbent view historically has been useful for demonstrating small loculated effusions. It has been largely replaced by ultrasound or CT. Some pleural effusions can be challenging to diagnose on plain chest radiograph and further imaging may be required.

CT scan can detect as little as 3 to 5 mL of pleural fluid and is the gold standard for the diagnosis of small pleural effusions. CT is particularly useful in distinguishing between pleural based disease and parenchymal disease to identify an underlying cause (e.g., PE, malignancy, pneumonia). It can also help quantify the amount of fluid and may help guide thoracentesis.

Thoracic ultrasound is more sensitive than chest radiography in diagnosing and estimating the size of pleural effusion and is readily available at the bedside. Ultrasound can identify pleural effusions as small as 50 mL of fluid. On ultrasound, pleural effusions can be classified as simple or complex. Simple transudative pleural effusions often appear as hypoechoic fluid above the diaphragm and are best visualized with a curvilinear or phased array probe in the midaxillary line (Fig. 63.7). Often, compressed lung can be visualized within the effusion. Complex pleural effusions are subtyped as heterogenous or homogenous echogenicity. Hemothorax and pyothorax may appear heterogeneous, with echogenic material or septations extending through the effusion. Effusions with heterogenic echogenicity with swirling echoes suggest a high cellularity content often seen in malignant effusion. Fibrinous stranding, septations, and loculations also suggest an exudative effusion.

Identification of fluid above the diaphragm, compressed lung tissue, as well as localization of the diaphragm, liver, and spleen can help aid in the correct localization for thoracentesis or tube thoracostomy. If available, ultrasound should be used to identify pleural effusions and to guide interventions, such as thoracentesis. Iatrogenic pneumothorax is the most common complication after a thoracentesis, and it can be significantly reduced by using ultrasound guidance.[5]

Most patients with a pleural effusion should undergo diagnostic thoracentesis to determine the nature of the effusion (i.e., transudate, exudate) and identify an underlying cause. Occasionally, the clinical scenario provides an obvious apparent cause (e.g., congestive heart failure) and thoracentesis is unlikely to contribute to changes in therapy. Not all pleural effusions need to undergo thoracentesis in the ED. In the ED, thoracentesis may be performed to evaluate the etiology of life-threatening pathology (e.g., empyema, esophageal rupture) or to

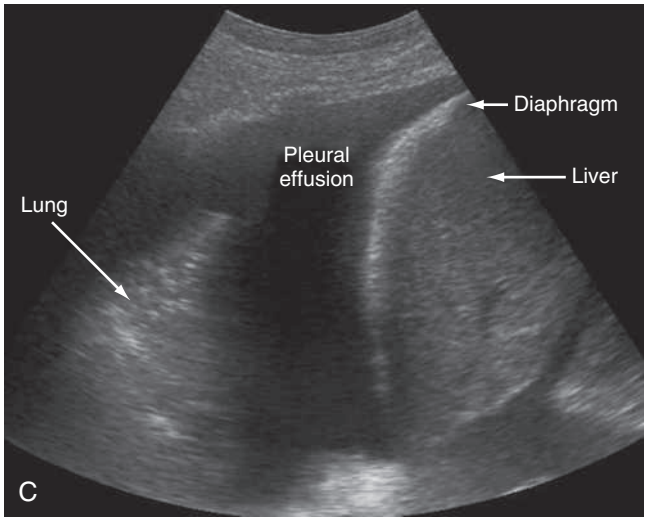

Fig. 63.7 Ultrasound image of the right upper quadrant demonstrating the typical hypoechoic appearance of a pleural effusion.

BOX 63.3 Light's Criteria for Differentiating Transudates from Exudates

Pleural fluid is considered an exudate if one or more of the following conditions are met:

1. Pleural fluid protein level/serum protein level exceeds 0.5.
2. Pleural fluid lactate dehydrogenase (LDH) level/serum LDH level exceeds 0.6.
3. Pleural fluid LDH level exceeds two-thirds of the upper limit of normal for the serum LDH level.

provide urgent symptomatic relief. In many other cases, diagnostic thoracentesis may be deferred.

Although numerous classifications have been proposed, Light's criteria remain the most widely accepted means of differentiating transudates and exudates (Box 63.3). Briefly, these criteria identify exudative effusions as being protein-rich and high in lactate dehydrogenase (LDH). A pleural fluid pH of less than 7.3 is associated with parapneumonic effusion, malignancies, rheumatoid effusions, tuberculosis, and systemic acidosis. A pH of less than 7.0 strongly suggests empyema or esophageal rupture and is an indication for tube thoracostomy. Pleural fluid should also be sent for Gram stain and culture to rule out empyema or parapneumonic effusion. If the diagnosis of malignant pleural effusion is being considered, and tumor is not already diagnosed, pleural fluid should be submitted for cytologic examination. The sensitivity for diagnosis of pleural malignancy does not depend on the volume of fluid collected during thoracentesis.

In the absence of a traumatic thoracentesis, bloody fluid suggests trauma, neoplasm, or pulmonary infarction. If the hematocrit of the pleural fluid is greater than 50% of the peripheral blood, the effusion is, by definition, a hemothorax. Atraumatic hemothorax is relatively rare but can occur with spontaneous rupture of a tumor or blood vessel.

Management

Most pleural effusions do not require emergent drainage, and there are few indications for urgent therapeutic thoracentesis in the emergency department. For the patients with massive effusions (>1.5–2 L), urgent thoracentesis may stabilize respiratory or circulatory status. Patients with empyema require timely chest tube drainage in the ED, operating room, or with interventional radiology in order to obtain source control and prevent complications. Traditionally, large-bore (28–40 Fr) chest tubes were placed in patients with empyema; however, small-bore tubes such as pigtail catheters (14 Fr) are now generally accepted as first-line therapy.[6] In most other cases, the timing of therapeutic thoracentesis can be individualized. For example, therapeutic thoracentesis would be reasonable to perform in the ED for a recurrent malignant pleural effusion if symptomatic relief would allow for discharge or would alter the diagnostic dyspnea workup.[7]

Relative contraindications to thoracentesis include coagulopathy and other bleeding disorders, history of pleurodesis, and chest wall infections. Pleural adhesions are also a relative contraindication to thoracentesis due to the potential for pneumothorax, but this risk can be minimized with ultrasound guidance.

Following a diagnostic or therapeutic thoracentesis, a chest radiograph or bedside ultrasound assessment should be obtained to evaluate for complications such as iatrogenic pneumothorax. Other potential complications include hemothorax, lung laceration, shearing of the catheter tip, infection, and transient hypoxia due to ventilation-perfusion mismatch. Hypotension can also occur after the removal of large volumes of fluid, particularly in patients that are already volume depleted.

Reexpansion pulmonary edema is a rare complication of thoracentesis and is traditionally correlated with large volume (>1500 mL) drainage. The symptoms of reexpansion pulmonary edema are generally mild and can be managed with supplemental oxygen and gentle diuresis. Safe aspiration of larger volumes of fluid has been described while using pleural manometry, however complications are rare when aspirating greater than 1500 mL during a single thoracentesis attempt. Therefore, the British Thoracic Society recommends removing no more than 1500 mL of pleural fluid in a single procedure to reduce the risk of reexpansion pulmonary edema (Grade C).

Disposition

The natural progression of pleural effusions is determined largely by the underlying diagnosis. The decision to admit a patient with a pleural effusion to the hospital must be individualized, considering the patient's underlying diagnosis, respiratory and hemodynamic status, and predicted clinical course. For example, small pleural effusions are common after abdominal surgery and in the postpartum state, but they almost always resolve spontaneously within a few days. Viral pleuritis, with or without effusion, is generally self-limited and resolves with only symptomatic support. In patients with congestive heart failure, pleural effusions generally respond well to diuresis, but patients may require admission for intravenous diuretics. Effusions may persist in patients with poorly compensated disease. In nearly 20% of pleural effusions, no definitive diagnosis can be established, even after investigation, and most of these effusions resolve spontaneously without sequelae.

Parapneumonic effusions contribute significantly to the morbidity and mortality associated with pleural disease. For this reason, the presence of a parapneumonic effusion is a reason to hospitalize a patient with community-acquired pneumonia. Empyema will develop in 5% to 10% of parapneumonic effusions and early surgical drainage results in better outcomes than conservative management.

Pleural effusions associated with malignancy are a marker of significant morbidity and mortality. Therapeutic thoracentesis can provide symptomatic relief in the short term, but malignant effusions tend to recur and often do so rapidly. Close management of recurrent malignant pleural effusions improves the patient's quality of life. Strategies for managing recurrent pleural effusions include chemical or mechanical

pleurodesis to obliterate the pleural space or placement of a permanent indwelling catheter or pleural peritoneal shunt to provide continued drainage.[7] Consistent use of definitive procedures in recurrent pleural effusions leads to fewer ED performed procedures and fewer complications when compared with repeat thoracentesis.[8] Patients with benign but recurrent pleural effusions refractory to other treatments may also benefit from chemical or mechanical pleurodesis or placement of an indwelling pleural catheter.[9]

CHAPTER 63: QUESTIONS AND ANSWERS

1. What is the most common condition associated with secondary spontaneous pneumothorax in adults in the United States?

a. Chronic obstructive pulmonary disease
b. Collagen vascular disease
c. *Pneumocystis* pneumonia
d. Pulmonary malignancy

Answer: A. Chronic obstructive pulmonary disease is the most common condition associated with secondary spontaneous pneumothorax, although all the conditions listed may also be causes.

2. Which of the following are indications of a pneumothorax on bedside ultrasound?

a. Identification of a lung point
b. Lack of lung sliding identified
c. When in M-mode, you see a "barcode" appearance
d. All of the above

Answer: D. Pneumothorax may be difficult to identify on bedside ultrasound and there are several ways to help identify a pneumothorax. Identifying an area of lung that lacks lung sliding and has a "barcode" appearance on M-mode indicates that the parietal and visceral pleura are not sliding over each other and is highly suggestive of a pneumothorax. Identifying a lung point, the point where a pneumothorax transitions to a normal pleural interface, can also help identify a pneumothorax.

3. A 32-year-old male with no significant past medical history presents with acute onset of right pleuritic chest pain, cough, and shortness of breath. The symptoms occurred at rest. Physical examination is remarkable for a tachycardia of 110 beats/min and respiratory rate of 32 and use of accessory muscles to breathe. Chest radiography reveals an estimated 5-cm right pneumothorax. Which of the following would be suitable management?

a. Admission for 100% face mask oxygen and repeat radiography in 1 day
b. One-time air aspiration and repeat radiography in 6 hours
c. Reassurance and observation
d. Tube thoracostomy

Answer: D. Large (2 cm) primary spontaneous cases and patients who are showing signs of respiratory distress should be treated with tube thoracostomy. If the primary spontaneous pneumothorax is small (<2 cm), then observation alone is appropriate. For a larger primary spontaneous pneumothorax (> 2cm) without significant symptoms, either observation alone or intervention with either simple aspiration or tube thoracostomy may be appropriate and a shared decision-making discussion with your patient is appropriate to determine best course of action.

4. Which of the following statements is true regarding the routine application of suction after tube thoracostomy?

a. It improves the rate of lung expansion.
b. It increases the risk of reexpansion pulmonary edema.
c. It is associated with increased rates of empyema.
d. It is not routinely indicated.

Answer: D. Suction neither accelerates lung reexpansion nor improves outcomes. It is indicated when reexpansion with a Heimlich or water seal device does not occur after 24 to 48 hours. A pressure of at least −20 cm H_2O should be used.

5. A 68-year-old man with a history of esophageal cancer presents with progressive fever, chest pain, and shortness of breath over 24 hours. Chest radiography demonstrates a possible left lower lobe pneumonia and large left pleural effusion. Pleural fluid analysis reveals pH of 6.95, glucose level of 47 mg/dL, 11,500 white blood cells (WBCs)/mm^3 (82% neutrophils), and protein level 75% of plasma levels. What are the indicated next steps in management?

a. Antibiotics and fluid resuscitation
b. Antibiotics and tube thoracostomy
c. Antibiotics, tube thoracostomy, and esophageal oral contrast study
d. One-time pleural aspiration for fluid analysis

Answer: C. This is an exudative pleural effusion as defined by Light's criteria (see Box 63.3). A pH less than 7.0 suggests emphysema or esophageal rupture. This patient is at risk for both; hence, the need to assess esophageal integrity. A pH less than 7.0 with glucose level less than 50 mg/dL are indications for tube thoracostomy. Normal pleural fluid has a WBC count of less than 1,000/mm^3.

64

Acute Coronary Syndromes

George F. Glass III and William J. Brady

KEY CONCEPTS

- Symptoms of acute coronary syndrome (ACS) are variable. Clinicians must consider ACS in a broad range of presentations, especially in patients prone to subtle or non-chest pain presentations (for example, women, older patients, or those with comorbidities such as diabetes).
- The ECG is crucial in the initial evaluation of ACS. Limitations of the 12-lead ECG in suspected ACS include initial nondiagnostic findings, evolving fluctuations with ongoing symptoms, anatomic myocardial blind spots, and confounding or obscuring patterns, such as left bundle branch block (LBBB).
- It is crucial to recognize ECG patterns that may indicate ischemia or impending infarction but do not meet traditional STEMI criteria (e.g., Wellens syndrome, significant aVR elevation, de Winter syndrome, Sgarbossa criteria). Patients with these findings may benefit from prompt catheterization.
- Patients with ECG findings of STEMI should undergo emergent reperfusion therapy. Percutaneous coronary intervention (PCI) is recommended with a goal door-to-balloon time of 90 minutes. If PCI is not feasible, patients should be administered fibrinolytic therapy within 30 minutes.
- Clinical decision tools, such as EDACS or the HEART score, may assist in the risk stratification of patients with suspected ACS.
- Serial troponin testing, combined with an accelerated diagnostic protocol, allows for identifying patients at low risk for ACS. High-sensitivity troponin (hs-T) testing may further reduce the time needed for evaluation. Validation of hs-T testing protocols is ongoing. Clinicians should be aware that testing characteristics vary by assay.
- Patients with suspected ACS who are low-risk by diagnostic protocols are unlikely to benefit from further diagnostic testing in the ED or admission and may be discharged with outpatient follow-up.

FOUNDATIONS

Acute coronary syndrome (ACS) refers to the constellation of clinical diseases occurring as a result of acute myocardial ischemia or infarction. ACS includes a spectrum of clinical presentations ranging from unstable angina (UA), involving ischemia, to acute myocardial infarction (AMI), characterized by myocardial cell death. Non–ST segment elevation myocardial infarction (NSTEMI) and ST segment elevation myocardial infarction (STEMI) are the two AMI subtypes. Sudden cardiac death (SCD), involving pulseless ventricular tachycardia or ventricular fibrillation, is frequently included in the ACS spectrum of illnesses and represents the most extreme clinical manifestation of acute coronary syndrome. ACS, particularly AMI and its sequelae, remain among the leading causes of death in the developed world.

Several advances in the mid-20th century have drastically changed the approach to acute coronary care. The first developments of significance—external defibrillators, cardiac pacemakers, and new pharmacologic agents—have provided emergency clinicians with effective approaches for treating life-threatening dysrhythmias occurring due to ACS. The introduction of selective coronary arteriography revolutionized the management of patients with coronary artery disease (CAD), including chronic, stable presentations and acute coronary syndrome. In 1960, Kouwenhoven inaugurated the era of cardiopulmonary resuscitation (CPR), providing an important tool in the management of SCD.

These developments led to the recognition that the time between onset of symptoms and initiation of therapy is critical. Fibrinolytic therapy and interventional catheter-based techniques revolutionized the treatment of patients with STEMI, starting in the late 1980s. Combination therapies with antiplatelet, antithrombotic, and fibrinolytic agents continue to be studied for STEMI patients, further optimizing reperfusion and adjunctive therapies. Interventional success has improved with the use of newer stenting devices and various platelet and coagulation system inhibitors.

STEMI systems of care address the management of STEMI from a systems-based perspective, starting with EMS in the prehospital setting through the ED to the cardiac catheterization laboratory (CCL) and coronary care unit (CCU). This systems-based approach stresses several factors crucial in the management of STEMI, including the time-sensitivity of treatment, the multidisciplinary composition of the

management team, and multistep nature of the overall process. In addition to further development of the STEMI systems of care approach, current efforts focus on the establishment of regional cardiac centers and expansion of interventional capabilities to smaller hospitals.

Diagnostically, methods of evaluation of potential ACS patients without obvious STEMI or other diagnostic findings continue to mature. The rule-out (R/O) myocardial infarction (MI) strategy has been shortened in total time, rendered more efficient, and made safer with respect to detection of ACS events. The R/O MI process is appropriately performed in various clinical venues, including the ED, observation settings, and acute and critical care hospital units. The most recent development is the addition of high-sensitivity troponin testing, which can increase the detection of significant ACS events and reduce the total evaluation time, thus improving throughput.

Although the modern chest pain evaluation strategy is more efficient than previous approaches, further improvements in reducing the already low missed MI rate in the ED are under development. However, attempts to lower the missed MI rate may increase unnecessary testing with associated risk, health system costs, and less resource availability for higher-risk patients. Patients, physicians, and society must recognize that atypical, unusual, unanticipated ACS presentations will occur and not be diagnosed initially, at times with poor outcomes. These "missed" MIs do not represent inappropriate medical practice.

EPIDEMIOLOGY

The overall age-adjusted prevalence of heart disease is 10.6%; the age-adjusted prevalence of coronary heart disease is 7.2% for men and 4.2% for women. Heart disease, including CAD and related ischemic heart disease, continues to be the leading cause of death among adults in many industrialized countries, including the United States and Canada. Ischemic heart disease accounts for over 1 million deaths in the United States annually, of which approximately 160,000 occur in persons 65 years of age or younger. More than half of all deaths from cardiovascular disease occur in women, and CAD remains a major cause of morbidity and mortality in women beyond their middle to late 50s. The incidence of cardiovascular disease is expected to increase due to lifestyle changes that promote heart disease.[1]

A significant reduction in age-adjusted mortality from CAD has occurred in the United States and Canada over the past 5 decades; this decline continues while ACS incidence is increasing. In large part, the decline has been accompanied by diminished mortality from AMI. This decrease results from a significant reduction in the incidence of AMI and a sharp drop in the case-fatality rate. Reduction in cigarette smoking and improved management of hypertension, hyperlipidemia, and diabetes mellitus undoubtedly play a role, along with significant advances in medical treatment.

Chest pain is the second most common reason for patient attendance in the ED, accounting for approximately 7.49 million annual visits to EDs in the United States. Among men, chest pain is the primary cause for presenting to the ED whereas, in women, chest pain is the third most common reason. The admission rate for ACS has not significantly changed over the past 15 years.[2] In the United States, approximately 900,000 persons experience an AMI every year. Thirty percent of these patients die within 30 days of acute myocardial infarction; approximately half of these deaths occur soon after symptom onset and before arrival in the ED, usually from an ACS-related dysrhythmia within 2 hours of event initiation. Approximately half of all patients with an MI are rehospitalized within 1 year of their index event. Overall, the prognosis is highly variable and depends largely on the extent of the infarct, time to intervention, whether the patient underwent some form of revascularization, and residual left ventricular function. Approximately 2% of patients with ACS, including both UA and AMI, are discharged from the ED and represent the true rate of "missed ACS in the ED."

Spectrum of Illness: Coronary Artery Disease and Acute Coronary Syndrome

Coronary heart disease occurs across a wide spectrum of acuity and severity. Asymptomatic CAD and stable angina are less severe, and the more severe manifestations of coronary heart disease include acute coronary syndrome, ranging from UA to AMI. AMI is further subdivided into NSTEMI and STEMI. Some experts also include sudden cardiac death, resulting from pulseless ventricular tachycardia or ventricular fibrillation, as the most severe form of ACS.

Stable Angina

Stable angina pectoris, not considered a form of ACS, is transient, episodic chest discomfort resulting from myocardial ischemia. This discomfort is typically predictable and reproducible, with a constant frequency of attacks over time. Physical or psychological stress (e.g., physical exertion, emotional stress, anemia, dysrhythmias, environmental exposures) may provoke an attack of angina that resolves spontaneously with rest or with nitroglycerin (NTG).

The Canadian Cardiovascular Society (CCS) classification for angina is defined as follows:

- Class I—no angina with ordinary physical activity;
- Class II—minimal limitation of normal activity as angina occurs with exertion or emotional stress;
- Class III—severe limitation of ordinary physical activity as angina occurs with exertion under normal physical conditions; and
- Class IV—inability to perform any physical activity without discomfort as anginal symptoms occur at rest or with minimal physical exertion

Unstable Angina

Unstable angina, the least severe form of ACS, should be considered from both semantic and pathophysiologic perspectives; when considered together, unstable angina is best defined from its description as well as the results of the clinical evaluation. From the semantic perspective, unstable angina is broadly defined as angina that is new onset or occurring at rest or with minimal exertion. Furthermore, it is defined as angina that is worsening from a previously stable pain occurrence pattern in terms of frequency or duration of attacks, resistance to previously effective medications, or provocation with decreasing levels of exertion or stress.

Rest angina is defined as angina occurring at rest, lasting longer than 20 minutes, and occurring within 1 week of presentation. New-onset angina is angina of at least CCS classification class II severity, with onset within the previous 2 months. Increasing or progressive angina is diagnosed when a previously known anginal pattern becomes more frequent, longer in duration, or increased by one class within the previous 2 months of at least class III severity. Symptoms that last longer than 20 minutes, despite cessation of activity, are consistent with angina at rest; in the appropriate clinical setting, such a presentation could be considered UA.

Unstable angina is also referred to as preinfarction angina, accelerating or crescendo angina, intermediate coronary syndrome, and preocclusive syndrome, underscoring its difference from stable angina. In its more severe forms, UA should be considered a possible harbinger of AMI and should be treated aggressively in such instances. These various UA definitions are made with overall consideration of the specific patient's presentation.

UA can also be defined from a pathophysiologic perspective. Plaque rupture, accompanied by thrombus formation and vasospasm,

illustrates the intracoronary events of UA. These events are frequently characterized by chest pain and electrocardiographic abnormality, including T wave and ST segment changes.

Variant angina—also known as Prinzmetal angina—is caused by coronary artery vasospasm at rest with minimal fixed coronary artery lesions; it may be relieved by exercise or NTG. The ECG reveals ST segment elevation that is impossible to discern from plaque rupture–related STEMI clinically and electrocardiographically.

Acute Myocardial Infarction

On a cellular level, acute myocardial infarction is myocardial cell death with necrosis of the myocardium. The American College of Cardiology (ACC) and European Society for Cardiology (ESC) developed clinical criteria to define both myocardial injury and myocardial infarction, referred to as the Fourth Universal Definition of Myocardial Infarction.[3] In addition, the clinical situation is also considered in AMI, resulting in types 1 through 5.

The term *myocardial injury* should be used with elevated cardiac troponin values with at least one value above the 99th percentile upper reference limit, and the injury is considered acute if there is a rise or fall of the troponin values.[3] Specifically, the term myocardial infarction should be employed when there is acute myocardial injury occurring in the setting of an abnormal serum troponin value elevated above the 99th percentile of the upper reference limit and associated with at least one of the following[3]:

- Symptoms of myocardial ischemia;
- Electrocardiographic abnormalities:
  - New changes consistent with myocardial ischemia (i.e., ST segment and/or T wave changes); or
  - Development of pathologic Q waves;
- Imaging evidence of a loss of viable myocardium or a regional wall motion abnormality consistent with ischemic cause; or
- Angiographic or autopsy evidence of coronary thrombus.

The subtype classification of AMI considers the myriad clinical situations in which acute myocardial infarction is encountered. The five primary types of infarction are described by the following classification[3]:

Type 1—spontaneous MI related to ischemia resulting from a primary coronary event, such as plaque erosion rupture, erosion, fissuring, or dissection with accompanying thrombus formation and vasospasm. Type 1 infarctions represent the true ACS event.

Type 2—MI secondary to ischemia caused by increased oxygen demand or decreased supply, as seen in coronary artery spasm, coronary embolism, severe anemia, compromising arrhythmias, or significant systemic hypotension related to a range of causes.

Type 3—sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumably new ST segment elevation or new left bundle branch block (LBBB) pattern. Fresh coronary thrombus is noted via angiography or autopsy; death occurs before appropriate blood sampling to detect the abnormal cardiac biomarker.

Type 4—MI associated with coronary instrumentation, such as occurring after percutaneous coronary intervention (PCI). For PCIs in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than three times the 99th percentile URL are designated as defining PCI-related MI. A subtype related to a documented stent thrombosis is similarly recognized.

- Type 5—MI associated with coronary artery bypass grafting (CABG). For CABG in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than five times the 99th percentile URL, plus any of the following, are designated as defining CABG-related MI:
  - New pathologic Q waves or new LBBB;
  - Angiographically documented new graft or native coronary artery occlusion; or
  - Imaging evidence of new loss of viable myocardium.

This categorization is more than a simple semantic description of AMI. Diagnostic and management issues are different depending on the subtype of MI encountered. For example, the type 1 event should be approached with attention to platelet and coagulation system inhibition and therapy aimed at correction of vasospasm, whereas the type 2 infarction should be managed by identifying and treating the inciting pathophysiologic situation causing imbalance in oxygen delivery and myocyte requirements.

Serum markers and ECG abnormalities further classify AMI at presentation as either NSTEMI or STEMI. NSTEMI is noted with the presence of chest pain or other anginal equivalent complaint, abnormal ECG (lacking ST segment elevation), and elevated serum troponin (in the typical rise and fall pattern); STEMI is noted with the presence of chest pain or other anginal equivalent complaint, abnormal ECG with ST segment elevation, and elevated serum troponin. Previous descriptors, such as transmural, non-transmural, Q wave, and non–Q wave MI, fail to describe the coronary event and its related pathophysiology, electrocardiographic presentation, and pathologic outcome adequately. The differentiation between STEMI and NSTEMI has important implications in management, outcome, and prognosis for patients with AMI. The ACC and American Heart Association (AHA) have separate clinical guidelines for the management of patients with non-ST segment elevation ACS (UA and NSTEMI) and with STEMI.

PATHOPHYSIOLOGY

The underlying pathophysiology of ACS is myocardial ischemia as a result of inadequate perfusion to meet myocardial oxygen demand. Myocardial oxygen consumption is determined by heart rate, afterload, contractility, and wall tension. Inadequate perfusion usually results from coronary arterial vessel stenosis as a result of atherosclerotic CAD. Usually, the reduction of coronary blood flow does not cause ischemic symptoms at rest until the vessel stenosis exceeds 95% obstruction to flow. Myocardial ischemia, however, may occur with increased physiologic stress and increased myocardial oxygen consumption with minimal to no vessel stenosis.

CAD is characterized by thickening and obstruction of the coronary vessel arterial lumen by atherosclerotic plaques. Although atherosclerosis is usually diffuse and multifocal, individual plaques vary greatly in composition. Fibrous plaques are considered stable but can produce anginal symptoms with exercise and increased myocardial oxygen consumption because of the reduction in coronary artery blood flow through the fixed stenotic lesions. Vulnerable, or unstable, fibro-lipid plaques consist of a lipid-rich core separated from the arterial lumen by a fibromuscular cap. These lesions are likely to rupture, resulting in a cascade of inflammatory events, thrombus formation, and platelet aggregation that can cause acute obstruction of the arterial lumen and myocardial necrosis; this rupture initiates the pathophysiologic process of ACS.

Thrombus formation is an integral factor in ACS, from UA to AMI. These syndromes are initiated by endothelial damage and atherosclerotic plaque disruption, which leads to platelet activation and thrombus formation. Platelets play a major role in the thrombotic response to rupture of coronary artery plaque and subsequent ACS. Platelet-rich thrombi

TABLE 64.1 Clinical Characteristics of Classic Anginal Chest Discomfort

Characteristic	More Likely To Be Angina	Less Likely To Be Angina
Type of pain	Dull, pressure	Sharp, stabbing
Duration	2–5 min, often 15–20 min	Seconds or hours
Onset	Gradual	Rapid
Location	Substernal	Lateral chest wall, back
Reproducible	With exertion	With inspiration
Associated symptoms	Present	Absent
Palpation of chest wall	Not painful	Painful, exactly reproduces pain complaint

Adapted from: Zink BJ. Angina and unstable angina. In: Gibler WB, Aufderheide TP, eds. *Emergency Cardiac Care*. St. Louis: Mosby; 1994.

are also more resistant to fibrinolysis than fibrin- and erythrocyte-rich thrombi. The resulting thrombus can occlude the vessel lumen, leading to myocardial ischemia, hypoxia, acidosis, and eventually infarction. The consequences of the occlusion depend on the extent of the thrombotic process, characteristics of the preexisting plaque, the extent of the vessel obstruction, and availability of collateral circulation.

In the setting of UA, acute stenosis of the vessel is usually noted; complete obstruction, however, is encountered in only 20% of cases. In these cases, extensive collateral vessel circulation likely prevents cessation of blood flow, averting frank infarction. With AMI, the occlusive, fibrin-rich thrombus is fixed and persistent, resulting in myonecrosis of the cardiac tissue supplied by the affected artery. Angiographic studies have demonstrated that the preceding coronary plaque lesion is often less than 50% stenotic, indicating that the most critical factors in the infarction are the acute events of plaque rupture, platelet activation, and thrombus formation rather than the severity of the underlying coronary artery stenosis.

Another important aspect of ACS is vasospasm. After significant coronary vessel occlusion, local mediators and vasoactive substances are released, inducing vasospasm, which further compromises blood flow. Central and sympathetic nervous system input increases within minutes of the occlusion, resulting in vasomotor hyperreactivity and coronary vasospasm. Sympathetic stimulation by endogenous hormones, such as epinephrine and serotonin, may also increase platelet aggregation and neutrophil-mediated vasoconstriction. Approximately 10% of MIs occur due to coronary artery spasm and subsequent thrombus formation without significant underlying CAD. This mechanism may be more prevalent during UA and other coronary syndromes that do not result in infarction.

Further myocardial injury occurs at the cellular level as inflammatory, thrombotic, and other debris from the occlusive plaque lesion is released and embolizes into the distal vessel. Such embolization can result in obstruction at the microvasculature, leading to hypoperfusion and ischemia of the distal myocardial tissue, even after reopening of the more proximal, initial obstructing lesion. In particular, the introduction of calcium, oxygen, and cellular elements into ischemic myocardium can lead to irreversible myocardial damage that causes reperfusion injury, prolonged ventricular dysfunction (known as myocardial stunning), or reperfusion dysrhythmias. Neutrophils probably play an essential role in reperfusion injury, occluding capillary lumens, decreasing blood flow, accelerating the inflammatory response, and producing chemoattractants, proteolytic enzymes, and reactive oxygen species.

CLINICAL FEATURES

Clinical features associated with ACS vary based on the patient type, including sex, comorbid conditions, and age considerations. Original studies of ACS focused on men, leading to a narrow description of "typical" chest pain symptoms. Women, patients with diabetes mellitus, and older adults, among other populations, can exhibit differing presentations of ACS. Women may demonstrate less remarkable ACS presentations. Diabetic patients frequently exhibit nontraditional symptoms of ACS, such as dyspnea. Older adults commonly note only extreme weakness, significant mental status abnormalities, or other nonclassic symptoms as the primary manifestation of ACS.

Prehospital Evaluation

Diagnosing ACS in the prehospital setting is difficult because chest pain is a poor predictor of the diagnosis of AMI, and adjunctive diagnostic tools are limited. A prehospital 12-lead ECG offers high specificity (99%) and positive predictive value (93%) for STEMI in patients with atraumatic chest pain while increasing the paramedic scene time by only 1 to 3 minutes; the prehospital ECG significantly reduces the time to hospital-based reperfusion therapy. The EMS diagnosis of STEMI via the prehospital ECG offers many advantages, including the following: (1) earlier detection of STEMI; (2) ability to select patient destination based on the availability of PCI; (3) hospital-based preparation prior to patient arrival; and (4) more rapid initiation of hospital-based reperfusion therapy, either fibrinolysis or PCI.

Emergency Department Evaluation

History

The character of the chest discomfort, as well as the onset, location, and duration should be considered in the evaluation. Associated symptoms, especially of a cardiac, pulmonary, gastrointestinal, or neurologic nature, should be elicited. Results from any prior cardiac testing should be obtained, if logistically and practically possible.

The term *angina* refers to a tightening sensation, not a pain. Angina pectoris may not be pain at all but rather described as a discomfort, with a squeezing, pressure, tightness, fullness, heaviness, or burning sensation. Classically, it is substernal or precordial in location and may radiate to the neck, jaw, shoulders, or either arm; importantly, either shoulder or arm can be involved in this radiation of discomfort. If the discomfort does extend down the arm, it typically involves the ulnar aspect. Discomfort in the left chest and radiation to left-sided structures is usual, but location and radiation to both sides or only to the right side can be consistent with angina. Refer to Table 64.1 for characteristics of angina chest pain.

Symptoms characteristically associated with angina pectoris include dyspnea, nausea, vomiting, diaphoresis, weakness, dizziness, excessive fatigue, or anxiety. If these symptoms arise without chest discomfort, alone or in combination, as a presenting pattern of known ischemic coronary disease, they are termed *anginal equivalent symptoms.* Recognition that coronary ischemia may arise with an anginal equivalent

TABLE 64.2 Key Entities in the Differential Diagnosis of Chest Pain

Acute myocardial infarction	Unstable angina
Stable angina	Prinzmetal angina
Pericarditis	Myocardial or pulmonary contusion
Pneumonia	Pulmonary embolism
Pneumothorax	Pulmonary hypertension
Pleurisy	Aortic dissection
Boerhaave syndrome	Gastroesophageal reflux
Peptic ulcer disease	Gastritis or esophagitis
Esophageal spasm	Mallory-Weiss syndrome
Cholecystitis or biliary colic	Pancreatitis
Herpes zoster	Musculoskeletal pain

rather than a classic symptom is the key to understanding the nontraditional presentation of ACS.

Dyspnea is the most common angina equivalent presentation. Isolated diaphoresis, nausea, emesis, anxiety, and fatigue are very uncommon sole presenting symptoms in ACS. Weakness, dizziness, excessive fatigue, and anxiety may occasionally occur as the single presenting complaint in the ACS patient, especially in the extreme older patient population (Table 64.1).

Complaints of gas, indigestion, or heartburn in the absence of a known history of gastroesophageal reflux disease should raise suspicion of ACS. Additionally, if the heartburn is different from the patient's usual gastroesophageal reflux, or there is a lack of reproducible pain on abdominal palpation, ACS should be considered. These presenting complaints, however, do not indicate ACS in the majority of cases. Nonetheless, gastroesophageal and upper gastrointestinal (GI) maladies are common misdiagnoses in cases of missed AMI.

Although certain features of the chest pain history serve to increase or decrease the likelihood of ACS, none of them is strong enough to establish a diagnosis or endorse discharge of the patient based on the single historical elements alone.

Nontraditional History. A description of typical symptoms may not be present in ACS. This nontraditional presentation may be a result of atypical features of the pain (e.g., character, location, duration, exacerbating and alleviating factors) or the presence of anginal equivalent symptoms (e.g., dyspnea). Patients with an ultimate diagnosis of ACS can have pain that is pleuritic, positional, or reproduced by palpation to a certain extent. Some patients describe their pain as burning or indigestion, sharp, or stabbing. Of course, a single historical point or combination of points does not establish a diagnosis or dictate management strategy. Rather, the emergency clinician evaluating the patient must consider the chief and related complaints as well as the other features of the presentation—in other words, the entire diagnostic picture.

Previous studies have shown that of the ED patients ultimately diagnosed with AMI, one-third did not have chest pain on presentation. Multiple studies have identified risk factors for presentations of ACS that did not feature classic anginal pain, including diabetes mellitus, older age, female sex, nonwhite ethnicity, dementia, no prior history of MI or hypercholesterolemia, no family history of coronary disease, and previous history of congestive heart failure (CHF) or stroke.

Below age 85, chest pain is found in most patients with AMI, although dyspnea, stroke, weakness, and altered mental status are notably present. In those older than 85 years, however, other symptoms are more common than chest pain, with 60% to 70% of patients older than 85 years having an anginal equivalent complaint, especially dyspnea. Coincident ACS is more likely to occur in older adults; patients with another acute condition (e.g., trauma, infection) can experience concurrent coronary ischemia due to the physiologic stress.

Patients with diabetes mellitus are at heightened risk for ACS and presenting with anginal equivalents. Medically unrecognized AMI can occur in 40% of patients with diabetes mellitus compared with 25% of a nondiabetic population, and a myocardial scar unaccompanied by an antemortem diagnosis of MI is three times more likely in people with diabetes. As with age and diabetes, female sex is a significant risk factor for AMI without a classic chest pain presentation. In some series, fewer than 60% of women reported typical chest discomfort at the time of their AMI, with others reporting dyspnea, indigestion, or vague symptoms, such as weakness, unusual fatigue, cold sweats, sleep disturbance, anxiety, and dizziness. Women are more likely to attribute their cardiac symptoms to anxiety, and clinicians are less likely to think their presentations are cardiac in nature, as compared to presentations of male patients.[4]

Finally, nonwhite populations may have underrecognized symptoms in ACS. Compelling data have demonstrated a disparity in treatment approaches related to race and ethnicity in patients with acute manifestations of coronary heart disease. ACS presentations without classic anginal chest pain are associated with worse outcomes due to delayed ACS diagnosis and treatment. If the diagnosis is not suspected, appropriate treatment cannot be started. Patients with an AMI without chest pain had two- to three-fold increased in-hospital mortality compared to patients with chest pain and were more likely to experience stroke, hypotension, or heart failure requiring intervention, possibly reflecting the older age and greater comorbidities. Patients without typical chest pain seek medical care later and are less likely to receive ACS-focused treatment. Patients 65 years of age or younger with NSTEMI have a 1% chance of dying during hospitalization, but this risk is increased to 10% for patients aged 85 years and older. Emergency clinicians should recognize the varied presentations of ACS and consider the diagnosis for all patients presenting with any chest discomfort, shortness of breath, weakness, dizziness, nausea, or vomiting. Although most patients with these symptoms will not have ACS, understanding the variation in presentation is essential to minimizing missed cases and improving outcomes.

Traditionally, a history of risk factors for CAD is sought; these include age, tobacco smoking, hypertension, diabetes mellitus, hyperlipidemia, and family history of AMI at an early age (usually <50 years). Additional risk factors to consider include markedly elevated body mass index, artificial or early menopause, and cocaine (or other sympathomimetic agent) use. In general, the cardiac risk factor burden has a limited impact on the ED evaluation and diagnosis of ACS; these data are important but, by themselves, do not dictate evaluation strategy. In older patients, ACS is significantly more likely if four of the five major risk factors—diabetes mellitus, smoking, hypertension, hyperlipidemia, and family history—are present (compared with none). Nevertheless, Bayesian analysis indicates that risk factors are a population phenomenon and do not increase or decrease the likelihood of any condition in any one individual patient. Thus, the presence of an individual risk factor or collection of risk factors is far less important in diagnosing ACS in the ED when compared to the history of presenting illness, prior diagnosis of ischemic cardiac disease in the patient, presence of ST segment or T wave changes, or cardiac marker abnormalities, or all these clinical features considered as a whole.

Several less-common risk factors for CAD should be considered in appropriate patients. Antiphospholipid syndrome, rheumatoid arthritis, human immunodeficiency virus (HIV), and particularly systemic lupus erythematosus (SLE) are associated with a higher risk of cardiovascular disease. In fact, women with SLE who are 35 to 44 years of

age are more than 50 times more likely to have an MI than a similar age- and sex-matched Framingham population.

Physical Examination of the ACS Patient

The physical examination focuses on the cardiac, pulmonary, abdominal, and neurologic examinations, looking for complications of ACS as well as alternative diagnoses for chest pain (Table 64.2). In general, the physical examination in the ill ACS patient will demonstrate few findings suggestive of ACS; pale appearance, anxiety, and diaphoresis are frequent findings in patients with severe forms of UA and AMI. Bradycardia, tachycardia, hypotension, and pulmonary edema, common in the AMI patient, are manifestations of ACS as complications; these findings also are ominous signs in patients with known or suspected ACS.

Historical studies, using untrained emergency staff (i.e., not emergency physicians), identified reproducible chest wall tenderness in up to 15% of patients ultimately diagnosed with AMI, but these data are of uncertain validity. The real incidence of truly reproducible chest wall tenderness (the patient reliably identifies that the pain on palpation is identical to the pain leading to presentation) in ACS is probably extremely rare. Patients with chest pain that is significantly pleuritic, positional, or reproducible by palpation are at low risk, but not no risk, for ACS.

Early Complications of Acute Myocardial Infarction

Bradydysrhythmia and atrioventricular (AV) conduction blocks occur in 25% to 30% of patients with AMI; sinus bradycardia is usually seen. Symptomatic bradydysrhythmias in the first few hours after inferior STEMI tend to be atropine-responsive; conduction abnormalities that appear beyond 24 hours of AMI tend not to respond to atropine. Patients with AV block in the setting of anterior STEMI tend to respond poorly to therapy and have a poor prognosis.

Tachydysrhythmias are common in the setting of AMI and may be atrial in origin (e.g., sinus tachycardia and atrial fibrillation) or ventricular (e.g., ventricular tachycardia and fibrillation). Not all require treatment, such as a compensatory sinus tachycardia in patients with AMI complicated by CHF (see Chapter 65). Primary ventricular fibrillation occurs in an estimated 4% to 5% of patients with AMI, with 60% of those cases occurring in the first 4 hours and 80% within 12 hours.

Cardiogenic shock is defined as end-organ hypoperfusion resulting from decreased cardiac output unresponsive to restoration of adequate preload. Patients at risk include those with large infarctions, prior MI, low ejection fraction on presentation (<35%), older age, and diabetes mellitus. Adjunctive diagnostic measures include bedside echocardiography and invasive hemodynamic monitoring, with the latter demonstrating systemic hypotension, low cardiac output, elevated filling pressures, and increased systemic vascular resistance. Therapeutic measures include vasopressor and inotropic support, mechanical circulatory support (see Chapter 66), and early revascularization; fibrinolytic therapy does not decrease mortality in cardiogenic shock.

Mechanical complications of AMI occur, including left ventricular free wall rupture, interventricular septum rupture, and papillary muscle rupture (with acute mitral value regurgitation). Over the past 30 years, the occurrence of these catastrophic complications has declined significantly, though when they occur, the outcome is frequently poor.[5]

Left ventricular free wall rupture is uncommon. Approximately one-third of cases occur in the first 24 hours, and the remainder occur 3 to 5 days after large MIs, typically anterior wall STEMIs. Clinically, free wall rupture presents with sudden death, pulseless electrical activity, or precipitous hemodynamic deterioration in the presence of acute or very recent STEMI. Signs of pericardial effusion on the ECG or echocardiogram are suggestive of the diagnosis in this setting. This diagnosis is difficult to establish. Free wall rupture is almost universally fatal, although prompt diagnosis followed by emergent surgical intervention may rarely be lifesaving.

Rupture of the interventricular septum or papillary muscle with acute mitral value regurgitation may also occur. These ruptures also most commonly occur 3 to 5 days after large MIs. Both are characterized by a new loud holosystolic murmur heard best at the left lower sternal border and flash pulmonary edema with hemodynamic collapse. The diagnoses can be confirmed by echocardiography with color flow Doppler imaging. The presentation of acute catastrophic deterioration with a new loud systolic murmur should prompt immediate cardiac surgery consultation for repair of a septal defect or ruptured papillary muscle of the mitral valve. Medical therapy, including vasopressor and inotropic support, as well as intraaortic balloon counterpulsation, are essential bridges to the definitive surgical treatment. As with free wall rupture, these diagnoses are difficult to establish.

Pericarditis, when associated with AMI, can occur early or in a delayed fashion; the former is termed *infarct-related pericarditis,* and the latter is known as post-MI or Dressler syndrome. Infarct-related, or infarct, pericarditis is associated with transmural insult and thus principally involves the pinnacle of the infarct zone near the epicardium. Although the characteristic ST segment changes may be obscured by ST segment abnormalities related to the infarction itself, they are localized if they are evident. Infarct pericarditis is a common cause of new chest pain in the first week after MI. This pain is characteristically pleuritic and worse in the supine position, likely quite different from the chest discomfort experienced resulting from the AMI. Embolic complications are more common in patients with infarct pericarditis, possibly because this population also has a higher rate of ventricular aneurysm development than other patients with AMI.

Dressler syndrome, unlike infarct pericarditis, does not require transmural involvement. It is a relatively uncommon late complication occurring from 1 week to several months after MI. Clinical features include fever, malaise, pleuro-pericardial pain, and, at times, the presence of a rub on cardiac auscultation. Laboratory findings are highly nonspecific and include an elevated erythrocyte sedimentation rate and leukocyte count. The ECG may show ST segment–T wave findings of pericarditis although, as with infarct pericarditis, these changes may be overshadowed by the evolving changes of the recent MI. PR segment depression is a telltale clue. Pericardial or pleural effusions may be evident and can be serous or bloody. Echocardiography assesses pericardial fluid and risk of tamponade. The pericardial reaction is believed to be immune-mediated; treatment includes antiinflammatory agents.

Stroke may also complicate AMI, usually ischemic or thromboembolic. The major predisposing mechanisms with a recent MI are embolization from a left ventricular mural thrombus with decreased ejection fraction, embolization from the left atrial appendage with atrial fibrillation, and hypercoagulability with concomitant carotid arterial disease. It is known that the rate of stroke is higher in the setting of MI (approximately 1.0%, declining to 0.1% at day 28 after MI) than in similar non-AMI patients (approximately 0.01%).

Hemorrhagic stroke is a risk for the patient undergoing fibrinolytic therapy. The rate of hemorrhagic stroke with varying fibrinolytic agents is less than 1%; the rate is marginally higher in older patients. PCI lowers the overall risk of stroke compared with fibrinolytic therapy. The overall difference in stroke rate was highly significant in one large study, at 1.6% in the fibrinolytic group vs. 0.7% in the PCI group, and was 1.0% in the fibrinolytic group versus 0.1% in the PCI group for hemorrhagic strokes.

Adverse events of ACS therapy should also be considered as potential complications. The various antiplatelet, anticoagulant, and fibrinolytic therapies (as noted earlier) are all associated with hemorrhage as

a major complicating issue. Within a single class of medications, many of these agents are so similar in efficacy that superiority is determined by the rate of adverse effects, largely hemorrhagic in nature. The rate of adverse events with anticoagulant-antiplatelet medications is the most important factor for agent selection.

Procedural complications include arterial injury with hemorrhage related to percutaneous interventions; the most typical is a pseudoaneurysm of the femoral artery with hemorrhage into the thigh compartment or retroperitoneal area. The diagnosis is made based on pain, swelling, or ecchymosis in a patient with recent femoral artery cannulization. Physical examination findings, including extensive bruising in the thigh and bruits over the femoral artery, are suggestive; ultrasonography or CT of the thigh and retroperitoneal area can confirm the diagnosis.

DIFFERENTIAL DIAGNOSES

The differential diagnosis of ACS is broad and includes both life-threatening diagnoses as well as relatively benign conditions. When evaluating a patient for nontraumatic chest pain, strong diagnostic consideration should be given to other potentially life-threatening conditions such as pulmonary embolism, aortic dissection, aortic aneurysm with perforation, pneumothorax, esophageal perforation, myopericarditis, myocarditis, and pneumonia. Non–life-threatening causes are numerous and include costochondritis, musculoskeletal chest pain, herpes zoster infection, and various gastrointestinal maladies; although these entities are usually non–life-threatening, significant morbidity can occur (see Table 64.2).

DIAGNOSTIC TESTING

Electrocardiography

In the patient with chest discomfort or other symptoms suggestive of ACS, the 12-lead ECG can assist in many critical applications, including establishing the diagnosis, determining candidacy for various therapies, and performing risk assessment. In the setting of STEMI, the ECG is diagnostic.

Per the Fourth Universal Definition of Myocardial Infarction, ECG findings consistent with STEMI include new ST elevation of greater than 1 mm in at least two contiguous leads except for leads V2 and V3, where diagnostic cut-offs are as follows: elevation 1.5 mm or greater in females of any age, 2.5 mm or greater in males less than 40 years of age, and 2 mm or greater in males greater than 40 years of age.[3] Furthermore, the ECG provides pivotal information regarding therapeutic intervention; ST segment elevation establishes candidacy for emergent reperfusion therapy, via PCI or fibrinolysis.

Regarding risk assessment, several electrocardiographic findings, such as total ST segment deviation, LBBB, left ventricular hypertrophy (LVH), and QT interval prolongation, may indicate an increased cardiovascular risk. Other 12-lead ECG determinations include cardiac rhythm, the evolution of the ACS event, response to therapy, and clinical information suggesting an alternative diagnosis. Rhythm determination is essential, particularly if a compromising dysrhythmia is present. Finally, an alternative diagnosis, such as pulmonary embolism (PE) or acute myopericarditis, can be suggested by the ECG.

In ACS, morphologic changes may occur in the T wave, ST segment, and QRS complex; the PR segment can also demonstrate abnormalities (e.g., PR segment depression in atrial infarction or infarct-related pericarditis), yet the current clinical use of this information remains uncertain. The diagnostic abilities of the ECG are further limited by individual variations in coronary anatomy and preexisting coronary disease (e.g., previous MI, LBBB, collateral circulation, coronary bypass surgery) and because it does not view the posterior, lateral, and apical left ventricular walls well. The ECG may be normal or nonspecifically abnormal in the presence of an early ACS event, including AMI. Importantly, a single ECG in isolation is neither 100% sensitive nor 100% specific for AMI and reflects a single point in time of cardiac electrical imaging.

A normal or nonspecifically abnormal ECG in a currently asymptomatic patient with history of intermittent anginal chest pain can be misleading and should not be overemphasized. Patients with an initial nondiagnostic ECG who later develop AMI during hospitalization are often pain-free or minimally uncomfortable on initial ED presentation. The elapsed time from symptom onset to the normal ECGs does not necessarily rule out an AMI. Although the negative predictive value is high, it is not 100%, even up to 12 hours after the onset of the patient's chest symptoms. The patient's reported history, and the emergency clinician's interpretation of that history, remains the most important diagnostic study, and the ECG should be interpreted in this context.

Electrocardiographic Abnormalities in Acute Coronary Syndromes

The earliest electrocardiographic finding in STEMI is the hyperacute T wave (Fig. 64.1), a tall and peaked structure that can appear within minutes of the interruption of blood flow and initiation of acute infarction. It is usually broad-based and asymmetrical in structure; the ST segment can be elevated at the J (or junction between the QRS complex and ST segment) point. The hyperacute T wave progresses to ST segment elevation in typical STEMI. This hyperacuity may not be appreciated on the initial ECG in that the finding occurs early in the course of acute infarction and is transient with rapid progression to obvious ST segment elevation. In addition to the hyperacute T waves of acute ischemia, the differential diagnosis of the tall T wave also includes hyperkalemia, benign early repolarization (BER), LVH, LBBB, and acute pericarditis.

As the STEMI progresses, ST segment elevation may become evident, allowing for the more definitive diagnosis. Morphologic variations of ST segment elevation (Fig. 64.2) can be seen from the J point at the end of the QRS complex to the apex of the T wave. This upsloping portion of the ST segment usually progresses as it elevates from flat to convex, domed, or "tombstoned"; if flat, it is characteristically horizontal or oblique. At times, the ST segment may be concave or scooped in its elevation with STEMI. This morphology may progress to a convex shape or may stay the same throughout the infarction. The concave morphology, if noted in all elevated ST segments, is atypical for STEMI and is more commonly seen with other ST segment elevation syndromes. ST segment elevation is measured in millimeters; one block on the electrocardiographic tracing is equivalent to 1 mm in height. The baseline is usually considered to be the TP segment, although some advocate use of the terminal point of the PR segment. In general, the most definable, constant baseline evident on the ECG should be used.

ST segment elevation, benign and pathologic, is a common finding on the ECG in adults with chest pain (Table 64.3). Some degree of ST segment elevation is common, especially in young males, where it is present upwards of 90% of the time. Commonly referred to as "benign early repolarization" (BER), this elevation is seen in the precordial leads and is usually 1 mm or more in men and 1 mm or less in women. The ST segment elevation of BER is concave and is more prominent as the corresponding S wave (or negative deflection of the QRS complex) becomes deeper. Because of prevalence of this finding, it is not a normal variant but rather a normal finding. A helpful point in differentiating normal ST segment elevation from the pathologic ST segment elevation of STEMI is that the latter is a dynamic phenomenon. ECGs recorded sequentially over time, with waxing and waning symptoms,

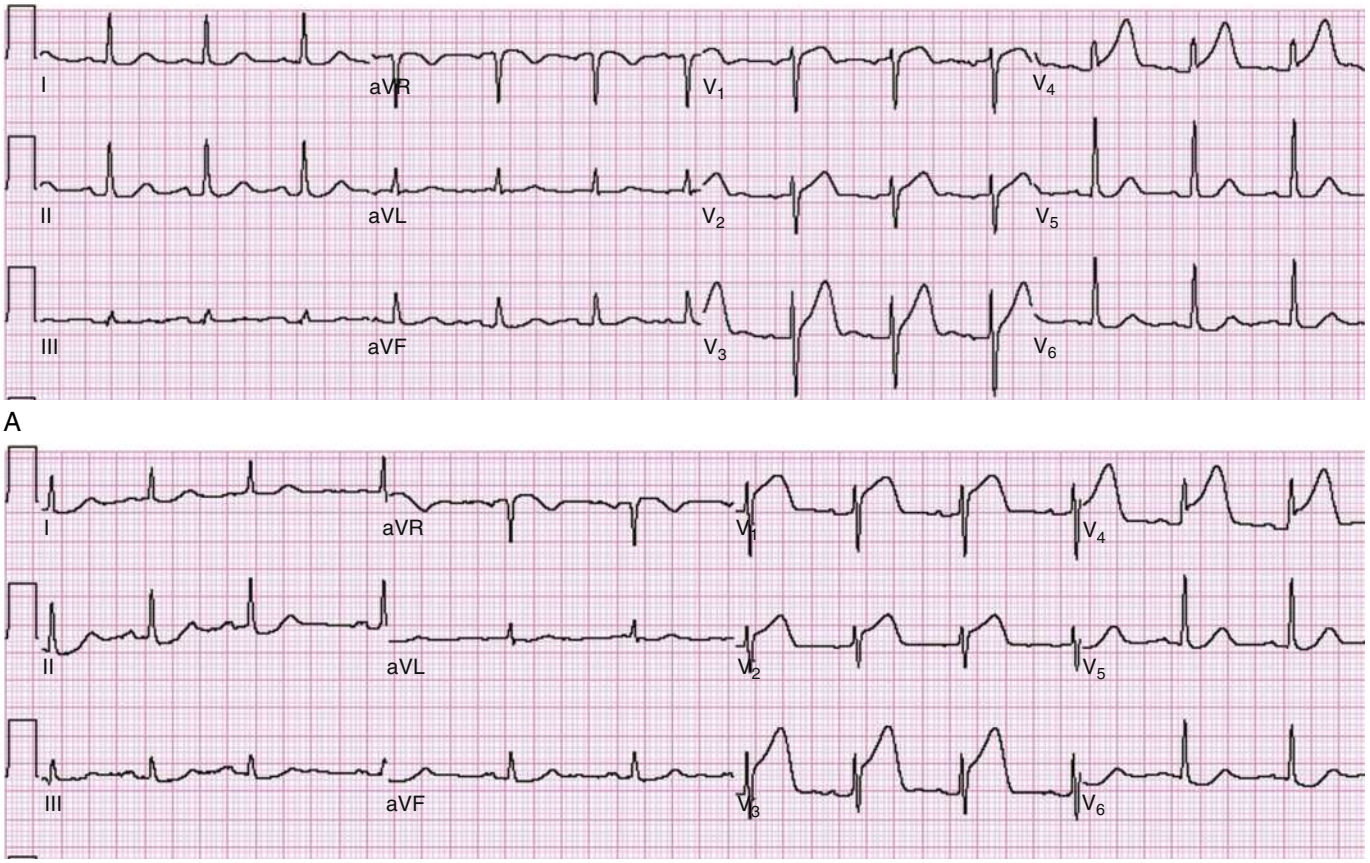

Fig. 64.1 Hyperacute T wave of acute myocardial infarction. (A) Note the broad, tall T waves in leads V_3 and V_4 in this patient with chest pain and diaphoresis. These are the hyperacute T waves of early ST segment elevation myocardial infarction. The ST segment is just beginning to rise in leads V_3 and V_4; leads V_1 and V_2 are also suspicious. (B) This tracing is from the same patient taken about 30 minutes after the electrocardiogram in A. Note the prominent ST segment elevation in leads V_1 to V_4.

should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

ST segment depression generally represents subendocardial ischemia in ED patients presenting with chest pain or anginal equivalent. Ischemic ST segment depression is typically horizontal or downsloping; an upsloping contour may be seen but is less frequently associated with ischemia. Subendocardial ischemic ST segment depression may be diffuse, spanning anterior and inferior leads. This finding can be seen in unstable angina or NSTEMI; the distinction is made considering the clinical presentation and the results of serial serum markers. Additionally, the standard 12-lead ECG will demonstrate ST segment depression in the right to mid precordial leads when transmural posterior wall infarction occurs. The differential diagnosis of ST segment depression includes myocardial ischemia or infarction, repolarization abnormality of left ventricular hypertrophy (the so-called strain pattern), bundle branch block, ventricular paced rhythm (VPR), digoxin effect, hyperkalemia, hypokalemia, PE, intracranial hemorrhage, myocarditis, rate-related ST segment depression, postcardioversion of tachydysrhythmias, and pneumothorax (Fig. 64.3).

ST segment depression in ACS (1) may be seen in NSTEMI, (2) may precede ST segment elevation in STEMI, (3) may reflect a mirror image of ST segment elevation from posterior MI when found in the right- to mid-precordial leads (i.e., ST segment depression in V_1 to V_3 in posterior MI), and (4) may represent reciprocal ST segment depression seen with STEMI. With reciprocal ST segment depression, such changes are seen in leads on the opposite side of the heart from simultaneous ST segment elevation. For example, the ST segment depression seen in leads V_1 to V_3 seen in posterior MI actually represents reciprocal change resulting from the ST segment elevation that would be recorded in posterior leads V_8 and V_9. An inferior MI with ST segment elevation more frequently manifests reciprocal ST segment depression than does anterior STEMI. The reciprocal ST segment depression in inferior MI is best seen in lead aVL, which is 150 degrees removed from lead III when the positive poles of these leads in the frontal plane are considered. Anterior STEMI may feature reciprocal ST segment depression in one or more inferior leads (II, III, or aVF). Reciprocal changes in the setting of STEMI increase the specificity and positive predictive value of the ECG in AMI and coincide with larger infarction, greater chance of cardiovascular adverse events, and more frequent death. Fig. 64.3 depicts the various forms of ST segment depression.

T wave inversions, although nonspecific, may be suggestive of chronic ischemic change or ACS in the appropriate clinical context. Normally, the T wave is upright in the left-sided leads (I, II, and V_3 to V_6) and inverted in the right-sided lead, aVR. T wave vectors are variable in leads III, aVL, and aVF. They are normally inverted in V_1 and may also be normally inverted in lead V_2. The T wave inversions of ACS are classically narrow and symmetrical (Fig. 64.4). The preceding ST segment is typically isoelectric and may be bowed slightly upward or concave. Associated ST segment depression may occur. T wave

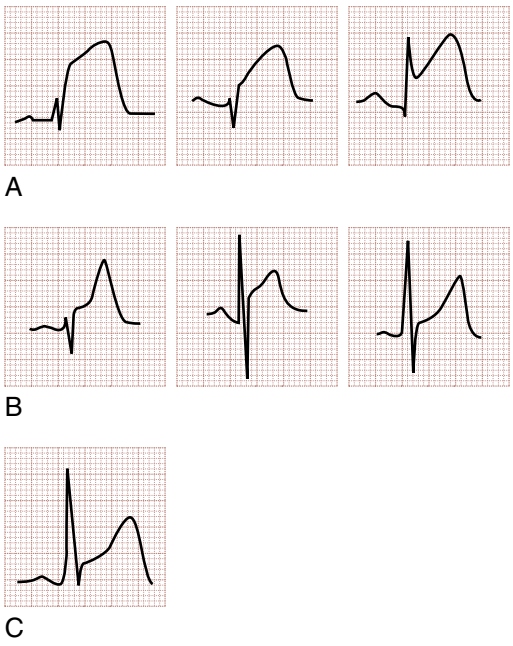

Fig. 64.2 Analysis of ST segment–T wave morphology in acute myocardial infarction (AMI), benign early repolarization (BER), and acute pericarditis. An analysis of the ST segment–T wave morphology (from the beginning at the J point to the end at the apex of the T wave) may be particularly helpful in distinguishing among the various causes of ST segment elevation (STE) and identifying the STE case. (A) The initial upsloping portion of the ST segment is usually flat (horizontally or obliquely) or convex in the patient with STEMI. This morphologic observation, however, should be used only as a guideline; it is not infallible. (B) Non-AMI causes of STE are seen here with concavity of the ST segment–T wave (*left,* BER; *middle,* pericarditis; *right,* BER). (C) Patients with STE related to STEMI may demonstrate concavity of this portion of the waveform. Serial ECGs may assist in discerning whether the presence of STE is pathologic.

TABLE 64.3 Differential Diagnosis of Electrocardiographic ST Segment Elevation in the Adult Chest Pain Patient

Acute myocardial infarction	Acute pericarditis
Left ventricular hypertrophy	Left ventricular aneurysm
Ventricular paced rhythm	Benign early repolarization
Normal variant	Osborn wave of hypothermia
Hyperkalemia	Brugada syndrome
Pulmonary embolism	Acute cerebral hemorrhage
Prinzmetal angina	Postelectrical cardioversion

inversions are best evaluated in comparison with the most recent prior ECG, given the multitude of normal variations.

A notable subgroup of ischemic T wave inversions is associated with Wellens syndrome: deep symmetrical T wave inversions (type I) or biphasic T wave changes (type II) in the anterior precordial suggestive of myocardial ischemia (Fig. 64.5). Other electrocardiographic features include isoelectric or minimally elevated (<1 mm) ST segments and lack of precordial Q waves. This finding may manifest in the anginal or pain-free state and may or may not be accompanied by cardiac marker elevations. Wellens syndrome is indicative of a lesion of the left anterior descending artery and the natural history of this presentation is progression to anterior wall STEMI.

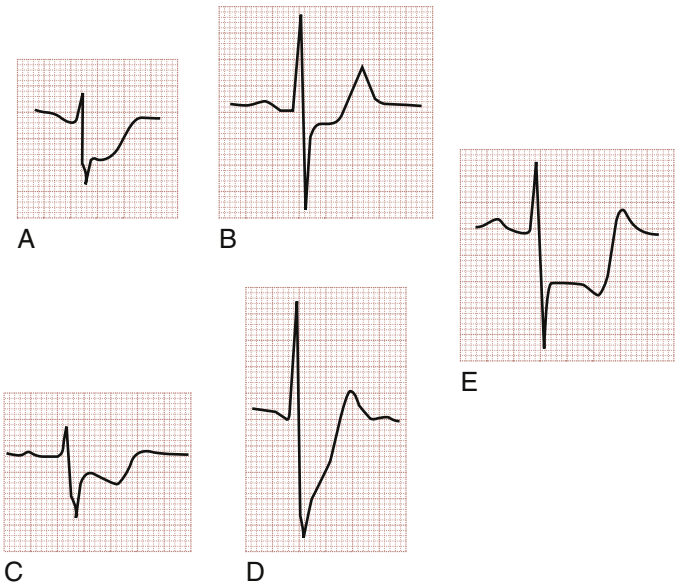

Fig. 64.3 ST segment depression (STD) in acute coronary syndrome. (A) Horizontal STD unstable angina pectoris (USAP). (B) Horizontal STD (non–ST segment elevation [STE] acute myocardial infarction). (C) Downsloping STD (USAP). (D) Upsloping STD (USAP). (E) Horizontal STD as seen in lead III in a patient with anterior wall acute myocardial infarction, an example of reciprocal STD, also known as reciprocal change.

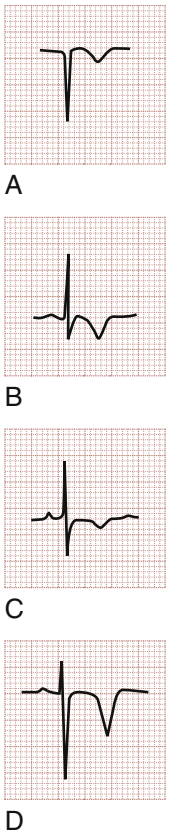

Fig. 64.4 T wave inversions of acute coronary syndrome (ACS). (A & B) T wave inversions in patients with ACS. (C) T wave inversion in a patient with non–ST segment elevation (STE) acute myocardial infarction. (D) Deeply inverted T waves in a patient with proximal left anterior descending artery stenosis—Wellens syndrome.

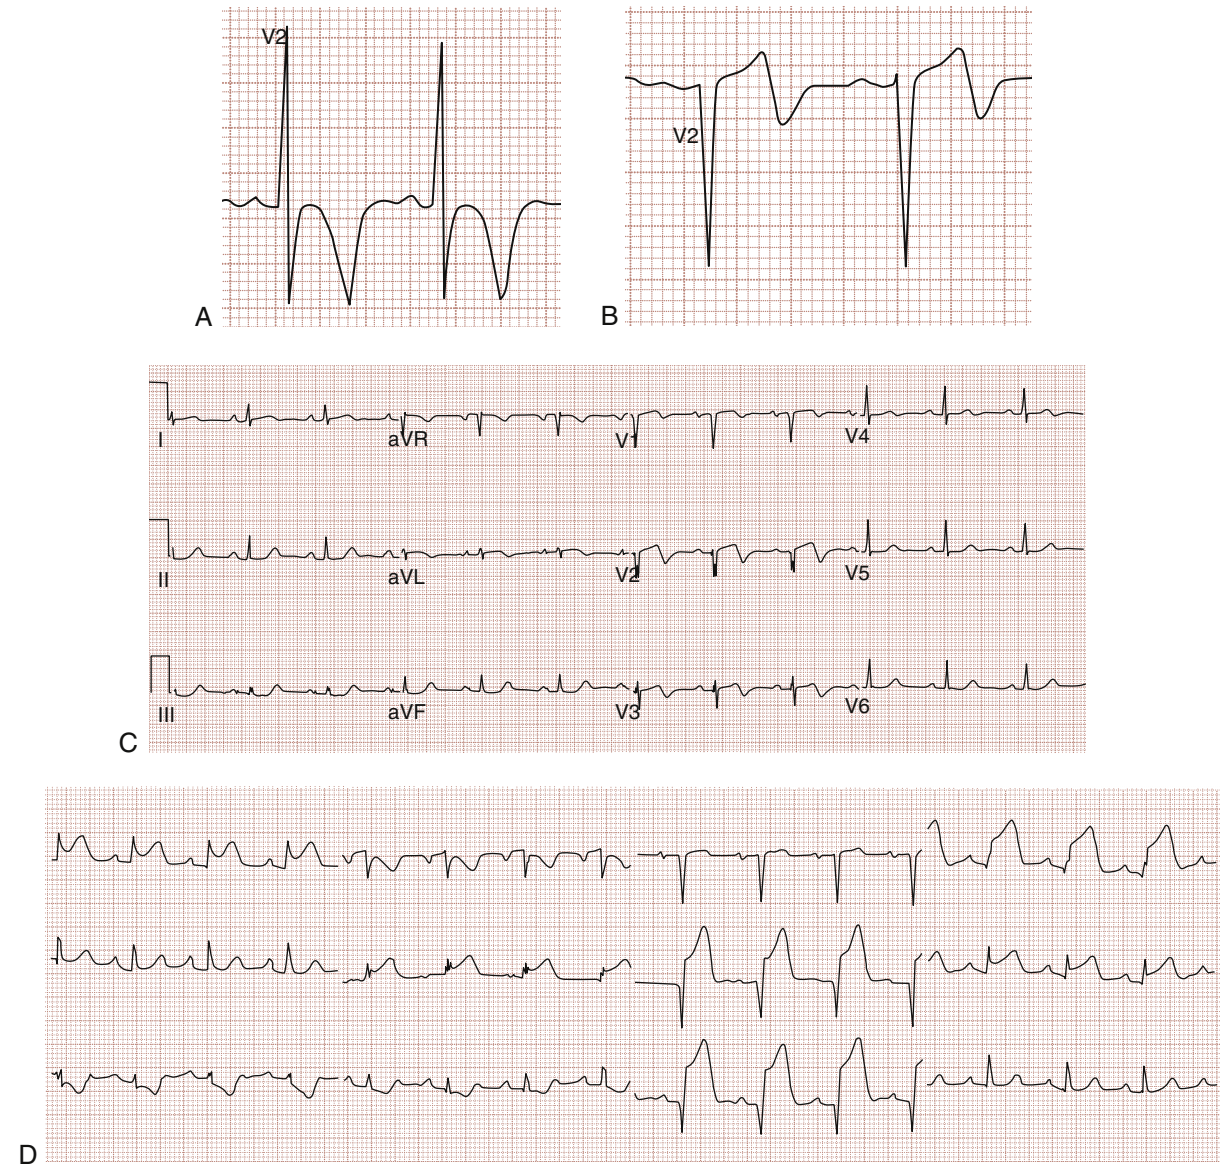

Fig. 64.5 Wellens syndrome. (A) Deeply inverted T waves seen in 75% of patients presenting with Wellens syndrome. (B) Biphasic T waves seen in 25% of patients presenting with Wellens syndrome. (C) Middle-aged male presenting with recent chest pain who is currently painfree; ECG demonstrates biphasic T waves in leads V_2 and V_3. (D) ECG in patient from "C" obtained 6 hours later with return of chest pain. Note the extensive anterolateral STEMI with STE in leads I, aVL, and V_2 to V_5. Emergency PCI was performed with stenting of a proximal LAD occlusion.

Although T wave inversion is sought as a harbinger of ACS, it can also occur as an evolutionary change after MI. In MI without culprit artery reperfusion, the T waves may invert as the ST segments return to baseline, although not particularly deeply. Following reperfusion, T wave inversion may follow ST segment elevation in a biphasic or deeply inverted morphology, an appearance much like the T wave changes of Wellens syndrome. The differential diagnosis of T wave inversion is broad and includes ACS, ventricular hypertrophy, bundle branch block, VPR, myocarditis, pericarditis, PE, pneumothorax, Wolff-Parkinson-White syndrome, cerebrovascular accident, hypokalemia, GI disorders, hyperventilation, persistent juvenile T wave pattern, and normal variants.

The emergency clinician must also consider pseudonormalization of the T wave as a potential electrocardiographic indicator of ACS. Pseudonormalization is the ECG finding of an apparently normal-appearing T wave on the ECG replacing a previously inverted T wave during an acute episode of chest discomfort or anginal equivalent. This "normal" appearing T wave may herald acute ischemia.

Q waves are generally representative of irreversible myocardial necrosis but are rarely the sole manifestation of AMI. Pathologic Q waves may emerge within the first hour of infarction but most commonly develop at 8 to 12 hours. It follows that ST segment elevation with concomitant Q waves does not preclude consideration of emergent reperfusion therapy; the patient's history is vital in considering the time of onset of continuous chest discomfort. Q waves may persist after MI as enduring markers of previous infarction on the ECG but may also disappear with time, regardless of whether the infarcted territory was reperfused.

Anatomic Location of Acute Myocardial Infarction

The regional distribution of an AMI can be derived from noting the pattern of the various morphologic changes that are described (Table 64.4).

Anterior infarctions are primarily evidenced by changes in the precordial leads V_1 to V_4 (Fig. 64.6). Septal involvement is reflected by changes in V_1 and V_2. Extension to the lateral wall (i.e., anterolateral MI) is evident if the pathologic changes extend beyond leads V_1 to V_4 to include leads V_5, V_6, I, and aVL (Fig. 64.7). In anterior STEMI, reciprocal ST segment depression may occur in leads III and aVF. The anterior wall is served by the left anterior descending artery. The first diagonal branch of the left anterior descending artery is likely to be involved when the ST segment elevation extends to leads I and aVL. Isolated occlusion of the diagonal branch of the left anterior descending artery displays similar findings, but of smaller amplitude, as those seen with left anterior descending artery occlusion (ST segment elevation in leads V_2 and V_3, and possibly leads V_1 and V_3, or both, along with ST segment depression in lead II and III, aVF, or both). Anterior or anterolateral STEMI resulting from left main coronary artery occlusion is a high-risk presentation; the ability to identify this high-risk

TABLE 64.4 Regional ST Segment Changes in Acute Myocardial Infarction (AMI)

Location	Leads	ST Segment
Anterior wall STEMI	V_1–V_4	Elevation
Lateral wall STEMI	I, aVL, V_5, V_6	Elevation
Inferior wall STEMI	II, III, aVF	Elevation
Right ventricular wall AMI	V_4R	Elevation
Posterior wall AMI	V_8, V_9 V_1–V_3	Elevation Depression

STEMI, ST segment elevation myocardial infarction.
Adapted from: Aufderheide TP, Brady WJ. Electrocardiography in the patient with myocardial ischemia or infarction. In: Gibler WB, Aufderheide TP, eds. *Emergency Cardiac Care*. St. Louis: Mosby; 1994.

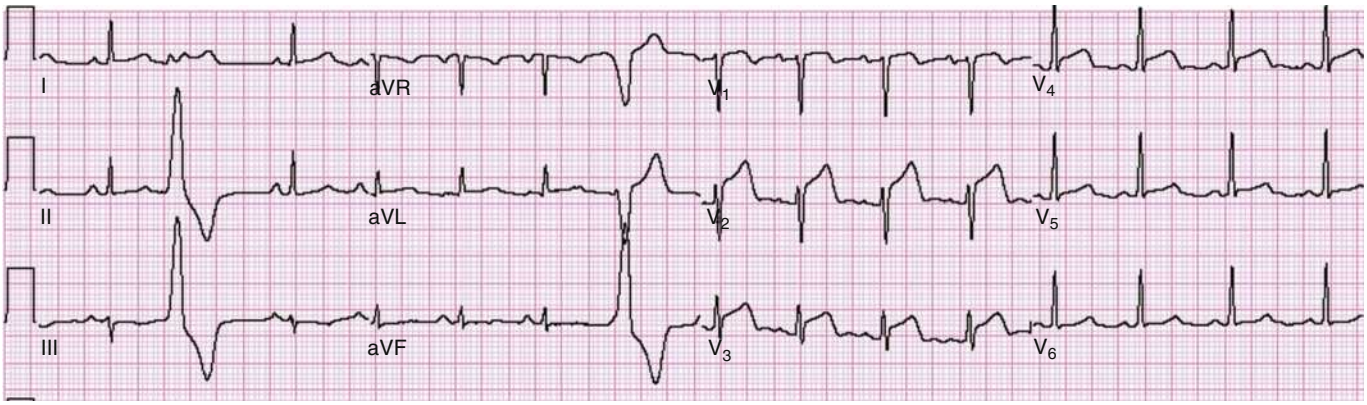

Fig. 64.6 Anterior wall acute ST segment elevation myocardial infarction (STEMI). ST segment elevation is evident in leads V_1 to V_4. The morphology seems obliquely straight. Emergency cardiac catheterization revealed a 90% stenotic lesion in the left anterior descending artery; the patient did well after placement of a coronary stent but showed serum marker evidence of acute myocardial infarction (AMI).

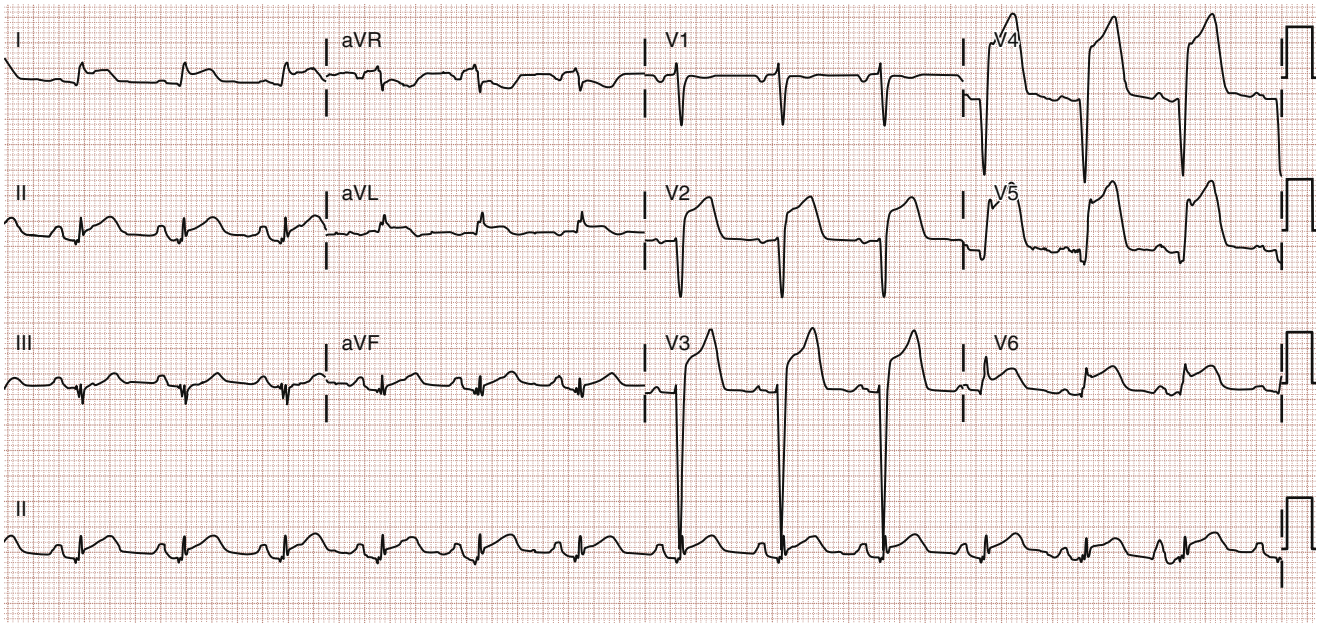

Fig. 64.7 Anterolateral ST segment elevation myocardial infarction (STEMI) with STE in leads V_2 to V_6, I, and aVL. The patient had previously undergone PCI with placement of an LAD stent 2 years prior. Emergency catheterization was undertaken and revealed a 100% in-stent thrombosis.

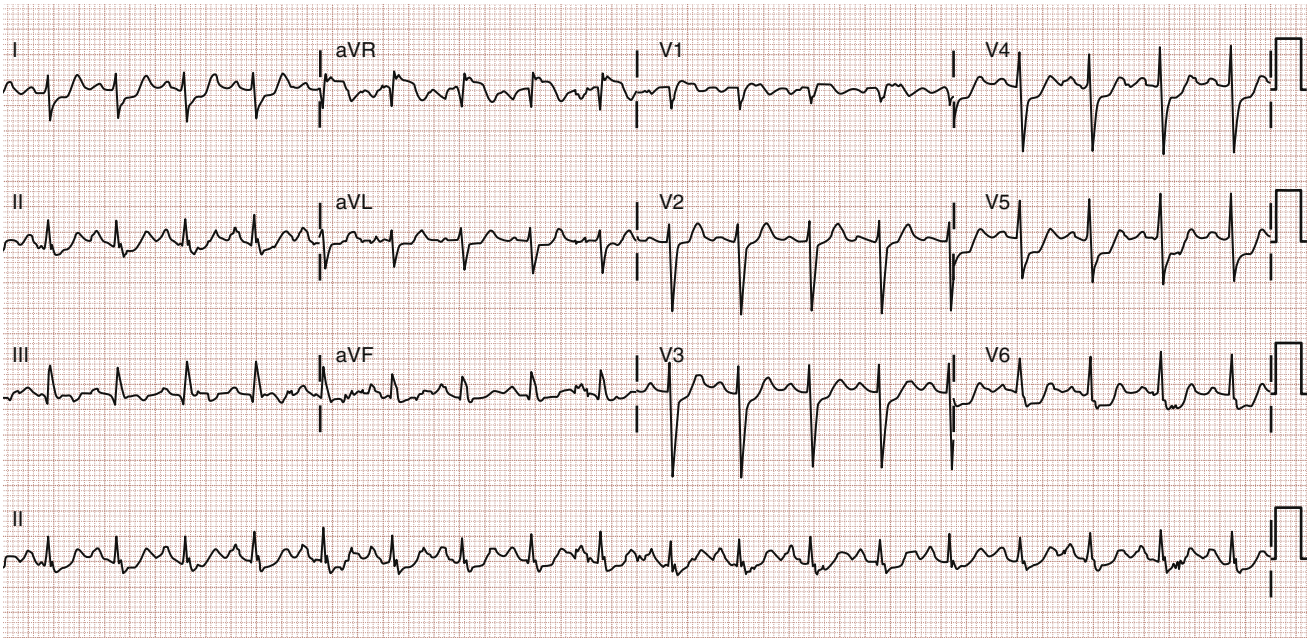

Fig. 64.8 ST segment elevation in lead aVR in a patient with history concerning for ACS. STE of greater than 1 mV is present in aVR. Widespread ST depression is also noted elsewhere on the ECG. The patient underwent catherization and was found to have an 80% stenotic lesion of the left main coronary artery.

STEMI subtype further enables the emergency clinician to adjust therapy appropriately.

In a patient with ACS symptoms, ST segment elevation in lead aVR should prompt consideration of occlusion of the left main coronary artery (Fig. 64.8). Data have demonstrated that ST segment elevation in lead aVR (>0.5 mV) is approximately 78% sensitive and 83% specific for left main coronary artery disease. Alternatively, this finding in lead aVR may represent multivessel disease, acute proximal left anterior descending occlusion, or, less commonly, left circumflex or right coronary occlusion. Similar findings may also be indicative of diffuse endocardial ischemia due to hypoperfusion. If ST segment elevation occurs in leads aVR and V_1, greater elevation in the former lead favors left main disease, whereas if it is greater in the latter lead, occlusion in the left anterior descending artery is more likely.

The so-called de Winter ECG pattern represents another presentation suggestive of ACS. The electrocardiographic findings associated with this presentation include prominent T waves with J point depression producing ST segment depression seen in the precordial leads, coupled with ST segment elevation in lead aVR (Fig. 64.9). Like Wellens syndrome, this presentation is associated with proximal left anterior descending artery lesions. These patients are usually ill-appearing with ongoing chest discomfort. ECG findings may progress to classic anterior STEMI, however lack of progression has also been associated with significant left anterior descending occlusion and subsequent large myocardial infarction. As such, some have advocated treatment of the de Winter syndrome as a so-called STEMI-equivalent.[6]

Lateral infarctions are frequently seen in concert with anterior infarction (anterolateral), inferior infarctions (inferolateral), or inferior infarctions with posterior extension (inferoposterolateral). This is because the lateral wall of the heart is variably served by the left anterior descending, right coronary, and left circumflex coronary arteries. Thus, lateral involvement is manifested by changes in some or all of the lateral leads I, aVL, V_5, and V_6 (Fig. 64.10). "High lateral" infarctions are manifest by ST elevation in leads I and aVL and suggest occlusion of the left circumflex coronary artery or first diagonal. The associated

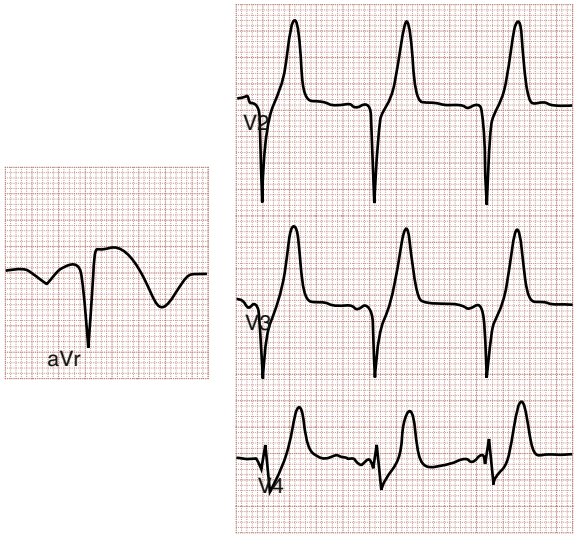

Fig. 64.9 The de Winter electrocardiographic finding, a pattern associated with proximal left anterior descending coronary artery obstruction. In the anterior leads, ST segment depression with depression of the J point is noted along with prominent, hyperacute T wave. In addition, ST segment elevation is also seen in lead aVR.

ECG findings may be subtle and potentially easy to overlook because leads I and aVL are not directly adjacent in the standard 12-lead format. ST segment elevation in these leads may also be accompanied by reciprocal ST segment depression in leads III, aVF, and V_1 (Fig. 64.11).

Inferior infarctions are characterized by morphologic changes in limb leads II, III, and aVF. The inferior wall of the heart and AV node are served by the right coronary artery in about 90% of cases (right dominant); in the remainder, the left circumflex artery serves that function (left dominant). An inferior STEMI is present if two or more contiguous inferior leads (II, III, aVF) are involved; reciprocal

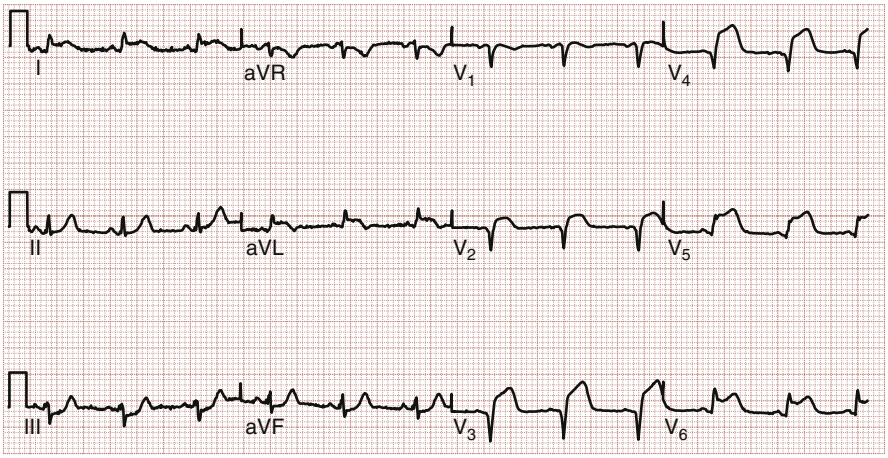

Fig. 64.10 Anterolateral ST segment elevation myocardial infarction. ST segment elevation is seen in leads V_1 to V_4 (anterior leads) and in leads I, aVL, V_5, and V_6 (lateral leads). A proximal left anterior descending artery lesion with thrombus was noted at emergent percutaneous coronary intervention.

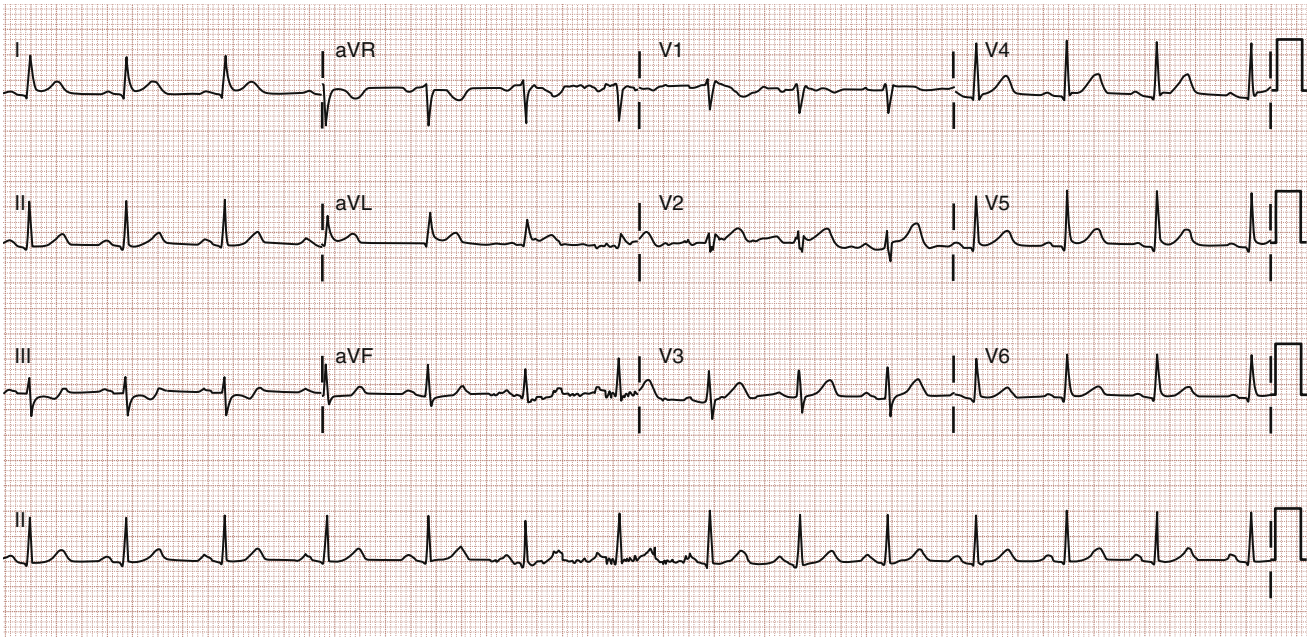

Fig. 64.11 High lateral acute myocardial infarction. ST elevation in leads I and aVL may be indicative of obstruction of the left circumflex, or first diagonal (D1). Findings may be accompanied by reciprocal ST depression in leads III, aVF and V_1. ST elevation in lead V_2 may also be appreciated, as seen here. This patient was taken for emergent catheterization and found to have a 90% stenotic lesion at the bifurcation of the LAD and D1 which was successfully treated with PCI.

ST segment depression is frequently seen in lead aVL, lead I, or both (Fig. 64.12), and perhaps in the anterior precordial leads, V_1 less than V_2 and V_3. ST segment depression in leads V_1 to V_3 in the presence of an inferior MI can be caused by reciprocal change, posterior extension, or simultaneous anterior ischemia during inferior infarction. ST segment elevation inferiorly that is greater in lead III than in lead II, accompanied by ST segment depression in lead aVL, I, or both, is 90% sensitive and 71% specific for right coronary artery occlusion. ST segment elevation in lead V_1 in the presence of an ST segment elevation inferior MI (with elevation greater in lead III than in lead II) suggests concomitant right ventricular infarction. Coexistent reciprocal change with inferior STEMI is associated with larger infarct size and increased mortality. Occlusion of the left circumflex artery may be occult on the 12-lead ECG. If it is responsible for inferior ST segment elevation, the ST segment elevation in lead III would not be expected to exceed that seen in lead II, and lead aVL may display an isoelectric or elevated ST segment.

Posterior infarctions are estimated to contribute to 15% to 20% of all AMIs and usually are seen with inferior or inferolateral infarctions. Posterior infarctions occur in isolation in approximately 5% of AMI cases (demonstrating elevated ST segments only in accessory leads, posterior leads V7 through V9). The culprit lesion may be in the right coronary artery, its posterior descending branch, or left circumflex artery. Because the 12-lead ECG features no electrodes placed directly over the heart's posterior wall, one has only the reciprocal ST segment changes in the right precordial leads (V_1 to V_3) with which to infer AMI of the posterior wall. Findings seen in leads V_1 to V_3 suggestive of acute posterior myocardial infarction include the following:

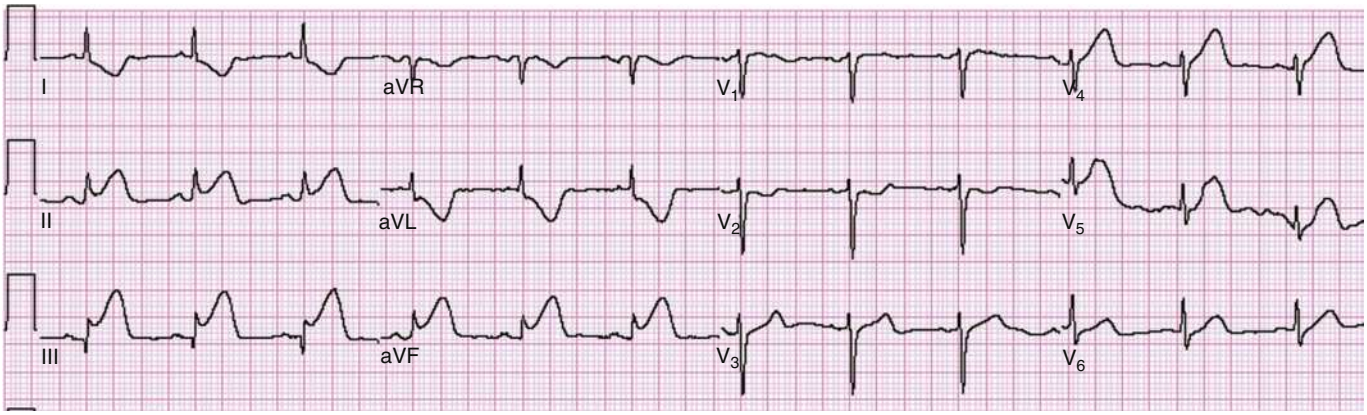

Fig. 64.12 Inferior acute myocardial infarction with reciprocal changes. Marked ST segment elevation is seen inferiorly (leads II, III, and aVF). Classic reciprocal ST segment depression is evident in leads I and aVL.

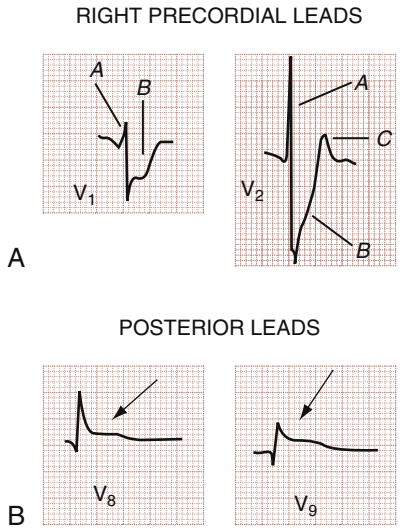

Fig. 64.13 ECG findings of acute posterior wall myocardial infarction. (A) Leads V_1 and V_2, which indirectly image the posterior wall of the left ventricle, demonstrate prominent R waves, ST segment depression (horizontal in lead V_1), and upright T wave (in lead V_2), findings consistent with acute posterior wall myocardial infarction. (B) Additional ECG leads (posterior leads) V_8 and V_9, which directly image the posterior wall, with subtle ST segment elevation, consistent with acute posterior wall myocardial infarction.

(1) horizontal ST segment depression; (2) an upright T wave; (3) tall, wide R wave; and (4) R wave amplitude–to–S wave amplitude ratio greater than 1 (Fig. 64.13). The combination of horizontal ST segment depression with an upright T wave increases the diagnostic accuracy of the 12-lead ECG for acute posterior MI. Furthermore, in that the tall R wave in the right precordial leads is actually the mirror image of a posterior Q wave, its emergence may be delayed in posterior infarction. Additional leads (posterior leads V_8 and V_9) may increase the sensitivity for detection of acute posterior MI. Patients with inferior MI who have ST segment depression in leads V_1 to V_3 or ST segment elevation in the posterior leads V_8 and V_9 generally have larger infarction zones, lower resultant ejection fractions, and higher rates of cardiovascular morbidity and mortality than patients with isolated inferior MI. Cardiac MRI suggests that these so-called posterior infarctions producing tall R waves in leads V_1 and V_2 are actually lateral left ventricular wall MIs. A consensus document has suggested reclassifying posterior infarctions as inferobasal MIs.[3]

Right ventricular infarctions rarely occur in isolation and are usually associated with inferior or inferoposterior MI, although only about one-third of inferior infarctions have associated infarction of the right ventricle. At times, an anterior MI involves some (but <50%) of the right ventricular wall. It follows that occlusion in any of the major coronary arteries may lead to right ventricular infarction, although the right coronary is most commonly involved. Clinically, right ventricular infarction features include elevated jugular venous pressure and hypotension in the setting of inferior wall MI. These findings, however, may also be suggestive of pericardial tamponade. Nitrate-induced hypotension may also be suggestive of right ventricular infarction or tamponade. Bedside cardiac ultrasound can distinguish between these two entities easily with the presence or absence of a pericardial effusion. Initial therapy for both would include volume loading and avoidance of vasodilators or other agents that may lower the blood pressure.

ST segment elevation in lead V_1 in the setting of inferior STEMI (i.e., ST segment elevation in leads II, III, and aVF rather than concomitant ST segment elevation in all anterior precordial leads) is suggestive of right ventricular infarction. This is not surprising because lead V_1 is the most rightward, or right ventricular–oriented, of the precordial leads. These changes occasionally extend into lead V_2 with right ventricular infarction. ST segment elevation is usually greater in lead III than in leads II and aVF when right ventricular infarction coexists with inferior STEMI. The positive vector of lead III (in the frontal plane) is also more rightward than that of leads II and aVF. Application of so-called right-sided precordial leads is the best means to diagnose right ventricular infarction with the ECG. These leads, as a mirror image of the left precordial leads, demonstrate ST segment elevation with right ventricular infarction in leads V_3R to V_6R, with V_4R having the highest sensitivity. Electrocardiographic changes in the right-sided precordial leads with right ventricular infarction may be subtle because of the smaller muscle mass of the right ventricle and resulting diminution in QRS complex size (Fig. 64.14). Patients with inferior STEMI with concomitant right ventricular infarction have larger infarcts, experience more in-hospital complications, and have higher mortality rates.

Electrocardiographic Differential Diagnosis of ST Segment Elevation

ST segment elevation on the ECG in the context of a presentation compatible with ACS is considered to represent STEMI until proven otherwise. Several other conditions, particularly LBBB and LVH, also feature ST segment elevation that mimics infarction (see Table 64.3). ST segment elevation resulting from STEMI is not the most common cause of ST segment deviation in adults with chest pain who are suspected of

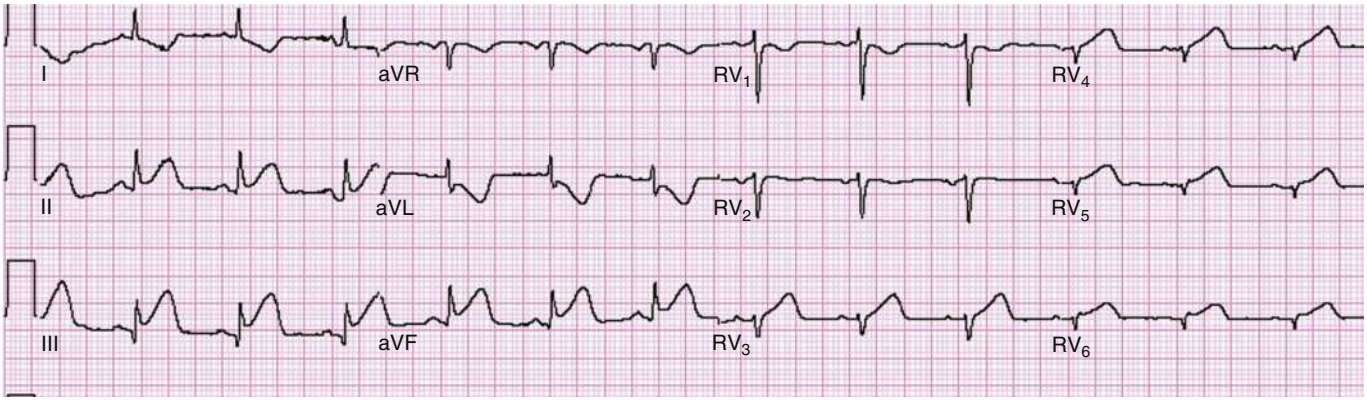

Fig. 64.14 Right ventricular infarction demonstrated with right-sided precordial leads (RV_1 to RV_6). This tracing is taken from the same patient as in Figure 64.12. The ST segment elevation of inferior acute myocardial infarction is still present, as is the reciprocal ST segment depression in leads I and aVL. The precordial leads are right-sided chest leads, as might be inferred from the relatively low voltage. ST segment elevation is noted in leads RV_3 to RV_6 (V_3R to V_6R), consistent with right ventricular infarction.

AMI. Caution is required when interpreting ST segment elevation in regard to the decision to initiate reperfusion treatment, whether it be PCI or fibrinolytic therapy.

Benign early repolarization (BER) is a normal electrocardiographic variant that does not imply or exclude ACS or CAD. BER includes the following electrocardiographic characteristics: (1) ST segment elevation; (2) upward concavity of the initial portion of the ST segment; (3) notching of the terminal portion of the QRS complex at the J point (i.e., junction of the QRS complex with the ST segment); (4) symmetric concordant T waves of large amplitude; (5) diffuse ST segment elevation on the ECG; and (6) relative temporal stability over the short term, although these changes may regress with advancing age. J point elevation is usually less than 3.5 mm, and the concave ST segment is usually elevated less than 2 mm in the precordial leads (although it may be elevated as much as 5 mm in some cases) and 0.5 mm in the limb leads. Maximal ST segment elevation in BER is typically seen in leads V_2 to V_5. Isolated BER in the limb leads is rare and should prompt reconsideration of STEMI (Fig. 64.15A and 64.16).

Pericarditis, in the acute phase, also features diffuse ST segment elevation. In pericarditis, the ST segments are concave, with an initial upsloping contour, and are usually less than 5 mm in height. Occasionally, the initial contour is obliquely flat, but convex or domed ST segment morphology strongly suggests STEMI. The ST segment elevation is usually seen in all leads except for aVR (where it is depressed); V_1 is variable. Focal pericardial inflammation manifests as a more accentuated change in the leads reflecting the affected region. PR segment depression is an insensitive yet specific associated electrocardiographic finding in pericarditis, which is typically best seen in the inferior leads and lead V_6; correspondingly, PR segment elevation may be evident in lead aVR (Fig. 64.17 and Fig. 64.15B). The pericardium is electrically silent; thus, ST segment changes result from epicardial irritation. Hence, the most appropriate term is *myopericarditis*, rather than pericarditis.

Left ventricular aneurysm (LVA), wherein a focal area of myocardium paradoxically bulges outward during systole, has characteristic electrocardiographic changes that can be difficult to differentiate from STEMI. Considerable overlap exists between populations of patients with potential for STEMI and LVA, and the electrocardiographic changes of LVA tend to be regional rather than diffuse. Anatomically, LVA is usually found anteriorly, and changes are most often seen in leads V_1 to V_6 and leads I and aVL. ST segment elevation may be of any morphology (e.g., convex or concave), and Q waves may be present

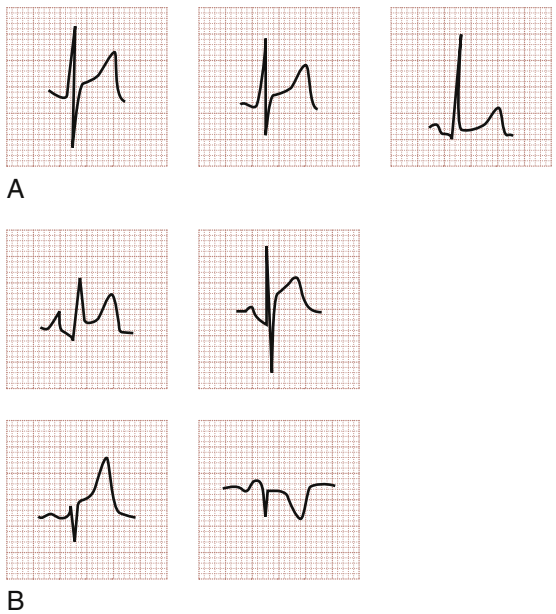

Fig. 64.15 Noninfarctional ST segment elevation (STE). (A) Benign early repolarization (BER) with concave STE. (B) Acute pericarditis with concave STE and PR segment depression (*upper two panels*); concave STE without PR segment abnormalities (*lower left panel*); and reciprocal STE and PR segment elevation in lead aVR (*lower right panel*).

(Fig. 64.18). The calculation of the ratio of the amplitude of the T wave to the QRS complex may help distinguish acute anterior MI from LVA. It has been shown that if the ratio of the amplitude of the T wave to the QRS complex exceeds 0.36 in any single lead, the ECG probably reflects STEMI. If the ratio is less than 0.36 in all leads, however, the findings are likely the result of a ventricular aneurysm.

LBBB is a confounding pattern that reduces the ECG's ability to indicate ACS. Furthermore, in a clinical situation strongly suggestive of ACS, a new LBBB may indicate ACS. Its sole presence, however, should not prompt AMI management. LBBB, whether new or preexisting, shares many similarities to various electrocardiographic findings of ACS. In the right precordial leads (leads V_1 to V_3), ST segment elevation and tall, vaulted, upright T waves mimic those seen in anterior STEMI. The QS pattern of LBBB in these leads resembles the Q waves seen in infarction. Depressed ST segments with T wave inversions are

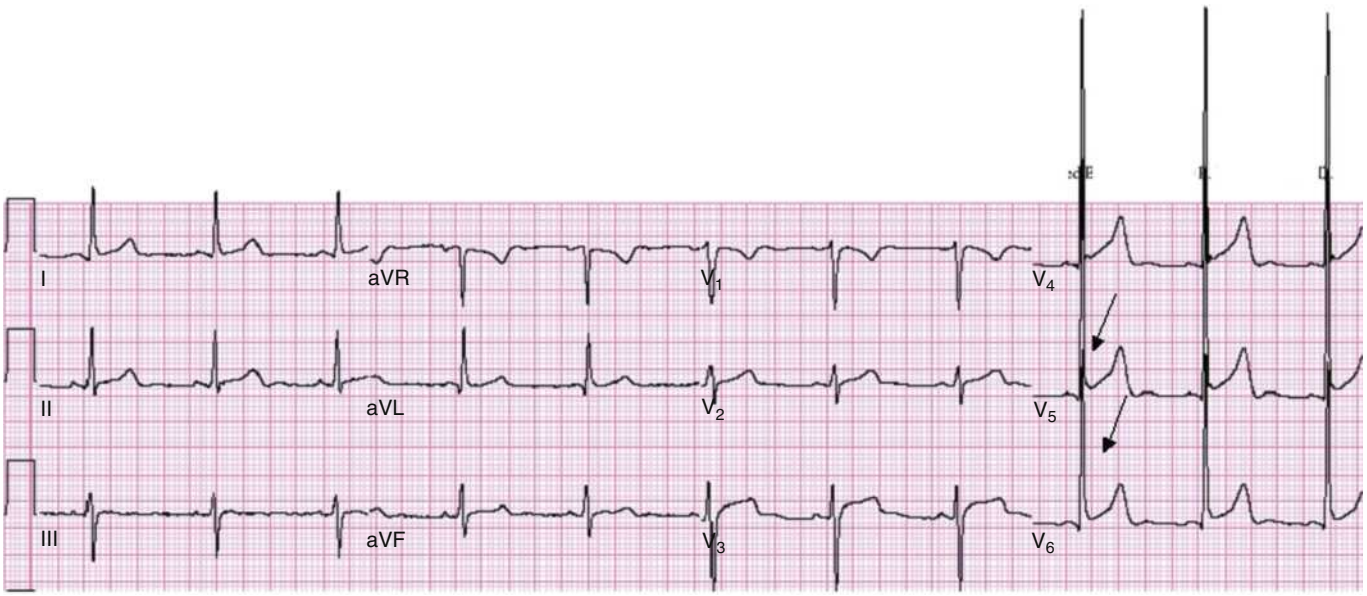

Fig. 64.16 Benign early repolarization. Note the upwardly concave ST segment elevation, best seen in leads V_4 to V_6. The T waves are relatively large in the same leads. Subtle irregularity of the J point is also seen in leads V_5 and V_6 (arrows). Prior electrocardiograms from this patient obtained approximately 18 months prior were unchanged.

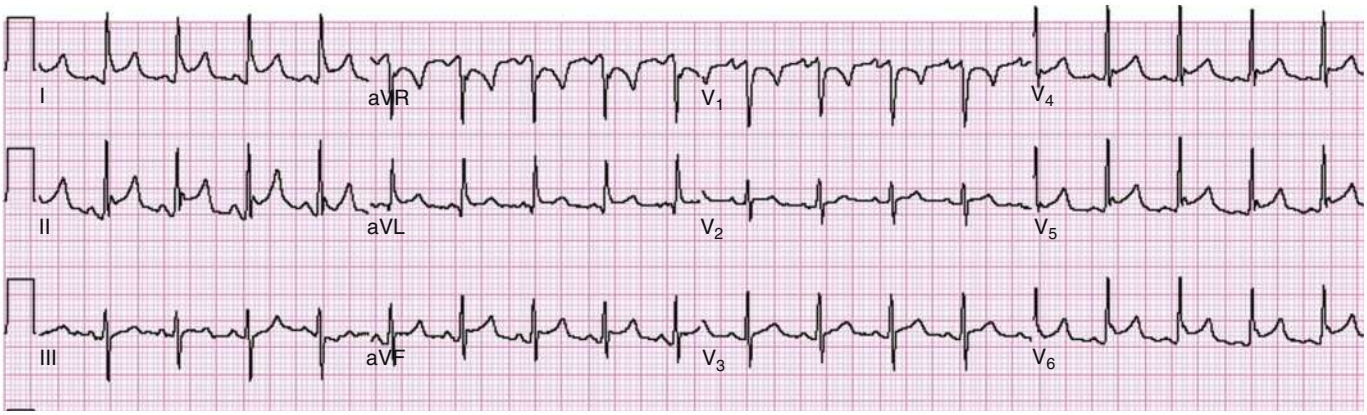

Fig. 64.17 Pericarditis. This tracing demonstrates several classic signs of pericarditis: (1) sinus tachycardia; (2) diffuse, concave upward ST segment elevation; (3) PR segment depression, best seen in lead II; and (4) PR segment elevation in lead aVR.

seen in some or all of the lateral leads (leads V_5, V_6, I, and aVL) in LBBB; both of these resemble ischemic changes seen in ACS. However, these findings in LBBB are merely expressions of the so-called "rule of appropriate discordance." The ST segment and T wave vectors are expectedly discordant, or opposite in direction, to the major vector of the QRS complex in those leads. Because LBBB is a frequent finding on the ECG of a patient at risk for CAD, the normal findings in LBBB (Fig. 64.19) and presentation of AMI in a patient with LBBB must be distinguished.

Sgarbossa and colleagues used a large AMI database to obtain a population of patients with LBBB and serum marker confirmation of AMI. Three independent electrocardiographic predictors of AMI in the presence of LBBB were identified: (1) ST segment elevation of at least 1 mm that is concordant with the QRS complex (Fig. 64.20 and 64.21A); (2) ST segment depression of at least 1 mm in lead V_1, V_2, or V_3 (see Fig. 64.20A and 64.21B): and (3) ST segment elevation of at least 5 mm that is discordant with the QRS complex (see Fig. 64.20B and 64.21C). These findings were assigned weighted scores of 5, 3, and 2, respectively. For accuracy in diagnosis, a specificity of 90% requires a score of at least 3. Thus, if an ECG features only discordant ST segment elevation of 5 mm or more but neither of the other two criteria, further testing is recommended before concluding that the ECG indicates AMI.

A more recent variant of the Sgarbossa criteria omits the third component (discordant ST segment elevation ≥ 5 mm) and instead substitutes the ratio of discordant ST segment deviation to S wave amplitude. Excessive discordance, defined by an ST/S ratio of greater than 0.25 is considered diagnostic of AMI (see Fig. 64.21D). This "modified Sgarbossa criteria" reportedly yields increased sensitivity without significant loss of specificity.[7] Ultimately, the approach to the patient with LBBB and possible AMI remains complicated. If the clinical presentation is consistent with AMI, diagnostic adjuncts to the history and physical examination (e.g., serial ECGs, comparison with prior ECGs, echocardiography, serum cardiac marker measurement) should be applied when the ECG is not diagnostic for acute infarction as noted by the Sgarbossa criteria. A newly noted LBBB occurring in a patient

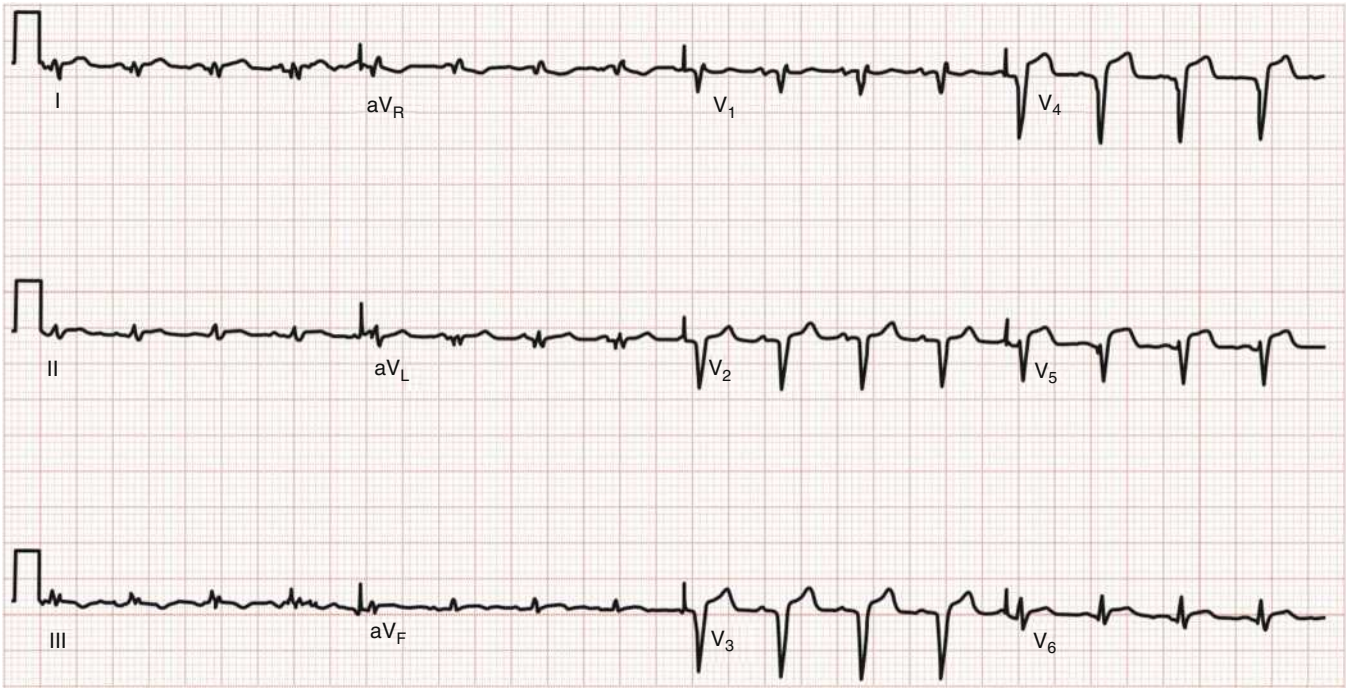

Fig. 64.18 Left ventricular aneurysm. This is a representative example of a 12-lead electrocardiogram from a patient with an anterior left ventricular aneurysm. Note the well-developed, completed Q waves in leads V_2 through V_5 and absence of reciprocal changes in contralateral leads. (Adapted from: Aufderheide TP, Brady WJ. Electrocardiography in the patient with myocardial ischemia or infarction. In: Gibler WB, Aufderheide TP, eds. *Emergency Cardiac Care*. St. Louis: Mosby; 1994: 196-216.)

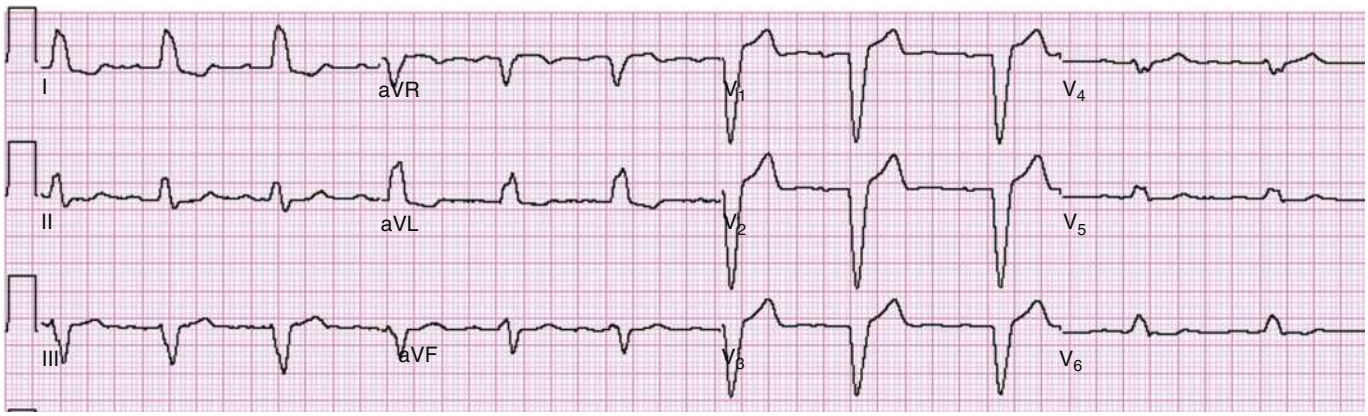

Fig. 64.19 Left bundle branch block (LBBB) with anticipated ST segment abnormalities and no ECG evidence of acute myocardial infarction. This tracing demonstrates the classic findings of LBBB: (1) QRS complex width > 0.12 sec; (2) absence of Q wave in lead V_6; (3) broad monophasic R wave in leads V_5, V_6, I, and aVL; (4) discordant ST segment–T wave changes in leads V_1 to V_3 (simulating acute myocardial infarction), I, and aVL. A first-degree atrioventricular block is also apparent.

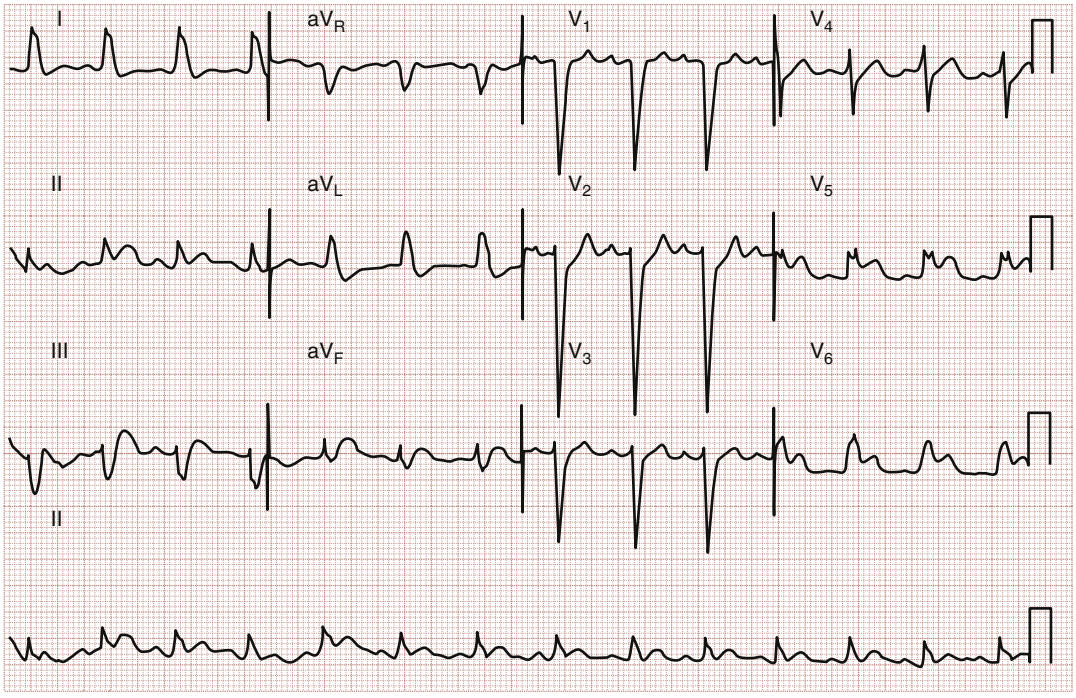
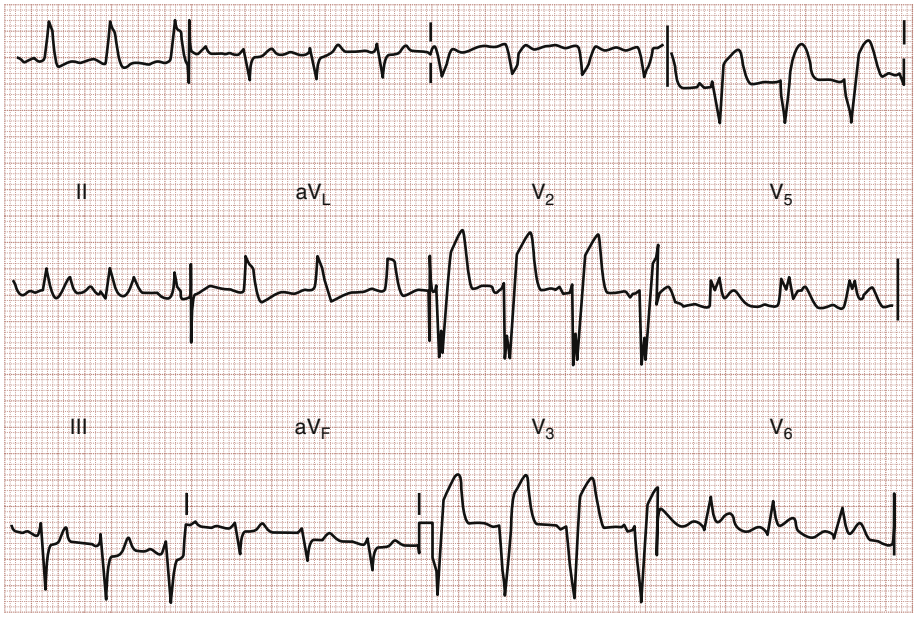
with a compelling presentation for AMI should be considered a high-risk presentation. AMI in this situation is likely.

Ventricular paced rhythms (VPRs) can mimic and mask the manifestations of AMI. VPRs originating in the right ventricular apex create a wide QRS complex, with a pseudo-LBBB pattern. As with LBBB, the right precordial leads in VPR typically feature predominantly negative QRS complexes with discordant ST segments and T waves that are elevated and tall or vaulted, respectively. Unlike LBBB, however, VPR originating in the right ventricular apex often yields a predominantly negative QRS complex in leads V_5 and V_6 as well; this is oriented leftward and slightly downward, whereas the impulse generated from the pacemaker wire is oriented superiorly. Furthermore, small vertical pacemaker spikes immediately preceding the QRS complex should be a clue to VPR although, at times, these deflections are hard to detect on the 12-lead ECG.

Limited data exist to guide the emergency clinician in interpreting the 12-lead ECG in this setting. As with the LBBB scenario, the VPR pattern represents a significant confounding variable in the evaluation of the patient with chest pain suspected of having ACS. Sgarbossa and associates have advanced criteria for the detection of AMI in the presence of VPR that were derived from the same database of patients and are essentially the same as the LBBB criteria: (1) ST segment elevation of at least 5 mm discordant with the QRS complex; (2) ST segment elevation of at least 1 mm concordant with the QRS complex; and (3) ST segment depression of at least 1 mm in lead V_1, V_2, or V_3 (Fig. 64.22).



A



B

Fig. 64.20 Acute myocardial infarction (AMI) in left bundle branch block (LBBB). (A) Using the modified Sgarbossa criteria, there is strong evidence of AMI because of the concordant ST segment elevation greater than 1 mm in leads II, V_5, and V_6. Also suggestive of AMI is the concordant ST segment depression seen in lead V_2. (B) Again, using the modified Sgarbossa criteria, there is strong evidence of AMI due to the concordant ST segment elevation in leads V_5 and V_6 which is greater than 1 mm. Furthermore, there is excessive discordant ST segment elevation in leads V_2, V_3, and V_4; the magnitude of this discordant ST segment elevation is greater than 25% of the accompanying S wave. The degree of this discordant ST segment elevation is not proportionally correct for the size of the accompanying negative portion of the QRS complex.

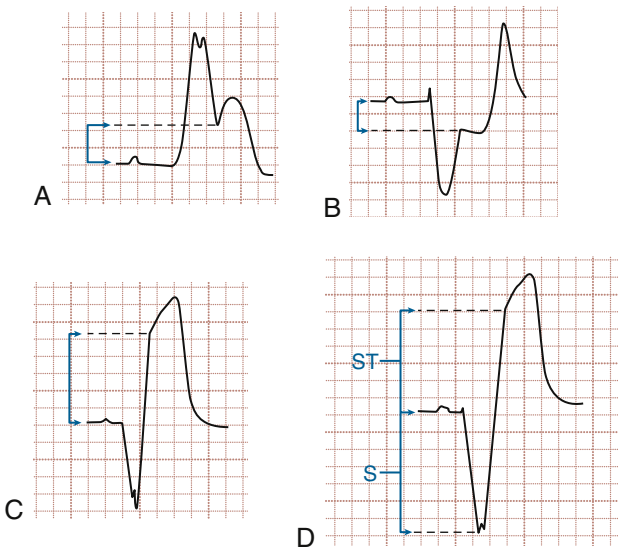


Fig. 64.21 In the presence of LBBB, the Sgarbossa Criteria, as follows, are suggestive of ACS. (A) ST segment elevation of at least 1 mm concordant with the QRS complex. (B) ST segment depression of at least 1 mm in lead V_1, V_2, or V_3 concordant with the QRS complex, and (C), ST segment elevation of at least 5 mm that is discordant with the QRS complex. (D) The modified Sgarbossa criteria utilize the ratio of discordant ST segment deviation to the S-wave amplitude instead of an absolute 5 mm cut-off. An ST to S ratio greater than 0.25 is suggestive of ACS.

LVH may mimic or obscure ACS on the ECG. LVH may feature prominent left-sided forces, manifesting as large rS or QS complexes in the right precordial leads, yet these changes seldom extend beyond V_1 and V_2 in the case of LVH. Consistent with the rule of appropriate discordance, the leads demonstrating such a pattern feature discordant ST segment elevation and tall vaulted T waves, paralleling the changes of AMI. The initial portion of the elevated ST segment in LVH is generally concave, as opposed to the obliquely straight or convex pattern that usually (but not always) is seen with ST segment elevation in AMI. In LVH, the left precordial leads (and, at times, leads I and aVL) may show evidence of a repolarization abnormality (often referred to as a strain pattern), with ST segment depression and asymmetrically inverted T waves. The presence of this strain pattern in the left precordial leads is reassuring when ST segment elevation and tall T waves in the right precordial leads are being attributed to LVH rather than to AMI because one is essentially the mirror image of the other. The changes in LVH should be static over time (Fig. 64.23).

Takotsubo cardiomyopathy is referred to as left apical ballooning or so-called broken heart syndrome. It features ST segment elevation (or deep T wave inversions) without evidence of obstructive CAD. Positive serum markers for cardiac ischemia may be present, as well as hemodynamic compromise. It is characteristically associated with intense emotional stress. Ballooning of the left ventricular apex is seen on ventriculography or echocardiography. Prognosis is excellent, typically with recovery of normal wall motion within 1 month or less.

Non–ST Segment Elevation Myocardial Infarction

Non–ST segment elevation myocardial infarction, or NSTEMI, supplants "non–Q wave MI," previously termed "subendocardial infarction." Precise terminology is difficult because Q waves may disappear with time and the criteria for significant Q waves vary. Moreover, transient ST segment elevation may simply be missed on the ECG. Nonetheless, it is useful to describe the entity wherein there is serum marker evidence of MI in the appropriate clinical scenario but no documented ST segment elevation.

Pathophysiologically, the diseased artery may not have been totally occluded, or the infarct zone may have been partially spared by collateral circulation or therapeutic intervention. Electrocardiographic manifestations of NSTEMI include ST segment depression and T wave inversion, which may be deep and symmetrical; nonspecific ST segment or T wave abnormalities may also be seen in the NSTEMI presentation. Absence of STEMI, however, does not necessarily translate to better outcomes. Previous studies have demonstrated that patients with ST segment depression on the initial ECG have an in-hospital mortality rate similar to that of patients with ST segment elevation or LBBB (15%–16%). Furthermore, ST segment depression in leads V_1 to V_3 or V_4 may herald true posterior infarction on the 12-lead ECG. Acute posterior (inferobasal) MI is one entity wherein emergent revascularization is indicated in the absence of ST segment elevation on the 12-lead ECG.

Electrocardiographic Adjuncts in the Diagnosis of Acute Coronary Syndrome

Additional lead ECGs can increase sensitivity for AMI by evaluating regions of the heart prone to electrical silence on the 12-lead tracing. Usually, additional lead ECGs use posterior (leads V_7 through V_9) and right ventricular (V_4R) electrodes, thus constituting the 15-lead ECG (Fig. 64.24). Posterior leads V_8 and V_9 are placed under the tip of the left scapula and at the left paraspinal area at the same level as leads V_4 to V_6. Morphologic changes in the posterior leads may be subtle, mainly because of the increased distance between these electrodes and posterior wall of the heart. Any elevation in these leads is considered ST elevation, even if it is not 1 mm.

Electrocardiographic imaging of the right ventricle is enhanced with the use of the right-sided chest leads V_1R to V_6R (also termed *RV_1 to RV_6*). These leads are placed in mirror image fashion across the right precordium. Of the right precordial leads, V_4R has the highest sensitivity for right ventricular infarction and is the lead of choice to include in the 15-lead tracing. Morphologically, less pronounced changes can be expected in the right-sided chest leads because of the relatively thinner wall of the right ventricle.

Use of the 15-lead ECG may improve diagnostic precision but does not appear to affect the rate of AMI diagnosis, use of reperfusion therapy, disposition, or outcome in all ED patients with chest pain evaluated for ACS. It has been shown that in the subset of ED ACS patients identified as candidates for admission to the cardiac care unit (i.e., high-risk patients), the 15-lead ECG increased the sensitivity of ACS detection by 12%.

Applications for additional lead ECGs include the following: (1) ST segment changes (depression or elevation) in leads V_1 to V_3, in an isolated lead or in more than one; (2) equivocal ST segment elevation in the inferior (II, III, aVF) or lateral (I, aVL) limb leads, or both; (3) all inferior STEMI; and (4) hypotension in the setting of ACS. Additional lead applications can be used, including the 18- and 24-lead ECG; electrocardiographic body mapping using multiple electrocardiographic leads, such as the 80-lead ECG, can also be used. Although it has been suggested that these additional lead ECGs can increase the rate of STEMI diagnosis, the data to indicate when additional ECG leads should be employed are limited and do not represent standard care. In general, opinion-based recommendations suggest that the patient with a classic ACS presentation who lacks significant 12-lead ECG abnormality may demonstrate findings consistent with AMI when additional electrocardiographic leads are applied.

Serial ECGs and ST segment trend monitoring overcome the limitations of the single snapshot of a 12-lead ECG. The use of increased

electrocardiographic surveillance demonstrates diagnostic benefit in patients with recurrent or continuous chest pain, particularly patients with an initially normal nondiagnostic or possible ST segment mimicking syndrome ECG (e.g., ST segment elevation potentially resulting from BER) in whom there is a high clinical suspicion for ACS. The examination of ST segment trends (measured every 20 seconds for at least the first hour) and automated serial ECGs (at least every 20 minutes) in ED patients with chest pain can significantly increase the sensitivity and specificity for detection of STEMI (16%) and ACS compared with just the initial ECG (Fig. 64.25). In patients admitted with nondiagnostic initial ECGs and symptoms consistent with ACS, 12 hours of continuous 12-lead electrocardiographic monitoring in a coronary care unit setting revealed that only serum cardiac marker elevation and presence of ST segment episodes (defined as ST segment elevation or depression > 1 mm different from baseline that endured for at least 1 minute) predict cardiac death or MI.

Limitations of Electrocardiography in Acute Coronary Syndrome

The sensitivity and specificity of a single ECG for AMI are approximately 60% and 90%, respectively. Serial ECGs in the setting of continued or recurrent pain in a patient with a higher clinical suspicion

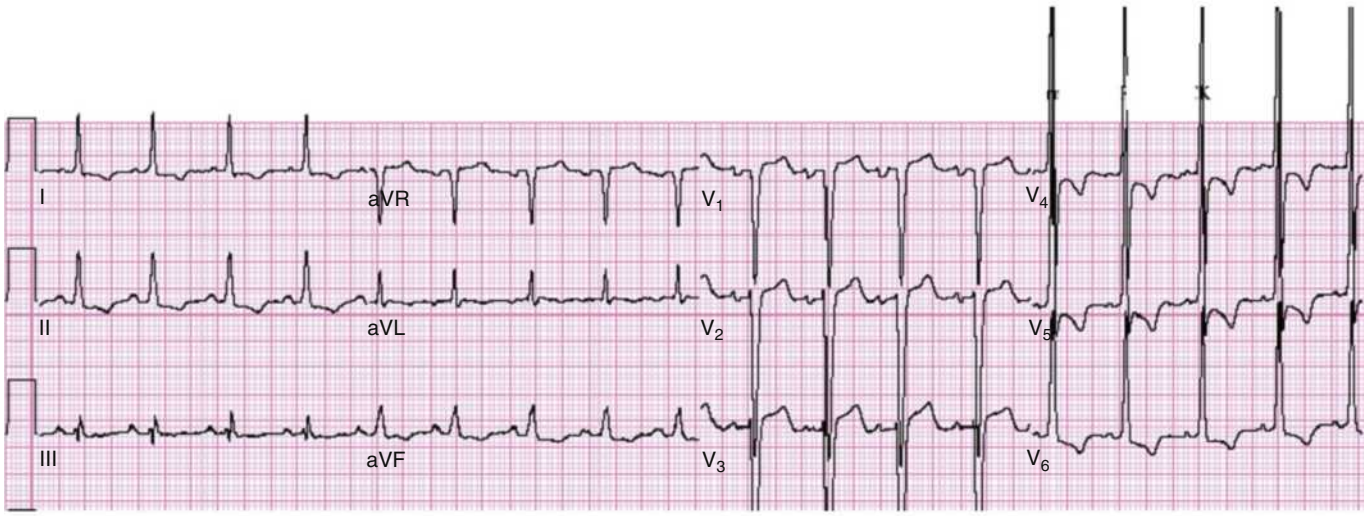

Fig. 64.23 Left ventricular hypertrophy (LVH) with repolarization abnormality. This tracing demonstrates classic repolarization abnormality with ST segment depression and inverted T waves in the left-sided (V_4 to V_6) precordial leads and large amplitude positive QRS complexes (prominent R waves); the T waves in these leads are asymmetrically inverted. The right precordial leads (V_1 to V_3), also demonstrating repolarization abnormality, demonstrate ST segment elevation with concave contour. These ST segment–T wave changes are the anticipated findings of the electrocardiographic LVH pattern with strain pattern; the strain pattern refers to the presence of these ST segment–T wave changes, seen in approximately 75% of patients with the LVH by voltage pattern.

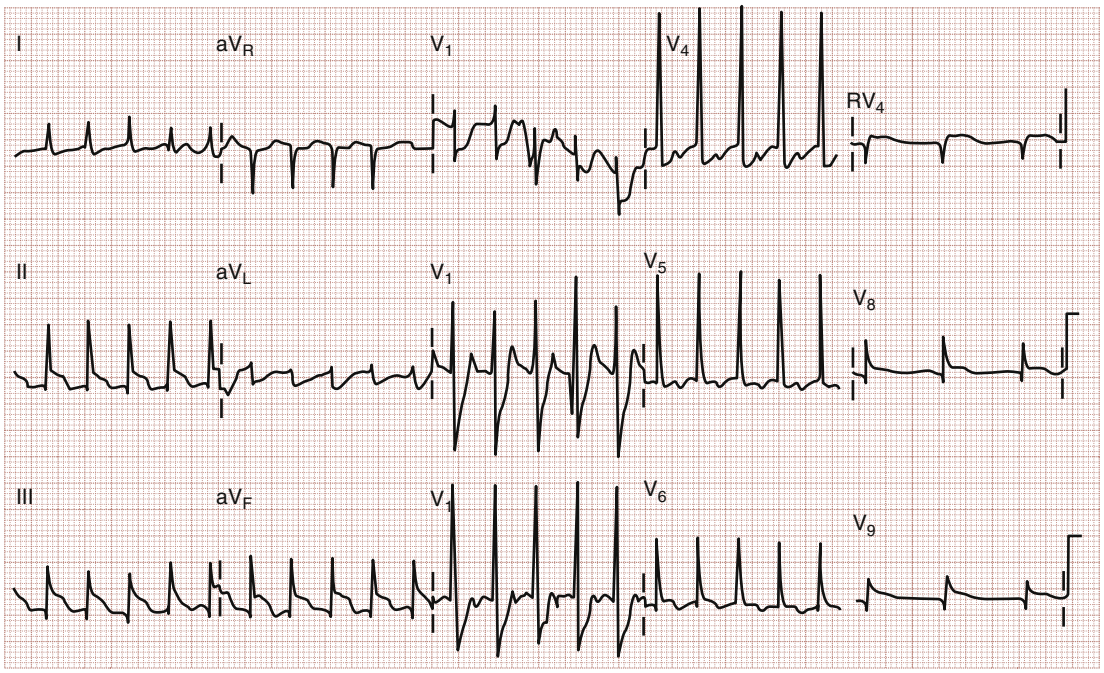

Fig. 64.24 Fifteen-lead electrocardiogram (ECG) with inferior, lateral, posterior, and right ventricular acute myocardial infarction (AMI). The standard 12-lead ECG reveals the typical ST segment elevation (STE) in the inferior and lateral leads, as well as ST segment depression (STD) with prominent R wave in the right precordial leads. Posterior AMI is indicated by the right precordial STD with a prominent R wave and the STE in posterior leads V_8 and V_9. Note that the degree of STE is less pronounced than that seen in the inferior leads because of a relatively longer distance from the posterior epicardium to surface leads. The right ventricular infarction is noted in this case, using the simplified approach with only RV_4, which demonstrates STE of relatively small magnitude.

Fig. 64.25 Serial electrocardiography. (A) Representative example of lead III in a patient with chest pain and an initially nondiagnostic electrocardiogram depicting the evolution of ST segment elevation myocardial infarction (STEMI). (B) Representative example of lead V_2 in a patient with the left ventricular hypertrophy pattern. Serial sampling of this patient with ongoing chest pain and a confounding electrocardiographic pattern reveals the progression to STEMI. (C) Representative example of lead V_3 in a patient with left bundle branch block and evolving acute myocardial infarction (AMI). (D) Representative examples of lead III in a patient with chest pain and noninfarctional ST segment elevation (STE). Note the lack of change (degree of elevation as well as morphology of elevation) over time in this patient with benign early repolarization.

for ACS and an initially nondiagnostic ECG increase the diagnostic value. The initial ECG is nondiagnostic in approximately 50% of patients in the ED who are ultimately diagnosed with STEMI. Moreover, nondiagnostic and even normal ECGs do not exclude the diagnosis for AMI in that about 20% of patients ultimately diagnosed with AMI have nondiagnostic ECGs earlier in their course. As time elapses from symptom onset to electrocardiographic recording, the ability of the ECG to exclude AMI does not markedly increase. Thus, in a patient with a presentation concerning for ACS, a single normal or nondiagnostic ECG does not ensure the absence of ACS, even if the ECG was recorded well after the onset of symptoms. In patients being evaluated for ACS, only serial electrocardiography, combined with serial cardiac marker determinations, can exclude AMI and, even then, UA without actual myocardial necrosis may be present.

Chest Radiography

The chest radiograph does not have typical findings in ACS, but can provide ancillary information. For example, the mediastinal width can be considered an insensitive sign of aortic dissection (see Chapter 71) and pulmonary congestion can be seen in heart failure (see Chapter 67). AMI patients who develop CHF have increased mortality, and therefore, the presence of heart failure on the chest radiograph, present in one-third of AMI patients, indicates higher risk. These patients may benefit from an aggressive therapeutic approach.

The chronicity of the CHF syndrome may also be suggested by heart size. Patients with AMI complicated by pulmonary edema who have a normal heart size usually have no past history of CHF. AMI is the most frequent cause of pulmonary edema with a normal cardiac size. In other cases, patients with AMI and cardiomegaly, with or without pulmonary edema, frequently have a preexisting history of CHF, anterior wall infarct, and multiple-vessel CAD (Fig. 64.26).

Serum Markers

Biochemical markers play a pivotal role in the diagnosis, risk stratification, and guidance of treatment of ACS. The European Society of Cardiology and the ACC have defined AMI diagnosis criteria on biochemical grounds because specific markers, particularly troponins, indicate irreversible cell damage.[3] The advancement in diagnostic tests, as well as medical and interventional therapies for AMI, has made the diagnosis and intervention of AMI in the first minutes to hours of the ED visit not only possible, but essential.

For patients with a nondiagnostic ECG, early elevation of serum markers specific for myocardial necrosis (troponin I or T) confirms a presumptive diagnosis of NSTEMI. Caution is advised, however, when a single initial serum marker level is not elevated. This single test, in the first hours following symptom onset, is currently too insensitive to support a decision that the patient can be discharged or determine that no acute coronary event has occurred.[8] The patient's history remains the most vital portion of the diagnostic evaluation of potential ACS. Serial testing substantially improves the sensitivity of these tests for AMI (Table 64.5 and Fig. 64.27), but if the patient's presentation is consistent with unstable angina, no marker can be used to rule out that diagnosis. A sensitive and specific marker to identify myocardial ischemia without myocardial necrosis is not yet available.

Troponin Testing

The role of cardiac troponin (cTn) measurement in the evaluation of ACS has been well established. Elevation of cTN is demonstrably superior in both sensitivity and specificity to other available biomarkers and,

as such, is the only cardiac marker referenced in the consensus universal definition of MI.[3] Because of this, it is the only biomarker utilized by the HEART score, HEART Pathway, and EDACS-ADP pathway, as well as most other modern decision rules for evaluation of ACS. The term *cardiac troponin* represents two myocardium specific proteins, myocardial troponin I (TnI) and troponin T (TnT), which precede the release of creatine kinase-MB fraction (CK-MB) into the serum during myocardial ischemia. TnI and TnT are very similar in their diagnostic and prognostic value and their serum kinetics and rates of increase and decrease associated with myocardial ischemia, infarction, and ACS.

The biokinetics of troponin release relate to the location of the protein within the cell. Normally, small quantities of troponins are free in the cytosol while most is entwined in the muscle fiber. After injury, a biphasic rise in serum troponin levels corresponds to early release of the free cytoplasmic proteins, followed by a slower and greatly prolonged rise from breakdown of the actual muscle fiber. The slow destruction of the myocardial cell contractile proteins provides a sustained release of the troponins for 5 to 7 days. Serum troponin levels begin to rise measurably in the serum at about the same time as CK-MB level elevations become detectable, as early as 2 to 3 hours after onset, but troponin levels remain elevated for 7 days or more.

Troponin levels as measured by standard, or traditional, troponin assays are generally undetectable in the serum of healthy individuals. An elevated level is defined as that exceeding the 99th percentile in a healthy population. Sensitivity to detect abnormal low troponin levels, however, varies among the multiplicity of existing assays, particularly with respect to TnI. Emergency clinicians, therefore, must be familiar with the sensitivity and limitations of the particular assay used at their institutions and the cutoff concentrations for clinical decisions.

It should be noted that, given the biokinetics of troponin release, a single standard troponin on presentation has limited value in excluding AMI in the first hours of symptom onset and no ability to detect unstable angina without infarction, because cell injury is required to elicit biomarker elevation. As such, in evaluating patients presenting with recent onset of symptoms, serial measurements are recommended.[9,10]

The relatively recent introduction of high-sensitivity troponin (hs-T) into clinical practice has increased the ability to detect ischemia early in the presentation of non-ST elevation AMI. An assay is labeled "highly sensitive" when it results in reportable levels of troponin in greater than 50% of healthy subjects. These assays reduce the window during which troponin elevation remains undetectable in patients with ACS and may aid in more rapid risk stratification. Some clinicians, however, have expressed concerns that increased utilization of hs-T could increase the incidental finding of myocardial injury unrelated to ACS. It is important to note that data indicate that even very low hs-T level elevations are associated with adverse outcomes. This is true not only in patients with chest pain, but also in asymptomatic individuals. Detectable serum troponin levels with a high-sensitivity troponin assay are associated with the presence of structural heart disease and all-cause mortality.

Data increasingly support the use of serial hs-T assay testing with an interval as short as 1 to 2 hours when combined with other appropriate clinical data in the form of a validated accelerated diagnostic protocol (e.g., a nonischemic ECG and low HEART score). Such use can identify patients at risk of 30-day major adverse cardiac event (MACE) with greater than 99% sensitivity.[11] The European Society of Cardiology has recommended a 1-hour serial marker protocol in patients with chest pain with onset greater than 3 hours from presentation with subsequent discharge after two negative markers or only minimally detected troponin without significant rise—the delta—on repeat testing.[12] Other emerging data also suggest that a very low or undetectable hs-T level upon presentation may be sufficient in "ruling out" acute myocardial injury.[13,14] These data require further validation, however, and current expert opinion is that consideration of such a strategy should be reserved for lower-risk patients presenting greater than 3 hours from symptom onset and only with utilization of appropriate, assay-specific cutoffs.[8]

Additionally, it should be noted that troponin elevation in isolation is not diagnostic of ACS. Cardiac conditions that can result in significantly increased troponin levels in patients without evidence of ACS include myocarditis, pericarditis, CHF, LVH, and nonpenetrating cardiac trauma. Although the presence of elevated troponin levels in these conditions might be considered false-positive results, studies have supported the contention that the source of these levels is underlying noninfarction myocyte injury that occurs with these conditions. Troponin elevations can also be seen in noncardiac conditions, including extreme physical exertion, renal insufficiency, and multiple trauma. Troponin level elevation may result from right ventricular dysfunction and myocyte injury in the case of intermediate and high-risk pulmonary emboli (PE) and is a significant predictor of an adverse outcome. Elevated troponin levels have been reported in patients with sepsis and critically ill patients with multiple organ system failure. In each of these subsets of patients, troponin level elevations are associated with increased morbidity and mortality.

Elevated troponin levels are commonly seen in asymptomatic patients with end-stage renal disease. Earlier studies in asymptomatic hemodialysis patients using a high-sensitivity troponin assay have shown that as many as 100% of samples have troponin levels exceeding the 99th percentile value. This finding may relate to the high prevalence of cardiac disease in this population rather than any reduced renal clearance and may still represent subclinical myocardial damage. The TnT isoform is associated with elevated levels in renal failure more often than TnI, particularly in patients undergoing hemodialysis. Elevated troponin levels in the setting of renal failure are associated with increased risk of death and major cardiac and vascular morbidity and should not be ascribed to chronic renal failure unless old records are available to corroborate that the elevated troponin level is actually the patient's baseline level. In unclear circumstances, it is prudent to measure a repeat

troponin level to elucidate whether the elevated level may represent acute myocardial injury.

Other Serum Markers

Creatinine phosphokinase (CK) is found in large quantities, not only in cardiac muscle but also in skeletal muscle, brain, kidney, lung, and GI tract. Myocardial cells are the most abundant potential sources of CK-MB; thus, the appearance of CK-MB in the serum is highly suggestive of MI. The CK-MB fraction remains the best alternative to troponin levels as a cardiac marker. In the setting of AMI, CK-MB is released and is detectable in the serum as early as 3 hours after onset of the necrosis, peaks at 20 to 24 hours, and becomes normal within 2 to 3 days after injury. Unfortunately, skeletal muscle contains small amounts of CK-MB, particularly the pelvic musculature. Abnormal CK-MB level elevations may be seen in patients with trauma, muscular dystrophies, myositis, and rhabdomyolysis, and after vigorous exercise. Because of this lack of specificity, CK and CK-MB are used rarely in contemporary EDs. As troponin level assays have become more sensitive, with detectable levels in the serum preceding CK and CK-MB changes, CK-MB has been virtually eliminated from the modern clinical decision rules for ACS evaluation in the ED.

Myoglobin, a small protein (17 kDa) found in muscle tissue, is rapidly released into the circulation after cellular injury. In cases of myocardial injury, the myoglobin level rises in the initial 1 to 2 hours, peaks at 5 to 7 hours, and returns to baseline by 24 hours. Because of its rapid rise, myoglobin was previously used as an early indicator of myocardial injury. Myocardial myoglobin, however, is not currently distinguishable immunologically from skeletal muscle myoglobin. Thus, the myoglobin level is elevated in any clinical situation involving the skeletal muscle, such as trauma, exercise, and significant systemic illness. In addition, myoglobin level increases are seen in patients with renal failure because of reduced clearance. Despite its high sensitivity for AMI, particularly early in the course of ACS, myoglobin has largely fallen out of favor due to its lack of specificity for myocardial injury.

Biochemical assays for potential new cardiac markers for necrosis are being developed in the hope of finding those with improved sensitivity, risk determination capability, and prognostic power. One such cardiac-specific myonecrosis marker is heart-type, fatty acid–binding protein. Another, ischemia-modified albumin (so-called cardiac albumin), is a potentially useful ACS biomarker that reportedly detects early myocardial ischemia rather than the later myocyte necrosis. Its level may be elevated even earlier than myoglobin. Other potential ischemia markers include unbound free fatty acid and whole blood choline levels.

A variety of biochemical markers for inflammation and plaque instability may have value in evaluating the risk of a cardiac event. Chief among these are the inflammatory markers C-reactive protein (CRP) and high-sensitivity CRP (hsCRP), which have long-term prognostic value for cardiac events in healthy individuals and potential short-term prognostic value when combined with other markers for ACS. Elevated plasma levels of myeloperoxidase, an abundant leukocyte enzyme found in vulnerable coronary plaques that have ruptured, predict the short-term risk of adverse cardiac events, even with negative cardiac troponin levels and no evidence of myocardial necrosis. However, none of the biochemical markers of ischemia (without necrosis) or inflammation have yet shown significant diagnostic value for ACS in the ED setting.

Markers of hemodynamic status, including the natriuretic peptides, may also be useful in the evaluation of ACS patients. These markers have shown value in determining future prognosis, rather than in making the diagnosis of ACS in the ED. These markers, such as B-type natriuretic peptide (BNP) and NT-proBNP (N-terminal pro-BNP), are released from cardiac myocytes in response to increases in ventricular wall stress. BNP is generally used as a marker for heart failure but is a useful adjunct to the standard cardiac markers and has good predictive power for recurrent ACS events and cardiac-related deaths, as well as heart failure exacerbations, in patients with AMI. Moreover, the natriuretic peptides are excellent predictors of short- and long-term mortality in patients with UA, NSTEMI, and STEMI.

Historically, multimarker approaches to ACS evaluation were standard practice in the ED. With the advent of standard and high-sensitivity troponin assays, however, multiple studies have shown limited benefit to additional markers in the ED evaluation of ACS. In addition to simplifying the evaluation, it has been shown that there is significant potential cost savings to the hospital by limiting excess cardiac biomarker testing. The multimarker approach does not offer benefit over individual troponin level evaluations for ACS and is no longer recommended.

Exercise Stress Testing

Exercise stress testing for ED patients is feasible, but provocative testing should generally be reserved for patients who have had resolution of symptoms and when suspicion for ACS is low to moderate. Current guidelines suggest that it is reasonable for these patients to undergo provocative testing, myocardial perfusion imaging, or coronary CT angiography (CCTA) prior to discharge or within 72 hours of discharge.[9] It should be noted, however, that such testing in a low-risk population may lead to further downstream testing and intervention without significant reductions in future rates of infarction.[15] As such, it may be reasonable to discharge patients appropriately deemed low-risk with appropriate return precautions and short-term outpatient follow-up.

Previous studies in ED patients with low-risk chest pain (5% incidence of CAD), who underwent exercise testing after negative serial markers and 9 hours of electrocardiographic monitoring in the ED, showed that stress testing had a negative predictive value of 98.7% for the diagnosis of ACS or cardiac event within 30 days. An abbreviated ED-based, so-called rule-out MI protocol, followed by mandatory stress testing, appears to be one effective diagnostic method for detecting symptomatic CAD in low- to moderate-risk patients. Current guidelines on exercise testing state that such testing can be performed when patients are free of active ischemic or heart failure symptoms for a minimum of 8 to 12 hours.[9]

Patients with a high pretest probability of CAD have a significant rate of false-negative results, and patients with a low pretest probability have a significant rate of false-positive stress test results. The specificity of the test is decreased in the presence of underlying electrocardiographic abnormalities secondary to medications, electrolyte abnormalities, LVH, or artifact. A false-positive test outcome may result from aortic stenosis or insufficiency, hypertrophic cardiomyopathy, hypertension, arteriovenous fistula, anemia, hemoglobinopathies, low cardiac output states, chronic obstructive pulmonary disease, digitalis toxic states, LVH, hyperventilation, mitral valve prolapse, or BBBs. A higher rate of false-positive test results in women may decrease the usefulness of graded exercise testing in this population.

Echocardiography

Two-dimensional echocardiography detects regional wall motion abnormalities associated with ACS due to the close correlation between wall motion and myocardial blood flow. Impaired myocardial contractility can range from hypokinesis to akinesis, with associated impaired myocardial relaxation during diastole. After AMI, paradoxical wall motion and decreased ejection fraction observed during systole indicate the subsequent loss of muscle tone from necrosis.

TABLE 64.6 Emergency Department Bedside Echocardiography in Acute Coronary Syndrome—Pros and Cons

Pros	Cons
• Readily accessible, portable • Inexpensive • Safe, noninvasive • Detection of wall motion abnormalities, useful for early diagnosis and presentations involving diagnostic uncertainty • Identification of nonischemic causes of symptoms	• Skill level—operator- and interpreter-dependent • Limited sensitivity, particularly in small areas of myocardial injury • Limited visual windows in ≈10% of patients • Inability to distinguish acute wall motion abnormalities from chronic

Particularly in individuals with nondiagnostic ECGs, the presence of regional systolic wall motion abnormalities in a patient without known CAD is a moderately accurate indicator of AMI or infarction, with a positive predictive accuracy of about 50%. When echocardiography is performed shortly after ED arrival, during an episode of chest pain, wall motion abnormalities have been detected in up to 90% of patients with ACS. The age of wall motion abnormalities, however, often cannot be determined without prior echocardiograms for comparison.

The absence of segmental abnormalities (presence of normal wall motion or diffuse abnormalities) has a significant high negative predictive value, as high as 98% for cases of suspected MI. Moreover, segmental wall motion abnormalities can be seen in the zone of acute infarction and in regions of ischemic stunning. Resting echocardiography provides an assessment of global and regional function, an important predictor of complications and mortality in patients with ACS. Prior studies have indicated that patients with mild and localized, as opposed to extensive, wall motion abnormalities have a low risk of ACS complications. In addition, echocardiography can help evaluate other causes of clinical presentations mimicking ACS, including valvular heart disease, aortic dissection, pericarditis, mitral valve prolapse, and pulmonary embolus. Finally, echocardiography is a vital tool to assess for various complications of AMI, including acute mitral regurgitation, pericardial effusion, ventricular septal and free wall rupture, and intracardiac thrombus formation.

Technical limitations restrict the use of echocardiography in the ED. These include the expertise of the operator and of the reader interpreting the study. In addition, the inability of the two-dimensional echocardiogram to distinguish among ischemia, AMI, or old infarction and potential absence of wall motion abnormality in nontransmural infarctions can further limit the use of two-dimensional echocardiography (Table 64.6).

Stress echocardiography, as opposed to resting echocardiography, can detect CAD and assess cardiac function early after an AMI. This can be performed with graded increases in cardiac workload by standardized exercise or pharmacologic adrenergic-stimulating agents, such as dobutamine. Graded dobutamine stress echocardiography assesses myocardial viability and ventricular function within the first few days after an AMI. In addition, vasodilating agents, such as dipyridamole and adenosine, induce heterogeneous myocardial perfusion and reveal functional myocardial ischemia in susceptible patients. Stress echocardiography is superior to conventional treadmill testing for CAD in women. Clinical studies of patients with nondiagnostic ECGs, negative markers, and negative rest echocardiography have suggested a role for emergency pharmacologic stress echocardiography as a provocative test after a period of observation with at least two marker and ECG assessments in a chest pain or ED observation unit.

Myocardial contrast echocardiography (MCE) uses microbubble ultrasonic contrast agents to assess microvascular perfusion and regional function with echocardiography. MCE evaluation of perfusion and regional function allows accurate risk stratification of ED patients with chest pain and nondiagnostic ECGs, even before serum markers are available. Smaller studies have reported low rates of adverse cardiac events in chest pain patients with normal MCE findings after a nondiagnostic ECG and negative serum markers. The clinical value of MCE in the ED, like that of resting and stress echocardiography, remains uncertain.

Myocardial Scintigraphy (Nuclear Imaging)

Radionuclide tracer injection and scintigraphy, such as with single-photon emission computed tomography (SPECT), allows real-time assessment of myocardial perfusion and function. Technetium-99 sestamibi has a slow redistribution to ischemic myocardium. This property allows immediate injection and imaging, which detects altered distribution consistent with some form of ischemic heart disease, followed by subsequent scanning, which provides more definitive data regarding the particular subtype of ACS. In patients with a normal initial study, the likelihood of ACS is extremely low. In patients with an initial study revealing abnormal distribution (i.e., reduced uptake) of the tracer, some form of ischemic heart disease is likely. Subsequent imaging then reveals one of two patterns—normal redistribution (normal uptake) or continued reduced uptake. The redistribution pattern is consistent with active coronary ischemia, and continued reduced uptake is found in patients with MI, remote or recent. Myocardial scintigraphy has promising positive and negative predictive values for cardiac events, with high sensitivity and good specificity for CAD.

Immediate myocardial scintigraphy is useful for detecting ACS and the risk of cardiac events in patients in the ED with atypical chest pain, nondiagnostic ECGs, and low to moderate risk of AMI. Multiple studies have found a relatively high incidence of cardiac events, presence of AMI, and need for revascularization in patients with a positive nuclear scan. A cardiac event's probability is tenfold higher in patients with abnormal scans than in patients with a normal scan. The incidence of cardiac events with a normal scan is <1% for the 30-day period after the index study. Myocardial scintigraphy, if available, can reduce the number of patients admitted from the ED with chest pain who are ultimately determined not to have ACS, without reducing appropriate admissions for patients with ACS.

Coronary Computed Tomography Angiography

Coronary computed tomography angiography (CCTA) is an increasingly utilized noninvasive modality to assess for coronary artery disease in patients who have been ruled out for AMI and other active forms of ACS. In a noninvasive fashion, CCTA may provide information regarding coronary anatomy and stenosis similar to that obtained from cardiac catheterization.

When considering the presence or absence of CAD, CCTA is accurate in the detection of coronary artery obstructive lesions. For example, in a large meta-analysis, the accuracy for significant coronary artery obstructive lesions was very high, assuming that high-resolution, newer-generation CT is used. Figures 64.28A and B illustrate representative CCTA images demonstrating normal coronary anatomy; Figures 64.28C to E illustrates CCTA images with proximal left anterior descending (LAD) artery occlusion.

In symptomatic stable patients with low to intermediate pretest probability of CAD, CCTA may be an appropriate imaging study. CCTA is accurate, not only for the detection of significant coronary obstructive lesions, but is also predictive of outcome. Patients with low- to intermediate-risk chest pain with negative CCTA have a very low

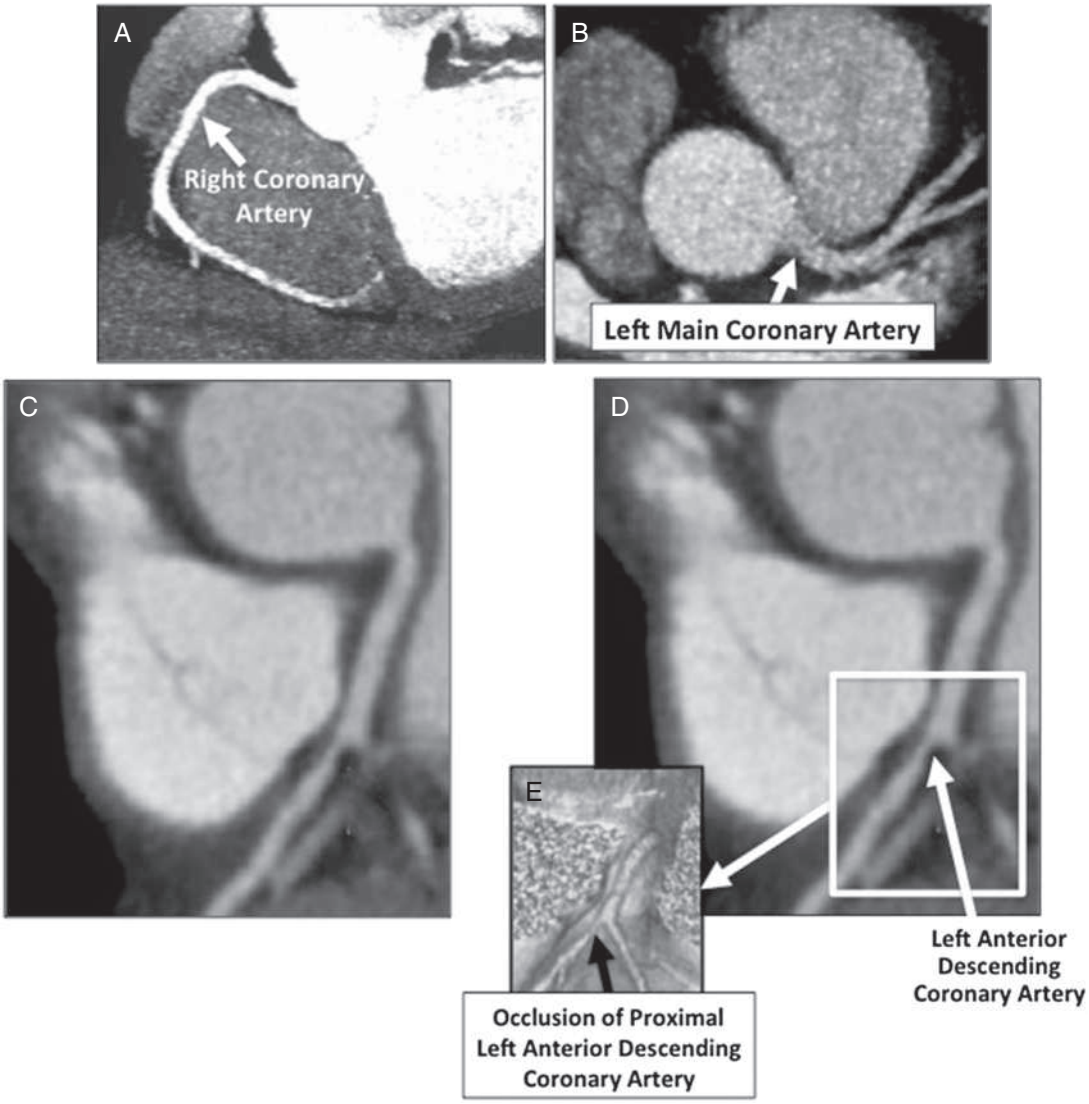

Fig. 64.28 Coronary CT angiography. (A) Normal right coronary artery. (B) Normal left main coronary artery. (C) Left anterior descending coronary artery (LAD) with proximal obstruction. (D) Labeling of LAD obstruction. (E) Three-dimensional image of LAD obstruction.

(<1%) incidence of MACE at 1 year.[16] In initial data of patients seen in the ED with symptoms suggestive of ACS, use of CCTA in the evaluation strategy improved ED throughput, with a reduction in length of stay and reduced rate of admission. An increase in outpatient testing was noted, ultimately resulting in no reduction in overall costs. Subsequent meta-analyses of CCTA studies have demonstrated no significant differences between CCTA and other functional stress testing on mortality or hospitalization for cardiac-related causes; however, they demonstrate a decrease in myocardial infarction patients with stable, but not acute, chest pain.[17,18]

The issue of radiation must also be considered in this study application. Newer CCTA testing modalities are associated with markedly lower doses of radiation. CCTA can be used with relatively smaller exposures to radiation, ranging from 2.0 to 5 mSv. For reference purposes, standard CT scanning and cardiac catheterization are associated with 9 mSv and 12 mSv, respectively.

Thus, in the ED population suspected of ACS, CCTA can be used in patients with low to intermediate suspicion for CAD after some form of ACS evaluation. This testing modality is accurate concerning the identification of significant CAD and prediction of adverse events related to ischemic heart disease. The test requires significant expertise for interpretation, whether by a radiologist or cardiologist. Utility may also be limited by the availability of appropriate equipment and the need for beta-blockade (or appropriately controlled heart rate) before imaging to optimize imaging quality. Although calcium scoring is not considered a useful testing modality in the ED population, calcium scoring may be considered when CCTA is performed. In general, a higher calcium presence in the coronary arteries is associated with less accuracy with the use of CCTA for the demonstration of significant CAD.

Risk Stratification Instruments

Risk stratification tools such as the GRACE risk model (Global Registry of Acute Coronary Events) and TIMI risk score (Thrombolysis in Myocardial Infarction) were derived for inpatients, examining the need for invasive therapy rather than the evaluation of individuals with undifferentiated chest pain. Neither tool was designed to identify patients who may safely be discharged from the ED. More recent developments, such as the Emergency Department Assessment of Chest Pain Score (EDACS), HEART Score, and HEART Pathway, have

TABLE 64.7 The HEART Score

Variable	Score of 0	Score of 1	Score of 2
History	Nonspecific history for ACS, a history that is not consistent with chest pain concerning for ACS	Mixed historic elements, a history that contains traditional & non-traditional elements of typical ACS presentation	Specific history for ACS, a history with traditional features of ACS
Electrocardiogram	Entirely normal ECG	Abnormal ECG, with repolarization abnormalities[a] yet lacking significant ST depression	Abnormal ECG, with significant ST deviation (depression ± elevation), either new or not known to be old (i.e., no prior ECG available for comparison)
Age (years)	Age less than 45 years	Age between 45 & 64 years	Age 65 years or older
Risk Factors[b]	No risk factors	1 to 2 risk factors	3 or more risk factors OR documented cardiac or systemic atherosclerotic vascular disease[c]
Troponin[d]	Troponin < discriminative level ± AccuTroponin I < 0.04 ng/ml	Troponin elevated 1–3 times discriminative level ± AccuTroponin I 0.04-0.12 ng/ml	Troponin elevated > 3 times discriminative level ± AccuTroponin I > 0.12 ng/ml

Total HEART Score: risk category & recommended management strategy
0–3: low risk, potential candidate for early discharge
4–6: moderate risk, potential candidate for observation & further evaluation
7–10: high risk, candidate for urgent or emergent intervention
[a]BBB, LVH, digoxin effect, implanted right-ventricular pacemaker, past MI, ± unchanged repolarization abnormalities.
[b]DM, tobacco smoker, HTN, hypercholesterolemia, obesity, ± family history of CAD.
[c]Peripheral arterial disease, MI, past coronary revascularization procedure, ± stroke.
[d]It is recommended to use the local hospital standards for troponin abnormality determination.

provided ED-appropriate, easily performed, accurate clinical decision tools for use in the ED by the emergency physician.

EDACS is a clinical aid for identifying low-risk individuals with a low short-term MACE rate eligible for discharge from the emergency department.[19,20] EDACS is calculated using demographic, historical, and patient complaint descriptors. After calculation of the EDACS score, serum troponin testing and ECG results are considered in the patient evaluation, illustrating the EDACS-Accelerated Diagnostic Pathway (EDACS-ADP).

Clinical data used in the EDACS-ADP risk calculation include the following: patient age, sex, history of CAD or three or more CAD risk factors, and several chest pain and related complaint descriptors (presence of diaphoresis [higher risk]; pain radiation to shoulder, jaw, neck or arm [higher risk]; pain worsened with inspiration [lower risk]; and pain reproduced with palpation [lower risk]).

In this rule, a history of CAD is defined as previous AMI, CABG, or PCI; CAD risk factors are defined as diagnosed medical conditions (dyslipidemia, diabetes mellitus, hypertension), current tobacco smoker, and family history of premature CAD. The risk score is calculated with patients divided into "low risk" and "not low risk" groups. Low-risk patients with two negative serum troponin values at 0 and 2 hours and an ECG without new ischemic changes can be safely discharged from the ED. Patients requiring additional evaluation include those identified as not low risk or having abnormal diagnostic results (serum troponins or ECG). EDACS-ADP performs reasonably well to identify low-risk patients, although not all studies are supportive.[19,20]

Similar to EDACS-ADP, the HEART Score is another beneficial prediction model for the ED to assist in the identification of low-risk patients, suitable for ED discharge after a limited evaluation.[21-23] This decision tool was developed in the Netherlands as a rapid risk stratification tool for patients with chest pain suspected of AMI in the emergency department. It is accurate in predicting short-term risk of MACE, defined as AMI, need for PCI or CABG, and death within 6 weeks of the index ED visit. Its value to the emergency physician and utility in the ED are based on the following characteristics: ease of use, separation of the patient population into three discrete risk subgroups, accuracy in identifying short-term cardiovascular risk, and readily available variables for calculation.

The HEART Score is easily calculated using information obtained from a standard ED evaluation. Based upon five different variables, the HEART Score is summed, using the patient history of the chest pain event (H), 12-lead ECG (E), patient age (A), risk factor burden (R), and single serum troponin determination (T). Scoring ranges from 0 to 2 for each of these five variables, with the lowest possible total score of 0 and the highest MACE rate possible total score of 10. Low-risk patients (a score 3 or less) were found to have a low rate of MACE (1.7%).These low-risk patients were categorized as appropriate and safe for ED discharge with short-term follow-up and without additional ED cardiac evaluation or inpatient admission; conversely, a higher score was associated with an increased MACE rate and warranted additional evaluation or intervention. In the higher score range, two additional subpopulations were noted, including intermediate- (or moderate) and high-risk groups. The intermediate-risk group, scored in the range of 4 to 6, is associated with a MACE rate of approximately 12% to 17%. The suggested ED evaluation strategy includes the consideration of ED observation and additional risk stratification testing, with or without cardiology consultation. The high-risk group, with a score of 7 to 10, is associated with a MACE rate of approximately 50% to 65%; in this score category, the patient is likely objectively ill and warrants the consideration of coronary intervention as well as admission to the hospital. The HEART score has been validated in many studies, both retrospective and prospective.[22-24]

The HEART Score was designed for use in ED patients suspected of AMI and should not be used in clinical settings outside of the ED population. In addition, an understanding of the five variable components of the HEART Score is mandatory; the application of incorrect variable definitions can result in inaccurate, and thus potentially compromised, scoring (Table 64.7 and Fig. 64.29)

When applying the HEART Score, clinicians can be hesitant to base clinical decision making on a single troponin. Consequently, the HEART Pathway was developed with additional improvement in diagnostic accuracy; it involves a combination of the HEART Score with

an additional troponin obtained at 3 hours.[25] To use this pathway, the clinician determines an initial HEART Score; patients are divided into two groups, including lower (HEART Score 0-3) and higher (HEART Score 4-10) risk groups. A repeat serum troponin is then obtained at 3 hours with further risk categorization into three evaluation-strategy groups: early ED discharge with short-term follow-up (HEART Score 0–3 and serial troponin negative); observation unit or short-term admission with consideration of additional testing (HEART Score 0–3 with serial troponin positive or HEART Score 4–10 with serial troponin negative); and inpatient admission with cardiology evaluation (HEART Score 4–10 with serial troponin positive). The HEART Pathway has been noted to have a higher sensitivity and greater negative predictive value for MACE as compared with the HEART score itself[25] (Fig. 64.30).

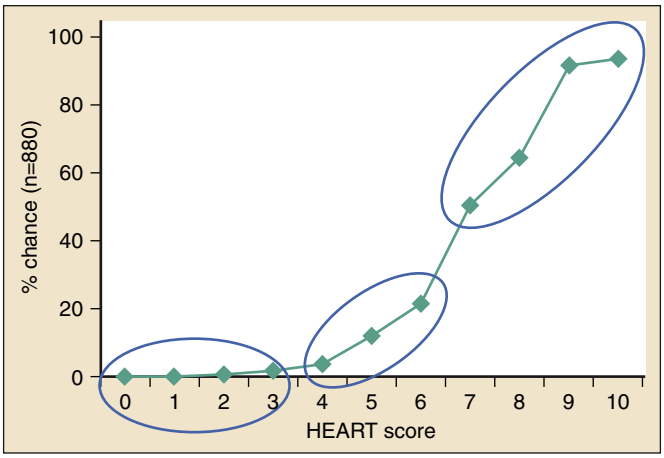

Fig. 64.29 Risk stratification via the HEART score can help identify patients at low, moderate, or high short-term risk of major adverse cardiac events.

Application of any of these decision tools can improve resource utilization in the ED. However, these decision tools applied in isolation of clinician judgment do not dictate evaluation or management strategies of the ED patient suspected of ACS. Treatment and intervention are guided by the patient's condition, local resource availability, and physician assessment.

ED Evaluation of the Chest Pain Patient with Suspected ACS

The ED evaluation of the patient with chest pain, or related complaint, suspected of ACS occurs during three distinct phases of care (Fig. 64.31),

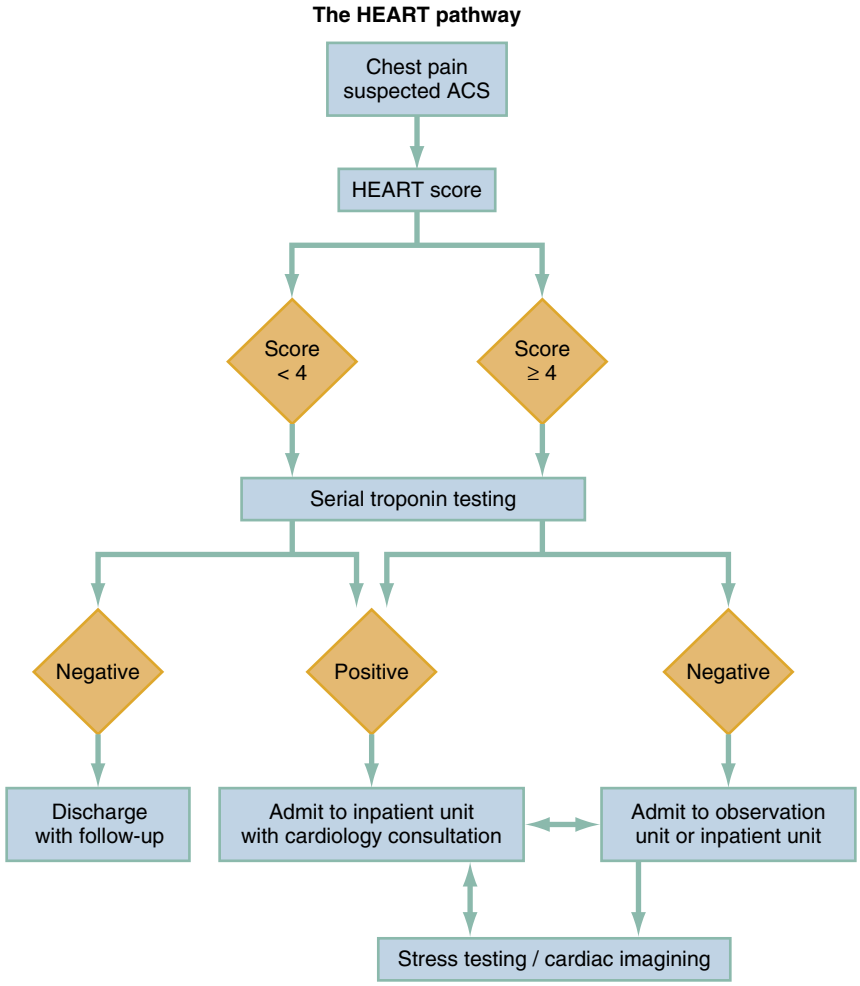

Fig. 64.30 The HEART Pathway utilized a combination of the HEART score and serial troponin testing at 0 and 3 hours. Patients deemed low-risk via the HEART Pathway may be eligible for early ED discharge with short-term follow-up. The HEART Pathway has a higher sensitivity and greater negative predictive value for MACE than the HEART score alone.

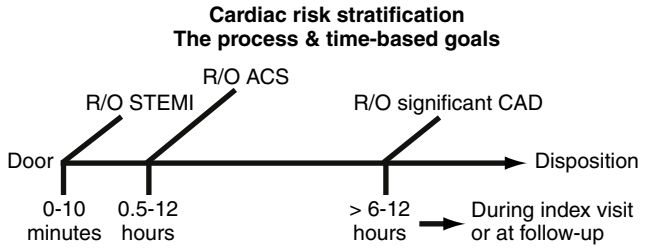

Time period	Goal	Tools
0 to 10 min	STEMI identification	Focused exam & ECG
0.5 to ~6-12 hrs	ACS identification	Serial exam, ECG, & biomarkers
>~6-12 hrs	CAD identification	Potential cardiac imaging

Fig. 64.31 The process of evaluation of the chest pain patient suspected of acute coronary syndrome (ACS) occurs through three distinct phases of care, including ST segment elevation myocardial infarction (STEMI) recognition, rule-out (R/O) acute coronary syndrome (ACS), and consideration of significant coronary artery disease (CAD) phases.

including STEMI recognition, rule-out of ACS, and consideration of significant CAD; this last phase may or may not occur in the ED. During this evaluation, risk assessment occurs. In the first phase, STEMI is the primary diagnostic consideration; rapid performance and competent interpretation of the 12-lead ECG are important goals during this stage so that STEMI is recognized with prompt activation of appropriate ED- and hospital-based resources. These patients are either admitted to the hospital for further care or transferred expeditiously to a more appropriately resourced facility. This phase of evaluation, the recognition of evolving STEMI, is usually quite short, likely less than 10 minutes.

If STEMI or other significant ACS presentation is not found, then the second phase focuses on a traditional rule-out MI approach, in which the patient is monitored clinically as serial ECGs and serum marker determinations are performed. The evolution of STEMI as well as the diagnosis of NSTEMI and significant ACS will be made during this phase of ED evaluation. Alternative diagnoses can be established during this period. If the patient "rules in" for NSTEMI or other significant ACS presentation, inpatient admission or transfer will follow. If the patient "rules out" for AMI and more significant ACS, then the final evaluation phase is considered.

Approximately 75% to 80% of patients with chest pain can be safely evaluated in the ED or observation unit with ultimate discharge to home. Expedited ED evaluations without hospital admissions result in significant cost savings, more appropriate resource utilization, and avoidance of complications related to hospital stays, with typical charges and actual costs ranging from 20% to 50% of the usual inpatient costs. This phase of care is quite variable in length and is largely based on the chosen serum marker determination strategy, ranging from an hour with one troponin sampling up to approximately 12 hours with serial serum biomarker assessments. This approach does require significant and appropriate resourcing of the ED in terms of space, personnel, and equipment.

In this final phase, the consideration of significant (i.e., obstructive) CAD is made. Multiple appropriate pathways, both during the ED stay and also after ED discharge, exist for this last goal and are highly dependent on many factors, including patient presentation features, patient stability, physician judgment, local medical resources, local resource availability, and patient desires; these different pathways include the following strategies:

- ED discharge with no further outpatient evaluation needed;
- Outpatient follow-up with primary care physician or cardiologist;
- Continued additional ED or observation unit evaluation with or without cardiology consultation; and
- Inpatient admission with continued diagnostic evaluation.

The first two dispositions end the ED stay most rapidly with discharge to home whereas the latter two dispositions extend the ED or hospital stay by hours or longer.

Patient risk stratification occurs during the first and second phases of the evaluation, using physician judgment, the results of the ED evaluation, and (potentially) clinical decision rules, such as EDACS-ADP, the HEART Score, and HEART Pathway. High-risk patients, those individuals with identified STEMI and other significant ACS presentations (i.e., obviously abnormal ECG, elevated serum troponin values, higher EDACS-ADP score, HEART score, or HEART Pathway result, or other significant clinical issues), are managed appropriately with inpatient admission or expeditious transfer to a resource-appropriate facility; furthermore, those patients with alternative non-ACS findings noted during evaluation are managed according to the specific diagnoses. Removing these ill patients from the consideration leaves the intermediate- and low-risk individuals.

These remaining patient groups, both in the intermediate- and low-risk categories, are identified using a range of qualitative and quantitative methods. The intermediate risk patient, identified by physician gestalt, diagnostic study results, ED course, or clinical decision rules, requires additional evaluation during that hospital visit. If used, intermediate HEART score or HEART Pathway results are found in this patient subgroup.

The intermediate-risk patient's continued evaluation can occur in the ED, an observation unit, or as an inpatient. The observation unit strategy can be employed in a specific unit designed for this type of evaluation; alternatively, the observation unit methodology can be employed in the ED, in essence using a virtual observation unit strategy. Regardless of the location within the hospital, a chest pain–accelerated diagnostic protocol is an appropriate approach to intermediate-risk patients. Many EDs, in partnership with cardiology, employ further ACS evaluation with stress testing, echocardiography, coronary CT angiography, or myocardial scintigraphy before disposition. Studies have compared the observation unit approach with the traditional hospital admission to rule out MI, showing a significant reduction in hospital admissions with no increase in adverse events.

The low-risk patient, identified using similar methodology as noted previously, likely can be managed as an outpatient with either primary care physician or cardiology follow-up. For instance, patients with either a low EDACS-ADP score, HEART score, or HEART Pathway result are safely discharged from the ED with subsequent follow-up. At follow-up, in some instances, no further evaluation for coronary heart disease is needed; in other cases, the outpatient physician can choose to pursue risk stratification via exercise stress testing, nuclear imaging, echocardiography, or coronary CT angiography. Alternatively, certain low-risk patients can be evaluated with further ED or hospital observation, as outlined for the intermediate-risk group.

MANAGEMENT

An understanding of the pathophysiology of ACS allows the emergency clinician to select the most appropriate therapies for the ACS patient. ACS pathophysiology includes the following: (1) endothelial damage through plaque disruption, irregular luminal lesions, and shear injury; (2) platelet aggregation; (3) thrombus formation causing partial or total lumen occlusion; (4) coronary artery vasospasm; and (5) reperfusion injury caused by oxygen free radicals, calcium, and neutrophils. In patients with noninfarction ACS, spontaneous fibrinolysis of the thrombus occurs rapidly, minimizing ischemic insult;

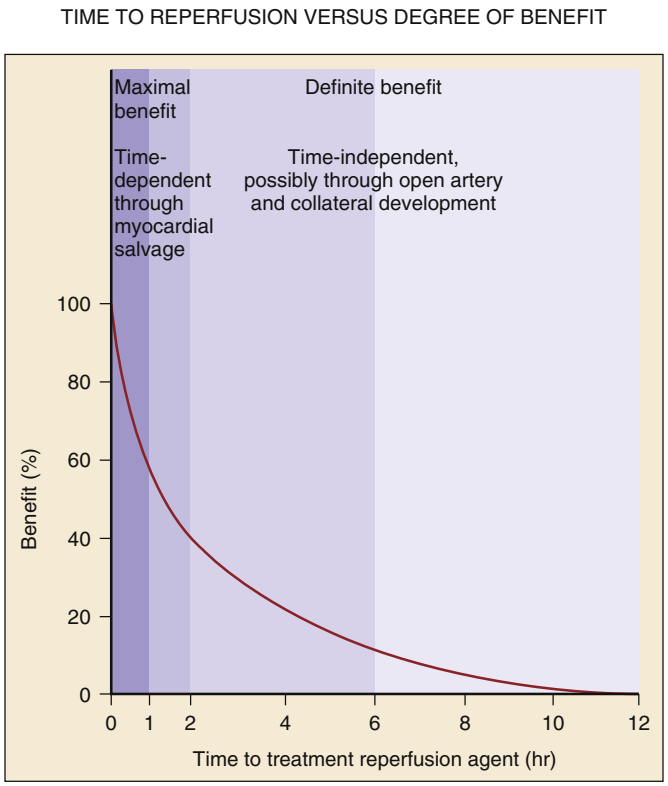

Fig. 64.32 Relationship between time to reperfusion and benefit in STEMI. This figure depicts combined human and animal data and represents the time-dependent benefit anticipated, depending on the length of the interval between coronary artery occlusion and reperfusion. (Adapted from: Tiefenbrunn AJ, Sobel BE: Timing of coronary recanalization. Paradigms, paradoxes, and pertinence. *Circulation.* 1992;85:2311; and from U.S. Department of Health and Human Services, Public Health Service, National Institutes of Health, National Heart, Lung, and Blood Institute [NIH Publication No. 93-3278], September 1993, p 8. Copyright ©1992 American Heart Association.)

persistence of the occlusive thrombus often results in more severe ACS forms including NSTEMI, STEMI, and sudden cardiac death.

Time-Sensitive Nature of Acute Coronary Syndrome Therapy

Early patency resulting in myocardial salvage is the key benefit of emergent reperfusion therapy, using either fibrinolysis or PCI. Timely treatment within the first hours after symptom onset may result in substantial, if not complete, myocardial salvage. Delivered later, from 3 to 12 hours after STEMI onset, treatment may result in a more modest, but still significant, benefit. The opening of the occluded artery causes less adverse ventricular modeling, reduces the occurrence of ventricular aneurysm, increases blood flow to the myocardium, and improves electrophysiologic stability. Angiographic patency at 90 minutes is strongly associated with preserved left ventricular function and mortality at the 24-hour and 30-day endpoints. The relationship between rapid revascularization and mortality has been clearly demonstrated, and it has been shown that with each additional 30 minutes of delay to PCI, the relative 12-month mortality risk increases by 7.5%. Figure 64.32 depicts the relationship between time to reperfusion and benefit in STEMI.

Prehospital delay factors occur from the time the patient decides to seek medical attention until the patient arrives at the ED. For nearly half of patients with suspected AMI, the EMS system is the point of first medical contact. Wide variations in the availability of EMS systems and their varied levels of integration into their local ED and hospital ACS identification and evaluation processes can further complicate and delay care. EMS system resources are related to patient care ability; in systems with advanced and robust local resources, very comprehensive state of the art care is possible.

Further delays can occur between the time a patient arrives at the hospital and initiation of acute revascularization therapy. Although studies have shown that the average time to fibrinolysis ranges from 45 to 90 minutes, the AHA recommends that all patients with STEMI undergo primary PCI (i.e., device across the culprit artery) no later than 90 minutes after arrival or receive fibrinolytic therapy within 30 minutes of arrival.[26]

STEMI patients who receive hospital-based reperfusion therapies (e.g., PCI, fibrinolytic agent) progress through a sequence of steps that can define process time points. Within each interval, various impediments to timely care can occur. Reducing delay times is applicable to all time points in the ED by addressing the four Ds: ***d***oor (events before arrival at the ED), ***d***ata (obtaining the ECG), ***d***ecision (arriving at the STEMI diagnosis and deciding on therapy), and ***d***rug (administering the fibrinolytic agent or passing the angioplasty catheter across the culprit lesion for PCI candidates).[27]

Prehospital notification to the ED of the impending arrival of a patient with a suspected STEMI, particularly when ST segment elevation is suspected, has become standard practice in many established EMS systems. A field 12-lead ECG may assist in diagnosis and decrease the reperfusion time by initiating the hospital-based sequence of necessary events to occur in parallel, as opposed to serially. Some systems have been able to bypass the ED in selected prehospital notifications of STEMI, and these patients go directly from the ambulance to the CCL for PCI. These systems have shown significant decreases in door to reperfusion times. However, data demonstrating improvement in clinical outcomes, including mortality, are lacking.

Self-transported patients with possible ACS should be evaluated by the triage nurse immediately and an ECG acquired within 5 to 10 minutes of arrival. This ECG should be interpreted rapidly by a competent clinician capable of recognizing STEMI. This interpretation is primarily aimed at detecting STEMI and other life threats; formal interpretation of the ECG occurs later at the time of complete ED evaluation. The development of hospital-based protocols and system response plans to identify and rapidly treat patients reduces the amount of time to treatment.

When using fibrinolysis in uncomplicated cases where PCI is not available, the emergency clinician should activate the hospital-based system for reperfusion. Checklists of inclusion and exclusion criteria for fibrinolytic therapy should be available, and those fibrinolytic agents should be stored and administered in the ED. In a system in which fibrinolysis is the sole reperfusion therapy, the decision to administer that therapy rests with the emergency clinician. Nonconsultative communications with family physicians, internists, or cardiologists before administration of the agent may result in unnecessary delays. Consultative discussions before the administration of therapy should only be obtained in complicated situations.

If the hospital offers primary PCI, many hospitals activate so-called STEMI alert responses when a STEMI patient is identified prehospital or in the ED. Analogous to the trauma alert, the cardiologist and catheterization laboratory personnel are immediately mobilized. Prehospital or emergency clinician activation of the catheterization laboratory demonstrates very high rates of accurate STEMI diagnosis, with very low rates of false activation (i.e., the STEMI mimic) while markedly reducing the time to definitive therapy. Interhospital transfer of STEMI patients for PCI when they are also candidates for fibrinolysis should be discouraged if definitive therapy (i.e., catheter placement across the

TABLE 64.8 Medications Used in Emergency Department Management of Acute Coronary Syndrome (ACS)

Medication and Medication Class	Examples	Indications	Risk Issues
Nitroglycerin	Nitroglycerin (sublingual, topical, IV)	Chest pain, pulmonary edema medication, blood pressure medication	Hypotension
Opioids	Morphine, fentanyl	Chest pain	Hypotension, respiratory suppression
β-Adrenergic Blockers			
• IV	Metoprolol, labetalol, esmolol	Blood pressure agent, dysrhythmia agent	Hypotension, bradycardia, cardiogenic shock
• Oral	Metoprolol	None; inpatient use	
ACE inhibitors	Captopril, enalapril, lisinopril, ramipril	None; inpatient use	
Statins	Lovastatin, atorvastatin, simvastatin, pravastatin	None; inpatient use	
Calcium channel blockers	Diltiazem	None; inpatient use	
Aspirin	Aspirin	Chest pain	Hemorrhage, gastric irritation
Other antiplatelet agents	Clopidogrel, ticagrelor, prasugrel, ticlopidine	ACS (with objective confirmation)	Hemorrhage
Antithrombin agents	Heparin, enoxaparin, bivalirudin	ACS (with objective confirmation)	Hemorrhage, heparin-induced thrombocytopenia (for heparins)
Fibrinolytic agents	Streptokinase t-PA r-PA Tenecteplase	STEMI	Hemorrhage

culprit lesion) is likely to be delayed beyond 120 minutes, except in cases of hemodynamic shock (see later) or in patients for whom fibrinolysis is contraindicated.[26]

Pharmacologic Intervention

A range of medications can be used in the patient with ACS (Table 64.8). These agents range from the basic to the complex, including oxygen, IV fluids, antiplatelet and anticoagulant agents, nitroglycerin, opioid analgesics, β-adrenergic blocking agents, and fibrinolytic agents.

Oxygen

Oxygen is considered a medication, one with significant potential to benefit and harm the patient with ACS. A brief mention of the most appropriate strategy for oxygen treatment in the ACS patient is warranted. Respiratory compromise can occur during ACS, usually as a result of acute pulmonary edema or exacerbation of chronic pulmonary disease. Suspected ACS patients with respiratory compromise, demonstrated by physical examination or oxygen saturations, should receive supplemental oxygen as standard therapy. The historical rationale for this oxygen therapy was that maximization of oxygen saturation may improve oxygen delivery to the tissues and thus reduce the ischemic process and related negative outcomes.

Recent investigation suggests that routine supplemental oxygen therapy in ACS patients with normal oxygen saturations and the absence of respiratory compromise does not provide benefit from such intervention; infarction size, mortality rates, and the occurrence of adverse events are not reduced by such oxygen use.[28-30] Furthermore, oxygen therapy delivered to these normoxic ACS patients can increase both myocardial injury and infarct size.[31] The practice of administering oxygen to all patients, regardless of their oxygen saturation, is based on rational conjecture and research performed before the current reperfusion era in acute coronary care. More recent studies of this issue have suggested that supplemental oxygen therapy does not offer any benefit; specifically, mortality rates, recurrent MI, cardiogenic shock, heart failure, arrhythmias, or infarction size are not impacted by supplemental oxygen administration.[28-30]

Additional work suggests that supplemental oxygen therapy can increase the rate of adverse outcomes in the ACS patient, particularly involving STEMI. Hyperoxia, developing as a result of excessive supplemental oxygen therapy, can potentiate coronary vasoconstriction and increase oxidative stress, worsening outcomes in these patients. The AVOID trial demonstrated that oxygen therapy, delivered to patients suspected of STEMI who also had normal oxygen saturations and no other evidence of respiratory compromise, likely increased early myocardial injury and was associated with larger myocardial infarct size assessed at 6 months. Furthermore, reinfarction and cardiac dysrhythmia were also increased in the oxygen therapy group.[31]

Thus, in suspected or confirmed ACS patients, supplemental oxygen therapy is appropriate for patients demonstrating respiratory compromise, noted by physical examination or oxygen saturations less than 94%. Conversely, in patients without respiratory compromise, oxygen therapy can be withheld.

Nitroglycerin

Nitrates decrease myocardial preload and, to a lesser extent, afterload. Nitrates increase venous capacitance and induce venous pooling, which decreases preload and myocardial oxygen demand. Direct vasodilation of coronary arteries may increase collateral blood flow to the ischemic myocardium.

Nitroglycerin has been used for decades in patients with suspected or known ACS. Most studies of IV NTG in the setting of ACS, however, are from the prefibrinolytic era. Although data from multiple trials performed in the prefibrinolytic era noted a 35% mortality reduction with IV NTG in the setting of AMI, no contemporary evidence (i.e., in the reperfusion era of acute cardiac care) has shown improved outcomes with the routine use of any form of nitrate therapy in patients with

AMI. In patients with significant, symptomatic coronary vasospasm, NTG can be quite beneficial; unfortunately, the ability to identify the presence of significant vasospasm at the bedside is not possible.

In the ACS patient, it must be noted that the use of NTG in any formulation is a management option, yet its use is not mandatory. If hypotension is present or is anticipated to occur (i.e., inferior wall STEMI with identified or suspected right ventricular infarction), it is very appropriate to withhold NTG in all formulations.

Patients with possible ACS and a systolic blood pressure greater than 90 mm Hg can receive a sublingual NTG tablet (0.4 mg [400 μg]) on presentation. If symptoms and pain are not fully relieved with three sublingual tablets, topical or IV NTG can be considered. Topical nitroglycerin is administrated in the form of a paste with dosages delineated by the inch; initial topical applications range from 0.5 to 2 inches. For intravenous administration, an initial infusion rate of 10 μg/min is titrated to pain symptoms. The emergency clinician can increase the infusion at regular intervals of at least every 5 minutes, allowing a 10% reduction in the mean arterial pressure if the patient is normotensive and a 20% to 30% reduction if hypertensive. With bradycardia, hypotension, inferior wall STEMI, and right ventricular infarction, a sudden decrease in preload associated with NTG can result in profound hypotension. Caution is advised in these settings.

Morphine and Other Opioid Analgesic Agents

Morphine is a potent opioid analgesic with weak sympathetic blockade, systemic histamine release, and anxiolysis. If a patient with possible ACS is unresponsive to NTG or has recurrent symptoms despite maximal antiischemic therapy, administration of morphine sulfate is a reasonable analgesic intervention. The relief of pain and anxiety can decrease oxygen consumption and myocardial work. Some vasodilatory effects are also noted with preload reduction. Standard doses of morphine sulfate are 2 to 4 mg up to 0.1 mg/kg IV, repeated every 5 to 30 minutes as necessary. Caution is advised with morphine use in this setting.

Although appropriate, it must be remembered that morphine is a potent medication with significant vasodilatory effects and profound sedation, with resultant respiratory depression. In addition to allergic reactions, another significant adverse effect of morphine sulfate administration is hypotension, which is managed with IV crystalloid as a bolus.

Recent reviews of morphine use in various populations of chest pain patients, including those with suspected ACS as well as those already diagnosed with STEMI have demonstrated no increased rate of adverse outcomes.[32,33] Its use in small to modest amounts in most patients is reasonable. In addition to its analgesic properties, it is also an anxiolytic agent, a valuable feature in certain ACS patients. Withholding morphine and other analgesic agents is appropriate if the emergency physician is concerned about the potential for iatrogenic hypoperfusion, sedation, or respiratory depression.

Other opioid agents, such as fentanyl, are reasonable for use in the ACS patient. Fentanyl can be used in dosing range of 12.5 to 50 mcg IV, repeated every 5 to 30 minutes as needed. The same caveats and general recommendations as noted with morphine apply to fentanyl and other opioid agent administrations in the ACS patient.

Beta-Adrenergic Blockers

Historically, β-adrenergic blocking agents have been used to ameliorate catecholamine-induced tachycardia, including ventricular fibrillation, increased contractility, and heightened myocardial oxygen demand during the acute infarction period. Although beta blockade was shown to decrease mortality for patients with AMI, these observations occurred when adjunctive therapies were few and β-adrenergic blockade was essentially monotherapy in AMI.

Contemporary management strategies include highly effective reperfusion therapies coupled with potent anticoagulant and antiplatelet agents; thus, the widespread use of β-adrenergic blocking agents must be reconsidered. In fact, multiple studies have suggested that the widespread intravenous use of β-adrenergic blockade should be curtailed. The use of the early IV β-adrenergic blocking agents in these studies was associated with higher rates of death, heart failure, cardiogenic shock, recurrent ischemia, and pacemaker use as compared to patients who received early oral administration. These increases occurred despite the exclusion of patients with obvious contraindications, including preexisting hypotension, bradycardia, or heart failure. Several large studies evaluated patients with suspected STEMI and β-adrenergic blocking agent use, comparing early IV administration followed by continued oral therapy versus placebo; these studies found no significant difference between the two groups in terms of mortality; the group receiving β-adrenergic blockers, however, demonstrated a minimal reduction of reinfarction and the occurrence of ventricular fibrillation. These benefits were at the expense of a significantly higher rate of cardiogenic shock and increased rates of development of heart failure requiring treatment, persistent hypotension, and bradycardia.

The early IV use of β-adrenergic blocking agents, when coupled with contemporary therapy in the setting of ACS, does not appear to offer significant benefit and is associated with an increased rate of adverse events. Therefore, early IV administration in the ED ACS patient is discouraged. Conversely, oral administration of beta blockers to ACS patients without contraindications during the first 24 hours of management is a class I recommendation from the ACC/AHA and can be accomplished in the hospital after admission.[26] This strategy allows for stabilizing the patient while additional clinical data are obtained to determine appropriateness of this therapy.

Empirical therapy in the ED should be reserved for only those patients who have adverse effects from significantly elevated blood pressure or significant tachydysrhythmia, despite other appropriate medications. If IV therapy is needed in the ED, metoprolol 5 mg can be administered once. Additional doses of 5 mg can be given intravenously at 15- to 30-minute intervals for a maximum cumulative dose of 15 mg.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitor agents benefit patients with CHF. ACE inhibitors may also reduce morbidity and mortality after AMI. In particular, patients treated with ACE inhibitors experience a reduction in cardiovascular mortality, decreased rates of significant CHF, and fewer recurrent AMIs. These benefits increase when ACE inhibitors are used in conjunction with other agents, such as aspirin and fibrinolytic agents. The mechanism of action regarding a reduction in recurrent AMI is unknown but may involve a reduction in plaque rupture related to decreased intracoronary shear force or neurohumoral influences. Therapy should be initiated within the first 24 hours following an ACS event, although ED administration is not indicated.

HMG–Coenzyme A Reductase Inhibitors

HMG–Coenzyme A reductase inhibitors (statins) have demonstrated a reduction in inflammation and reinfarction, angina, and lethal arrhythmia in the first few days after an ACS event. Although there is no indication for statin therapy in the ED management of ACS, initiation of this therapy should occur within the first 24 hours or continue if patients are already undergoing statin therapy, because discontinuation during hospitalization is associated with an increase in near-term mortality and adverse events. The administration of statin therapy before elective or urgent PCI for ACS is reasonable to decrease periprocedural

AMI; however, there are no specific risk or safety data regarding its use in this setting.

Calcium Channel Blockers

Calcium channel blockers have a minimal role in the ED management of the ACS patient. As with beta blockade, the primary benefit of calcium channel blockers appears to be limited to symptom resolution. Unfortunately, these agents may be accompanied by significant vasodilation, resulting in hypotension and potentiation of the coronary ischemic process. Like beta blockers, calcium channel blockers have a substantial negative inotropic effect. AV nodal blockade is also a significant side effect that may be exacerbated in patients previously treated with beta blockers or with ischemia-related conduction disturbance. Unless used explicitly for rate control of supraventricular dysrhythmia (e.g., atrial fibrillation with rapid ventricular response) in a patient who cannot tolerate beta blockade, calcium channel blocker agents have no role in the ED management of ACS.

Antiplatelet Therapy

In non-AMI ACS patients (i.e., unstable angina), dramatic reductions in the progression to acute infarction are noted with appropriate antiplatelet therapy. The administration of antiplatelet therapy, particularly aspirin, is indicated in the ED for most ACS patients. For AMI, the administration of aspirin and other antiplatelet agents is associated with significant reductions in mortality, ranging from 25% to 50%; mortality reduction is most prominent in the AMI patient when aspirin is used in the setting of reperfusion therapy.

Aspirin. Aspirin, the prototypical antiplatelet agent, is the most cost-effective treatment in ACS care. It irreversibly acetylates platelet cyclooxygenase, thereby removing all activity for the life span of the platelet (8 to 10 days). Thus, aspirin stops the production of proaggregatory thromboxane A2 and is an indirect antithrombotic agent. Aspirin also has significant nonplatelet effects because it inactivates cyclooxygenase in the vascular endothelium, thereby diminishing the formation of antiaggregatory prostacyclin.

It is well established that aspirin independently reduces the mortality of patients with AMI without fibrinolytic therapy (overall 23% reduction) and is synergistic when used with fibrinolytic therapy (42% reduction in mortality). The usual dose is 324 mg of non–enteric-coated aspirin, chewed and swallowed. Enteric-coated aspirin should be avoided in the acute setting of ACS due to its delay in the onset of antiplatelet activity.

The administration of aspirin in the ED is strongly recommended as soon as possible for any patient with suspected ACS. It should be administered to all such patients unless significant allergy, hemorrhage, or other issues, such as suspected aortic dissection, contraindicates its use. It must be noted that a hemoccult positive stool result, without bright red blood or melena, is not a contraindication for aspirin administration. More recent studies have established that lower dose aspirin (<162 mg) appears to be as effective as higher dose aspirin (>162 mg) at preventing adverse cardiac events, with fewer bleeding risks, although most clinicians continue to administer 324 mg dose. These findings were consistent when given alone or with other antiplatelet agents (e.g., clopidogrel).

$P2Y_{12}$ Receptor Inhibitor Agents. The $P2Y_{12}$ inhibitors include the thienopyridines ticlopidine, clopidogrel, and prasugrel, as well as ticagrelor and cangrelor. They are more potent platelet inhibitors than aspirin. The thienopyridines inhibit the transformation of the $P2Y_{12}$ receptor into its high-affinity ligand-binding state, irreversibly inhibiting platelet aggregation for the duration of the life of the platelet. Ticlopidine has nonlinear kinetics and, with repeated administration, reaches a maximal effect after 8 to 11 days of use. Clopidogrel, a ticlopidine analogue, and prasugrel have the advantage of a rapid onset of action.

Clopidogrel has traditionally been the preferred ED agent of this class due to its relatively rapid onset of action, good safety profile, and efficacy when given in ACS and associated with thrombolytic therapy. Prasugrel incurs a higher bleeding risk than clopidogrel. Relative contraindications include use in patients older than 75 years and those who weigh less than 60 kg. Absolute contraindications include in those who have had a previous transient ischemic attack (TIA) or stroke, and those at high risk for bleeding. TRITON-TIMI 38 demonstrated that prasugrel was superior to clopidogrel using a composite outcome; however, this is tempered by an increased risk of bleeding. The ACCOAST trial showed no improvement in outcomes for patients treated with prasugrel in the ED versus dosing at the time of PCI. Because of this and other similar studies, prasugrel has traditionally not been recommended for upstream use in the ED in ACS patients.

Ticlopidine is associated with a risk of neutropenia, thrombotic thrombocytopenic purpura, and agranulocytosis; furthermore, it demonstrates a much slower onset of platelet inhibition. With clopidogrel, maximal platelet inhibition occurs after 3 to 5 days of clopidogrel therapy with 75 mg daily; an earlier onset of platelet inhibition is seen when a higher loading dose is used (300–600 mg). For example, there is clear benefit to clopidogrel administration (300 mg loading dose) at least 6 hours before PCI in patients with STEMI; higher doses (e.g., 600 mg) demonstrate a trend toward improvement at slightly earlier time periods (i.e., 3–4 hours).

Ticagrelor and cangrelor also act as $P2Y_{12}$ receptor inhibitors, although its activity is reversible and occurs via a different mechanism not requiring hepatic activation. Ticagrelor is rapidly absorbed, reaching peak serum concentration at 2.5 hours. Clinical data have demonstrated that ACS patients given ticagrelor were less likely to die from cardiovascular causes. However, these improved outcomes are tempered by higher rates of non-procedure-related bleeding, including more frequent fatal intracranial hemorrhage when compared with clopidogrel administration. Further analysis of the PLATO study has assessed the increased cost of ticagrelor versus clopidogrel when combined with aspirin and determined that, with the increased life expectancy, ticagrelor plus aspirin is cost-effective.

Cangrelor, an IV $P2Y_{12}$ receptor inhibitor, has potential for significant therapeutic advantages over the other drugs in this class due to its immediate onset of antiplatelet activity and very short half-life. It is administered IV in its active form (unlike clopidogrel), not as a prodrug requiring metabolism prior to its onset of action. Unlike the oral drugs in this class, which require 2 to 6 hours to reach active levels, cangrelor is active immediately on injection. This near-immediate onset of action has potential benefits in patients who are undergoing rapid PCI—specifically, the STEMI population with an invasive management plan. Some experts have also proposed its use in patients with STEMI who have been resuscitated from cardiac arrest and are unable to take oral medications.[34] Cangrelor also has a very short half-life (4–6 minutes), which makes the treatment of potential CABG patients with a $P2Y_{12}$ receptor inhibitor possible up until the time of surgery. Initial studies have demonstrated the ability to maintain low levels of platelet activity in the presurgical time period on cangrelor, compared to the recommended 5 days off of the other oral $P2Y_{12}$ receptor inhibitors, without an increase in major bleeding in CABG patients. Cangrelor also appears to have the potential for improved outcomes in patients undergoing PCI when compared to current antiplatelet therapy.

The 2013 AHA Guidelines for STEMI management recommend patients receive a loading dose of clopidogrel or ticagrelor in addition to standard ACS care (ASA, anticoagulants, and reperfusion therapy), assuming there are no contraindications to use, prior to PCI.[35] For patients with definite or likely NSTEMI, following the 2014 AHA

guidelines for NSTEMI management, the administration of a $P2Y_{12}$ receptor inhibitor should also be initiated in the ED prior to PCI.[9]

The current data to support one particular $P2Y_{12}$ inhibitor over another is mixed. Initial data from the PLATO trial favored the use of ticagrelor over clopidogrel, however more recent data have shown no significant differences in MACE rates at 1 year.[36] Additionally, the recent ISAR-REACT 5 trial demonstrated a decrease in 1-year MACE in ACS patients receiving prasugrel over ticagrelor.[37] Notably, in this trial, patients with NSTEMI randomized to ticagrelor received therapy as soon as possible after diagnosis and randomization, whereas prasugrel was held until after diagnostic angiography was completed, but given before percutaneous intervention. In STEMI patients, treatment was administered as soon as possible in both treatment groups.

Given the current state of the literature, therapy with clopidogrel, ticagrelor, or prasugrel is reasonable in patients likely to undergo PCI. Considerations should be given to each agent's potential risks and benefits (e.g., prasugrel should not be given in patients with a history of stroke or TIA and used with caution in patients ≥75 years of age or <60 kg). Clopidogrel administration is recommended (ACC/AHA class I indication) for patients with a high-risk ACS presentation and true aspirin allergy. This high-risk presentation would be characterized by objective clinical abnormality, including a significantly abnormal serum marker or 12-lead ECG.

In the patient with UA or NSTEMI, clinical benefit has been demonstrated with clopidogrel when a noninvasive treatment strategy is utilized, albeit with an increase in the incidence of major hemorrhage. Invasively managed patients receiving the drug with less time to procedure do not benefit from earlier treatment. Patients with NSTEMI demonstrate improved outcomes with clopidogrel therapy when a conservative treatment scenario is initially followed. Of note, a large portion of these patients will undergo PCI within the first 24 hours after admission; however, this so-called delayed PCI allows for benefit to occur from clopidogrel administered earlier in the course of management.

The medically managed STEMI patient (i.e., with a fibrinolytic agent) also benefits from clopidogrel use. Clopidogrel therapy in conjunction with fibrinolysis, followed by deferred cardiac catheterization occurring at least 2 days after AMI, decreases the rates of death, recurrent ACS, and urgent coronary revascularization. This improvement occurs without a significant increase in hemorrhage.

The potential need for urgent CABG should also be considered. The higher risk ACS patient will more likely benefit from $P2Y_{12}$ receptor inhibitor therapy, but that same patient is also more likely to need urgent CABG. It is difficult, however, to identify ACS patients requiring urgent CABG reliably, and reviews of ED ACS patients have been unable to demonstrate consistent clinical features apparent in the ED that reliably identify patients not requiring CABG. CABG patients undergoing dual antiplatelet therapy (DAPT) have a greater incidence of bleeding perioperatively. However, this increased hemorrhagic rate must be weighed against the benefit in reducing ischemic risk in these patients.[38]

The ACC and AHA have suggested, in the form of a class I recommendation, that clopidogrel or ticagrelor should be withheld for at least 24 hours before urgent on-pump CABG, if possible.[9] Nevertheless, the recommendation suggests that early $P2Y_{12}$ receptor inhibitor therapy be considered in patients who likely will not require CABG. Because it is not currently possible for the emergency clinician to predict which patients will require urgent CABG, collaborative multidisciplinary pathways should be developed, with emergency clinicians, cardiologists, and cardiovascular surgeons providing input.

Glycoprotein IIb/IIIa Receptor Inhibitors. Glycoprotein IIb/IIIa receptor inhibitors (GPIs) are potent antiplatelet agents; they include abciximab, eptifibatide, and tirofiban. GPIs, however, demonstrate clinical usefulness in only the subset of ACS patients undergoing PCI as a reperfusion strategy. Therefore, the primary indication regarding GPI administration is planned mechanical coronary intervention. Furthermore, the largest studies on GPI administration timing have not shown outcome benefit to upstream use in the ED when compared to catheterization laboratory administration. Currently, there is no clear indication for the ED administration of GPIs unless other antiplatelet agents are not tolerated or unavailable. This class of medications is not usually given in the ED setting, and other antiplatelet agents ($P2Y_{12}$ receptor inhibitors) are preferred for administration in the care of ACS. If administered, current guidelines suggest the use of eptifibatide or tirofiban as the preferred agents.[9]

Antithrombins

As with antiplatelet therapies in ACS patients, significant reductions in the progression to acute, recurrent, or extensive infarction and death are noted in individuals treated with aggressive antithrombin therapy. There are currently four options for antithrombin therapy in the setting of ACS, including unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), direct thrombin inhibitors (bivalirudin), and factor Xa inhibitors (fondaparinux). Antithrombotic therapy is indicated for ACS patients with recurrent anginal pain, AMI (NSTEMI and STEMI), a significantly positive serum marker, or a dynamic 12-lead ECG.

Heparins. The term *heparin* refers not to a single structure but to a family of mucopolysaccharide chains of varying lengths and composition—hence, unfractionated—with pronounced antithrombotic properties. At standard doses, UFH binds to antithrombin III, forming a complex that is able to inactivate factor II (thrombin) and activate factor X. This prevents the conversion of fibrinogen to fibrin, thus preventing clot formation. Heparin by itself has no anticoagulant property. This indirect effect on thrombin inhibits clot propagation; it prevents heparin, however, from having any effect on bound thrombin in a thrombus. UFH also assists in the inactivation of factors XIa and IXa through antithrombin and interacts with platelets.

UFH has a profound synergistic effect with aspirin in preventing death, AMI, and refractory angina in ACS patients, particularly those with AMI and, to a lesser extent, high-risk UA. UFH should be administered early in patients with the following ACS features: recurrent or persistent chest pain, AMI, positive serum marker, or a dynamic ECG. In patients receiving thrombolytic therapy and UFH, it has been shown that bleeding and mortality were higher in patients receiving an 80-unit/kg bolus and 18-unit/kg infusion compared with patients with a lower bolus amount and infusion rate. Therefore, the weight-adjusted regimen recommended for UFH in the setting of a STEMI receiving thrombolytic therapy or non-ST elevation ACS patients is an initial bolus of 60 units/kg (maximum, 4000 units) and an initial infusion of 12 units/kg/hr with an activated partial thromboplastin time goal of 1.5 to 2.5 times the control value.[9,35] The weight-adjusted regimen UFH in STEMI patients receiving PCI is dependent on the planned use of a GPI during PCI. If GPI use is planned during PCI, the bolus dose should be 50 to 70 units/kg (no maximum dose) and, if no GPI use is planned, the bolus dose should be 70 to 100 units/kg (no maximum dose).

LMWHs constitute approximately one-third of the molecular weight of heparin and are less heterogeneous in size. LMWHs inhibit the coagulation system in a fashion similar to that of UFH. Approximately one-third of the heparin molecules bind to antithrombin III and thrombin. The remaining molecules bind only to factor Xa. The variable efficacy found among the LMWHs is attributed to different ratios of antifactor Xa to antifactor IIa. High-ratio preparations have a clear

advantage over standard heparin; enoxaparin has the highest ratio of available LMWHs. LMWH was designed based on the hypothesis that the inhibition of earlier steps in the blood coagulation system would be associated with a more potent antithrombotic effect than inhibition of subsequent steps. This results from the amplification process inherent in the coagulation cascade—that is, a single factor Xa molecule can lead to the generation of multiple thrombin molecules.

Potential advantages of LMWH over UFH include easier administration, greater bioavailability, more consistent therapeutic response among patients, and longer serum half-life, producing a more manageable administration schedule, albeit at a higher cost. The combination of aspirin, beta blocker, and LMWH significantly decreases the rate of nonfatal AMI or death in the first several weeks after treatment but has much less pronounced impact out to multiple months. Studies comparing outcomes between LMWH and UFH have shown mixed results; some show better outcomes with LMWH, but others do not. In summary, the LMWH enoxaparin demonstrates some degree of benefit compared with UFH in patients at higher risk for non–ST segment elevation ACS who are treated conservatively without immediate PCI (i.e., beyond 24 hours). For STEMI patients managed aggressively with rapid PCI, UFH is preferred over enoxaparin.

Enoxaparin is administered in a twice-daily regimen subcutaneously at a dose of 1 mg/kg for all ACS patients. If patients have renal dysfunction, with an estimated glomerular filtration rate of less than 30 mL/min, the dose should be reduced to 1 mg/kg in a single daily administration. Few safety data are available for enoxaparin in ACS patients with renal insufficiency, and UFH may be preferable.

Most patients with AMI require therapy with heparin, whether it is fractionated or unfractionated. Non-AMI ACS, however, is different because UA is a heterogeneous condition. Only high-risk UA patients with recurrent or continued pain, or new ischemic electrocardiographic changes, should be considered for heparin therapy. For example, the stable patient with a classic description of new-onset angina, who is pain-free with a negative serum marker and normal ECG, is still correctly diagnosed with UA. In contrast, an individual with ongoing pain, intermittent or constant, with a dynamic ECG clearly is experiencing an active, unstable coronary event. The latter patient, who is at higher risk, can benefit from heparin therapy more than the former.

Heparin therapy, however, can be a major contributor to morbidity and mortality among hospitalized patients. Major bleeding develops in 1 of every 90 patients treated, and heparin-induced thrombocytopenia in 1 of 34 patients. LMWH is as effective as UFH in patients with non–ST segment elevation ACS and does not greatly increase the bleeding risk while decreasing the risk of thrombocytopenia. Contraindications to any heparin therapy include known allergy, active ongoing hemorrhage, and predisposition to such hemorrhage. Furthermore, patients who have their heparin therapy changed (UFH to LMWH and vice versa) during the active treatment phase of their ACS care experience higher rates of bleeding.

Other Antithrombins: Bivalirudin and Fondaparinux. The direct thrombin inhibitor bivalirudin is a potent antithrombin anticoagulant providing significant theoretical advantages compared with heparin. Bivalirudin is a bifunctional 20–amino acid peptide designed on the basis of the structure of hirudin. It has properties similar to those of hirudin but also interacts with the catalytic site of thrombin.

Bivalirudin is at least as effective as heparin in reducing death or reinfarction in patients with ACS, particularly those patients undergoing very early PCI. Bivalirudin, compared with heparin, produces similar rates of ischemia and major bleeding at 1 month. Bivalirudin when used with clopidogrel is comparable to the combination of heparin and GPI before coronary angiography or PCI. When used alone, it is inferior to the combination of heparin and GPI. Bivalirudin should be considered an acceptable alternative anticoagulant agent in the STEMI patient undergoing PCI.[35] Its use is in the ED for ACS patients is primarily limited to those who cannot receive heparin (e.g., known heparin-induced thrombocytopenia).

Fondaparinux is a synthetic oligosaccharide with a structure similar to the heparins. It is the first widely used selective factor Xa inhibitor. In previous comparison studies, fondaparinux was found to be similar to enoxaparin in the short-term reduction of ischemic events, yet substantially reduced major bleeding and improved long-term outcome. When the use of fondaparinux was reviewed in STEMI patients managed medically with streptokinase, it was found that fondaparinux significantly reduced hemorrhage, MI, and death when compared to UFH and LMWH. As a result, fondaparinux has a class 1 AHA recommendation as an alternative to UFH and LMWH in NSTEMI and STEMI patients who are not undergoing PCI.[9,35] However, the increased risk of catheter-associated thrombi during PCI prevents its use without additional UFH administration when an invasive strategy is chosen.

Reperfusion Therapies

Rapidly reestablishing perfusion in the infarct-related coronary artery using fibrinolytic therapy or PCI increases the opportunity for myocardial salvage, with resultant reductions in mortality and improvements in quality of life post-MI. Pharmacologic and mechanical methods of reperfusion are both effective under specific clinical conditions. More than 3 decades ago, the importance of early coronary artery patency was recognized; furthermore, it was demonstrated that 90-minute patency predicts improved survival rates and preserves left ventricular function, thereby optimizing outcome.

Fibrinolytic therapy unequivocally improves survival in STEMI patients and remains an ACC/AHA class I recommendation.[26] Although fibrinolysis has widespread availability and proven ability to improve coronary flow, limit infarct size, and improve survival in STEMI patients, many individuals with acute infarction are not suitable candidates. Patients with absolute contraindications to fibrinolytic therapy, certain relative contraindications, cardiogenic shock, and non-ST segment elevation ACS (most NSTEMI and all UA patients) may not be eligible. PCI is the treatment of choice in the STEMI patient given the limitations of fibrinolytic therapy and the benefits of PCI. However, to provide the most significant benefit, PCI must be performed as soon as possible after the initial presentation. A substantially delayed PCI is inferior to fibrinolytic agents, assuming that the patient has no contraindications to this therapy.

Fibrinolytic Therapy

Fibrinolytic Agent Selection. Options for fibrinolytic therapy include streptokinase (the original fibrinolytic agent) and three types of plasminogen activator: tissue-type plasminogen activator (t-PA) and two recombinant tissue-type plasminogen activators, r-PA (reteplase) and tenecteplase (TNK). Due to more effective, contemporary options for fibrinolytic therapy, and easier to administer alternatives, streptokinase is no longer marketed in the United States. However, it is still used in many areas of the world due to its low cost compared to the other fibrinolytic options.

If t-PA is used, the most effective strategy is described as an accelerated or front-loaded regimen administered over 90 minutes, along with appropriate antiplatelet and anticoagulant therapies. In addition to mortality reduction in all subgroups (i.e., older patients, AMI location, and time since symptom onset), coronary artery patency and degree of normalization of flow were also improved with this protocol. In addition, the angiographic evaluation demonstrated a strong relationship between TIMI flow and outcome; patients with strong forward flow (i.e., TIMI grade 3 flow) at 90 minutes had significantly lower mortality rates than patients with little to no flow. This early t-PA patency

advantage over other agents was lost by 180 minutes after symptom onset. These observations were the first indications of the relationship between early coronary artery patency and improved clinical outcome.

Other large studies have compared accelerated t-PA with r-PA; r-PA can be administered in a fixed, double-bolus dose with no adjustment required for weight, which simplifies administration. r-PA has been found to be equivalent to accelerated t-PA, and results have been nearly identical for the two drugs. The one exception was the patient with presentation more than 4 hours after onset of symptoms, which is a significant number of patients at many institutions. In this group, accelerated t-PA is likely superior to r-PA because of its greater fibrin specificity.

The most recent fibrinolytic agent addition is tenecteplase, referred to in the clinical realm as TNK. TNK has several potential benefits over existing agents, including: (1) its longer half-life, allowing for a single bolus administration; (2) it is 14 times more fibrin-specific than t-PA and even more so than r-PA; and (3) it is 80 times more resistant to plasminogen activator inhibitor type 1 than t-PA. In comparisons of single-bolus TNK (30–50 mg on the basis of body weight) or accelerated t-PA (100 mg total infusion), there were no differences in mortality or intracranial hemorrhage. For the subgroup of patients presenting more than 4 hours after onset of symptoms, however, there may be a 30-day mortality benefit and fewer non-intracranial major bleeding episodes with TNK. Thus, it appears that TNK is marginally more effective, minimally safer, and easier to administer than t-PA, and thus is the recommended fibrinolytic agent. Furthermore, cost differences are minimal.

Eligibility Criteria for Fibrinolytic Agent Therapy. In the absence of contraindications, fibrinolytic therapy should be considered in patients with STEMI and the onset of ischemic symptoms within the previous 12 hours when it has been anticipated that primary PCI cannot be performed in a timely fashion.[26] The following section discusses the specific issues regarding fibrinolytic agent eligibility, with a focused discussion of contraindications.

12-Lead Electrocardiogram. Combined with the patient's history and physical examination, the 12-lead ECG is the key determinant of eligibility for fibrinolysis. The electrocardiographic findings should be consistent with STEMI based on the European Society of Cardiology (ESC)/American College of Cardiology Foundation (ACCF)/AHA/World Heart Federation Task Force for the Fourth Universal Definition of Myocardial Infarction.[3] These findings include diagnostic ST elevation—in the absence of LVH, LBBB, and right ventricular paced pattern from an implanted pacemaker—including ST elevation at the J point in at least two contiguous leads with cutoffs as follows: (1) in leads V_2 and V_3, elevation of more than 2 mm in men greater than 40 years of age, 2.5 mm in men less than 40, or more than 1.5 mm in women of any age OR (2) more than 1 mm in other contiguous chest or limb leads. Evidence of acute posterior wall myocardial infarction, indicated by ST segment depression in two or more precordial leads (V_1–V_4), is also a potential indication for fibrinolysis.

Patients with new LBBB and AMI are at increased risk for a poor outcome and benefit significantly from the administration of rapid reperfusion therapy. The new development of LBBB in the setting of AMI suggests proximal occlusion of the LAD artery, placing a significant portion of the left ventricle in ischemic jeopardy. Contemporary data, however, note that a new or presumably new LBBB as a presentation of AMI occurs infrequently; thus, a new or presumably new LBBB at presentation should not be considered diagnostic of AMI in isolation. Stated more simply, a new or presumably new LBBB is no longer considered a STEMI equivalent pattern. Nonetheless, a new or presumably new LBBB, lacking any abnormality as described by the modified Sgarbossa criteria, is a marker of significant cardiovascular risk and can be the electrocardiographic presentation of AMI in a minority of patients. A new or presumably new LBBB, lacking electrocardiographic evidence of AMI, in an ill patient with a classic presentation for ACS should be expeditiously evaluated with a cardiology consultation, if possible, to expedite cardiac-focused care.

Patients with STEMI in anterior, inferior, or lateral anatomic locations benefit from fibrinolytic therapy. Acute, isolated posterior wall MI, diagnosed using either the standard 12-lead ECG or posterior electrocardiographic leads V_8 and V_9, may be another electrocardiographic indication for fibrinolysis. Although unproven in large fibrinolytic agent trials, patients with isolated posterior AMI may be considered for reperfusion therapy when ST segment depression is noted in the right to mid-precordial leads; the emergency physician at the bedside is in the most appropriate position to make these treatment decisions.

Fibrinolytic therapy should not be used routinely in patients with only ST segment depression on the 12-lead ECG. In fact, the mortality rate may be increased—with the noted exception of right to mid precordial lead ST segment depression, representing a posterior wall AMI. Multiple studies have demonstrated a significant increase in mortality in fibrinolytic-treated patients who presented with ST segment depression.

Patient Age. Past trials do not provide evidence to support withholding fibrinolytic therapy or choosing one particular agent over another on the basis of the patient's age. It is consensus at this point that age alone should no longer be considered a contraindication to fibrinolytic therapy. However, it must be noted that patients older than 75 years do have a higher incidence of hemorrhagic stroke than younger patients.

Time from Symptom Onset. The generally accepted therapeutic time window for administration of a fibrinolytic agent after the onset of STEMI is 12 hours. Patients treated within the first 6 hours of STEMI have the best outcome. Later administration, from 6 to 12 hours after STEMI onset, also confers benefit, although of a lesser magnitude. The Late Assessment of Fibrinolytic Efficiency (LATE) trial, which compared fibrinolytic therapy with placebo, found a significant 26% decrease in 35-day mortality in patients treated with t-PA, heparin, and aspirin 6 to 12 hours after the onset of symptoms. There was no significant decrease in mortality among patients treated 12 to 24 hours after symptom onset.

Blood Pressure Extremes. Patients with a history of chronic hypertension should not be excluded from fibrinolytic therapy if their blood pressure is adequately controlled or can be lowered to acceptable levels with standard therapy for ischemic chest pain. The admission blood pressure is also an important indicator of risk of intracerebral hemorrhage. It has been shown that the risk of cerebral hemorrhage increases with systolic blood pressure higher than 150 mm Hg on admission and further increases when systolic blood pressure is 175 mm Hg or higher. Despite an increased mortality rate during the acute setting, fibrinolytic therapy in the setting of hypertension has shown an overall long-term benefit for patients with systolic blood pressure higher than 150 to 175 mm Hg. The literature appears to indicate an acceptable risk-benefit ratio for patients with substantially increased systolic blood pressure. However, a persistently elevated blood pressure (higher than 200/120 mm Hg) despite administration of standard therapy for ischemic chest pain during the ED presentation is generally considered to be a contraindication to fibrinolytic therapy.

The benefit of fibrinolytic therapy in patients with hypotension is unclear. Multiple trials have shown no apparent reduction in mortality rate with fibrinolytic therapy among high-risk AMI patients. Reviews of data on STEMI patients, however, have demonstrated that patients with an initial systolic blood pressure below 100 mm Hg who were not treated with fibrinolytic therapy had a very high risk of death (35.1%), and those who were treated with fibrinolytic therapy had the largest

absolute benefit (60 lives saved/1000 patients). Although cardiogenic shock and CHF are not contraindications to fibrinolysis, PCI is the preferred method of reperfusion if it can be accomplished expeditiously. The physicians involved in the individual patient's care are in the best position to determine the most appropriate treatment strategy, considering the patient and current medical condition, local resources, and transport times if transfer is required.

Retinopathy. Active diabetic hemorrhagic retinopathy is a strong relative contraindication to fibrinolytic therapy because of the potential for permanent blindness caused by intraocular bleeding. There is no reason, however, to withhold the use of a fibrinolytic agent in a diabetic patient with evidence of simple background retinopathy. Patients with diabetes mellitus who sustain a STEMI have an almost doubled incidence of mortality. It is impossible to determine the presence or absence of active retinal hemorrhage in the ED during the care of STEMI; thus, the emergency clinician should consider the risk-benefit analysis with respect to the presentation and involve the patient in the decision making.

Cardiac Arrest Requiring Cardiopulmonary Resuscitation. CPR is not a contraindication to fibrinolytic therapy unless CPR is prolonged—more than about 10 minutes—or extensive chest trauma from manual compression is evident. Although the in-hospital mortality rate is higher in AMI patients who experience cardiac arrest and then receive fibrinolytic agents in the ED, no difference has been found in the rates of bleeding complications, specifically, hemothorax and cardiac tamponade. Even CPR prolonged beyond 10 minutes does not appear to be associated with higher rates of complication. Again, the emergency clinician should consider the risk-benefit analysis for the presentation in this high-acuity, complex situation. If available, PCI is the preferred method of reperfusion in these critically ill patients.

Previous Stroke or Transient Ischemic Attack. A history of a previous stroke or TIA is a major risk factor for hemorrhagic stroke after treatment with fibrinolytic therapy. A history of previous ischemic stroke should remain a strong relative contraindication to fibrinolytic therapy, and previous hemorrhagic stroke is an absolute contraindication.

Previous Myocardial Infarction or Coronary Artery Bypass Graft. In the setting of STEMI, a previous MI should not preclude consideration for treatment with fibrinolytic agents. Without treatment, there is a potential for greater loss of function in the newly infarcting region of the myocardium. In patients with a previous MI, studies of fibrinolysis have demonstrated a 26% relative mortality rate reduction, and patients with a history of past MI who received fibrinolytic therapy for recurrent acute infarction have a decreased mortality rate compared to control patients without fibrinolytic therapy.

Many studies have reported successful fibrinolysis in STEMI patients with a prior CABG, but these patients should be preferentially considered for PCI if available in timely fashion or fibrinolysis followed by "rescue" PCI if needed. Complete thrombotic occlusion of the bypass graft is the cause of AMI in approximately 75% of cases as opposed to native vessel occlusion. Because of the large mass of thrombus and absent flow in the graft, conventional fibrinolytic therapy may be inadequate to restore flow.

Recent Surgery or Trauma. Recent surgery or trauma is considered a relative contraindication to fibrinolytic therapy. The term *recent* has been subject to variable interpretation in fibrinolytic trials. The ACCF/AHA guidelines list significant head or facial trauma in the past 3 months and intracranial or intraspinal surgery within the past 2 months as absolute contraindications to fibrinolytic therapy in STEMI. Major surgery within the past 3 weeks and recent internal bleeding (2–4 weeks) are also listed as relative contraindications to fibrinolytic therapy in the setting of STEMI.

Menstruation. There is minimal clinical experience with fibrinolysis in premenopausal women. Any excessive vaginal bleeding that may occur after undergoing fibrinolytic therapy should be readily controllable by vaginal packing and therefore can be considered as a compressible site of bleeding.

Percutaneous Coronary Intervention. Although fibrinolysis has widespread availability and a proven ability to improve coronary flow, limit infarct size, and improve survival in STEMI patients, many individuals with acute infarction are not suitable candidates. PCI has many advantages over fibrinolysis, including an increased number of eligible patients, lower risk of intracranial bleeding, significantly higher initial reperfusion rate, earlier definition of overall coronary anatomy with rapid triage to surgical intervention if appropriate, and risk stratification allowing safe early hospital discharge. Potential disadvantages include lack of operator expertise and numerous catheterization laboratory logistic issues, including limited geographic availability and delays to therapy application.

Primary PCI has been compared with fibrinolysis in several trials. Compared with standard-dose t-PA, PCI reduces the combined occurrence of nonfatal reinfarction or death, is associated with a lower rate of intracranial hemorrhage, and results in similar left ventricular function. Other studies have indicated that PCI is associated with a higher rate of patency of the infarct-related artery, less severe residual stenotic lesion, better left ventricular function, and less recurrent myocardial ischemia and infarction than in patients receiving fibrinolysis. Longer term outcomes comparing PCI with fibrinolysis are less straightforward yet, with the widespread use of drug-eluding stents (DES), have shown sustained benefit to 6 months and 1 year, assuming continued dual-agent platelet therapy and continued management of comorbid illnesses and conditions. In sum, PCI is superior when applied early and rapidly in the STEMI patient but loses its treatment advantage over fibrinolysis if time to procedure is prolonged.

Rescue Percutaneous Coronary Intervention. Historically, rescue PCI was considered advantageous in patients whose infarct-related arteries failed to reperfuse after fibrinolytic therapy. These patients are profoundly ill, with markedly worse outcomes. Some centers routinely catheterize patients after fibrinolytic therapy to determine whether successful reperfusion has occurred and to perform PCI if feasible. Other centers catheterize patients after fibrinolytic therapy only if there is clinical evidence that the infarct-related artery fails to open, as suggested by continued chest pain or persistent ST segment elevation.

Large trials have compared outcomes after rescue PCI with a conservative management strategy in STEMI patients in whom fibrinolysis has failed. Rescue PCI has not been associated with improved short-term or long-term survival; furthermore, increased rates of stroke and transfusion were noted in this group. In a meta-analysis of STEMI patients who did not achieve satisfactory reperfusion after fibrinolysis, rescue PCI was not associated with a mortality reduction. In this very ill group, however, the incidence of heart failure and recurrent infarction was reduced. Repeat fibrinolysis was not associated with significant improvements in mortality or recurrent infarction. Although the decision to offer rescue PCI to the patient in whom fibrinolytic therapy has failed remains controversial, the evidence favors rescue PCI (class IIa recommendation) and does not support the use of repeat fibrinolysis.[26]

Facilitated Percutaneous Coronary Intervention. Facilitated percutaneous coronary intervention refers to combination therapy involving fibrinolysis coupled with emergent PCI. This concept was initially developed to maximize therapy in STEMI patients who would be transferred urgently for PCI. The patient would receive the additive benefit of medical therapy (a fibrinolytic agent) before transfer, optimizing perfusion in the culprit artery before arrival at the

PCI-capable institution. Unfortunately, outcomes from this facilitated approach are inferior to fibrinolysis or standard PCI alone. In fact, in the treatment of patients with suspected STEMI, the combined application of fibrinolytic therapy followed by immediate PCI is not recommended and has received a Class III indication from the American Heart Association.[26] A facilitated PCI approach should not be used at this time outside of a scientific investigation.

Choice of Reperfusion Therapy. As noted, the two primary choices for reperfusion therapy in the STEMI patient include fibrinolysis and PCI. Important issues to consider in this treatment choice include the selected form of reperfusion therapy, total elapsed time of infarction, patient's candidacy for fibrinolysis (i.e., presence or absence of contraindications), type of hospital facility (i.e., PCI-capable or not), and anticipated time to transfer to the PCI-capable facility. Regardless of the strategy selected, the system's reperfusion goal should be a first medical contact to therapy time that is within 30 minutes for the initiation of fibrinolysis and within 60 to 120 minutes for PCI performance, with the noted range based on the varying time interval defined as symptom onset to medical contact. These time periods include transfer for PCI.

Delays in reperfusion are associated with increased mortality for PCI and fibrinolysis treatment strategies and appear to be more pronounced in patients undergoing fibrinolysis. With respect to treatment benefit, there are critical time-based differences when one considers PCI and fibrinolysis. First, PCI is the preferred strategy for STEMI reperfusion therapy, assuming that it can be performed in timely fashion. Second, deterioration in efficacy as total infarction time increases is more pronounced with fibrinolysis than with PCI. The success of PCI in reestablishing perfusion in the early hours after STEMI does not change significantly with time. Conversely, the ability of fibrinolytic therapy to restore coronary perfusion decreases significantly with increasing time of infarction, reaching a significant reduction at approximately 6 hours of total STEMI time.

When a patient with a STEMI with onset of ischemic symptoms within the last 12 hours arrives at a non-PCI-capable facility, the preferred reperfusion strategy is immediate transfer without fibrinolysis to a PCI-capable facility within an appropriate time period (AHA class I recommendation).[9,26,35] If the patient is a candidate for fibrinolysis and cannot be transferred to a PCI-capable hospital within an appropriate time period, immediate fibrinolytic therapy should be administered, with consideration of subsequent transfer for cardiac catheterization within the next 24 hours; at this time, PCI can be performed, if indicated. If the patient is not a fibrinolytic candidate, transfer should be arranged as soon as possible.[9,26,35]

In this series of recommendations, "appropriate time period" is a key phrase and must be considered from the perspective of two important variables—the total time duration of acute infarction at the time of presentation and the anticipated time to performance of PCI. The summary recommendations for reperfusion management of the STEMI patient who arrives at a non–PCI-capable hospital are as follows. Note that time zero in these recommendations is based on symptom onset time, not time of first medical contact.

- If presentation is within 2 hours or less of symptom onset, consider immediate fibrinolysis unless transfer time for PCI is anticipated to be no more than 60 minutes (AHA class IIB recommendation).
- If presentation is within 2 to 3 hours of symptom onset, consider immediate fibrinolysis or PCI if time to transfer for PCI is anticipated to be no more than 60 to 120 minutes (AHA class IIB recommendation).
- If presentation is within 3 to 12 hours of symptom onset, consider PCI as opposed to initial fibrinolysis if time to transfer for PCI is anticipated to be no more than 120 minutes (AHA class IIB recommendation).

As the total STEMI time increases, the overall effectiveness of fibrinolysis decreases significantly; at 6 hours of STEMI time, a longer delay allowing for transfer for PCI is a reasonable management option.[26]

Conversely, for the STEMI patient who arrives at a PCI-capable hospital, PCI remains the reperfusion therapy of choice, with the same time recommendations as noted above. The STEMI patient should arrive in the catheterization laboratory with initiation of the procedure within 90 minutes of initial medical contact.[9,26,35] If PCI is not possible at the PCI-capable hospital, and the patient is a fibrinolytic candidate, fibrinolytic therapy should be administered if a delay beyond 120 minutes is anticipated.

Regardless of the initial hospital's PCI capability, other candidates for PCI include high-risk STEMI patients, so-called late presenters (i.e., >3 hours since the onset of STEMI symptoms), patients in cardiogenic shock, and individuals with contraindication to fibrinolysis. Furthermore, when the diagnosis of STEMI is in doubt, PCI is the most appropriate strategy, with both diagnostic and therapeutic value. Obviously, if the patient presents to a PCI-capable facility initially, these additional scenarios are most appropriately addressed in the cardiac catheterization laboratory; alternatively, if the patient initially presents to a non-PCI-capable facility, then expeditious transfer to a PCI-capable hospital is needed for appropriate management of these scenarios.

Hospitals should have a fibrinolytic therapy plan in place for the treatment of STEMI patients in the event of PCI delay or unavailability. If the time required to mobilize staff and arrange for PCI is prolonged, or if delays in transfer are anticipated, fibrinolysis is preferred within the first several hours of STEMI occurrence. Emergency physicians and cardiologists at institutions with invasive capability should collaborate on a transfer pathway so that PCI consideration does not introduce further delays in fibrinolytic drug administration.

A cooperative effort among all providers can markedly reduce the door to therapy time in STEMI patients.[27] A so-called STEMI alert system, analogous to the trauma alert approach, mobilizes hospital-based resources, optimizing the approach to the AMI patient. This system, whether activated by data gathered in the ED or in the field, has the potential to offer time-sensitive therapies in a rapid fashion. Emergency clinician activation of the catheterization laboratory has demonstrated very high rates of accurate STEMI diagnosis while markedly reducing the time to definitive therapy, with very low rates of inappropriate activation (i.e., the STEMI mimic). The ACC and AHA recognize the numerous challenges and potential difficulties in achieving these reperfusion therapy time goals.[35]

Reperfusion Therapy in Cardiogenic Shock. Patients with STEMI complicated by cardiogenic shock, occurring in up to 10% of cases, demand special consideration because of a mortality rate approaching 80%. Fibrinolysis is not effective in these patients, likely due to significantly lower coronary perfusion pressure resulting in the occlusive thrombus not being exposed to the fibrinolytic agent. Conversely, primary PCI is associated with a significantly lower mortality rate (40%) than placebo and historical controls.

In previous studies that compared the outcomes of STEMI patients in cardiogenic shock, patients were randomly assigned to emergency revascularization (PCI or emergent CABG) or initial medical stabilization, including fibrinolysis. Overall mortality at 30 days did not differ significantly between the revascularization and medical therapy groups, but the 6-month mortality was lower in the revascularization group. This finding of reduced mortality in PCI compared to fibrinolytic therapy for patients with cardiogenic shock in the setting of STEMI has been repeated in multiple studies. Thus, emergency revascularization

with PCI or CABG is preferred for patients with STEMI complicated by cardiogenic shock, irrespective of the delay to treatment.[35] Fibrinolytic therapy should be considered in eligible STEMI patients with cardiogenic shock who are not candidates for PCI or CABG, or for whom those interventions are not available.

Resuscitated Cardiac Arrest with Suspected ACS

In the patient who has been resuscitated from out-of-hospital cardiac arrest (OHCA), postresuscitation care in the ED includes many important areas of management. Beyond the essential critical care interventions, urgent coronary reperfusion should be considered in these patients, particularly in those who demonstrated pulseless ventricular tachycardia (pVT) or ventricular fibrillation (VF) during the arrest or who have been identified as experiencing a cardiogenic cardiac arrest. The OHCA population should be considered as the most severe form of ACS. These patients frequently have considerable coronary artery disease, including acute and acute-on-chronic presentations.[39,40] Regarding outcome, more than 50% of these resuscitated cardiogenic OHCA patients who have undergone urgent coronary reperfusion survive to hospital discharge, a survival rate markedly higher than the approximately 8% to 10% survival rate of all patients experiencing OHCA cardiac arrest in the United States. However, these findings likely reflect selection bias, as patients have to achieve return of spontaneous circulation to go to PCI. Most of these patients have satisfactory neurologic function at the time of hospital discharge.

Many OHCA patients have a cardiogenic cause responsible for the cardiac arrest; they frequently presented with either pVT or VF. In fact, ACS (both STEMI and NSTEMI) is considered to be the most frequent cause; not surprisingly, the ECG demonstrates ST segment deviation in many of these patients. For example, the alert patient with pVT or VF who has been resuscitated and demonstrates STEMI on the ECG likely will benefit significantly from emergent PCI.[39,40]

Current consensus statements and guidelines suggest that early cardiac catheterization with PCI, if needed, has both survival and neurologic outcome benefit for resuscitated OHCA patients demonstrating electrocardiographic ST segment elevation.[26,39,40] The evidence for resuscitated OHCA patients lacking ST segment elevation is heterogeneous and retrospective in nature. Thus, no consensus guidelines exist addressing the early application of cardiac catheterization with PCI, if needed, in patients presenting without ST segment elevation.

A recent investigation, the COACT trial, addressed the resuscitated OHCA patient without ST segment elevation. No survival or neurologic function benefit was found in individuals undergoing immediate coronary angiography with PCI, if indicated, compared to those who were medically managed initially and then taken to the cardiac catheterization laboratory once they had recovered neurologically.[41] Thus, the most appropriate candidate types for urgent coronary reperfusion have not been conclusively identified.

However, it must be noted that the AHA recommends urgent coronary angiography with PCI, if needed, in the resuscitated OHCA patient with a cardiogenic etiology of cardiac arrest.[26] The 2015 AHA guidelines suggested that urgent cardiac catheterization with PCI, if indicated, should be considered in the resuscitated OHCA patient, regardless of the presence or absence of ST segment elevation. These guidelines noted that "…coronary angiography with PCI, if indicated, should be performed emergently in those resuscitated patients with suspected cardiogenic cardiac arrest who demonstrate electrocardiographic ST segment elevation…" as a class I indication.

Importantly, a clinical presentation of coma after OHCA should not be considered a contraindication to reperfusion therapy because this finding is commonly present. Multiple investigations have followed patients with resuscitated cardiac arrest complicated by STEMI. Among those patients who were unconscious at the time of PCI, invasive therapy restored coronary perfusion not infrequently; these initially comatose patients demonstrated approximately a 50% survival rate and good neurologic outcome. The AHA guidelines state that emergent coronary angiography is a reasonable intervention in resuscitated comatose cardiac arrest patients who do not demonstrate ST segment elevation on the ECG, as a class IIA indication.[26]

A rational approach to the resuscitated OHCA patient suspected of experiencing ACS as a cause of the cardiac arrest is suggested by the Interventional Council of the American College of Cardiology[39] and supported by the AHA in a scientific statement addressing the evolving role of the cardiac catheterization laboratory in the management of OHCA patients.[40] In this approach, urgent consultation and evaluation by a multidisciplinary team, including the interventional cardiologist, is strongly encouraged.[39] A 12-lead ECG is recommended within the first 10 minutes of hospital arrival, with the presence or absence of ST segment elevation as the first major decision point.

At this time, unfavorable resuscitation features must be considered as the ECG is interpreted; these features include unwitnessed arrest, initial nonshockable rhythm, no bystander interventions, prolonged arrest time (>30 minutes), ongoing CPR at ED arrival, abnormal serum studies (pH < 7.20, lactate > 7 mmol/l), age over 85 years, end-stage renal disease, and noncardiogenic cause of arrest. The patient with ST segment elevation who lacks multiple unfavorable resuscitation features may be appropriate for emergency angiography with PCI if indicated. The patient without ST segment elevation and an absence of multiple unfavorable resuscitation features is also suitable for early coronary angiography with PCI if indicated. In either electrocardiographic presentation, the presence of multiple unfavorable resuscitation features likely describes the patient that is not an appropriate candidate for coronary angiography, either emergent or early.[39]

Management Summary: Potential Pharmacologic Management Approach

The patient with stable or resolved chest pain, with a normal to minimally abnormal ECG and a negative serum marker(s), is best managed initially with aspirin; NTG (sublingually, topically, or in combination) is also appropriate. Resolution of the discomfort with continued stability generally does not warrant further ED pharmacologic management. Continued or recurrent pain in the ED may be treated with NTG and parenteral opioids (morphine or fentanyl). Continued pain may ultimately require IV NTG, anticoagulation with UFH or LMWH, and additional antiplatelet therapy with a thienopyridine (e.g., clopidogrel, ticagrelor). The patient with stable UA (i.e., new-onset or altered pattern but now symptom-free and lacking abnormal serum markers and an abnormal ECG) does not require heparin or other more aggressive platelet inhibition therapy in most cases.

The ACS patient with an abnormal ECG, particularly ST segment and T wave abnormalities, or elevated serum marker levels may warrant numerous therapies, including ASA, heparin, and other antiplatelet agents (typically a thienopyridine). NTG may be administered by the topical or IV route. The patient with recurrent angina may also benefit from such an approach. Heparin therapy is generally indicated in this case.

The AMI patient without ST segment elevation—the NSTEMI patient—requires aspirin, NTG, heparin, and a thienopyridine or an alternative second antiplatelet agent; opioids can also be administered, using either morphine or fentanyl. The patient with STEMI is treated with the preceding medications noted and should be considered for urgent revascularization, achieved by PCI, fibrinolytic agents or, rarely, CABG after cardiac catheterization. If PCI is the selected reperfusion therapy, some of these medications can be administered in the

catheterization laboratory; the patient need not remain in the ED to receive all such agents if the catheterization laboratory is ready.

DISPOSITION

Just as coronary artery disease and ACS represent a spectrum of disease, there is a similar spectrum of disposition options for patients presenting to the ED with chest pain or other complaints concerning for ACS. These options include rapid transport to the cardiac catheterization laboratory (CCL) within minutes of arrival for emergent intervention, ICU admission, acute care admission with cardiac monitoring, observation unit placement (actual or virtual), and discharge to home after ED evaluation. Patients with evidence of an acute or ongoing ACS event will require admission to the hospital, at times with transfer if the initial facility is resource limited. The final location of these admissions will depend on the patient's clinical presentation, electrocardiographic findings, results of the troponin assay, and cardiorespiratory status.

If the patient's presentation and ECG are consistent with STEMI, the disposition is determined by the reperfusion options available at the facility. In a facility where interventional cardiology and PCI are available, the patient can be urgently transported to the CCL for reperfusion via PCI, as long as this can be accomplished without delay. If PCI is not available as a timely option, fibrinolytic therapy should be initiated rapidly, assuming the patient has no contraindications to such intervention. Regardless of the reperfusion strategy chosen, patients with STEMI will require ICU admission due to the significant risk of adverse events during the first 24 hours of hospitalization. All hospitals, regardless of their size or resources, should have a clear care pathway for STEMI patients that may include CCL activation or fibrinolysis, followed by admission to the ICU; an expedited transfer should also be considered for the appropriate patient, dependent on the initial facility's capabilities.

In patients who have evidence of ACS without STEMI, disposition is based on the emergency clinician's risk assessment of the patient and their clinical presentation. Patients with high-risk presentations, including dynamic electrocardiographic changes, uncontrolled ischemic pain, rising troponin levels (consistent with NSTEMI or unstable angina), or evidence of hemodynamic or rhythm instability will likely benefit from ICU-level care and monitoring due to their significant risk of adverse events.

If the patient has no evidence of active ischemia, most risk stratification tools recommend separating patients into categories based on the risk of ACS and adverse events. In this category of individuals, higher-risk patients without dynamic electrocardiographic changes or elevated troponin levels often benefit from hospitalization in a monitored bed, with further diagnostic testing and management. Intermediate risk patients often benefit from abbreviated stays in an observation unit (structural or virtual unit) for repeat troponin level tests and possible provocative testing or anatomic imaging, if indicated. Patients at low risk of ACS can often receive evaluation in the ED setting, followed by discharge with follow-up with either a primary care physician or cardiologist and possible outpatient testing, as indicated.

Transfer of a Patient with Acute Coronary Syndrome

There are several indications for the transfer of a patient with ACS to a facility with PCI capability. These include rapid access to PCI, persistent hemodynamic instability or ventricular dysrhythmias, and postinfarction or post-reperfusion ischemia (i.e., after receiving a full-dose fibrinolytic agent). Hospital transfer for PCI is also suggested for patients with fibrinolytic contraindications who may benefit from PCI or CABG.

The urgent transfer of a fibrinolytic-eligible STEMI patient to another institution for PCI is not recommended until fibrinolytic therapy has been initiated if a delay in PCI application is anticipated. The ACC/AHA guidelines have noted that in hospitals without PCI capability, immediate transfer for primary PCI is a treatment option when it can be accomplished within 60 to 120 minutes of first medical contact, depending on the duration of STEMI at the time of presentation.[26] If delays in PCI performance are anticipated, and the patient is an acceptable candidate for fibrinolysis, the fibrinolytic should be started before or during transport to the receiving hospital. This decision is made in conjunction with the receiving cardiologist.

Many institutions are not PCI-capable. Thus, the decision for the emergency clinician involves not only the relatively simple fibrinolysis versus PCI issue but also the potential need for urgent transfer to a larger center. Previous studies have revealed about a 25% reduction in the composite endpoints of death, recurrent infarction, stroke, or revascularization in patients treated with PCI compared to those treated with fibrinolysis. The conclusion was that the early benefit from a transfer-related invasive strategy was sustained over long-term follow-up, but the benefit was largely due to a lower event rate in the PCI patients in the first 30 days after presentation.

The potential need to transfer the STEMI patient over long distances can also affect reperfusion therapy decisions. This is usually seen in rural areas with long transport times to the nearest PCI facility. In this setting, organized processes for rapid transfer should be in place to address the expected delays, including a rapid initiation of transfer by the emergency clinician, an agreed-on expedited transfer process to the PCI center, and rapid access to a transport vehicle (ground or air) that will be needed for safe transport. Multiple investigations have suggested that rapid transfer for PCI in the STEMI patient can occur in the rural setting with acceptable time to therapy.

Missed Diagnosis of Acute Coronary Syndrome

Approximately 2% to 4% of patients with AMI in the ED are discharged without diagnosis. Missed ACS is the misdiagnosis that accounts for the most considerable payments by emergency clinicians in medical malpractice claims. Patients with undiagnosed ACS discharged from the ED are younger, more likely to be women or nonwhite, more likely to have non–chest pain presentations, and less likely to have electrocardiographic evidence of acute ischemia. Among all patients with cardiac ischemia, women younger than 55 years seem to be at the highest risk for inappropriate discharge. With respect to electrocardiographic findings, approximately 50% of patients with missed AMI and approximately 60% of patients with missed UA have normal or nondiagnostic (i.e., minimally abnormal) ECGs. Finally, the risk-adjusted mortality ratio for all patients with acute cardiac ischemia is 1.9 times higher among nonhospitalized patients. Factors associated with misdiagnosis of ACS in medical malpractice closed claims analysis include emergency clinicians with less experience who document histories less clearly, admit fewer patients, and misinterpret the ECG.

CHAPTER 64: QUESTIONS AND ANSWERS

1. A 44-year old male presents after an episode of left-sided chest pain without radiation that lasted for approximately 5 minutes. He described the pain as a "pressure" without radiation or other significant symptoms. Onset was at rest and the symptoms are now resolved. The patient is a non-smoker, and medical history is significant only for hypertension. There is no significant family history of CAD. ECG is significant for LVH without other findings. Initial troponin testing is negative (less than the normal limit). What is the most appropriate next step in management?

a. Admission for serial troponin testing
b. Coronary CT angiography
c. Discharge to outpatient follow-up
d. Stress echocardiography

Answer: C. Utilizing the HEART score can assist in the risk stratification of this patient. Ten minutes of chest "pressure" without other typical features of ACS may be considered "moderately suspicious." Given this, the patient's heart score is 3 (1 point each for history, nonspecific repolarization disturbance on ECG, and the presence of 1 to 2 risk factors). This patient is at low risk for ACS and may be appropriately discharged from the emergency department.

2. A 48-year-old man with history of hypertension and hypercholesteremia presents with chest pain and hyperacute T waves in an anterior distribution on the initial ECG. During your initial history and physical examination the patient experiences ventricular fibrillation that responds to cardiopulmonary resuscitation (CPR) and defibrillation after being pulseless for a period of 3 minutes. Following cardiac arrest, the patient is comatose, with the following vital signs: HR 110 beats/min, BP 160/98 mm Hg, RR 12 breaths/min (intubated), temperature 36.5°C, and O_2 saturation 96%. A repeat ECG demonstrates a large, evolving anterior STEMI. Which of the following treatment plans is most appropriate?

a. Administer aspirin, PSY_{12} inhibitor, IV UFH, IV fibrinolysis, and admission to intensive care unit (ICU)
b. Administer aspirin, PSY_{12} inhibitor, IV UFH, IV fibrinolysis, initiation of therapeutic hypothermia, and admission to ICU
c. Neurologic examination for brain death and admission to palliative care because outcome is almost universally fatal
d. Rapid revascularization with percutaneous coronary intervention (PCI), initiation of therapeutic hypothermia, and admission to ICU for comprehensive postresuscitation care
e. Supportive care, and admission to ICU

Answer: D. A neurologic examination immediately following cardiac arrest is poorly prognostic of a favorable neurologic outcome with modern postresuscitation care. In the absence of multiple "unfavorable resuscitation features" (prolonged arrest, unwitnessed arrest, nonshockable rhythm, advanced age, etc.), revascularization with percutaneous coronary intervention (PCI) and immediate application of therapeutic hypothermia is warranted. Although not contraindicated, fibrinolysis is inferior to PCI following cardiac arrest and should only be used when a patient is not a candidate for PCI.

3. Which of the following is an absolute contraindication to fibrinolytic therapy?

a. Age older than 75 years
b. Appendectomy performed 2 months ago
c. Previous coronary artery bypass grafting (CABG)
d. Previous hemorrhagic stroke
e. Systolic blood pressure of 175/90 mm Hg following administration of vasoactive agents

Answer: D. Although patients older than 75 years have a higher risk of intercerebral hemorrhage, age should not be considered a contraindication to fibrinolysis. Recent major surgery or trauma is a relative contraindication for fibrinolysis; however, the term *recent* is variably defined in the fibrinolytic literature and never as more than 6 weeks. Although prior CABG patients should be preferentially considered for PCI, there is no contraindication to fibrinolytic use in these patients if PCI is not available. Systolic blood pressure above 150 mm Hg is a risk factor for intracerebral hemorrhage. Only hypertension persistently above 200/120 mm Hg, despite reasonable efforts, should be considered an absolute contraindication.

4. Which of the following drugs provides mortality benefit in the setting of AMI?

a. Aspirin
b. Intravenous beta blocker
c. Intravenous morphine
d. Nitroglycerin
e. Oxygen

CHAPTER 64: QUESTIONS AND ANSWERS—Con't

Answer: A. The ISIS-2 trial has demonstrated that aspirin independently reduces mortality by 23% in the setting of AMI. Intravenous morphine has not been shown to improve mortality and has been associated with mortality. Although nitroglycerin does improve symptoms and cause vasodilation, it has never been proven to improve mortality. Oxygen beyond that needed to maintain an oxygen saturation of 94% has been associated with additional mortality. The use of intravenous beta blockers does not offer significant benefit and is associated with an increased rate of adverse events.

5. A 42-year-old male patient presents with 45 minutes of chest pain. The ECG is depicted below (Fig. Q64.5). You are working at a noninvasive (i.e., no PCI capability) hospital; transfer time to the closest major medical center with PCI capability is 4.5 hours considering weather and logistics. The patient has no contraindications for fibrinolysis. Which of the following statements is most appropriate?

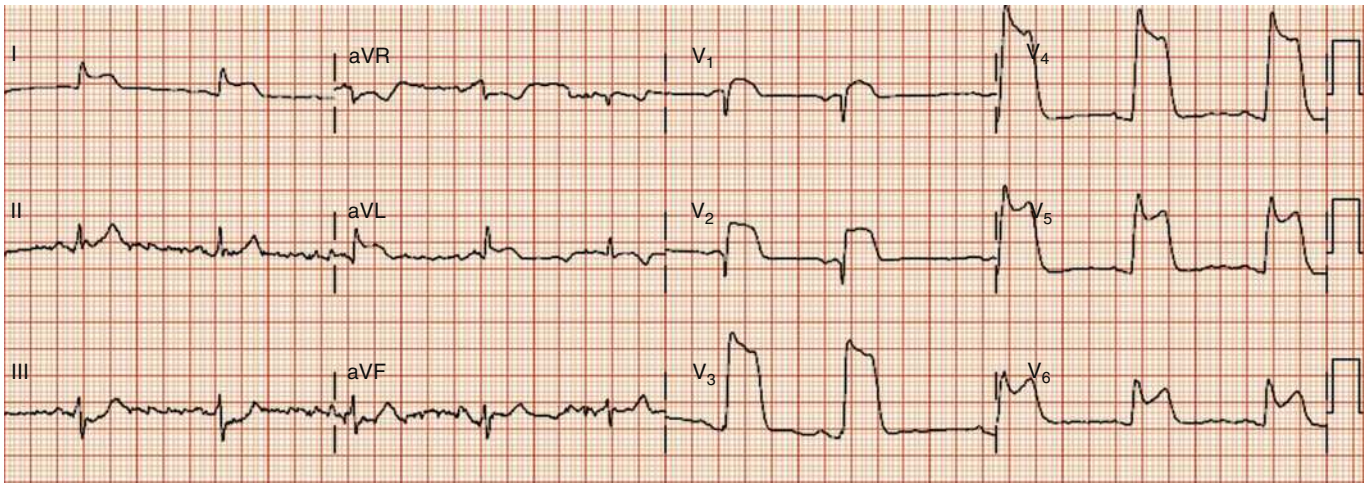
a. The patient must be transferred rapidly to the closest PCI center, with initiation of appropriate β-adrenergic blocking agents and antiplatelet and anticoagulant therapies before transfer.

b. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies with admission to your hospital's ICU.

c. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies, with transfer to the closest PCI center for immediate PCI.

d. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies, with transfer to the closest PCI center within 24 hours for reevaluation and consideration of immediate PCI.

Answer: D. The ECG demonstrates an extensive anterolateral STEMI. The patient is young and has presented early in the STEMI evolution. This patient is at extreme risk due to the extensive nature of the STEMI and yet can benefit significantly from early reperfusion therapies. A delay of more than 60 to 120 minutes in this patient is not appropriate for the initiation of reperfusion therapies; furthermore, he is a candidate for a fibrinolytic agent. The early initiation of reperfusion therapy (fibrinolysis or PCI) is vital to reduce morbidity and mortality. Such a significant delay in this case for PCI is not justified, so a fibrinolytic agent is preferred. On arrival at the closest PCI center, the patient can be evaluated for PCI if he has not demonstrated successful reperfusion with resolution of chest discomfort and normalization of the ST segment elevation.



65

Dysrhythmias

Donald M. Yealy and Joshua M. Kosowsky

KEY CONCEPTS

- Electrical therapy is appropriate for unstable patients in whom a dysrhythmia is the cause of symptoms—pacing if the heart rate is slow, countershock with sedation if fast.
- Any regular new-onset, symptomatic, wide-complex tachycardia should be assumed to be ventricular tachycardia until proven otherwise.
- Type II second-degree AV block is never a normal variant and implies a conduction block below the AV node. When the conduction ratio is 2:1, a type II block should be assumed until proven otherwise. Pacing should be readily accessible.
- Any tachycardia exceeding a rate of 225 to 250 beats/min, regardless of the QRS complex morphology, should be considered an accessory pathway syndrome. Nodal blocking agents should be avoided.
- Irregularity can be difficult to appreciate in tachycardia over 200 beats/min. Atrial fibrillation can be missed if R-R intervals at fast rates are not carefully tracked.

FOUNDATIONS

Cardiac Cellular Electrophysiology

The term *dysrhythmia* denotes any abnormality in cardiac rhythm; it is often used interchangeably with the term *arrhythmia*. Understanding dysrhythmias begins with understanding the normal electrophysiologic function of cardiac cells. Electrophysiology depends on an intact resting membrane potential, largely the result of differential concentrations of Na^+ and K^+ on either side of the cell membrane, measuring approximately −90 mV in normal resting nonpacemaker cells. This gradient exists because of the Na^+ K^+ exchange pump and concentration-dependent flow of K^+ out of the cell. The influx of Ca^{2+} through passive exchange with Na^{2+} also allows for conduction and myofibril contraction (Fig. 65.1).

In normal nonpacemaker cells, an electrical stimulus causes the membrane potential to become less negative, termed *depolarization*. When the membrane potential reaches −70 mV, specialized Na^{2+} channels open, causing a rapid influx of positive charge into the cell. This so-called fast channel activity further decreases the membrane potential and is augmented at 30 to 40 mV by a second slow channel that allows Ca^{2+} influx. When these channels close, the resting potential is restored by the sodium-potassium pump, an event termed *repolarization* (Fig. 65.2).

In nonpacemaker cells, depolarization from a second electrical stimulus is not possible when the membrane potential remains more positive than −60 mV, called the effective refractory period (Fig. 65.3). When the membrane potential reaches −60 to −70 mV, some fast channels are capable of responding but impulse propagation is not normal; this is known as the relative refractory period. At a membrane potential of −70 mV or less, fast channels are ready for activity (see Fig. 65.3).

Pacemaker cells differ from non–impulse-generating cells in that they can spontaneously depolarize via slow Na^+ influx. Dominant pacemaker cells are present in the sinoatrial (SA) node, but other pacemaker cells exist in the atrioventricular (AV) node, within the His-Purkinje system, and elsewhere. With a failure of normal pacemaking cells, or in the setting of other pathologic conditions such as metabolic derangement or myocardial ischemia, nonpacemaker cells undergo spontaneous depolarization.

Anatomy and Conduction

The SA node is an area of specialized impulse-generating tissue at the junction of the right atrium and the superior vena cava. Its blood supply is from the right coronary artery (RCA) in 55% of patients and left circumflex artery (LCA) in 45%. The normal SA node produces spontaneous depolarization faster than other pacemakers and is usually the dominant pacemaker. In healthy adults, the SA node typically maintains a rate of 60 to 90 beats/min. Hypothermia and vagal stimulation slow the sinus rate, whereas hyperthermia and sympathetic stimulation increase the rate. Low or absent parasympathetic tone—for example, with certain drugs or after heart transplantation—results in a faster sinus rate.

In the absence of normal SA node impulses, other myocardial tissues may assume the role of a pacemaker. The AV node has an intrinsic impulse-generating rate of 45 to 60 beats/min. Infranodal pacemakers within the His bundle, Purkinje system, and bundle branches maintain intrinsic rates ranging from 30 to 45 beats/min. Under pathologic conditions, other atrial and ventricular tissues may pace the heart at varying rates.

Impulses from the SA node are propagated through the atrial tissue to the AV node. Atrial depolarization is characterized by the P wave on the surface electrocardiogram (ECG; Fig. 65.4).

The AV node is an area of conduction tissue separating the atria and the ventricles, located in the posterior-inferior region of the interatrial septum. Its blood supply is from a branch of the RCA in 90% of patients (right dominant) and from the LCA in the remaining 10% (left dominant). Transmission of impulses within the AV node is slower than in other parts of the conducting system (Table 65.1) because of a dependence on slow-channel ion influx for membrane depolarization. An accessory pathway refers to conduction tissue outside the AV node that forms an alternative, or bypass, tract between the atria and ventricles. The term *preexcitation* refers to early ventricular depolarization via an accessory pathway.

On the surface ECG, the time it takes to conduct an impulse through the atria to the ventricles is represented by the PR interval, normally ranging from 0.10 to 0.20 second (see Fig. 65.4). Impulses originating in lower atrial tissues or accessory pathways often have a shortened PR interval. PR prolongation is usually a result of nodal or supranodal conduction system disease.

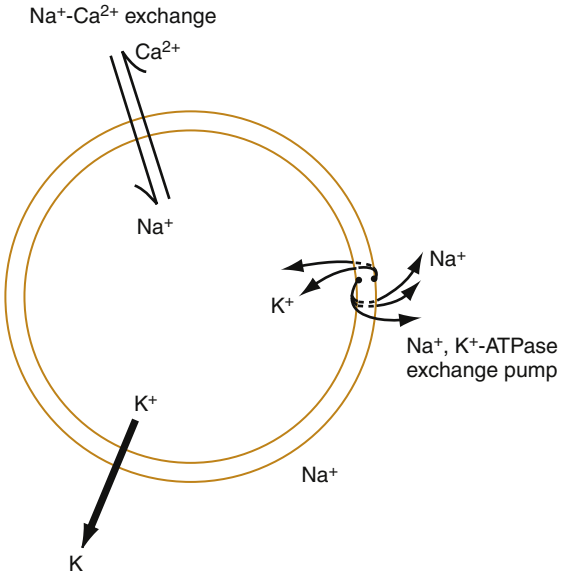


Fig. 65.1 Flow of various ions across the myocardial cell membrane. The Na^+-K^+ pump exchanges three Na^+ ions for each two K^{2+} ions, generating a net negative flow of 10 mV. The flow of K down the concentration gradient (*dark arrow*) generates another 80 mV of current. The Na^+–Ca^{2+} exchange adds little to the resting potential. *ATPase,* Adenosine triphosphatase. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby; 1989.)

After passing through the AV node, impulses propagate to the His bundle onto the three main bundle branch fascicles—the right bundle branch (RBB), left anterior-superior bundle (LASB), and left posterior-inferior bundle (LPIB). The RBB and LASB are typically supplied by the left anterior descending (LAD) artery, whereas the RCA or LCA may supply the LPIB. After conduction down the three main bundle branches, impulses are delivered to the Purkinje fibers, propagating impulses to myocardial tissues in a swift and orderly fashion, allowing for coordinated ventricular contraction. If an impulse arrives prematurely, it may be conducted abnormally (termed *aberrant*, associated with bundles that are relatively refractory) or blocked (if the bundles are entirely refractory).

On the ECG, the QRS complex represents ventricular depolarization (see Fig. 65.4), normally 0.09 second or less; 0.12 second or longer is abnormal. The T wave corresponds to ventricular repolarization and its duration depends, among other things, on the length of the cardiac cycle. The QT interval represents the total time of ventricular depolarization and repolarization and is altered by inherent physiologic abnormalities, metabolic changes, drugs, or structural changes. This interval is key to assess for QT prolongation in any patient with syncope or ventricular dysrhythmia, given the link to ventricular dysrhythmia recurrence.

Mechanisms of Dysrhythmia Formation

Enhanced automaticity refers to spontaneous depolarization in nonpacemaker cells or depolarization at an abnormally low threshold in pacemaker cells (Fig. 65.5). Classic examples of enhanced automaticity include the idioventricular rhythms of severe hyperkalemia or myocardial ischemia and the atrial or junctional tachycardias (JTs) associated with digoxin toxicity.

Triggered activity refers to abnormal impulse(s) resulting from afterdepolarizations. Afterdepolarizations are fluctuations in membrane potential that occur as the resting potential is restored. These fluctuations may precipitate another depolarization just before the full resting potential is reached (early afterdepolarizations) or after full resting potential is reached (delayed afterdepolarizations). The classic dysrhythmia associated with early afterdepolarization is acquired torsades de pointes, which typically arises in the setting of a prolonged QT interval and a new metabolic or drug trigger. Delayed afterdepolarizations classically arise in the setting of rapid heart rates and intracellular Ca^{2+} overload, as seen with digoxin toxicity or reperfusion therapy for acute myocardial infarction.

Reentry dysrhythmias arise from repetitive conduction of impulses through a self-sustaining circuit (Fig. 65.6). To maintain a reentry circuit, one conduction pathway must have a longer refractory period than the other so that when an impulse exits one limb of the circuit, it may then reenter the other in retrograde fashion. The cycle is then repeated, creating self-sustaining dysrhythmia. Reentry mechanisms are responsible for most regular narrow-complex tachycardias and many ventricular tachycardias (VTs). Treatment is predicated on altering conduction in one or both limbs of the circuit.

CLASSIFICATION OF ANTIDYSRHYTHMIC DRUGS

The four classes of antidysrhythmic medications are categorized according to their electrophysiologic effects (Box 65.1). Class I agents exert their major effects on the fast Na^+ channels, resulting in membrane stabilization. The subclasses IA, IB, and IC have differing effects on depolarization, repolarization, and conduction. Class II agents are the β-adrenergic antagonists, which depress SA node automaticity, slow AV node conduction, and suppress conduction in ischemic myocardial tissue. Class III agents prolong repolarization and refractory period duration, predominantly via their effects on K^+ channels. Class IV agents are the Ca^{2+} channel blockers, which slow conduction through the AV node and suppress other calcium-dependent dysrhythmias. Other agents important in the emergency treatment of dysrhythmias include magnesium sulfate, digoxin, and adenosine.

Class IA Agents

Class IA agents slow conduction through the atria, AV node, and His-Purkinje system and suppress conduction in accessory pathways. As such, they slow both depolarization and repolarization. Class IA agents also exhibit anticholinergic and mild negative inotropic effects.

Procainamide

Procainamide is the only class IA agent commonly used in the emergency treatment of ventricular and supraventricular dysrhythmias, and it can alter normal and accessory pathway conduction. In stable patients, the recommended administration is a rate of 20 to 30 mg/min until the dysrhythmia is terminated, hypotension occurs, or the QRS complex widens (to 50% of the pretreatment width), up to a total dose of 18 to 20 mg/kg (12 mg/kg if congestive heart failure is present). Procainamide triggers hypotension from vasodilatory effects in 5% to 10% of patients and may be associated with or worsened by infusion rate. It is the preferred agent in treating Wolff-Parkinson-White syndrome.

Class IB Agents

Class IB agents slow conduction and depolarization less than other class I agents, and they shorten repolarization rather than prolonging it. Class IB agents have little effect on accessory pathway conduction.

Lidocaine

Lidocaine is the sole class IB agent used in emergency rhythm management. Lidocaine can suppress dysrhythmias from enhanced

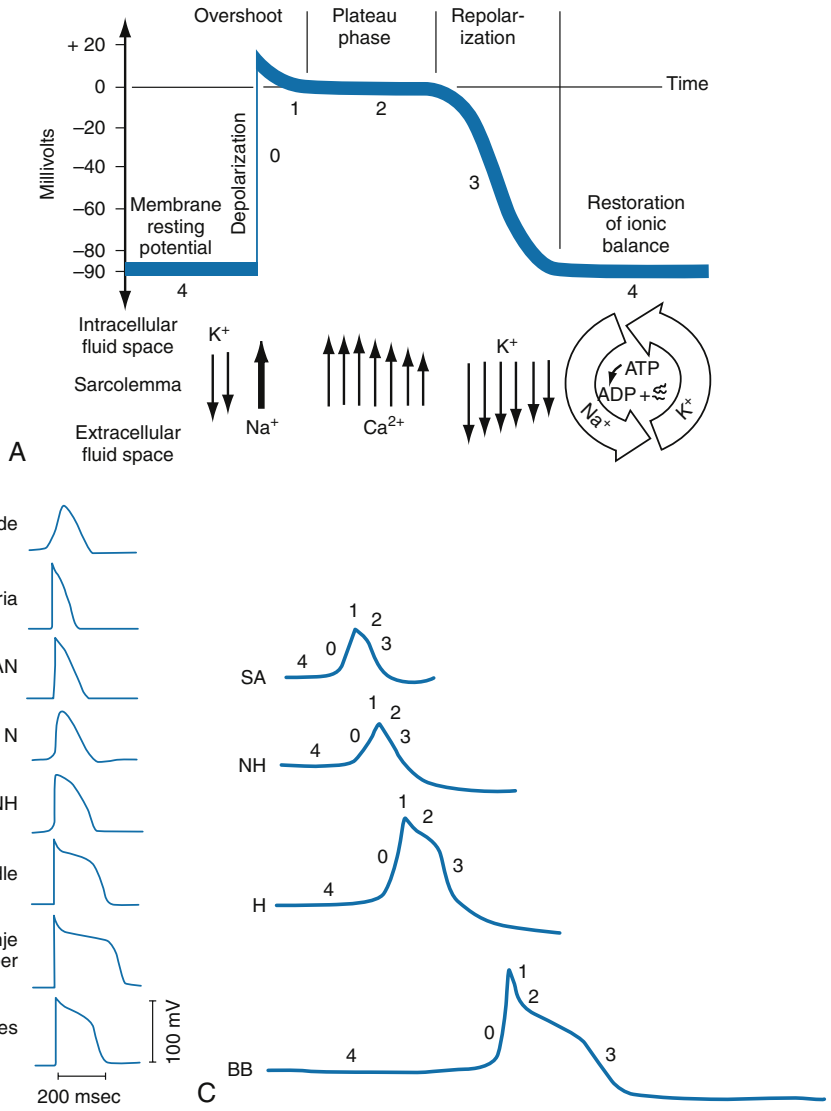

Fig. 65.2 (A) Action potential of a myocardial cell and its relation to ion flow. (B) Action potentials of various myocardial tissues. (C) Action potentials of various pacemaker cells. Note that phase 4 becomes flatter as its location becomes more distal. *AN,* Atrial-nodal; *AV,* atrioventricular; *BB,* bundle branch fascicles; *H,* His bundle; *N,* nodal; *NH,* nodal-His; *SA,* sinoatrial. ([A and B] From Calcium in cardiac metabolism, Whippany, NJ, 1980, Knoll Pharmaceutical; and [C] from Conover M. Understanding electrocardiography. ed 5. St Louis: Mosby; 1988.)

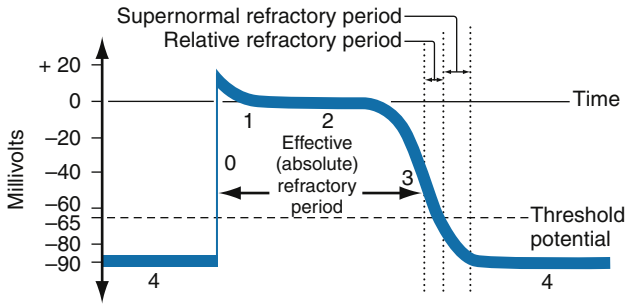

Fig. 65.3 Action potential showing various refractory periods. (From Calcium in cardiac metabolism, Whippany, NJ, 1980, Knoll Pharmaceutical.)

automaticity, such as VT. Lidocaine also suppresses SA and AV node function and is associated with asystole in the setting of acute myocardial ischemia. Lidocaine is an alternative to amiodarone but has no efficacy in SVT.

Class IC Agents

The class IC agents profoundly slow depolarization and conduction. More than any other class, these agents are associated with *prodysrhythmia*, the creation of a new dysrhythmia; this potential new dysrhythmic event also exists with class IA agents albeit much less than class IC. Class IC agents are approved for oral use in the United States.

Flecainide

Flecainide is a class 1C antidysrhythmic agent used for paroxysmal supraventricular tachycardia and certain forms of VT. Flecainide has high oral bioavailability, variable half-life, and narrow therapeutic index, all hampering its use. Flecainide is not recommended for patients with ischemic or structural heart disease.

Propafenone

Propafenone shares electrophysiologic properties with classes IA and IC agents and possesses some β-adrenergic and calcium channel-blocking

properties. Oral propafenone is used to prevent atrial fibrillation and ventricular dysrhythmias. Like flecainide, propafenone is used with caution in patients who have ischemic or structural heart disease.

Class II Agents

Class II agents—β-adrenergic blockers—suppress SA node automaticity and slow conduction through the AV node. Because of their effect on AV node conduction, class II agents are well suited to control the ventricular rate in patients with atrial tachydysrhythmias and can be useful to terminate AV nodal reentrant tachycardias (AVNRTs). In the setting of acute myocardial ischemia, beta blockers may lessen the frequency of ventricular dysrhythmias.

All beta blockers are active at β_1 and β_2 receptors (Table 65.2) to varying degrees; those with more prominent β_1 effects are called cardioselective. Relative contraindications to the use of beta blockers include advanced congestive heart failure and third-trimester pregnancy. Historically, beta blockers have been avoided in patients with asthma and chronic obstructive pulmonary disease. However, cardioselective beta blockers are not associated with an increased risk of asthma or chronic obstructive pulmonary disease (COPD) exacerbations.[1] Beta blockers should not be used in patients with preexisting bradycardia or heart block beyond first-degree. Acute side effects of beta blockers include heart failure, excessive bradycardia, and hypotension. In rare cases, they may cause bronchospasm, but most instances are not clinically apparent. Intravenous (IV) beta blockers can trigger additive side effects when used in conjunction with calcium channel blockers, notably hypotension or bradycardia. Only two beta blockers are commonly used in emergency care of dysrhythmias.

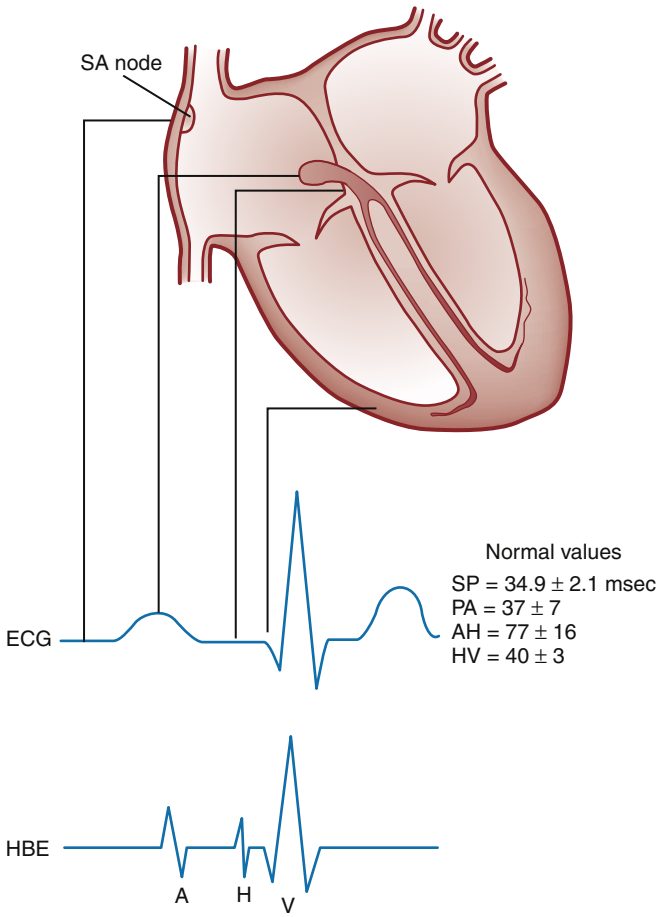

Fig. 65.4 Electrical events in the heart related to surface electrocardiogram (ECG) and His bundle electrogram (HBE). The approximate relationship of sinus node discharge is also related to the surface ECG. *AH,* Atrioventricular nodal conduction time; *HV,* His-Purkinje conduction; *PA,* intra-atrial conduction time; *SA,* sinoatrial; *SP,* SA conduction time. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby; 1989.)

Esmolol

Esmolol is an intravenous β_1-selective agent useful in the emergency setting because of its rapid onset of action and short elimination half-life (minutes). Common dosing of esmolol is an IV bolus of 500 μg/kg followed by a continuous infusion beginning at 50 μg/kg/min and titrating to need and effect.

Metoprolol

Metoprolol is available in oral and IV preparations. Although not approved for dysrhythmia treatment in the United States, metoprolol (5 to 10 mg IV every 10 to 15 minutes in an adult, titrated to response) will slow atrial and nodal tachycardias.

Class III Agents

All class III agents prolong the refractory period primarily by blocking K^+ channels, with variable effects on the QT interval. In general, class

TABLE 65.1 Conduction Velocities in Various Heart Tissues

Tissue	Velocity (m/s)
Atrium	1000
Atrioventricular node	200
His-Purkinje system	4000
Ventricles	400

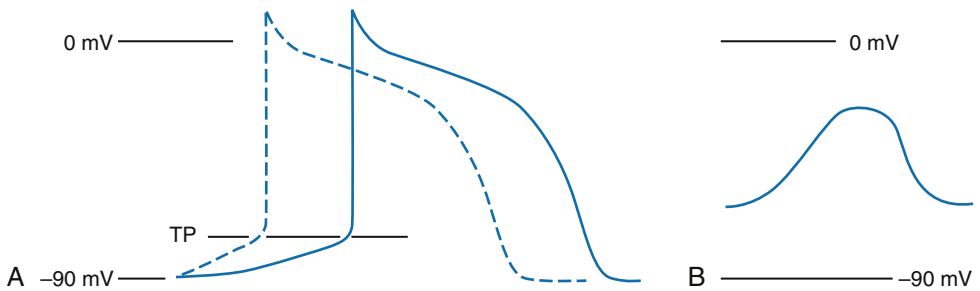

Fig. 65.5 (A) Enhanced normal automaticity (*dashed line*). (B) Abnormal automaticity. *TP,* Threshold point. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby; 1989.)

III agents are alternatives to class I agents for the treatment of many ventricular and atrial dysrhythmias.

Amiodarone

Amiodarone is approved for the treatment of ventricular and supraventricular dysrhythmias and is a first line drug treatment for acute ventricular tachycardia. In addition to features in common with all class III agents, amiodarone has other effects, including actions similar to those of class IA, II, and IV agents.

The serum half-life of amiodarone is 9 to 36 days after a single IV dose and up to 107 days during long-term oral use. Because of its unusual pharmacokinetics, oral regimens vary widely. The acute side effects of amiodarone include hypotension, bradycardia, and heart failure (Box 65.2). There is an additive risk of bradycardia and hypotension when amiodarone is used in conjunction with calcium channel or β-adrenergic blockers. Rates of prodysrhythmia are relatively low. Long-term amiodarone use may create extracardiac side effects, including both reversible and irreversible lung and thyroid disease. Amiodarone alters the pharmacokinetics of numerous other drugs, including digoxin and warfarin.

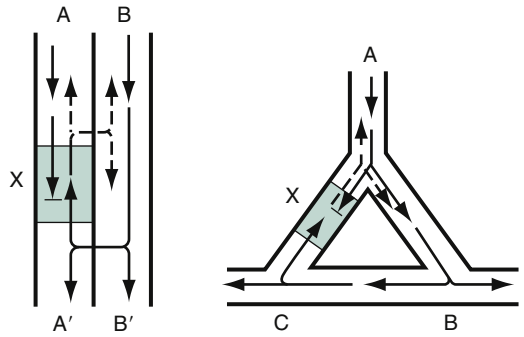

Fig. 65.6 Mechanism of reentry.

Ibutilide

Ibutilide is a parenteral agent that induces a slower inward Na^{2+} current, prolonging the refractory period. IV ibutilide approved indications include cardioversion of atrial fibrillation and atrial flutter. Because of QT prolongation and the risk of polymorphic VT, we recommend to start ibutilide with continuous cardiac rhythm monitoring.

Sotalol

Sotalol is an oral β-adrenergic receptor blocker with type III antidysrhythmic properties. Uses are for the suppression of supraventricular and ventricular dysrhythmias. Like ibutilide, sotalol initiation is best with cardiac monitoring setting, watching for QT prolongation; it has a very limited role in emergency care.

Dofetilide

Dofetilide is a powerful class III agent approved for chemical cardioversion and maintenance of sinus rhythm in patients with atrial fibrillation or flutter. However, because of its high risk for prodysrhythmia, it is used sparingly and prescribed by physicians with specialized training. It has no current role in emergency care.

Dronedarone

Structurally related to amiodarone, dronedarone displays class III properties in addition to those of other antidysrhythmic classes. Dronedarone is approved for oral use to maintain sinus rhythm in patients

BOX 65.1 Classification of Antidysrhythmic Drugs

Class I
Sodium (fast) channel blockers—slow depolarization with varying effects on repolarization. These drugs have membrane-stabilizing effects.

Class IA
Moderate slowing of depolarization and conduction; prolong repolarization and action potential duration.
Procainamide
Quinidine
Disopyramide

Class IB
Minimally slow depolarization and conduction; shorten repolarization and action potential duration.
Lidocaine
Phenytoin
Tocainide
Mexiletine

Class IC
Markedly slow depolarization and conduction; prolong repolarization and action potential duration.
Flecainide
Propafenone (shares properties with class IA agents)
Vernakalant (atrial-specific, investigational)

Class II
β-Adrenergic blockers
Propranolol
Esmolol
Metoprolol
Atenolol

Class III
Antifibrillatory agents—prolong action potential duration and refractory period duration with antifibrillatory properties.
Bretylium (historical significance)
Amiodarone
Dofetilide
Ibutilide[a]
Sotalol[b]
Dronedarone
Azimilide

Class IV
Calcium (slow) channel blockers
Verapamil
Diltiazem

Miscellaneous
Digoxin
Magnesium sulfate
Adenosine

[a] Shares activity with class I agents.
[b] Shares activity with class II agents.

TABLE 65.2 Cardiac and Respiratory β-Adrenergic Receptors and Responses to Pharmacologic Manipulation

Response to Receptors	Location	Stimulation	Antagonism
β_1-Adrenergic	Heart	Increased heart rate and ectopy	Decreased heart rate and ectopy
		Increased contractility	Decreased contractility
β_2-Adrenergic	Airway (smooth muscle)	Decreased tone (relaxation)	Increased tone (contraction)
	Peripheral vasculature	Decreased tone (relaxation)	Increased tone (contraction)

BOX 65.2 Adverse Effects of Amiodarone

Acute Effects
Hypotension
Slowing of heart rate
Decreased contractility

Long-Term Effects
Common Effects
Corneal deposits
Photosensitivity
Gastrointestinal intolerance

Less Common Effects
Hyperthyroidism
Heart failure
Pulmonary toxicity, fibrosis
Hypothyroidism
Bradycardia
Prodysrhythmic effect
Blue-green skin discoloration

Drug Interactions
Increased Levels
Phenytoin
Procainamide
Warfarin
Digoxin
Flecainide

with atrial fibrillation or flutter but is contraindicated in patients with severe or recent heart failure. It has no current role in emergency care.

Class IV Agents

Class IV agents block slow Ca^{2+} channels, slowing conduction within the AV node and suppressing the SA node to a lesser degree. Like beta blockers, these are used in patients with supraventricular tachycardia. All class IV agents are associated with peripheral vasodilation. Verapamil has the least effect on peripheral vascular tone, and diltiazem has an effect between that of verapamil and purely peripherally acting calcium channel blockers (e.g., nifedipine). Both agents can be given orally after IV use if needed. Class IV drugs are should be avoided in patients with second- or third-degree AV block unless the patient has an external pacemaker. Class IV drugs may cause excessive bradycardia in those with first-degree AV block.

Diltiazem

IV diltiazem dosing is a 0.25 to 0.35 mg/kg bolus over 2 minutes. For longer-term rate control, a continuous infusion (5 to 15 mg/hr IV initially, then titrated to need) or an oral dose (60 to 90 mg immediate-release formulation initially) will sustain the response.

Verapamil

Verapamil is rarely used in emergencies, although it is effective. A starting dose of 0.1 mg/kg IV over 1 to 2 minutes; for the average healthy adult, this translates to a dose of 5 to 10 mg, which can be repeated or increased by 50% if unsuccessful and there is no hypotension 10 minutes after administration. In older adults or those with borderline hypotension (systolic blood pressure of 90 to 110 mm Hg), use a smaller dose (0.05 mg/kg IV or 2.5 mg increments).

Miscellaneous Agents

Adenosine

Adenosine is a naturally occurring purine nucleoside used to terminate regular, nonatrial, narrow-complex tachydysrhythmias, notably junctional reentry. Administered as an IV bolus, adenosine causes an abrupt slowing of AV conduction in anterograde and retrograde pathways. Adenosine has an onset of action of 5 to 20 seconds and a duration of effect of 30 to 40 seconds. Except in rare cases, adenosine has little or no effect on infranodal conduction pathways. For this reason, adenosine is an option as a diagnostic (and sometimes therapeutic) agent in patients with wide-complex tachydysrhythmia when the specific rhythm is unclear. Patients with transplanted hearts are very sensitive to adenosine and may have profound nodal block.

Start adenosine by using a 6-mg rapid IV bolus (through a large, non–distal vein followed by a rapid flush) for adults (≥50 kg body mass); one key to success is the rapid bolus adherence. If no response is seen within 1 to 2 minutes, increase the dose to a 12-mg rapid IV bolus. If no effect is seen after a second 12-mg dose, then reassess the rhythm and use another therapy. There is no benefit to repeating adenosine when transient lowering of the heart rate occurs after a dose is given, followed by a return to the previous rhythm. Pediatric doses are 0.05 mg/kg initially, with doubling at similar intervals, up to a total dose of 0.25 mg/kg. Heart transplant patients should receive 0.025 mg/kg, for starting doses of 1.5 to 3 mg.[2]

Side effects occur in up to one-third of patients given adenosine but are usually minor and self-limited. These include flushing, dyspnea, chest pressure, nausea, headache, dizziness, transient bradycardia or heart block, sense of impending doom, and hypotension. Asystole is possible but generally transient.

Because of its short duration of action, adenosine is not an effective rate-control agent for atrial fibrillation or flutter, although it can help unmask these rhythms when not apparent on the initial surface ECG.

Digoxin

Digoxin compounds have a variety of effects on myocardial cells: They inhibit the adenosine triphosphate (ATP)–dependent Na^+-K^+ exchange pump, increasing intracellular Na^+ concentrations, and decrease intracellular K^+ concentrations. The resultant increase in intracellular Ca^{2+} concentration accounts for the positive inotropic effects of digoxin. The prodysrhythmic effects of digoxin are enhanced automaticity and triggered activity, particularly at high therapeutic or toxic doses. At the

BOX 65.3 Adverse Effects of Digoxin

Common Effects

Gastrointestinal intolerance (e.g., nausea, vomiting, abdominal pain, diarrhea, anorexia)
Fatigue
Drowsiness

Psychosis
Cardiac symptoms
Heart block
Increased ectopy
Combined block and ectopy (multifocal atrial tachycardia with block or complete atrioventricular block with accelerated junctional rhythm, usually in the overdose setting)
Ventricular tachycardia
Visual color disturbances

same time, digoxin slows AV node conduction via lengthening of the refractory period. Classic (albeit not common) digoxin toxicity shows signs of both enhanced excitability and slowed conduction (rapid atrial activity with slow ventricular responses or AV block.)

Digoxin (0.25 to 0.5 mg IV) can control the ventricular rate in patients with supraventricular tachycardia, notably atrial fibrillation and atrial flutter. Because of its slower onset of action (often not therapeutic for 30 minutes or longer and peaking at 6 hours), digoxin is not a first-line agent for emergency therapy. However, digoxin can be beneficial in the acute treatment of dysrhythmias in patients with cardiogenic shock or heart failure.

Side effects of digoxin are listed in Box 65.3 and are aggravated by hypokalemia, hypercalcemia, hypomagnesemia, increased catecholamine levels, and acid-base disturbances. Digoxin toxicity is discussed in Chapter 147.

Magnesium

Magnesium can abort ventricular dysrhythmias via its membrane-stabilizing properties. Magnesium (1 to 2 g IV) may terminate torsades de pointes and is an adjunct in ventricular tachycardia therapy.

Isoproterenol

This non-selective beta-adrenergic agonist is used to treat some bradycardic patients—notably those with denervation like post-heart transplantation—or to prevent acquired torsades de pointes recurrence in some cases of beta-blocker overdose. It directly stimulates beta-1 and beta-2 receptions, speeding SA and AV activity and enhancing contractility while relaxing vascular and other smooth muscles. It may increase heart rate, but blood pressure effects vary by the relative impact on cardiac output (increase) and vasodilation (decrease). Administration is via IV bolus if needed (1 to 2 mcg), but more commonly by IV infusion (2 to 10 mcg/minute titrated to effect).

Clinical Features

Dysrhythmias are classified according to their electrophysiologic origin, appearance on the ECG, and underlying ventricular rate. Although overlap exists, the following categorization is useful:

- Bradycardias
- Extrasystoles
- Narrow-complex (QRS < 0.12 second) tachycardias (regular and irregular)
- Wide-complex (QRS ≥ 0.12 second) tachycardias (regular and irregular)

The clinical approach to a patient with suspected dysrhythmia starts with assessing clinical stability, which is driven by the effect on perfusion. Unstable patients have severe or multiple end-organ features of hypoperfusion, such as altered sensorium, respiratory distress, hypotension, syncope, or chest pain suggestive of myocardial ischemia. Stable patients may be asymptomatic or have mild symptoms, such as lightheadedness, dyspnea on exertion, palpitations, or mild anxiety. In practice, clinical stability is a continuum; in the absence of profound altered sensorium or hypotension, distinguishing stable and unstable patients with precision is often not possible. One simple axiom is important:

- Unstable patients with a dysrhythmia outside of a clear external trigger (e.g., bradycardia for hypothermia or tachycardia for hypovolemic or distributive shock) need prompt electrical therapy—a countershock if there is a fast rate with a pulse, or cutaneous pacing if there is a slow rate with a pulse. Care of patients with cardiac arrest (i.e., those with no pulse) is discussed in Chapter 8.

A key consideration is whether dysrhythmia is the cause or effect of a clinical presentation; for example, rapid atrial fibrillation may cause hypotension or may be a response to volume depletion. Failure to consider the clinical situation can harm a patient (e.g., giving a rate-slowing agent when the tachycardia is a response to hypovolemia). Thus, the most important decision is often whether dysrhythmia is likely the primary cause of instability. When there does not appear to be another cause, treating the dysrhythmia as primary is appropriate. In a stable patient, a more systematic approach allows identifying the cause and choosing the most appropriate therapy.

Initial Assessment of Stable Patients

The approach begins with gathering evidence from the history, physical examination, and 12-lead ECG with a rhythm strip. The symptom characteristics are important, including the timing, velocity of onset (gradual vs. abrupt), and duration. For patients with palpitations, clinicians should ask about the rate and regularity of the heartbeat or have the patient tap out the rhythm with a finger. Other important questions include precipitating events and associated symptoms, such as dizziness, chest pain, dyspnea, or syncope. A history of rhythm disturbances, ischemic or structural heart disease, and the medication history may raise a concern for specific rhythms. For example, a new and symptomatic wide-complex tachycardia in a patient with known ischemic heart disease is much more often VT than a supraventricular dysrhythmia. Occasionally, the family history helps, particularly if there are first-degree relatives with a history of dysrhythmia, unexplained syncope, or sudden death—all of which suggest an inherited disorder, such as an accessory pathway or Brugada syndrome.

Aside from palpating the pulse and listening to the heart sounds, the physical examination should be focused on detecting evidence of end-organ hypoperfusion or clues to an underlying cause of the dysrhythmia (e.g., left ventricular failure or thyromegaly). Observing the patient's rhythm on a continuous cardiac monitor while he or she reports symptoms can determine if symptoms link to electrocardiographic findings.

Differential Diagnosis

Loose leads, muscle contraction, shivering, tremors, and other movements can produce artifactual findings on a monitor, rhythm strip, or 12-lead ECG (Fig. 65.7). Such *pseudodysrhythmias* mimic serious dysrhythmias, including ventricular fibrillation. One should avoid

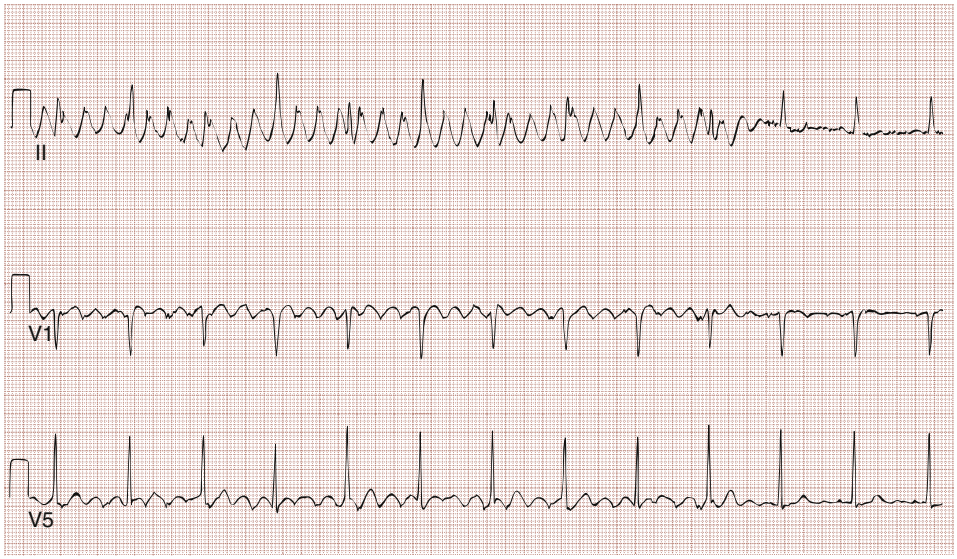

Fig. 65.7 Pseudodysrhythmia. In this case, atrial flutter waves appear to be present but are recognized as an artifact when the patient and right side of the electrocardiogram are examined.

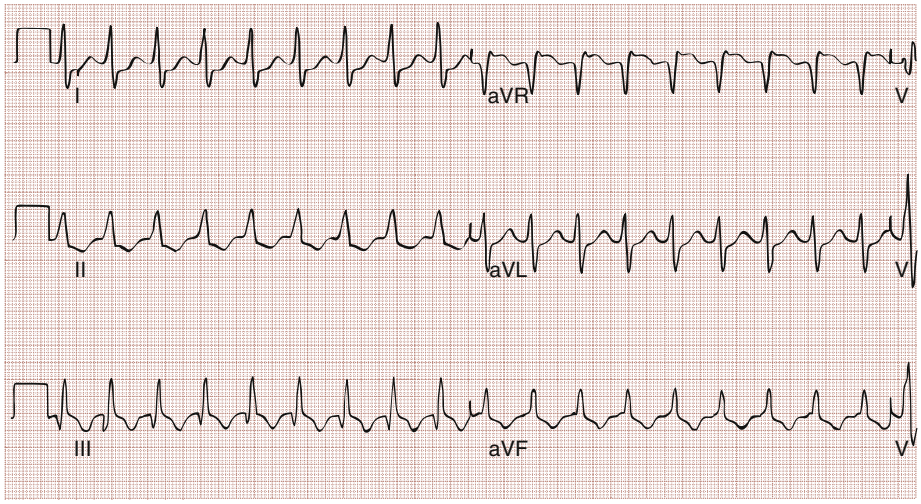

Fig. 65.8 Note the P waves before the QRS complexes in lead aVF.

decisions based solely on the ECG without incorporating the clinical context.

The 12-lead ECG is essential to evaluating any patient with a suspected dysrhythmia. The use of a single ECG lead is often adequate for diagnosis, especially in unstable patients; multiple leads are optimal in stable patients. The latter helps detect the presence or absence of P waves (often best seen in inferior leads or $V_{1\text{-}2}$; Fig. 65.8), the relationship between P waves and QRS complexes, prolongation of the QRS and QT interval, and evidence of ischemia or prior myocardial infarction (Box 65.4). For certain conditions, such as Brugada syndrome, the 12-lead ECG, together with a history of syncope, is diagnostic. Because useful information about paroxysmal dysrhythmias occurs at the onset or termination of the rhythm, inspect those areas carefully and save the strip(s) for future reference.

Vagal maneuvers, such as carotid sinus massage and the Valsalva maneuver, increase parasympathetic tone through the vagus nerve to transiently slow AV conduction, which may help uncover or terminate a supraventricular rhythm disturbance. In the ED, these maneuvers often fail, likely from a selection bias (easy responders terminate before arrival) or ineffective technique. The key to using physical methods of

BOX 65.4 Basic Electrocardiographic Observations During Dysrhythmia Analysis

1. Ventricular rate—fast (>100 complexes/min), slow (<60 complexes/min), or normal (60–100 complexes/min).
2. Rhythm—regular, completely irregular (irregularly irregular or chaotic), regular with occasional irregularity, or grouped impulses; calipers, long strips help detect subtle irregularities
3. QRS width—prolonged (>0.12 s), borderline (0.09–0.12 s), or normal. If determined without electrocardiogram being physically present (e.g., prehospital radio medical command), ask for QRS duration in "number of small boxes" from printed rhythm strip (each box = 0.04 s) to ensure accuracy.
4. P wave presence and relationship to QRS complexes—May require mapping of P waves with calipers to detect those falling within QRS complex or T wave.
5. Rhythm changes—examine these areas closely for clues.
6. Multiple leads, especially chest leads or esophageal lead if difficulties with P wave visualization are experienced.
7. Comparison with previous tracings (if available) is often valuable.

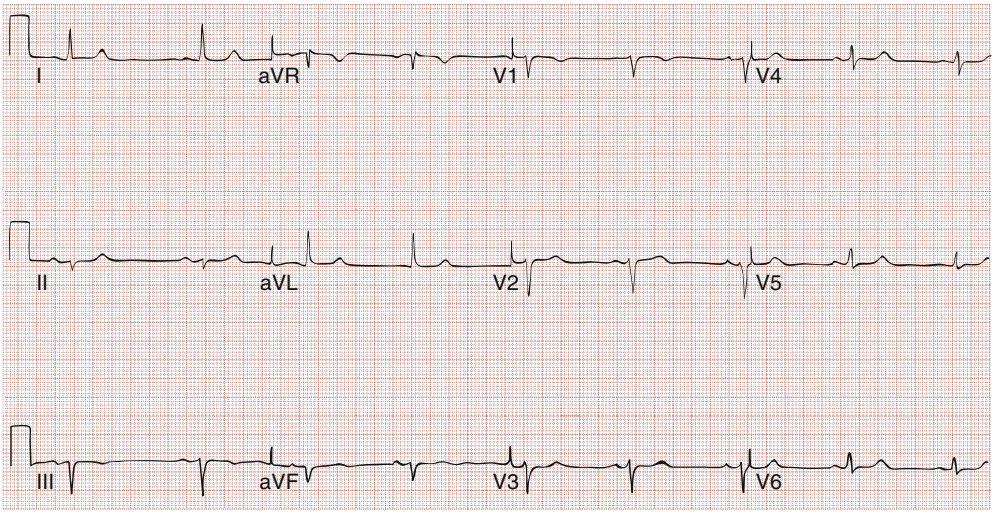

Fig. 65.9 Sinus bradycardia.

enhancing parasympathetic tone is to optimize technique—have the patient lie flat, lift the legs, and ask for a Valsalva effort, with or without massage, to enhance success. A nodal reentrant tachycardia may terminate abruptly with vagal maneuvers, whereas it often temporarily slows the ventricular rate in those with atrial fibrillation or atrial flutter; ventricular tachycardia patients rarely have any change after vagal maneuvers. Vagal maneuvers are frequently unsuccessful in the ED but rarely result in clinical deterioration. Auscultate the neck for bruits before carotid sinus massage, particularly in older patients, and avoid the maneuver if any are found or preexisting carotid disease is likely. Other vagotonic maneuvers, such as rectal or ocular massage and ice water head dunking, are impractical and less effective.

MANAGEMENT

Sinus Bradycardia and Sinoatrial and Atrioventricular Block

Bradycardia is defined as a ventricular rate of less than 60 beats/min, although in practice, rates above 50 beats/min are not usually a concern. Bradycardia occurs because of depression of the sinus node or because of a conduction system block; when the rate falls below a threshold, a subsidiary pacemaker elsewhere in the atrium, AV junction, or ventricle may assume the dominant role, resulting in an escape rhythm.

Sinus Bradycardia

Sinus bradycardia shows an ECG with a P wave assuming normal morphology, a fixed P-P interval equal to the R-R interval, and a ventricular rate below 60 beats/min (Fig. 65.9). This pattern may be found in healthy individuals, particularly well-conditioned athletes or young adults with a high resting vagal tone. Sinus bradycardia occurs in a variety of pathologic conditions associated with vagal stimulation, ranging from autonomic-mediated syncope to hemoperitoneum or acute inferior wall myocardial infarction. Other pathologic causes of sinus bradycardia include hypothermia, hypoxia, drug effects (especially β-adrenergic blockers and calcium channel blockers), and intrinsic sinus node disease (i.e., sick sinus syndrome). When sinus bradycardia drops below 40 beats/min, a junctional escape rhythm may emerge.

Sinus bradycardia is usually asymptomatic and requires no specific treatment. If needed, first-line treatment for symptomatic sinus bradycardia in adults is atropine, 1 mg IV every 3 to 5 minutes, to a total dose of 3 mg. Rarely, dopamine or epinephrine infusion may be administered. Emergency cutaneous pacing for sinus bradycardia is rarely indicated. In the post-heart transplant patient, use an isoproterenol infusion (2 to 10 mcg/min titrated to effect) as atropine is ineffective.

Sinus Dysrhythmia

Sinus dysrhythmia is a manifestation of the natural variation in heart rate that occurs during the respiratory cycle, manifested on the surface ECG as normally conducted P waves with a variable P-P interval (Fig. 65.10). It is a normal variant and frequent in children and young adults.

Sinus Arrest and Sinoatrial Exit Block

A lack of atrial depolarization occurs because of failure of the sinus node to generate an impulse (sinus arrest) or failure of impulse conduction out of the SA node (SA exit block; Fig. 65.11). With SA exit block, it is not uncommon to see dropped P waves in regularly occurring patterns, representing 2:1, 3:1, or 4:1 block. Sinus arrest and SA exit block may be from intrinsic SA node disease but can occur with increased vagal tone, whether benign or pathologic. When symptomatic, the approach to treatment is similar to that for sinus bradycardia.

Sick Sinus Syndrome

Sick sinus syndrome (SSS) is a group of dysrhythmias caused by disease of the sinus node and its surrounding tissues, creating sinus bradycardia, sinus arrest, or SA exit block. A variant of SSS known as bradycardia-tachycardia syndrome is characterized by one or more of these bradydysrhythmias alternating with a tachydysrhythmia, typically atrial fibrillation. SSS is most common in older adults, a result of fibrotic degeneration. It is associated with cardiomyopathies, connective tissue diseases, and certain drugs. In the acute setting, the specific rhythm should be treated, although subsequent bradycardia could require temporary pacing following the use of a nodal blocking agent (especially a calcium channel blocker) for the tachycardic presentation. Long-term management requires permanent pacemaker placement for symptomatic bradycardia to allow for pharmacologic therapy for atrial fibrillation.

Atrioventricular Block

AV block results from impaired conduction through the atria, AV node, or proximal His-Purkinje system. First- and second-degree AV blocks represent partial impairment of conduction, whereas third-degree block indicates complete interruption. Advanced or high-grade

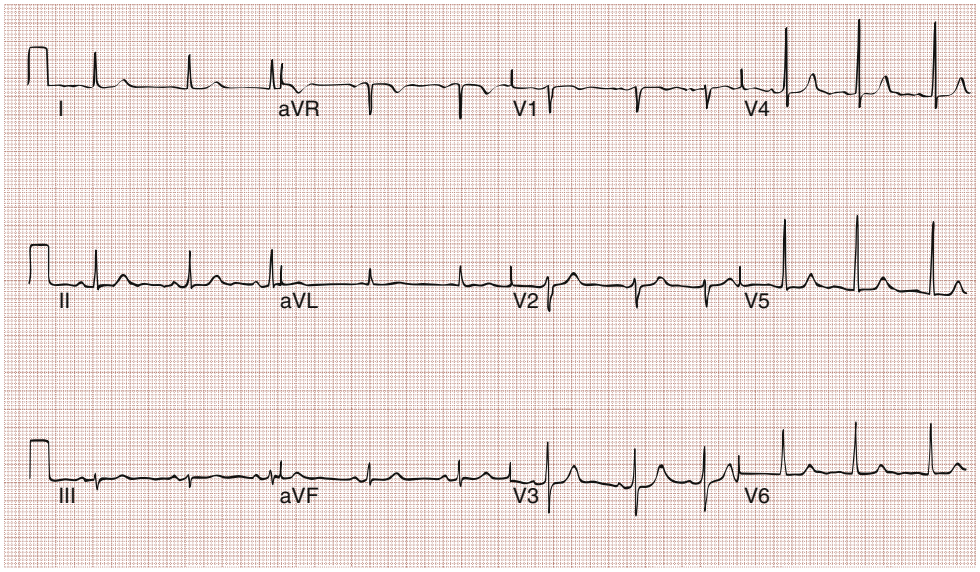

Fig. 65.10 Sinus dysrhythmia (note slight irregularity).

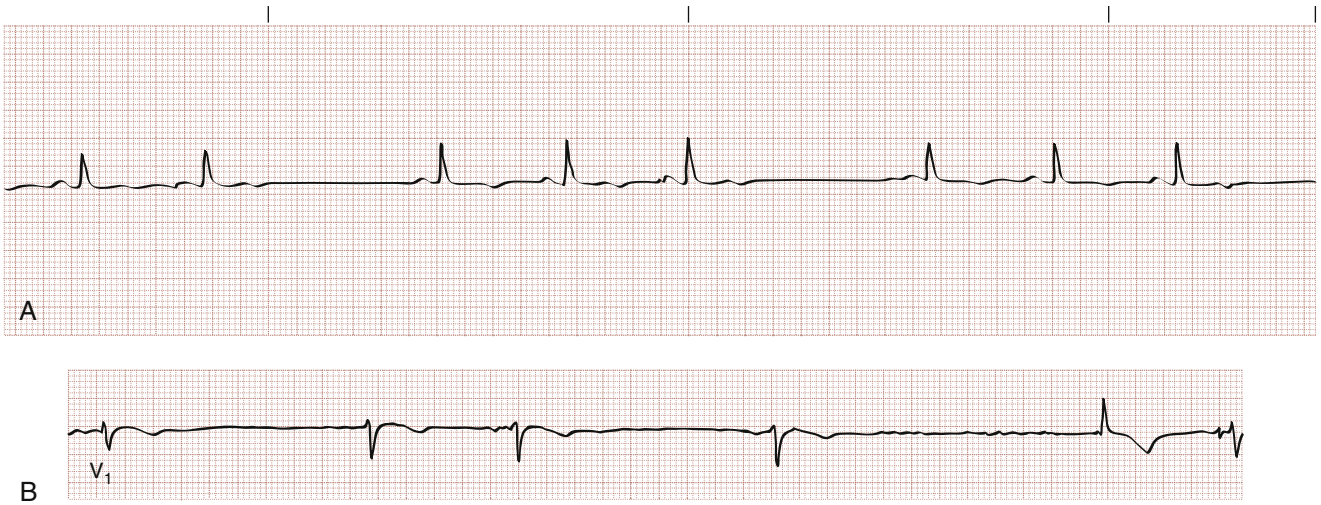

Fig. 65.11 (A) Incomplete sinus block. (B) Complete sinus block (sinus arrest) with ventricular escape rhythm.

AV block refers to AV block resulting in a ventricular rate that is pathologically slow.

First-Degree Atrioventricular Block

First-degree AV block is from prolonged conduction at the level of the atria, AV node (most common), or His-Purkinje system. On the ECG, first-degree AV block shows a prolonged PR interval (>0.20 second), typically with a narrow-QRS complex (Fig. 65.12). First-degree AV block is a normal variant in up to 2% of healthy young adults. First-degree AV block requires no specific treatment other than avoiding nodal blocking agents.

Second-Degree Atrioventricular Block

Second-degree AV block is when one or more (but not all) atrial impulses fail to reach the ventricles. The conduction ratio is the number of P waves to the number of QRS complexes over a period (e.g., 3:2, 2:1). When the atrial rate is unusually fast, such as with atrial flutter, a conduction ratio of 2:1 may be physiologic, reflecting the normal refractory period of the AV node. However, in most other cases, a conduction ratio greater than 1:1 is pathologic. Second-degree AV block is classified into two types based on the underlying pathophysiology and appearance of the ECG (Table 65.3).

Type I Second-Degree Atrioventricular Block. Type I second-degree AV block, also called Wenckebach or Mobitz I AV block, is associated with progressive impairment of conduction within the AV node. The surface ECG shows a lengthening of the PR interval from beat to beat until a P wave fails to conduct to the ventricle (so-called dropped beat). This pattern gives the appearance of successive P waves retreating into the preceding QRS complexes (Fig. 65.13). Grouped beating (e.g., pairs, trios) occurs but is not unique to type I second-degree AV block (Box 65.5).

Type I second-degree AV block occurs in a variety of conditions, benign and pathologic; often, these are associated with increased vagal tone and do not require specific treatment. In the setting of acute myocardial infarction, type I second-degree AV block is generally transient and associated with a good outcome.

Type II Second-Degree Atrioventricular Block. Type II second-degree AV block, or Mobitz II block, is a conduction block just below the level of the AV node. On the surface ECG, conduction of atrial impulses is sporadic and typically periodic, but the PR interval does

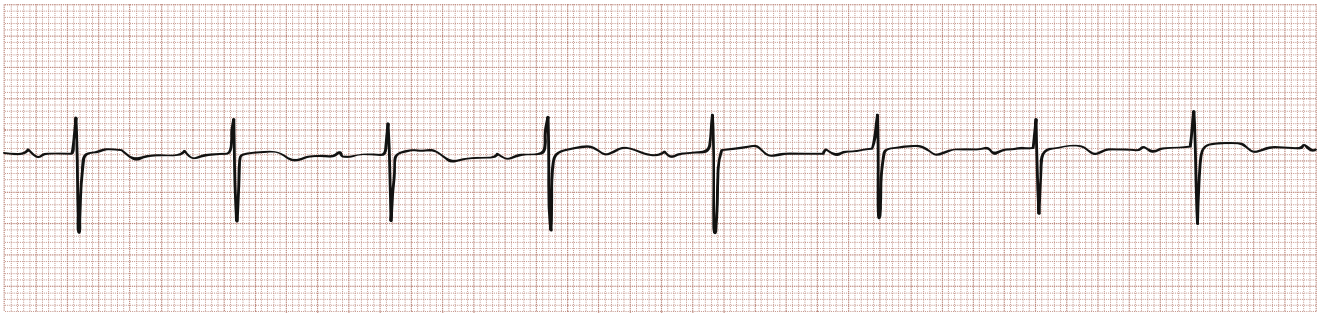

Fig. 65.12 First-degree atrioventricular block.

TABLE 65.3 Features of Types I and II Second-Degree Atrioventricular Block

Feature	Type I	Type II
Clinical	Usually acute	Often chronic
	Inferior myocardial infarction	Anteroseptal
	Rheumatic fever	Lenègre disease (Lev disease)
	Digoxin or beta blockers	Cardiomyopathy
Anatomic	Usually AV node	Infranodal
Electrophysiology	Increased relative refractory period	No relative refractory period
	Decremental conduction	All or none conduction
Electrocardiographic features	RP/PR reciprocity	PR interval stable
	Prolonged PR interval	PR interval usually normal
	QRS duration normal	QRS duration prolonged
Response to atropine and exercise	Improves	Worsens
Response to carotid massage	Worsens	Improves[a]

AV, Atrioventricular.
[a]Primarily refers to conduction ratio.

not widen from beat to beat (Fig. 65.14). The QRS complex is usually narrow, but concomitant infranodal conduction disturbances (i.e., bundle branch blocks) can be seen in those with type II second-degree AV block.

When the conduction ratio is exactly 2:1, it is hard to distinguish type I from type II second-degree AV block on the surface ECG. In general, a prolonged PR interval makes type I block more likely, whereas the presence of wide-QRS complexes makes type II block more likely.

Type II second-degree AV block arises from senescent degeneration, drug toxicity, ischemia, or other pathologic conditions; it generally carries a worse prognosis than type I second-degree AV block. In acute myocardial infarction, type II second-degree AV block is associated with anterior wall injury and is often a precursor to complete AV block. No specific therapy is needed aside from ensuring that pacemaking capability is immediately available.

Third-Degree Atrioventricular Block

Third-degree AV block, also known as complete heart block, is absent conduction of any atrial impulses (Fig. 65.15). Complete heart block is typically accompanied by a slow escape rhythm, with the width and frequency of QRS complexes depending on the site of the escape rhythm pacemaker. Pacemakers above the His bundle often have a narrow-QRS complex at a rate of 45 to 60 beats/min, whereas pacemakers at or below the His bundle produce a wide-QRS complex at a rate of 30 to 45 beats/min.

The hallmark of complete heart block is AV dissociation (i.e., no electrocardiographic relationship between P waves and QRS complexes), with an R-R interval longer than the P-P interval. Conversely, the presence of AV dissociation with an R-R interval shorter than the P-P interval (e.g., as occurs with accelerated junctional rhythms and VTs) does not imply third-degree heart block. When the atrial rate and the escape rates are similar (termed *isorhythmic*), detecting AV dissociation may require a long rhythm strip to track the P waves and QRS complexes. When a complete heart block occurs in the presence of atrial fibrillation, the fibrillatory atrial waves are accompanied by a slow and regular ventricular response (so-called regularized atrial fibrillation). This specific dysrhythmia is classically associated with digoxin toxicity.

Third-degree AV block can be congenital but is usually acquired because of senescent degeneration of the electrical conduction system or as a result of acute ischemia, drug therapy, or other pathologic conditions (e.g., Lyme or Chagas' disease).

In the ED setting, management of type II second-degree or third-degree block depends on the cause and presence of symptoms. Symptomatic patients with signs of hypoperfusion at rest should be treated with temporary transcutaneous or transvenous pacing, while reversible causes (e.g., ST-elevation myocardial infarction, beta-blocker overdose) are sought and treated. These patients require cardiology consultation for consideration of a permanent pacemaker. Atropine is usually ineffective; it should be avoided, particularly when the cause of the block is acute myocardial ischemia.

Extrasystoles

An extrasystole is an electrical impulse originating from an ectopic atrial or ventricular focus. Depending on the site of origin and timing of the impulse, there may not be an associated mechanical contraction. The terms *premature atrial contraction* and *premature ventricular contraction* are widely used but are misleading because contraction may not occur with the extra electrical activity seen on the ECG. The extrasystole and its preceding impulse are the couplet, and the coupling interval is the period between these two beats. Bigeminy (Fig. 65.16) occurs when there is an extrasystole after every native beat so that every other impulse is extrasystolic; trigeminy (every third beat) and quadrigeminy (every fourth beat) are similar. Most extrasystoles are the result of enhanced automaticity from the atria, AV node, His-Purkinje system, or ventricles.

Premature Atrial Contractions

Premature atrial contractions (PACs; Fig. 65.17) are common and usually have little clinical significance. PACs on the ECG are an abnormal

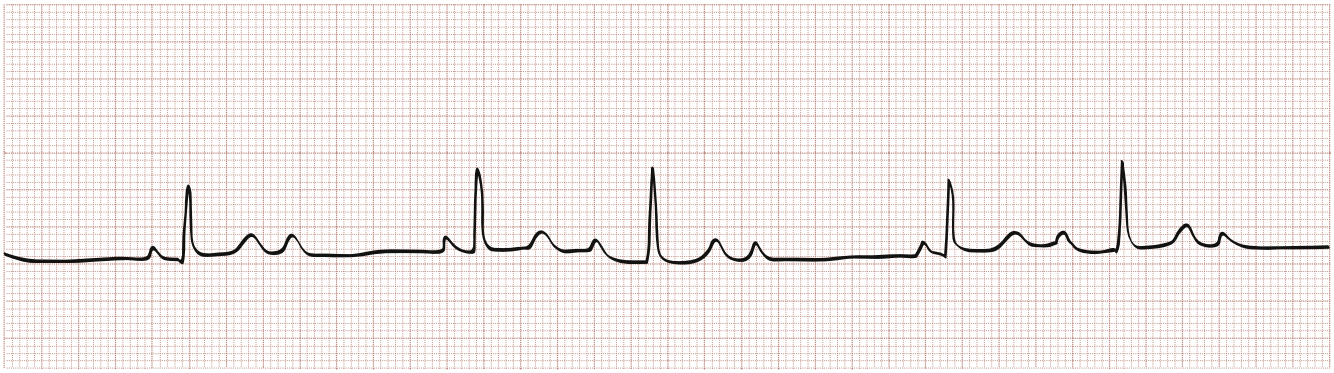

Fig. 65.13 Second-degree atrioventricular block, type I (Wenckebach). Note the prolongation of the PR interval between the second and third beats, followed by a nonconducted atrial impulse.

BOX 65.5 Causes of Grouped Impulses

- Wenckebach mechanism (usually at atrioventricular node, but can occur elsewhere)
- Sinoatrial exit block
- Atrial tachycardia or flutter with alternating conduction
- Frequent extrasystoles
- Nonconducted atrial trigemini
- Concealed or interpolated extrasystoles

P wave early within a cardiac cycle, although sometimes the P wave may be difficult to detect if it is buried within the preceding T wave.

Most PACs will depolarize the sinus node, resetting its refractory period. Because of this, the P-P interval between two sinus beats surrounding a PAC will be less than twice the intrinsic P-P cycle length (see Fig. 65.17). If a PAC reaches the AV node or infranodal conducting system during its absolute refractory period, there will be no ventricular depolarization. A nonconducted (or blocked) PAC typically results in a noncompensatory pause (i.e., R-R interval less than twice the intrinsic R-R cycle; Fig. 65.18) because the sinus node is reset. Blocked PACs are a common cause of electrocardiographic pauses and are easily overlooked. On occasion, a PAC can be the precipitant of a more important dysrhythmia, such as atrial fibrillation, atrial flutter, or paroxysmal supraventricular tachycardia (PSVT).

If a PAC reaches the infranodal conducting system during its relative refractory period, the QRS complex is widened (or aberrant), typically with a right bundle branch block (RBBB) pattern. Because the refractory period depends on the previous cycle length, an early-arriving PAC that follows a long cardiac cycle is more likely to be aberrantly conducted. This pattern can happen in atrial fibrillation, creating wide-QRS complex impulses that are not ventricular in origin.

PACs are benign and require no specific treatment, but they may accompany catecholamine excess, myocardial ischemia, heart failure, hyperthyroidism, or a metabolic abnormality.

Premature Ventricular Contractions

Premature ventricular contractions (PVCs) occur in a wide variety of states. Occasional PVCs are common in healthy adults or conditions associated with catecholamine excess, such as pain, anxiety, and use of stimulants (e.g., caffeine, nicotine, cocaine, amphetamines). Pathologic conditions associated with frequent PVCs include myocardial infarction, potassium or magnesium disturbances, and medication toxicity (notably any with sodium channel-blocking or sympathetic enhancing activity). Although usually not requiring intervention, frequent PVCs may herald VT, especially in the setting of acute myocardial infarction or in patients with a prolonged QT interval.

A PVC appears as a wide-QRS complex extrasystole without a preceding P wave (Fig. 65.19). Because retrograde conduction of a PVC rarely extends far enough to capture and reset the SA node, atrial impulses continue to arrive at the AV node at the intrinsic sinus rate. As a result, the R-R interval surrounding a PVC ends up being equal to exactly twice the intrinsic R-R interval length (see Fig. 65.19), a phenomenon termed a *compensatory pause.* Rarely, a PVC will capture the SA node, resulting in a noncompensatory pause, or will fail to capture the AV node, leaving the underlying rhythm completely unaffected (a so-called interpolated PVC; Fig. 65.20).

The morphology of a PVC depends on the origin of the impulse, with a left bundle branch block (LBBB) appearance resulting from an extrasystolic focus in the right ventricle, and vice versa. Multiform (or multifocal) PVCs come from more than one source and have variable morphologies. When a PVC occurs at or around the time that a supraventricular impulse is set to depolarize the ventricle, the result is a fusion QRS complex (Fig. 65.21). Table 65.4 lists common features of PACs and PVCs.

Direct therapy for PVCs is focused on correcting any precipitating condition whether it is catecholamine excess, drug effect, electrolyte imbalance, or cardiac ischemia (Box 65.6). Often, PVCs do not require treatment in the ED. When occurring in isolation, symptomatic PVCs may be treated with a beta blocker (metoprolol, 5 to 10 mg IV or 25 to 50 mg PO), although this is rarely needed. Although IV lidocaine suppresses PVCs, it should not be used in the absence of VT because of the risk of asystole with limited clinical benefit.

Narrow-Complex Tachycardia

Narrow-complex tachycardias have a QRS complex duration of 0.12 seconds or less on the surface ECG and a ventricular rate of more than 100 beats//min. The term *supraventricular tachycardia* may be confusing; sometimes it is used specifically to note AV reentry tachycardia, but it can denote any tachycardia originating at or above the AV node.

ECG features that help distinguish between different narrow-complex tachycardias include the appearance of P waves and the regularity or irregularity of the R-R interval. For example, a narrow-QRS complex tachycardia with an irregular R-R interval and no clear P waves is almost certainly atrial fibrillation. With rapid tachycardias, evidence of atrial depolarization is often obscured by ventricular repolarization; for example, with a regular, narrow-complex

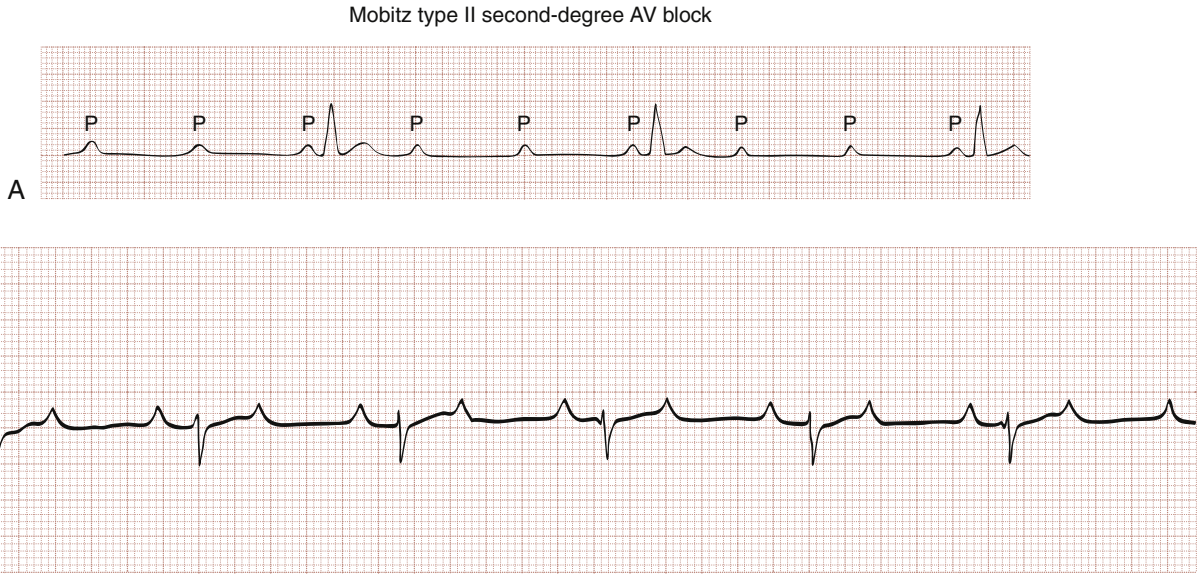

Fig. 65.14 (A) Second-degree atrioventricular (AV) block, type II. In this example, 3:1 conduction is shown. (B) Second-degree AV block with 2:1 conduction. From the rhythm strip alone, it is difficult to categorize this as a type I or II block. (**A** from Goldberger AL, Goldberger E. Clinical electrocardiography. ed 2. St Louis: Mosby; 1981.)

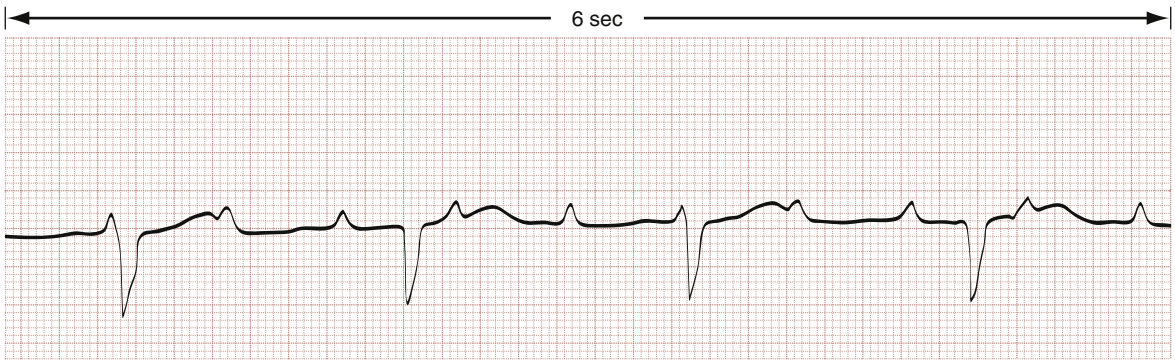

Fig. 65.15 Complete (third-degree) atrioventricular block. Note that there is no constant relationship of P waves to QRS complexes, even though some are noted in close proximity.

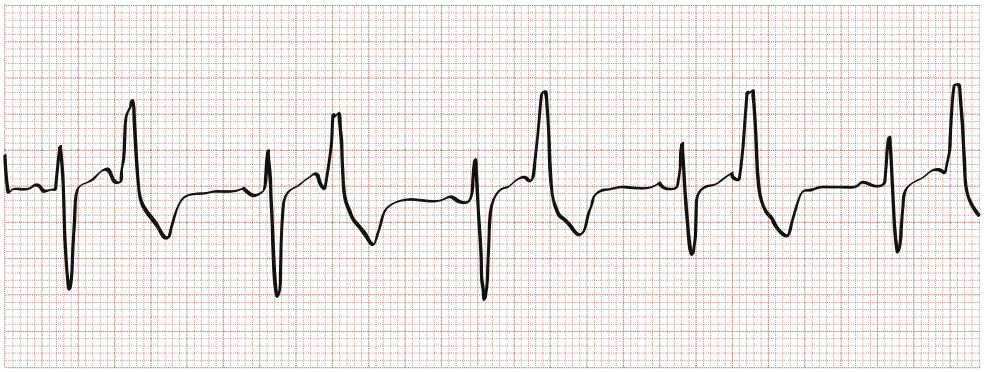

Fig. 65.16 Ventricular bigeminy.

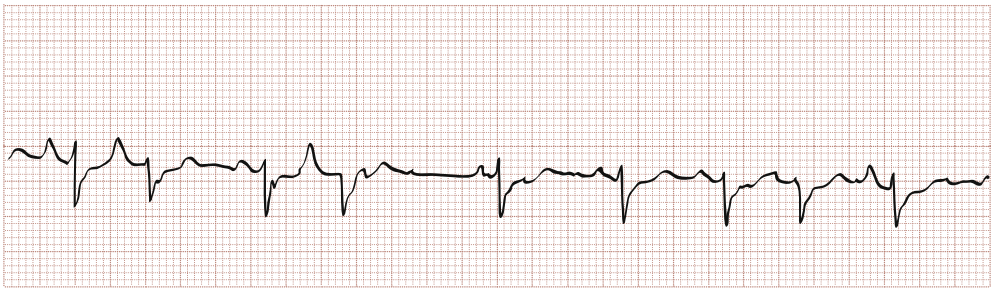

Fig. 65.17 Premature atrial contractions.

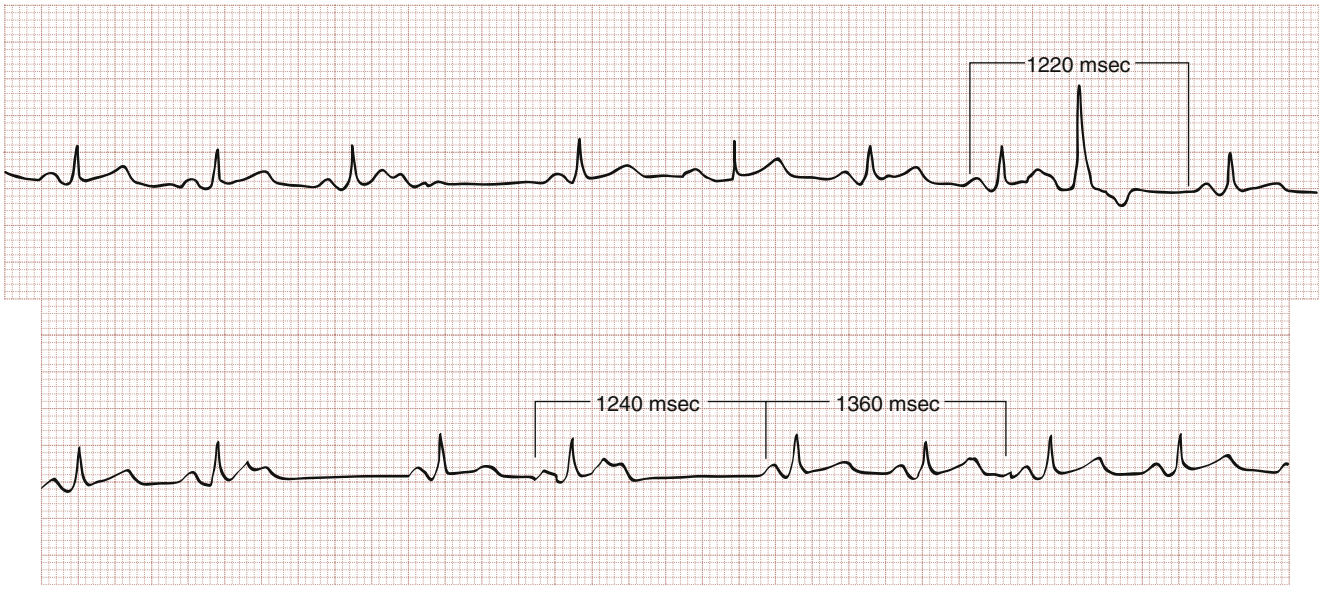

Fig. 65.18 Premature atrial contractions (PACs) with noncompensatory pauses and one aberrantly conducted impulse (*upper strip*). Note that conducted and nonconducted PACs reset the sinus node, with the latter creating a pause.

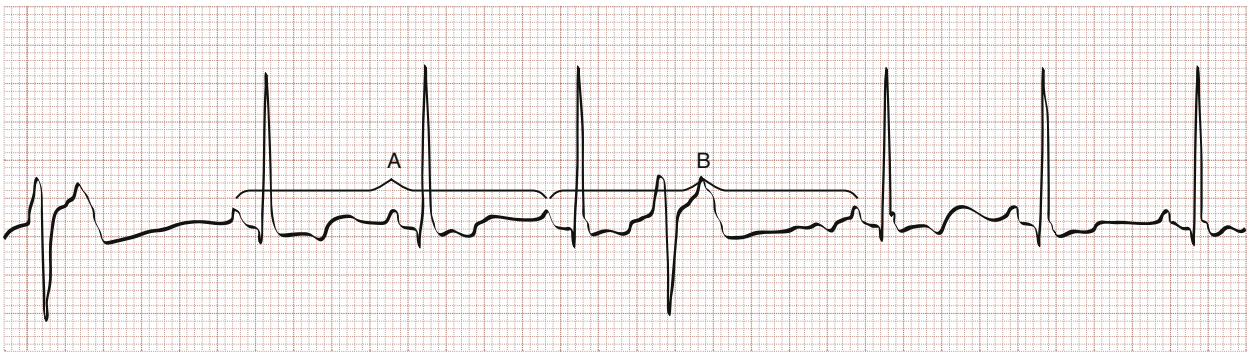

Fig. 65.19 Premature ventricular contractions with compensatory pause. Note that a sinus P wave can be seen in the T wave of the extrasystolic beat. Also, note the secondary T wave changes in beats 1 and 4 (the T wave is opposite the main deflection of the QRS complex).

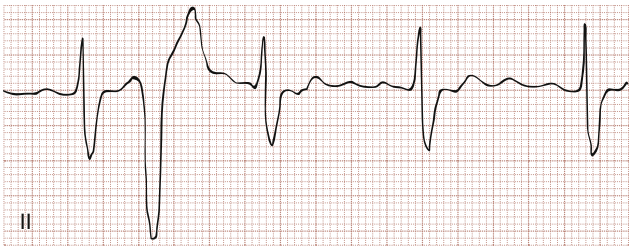

Fig. 65.20 Interpolated premature ventricular contraction.

tachycardia at a rate of 150 beats/min, it can be challenging to distinguish sinus tachycardia from atrial flutter or a junctional rhythm. Vagal maneuvers or adenosine may transiently slow AV nodal conduction and expose atrial depolarization to aid diagnosis. Alternatively, the patient may convert to sinus rhythm, in which case an AV nodal reentrant tachycardia exists. In the post-heart transplant patient or anyone with cardiac denervation, adenosine may cause an exaggerated response. It should be used carefully and doses of 1.5 to 3 mg for adults, if not avoided altogether.

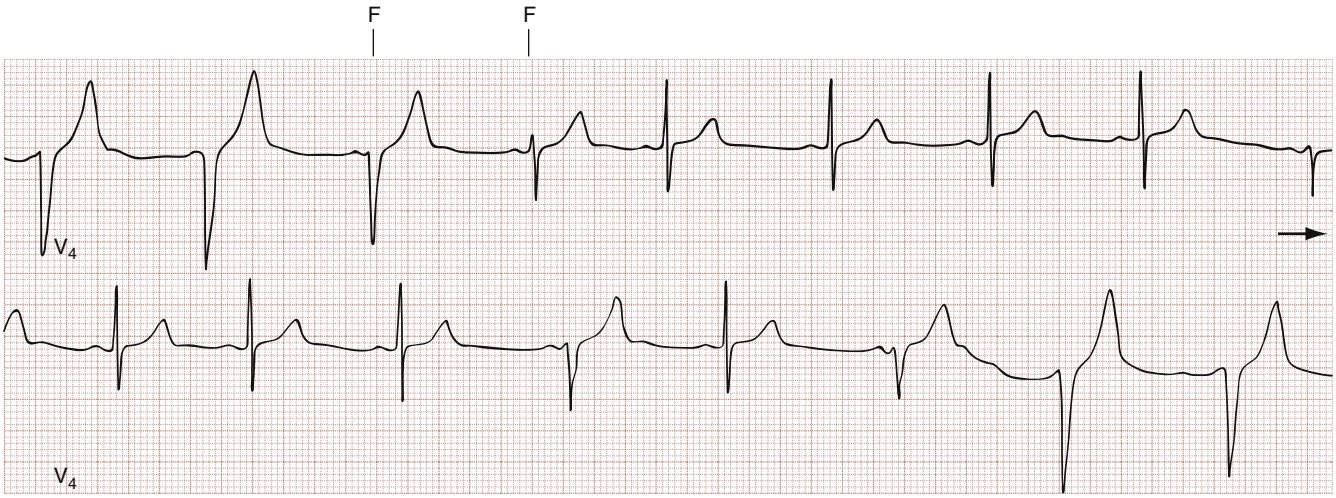

Fig. 65.21 Sinus rhythm with premature ventricular contraction and run of accelerated idioventricular rhythm. Note fusion beats (F) displaying a hybrid appearance of both morphologies.

TABLE 65.4 Features Distinguishing Premature Atrial Contractions With Abnormal Conduction From Premature Ventricular Contractions

Premature Atrial Contractions	Premature Ventricular Contractions
No compensatory pause	Fully compensatory pause (unless interpolated)
Preceding P wave (different from sinus P wave; occasionally buried in T wave)	No preceding P waves (although retrograde atrial conduction can cause inverted P wave after QRS)
Usually classic right bundle branch block pattern (especially if long-short cycle sequence appears) identical to sinus QRS	Left bundle branch block, right bundle branch block, or hybrid pattern
QRS axis normal or near-normal	Frequently bizarre QRS axis
QRS rarely > 0.14 s	QRS often > 0.14 s

BOX 65.6 Causes of Premature Ventricular Contractions and Ventricular Tachycardia

Acute or previous myocardial infarction or ischemia
Hypokalemia
Hypoxemia
Ischemic heart disease
Valvular disease
Catecholamine excess[a]
Other drug intoxications (especially cyclic antidepressants)
Idiopathic causes[b]
Digoxin toxicity
Hypomagnesemia
Hypercapnia
Class I antidysrhythmic agents
Ethanol
Myocardial contusion
Cardiomyopathy
Acidosis
Alkalosis
Methylxanthine toxicity

[a] Relative increase in sympathetic tone from drugs (direct or indirect) or conditions that augment catecholamine release or decrease parasympathetic tone.
[b] Isolated premature ventricular contractions (PVCs) can occur in up to 50% of young subjects without obvious cardiac or noncardiac disease; however, multiform and repetitive PVCs and ventricular tachycardia are rarely seen in this population.

Sinus Tachycardia

Sinus tachycardia displays a regular, usually narrow-complex tachycardia, with normal P waves preceding each QRS complex (Fig. 65.22) on the ECG. In adults, sinus tachycardia rarely exceeds a rate of 170 beats/min; in infants and young children, it is not unusual to see rates above 200 to 225 beats/min. Sinus tachycardia tends to speed up or slow down in a graded and continuous manner over time, relayed by history or observed under care.

Sinus tachycardia is often a response to physiologic stress or a compensation to increase cardiac output in the setting of a relative lack of perfusion or oxygen delivery. Usually, the effect is beneficial, as seen with hypovolemia, anemia, or hypoxemia; efforts to slow the heart rate compensation without addressing the underlying pathophysiology are likely to exacerbate the situation. Occasionally, sinus tachycardia is counterproductive, as in acute decompensated heart failure or aortic stenosis, in which a decrease in filling time further compromises cardiac output. Even in these settings, therapy is aimed first at the underlying problem rather than the tachycardia.

Sinus tachycardia can be seen with any sympathetic excess, whether endogenous (e.g., pain, anxiety, fever, hyperthyroidism) or exogenous (e.g., stimulants, other drugs). The approach to the patient with sinus tachycardia centers on identifying and addressing the cause(s). Beta blockers are rarely used to treat sinus tachycardia.

Atrial Tachycardia

Atrial tachycardia (AT) is an atrial rhythm with more than 100 QRS complexes/min arising from a nonsinus node atrial site(s). An ECG will be notable for abnormal P waves, all or mostly related to each QRS complex (Fig. 65.23). If the site of origin is close to the sinus node,

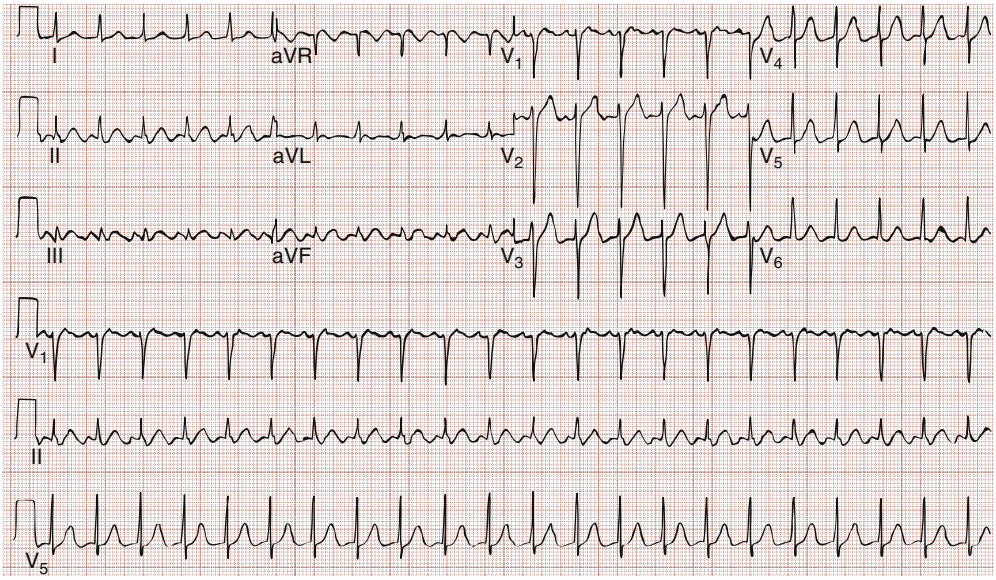

Fig. 65.22 Sinus tachycardia.

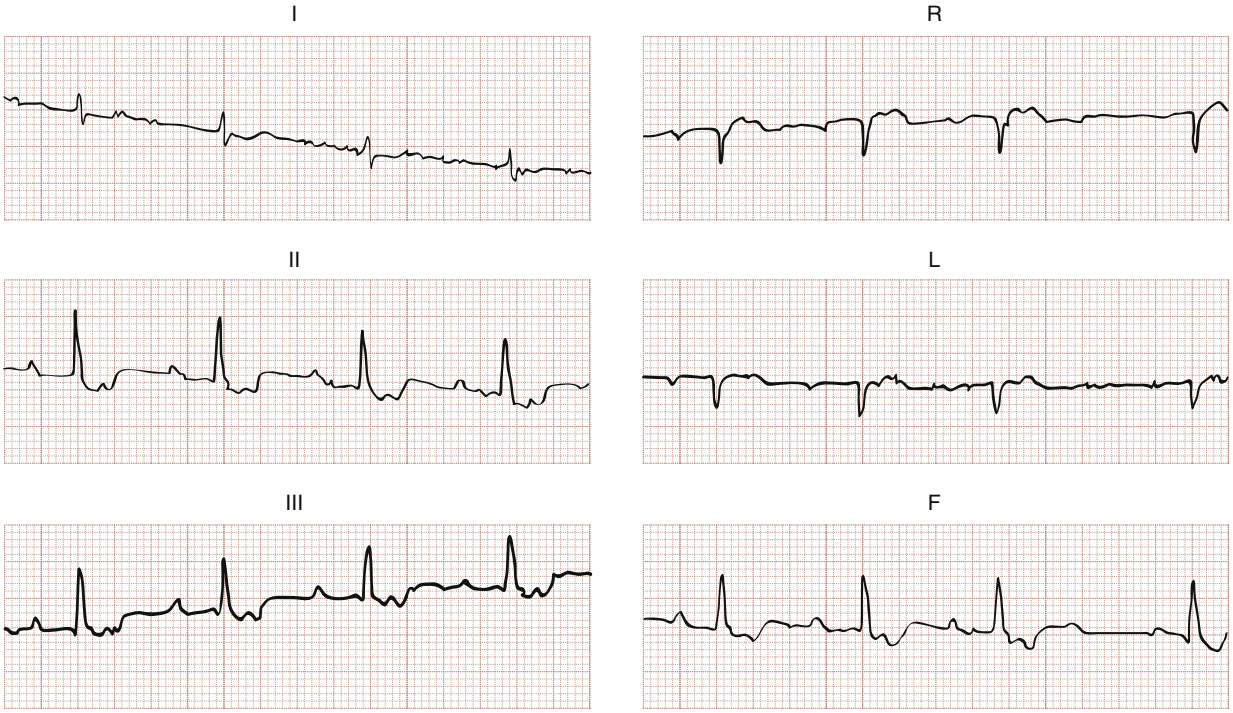

Fig. 65.23 Atrial tachycardia (with 2:1 conduction) in a patient with digoxin toxicity. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby; 1989.)

atrial depolarization waves may look like a normal P wave. Depending on the atrial rate, the AV conduction ratio may be 1:1, 2:1, or higher.

AT is common in children and young adults with structural heart disease, often precipitated by the occurrence of a PAC. The rhythm is usually transient and does not require specific therapy. AT can also occur in patients with hypoxemia, metabolic disturbances, or drug toxicity. In patients taking digoxin, suspect toxicity with AT, particularly in the presence of 2:1 or higher-grade AV block.

Multifocal AT (MAT) is a form of AT with three or more distinct P wave morphologies, and varying PR and P-P intervals from the multiple ectopic atrial foci (Fig. 65.24). MAT is associated with pulmonary disease (usually chronic obstructive pulmonary disease) in up to 60% of cases but can also be seen in the presence of primary cardiac pathology. On the surface ECG, MAT is often mistaken for atrial fibrillation because of the nonuniform atrial activity and irregular R-R intervals.

The approach to patients with AT is to identify and treat any precipitating factors, such as hypoxia or hypoxemia, electrolyte abnormalities, or drug toxicity. In patients with suspected hypomagnesemia, give supplemental magnesium (2 g IV over 5 minutes). Vagal maneuvers and adenosine are unlikely to be effective in AT or MAT, although these may help unmask the atrial activity. Pharmacologic therapy to slow AV conduction with a beta blocker or calcium channel blocker aids in the symptomatic but stable patient. Because AT and MAT are

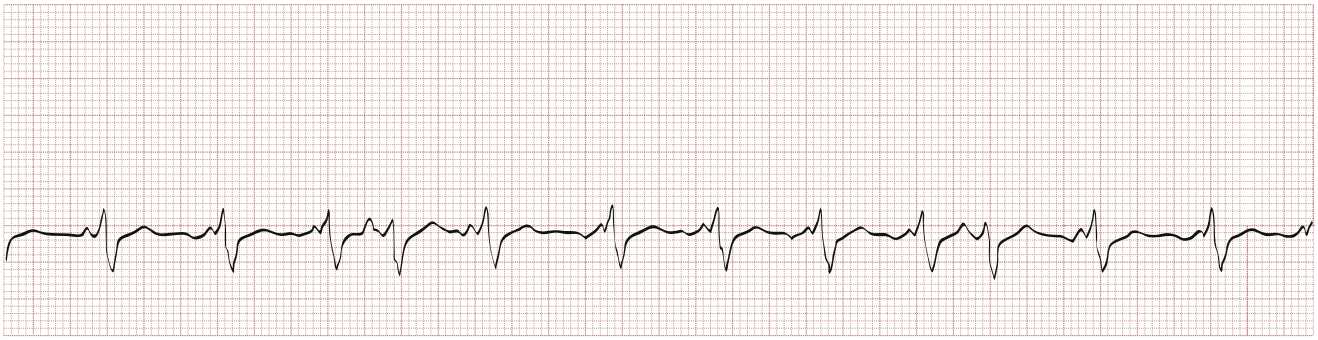

Fig. 65.24 Multifocal atrial tachycardia. Note that although the rhythm is irregular, at least three distinct P wave morphologies are present.

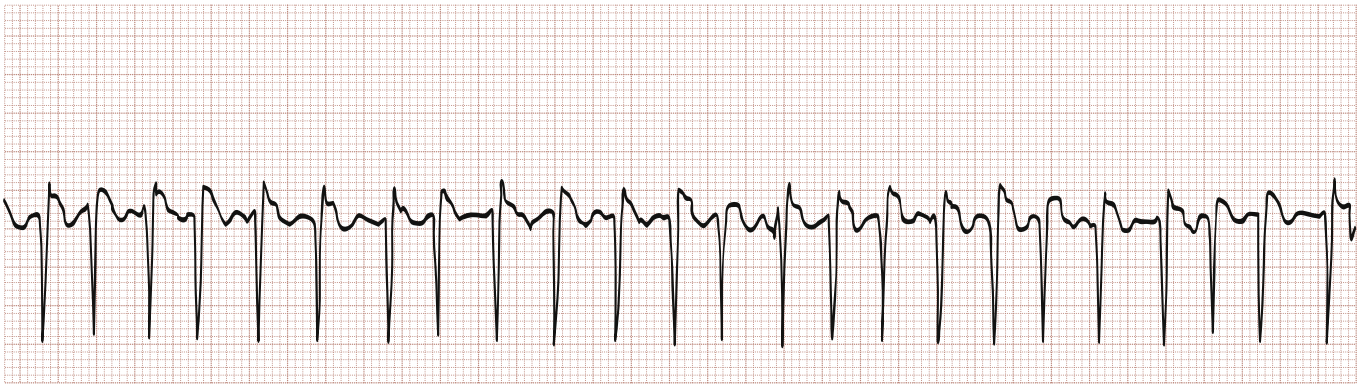

Fig. 65.25 Atrial fibrillation with rapid ventricular response. Note that the irregularity could be easily overlooked.

often precipitated by underlying illnesses, electrical cardioversion often fails or the rhythm recurs.

Atrial Fibrillation

Atrial fibrillation is electrical supranodal chaos; it starts from unpatterned depolarization of atrial tissues caused by multiple microreentry circuits, generating 300 to 600 atrial impulses/min. This chaotic activity reduces cardiac output due to both a loss of coordinated atrial contractions and a rapid ventricular rate, both of which may limit the diastolic filling and stroke volume of the ventricles.

Atrial fibrillation is the most common sustained dysrhythmia, increasing with age; it affects 1% of the population older than 60 years and 5% of those 69 years old or more. Patients with atrial fibrillation can develop left atrial thrombi, especially in the left atrial appendage, with consequent embolic events. The risk of stroke is three to five times greater than in those without atrial fibrillation. Appendageal occlusion through transcatheter approaches may alter the need for long-term, clot-directed therapy to mitigate embolic risks. Also, ablation therapies may restore sinus rhythm without the need for ongoing drug therapy.

Atrial fibrillation may be paroxysmal (spontaneously converts), persistent (requires cardioversion to convert), or permanent (when no further efforts to restore sinus rhythm are planned). Long-term approaches to management depend on many factors, including chronicity, symptomatology, underlying heart disease, and other comorbidities.

The electrocardiographic hallmark of atrial fibrillation is an irregularly irregular QRS pattern (Fig. 65.25). Although atrial fibrillation is not the sole cause of an irregular ventricular rhythm, it is the most common (Box 65.7). Atrial fibrillatory waves appear coarse or fine based on their amplitude and are often best appreciated in the inferior leads or lead V_1.

BOX 65.7 Causes of Completely Irregular (Chaotic) Rhythms

- Atrial fibrillation
- Atrial tachycardia or flutter with varying conduction
- Multifocal atrial tachycardia
- Multiple extrasystoles
- Wandering pacemaker (usually atrial)
- Parasystole

Typically, the ventricular rate in adults with atrial fibrillation does not exceed 150 to 170 beats/min and often is slower, particularly in the presence of nodal blocking agents. Atrial fibrillation in an adult with a ventricular rate exceeding 200 beats/min strongly suggests the presence of an accessory conduction pathway and has important implications for management (see later). Frequently, rapid atrial fibrillation with an accessory path will have a wide-QRS complex, but not always; if the irregularity of ventricular depolarization is not sought by the careful use of a caliper or similar measurement, it is easy to mistake this wide but chaotic rhythm for VT. When a wide-QRS complex is seen at rates below 200 beats/min but with ventricular chaos, an existing or acquired bundle branch block with atrial fibrillation is likely present.

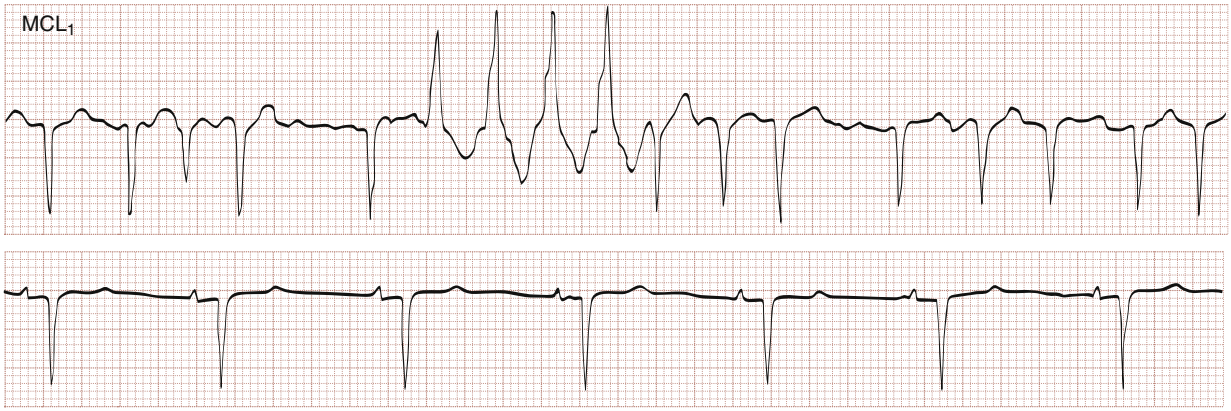

Fig. 65.26 Atrial fibrillation with classic Ashman phenomenon series of beats. Note the long-short cycle before aberrantly conducted impulses are sustained for four beats. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby; 1989.)

BOX 65.8 Causes of Atrial Fibrillation

Hypertensive heart disease
Cardiomyopathy
Ischemic heart disease
Valvular disease (especially mitral)
Congestive heart failure
Pericarditis
Hyperthyroidism
Sick sinus syndrome
Myocardial contusion
Acute ethanol intoxication (holiday heart syndrome)
Idiopathic
Cardiac surgery
Catecholamine excess
Pulmonary embolism
Accessory pathway (Wolff-Parkinson-White) syndrome

The Ashman phenomenon refers to aberrant ventricular conduction of an early-arriving atrial impulse following a relatively long R-R interval, the result of a partially refractory His bundle. Such aberrantly conducted impulses are commonly seen in atrial fibrillation but can occur in any irregular rhythm in which long-short cycle sequences occur; they typically assume an RBBB pattern (Fig. 65.26). Ashman beats can be mistaken for PVCs or runs of VT if sustained.

Atrial fibrillation is usually associated with underlying heart disease. The most common etiology is hypertension, but it can also occur with ischemic or valvular disease (Box 65.8). Atrial fibrillation may occur in isolation (lone atrial fibrillation) or as a manifestation of systemic conditions such as hyperthyroidism. As many as one-third of patients with congestive heart failure also have atrial fibrillation.

The presentation of patients with atrial fibrillation is variable.[3,4] For example, patients without underlying cardiopulmonary disease may tolerate atrial fibrillation with ventricular rates up to 150 beats/min, noting only palpitations or exercise intolerance. Conversely, a patient with left ventricular dysfunction and new atrial fibrillation may experience dyspnea at rest. In a patient with preexisting atrial fibrillation who presents with a rapid ventricular rate, the initial evaluation should determine if the tachycardia is a response to some other hemodynamic stress, such as decompensated heart failure, sepsis, hypovolemia, massive pulmonary embolism, or cardiac tamponade. Identifying acute underlying conditions may direct timely interventions.[5] Failure to recognize the underlying cause of tachycardia may result in counterproductive attempts at rate control or cardioversion.

For stable patients with rapid atrial fibrillation, administration of an AV nodal blocking agent to achieve a target ventricular rate of 120 beats/min or less is the first step.[3,4] IV calcium channel blockers (e.g., diltiazem, verapamil) or beta blockers (e.g., metoprolol) are easily titrated and can be followed by an oral agent. Nodal agents should not be used for rate control in the setting of anterograde (wider QRS) accessory pathway conduction because AV conduction may be preventing the ventricular rate from accelerating and degenerating into ventricular fibrillation.

The debate over rhythm or rate control for patients with established atrial fibrillation is ongoing without a definitive answer for all patient populations. Among patients with heart failure, a rhythm control strategy via catheter ablation (but *not* with antidysrhythmic drugs) is associated with improvement in clinical outcomes.

In choosing rate control for the long term, the ideal target is unclear, with some advocating for a resting rate of 80 beats/min or less (American Heart Association (AHA) class IIa recommendation) while acknowledging that for patients with preserved left ventricular function, a lenient rate-control strategy of <110 bpm may be reasonable as long as patients remain asymptomatic.[3]

If atrial fibrillation has been present longer than 2 days in the absence of therapeutic anticoagulation, cardioversion may increase the risk of systemic embolization from preexisting atrial thrombus. However, for patients with new-onset or newly recurrent atrial fibrillation (i.e, duration of 48 hours or less) or for those already on therapeutic anticoagulation, ED cardioversion is safe. Cardioversion can also be performed following transesophageal echocardiography demonstrating the absence of atrial thrombus.

The choice of electrical versus pharmacologic cardioversion depends on institutional factors and patient preference, but success rates are generally higher with electrical conversion.[3,4,6] A strategy of procainamide therapy first, followed by electrical cardioversion for patients not converted pharmacologically within 30 minutes, is another option that obviates the need for electrical cardioversion in about half of patients.[7] In patients with new or recurrent atrial fibrillation of less than 48 to 72 hours duration, up to 50% will convert spontaneously to sinus rhythm within 24 hours.

Various agents are available for the pharmacologic cardioversion of patients with stable atrial fibrillation in the ED, including the class

BOX 65.9 Pharmacologic Approach to Atrial Fibrillation and Flutter Conversion

IV procainamide, 30–50 mg/min, up to a total dose of 18–20 mg/kg (12 mg/kg in patients with congestive heart failure) or until conversion or side effects occur

or

Amiodarone, 150 mg IV over 10{en dash}15 minutes, followed by 1 mcg/min IV infusion for 6 hours then 0.5 mcg/min IV for 18 hours (or switch to oral)

or

Ibutilide, 0.015–0.02 mg/kg IV, over 10–15 min (conversion usually occurs within 20 min if successful)

or

Oral propafenone, 600 mg (contraindicated in the setting of structural heart disease or ischemia)

or

Oral flecainide, 300 mg (contraindicated in the setting of structural heart disease or ischemia)

NOTE: If needed, a calcium channel blocker can be given before the type IA agent (if no contraindications are present) to lower the ventricular response rate to below 120 beats/min and to attenuate further tachycardia from the vagolytic effects of these agents.

BOX 65.10 CHA_2DS_2VASC Scoring for Guiding Clot-Directed Therapy in Atrial Fibrillation

Clinical Feature	Points
Congestive heart failure	1
Hypertension	1
Age ≥ 75 yr	2
Diabetes mellitus	1
Any previous stroke, transient ischemic attack, embolism	2
Gender—female	1
Age, 65–74 yr	1
Vascular disease (history of MI, PAD, or aortic atherosclerosis)	1

Vascular disease—myocardial infarction, peripheral vascular disease, aortic plaque

Actions:

- Score 0— no anticoagulant therapy
- Score 1—oral anticoagulation should be considered
- Score 2 or higher—oral anticoagulation is recommended

BOX 65.11 HAS-BLED Scoring System to Assess 1-Year Risk of Major Bleeding in Patients Taking Anticoagulants with Atrial Fibrillation

Condition		Points
H	*Hypertension*: (uncontrolled, >160 mmHg systolic)	1
A	*Abnormal renal function*: Dialysis, transplant, Cr >2.26 mg/dL or >200 μmol/L	1
	Abnormal liver function: *Cirrhosis* or Bilirubin >2× Normal or AST/ALT/AP >3× Normal	1
S	*Stroke*: Prior history of stroke	1
B	*Bleeding*: Prior Major Bleeding or Predisposition to Bleeding	1
L	Labile *INR*: (Unstable/high INR), Time in Therapeutic Range < 60%	1
E	Elderly: Age > 65 years	1
D	Prior Alcohol or Drug Usage History (≥8 drinks/week)	1
	Medication Usage Predisposing to Bleeding: (Antiplatelet agents, NSAIDs)	1

A score of ≥3 indicates "high risk" and indicates the need for caution

IA, IC, and III antidysrhythmics (Box 65.9). In practice, ibutilide, amiodarone, and procainamide are most commonly used in the ED setting. Of these agents, ibutilide is associated with the highest rates of conversion to sinus rhythm, but, like all class IC antidysrhythmics, is best avoided in patients with structural or ischemic heart disease. Amiodarone is safe in this population and has the additional advantage of slowing the ventricular response. Procainamide is a first-line agent in patients with a suspected accessory pathway (very fast ventricular responses or known presence) because it does not impact AV conduction.

Rarely, rapid rates or irregularity make synchronized cardioversion efforts impossible; in this setting, it is appropriate to proceed with unsynchronized cardioversion while being prepared to re-shock if ventricular dysthymia ensues.[8,9] Following electrical cardioversion, there is an increased risk of thromboembolism in the initial 30 days.

Although long-term antiplatelet or anticoagulation therapy typically falls beyond the scope of the ED, starting early can enhance help avoid embolism and enhance patient compliance. The AHA and European Society of Cardiology recommend using the CHA_2DS_2-VASc score to guide anticoagulation therapy in those with atrial fibrillation (Box 65.10).[3,4] Anticoagulation reduces the overall risk of stroke by almost 70 percent, but with an increased risk of major bleeding; therefore, the risk-to-benefit ratio of any anticoagulation strategy must be assessed for patients at higher risk for bleeding (Box 65.11). The choice of coagulation therapy may be influenced by many institutional and patient-specific factors, but the direct oral anticoagulants (DOACs), including apixaban, dabigatran, edoxaban, or rivaroxaban, have an overall safety profile that is superior to warfarin[10,11].

Atrial fibrillation alone is not an indication for hospital admission. Observation or admission are appropriate for atrial fibrillation complicated by other conditions, accompanied by acute or exacerbated cardiopulmonary disease, when duration is unknown and follow-up uncertain, and for symptomatic patients who fail cardioversion. Ablation therapy is another option after new-onset or recurrent episodes.[12]

Atrial Flutter

Atrial flutter has ECG features of atrial depolarization occurring at a regular rate of 250 to 350 beats/min (300 beats/min is classic) caused by an atrial reentry mechanism (Fig. 65.27). Flutter waves on the ECG are broad, sawtooth-appearing, regular depolarizations prior to QRS complexes, with the latter occurring at some fraction of the atrial rate. The ventricular rate in atrial flutter is often rapid, but in the absence of a bypass tract (in which 1:1 conduction is possible), the conduction ratio is limited by the refractory period of the AV node. With 2:1 conduction, the classic ventricular rate is 150 beats/min, often making flutter waves difficult to appreciate and allowing the rhythm to be mistaken for sinus tachycardia. Because the atrial rate can vary, the ventricular rate range widely varies also. When the conduction ratio changes from beat to beat, this is termed *atrial flutter with variable conduction*, with a resultant irregular ventricular rate. This can be distinguished from atrial fibrillation by looking for a pattern of atrial depolarization rather than chaotic atrial activity.

Atrial flutter often accompanies pulmonary disease, structural heart disease, particularly valvular heart disease, and cardiomyopathies. The acute management of atrial flutter parallels that of atrial fibrillation with a few special considerations. Because AV conduction occurs at fixed ratios in atrial flutter, the administration of beta blocker or calcium channel blocker therapy can result in an abrupt rate change, making it more challenging to titrate therapy to a desired target rate.

Atrial flutter is more sensitive to DC cardioversion (up to 90% conversion rate) than atrial fibrillation and usually requires lower energy (20 to 50 J) for conversion to sinus rhythm. Atrial flutter is more resistant to chemical cardioversion (<50% success) than new-onset, nonvalvular atrial fibrillation. In most other respects, ED patients with atrial flutter are managed similarly to those with atrial fibrillation; in particular, anticoagulation therapy at discharge should be considered similarly to atrial fibrillation.

Atrioventricular Nodal Reentrant Tachycardia

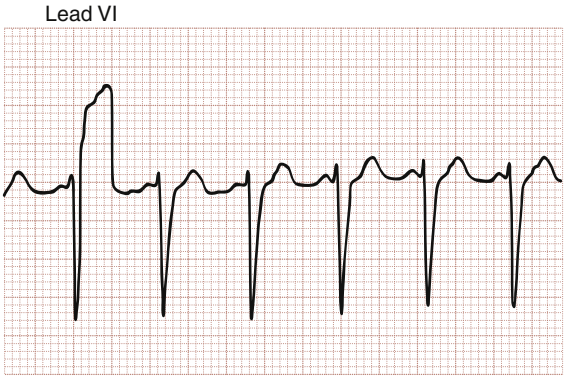
Also known by the less precise term *PSVT*, or just SVT), AVNRT is a regular, narrow-complex rhythm with a ventricular rate of 130 beats/min or greater, commonly more than 160 beats/min (Fig. 65.28). It is the most common nonsinus tachydysrhythmia in young adults. AVNRT is the result of a reentry circuit within the AV node, with normal conduction (narrow QRS) down the bundles of His and with retrograde conduction (inverted P waves typically buried within the QRS) up into the atria (Fig. 65.29).

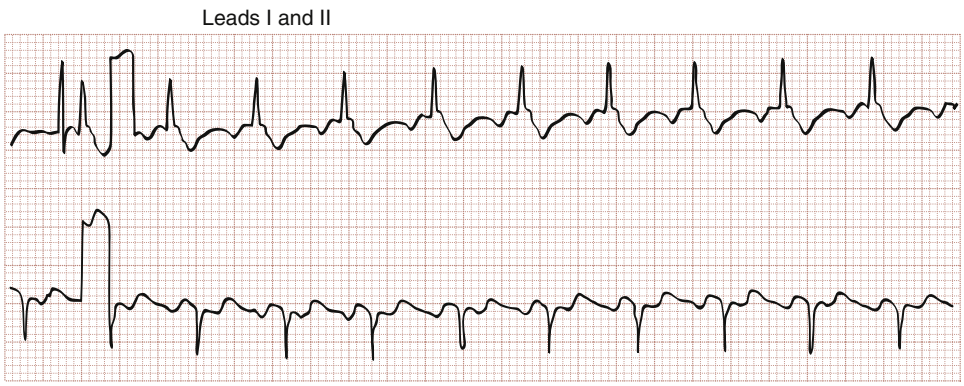
The onset and spontaneous end of AVNRT is typically abrupt, and it frequently arises in the context of strenuous exercise or emotional stress. Most patients with AVNRT are symptomatic, but hemodynamic instability is unusual in the absence of underlying cardiopulmonary disease.

If vagal maneuvers fail to restore sinus rhythm, first-line therapy for AVNRT is adenosine (6 mg rapid, large-bore IV bolus followed by a flush; repeat with 12 mg if no effect on rate). This approach is successful in 85% to 90% of cases and is safe. In refractory cases, diltiazem, esmolol, or metoprolol are options. Rarely needed, synchronized cardioversion (at 100 to 200 J, biphasic preferred) can terminate AVNRT refractory to pharmacologic therapy or in a patient with hemodynamic instability.

No specific laboratory testing is needed, although mild troponin level elevations occur but are of uncertain significance aside from concerns for myocardial ischemia. Most patients can be discharged after

A





B

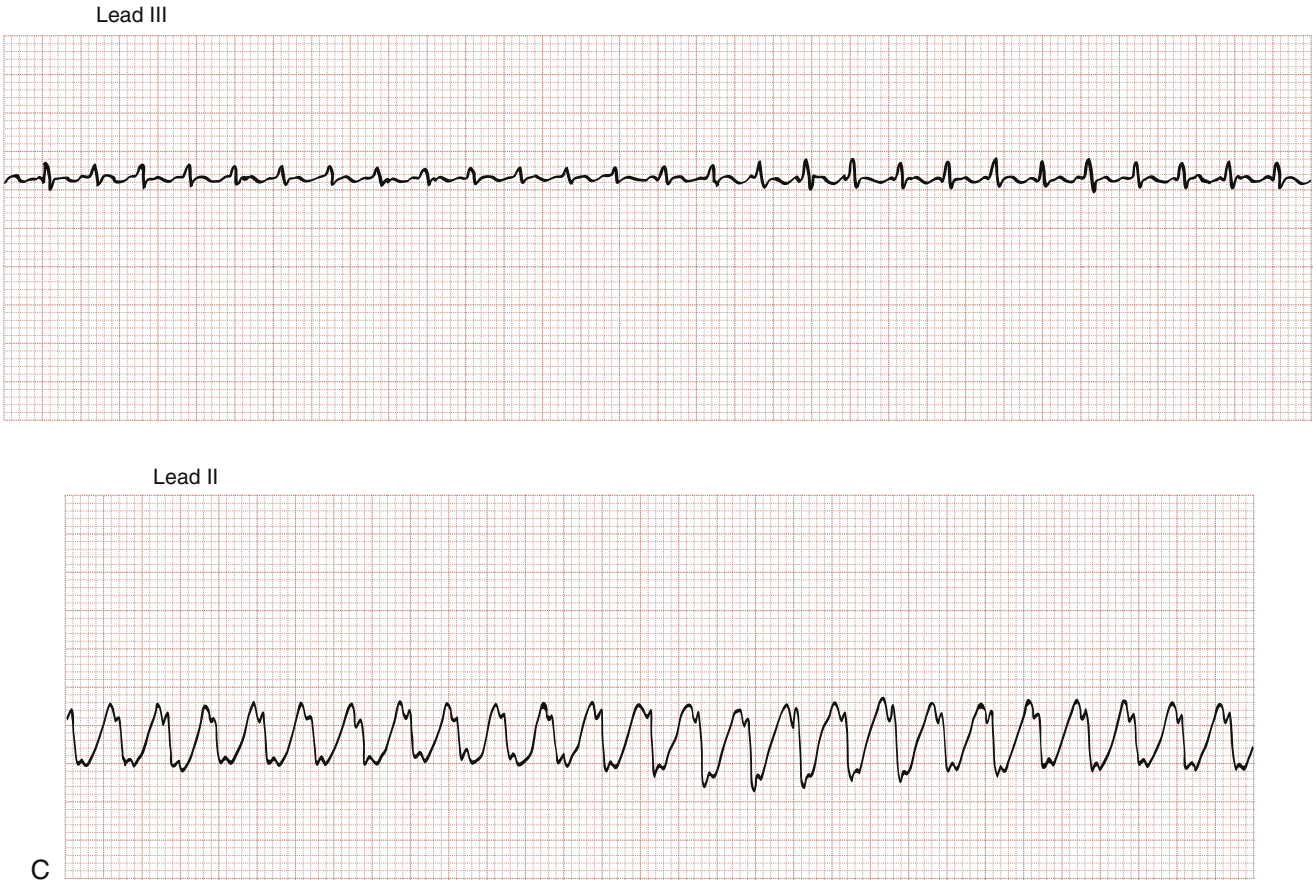


Fig. 65.27 (A) Atrial flutter with 2:1 conduction and isolated premature ventricular contraction. (B) Atrial flutter with 2:1 conduction. Lead II helps identify characteristic flutter waves. (C) Atrial flutter with 1:1 conduction. This is rare and can be mistaken for ventricular tachycardia (lead II).

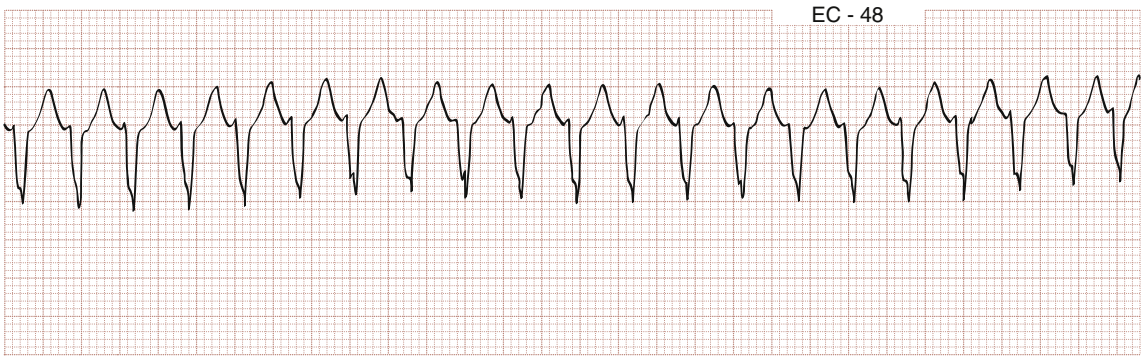

Fig. 65.28 Paroxysmal supraventricular tachycardia. Note the narrow, regular QRS complexes.

terminating AVNRT with adenosine or vagal maneuvers and typically require no testing beyond an ECG, including in the field setting. Patients with frequent recurrences are candidates for prophylaxis with a beta blocker or calcium channel blocker or ablation therapy. Starting prophylactic therapy from the ED is appropriate for those patients with an established plan for follow-up.

Junctional Tachycardia

In contrast to the bursts seen in AVNRT, JT show sustained ventricular rates but rarely exceeds 130 beats/min. JT is associated with structural heart disease, metabolic disturbances, or drug toxicity. Treatment should address underlying conditions, although a trial of nodal blockade with calcium channel blockers or beta blockers is an option if the rate seems to be deleterious.

Preexcitation and Accessory Pathway Syndromes

The term *preexcitation* is depolarization of the ventricular myocardium via an accessory pathway (or bypass tract) linking the atria to the ventricles, circumventing the normal AV node. Accessory pathways do not have the natural rate limits of the AV node, lending themselves

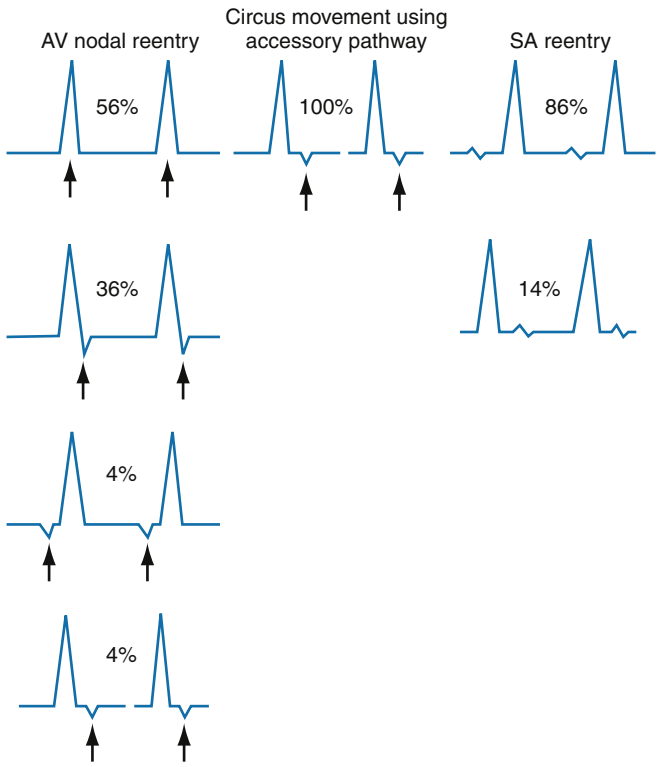

Fig. 65.29 Location of P waves in common causes of regular narrow-complex tachycardia. *AV,* Atrioventricular; *SA,* sinoatrial. (From Marriott HJL, Conover MB. Advanced concepts in dysrhythmias. ed 2. St. Louis: Mosby, 1989.)

to reentry tachycardia and rapid ventricular rates. Wolff-Parkinson-White (WPW) syndrome is the classic accessory pathway syndrome, characterized by paroxysmal tachycardia and three resting electrocardiographic features (Fig. 65.30):

- Short PR interval (<0.12 second)
- QRS duration longer than 0.10 second
- Slurred upstroke to the QRS complex, referred to as a delta wave

Not all patients with WPW or other preexcitation syndromes have all the classic features on their surface ECG. Conversely, some patients with WPW-like patterns on their resting ECG never develop reentry tachycardia. Although some with WPW syndrome have structural disease, most patients have no other underlying cardiac abnormality (Box 65.12). Atrial fibrillation is seen in up to 30% of patients with WPW.

The presence of an accessory pathway can form a reentry circuit together with an AV nodal pathway to produce and sustain a rapid ventricular rate (Fig. 65.31). When the AV node is being used for anterograde conduction to the ventricles, and the accessory path is used for retrograde conduction, it is called an orthodromic AV reciprocating tachycardia. The QRS complex is typically narrow, and the ventricular rate is constrained by the refractory period of the AV node. Conversely, when the accessory pathway is the anterograde limb and the AV node is the retrograde limb of the reentry circuit, it is called an antidromic AV reciprocating tachycardia. In this scenario, the QRS complex is wide and ventricular rates can be extremely rapid.

Orthodromic AV reciprocating tachycardia is the most common presenting dysrhythmia in WPW syndrome and is indistinguishable clinically from AVNRT. Like AVNRT, orthodromic AV reciprocating tachycardia is treated with vagal maneuvers and adenosine as first-line therapies, followed by calcium channel blockers and beta blockers as second-line agents.

In contrast, antidromic AV reciprocating tachycardia has characteristic wide-QRS complexes and may have ventricular rates of 200 beats/min or more and clinical instability. When the typical QRS antidromic changes are coupled with tachycardia, AV nodal blocking agents may trigger degeneration into ventricular fibrillation. Similarly, in patients with a very rapid (>220/min) irregular tachycardia accompanied by a wide-complex QRS, nodal blockade may risk rapid deterioration to ventricular fibrillation from unbridled conduction down the accessory pathway. Procainamide is first-line therapy for tachycardia when wide-QRS complexes suggest conduction down an accessory pathway; amiodarone is an alternative. Use prompt synchronized electrical cardioversion (100 to 200 J) if there is any clinical deterioration, failure of pharmacologic therapy, or extreme tachycardia (>250 beats/min).

The Lown-Ganong-Levine syndrome is an uncommon accessory pathway syndrome associated with paroxysmal narrow-complex tachycardia, short PR interval, and normal QRS complex without a delta wave. The treatment parallels that for the WPW syndrome.

Refer all patients with a new or symptomatic accessory pathway for advanced electrophysiologic care, including pathway identification and ablation.

Wide-Complex Tachycardia

Wide-complex tachycardia refers to any tachydysrhythmia accompanied by a QRS duration of 0.12 seconds or more. Wide-complex tachycardia can start in the ventricles (i.e., VT) or can originate from above the AV node but be accompanied by aberrant AV conduction. The aberrant conduction is caused by an accessory pathway or a bundle branch block. The presence of AV dissociation or fusion beats on the 12-lead ECG clearly points to VT; older age and a prior history of myocardial infarction make VT more likely than a supraventricular tachycardia with aberrancy. On the other hand, an irregular tachycardia with a wide QRS approximating a bundle branch morphology is most likely atrial fibrillation with aberrant conduction. Although new-onset VT patients are usually unstable, the presence of hemodynamic stability does not exclude VT.

It can be difficult to make the distinction between VT and an SVT with abnormal conduction when confronted with a wide-complex tachycardia in a patient. Many of the decision rules rely on an ability to discern subtleties of the QRS morphology, and none has perfect discriminatory power. (Table 65.5; Fig. 65.32) As a general rule, consider any new wide-complex tachycardia to be VT until proven otherwise.

The classic Wellens criteria are time-honored but hard to use criteria because of their complexity and lack of order or weighting of findings. The Brugada ECG criteria describe four features of VT from among those described in the original Wellens criteria, any one of which makes the diagnosis of VT. The rhythm needs to be regular for these to be used because irregularity suggests atrial fibrillation with altered conduction. The sequential criteria are as follows (Fig. 65.33, see also Fig. 65.32):

1. Absence of any RS complexes in the precordial leads
2. RS duration (measured from beginning of R to deepest part of S wave) greater than 100 msec
3. AV dissociation (often present but overlooked; may be best appreciated in inferior limb leads and $V_{1\text{-}2}$; Fig. 65.34)
4. Specific VT morphologic criteria (see Fig. 65.33)

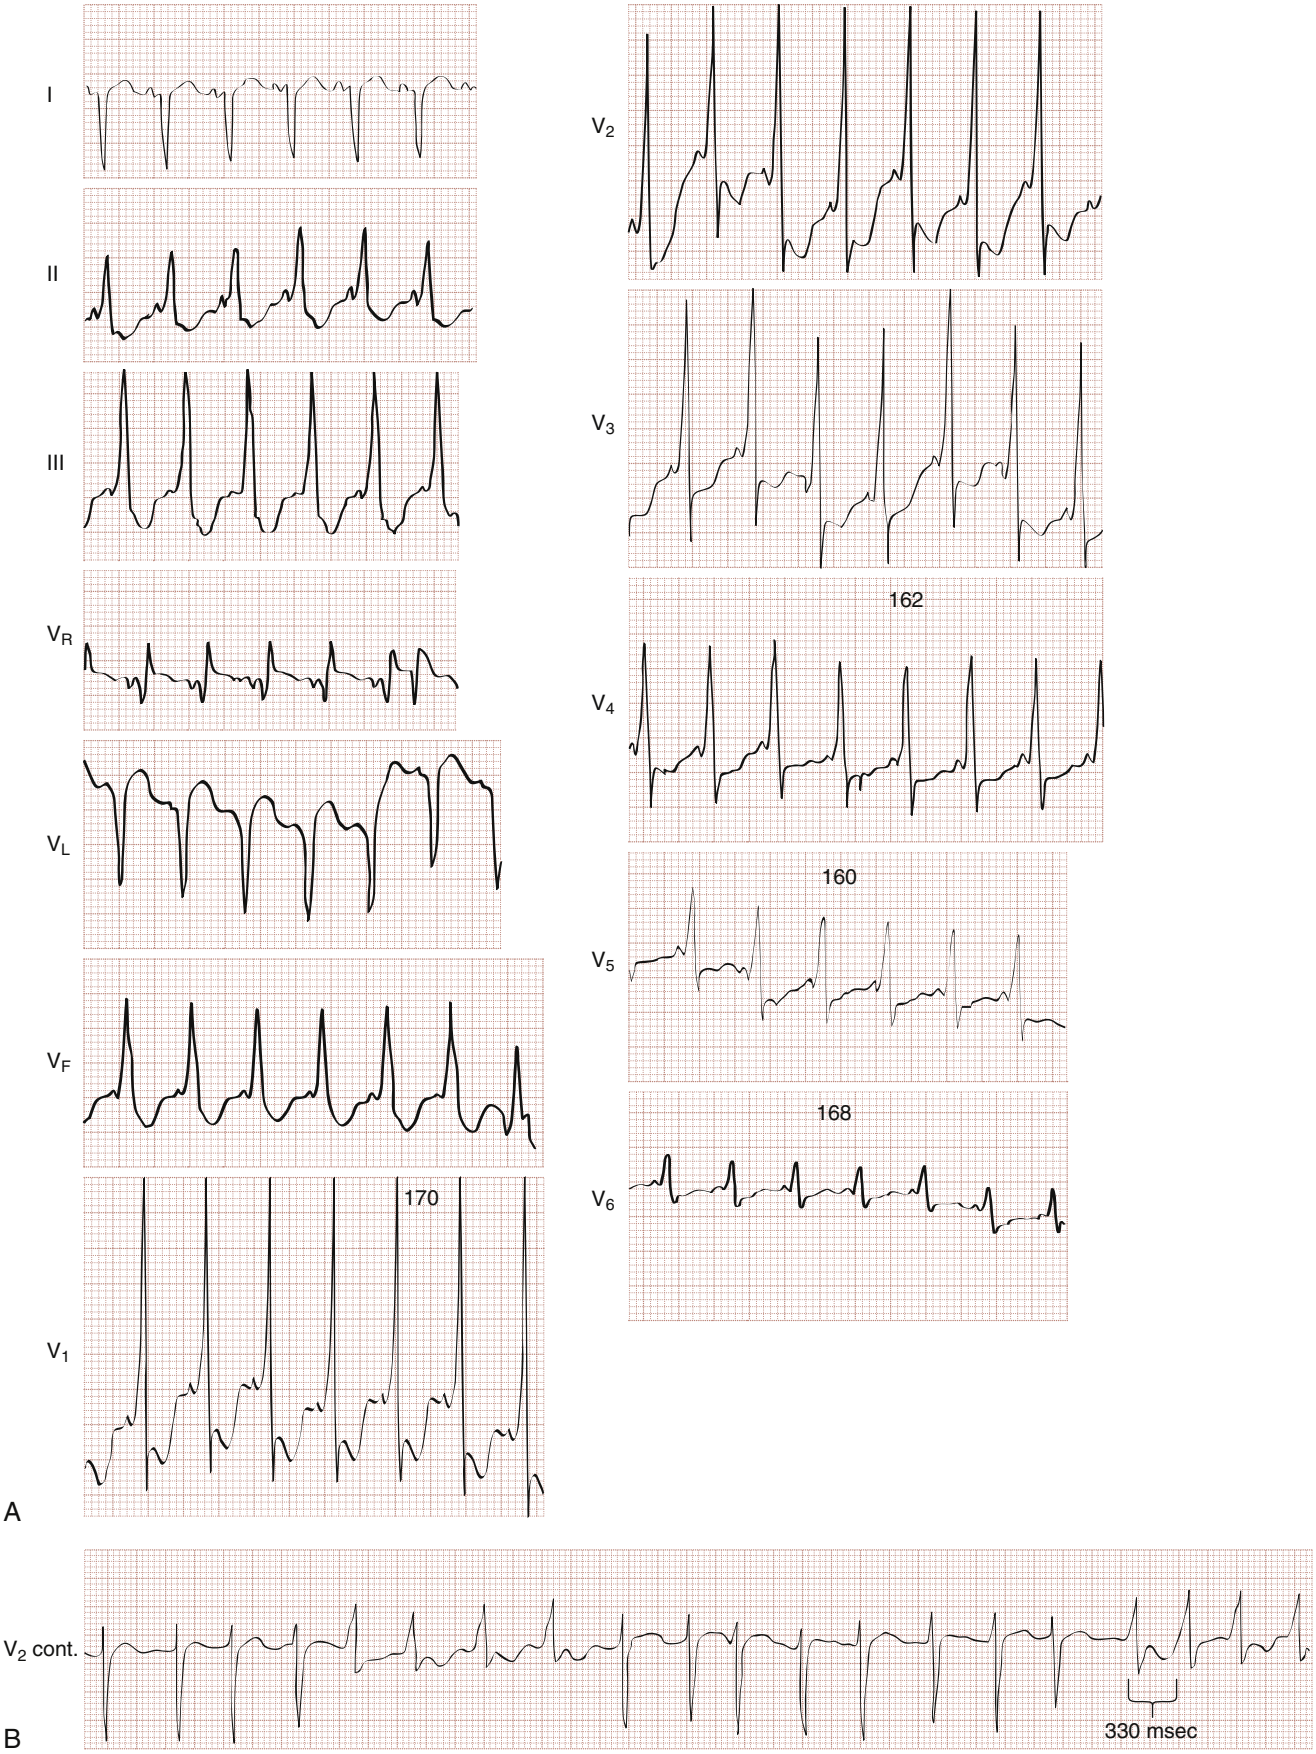

Fig. 65.30 (A) Wolff–Parkinson–White (WPW) syndrome. (B) WPW syndrome with atrial fibrillation. Note the short refractory period (330 ms). (**A** from Watanabe Y, Dreifus LS. Cardiac dysrhythmias. New York: Grune & Stratton; 1977.)

Only the absence of all the Brugada criteria allows the diagnosis of SVT. Although the original investigators found excellent sensitivity (98.7%) and specificity (96.5%) in detecting VT, follow-up investigations have shown a lower level of accuracy in ED patients (sensitivity of 92% to 94%). Often, emergency clinicians are not able to complete the assessment or agree on the findings. In patients receiving class I agents, the Brugada criteria are less reliable.

The Griffith criteria use a three-step approach to identify aberrancy, first through classic RBBB or LBBB morphologies in V_1 and V_6 to identify an SVT and then seeking AV dissociation in the remainder to identify VT (see Figs. 65.32 and 65.34). This approach has a sensitivity of 92% with a lower specificity than that seen with the Brugada approach. There are no direct, in-practice comparative data between these two approaches. Finally, the Vereckei criteria (Fig. 65.35) examine lead aVR to differentiate between VT and SVT; however, in practice, these have not been shown to be more effective or accurate, limiting their use.

Unstable patients with a wide-complex tachycardia should undergo electrical cardioversion (100 J, synchronized and biphasic, if possible). For borderline patients, electrical cardioversion with systemic sedation or analgesia or pharmacologic treatment with procainamide or amiodarone are options.

Adenosine is an option after a careful search of the ECG does not suggest VT. Adenosine is should be avoided in suspected VT

BOX 65.12 Diseases Associated With Wolff-Parkinson-White Syndrome

- Idiopathic[a]
- Cardiomyopathy (especially hypertrophic)
- Transposition of great vessels
- Endocardial fibroelastosis
- Mitral valve prolapse
- Tricuspid atresia
- Ebstein disease

[a] Most common.

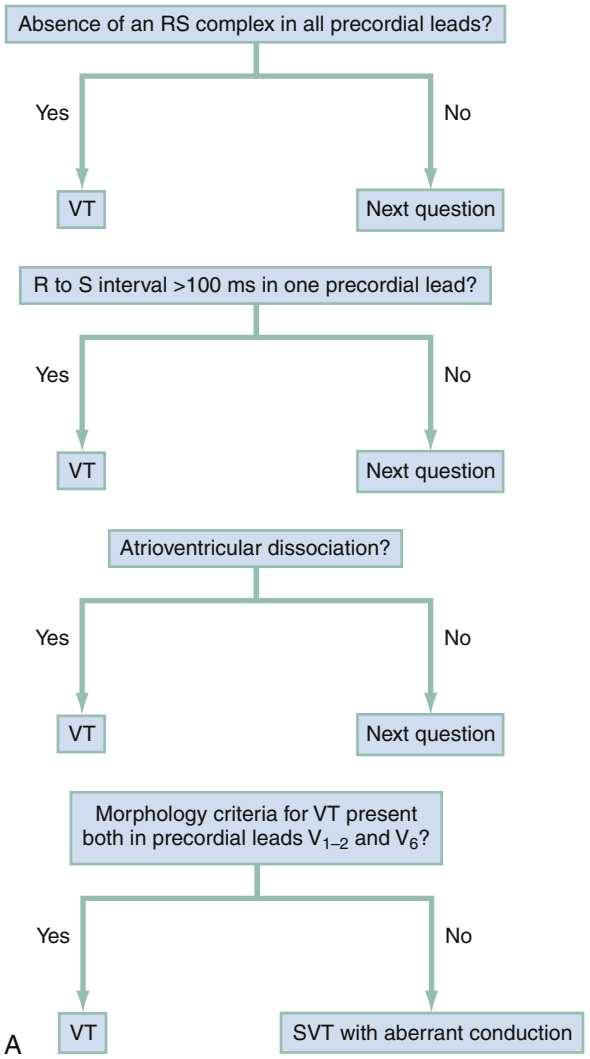
TABLE 65.5 Features Distinguishing Ventricular Tachycardia From Supraventricular Tachycardia With Abnormal Conduction

Parameter	Ventricular Tachycardia	Supraventricular Tachycardia Plus Aberrancy
Clinical features	Age ≥ 50 yr	Age ≤ 35 yr
	History of myocardial infarction, congestive heart failure, CABG, or ASHD	None
	Previous history of ventricular tachycardia	Previous history of supraventricular tachycardia
Physical examination	Cannon A waves	Absent
	Variation in arterial pulse	Absence of variability
	Variable first heart sound	Absence of variability
Electrocardiogram	Fusion beats	None
	AV dissociation	Preceding P waves with QRS complexes
	QRS >0.14 s	QRS usually <0.14 s
	Extreme left axis deviation (30 degrees)	Axis normal or near-normal
	No response to vagal maneuvers	Slow or terminate with vagal maneuvers
Specific QRS patterns	V_1: R, qR, or RS	V_1: rSR′
	V_6: S, rS, or qR	V_6: qRs
	Identical to previous ventricular tachycardia tracing[a]	Identical to previous supraventricular tachycardia tracing[a]
	Concordance of positivity or negativity[b]	

ASHD, Arteriosclerotic heart disease; *AV,* atrioventricular; *CABG,* coronary artery bypass graft; *LAD,* left anterior descending.
[a] If proven by electrophysiologic studies or by a preponderance of evidence.
[b] Main deflection of QRS complex either positive or negative in every precordial lead.



A

	BBB pattern
Right	
V_1	rSR′ pattern with R′ > rRS (RS) pattern with R > S; Q wave
V_6	<40 msec and <2 mm (0.2 mV) were allowed
Left	
V_1	rS or QS pattern with time to 5 wave nadir <70 msec
V_6	R wave with no Q wave

BBB = bundle branch block.

If no classic BBB pattern as noted above that would define SVT with aberrancy, search for AV dissociation; if present, VT is diagnosed and if absent, SVT is diagnosed by default.

B

Fig. 65.32 (A) Brugada four-step approach for differentiating ventricular tachycardia (VT) and wide-QRS supraventricular tachycardia. Only when the response to all four questions is negative is a supraventricular rhythm with abnormal conduction diagnosed. As soon as a single "yes" answer is noted, VT is diagnosed. (B) Griffith approach, in which aberrant conduction is sought in leads V_1 and V_6 (right bundle branch block [RBBB] or left bundle branch block [LBBB], classic appearances), followed by a search for atrioventricular (AV) dissociation. If classic RBBB and LBBB patterns are absent, or if the remainder of the leads have AV dissociation, VT is diagnosed. ([A] From Brugada P, Brugada J, Mont L, et al. A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex. *Circulation.* 1991;83:1649–1659; [B] adapted from Griffith MJ, Garratt CJ, Mounsey P, Camm AJ. Ventricular tachycardia as default diagnosis in broad complex tachycardia. *Lancet.* 1994;343:386–388.)

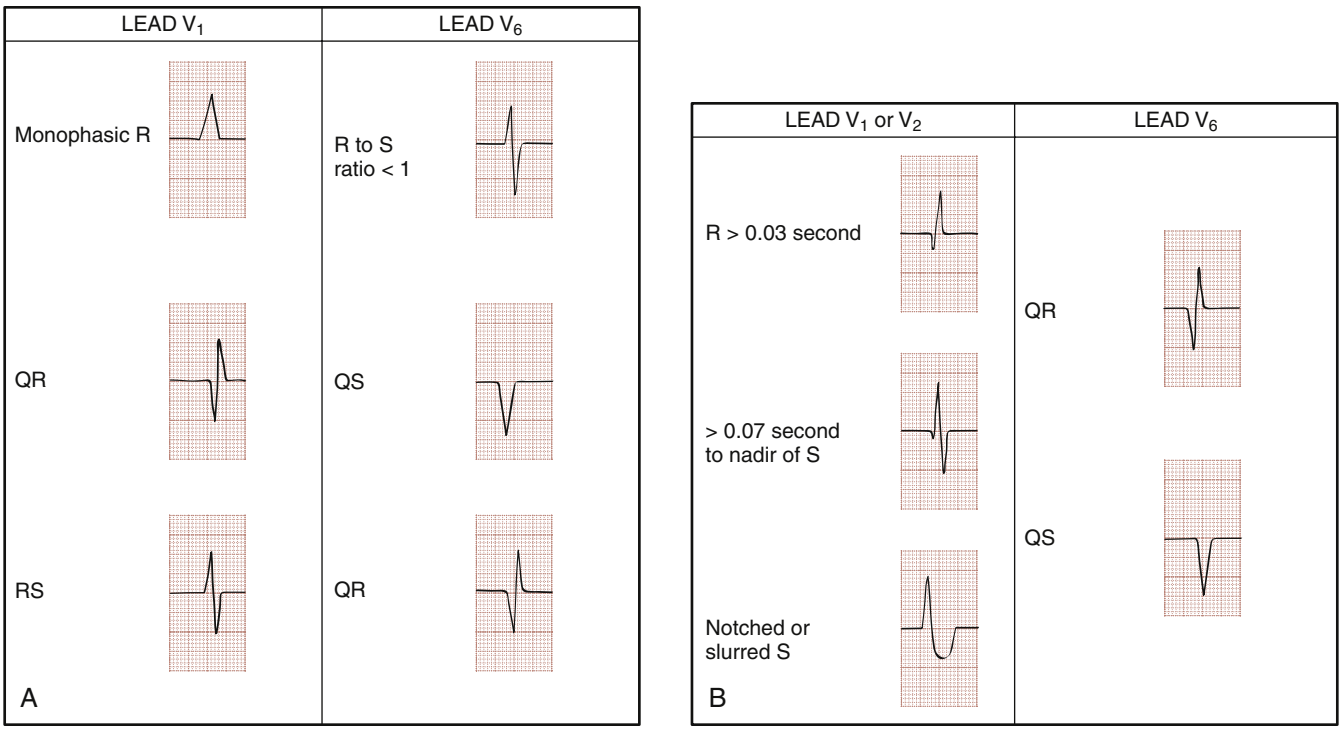


Fig. 65.33 Morphology associated with the fourth criterion in the Brugada system. (A) In patients with a right bundle branch-appearing complex. (B) In patients with a left bundle branch-appearing complex.

or if there is an irregular or very rapid ventricular rate (≥250 beats/min). It should be used with caution after heart transplantation. Most SVTs will slow or terminate with adenosine, and only rare VT forms respond; any ill effects of adenosine are usually fleeting. Other pharmacologic therapies for stable VT are discussed later. If pharmacologic treatment fails, synchronized cardioversion should be performed.

Ventricular Tachycardia

VT originates within or below the His bundle. Nonsustained VT refers to short episodes (<30 seconds) reverting spontaneously, whereas sustained VT is prolonged. Reentry mechanisms are the most common cause of VT, although automatic and triggered mechanisms occur. Most patients with VT have underlying heart disease, especially ischemic and nonischemic cardiomyopathy.

Monomorphic ventricular tachycardia is the most common form of VT and is characterized by morphologically consistent QRS complexes, usually in a regular pattern at a rate of 150 to 200 beats/min (Fig. 65.36). Polymorphic ventricular tachycardia is seen with varying QRS morphologies and suggests a more severe underlying disease (Figs. 65.37 and 65.38).

For stable patients with VT, amiodarone (3 to 5 mg/kg IV over 20 minutes, often 250 to 350 mg) is the first-line agent, with reported successful termination of up to 90%. Procainamide (30 to 50 mg/min IV, up to a total of 18 mg/kg or until VT is terminated) is a second-line agent. Lidocaine (1.0 to 1.5 mg/kg IV bolus, up to 3 mg/kg maximum, followed by an infusion) is an alternative to amiodarone with similar success rates in some studies. Unstable patients or those with VT refractory to pharmacotherapy should undergo synchronized cardioversion with 100 J (biphasic preferred); escalating doses of up to 200 J biphasic or 360 J monophasic are occasionally needed.

Cardiology should be consulted for patients with VT. Ablation therapy, along with medical optimization, may aid long-term management.

Torsades de Pointes

Torsades de pointes is translated as "twisting of the points" and is a paroxysmal form of polymorphic VT that meets the following clinical criteria (see Fig. 65.38):

1. Ventricular rate greater than 200 beats/min
2. Undulating QRS axis, with the polarity of the complexes appearing to shift about the baseline
3. Paroxysms of less than 90 seconds

Torsades de pointes occurs in the setting of a prolonged QT interval, a reflection of abnormal ventricular repolarization. A prolonged QT interval can be congenital or acquired. Women are at a greater risk for torsades de pointes. Acquired torsades de pointes is much more common than congenital and is pause-dependent, triggered by a slow heart rate.

Acquired QT prolongation is the most common form seen outside a specialized pediatric setting and usually has multifactorial causes (Box 65.13). Common triggers include electrolyte disturbances (e.g., hypokalemia, hypomagnesemia) or many different medications (notably class IA and IC agents but also many others; see Box 65.13), especially when used in combination.

Treatment of torsades de pointes in stable adult patients involves correcting any underlying metabolic or electrolyte abnormalities and increasing the heart rate to shorten ventricular repolarization. Class IA and IC antidysrhythmics should not be used in patients with torsades

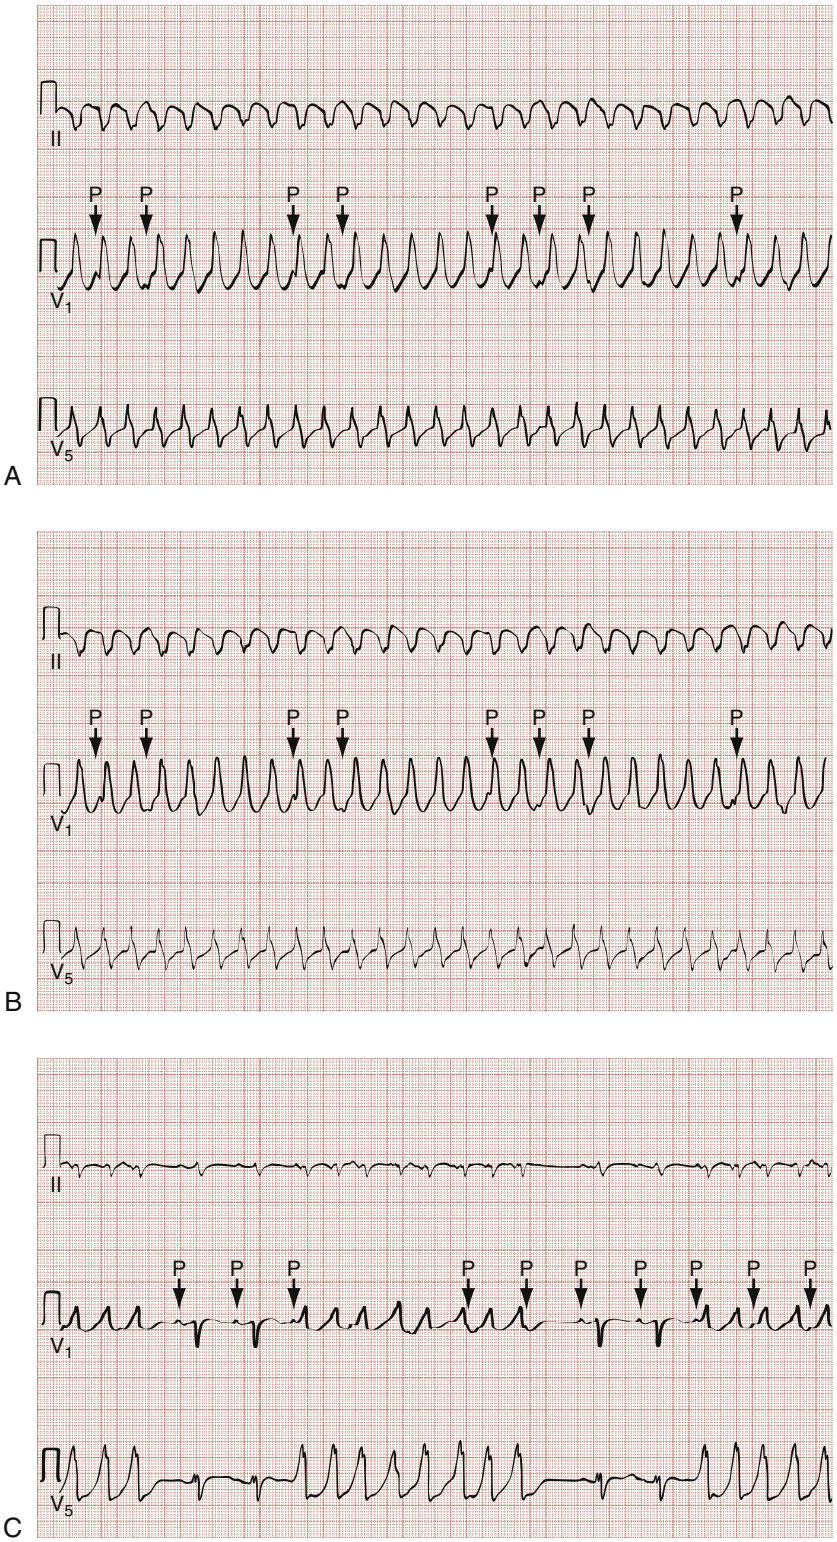

Fig. 65.34 (A, B) Ventricular tachycardia. Note atrioventricular dissociation. (C) Intermittent, nonsustained ventricular tachycardia. Atrioventricular dissociation is evident. (Courtesy Dr. Edward Curtis.)

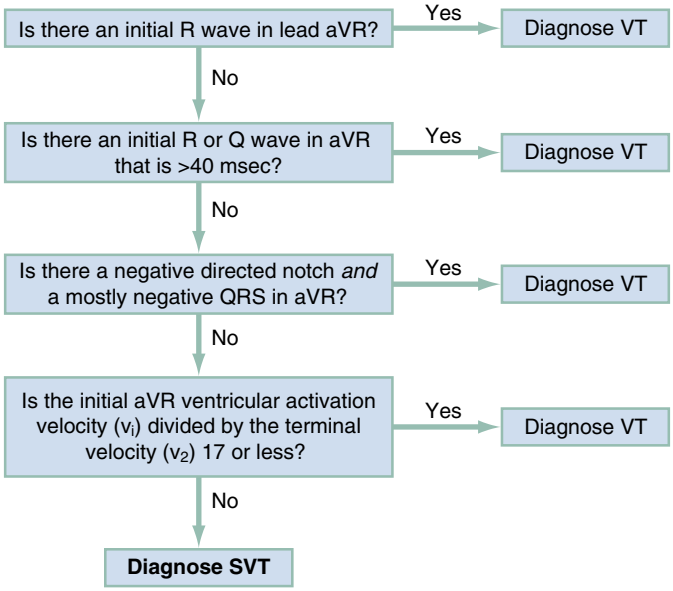

Fig. 65.35 Vereckei criteria for differentiation of ventricular tachycardia (VT) from supraventricular tachycardia (SVT).

de pointes. Empirical IV magnesium sulfate (1 to 2 g quickly) effectively treats torsades de pointes, even in the absence of hypomagnesemia, and may prevent recurrence if electrical cardioversion succeeds.

A baseline ventricular rate of 100 to 120 beats/min is usually enough to prevent acquired torsades de pointes, achieved by overdrive pacing (i.e., external pacing at a rate greater than the patient's intrinsic rate) or via β-adrenergic (isoproterenol) infusion. Unstable patients or those with sustained torsades de pointes should undergo electrical cardioversion, recognizing that synchronization may not be possible.

Congenital torsades de pointes is rare and triggered by sympathetic excess or tachycardia; it is usually seen in children and young adults. Patients often have syncope during exertion and a prolonged QT interval on the ECG. In contrast to acquired forms, congenital torsades de pointes is treated with beta blockers.

Brugada Syndrome

Brugada syndrome is a ventricular dysrhythmia triggering syncope or sudden cardiac death in the absence of structural heart disease. This syndrome links to an inherited disorder of sodium channels and is commonly diagnosed in men during young adulthood. The Brugada electrocardiographic pattern shows a downward coved or humped (saddleback) ST segment elevation in leads V_1 to V_3 (Fig. 65.39), sometimes simulating an RBBB appearance. The ST segment findings may be transient or elicited only with pharmacologic stimulation or exertion.

Any patient with unexplained syncope and a Brugada pattern ECG requires admission for consideration of an implanted defibrillator. For patients in whom a Brugada pattern ECG is noted incidentally, there is no consensus on treatment, but we recommend referral to a cardiologist.

DISPOSITION

Patients with dysrhythmias that are symptomatic and nonresponsive to ED therapy require admission. Outpatient ambulatory monitoring and close contact with a cardiologist is an option for patients with no evidence of structural heart disease who are asymptomatic or only have palpitations and for patients whose dysrhythmias resolve.[4,6] When evaluating anyone with symptomatic rhythm changes, we recommend a cardiology consultation. Those with VT, torsades de pointes, type II second-degree block, or complete heart block require admission.

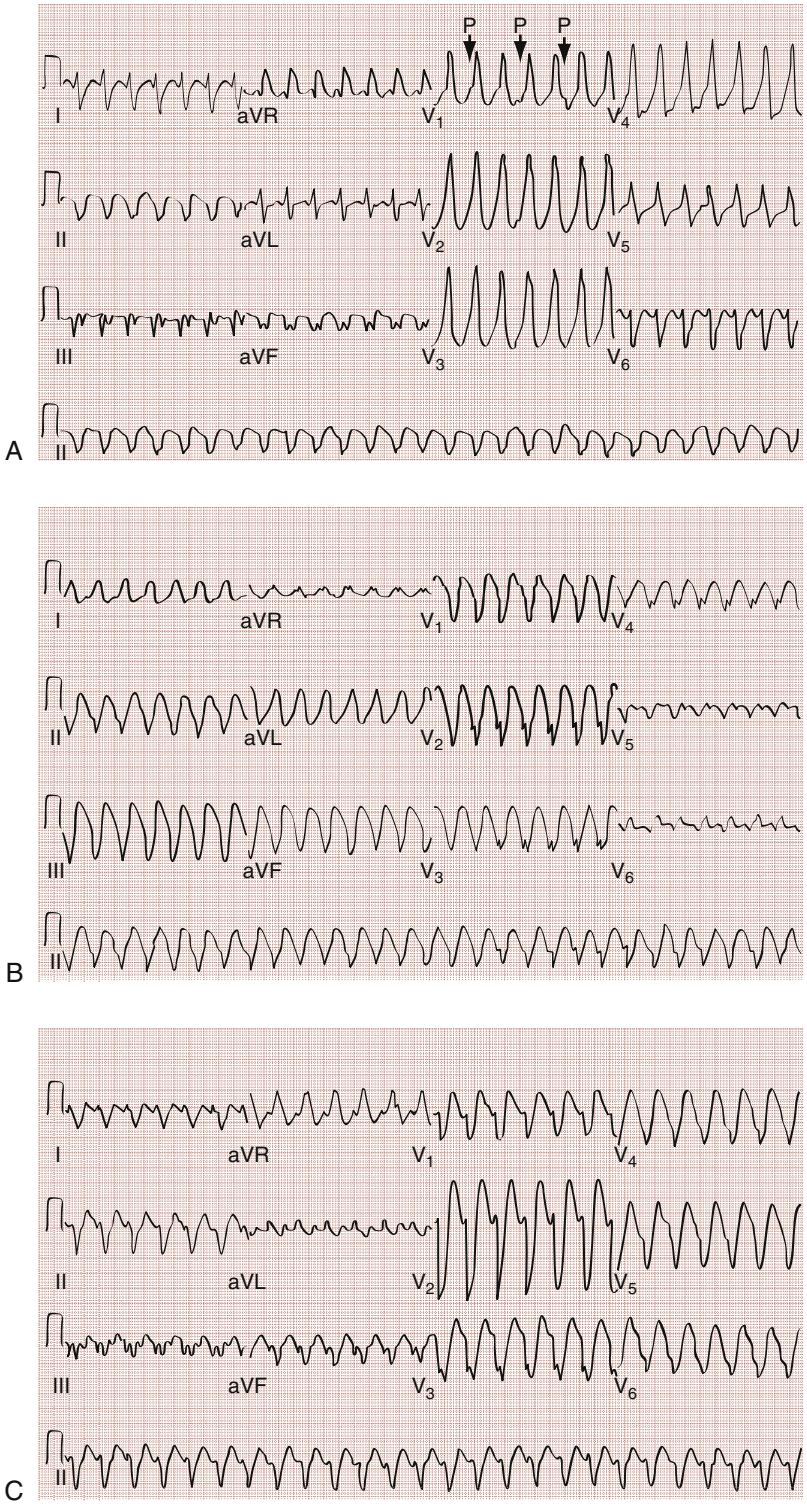

Fig. 65.36 Ventricular tachycardia. (A) RS complexes are present in chest leads, but RS duration is greater than 100 ms. Although the Brugada criteria indicate that no further analysis is necessary, atrioventricular dissociation is also evident, and QRS morphology in lead V_6 is consistent with ventricular tachycardia. (B) Some RS complexes are present, RS duration is no longer than 100 msec, and atrioventricular dissociation is difficult to appreciate. The morphologic criteria for ventricular tachycardia are fulfilled because S is notched in V_1 and QR is present in V_6. (C) Diagnosis is based on morphologic criteria because S is notched in V_1 and V_2 and QS are present in V_6. (Courtesy Dr. Edward Curtis.)

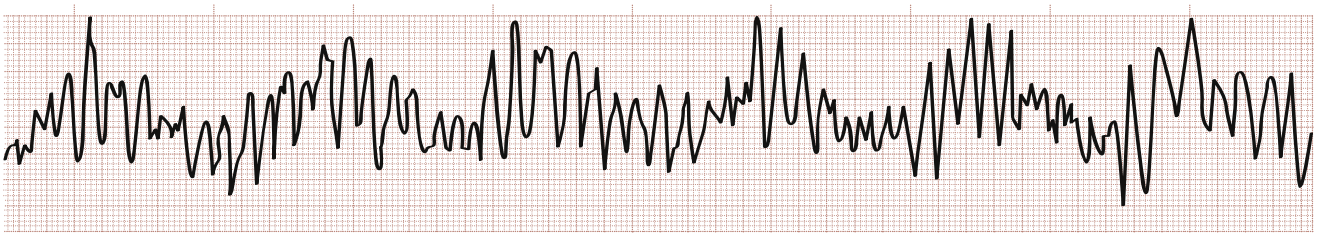

Fig. 65.38 Torsades de pointes with the classic spiraling of QRS complexes around the baseline.

BOX 65.13 Classification and Causes of Prolonged QT Syndromes That Produce Torsades de Pointes

Pause-Dependent (Acquired)

Drug-induced—class IA and IC antidysrhythmics; many phenothiazines and butyrophenones (notably haloperidol and droperidol), cyclic antidepressants, antibiotics (especially macrolides), organophosphates, antihistamines, antifungals, antiseizure and antiemetic agents

Electrolyte abnormalities—hypokalemia, hypomagnesemia, hypocalcemia (rarely)

Diet-related—starvation, low protein

Severe bradycardia or atrioventricular block

Hypothyroidism

Contrast injection

Cerebrovascular accident (especially intraparenchymal)

Myocardial ischemia

Adrenergic-Dependent (Tachycardia-Prompted)

Congenital

Jervell and Lange-Nielsen syndrome (deafness, autosomal recessive)

Romano–Ward syndrome (normal hearing, autosomal dominant)

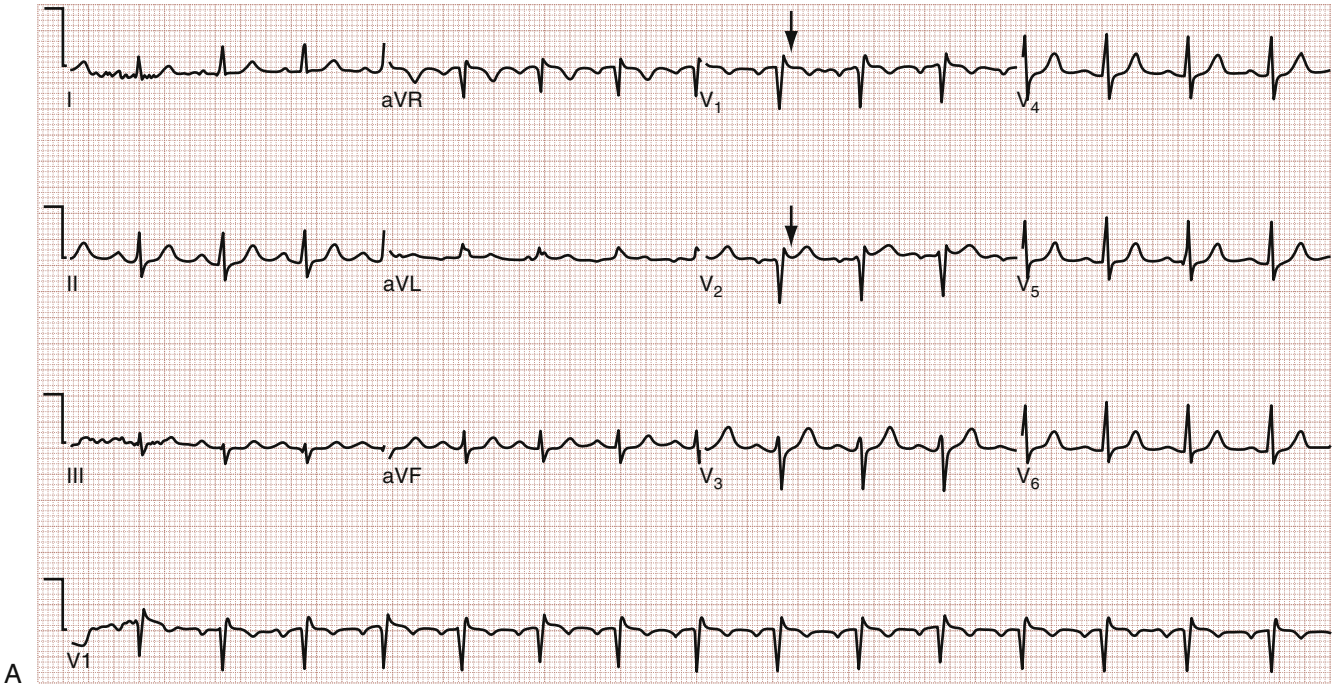
Sporadic (normal hearing, no familial tendency)

Mitral valve prolapse

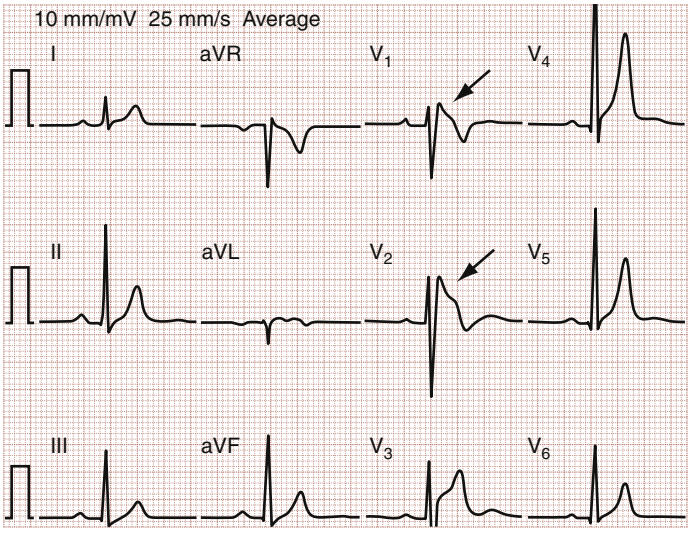
Acquired (Rare)

Cerebrovascular disease (especially subarachnoid hemorrhage)

Autonomic surgery: radical neck dissection, carotid endarterectomy, truncal vagotomy



A



B

Fig. 65.39 Brugada syndrome, with ST elevation in V_{1S}. The ST elevation is coved (*upper,* (A) or saddleback (*lower,* (B) and may be transient.

CHAPTER 65: QUESTIONS AND ANSWERS

65.1. What is the primary electrochemical difference between pacemaker and nonpacemaker cells?

- **a.** Lack of a plateau phase 3 in nonpacemaker cells
- **b.** Rapid phase 0 upstroke in nonpacemaker cells after stimulus
- **c.** Slow calcium ion influx during phase 2 for pacemaker cells
- **d.** Slow phase 4 spontaneous depolarization in pacemaker cells
- **e.** Transient membrane repolarization by potassium channel closure during phase 1 for pacemaker cells

Answer: d. The spontaneous return to a depolarization threshold during phase 4 (diastole) characterizes pacemaker cells. Both cell types then exhibit a rapid phase 0 upstroke resulting from sodium ion (Na^+) influx, brief repolarization resulting from potassium ion (K^+) efflux (phase 1), plateau phase resulting from balanced calcium ion (Ca^{2+}) entry and K^+ efflux (phase 2), and then repolarization resulting from Ca^{2+} channel closure and K^+ efflux (phase 3).

65.2. For a reentrant tachydysrhythmia to occur, what three conditions exist?

- **a.** Electrolyte disturbance, ischemia, and altered conduction in an endogenous atrioventricular pathway
- **b.** Electrolyte disturbance, two conduction pathways, with one of the pathways being slower
- **c.** Ischemia, two conduction pathways, with one of the pathways being slower
- **d.** Two conduction pathways, one path being slower, and differing responsiveness
- **e.** Two conduction pathways with equal responsiveness

Answer: d. Remember that a conducting pathway is bidirectional. In a typical scenario, the alpha pathway of the atrioventricular (AV) node is the anterograde conducting limb, and the beta pathway is the retrograde conducting limb. Reentrant dysrhythmias are almost always AV nodal and narrow complexes that start and end abruptly.

65.3. Classic antifibrillatory effects are seen with which class of antidysrhythmic?

- **a.** IA
- **b.** IB
- **c.** IC
- **d.** II
- **e.** III

Answer: e. Class III agents, of which amiodarone is the prototype, prolong the action potential and refractory period duration. Class I agents have variable effects on depolarization rate and repolarization duration.

65.4. The most frequent proarrhythmic effects are seen with which class of antidysrhythmic?

- **a.** IA
- **b.** IB
- **c.** IC
- **d.** II
- **e.** III

Answer: c. Class IC agents, such as flecainide, encainide, and propafenone, markedly slow depolarization and conduction and prolong repolarization and action potential duration. Class IB agents generally have the least proarrhythmic effect.

65.5. A 49-year-old woman presents with a sudden onset of palpitations and shortness of breath. This has happened once before. She has no past history and takes no medications. Vital signs are temperature, 36.0°C (96.8°F) oral, blood pressure, 115/69 mm Hg, heart rate 156 beats/min, respiratory rate 24 breaths/min, and oxygen (O_2) saturation, 98%. Her electrocardiogram (ECG) is shown in Fig. 65.28. What is the most appropriate intervention?

- **a.** Adenosine, 6 mg IV
- **b.** Digoxin, 0.25 mg IV

CHAPTER 65: QUESTIONS AND ANSWERS—cont'd

c. Diltiazem, 0.4 mg/kg IV
d. Propranolol, 1 mg IV
e. Synchronized electrical cardioversion after IV sedation with midazolam

Answer: a. Adenosine causes slowing of conduction in the anterograde and retrograde pathways, with no effect on ventricular contractility. It converts a high percentage of narrow-complex tachycardias to sinus rhythm, but with a 25% recurrence rate. Diltiazem would not be unreasonable, but the quoted dose is too high. Calcium channel blockers also exert their effects only on the anterograde pathway, with little direct effect on accessory pathways. Contractility may be diminished. Digoxin use has been largely supplanted by adenosine and class IV agents. Its onset of action after IV use is 1.5 to 2 hours. Cardioversion would not be indicated unless the patient exhibited hemodynamic instability.

Implantable Cardiac Devices

Christopher R. Tainter and Gabriel Wardi

KEY CONCEPTS

- Pacemaker malfunction soon after implantation (within 6 to 8 weeks) is usually a result of a lead problem, such as a lead displacement, or a pacemaker programming issue, such as a pacing rate too slow for the patient's needs.
- Pacemaker malfunction is categorized as failure to pace, oversensing, undersensing, or pacing at an inappropriate rate (too fast or too slow).
- Pacemaker or implantable cardioverter-defibrillator (ICD) interrogation should be performed if a patient's presentation (e.g., shortness of breath, palpitations, syncope, shock, cardiac arrest, etc.) or ECG (electrocardiogram) is suggestive of device malfunction, abnormal intrinsic rhythm, or worsening cardiac function.
- Modern lithium-iodine batteries are highly reliable; battery-related issues are unlikely to be the cause of abrupt pacemaker failure.
- Consider pacemaker lead infection and endocarditis if a patient with a pacemaker has a fever of unclear cause.
- Right ventricular-paced complexes are normally conducted with a left bundle branch block pattern. A right bundle branch pattern is abnormal and suggests lead displacement.
- Magnet application turns off the sensing and inhibition function, causing the pacemaker or ICD to fire at a preprogrammed fixed rate (typically near 60 beats/minute) and inhibits antitachycardia pacing in ICDs. Magnet removal returns the pacemaker to its programmed pacing mode.
- Defibrillation is safe in patients with a pacemaker or ICD. Pads should be placed at least 10 cm from the subcutaneous implant site of the device.
- Most left ventricular assist device (LVADs) do not produce pulsatile flow; therefore, these patients will not have a palpable pulse.
- All modern VADs tolerate external defibrillation and cardioversion.
- Chest compressions can be performed in an unresponsive, nonperfusing patient with a VAD, supported by typical resuscitative measures.

PERMANENT PACEMAKERS

PRINCIPLES

Electrical cardiac pacing for the management of bradyarrhythmias was first described in 1952, and permanent transvenous pacing devices were introduced into clinical practice in the early 1960s. Implanted electrical devices for the management of cardiac dysrhythmias have changed significantly over the decades, with increasing complexity, miniaturization, and the development of leadless systems. Permanent pacemaker (PPM) placement is now almost exclusively performed via minimally invasive techniques and has a low complication rate. Over 250,000 new permanent pacemakers are placed each year in the United States. Indications for the use of permanent pacemakers have expanded beyond the treatment of dysrhythmias and now include cardiac resynchronization therapy (CRT), or biventricular pacing, for patients with depressed ventricular function and ventricular dyssynchrony. Patients may present to the ED after firing of an internal defibrillator or with symptoms related to malfunction of implanted devices.

CLINICAL FEATURES

Guidelines for the implantation of permanent pacemakers have been developed by a joint task force of the American Heart Association (AHA) and the American College of Cardiology (ACC), and are periodically updated.[1] Class I recommendations include conditions for which there is general agreement that a device should be implanted (listed in Box 66.1). A class II recommendation includes conditions for which these devices are frequently used, but for which there is disagreement about their need or benefit. Class III is reserved for conditions for which there is general agreement that a device is not needed. In general, pacing is recommended for patients with sinus node dysfunction, symptomatic heart block, symptomatic sinus bradycardia, and atrial fibrillation with symptomatic bradycardia in the absence of medications that affect atrioventricular (AV) conduction. International guidelines strongly recommend cardiac resynchronization therapy (CRT) for patients with systolic heart failure with left ventricular ejection fracture under 35% and left bundle branch block.[2,3]

Pacemaker Terminology

A descriptive letter code, initially established in 1974 and revised as technology advances, standardizes nomenclature for pacemakers. Table 66.1 includes a description of the five-letter code scheme and standard abbreviations. Most discussions regarding permanent pacemaker function truncate the abbreviation to just the first three or four letters.

Pacemaker Components

Traditional permanent pacemakers have two basic components: a pulse generator, which houses the battery, and a lead system, which connects the pulse generator to the endocardium. Nearly all pulse generators use lithium-iodine cells as an energy source. Contemporary pulse generators typically last 4 to 10 or more years, although this depends on many variables including size, current required for circuitry, and composition of the pacemaker. Power output of lithium-iodine cells decreases gradually (unlike the early mercury-zinc cells), which makes sudden pulse generator failure an unlikely cause of pacemaker malfunction. Leadless pacemakers have recently been introduced and are a self-contained generator and electrode system implanted directly in the right ventricle.[4]

Permanent pacemakers have endovascular leads that are positioned in contact with the endocardium of the right ventricle and, in the case

of a dual-chamber device, the right atrium. A subclavian or cephalic venous approach is used for insertion, whereas leadless pacemakers are inserted via the femoral vein. Biventricular pacemakers have conventionally placed right atrial and ventricular leads and an additional left ventricular lead positioned in a left ventricular epicardial location via the coronary sinus. An epicardial lead may be implanted during open-heart surgery performed for another indication, such as prosthetic valve insertion or correction of a congenital cardiac defect, although these are most commonly used only temporarily in the perioperative period.

Pacemaker leads may have either a bipolar or unipolar configuration. A bipolar endocardial lead has both the negative (distal) and the positive (proximal) electrodes, separated by approximately 1 cm, within the heart. A unipolar lead has the negative electrode in contact with the endocardial surface, and the positive pole is the metallic casing of the pulse generator. The unipolar configuration is not compatible with implantable cardioverter-defibrillator (ICD) systems and is prone to oversensing of myopotentials and electromagnetic interference, thus is less commonly encountered.

BOX 66.1 Class I Indications for Permanent Pacing in Adults

1. Patients with symptoms directly attributable to sinus node dysfunction
2. Patients with symptomatic sinus node dysfunction or AV block secondary to guideline-directed therapy for which no alternative therapy is available and continued treatment is necessary
3. Patients with permanent AF and symptomatic bradycardia
4. Patients with symptomatic AV block attributable to a known reversible cause (e.g., Lyme disease or drug toxicity) without resolution of the block despite appropriate therapy for the underlying cause
5. Patients with acquired second-degree Mobitz type II AV block, high-grade AV block, or third-degree block not attributable to reversible or physiologic causes, regardless of symptoms
6. Patients with neuromuscular diseases associated with conduction disorders (muscular dystrophy, Kearns-Sayre syndrome, etc.) with evidence of second- or third-degree AV block regardless of symptoms with meaningful survival greater than 1 year
7. Patients with syncope and bundle branch block with an HV interval > 70 ms or an infra-nodal block
8. Patients with an alternating bundle branch block
9. Patients with postoperative sinus node dysfunction or AV block with persistent symptoms or hemodynamic instability following coronary artery bypass, surgery for AF, valvular surgery or replacement
10. Patients with adult congenital heart disease and symptomatic sinus node dysfunction, chronotropic incompetence, symptomatic bradycardia from AV block, mean daytime heart rate below 50 bpm, complex ventricular ectopy, or ventricular dysfunction
11. Patients with Mobitz II AV block, high-grade AV block, third-degree block, alternating bundle-branch block after an MI following a waiting period

AV, Atrioventricular; *AF,* atrial fibrillation; *HV,* His bundle-ventricular interval (measured from the onset of the His potential to the onset of the earliest ventricular activation).

History

Patients with a pacemaker usually carry a pacemaker identification card that identifies the device, the indication for placement, and the pacing modality. If the card is not available, information may be obtained by calling the device manufacturer. All manufacturers provide support including representatives on call to respond to the hospital to interrogate a device. Over 90% of permanent pacemakers in the United States are produced by Medtronic, St. Jude, or Boston Scientific.

Most patients with pacemaker malfunctions have symptoms reminiscent of those that prompted pacemaker therapy (e.g., syncope, lightheadedness, palpitations). The majority of pacemaker complications occur within the first few weeks or months of pacemaker implantation. After wound healing, palpation of the pulse generator site should not elicit tenderness. A wound infection or pocket infection typically presents with localized pain and tenderness. Bacteremia secondary to infection of the pacemaker may present only with fever. Pacemaker placement can cause acute upper extremity venous thrombosis (see Chapter 74).

Patients who develop AV dyssynchrony with the loss of the atrial kick may have nonspecific complaints of easy fatigability, generalized weakness, dyspnea, or an uncomfortable fluttering or "pounding" sensation in the neck or abdomen. Syncope or near-syncope may also occur, but these complaints should prompt an evaluation for true pacemaker malfunction.

Physical Examination

Pacemaker infection should be suspected when there is evidence of erythema, tenderness, purulent drainage, or exposed device hardware. An unexplained fever should also prompt consideration of a pacemaker infection. Extremely low (<60 beats/min) or high (>100 beats/min in the resting patient) pulse rates are suggestive of altered pacing parameters. This may be caused by battery depletion if the battery is more than 5 to 7 years old, or may represent a pacemaker-mediated tachycardia. Cannon "A" waves on inspection of the jugular venous pulse wave indicate AV dyssynchrony. Left sided heart failure will present typically with bibasilar rales right sided failure may cause jugular venous pressure elevation.

During pacing, the first heart sound may vary in intensity as a result of AV dissociation (VVI mode), and the second heart sound may be paradoxically split when ventricular pacing occurs (the right ventricle is activated first). A pericardial friction rub or signs of tamponade (hypotension, muffled heart sounds, elevated jugular venous pressure) may

TABLE 66.1 Five-Letter Pacemaker Code

Letter 1: Chamber Paced	Letter 2: Chamber Sensed	Letter 3: Sensing Response	Letter 4: Programmability	Letter 5: Antitachycardia Functions
A = Atrium	A = Atrium	T = Triggered[a]	P = Simple	P = Pacing
V = Ventricle	V = Ventricle	I = Inhibited	M = Multiprogrammable	S = Shock

O = None	O = None	O = None	C = Communicating	
			O = None	

[a]In the triggered response mode, the pacemaker discharges or fires when it recognizes an intrinsic depolarization. As a result, pacemaker spikes occur during initiation of the QRS complex, which results in high energy consumption and a shortened battery life and can be misinterpreted as pacemaker malfunction. This sensing mode is generally not used with modern pacemakers.

be present if the tip of the pacing catheter has perforated the wall of the right ventricle. Although the pacing catheter traverses the tricuspid valve, tricuspid regurgitation represents concomitant valvular disease.

12-Lead Electrocardiogram

The 12-lead ECG interpretation is facilitated by examination of the chest x-ray. A single lead in the apex of the right ventricle indicates a VVI pacemaker. The pacer spike (or stimulus artifact) is a narrow deflection that is usually less than 5 mm in amplitude with a bipolar lead configuration and usually 20 mm or more in amplitude with a unipolar lead. A wide QRS complex appears immediately after the pacer spike, usually with a morphology similar to a left bundle branch block, because depolarization begins in the right ventricular apex, and the spread of excitation does not follow normal conduction pathways. With VVI pacing, only one stimulus artifact is seen with each stimulated ventricular depolarization (Fig. 66.1). If sinus node activity is present, the paced QRS complex is dissociated from the intrinsic P waves. If separate leads are identified in the right atrium and right ventricle on chest x-ray, the pacing modality is most often DDD or DVI, and paced P waves and QRS complexes (two spikes for each QRS complex) are seen (Fig. 66.2). Although DDD and DVI units are capable of pacing both the right atrium and the right ventricle, only one spike may be seen if the other lead is inhibited during normal function (Fig. 66.3). In biventricular pacing, two stimulus artifacts or "spikes" may be seen preceding a paced QRS complex on the standard ECG (Fig. 66.4). A normal-appearing QRS complex may follow an intrinsic P wave as a result of normal sinoatrial node discharge if the intrinsic atrial depolarization is conducted to the ventricles. The intrinsic P wave and QRS complex are sensed, and inhibit stimulus discharge by the atrial and ventricular leads. A normal QRS complex follows a paced P wave if the paced atrial beat is conducted through the AV node and the programmed AV delay period is not exceeded. If the atrial impulse is not conducted to the ventricles (AV delay period exceeded), the pacemaker stimulates the ventricle, resulting in a paced P wave and a wide, paced QRS complex with left bundle branch block configuration.

DIFFERENTIAL DIAGNOSIS

Complications of Implantation

Infection

Pacemaker implantation carries a lifetime risk of infection below 2%, although this risk is up to threefold higher in patients with CRT or who

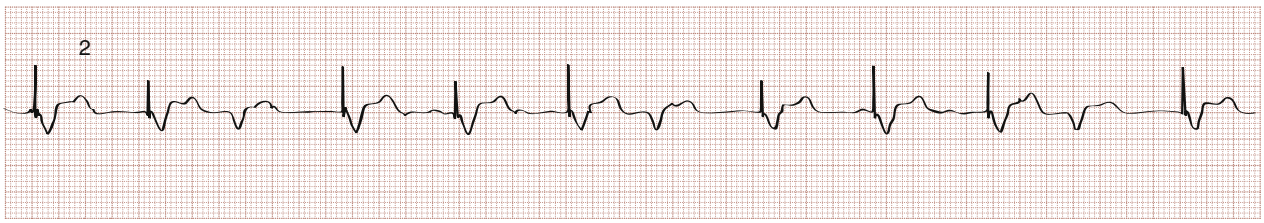

Fig. 66.1 Normal VVI pacemaker (rhythm strip). This rhythm strip was recorded in a patient with a VVI pacemaker implanted for the treatment of symptomatic complete heart block. Each pacemaker spike is followed by a paced QRS complex with a rate of 75 beats/min. The third QRS from the left has a slightly different morphology than the paced QRS complexes. It is an intrinsic QRS complex that is sensed by the pacemaker, and a paced beat does not occur again until the programmed rate of the pacemaker is exceeded.

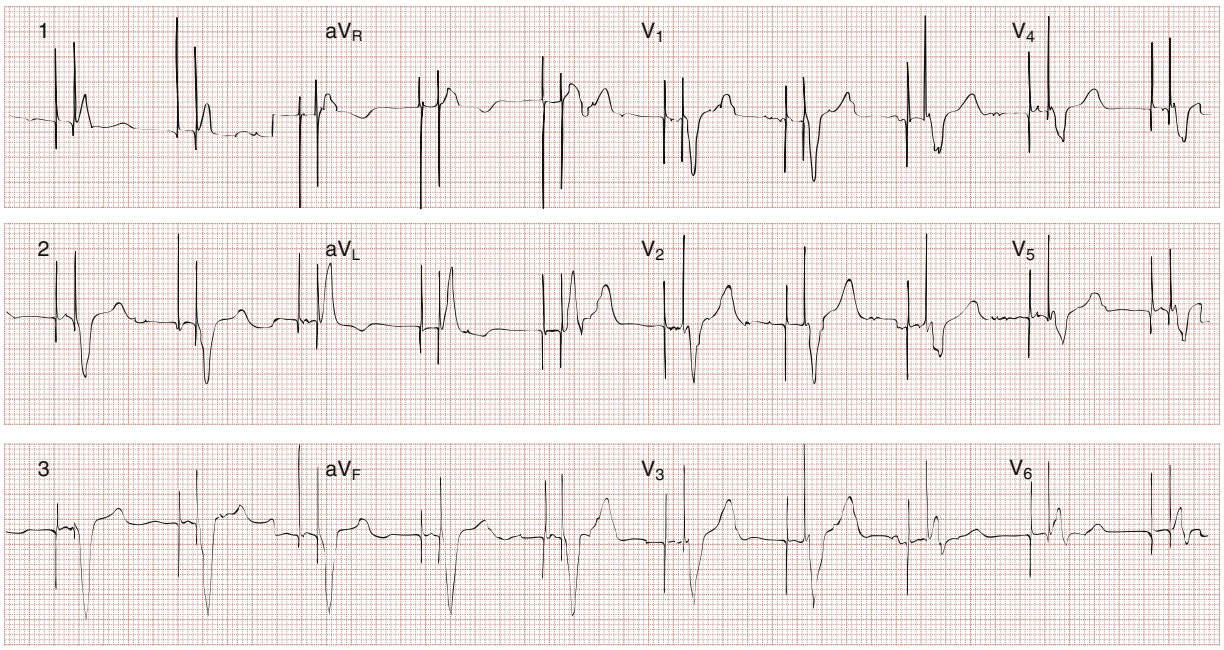

Fig. 66.2 Normal DDD pacemaker (12-lead electrocardiogram). Each QRS complex is preceded by two pacemaker spikes. The first spike results in atrial depolarization, and the second produces a wide QRS complex. The QRS complex is conducted with a left bundle branch morphology, which is expected with endocardial pacing at the right ventricular apex.

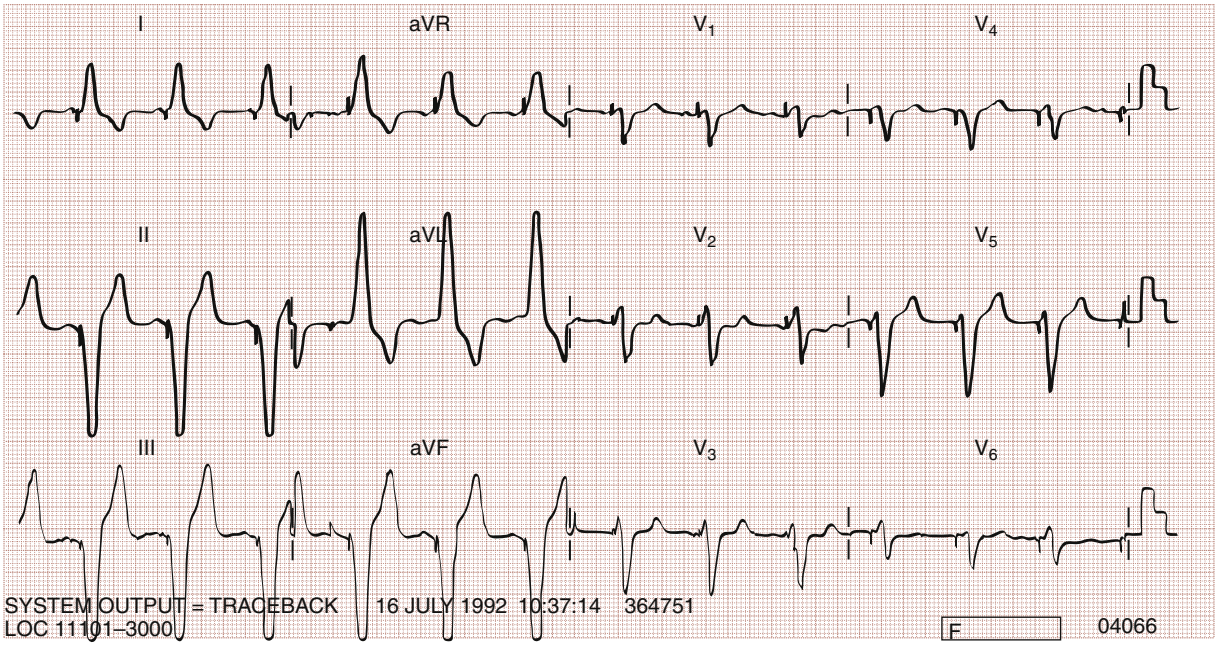

Fig. 66.3 Normal DDD pacemaker (half-standard 12-lead electrocardiogram). Three paced QRS complexes preceded by a stimulus artifact or spike are evident in leads I, II, and III. Paced QRS complexes occur after spontaneous or intrinsic P waves are sensed and atrioventricular (AV) conduction delay exceeds the pacemaker's programmed AV interval. The first QRS complex in the augmented leads, best seen in lead aVF, demonstrates both a paced P wave and a paced QRS complex. Although the pacemaker is a dual-chamber device, two spikes may not always be seen preceding every QRS complex, and the presence of only one spike, or no spikes, should not be interpreted as evidence of pacemaker malfunction.

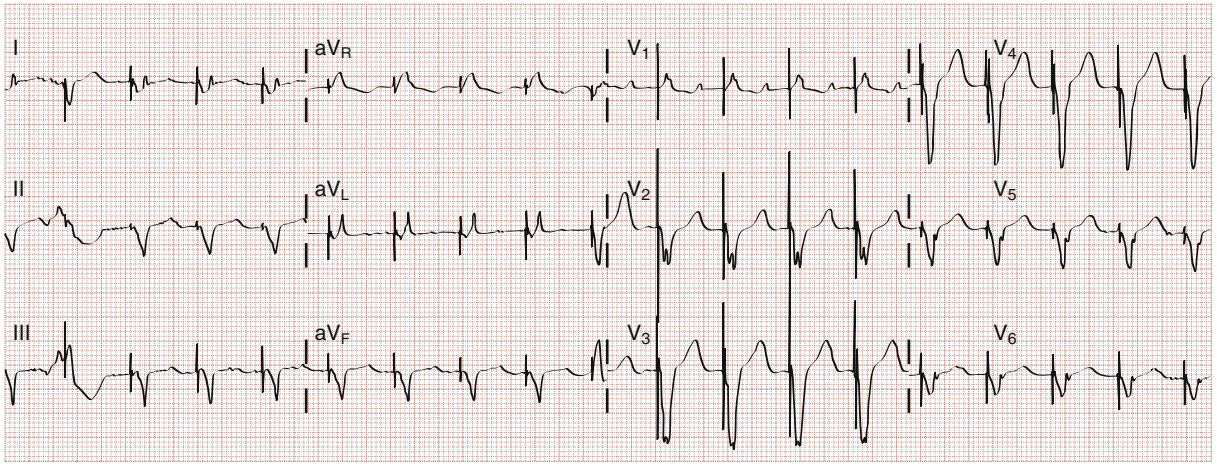

Fig. 66.4 Biventricular pacemaker (12-lead electrocardiogram) in an atrial sensed pacemaker in a patient with cardiac synchronization therapy (CRT) and implantable cardioverter-defibrillator system (CRT-D). The paced QRS complexes have an S wave in lead I and an R wave in lead V_1 that are distinctly different from the morphology and axes seen with right ventricular apical pacing. The second beat from the left is a premature ventricular contraction. There is a pacemaker "spike" superimposed on this complex, likely representing safety pacing in CRT-D.

undergo repeated manipulation of the device.[5,6] Risk factors for pacemaker infection are: chronic renal insufficiency, chronic obstructive pulmonary disease, chronic steroid use, diabetes mellitus, malignancy, and advanced age.[7] Pain and local inflammation at the site of the pacemaker are the first manifestations of a wound infection, cellulitis, or pocket infection. Approximately 20% to 25% of patients with a local infection have positive blood cultures. Bacteremia may occur in the absence of a focal infection and may arise with the typical manifestations of the systemic inflammatory response syndrome or sepsis. A hematoma of the pacemaker pocket may mimic a wound or pocket infection, but the patient will be afebrile and local inflammation will be minimal or absent. Diagnosis is confirmed by needle aspiration of the pocket under fluoroscopic guidance to ensure the needle does not damage the insulation surrounding the pulse generator or the portion of the pacemaker lead that lies within the pacemaker pocket.

When a local infection or bacteremia is suspected, blood cultures are obtained and intravenous antibiotic therapy should be initiated. Given the high prevalence of infection with *S. aureus* and *S. epidermidis*, first-line

therapy is vancomycin, with a loading dose of 20 to 35 mg/kg actual body weight (not to exceed 3000 mg) or 20 to 25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, followed by 15 to 20 mg/kg actual body weight every 8 to 12 hours. For patients who cannot tolerate this, we recommend daptomycin 6–10 mg/kg ideal body weight every 24 hours. For patients with hemodynamic instability, we recommend the addition of a second antimicrobial agent to broadly cover gram-negative pathogens, including *P. aeruginosa* (e.g., piperacillin-tazobactam 4.5 g every 6 to 8 hours IV or cefepime 2 g every 8 to 12 hours; see Chapter 127). In patients with a pocket infection, evidence of endocarditis, or blood cultures with pathogenic bacteria, the pulse generator and pacemaker leads are generally removed.[8]

Venous Thrombosis and Stenosis

Upper extremity deep vein thrombosis (UEDVT) associated with permanent pacemakers can involve the axillary, subclavian, and innominate veins or the superior vena cava (SVC). Patients with an acute UEDVT from their pacemaker typically complain of pain, swelling, and fatigue in the ipsilateral upper extremity. Chronic thrombosis of the veins of the upper arm is present in up to 23% of patients. These patients are usually asymptomatic owing to extensive venous collateral circulation. On examination, edema and warmth of the affected upper extremity are common in acute UEDVTs. Rarely, collateral vessels at the shoulder girdle or jugular venous distention may be present in chronic UEDVTs. If the proximal superior vena cava is obstructed, patients may present with facial plethora or chest wall edema. The initial imaging study of choice for patients with suspected UEDVT is venous duplex ultrasound. Indications for treatment and agent selection are as for non–pacemaker related UEDVT, as outlined in Chapter 74.

Venous stenosis is another recognized complication of PPM placement, occurring in over half of patients.[9] Complaints from stenosis are uncommon, however, unless complete occlusion occurs. Although rare, SVC syndrome can occur from pacemaker lead–induced thrombosis. The signs and symptoms of lead-induced SVC syndrome are identical to those described in patients with SVC syndrome and malignancy (see Chapter 112). Unlike patients with malignancy, however, these patients have excellent outcomes following endovascular repair.[10] Rare complications, such as septic thrombophlebitis and varices from vascular occlusion have also been reported.

Complications of Existing Pacemakers

The "Pacemaker Syndrome"

After single-chamber pacemaker implantation, a patient may develop symptoms of heart failure or report a worsening of the symptoms that prompted pacemaker placement. This constellation of symptoms is referred to as the *pacemaker syndrome* and is the result of AV and VV dyssynchrony with resultant increases in jugular and pulmonary venous pressures. Rarely, hypotension may occur due to loss of the atrial kick and impaired left ventricular filling. Approximately 20% of patients report symptoms suggesting pacemaker syndrome after PPM insertion. In most instances, symptoms are mild, and patients adapt to them. Treatment for severe symptoms usually requires replacing a VVI pacemaker with a dual-chamber pacemaker or lowering the pacing rate of the VVI unit to improve AV and VV synchrony. If symptoms occur in a patient paced in the DDD mode, optimizing the timing of atrial and ventricular pacing is usually required. Patients usually prefer dual-chamber pacing to the VVI modality for these reasons.

Complications Unique to Biventricular Pacing

Biventricular pacing carries risks related to placement of the left ventricular pacing lead through the coronary sinus. In large clinical trials, coronary sinus dissection occurred in 0.3% to 4.0% of patients and coronary vein or coronary sinus perforation in 0.8% to 2.0% of patients. Cardiac tamponade caused by perforation of the coronary venous system is seen in less than 1% of patients. Dislodgement of the left ventricular electrode with resultant loss of pacing occurs as an early complication in approximately 10% of patients.

Pacemaker Malfunction

The term *pacemaker malfunction* refers specifically to problems with the circuitry or power source of the pulse generator, the pacemaker lead (most commonly displacement or fracture), or the interface between the pacing electrode and the myocardium (pacing or sensing threshold). In addition, environmental factors, such as extracardiac or extracorporeal electrical signals, may interfere with normal pacemaker function. With use of the standard electrocardiogram (ECG), pacemaker malfunction can be separated into three broad categories: (1) failure to capture (2) inappropriate sensing or (3) inappropriate pacemaker rate. Symptomatic pacemaker malfunction after implantation occurs in less than 5% of patients and is rarely life-threatening. Malfunction is most commonly a result of inappropriate sensing, followed by failure to capture. Typical presentations and causes of pacemaker malfunction are listed in Box 66.2.

When a patient presents reporting symptoms consistent with intermittent pacemaker dysfunction (e.g., episodes of lightheadedness, palpitations, rapid pulse, weakness, or shortness of breath), and pacemaker sensing and capture cannot be assessed because the patient's native heart rate exceeds the pacemaker's set rate, the sensing function of the pacemaker may be temporarily disabled by placing a "pacemaker" magnet externally over the pulse generator. Magnet application causes closure of a reed switch, turning off sensing function, thus converting the pacemaker to fixed-rate pacing. Magnet application thus allows pacing to occur, despite the patient's native cardiac activity, and pacing rate and the presence of capture can be determined. Magnets are made by each manufacturer, but any cardiac pacemaker magnet will typically activate the reed switch in any device.

Failure to Capture

Failure to capture may range from the complete absence of pacemaker spikes to spikes not followed by a stimulus-induced complex (Fig. 66.5). A complete absence of pacemaker spikes may result from battery

BOX 66.2 Causes of Pacemaker Malfunction

Failure to Capture
- Lead disconnection, break, or displacement
- Exit block
- Battery depletion

Undersensing
- Lead displacement
- Inadequate endocardial lead contact
- Low-voltage intracardiac P waves and QRS complexes
- Lead fracture

Oversensing
- Sensing extracardiac signals: myopotentials
- T wave sensing

Inappropriate Rate
- Battery depletion
- Ventriculoatrial conduction with pacemaker-mediated tachycardia
- 1 : 1 response to atrial dysrhythmias

depletion, fracture of the pacemaker lead, or disconnection of the lead from the pulse generator unit. Current lithium-iodine batteries are not subject to sudden power failure, and they display typical end-of-life functional changes over a period of months to a year before complete depletion. Usually the first sign of voltage depletion is a gradual decrease in the programmed pacing rate. When voltage output falls to a critical level, stimulus strength falls below the required threshold, and failure to capture or intermittent failure to capture may be observed late in battery life. As a result, urgent or emergent battery replacement is rare.

Failure to capture, which may be complete or intermittent, is most commonly a problem with the pacing lead. Lead displacement is the most common cause and is most likely to occur within the first month of pacemaker insertion. Lead fracture, which is uncommon with the current polyurethane lead coating, produces an insulation break, resulting in failure to capture as a result of current leakage. It can be detected as a change in pacing threshold during pacemaker interrogation. Lead fractures occur at predictable locations, usually at the site of attachment to the pulse generator or at abrupt angulations, which serve as stress points. Inadequate contact of the lead with the pulse generator can mimic a lead fracture. Occasionally, when a lead fracture is complete or nearly complete, a break in the catheter or its insulation can be detected on an over-penetrated posteroanterior chest radiograph. Loss of lead-pulse generator contact can be detected on the chest radiograph with close inspection of the pulse generator.

Exit block (the failure of an adequate stimulus to depolarize the paced chamber) can also result in failure to pace. Exit block should be considered when the preprogrammed pacing stimulus output fails to result in capture in the presence of a normally functioning pulse generator and an intact lead system. Most commonly this problem is a result of changes in the endocardium in contact with the pacing system. Causes include ischemia or infarction of the endocardium in contact with the electrodes, systemic hyperkalemia, and the use of class III antiarrhythmic drugs (such as amiodarone), which affect ventricular depolarization. Although other drugs alter pacemaker threshold, the effect is small and is rarely clinically important.

Inappropriate Sensing

For a pacemaker to function in a noncompetitive mode, it must be capable of sensing the intrinsic or "native" electrical activity of the heart. The electrical activity that is sensed is determined by the pacing modality (see Box 66.1). Sensing parameters are determined at the time of pacemaker insertion on the basis of the signal size of the intracardiac ECG and can be changed or fine-tuned externally at a later time if needed.

Failure to sense may be complete or intermittent. It may result from a change in the sensing parameters selected at the time of insertion. This is most commonly encountered after acute right ventricular infarction or during the progressive fibrosis that accompanies many cardiomyopathies, causing intracardiac signals to decrease in amplitude. Lead displacement, fracture, and poor contact with the endocardium may also cause undersensing.

Undersensing is typically recognized electrocardiographically as the appearance of pacemaker spikes occurring earlier in the cycle than would be expected, based on the programmed rate. The spike may or may not be followed by a paced complex, depending on when it occurs during the cardiac refractory period (Fig. 66.6). Failure of a stimulus spike to produce a complex when it occurs during the atrial or ventricular refractory period does not represent failure to pace.

In rare instances, the pacemaker may detect electrical activity that is not associated with cardiac contraction, which is called *oversensing*. The result may be intermittent, irregular pacing or an apparent complete absence of pacemaker function. Myopotentials produced by the pectoralis muscle (Fig. 66.7) and extracorporeal electrical signals are frequently oversensed by unipolar lead systems. T waves that follow an intrinsic ventricular depolarization are the most common oversensed cardiac signals. Common medical sources of electrical interference include electrocautery, which can cause temporary pacemaker inhibition, and magnetic resonance imaging (MRI), which can alter pacemaker circuitry and result in fixed-rate or asynchronous pacing. Electromagnetic interference resulting from close proximity to a microwave oven should not cause problems with currently implanted

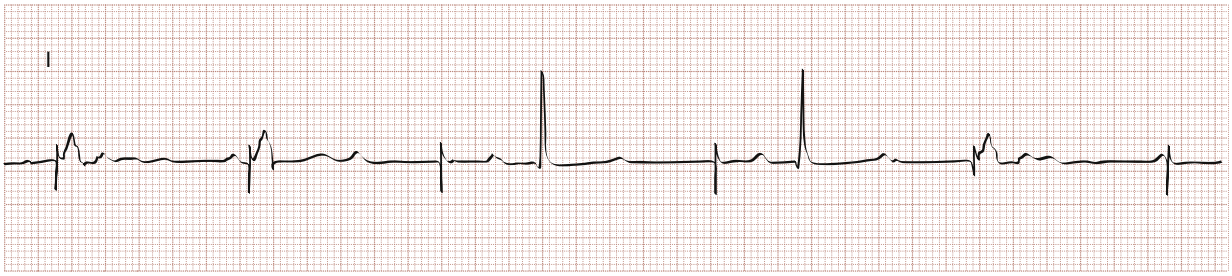

Fig. 66.5 Intermittent failure to capture and slow pacing rate (lead I) characteristic of a depleted battery in a VVI pacemaker. The first and second pacemaker spikes are followed by wide-paced QRS complexes; the third and fourth spikes are not. The pacemaker spikes occur at a rate of approximately 50 beats/min, although the device was programmed to pace at 75 beats/min.

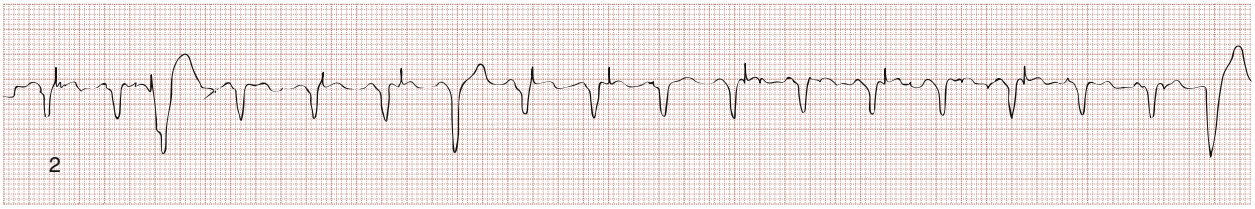

Fig. 66.6 Failure to sense or undersensing (lead II). Pacemaker spikes are evident during inscription of the ST segment on this rhythm strip. These spikes do not produce QRS complexes because they occur during the ventricular refractory period of the preceding spontaneous QRS complex. The third QRS complex on the strip is a paced QRS complex. The device is capable of capture but is undersensing the spontaneous rhythm.

pacemaker units. The current generation of cellular phones do not interfere with implanted pacemakers.

Inappropriate Pacemaker Rate

A pacing rate below the programmed rate is a typical finding in pulse generator depletion and does not occur abruptly with lithium-iodine batteries. An extreme increase in pacing rate, the so-called "runaway pacemaker," is rarely, if ever, encountered with current pacemaker technology and circuitry in which upper rate limits are set (typically 140 beats/min). An "endless loop" tachycardia may develop during dual-chamber pacing when ventriculoatrial conduction occurs, and the resulting retrograde atrial depolarization results in a stimulated or paced ventricular depolarization. If atrial flutter develops during dual-chamber pacing, flutter waves may be sensed and tracked, resulting in a rapid, paced ventricular rate. In both instances, the ventricular rate does not exceed its set upper limit. Patients with such rhythms may complain only of palpitations or symptoms of hemodynamic compromise. When such rhythms are detected, magnet application converts the pacemaker to a fixed rate and terminates the tachyarrhythmia.

DIAGNOSTIC TESTING

Chest Radiograph

A chest radiograph should be obtained to define pacing catheter tip position and to determine the number of pacing leads, unless this information is available from another source, usually the patient's pacemaker card or the medical record. A ventricular pacing catheter tip in the right ventricular outflow tract or an atrial catheter tip in the SVC or right ventricle is always abnormal.

12-Lead Electrocardiogram

A standard ECG and a long rhythm strip should be obtained in all patients. ECG interpretation was described previously.

Pacemaker Interrogation

Interrogation of a pacemaker allows for information regarding battery level, lead integrity, device settings, and identification of intrinsic dysthymias. Any patient complaint or presentation (e.g., shortness of breath, lightheadedness, syncope, cardiac arrest, etc.) or findings on ECG that suggest device malfunction, abnormal intrinsic rhythm, or worsening cardiac function should prompt interrogation.

Magnetic Resonance Imaging in Patients with a Pacemaker

Many modern pacemakers are approved for magnetic resonance (MR) by the Food and Drug Administration (FDA) for certain indications and are referred to as "MR-conditional" devices. Older devices that lack FDA approval for MRI use are referred to as "legacy" systems. No pacemakers are "MR-safe," a designation that requires there be no hazard in any MR environment. Recent studies have shown no long-term clinically significant adverse events or disruption of device components even for patients with "legacy" systems in place, but the devices did require reprogramming to an asynchronous mode prior to MRI.[11,12] Despite this, recent guidelines recommend institution-specific protocols and checklists to mitigate risk of adverse events even in MR-conditional devices.[13] Thus, the ability to obtain an MRI in a patient with a pacemaker is institution-dependent and specifically limited by the type of MRI system present, availability of necessary staff (including a cardiologist) to ensure proper patient safety, and potential need for temporary pacemaker reprogramming.

MANAGEMENT

Resuscitation

Electrical defibrillation at recommended shock strengths can be safely performed in a patient with a pacemaker. Place the sternal defibrillation pad adjacent to the sternum, at a safe distance (>10 cm) from the pulse generator. Alternatively, defibrillation electrodes can be placed in an anteroposterior configuration. All pacemakers should be interrogated after successful resuscitation. A chest radiograph should also be obtained to ensure that the pacing leads have not been displaced during chest compressions.

Immediate return of pacing (capture) may not occur after defibrillation; this is commonly the result of global myocardial ischemia and increased pacing threshold and is not an indication of pacemaker malfunction. Temporary transcutaneous or transvenous pacing may be needed if the pacemaker cannot be reprogrammed or normal pacing does not resume spontaneously. Transcutaneous pacing is preferred, using guidelines as for defibrillator pad placement, because temporary transvenous pacing can be challenging in the presence of a PPM, particularly if chronic venous thrombosis is present. Insertion through the femoral vein is also difficult because the permanently implanted catheter may prevent entry into the right ventricle.

DISPOSITION

As a result of the current design of modern pacemakers and the frequent follow-up evaluation of patients with pacemakers, life-threatening emergencies resulting from pacemaker malfunction requiring emergent intervention are rare. Most instances of malfunction are subtle and difficult to recognize without interrogation of the pacemaker with manufacturer-specific devices by an individual trained in pacer interrogation. In all instances of suspected pacemaker malfunction, the patient's cardiologist should be consulted. Patients with a pacemaker infection or symptoms due to significant pacemaker malfunction (e.g., lead fracture or displacement, battery depletion) require admission for device adjustment or replacement. If interrogation of the pacemaker does not show evidence of malfunction and a patient's presenting complaint can be attributed to another cause (e.g., electrolyte abnormality or inappropriate doses of cardiac medications), discharge.

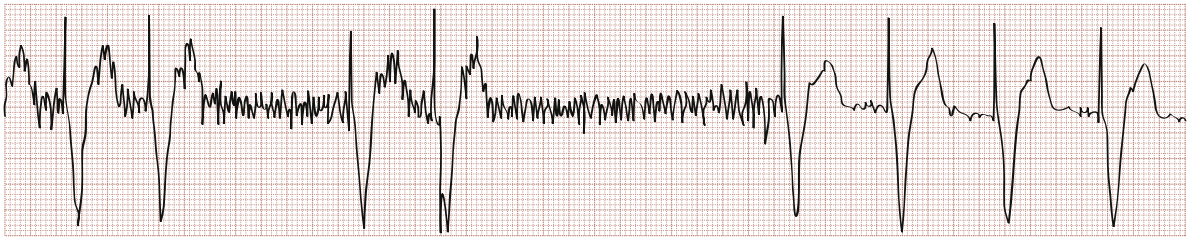

Fig. 66.7 Oversensing (lead II). This VVI unipolar lead pacemaker is oversensing myopotentials produced by contraction of the pectoralis major. Myopotentials result in the undulating and irregular baseline seen in the middle of the strip. After muscular contraction ceases, normal pacing resumes.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

PRINCIPLES

The implantable cardioverter-defibrillator (ICD) was first used clinically for treating ventricular dysrhythmias in 1980. Technical refinements to ICDs have progressed even more rapidly than refinements to the less complex standard pacemaker. A surge in the use of ICDs reflects improved survival with ICDs versus antiarrhythmic therapy in patients at risk for sudden cardiac death. Recent guidelines for ICD implantation are provided in Box 66.3. ICDs are placed for either primary prevention of sudden cardiac death or, in patients that have had cardiac arrest, secondary prevention.[14] Many patients still require drug therapy after ICD implantation to suppress ventricular dysrhythmias, minimize the frequency of ICD shocks, and decrease energy use, which prolongs ICD life and improves patients' tolerance.

CLINICAL FEATURES

Terminology and Components

The majority of ICDs are now placed in a percutaneous manner similar to that of the standard pacemaker. A transvenous electrode system has largely replaced epicardial lead placement, which required thoracotomy. The typical modern ICD consists of a power source, electronic circuitry, and lead system. In addition, the standard ICD has complex storage and monitoring abilities that allow for remote monitoring. The power source is lithium chemistry based with a battery life of 5 to 10 years. The longevity is largely determined by the frequency of shocks. All ICDs are also ventricular pacemakers. The right ventricular lead is used for sensing and pacing, and shocks are typically delivered between a coil in the right ventricular lead and the pulse generator. Patients with a depressed left ventricular ejection fraction and wide QRS may have a cardiac resynchronization therapy–defibrillator (CRT-D) that combines biventricular pacing with the ability to deliver a shock. If dual-chamber pacing is required, a second lead is placed in contact with the endocardium of the right atrium. A biphasic waveform is the preferred waveform for internal defibrillation because it is more effective at lower energies than monophasic waveforms.

The diagnostic and treatment functions of the ICD are determined at the time of implantation. The cardioversion and defibrillation thresholds are determined by inducing ventricular tachycardia (VT) and ventricular fibrillation (VF) and adjusting the shock strength at a level above the minimum required to terminate the induced rhythm. VT is typically managed with use of either low-energy shocks or antitachycardia pacing (ATP), a brief paced rhythm at a very high rate that interrupts the VT reentrant circuit and restores a normal sinus rhythm. In the setting of VF, ICDs are capable of delivering up to five additional shocks if the first shock fails.

BOX 66.3 Class I Indications for Implantable Cardioverter-Defibrillator Therapy

1. Patients with ischemic heart disease and sudden cardiac arrest resulting from VF or VT or stable sustained VT not caused by a transient or reversible event and meaningful survival is expected to be greater than 1 year
2. Patients with ischemic heart disease and unexplained syncope that have induced sustained monomorphic VT during electrophysiologic study and meaningful survival is expected to be greater than 1 year
3. Patients with depressed left ventricular function at least 40 days post myocardial infarction and at least 90 days post-revascularization and persistent heart failure symptoms if meaningful survival is expected to be greater than 1 year
4. Patients with nonsustained VT due to prior MI with depressed left-sided systolic function and inducible VT or VF during electrophysiologic study if meaningful survival is expected to be greater than 1 year
5. Patients with nonischemic cardiomyopathy, depressed left ventricular function if meaningful survival is expected to be greater than 1 year
6. Patients with sudden cardiac arrest or sustained ventricular arrhythmias from: nonischemic cardiomyopathy, arrhythmogenic right ventricular dysplasia, hypertrophic cardiomyopathy, cardiac sarcoidosis, neuromuscular disorders, cardiac channelopathies, high-risk patients with symptomatic long QT syndrome failing beta-blocker therapy, catecholaminergic polymorphic ventricular tachycardia failing beta-blocker therapy, Brugada syndrome, early repolarization, short QT syndrome, idiopathic polymorphic ventricular tachycardia, congenital heart disease

VF, Ventricular fibrillation; *VT,* ventricular tachycardia; *MI,* myocardial infarction.

DIFFERENTIAL DIAGNOSIS

Complications of Implantation

Complications of ICD implantation are similar in type and frequency to those of permanent pacemaker implantation, although the risk for infection is slightly higher. In patients with repeated instrumentation and repair of their ICDs, rates of infection may be as high as 11.7%.[6] Management is the same, whether from an ICD or permanent pacemaker.

Malfunction

Patients with ICD malfunction usually present with specific complaints (Box 66.4), the most common being the occurrence of a single or multiple shocks. An increasing shock rate may be appropriate if the patient is experiencing an increase in the frequency of VT or VF episodes, such as in the setting of hypokalemia, hypomagnesemia, myocardial ischemia, or the proarrhythmic effect of medications, and this may not be indicative of ICD malfunction. A "phantom shock" refers to the sensation of a shock without any evidence of this on device interrogation. This occurs in approximately 10% of patients with an ICD and is associated with significant psychosocial distress and posttraumatic stress disorder.

A single shock is a manifestation of ICD sensing malfunction if (1) a supraventricular tachyarrhythmia is inappropriately sensed as VT, (2) a shock is delivered for nonsustained VT, or (3) intracardiac T waves

BOX 66.4 Symptoms of Implantable Cardioverter-Defibrillator Malfunction

Increase or abrupt change in shock frequency
- Increased frequency of VF or VT (consider ischemia, electrolyte disorder, or drug effect)
- Displacement or break in ventricular lead
- Recurrent nonsustained VT
- Sensing and shock of supraventricular tachyarrhythmias
- Oversensing of T waves
- Sensing noncardiac signals

Syncope, near-syncope, dizziness
- Recurrent VT with low shock strength (lead problem, change in defibrillation threshold)
- Hemodynamically significant supraventricular tachyarrhythmias
- Inadequate backup pacing for bradyarrhythmias (spontaneous or drug induced)

Cardiac arrest
- Assume malfunction, but probably caused by VF that failed to respond to programmed shock parameters

VF, Ventricular fibrillation; *VT,* ventricular tachycardia.

detected by the ICD system are sensed as QRS complexes and the ICD interprets this as an increased heart rate. Temporary ICD deactivation with magnet application may be necessary if oversensing is the problem. Placement of a magnet will temporarily reprogram a PPM into an asynchronous mode (e.g., AOO, VOO, DOO) allowing for pacing at a preprogrammed rate without sensing, and it will disable interventions, including ATP and defibrillation. Syncope, near-syncope, dizziness, or lightheadedness in the patient with an ICD may indicate undersensing of sustained VT or inappropriately low shock strength to terminate the rhythm.

DIAGNOSTIC TESTING

As with pacemakers, chest radiograph can allow clinicians to identify lead placement, quickly detect lead fracture or displacement, and identify the type and make of ICD present. An ECG is indicated to evaluate for arrhythmias. ICD interrogation provides assessment of device function (battery life, lead integrity) and quantification of the burden of intrinsic dysrhythmias, shocks, and ATP. Any patient who presents with complaints of a shock, symptoms concerning for worsening cardiac function or device malfunction, or has an ECG with evidence of an intrinsic dysrhythmia requires ICD interrogation.

MANAGEMENT

ICD Defibrillation

It is helpful to differentiate between a single shock or multiple shocks, and whether they were appropriate. In cases in which the patient reports a single ICD shock, an assessment for acute cardiac ischemia, worsening of chronic congestive heart failure, symptoms of new-onset heart failure, and electrolyte abnormalities should be performed. When multiple defibrillator discharges are confirmed by interrogation, emergent consultation is required. Based on the findings of ICD interrogation, reprogramming may be necessary. If a lead problem is detected, reimplantation is required. Similar to a pacemaker, a magnet can be placed over the ICD to inactivate the defibrillator if the patient is receiving inappropriate shocks. This should be done only if the emergency clinician is confident that the ICD is delivering inappropriate shocks, such as in response to a supraventricular tachycardia. If frequent ventricular ectopy is noted, intravenous antidysrhythmic therapy is indicated (amiodarone IV/IO bolus 150 mg followed by an infusion of 1 mg/min for 6 hours followed by 0.5 mg/min for 18 hours, consider lidocaine 1 to 1.5 mg/kg IV/IO bolus followed by a maintenance infusion of 1 to 4 mg/min if amiodarone is unavailable or ineffective).

Resuscitation

An ICD does not prevent sudden death in all patients at risk. Cardiac arrest occurs in approximately 2% of patients with implanted devices annually. Resuscitation efforts in the patient with an ICD should be undertaken following current recommendations. Shockable rhythms should be treated with transthoracic defibrillation in the standard manner with a monophasic or biphasic defibrillator. The sternal electrode or paddle should be placed in a parasternal location at least 10 cm from the ICD subcutaneous pouch. ICD discharge during manual chest compressions poses no risk to providers, although the rescuer may feel a weak shock. Ventricular dysrhythmias may occur due to prolonged global myocardial ischemia during the arrest period, reperfusion, and the hyperadrenergic state, which is exacerbated by the use of intravenous epinephrine during resuscitation. ICD malfunction should be assumed, and these postresuscitation rhythms treated with standard pharmacologic agents (e.g., for VT/VF cardiac arrest: 300 mg amiodarone bolus via IV push followed by an additional bolus of 150 mg IV/IO if VT/VF persists, consider lidocaine 1 to 1.5 mg/kg IV/IO bolus if amiodarone is unavailable or ineffective; see "ICD Defibrillation" section above). Although class 1 antidysrhythmic agents may raise the defibrillation threshold of the ICD, their impact on the defibrillation threshold during transthoracic shocking is clinically inconsequential.

DISPOSITION

Patients who receive a single shock maybe discharged after ICD interrogation and discussion with the patient's cardiologist in the absence of a change in clinical status and if early follow-up can be arranged. If a single shock occurs due to a ventricular dysrhythmia secondary to myocardial ischemia or worsening heart failure, these patients benefit from admission. When multiple defibrillator discharges are confirmed by interrogation, admission to a telemetry monitored setting for extended observation is appropriate.

MECHANICAL CIRCULATORY SUPPORT DEVICES

PRINCIPLES

Mechanical circulatory support (MCS) devices are broadly classified as those providing temporary support (often percutaneously), and those providing more long-term support (surgically implanted). These devices may support the right side, left side, or both sides of the heart, each with their own advantages and complications. Although emergency clinicians may not be involved with the placement of the devices, they should be familiar with the available options and considerations.[15]

Temporary MCS is most commonly employed in the setting of cardiogenic shock (Table 66.2). The first commonly used device of this type was the intra-aortic balloon pump (IABP). It is placed percutaneously into the descending aorta and inflates in diastole to augment diastolic

TABLE 66.2 Temporary Mechanical Circulatory Support Devices

	IABP	Tandem Heart	Impella	VA ECMO
Flow (liters per minute)	≈0.5	up to 4	2.5–4.0[a]	≈2–6
Support type	Diastolic BP	LV[b]	LV[c]	Biventricular
Oxygenation	No	No[d]	No	Yes
Common Complications [a]	Thrombocytopenia	Hemolysis, bleeding, specialist insertion	Hemolysis, bleeding, displacement, specialist insertion	Hemolysis, bleeding
Advantages	Fast, available at most centers	Percutaneous LV bypass	Percutaneous LV support	Biventricular support

[a]Depends on device. There is also a surgically implanted version, which can provide up to 5 liters per minute of flow.
[b]This is the standard configuration (left atrium to aorta). There is also an RV catheter available to provide RV support.
[c]There is also a right ventricular version which can provide RV support.
[d]The TandemHeart Pump can be configured with an oxygenator to provide biventricular support and oxygenation.
IABP, Intra-aortic balloon pump; *VA ECMO*, venoarterial extra-corporeal membrane oxygenation; *LV*, left ventricle.

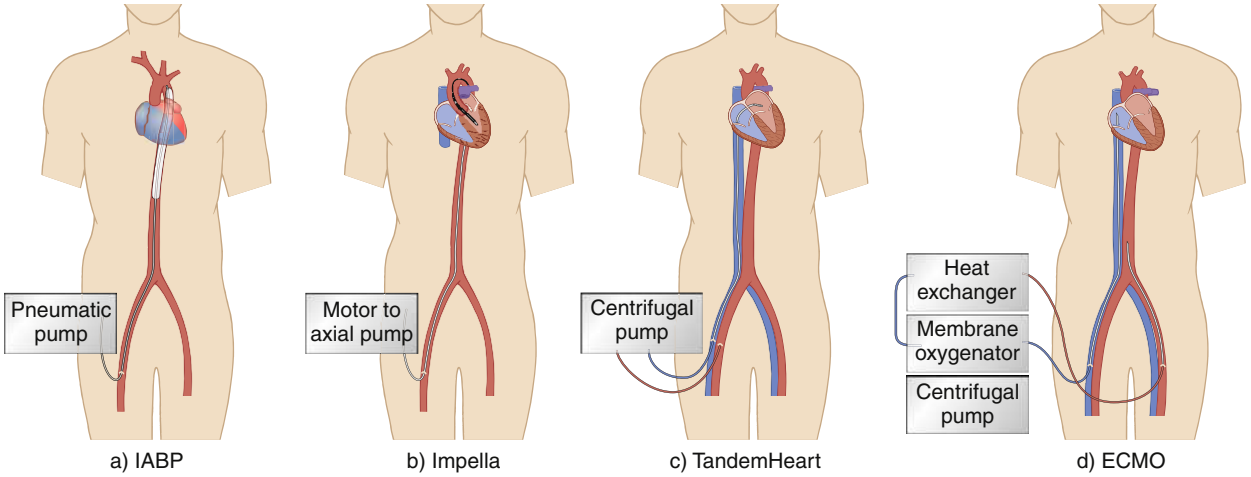

Fig. 66.8 Common configurations for temporary ventricular support. Schematic diagram to demonstrate the access sites and mechanisms of action of (A) IABP, (B) Impella, (C) TandemHeart and (D) ECMO (*ECMO*, Extracorporeal membrane oxygenation; *IABP*, intra-aortic balloon pump). (Adapted from: Thiele H, Ohman EM, Desch S, et al. Management of cardiogenic shock. *Eur Heart J.* 2015;36(20):1223-1230, Fig 2.)

filling pressure. By deflating during systole, it may also decrease left ventricular afterload and augment cardiac output by approximately 0.5 to 1 liter per minute.[16]

More recently, other percutaneous devices have become more common. Although these devices are generally not placed in the ED, early specialist consideration may benefit ED patients presenting in refractory cardiogenic shock. The Impella devices are intravascular impeller pumps, placed either percutaneously or via a surgical technique. They can provide left- or right-sided support of 2.5 to 5.5 liters per minute, depending on the device. Extracorporeal pumps have also been configured to provide left- and right-sided support with a variety of configurations (TandemHeart, Rotaflow, CentriMag).

By attaching an oxygenator, it is possible to bypass the lungs and provide hemodynamic support by veno-arterial extracorporeal membranous oxygenation (VA ECMO), similar to cardiopulmonary bypass, but with more portability (Fig. 66.8). This may also be configured to provide oxygenation and ventilation in a venous-venous configuration (VV ECMO).

Recent data have suggested a benefit for temporary MCS, specifically VA ECMO, as a bridging therapy for definitive care or recovery after a cardiac arrest.[17-21] While this does represent a tremendous opportunity for improving outcomes in those with a definitive trajectory, caution must be taken to avoid nonbeneficial use in those without a suitable plan or decision pathway. In particular, patients with advanced age, multiple comorbidities, poor baseline function, or end-stage organ failure without possibility of transplant are unlikely to benefit from these invasive and resource-intensive interventions.

More long-term support is available in the form of intracorporeal (also called "implanted" or "durable") ventricular assist devices (VADs), most commonly supporting the left ventricle (LVAD). These devices may act as a bridge to recovery or a heart transplant, or as a destination therapy to improve quality and potentially duration of life. More than 2500 implantations of intracorporeal LVADs occur each year in the United States.[22] The most common devices in use are the HeartWare HVAD (Medtronic), the Heartmate II (Abbott), and the Heartmate III (Abbott) (Fig. 66.9).[23] Earlier devices providing pulsatile flow were limited by complications, especially hemolysis and thrombosis, and these newer, continuous-flow devices have become standard.[24]

CLINICAL FEATURES

Temporary MCS devices, including VA ECMO, provide augmented flow by partially bypassing one or both ventricles. They may be implanted percutaneously or surgically through the aorta or IVC, in a variety of configurations, depending on the device (see Fig. 66.8). Patients receive anticoagulation to prevent device thrombosis and embolic complications. Thrombotic complications and therapeutic anticoagulation strategies vary by device. Smaller devices like Impella, and exclusively right-sided devices like VV ECMO carry less risk for arterial embolization and require less anticoagulation. Devices that return blood to the arterial circulation have higher risk for devastating thromboembolic complications such as CVA, and receive higher levels of anticoagulation, with consequent increased bleeding risk.

Intracorporeal VADs support cardiac output via a mechanical pump that draws blood from an inflow cannula in the left ventricle and pumps it into the ascending aorta via an outflow cannula. The pump is connected to a percutaneous driveline connected to a controller and a power source. The controller and batteries are worn by the patient on a belt and shoulder harness, allowing them to be carried (Fig. 66.10). The controller displays battery life and alarms, and may provide additional information such as power level and estimated flow. Patients may be familiar with their baseline parameters, and may be able to report which changes have occurred. Listening to the epicardium should reveal a continuous "hum" if the pump is operating.

Modern VADs produce a relatively nonpulsatile flow, making traditional hemodynamic interpretation challenging. Adequate perfusion can be assessed by evaluating clinical signs, including mental status, urine output, and skin turgor, but these have obvious limitations. Automated oscillometric blood pressure cuffs may not work to measure blood pressure with LVADs because of the low pulse pressure. Blood pressure can be measured using a manual cuff and a stethoscope or Doppler probe. The cuff pressure is reduced until a continuous sound is heard, which represents the systolic pressure. This is essentially equal to the mean arterial pressure because of the low pulse pressure. Blood pressure can also be measured invasively using an arterial catheter.

Patients with intracorporeal VADs receive lifelong anticoagulation and antiplatelet therapy to prevent device thrombosis. Most patients also have a permanent pacemaker or automatic ICD placed. They

Device	HeartWare HVAD*	Heartmate II**	Heartmate III**
			
Pump type	Centrifugal	Axial	Centrifugal
Pulsatility	Continuous	Continuous	"Artificial" pulse
Flow (LPM)	Up to 10	Up to 10	Up to 10
Speed (RPM)	1800-4000	6000-15,000	4800-6500
Battery life (h)	4-6	14	17

commonly present with issues related to anticoagulation or their pacemaker/ICD, as well as issues related to the VAD itself (e.g., alarms, decreased flow).

DIFFERENTIAL DIAGNOSIS

Complications from both temporary and intracorporeal MCS may be related to the device itself, underlying physiology, or concomitant therapies such as anticoagulation. Thrombotic complications may include pump thrombosis (and subsequent hemolysis), ischemic CVA, or other thromboembolic phenomena such as limb or intestinal ischemia. Because the risk for thrombotic complications is so high, anticoagulation is nearly ubiquitous among these patients (who are usually treated with antiplatelet therapy as well). Consequently, bleeding is one of the most commonly encountered problems. This may range from life-threatening intracranial or gastrointestinal bleeding to epistaxis or musculoskeletal hematomas. Infectious complications are also common and can be devastating for patients with intracorporeal VADs.[25] In addition to typical infections (pneumonia, urinary tract infections, etc.) or endocarditis, they are at risk for cutaneous infections due to the transcutaneous nature of the driveline.

Mechanical complications limiting flow are a significant concern as well, because these devices support perfusion to all of the organs. These can broadly be classified as problems with preload (hypovolemia, hemorrhage, RV failure, dysrhythmia), problems with the pump itself (thrombosis, power source), or problems with afterload (sepsis). Device alarms may vary slightly between VAD models, but may help guide the provider toward appropriate therapy (Table 66.3).

DIAGNOSTIC TESTING

There is no single diagnostic strategy for patients with mechanical circulatory support, either temporary or intracorporeal. Testing should be directed at identifying and managing treatable complications. Generally, ECG and cardiac monitoring may help evaluate for dysrhythmias, which may impair flow. ECG recordings may demonstrate significant artifact from mechanical interference caused by intracorporeal VADs, but generally the rhythm is still discernable. Right ventricular failure or septal deviation (due to inappropriate pressure distribution between the ventricles) can be evaluated with point-of-care echocardiography. Coagulation studies (PT/INR, PTT, anti-Xa, etc.) should be sent to evaluate and manage thrombotic or bleeding complications. Haptoglobin or LDH levels evaluate for hemolysis, as can occur with a pump thrombosis. Additional testing (imaging, laboratory, etc.) should be directed by history and physical examination.

Problems with flow related to an intracorporeal VAD can also be generally classified into those related to preload, afterload, and pump function. The device controller may provide some guidance by paying attention to which alarms are present (see Table 66.3).

Inadequate preload will lead to decreased vascular volume and may cause "low flow" or "suction" alarms. Preload can be assessed with invasive pressure monitoring (central venous or pulmonary capillary wedge pressure), or noninvasively with point-of-care echocardiography, similar to patients without VADs. The most common causes for low preload are hypovolemia, hemorrhage, and vasodilation (e.g., sepsis), and should be treated accordingly. Additional causes for inadequate VAD preload include obstructive shock (e.g., pulmonary embolism, tamponade, tension pneumothorax), dysrhythmia, or other causes of contralateral heart dysfunction, particularly if a patient has a typical one-sided device (i.e., LVAD).

Low afterload (arterial hypotension) may result in increased VAD flow initially, as it becomes easier for the mechanical pump to eject blood into the aorta; however, it may lead to decreased LV volume and "suction" problems as the walls of the ventricle collapse on the VAD intake ports. This can lead to decreased flow, suction alarms, and ventricular dysrhythmias. The most common cause for excessive vasodilation in these patients is sepsis, and the percutaneous driveline places them at increased risk for significant infections. Vasopressors such as norepinephrine should be titrated to increase mean arterial pressure to a perfusing level (usually ≥ 65 mm Hg), as with other forms of sepsis. Antibiotics should be considered in line with local practice patterns, with broad coverage for potential sources, including skin flora and health care–associated organisms.

Failure of the mechanical device itself is exceedingly rare. However, if there is no power to the device, it will not function. If no alarms are heard, and there is no mechanical "hum" from the pump, it is likely that the power source has been interrupted and must be replaced immediately. Patients and EMS providers are advised to bring backup batteries and charging materials when they come to the hospital. It is important to ensure this as soon as the patient arrives, or request them from the heart failure specialists or VAD coordinator, because there is no available alternative.

TABLE 66.3 Common Intracorporeal VAD Alarms

Alarm Type	Problem	Cause	Action[a]
No display[b]	Power source	No power	Check connections
Low flow	High BP	High afterload	Antihypertensive
	Low BP	Hypovolemia, hemorrhage, RV failure, rhythm	IV fluids/Blood products, evaluate for sepsis
Suction	Low preload or afterload	Hypovolemia, hemorrhage, RV failure, rhythm, vasodilation	IV fluids, vasopressor, evaluate cause
High power[c]	Pump resistance	Thrombosis or high BP	Evaluate for hemolysis, anticoagulation
Low battery	Low battery	Low battery reserve	Replace battery or plug in to power source

[a]Call referral center and/or VAD coordinator.
[b]A loud alarm will sound for about 1 hour.
[c]May display "High Watts."
BP, Blood pressure; *RV*, right ventricle; *IV*, intravenous.

MANAGEMENT

Inadequate perfusion in the setting of a mechanical circulatory support device is most likely to benefit from efforts to increase flow through the device. These patients have severely abnormal heart function, so efforts toward restoring adequate native cardiac function are likely futile and efforts instead should be focused on optimizing device function.

Management of temporary MCS devices is generally performed in cooperation with expert consultation (e.g., critical care, cardiology, or cardiothoracic surgery). Issues focus on optimizing flow by adjusting vascular resistance (vasopressors), adjusting pump speed, or manipulating preload (IV fluids, blood products). In addition, anticoagulation must be optimized to mitigate thrombotic and bleeding complications.

An expert at a referral center should be contacted immediately for any patient presenting to an emergency department with an intracorporeal VAD, but initial management decisions may need to be directed by the emergency clinicians.[26]

Bleeding complications are common because of the need for anticoagulation, the development of arterio-venous malformations due to nonpulsatile flow, and acquired coagulopathies related to the device.[27] Hemorrhage should be managed by transfusion of blood products, which should be coordinated with the heart failure specialist or VAD coordinator, as they may have significant downstream effects such as antibody formation affecting transplant eligibility. Because the complications of device thrombosis are so severe, generally reversal of anticoagulation is reserved as a last-line measure, even for life-threatening bleeding.

Thrombotic complications may be managed initially with systemic anticoagulation if the patient is subtherapeutic on their home regimen. Ischemic thromboemboli (CVA, intestinal ischemia, etc.) are likely to benefit from expert consultation. Complete device thrombosis is often fatal. In addition to anticoagulation, thrombolysis may be considered, but is unlikely to succeed if there is no flow through the device and may lead to additional bleeding complications. Surgical replacement is the predominately viable option for device thrombosis, but often takes a significant amount of time to arrange.

Problems related to flow with a mechanical circulatory support device should be approached systematically (Fig. 66.11). If preload is inadequate, resuscitation with crystalloid, colloid, or blood products is appropriate. If hypotension persists after adequate volume resuscitation, systemic vascular resistance should be increased with vasopressor medications such as norepinephrine, which may be considered concurrently with volume resuscitation. Unstable dysrhythmias should be cardioverted or defibrillated immediately. Obstructive causes of shock should be relieved (tamponade, tension pneumothorax, pulmonary embolism, etc.). It is appropriate

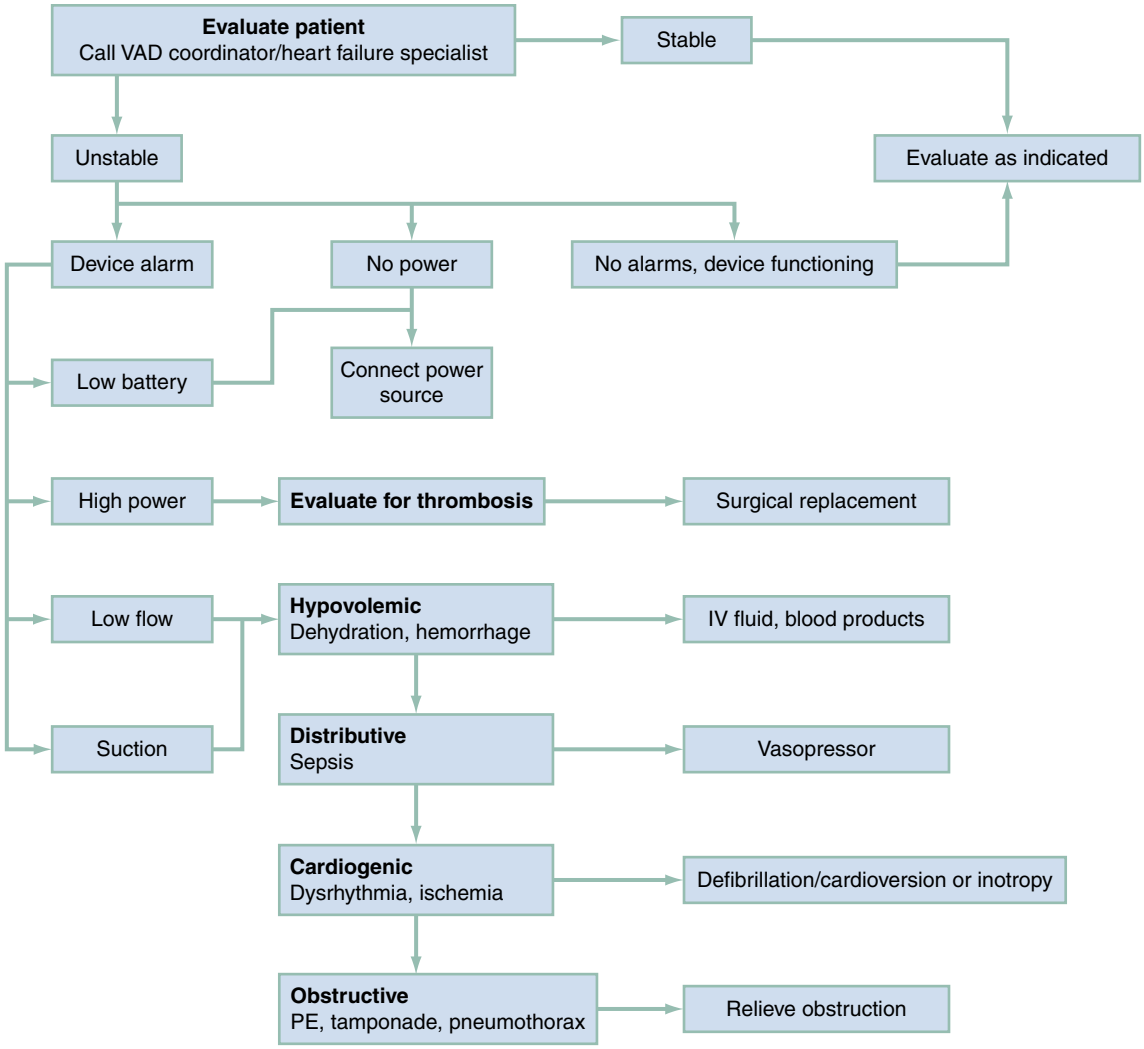

Fig. 66.11 Intracorporeal VAD emergency management.

to perform chest compressions if the VAD is not functioning and the patient is not perfused, while attempts are made to address the underlying physiology.

DISPOSITION

Patients with temporary MCS are admitted to an intensive care unit (ICU), usually with cardiology consultation. Although many complications related to intracorporeal VADs necessitate admission, a significant number of problems presenting to the emergency department may be managed in the outpatient setting, such as minor bleeding, dehydration, or medication adjustments.[28] These cases should be discussed with the advanced heart failure specialists following the patient, and close follow up should be arranged.

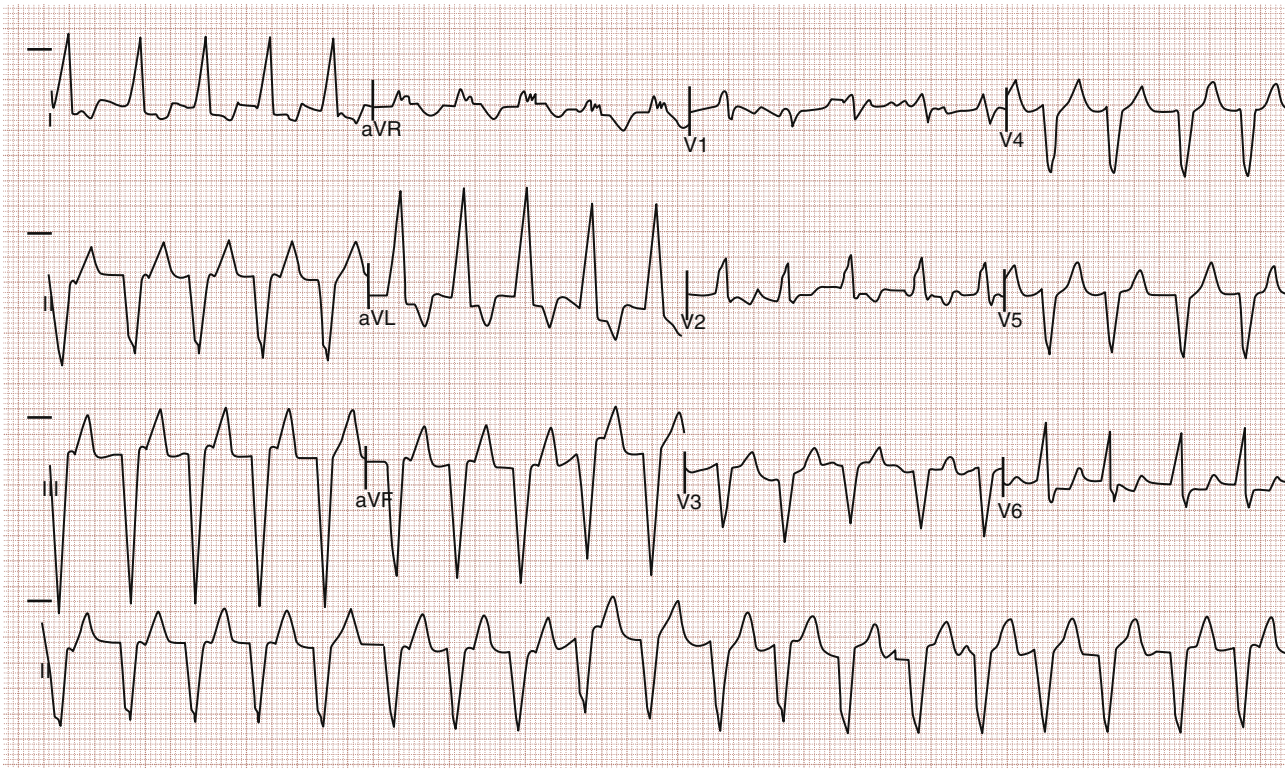
CHAPTER 66: QUESTIONS AND ANSWERS

1. Which of the following conditions is an indication for placement of a biventricular pacemaker?

a. Third-degree AV block
b. Brugada syndrome
c. Severely depressed systolic heart failure and a left bundle branch block
d. Slow atrial fibrillation

Answer: C. Cardiac resynchronization therapy, or biventricular pacing, is indicated for patients with systolic heart failure with an ejection fraction less than 35% and a left bundle branch block. By ensuring appropriate synchrony between the ventricles, cardiac output is improved, and multiple studies have shown a mortality benefit in these patients. Options A and C have an indication for a permanent pacemaker but would not benefit from biventricular pacing. Option B has an indication for implantable cardioverter-defibrillator.

2. A 67-year-old female presents with complaints of shortness of breath and a fluttering sensation in her chest. She had a dual-chamber pacemaker placed 10 years ago for sinus node dysfunction. Blood pressure is 124/96 mm Hg. On examination, she is anxious with clear lungs and no evidence of jugular venous distention or peripheral edema. There is no tenderness over her pacemaker insertion site. An ECG is provided as follows.



Which of the following is the next best step in the management of this patient?

a. Administration of IV amiodarone
b. Drawing blood cultures and starting antibiotics
c. Immediate cardioversion
d. Placement of a magnet over the pacemaker

Answer: D. This patient has a pacemaker with an inappropriately fast rate due to a pacemaker-mediated tachycardia. Management of this condition involves disruption of the circuit and can be accomplished by placing a magnet over the pacemaker, which sets the pacemaker into an asynchronous mode with no sensing (e.g., DOO). Cardioversion and amiodarone are less appropriate in this situation. Consultation with a cardiologist and interrogation of the pacemaker should be performed, although this can be done after placement of a magnet over the pacemaker. In the absence of potential for pacemaker infection, there is no role for blood cultures or antibiotics

3. A 67-year-old male with a history of an ischemic cardiomyopathy and an implantable cardiac defibrillator (ICD) presents with complaints of multiple shocks from his ICD in the past day. Interrogation of his ICD shows no evidence of any shocks in the past 2 months. What is the most appropriate management plan?

a. Administration of intravenous amiodarone
b. Cardiology consultation for reprogramming of ICD
c. Reassurance and follow-up with his cardiologist
d. Temporary ICD deactivation with magnet application

Answer: C. This patient has experienced 2 "phantom shocks." The perception of a shock in the absence of the actual ICD firing occurs in approximately 10% of patients with an ICD and is associated with significant anxiety and stress. Appropriate management includes reassurance and discharge with a patient's cardiologist. There is no role for IV amiodarone, reprogramming of the ICD or magnet application.

4. A 55-year-old man presents with chest pain and hypotension. ECG reveals ST-elevation MI in the inferior and lateral leads, and bedside echocardiogram shows poor systolic function of both ventricles. He has elevated jugular venous pressure, and a plethoric IVC on ultrasound. In addition to percutaneous coronary interventions, which of the following therapies would be most appropriate to consider?

a. Intra-aortic balloon pump
b. Temporary LVAD (e.g., Impella or Tandem Heart)
c. Veno-venous ECMO
d. Veno-arterial ECMO

Answer: D. This patient shows evidence of right heart failure, with poor RV systolic function and elevated jugular venous and IVC pressures. Intra-aortic balloon pumps and temporary left ventricular assist devices will support primarily the left ventricle. Veno-venous ECMO provides effective oxygenation and ventilation, but very little hemodynamic support. Veno-arterial ECMO may be considered as temporary biventricular support, if there is expected recovery of ventricular function, or if the patient is a candidate for another therapy (e.g., heart transplant or intracorporeal VAD).

5. A 65-year-old man with an intracorporeal left ventricular assist device (LVAD) presents to the emergency department and tells you he has felt lethargic for the past two days. A manual blood pressure cuff and Doppler ultrasound show a systolic blood pressure of 75 mm Hg, and a continuous "hum" is heard on auscultation. The cardiac monitor shows a wide complex tachycardia, and no pulse is palpable. Which is the most appropriate next step in management?

a. Administer amiodarone
b. Begin chest compressions

CHAPTER 66: QUESTIONS AND ANSWERS—cont'd

c. Call heart failure specialist and continue diagnostic evaluation
d. Immediate cardioversion/defibrillation

Answer: C. A low systolic pressure is expected with a continuous-flow LVAD, as there is generally a very low pulse pressure. The fact that the patient is awake suggests that he is adequately perfusing. His wide complex tachycardia may be a result of a ventricular dysrhythmia, or may be SVT or sinus tachycardia with aberrancy, and should be further investigated in a stable patient before starting interventions. He does not require chest compressions or immediate defibrillation/cardioversion with evidence of adequate perfusion, despite the lack of palpable pulse. While amiodarone may be an appropriate therapy, more information regarding his rhythm and current medications is required before giving this therapy.

67

Heart Failure

Nicholas Harrison and Phillip D. Levy

KEY CONCEPTS

- Heart failure (HF) is the clinical syndrome defined by signs and symptoms of elevated intracardiac pressures or depressed cardiac output, which in turn are due to either functional or structural cardiovascular (CV) abnormalities. By definition, HF presentations managed in the emergency department (ED) are acute heart failure (AHF) (ie, HF in which the signs and symptoms require unscheduled care).
- AHF is a multiorgan, multifactorial, and multiple phenotype disease state. Abnormalities in renal function, central venous volume and fluid shifts, arterial vascular tone, neuroendocrine overactivity, microvascular dysfunction, respiratory failure, or myocardial ischemia have bidirectional relationships with AHF as both potential causes and effects.
- Central congestion without hypervolemia is typically due to intercompartmental fluid shifts to the central circulation from venous reservoirs with reduced capacitance (increasing preload) or abrupt increases in central arterial tone (ie, increasing afterload).
- Emergency physician (EP) clinical gestalt based on history and physical exam is inaccurate for AHF diagnosis as often as a quarter of the time.
- The most useful diagnostic test for identifying lung congestion due to AHF is an 8-point lung ultrasound B-line scan, which is more sensitive than chest x-ray for pulmonary edema, and has a higher positive predictive value for AHF than natriuretic peptides.
- Focused cardiac ultrasound (FOCUS) for detecting reduced ejection fraction (EF) misses the 40% to 50% of AHF presentations with preserved EF. It adds little information to risk stratification because EF does not typically change with dynamic worsening of cardiac function or improvement after treatment.
- A useful clinical classification of AHF distinguishes between a vascular phenotype and a cardiac phenotype, though overlap can exist. Distinguishing between systolic and diastolic dysfunction is less helpful in the ED, because EF is preserved in about half of AHF cases, and most AHF patients have both systolic and diastolic dysfunction regardless of their EF.
- The "vascular phenotype" describes an AHF presentation where functional (ie, reversible) CV abnormalities such as increased vascular tone and fluid shifts predominate over structural (ie, irreversible) ones. These patients tend to be hypertensive, less likely to be hypervolemic, respond favorably to intravenous (IV) nitroglycerin, and have a better prognosis despite more abrupt symptom onset.
- The "cardiac phenotype" of AHF involves a predominance of structural (ie, irreversible) CV abnormalities such as more severe chronic myocardial disease, myocardial ischemia, and more complex multiorgan interactions (eg, cardiorenal syndrome). These patients are often hypervolemic and require high-dose IV diuresis. They typically present with a more indolent symptomatic progression, but paradoxically are at higher risk for worse outcomes.
- Noninvasive positive-pressure ventilation is the first-line approach for respiratory distress in AHF and may obviate a need for intubation in most cases.
- The initial dose of furosemide in the ED for AHF is 1 to 2.5 times the patient's total daily oral dose (or 40–80 mg if loop-diuretic naïve) and should be given IV. Although creatinine may rise after IV furosemide, it is rarely indicative of iatrogenic acute kidney injury, and patients with acute cardiorenal syndromes typically benefit from aggressive diuresis.
- Inotropes are only indicated in cases of cardiogenic shock (CS), because they may increase mortality as a pharmacologic class.
- Resuscitation and stabilization of CS should be followed by rapid evaluation from interjectional cardiology or cardiac surgery. While STEMI was traditionally the predominant cause of CS, it may only account for 30% of contemporary cases due to improvements in coronary intervention.
- Numerous high-moderate risk features in AHF define which patients likely require admission or observation, however, low-risk factors (ie, for discharge) are less well defined. When high or moderate risk factors are absent, the patient is adherent to the appropriate guideline-directed medical therapy, and can secure close outpatient follow-up (≤1 week), a shared decision-making discussion regarding discharge from the ED may be appropriate.

FOUNDATIONS

Background and Importance

Heart failure (HF) is a clinical syndrome defined by three components (Fig. 67.1)[1]:

- Structural or functional cardiovascular abnormalities
- Elevated intracardiac pressures or depressed cardiac output (CO) due to these abnormalities
- Clinically recognizable signs or symptoms (eg, dyspnea, edema, fatigue, exertional intolerance, or others) due to the elevated intracardiac pressures or depressed cardiac output

Management of clinical manifestations of HF with scheduled care is classified as chronic HF. Conversely, HF symptoms that require unscheduled care define the presentation of acute HF (AHF). Thus, when HF is managed and treated in the ED, it is, by definition nearly always AHF. Some exceptions exist (eg, a stable chronic HF patient presenting to the ED for a medication refill), however, these are relatively few, and AHF is therefore the primary focus of this chapter.

AHF may further be subdivided as decompensated chronic HF versus "de novo HF."[2,3] The former describes AHF occurring in a patient with known chronic HF history, while in the latter the AHF episode is the patient's first known clinical presentation of HF. De novo AHF accounted for over 50% of presentations in a large AHF registry study of Asia and Europe,[2] but is a less common ED presentation in North America. Epidemiologic registry data from 2005 to 2014 suggest that

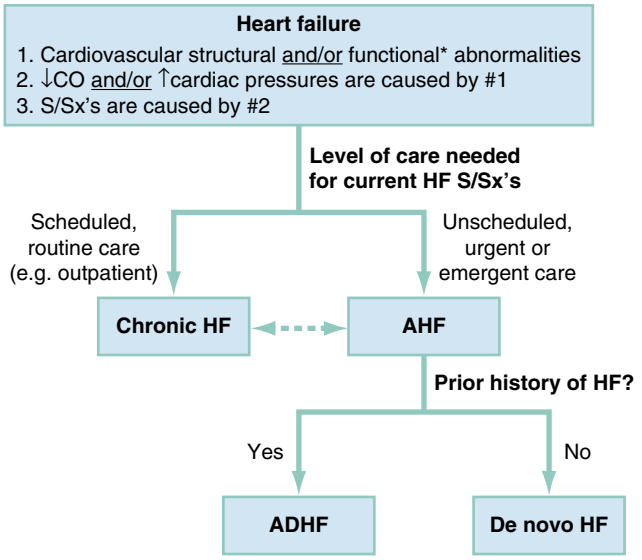


Fig. 67.1 Flowchart algorithm for clinical definition and classification of heart failure (HF). Three criteria define HF in general: cardiovascular structural or functional abnormalities, which cause decreased CO or increased intracardiac pressures, and clinical symptoms resulting from these physiologic derangements. Examples of cardiovascular structural (ie, fixed, anatomic) abnormalities include cardiomyopathies, valvular disease, myocardial scar and fibrosis, etc. Functional (ie, dynamic) abnormalities include arterial vasoconstriction, acute volume shifts and redistribution, transient ischemia without infarction, toxicologic or reversible metabolic myocardial dysfunction, and numerous others. In most cases, both structural and functional abnormalities coexist to cause depressed CO, increased intracardiac pressures, or both. HF is also by definition symptomatic, and does not include subclinical myocardial dysfunction (which nevertheless may progress to clinical HF with time or acute physiologic stressors). The three most common presenting signs/symptoms in the ED setting are (in order) dyspnea, edema/swelling, and fatigue. HF is further subdivided into chronic and acute (AHF), based on whether or not the symptoms lead a patient to seek urgent or emergent management in an acute setting such as the ED. When HF is treated in the ED, it is therefore (by definition) AHF. Many AHF patients will have a chronic HF history (ADHF), but a significant proportion will not (de novo AHF). For emergency medicine this distinction has mostly prognostic significance for disposition. *HF*, heart failure; *ED*, emergency medicine; *CO*, cardiac output; *S/Sx's*, signs and symptoms; *AHF*, acute heart failure; *ADHF*, acutely decompensated heart failure.

around 28% of ED AHF presentations in the United States (US) are de novo[3].

It is important to note that many HF terms commonly used in the past are now considered outdated, inaccurate, or clinically misleading. "Congestive heart failure," for instance, is no longer favored given that volume profiles in HF are heterogeneous and include many patients with normal or even hypovolemic total body water profiles.[4-7] Also, the terms "systolic HF" and "diastolic HF" are no longer used to describe patient phenotypes. The following, more accurate terms are preferred: "HF with reduced ejection fraction" when the ejection fraction (EF) is less than 40%; "HF with midrange EF" when the EF is 40% to 50%, and "HF with preserved EF" when EF is greater than 50% (HFrEF, HFmrEF, and HFpEF, respectively). The terms "systolic dysfunction" (ie, decreased inotropy) and "diastolic dysfunction" (ie, impaired relaxation) still apply as physiologic concepts but are often overlapping and do not describe clinical phenotypes that warrant particular approaches to management.[8] Combining terms to summarize a patient's presentation, such as "acutely decompensated chronic HF with reduced EF," is useful.

Epidemiology

Chronic HF is highly prevalent (≈2.5% of the US population) and is strongly associated with common cardiovascular risk factors.[9] Onset increases sharply with advancing age, such that, by age 65, the annual incidence of new chronic HF diagnosis approaches 2.1%.[3] Other risk factors observed in population-based samples include obesity, hypertension, diabetes mellitus (DM), tobacco smoking, hyperlipidemia, low socioeconomic status, and ischemic heart disease.[9]

Nearly 1 million admissions for AHF occur each year in the United States, and more than 80% of these originate from the ED with a nearly 50/50 split between HFpEF and HFrEF. Outcomes are poor with 30-day and 1-year mortality of 10% and 30%, respectively, after an AHF episode, and appear to be similar regardless of EF.[3] After hospital discharge, roughly 20% of AHF patients will be readmitted within 30 days.[10]

Myocardial Physiology and the Cardiac Cycle in Heart Failure

The cardiac cycle (Fig. 67.2A) and its relationship to CO is often described by three physiologic parameters: chronotropy, inotropy, and lusitropy. CO is the mathematical product of heart rate (HR; ie, chronotropy) and the stroke volume (SV). SV is itself the product of end diastolic volume (EDV; ie, lusitropy) and EF (ie, inotropy). Thus, mathematically

$$CO = HR \times EDV \times EF$$

and conceptually

$$CO = Chronotropy \times Lusitropy \times Inotropy.$$

Recall that the second criterion of the HF definition requires that CO be reduced or intracardiac cardiac pressures be increased; however, these two defining hemodynamic insults tend to coexist and are distinctly related.

Lusitropy and inotropy (Fig. 67.2C–E) may be chronically depressed due to underlying chronic structural or functional cardiac changes, as in the setting of ischemic heart disease or hypertensive heart disease, or acutely impaired by a new hemodynamic stressor such as hypertensive emergency, infection, volume redistribution or overload. As shown in Figure 67.3, AHF is also an inherently multiorgan process, with bidirectional feedback between cardiac dysfunction, vascular tone, and multiple organ involvement.

SV is classically modeled by the Frank-Starling mechanism, which describes a relationship between stroke volume and EDV (Fig. 67.4A). In the idealized scenario, increasing EDV leads to increasing SV because stretching myocardial sarcomeres further apart in diastole allows them a further distance to contract during systole, increasing inotropy. This model describes the preload-SV relationship well under conditions where EDV is far below the heart's maximum capacity. Eventually, an inflection point is reached where sarcomeric stretch is maximized and increases in inotropy level-off despite further increases in EDV, noted as the flat portion of a Starling curve. If EDV increases even further, sarcomeres are stretched into abnormal configurations that inhibit inotropy and produce systolic dysfunction. Even brief and transient exposure to excessive left ventricular (LV) EDV can trigger a cascade of stretch-related insults to myocardial function, including subendocardial ischemia with cardiomyocyte injury and necrosis with associated cardiac troponin [cTn] release. Further or sustained stretch results in myocardial stunning and sarcomere proteomic remodeling, culminating in clinical deterioration that manifests as AHF.[11,12,13,14]

Repeated exposures to increased LVEDV (and resultant LVEDP) cause fibrosis and myocardial hypertrophy that ultimately lead to a stiff, noncompliant ventricle.[15] The net effect is an impairment of lusitropy (ie, diastolic dysfunction) that serves to limit the degree

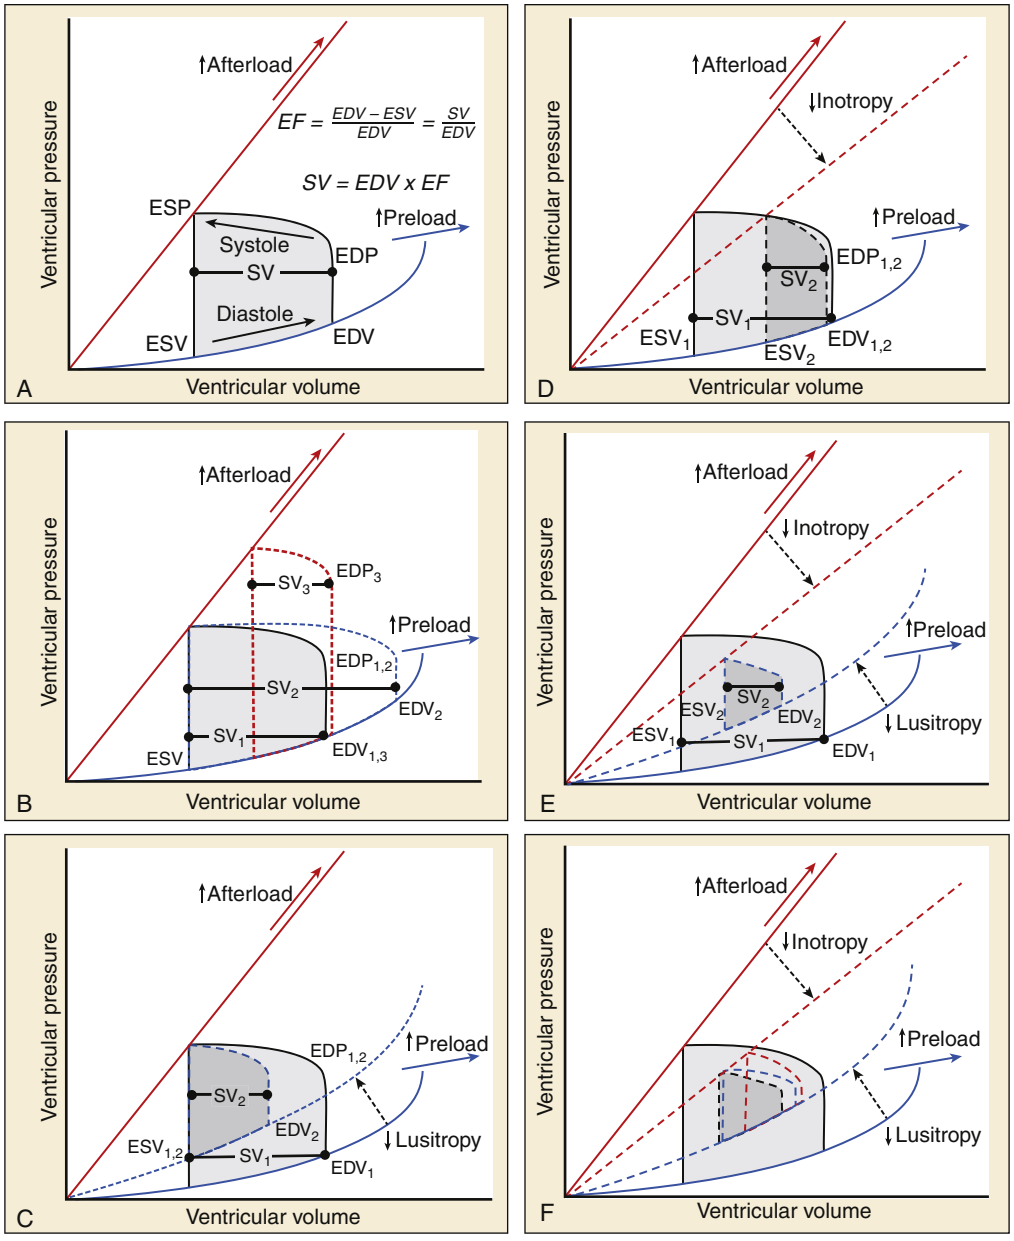

Fig. 67.2 Pressure-volume (PV) loop concept diagrams demonstrating the relationship between underlying cardiac function, SV, and changes in preload or afterload. Each loop is delimited by underlying limits to inotropy (top limit line) and lusitropy (bottom limit line). Stroke volume alterations (by changes in preload and afterload) are limited to these confines. (A) Baseline PV loop of a hypothetical healthy heart. (B) Isolated increases in afterload (*red dotted line*) or preload (*blue line*) under healthy conditions lead to decreased or increased SV, respectively. (C) Isolated impairment of lusitropy (ie, diastolic dysfunction) decreases SV by reducing EDV for a given EDP, ESP, and ESV (*dotted line*). This is representative of many, but not all, cases of HFpEF (since diastolic dysfunction may be isolated or may coexist with systolic dysfunction, even in HFpEF; see panel E). (D) Isolated impairment of inotropy (ie, systolic dysfunction) decreases SV by reducing ESV for a given EDP, ESP, and EDV (*dotted line*). EF is observed to decrease, though the reduction in SV is just as severe as isolated diastolic dysfunction in panel C. This curve is mostly hypothetical because in reality systolic dysfunction is nearly always accompanied by diastolic dysfunction in both HFrEF and HFpEF. (E) Combined inotropic and lusitropic impairment decreases SV by reducing ESV and EDV for a given EDP and ESP. This represents nearly all cases of HFrEF and many cases of HFpEF. (F) Compared to the healthy heart in panel B, preload (*blue dotted line*) has only marginal effects on SV in HF (ie, decreased preload tolerance). For afterload, the direction of effect is the same as the healthy heart: increased afterload reduces SV (*red dotted line*) when all other parameters are held constant. *SV*, stroke volume; *EF*, Ejection fraction; *EDP/ESP/EDV/ESV*, end-diastolic/systolic pressure/volume; *HF*, heart failure; *HFpEF*, HF with preserved EF; *HFrEF*, HF with reduced EF.

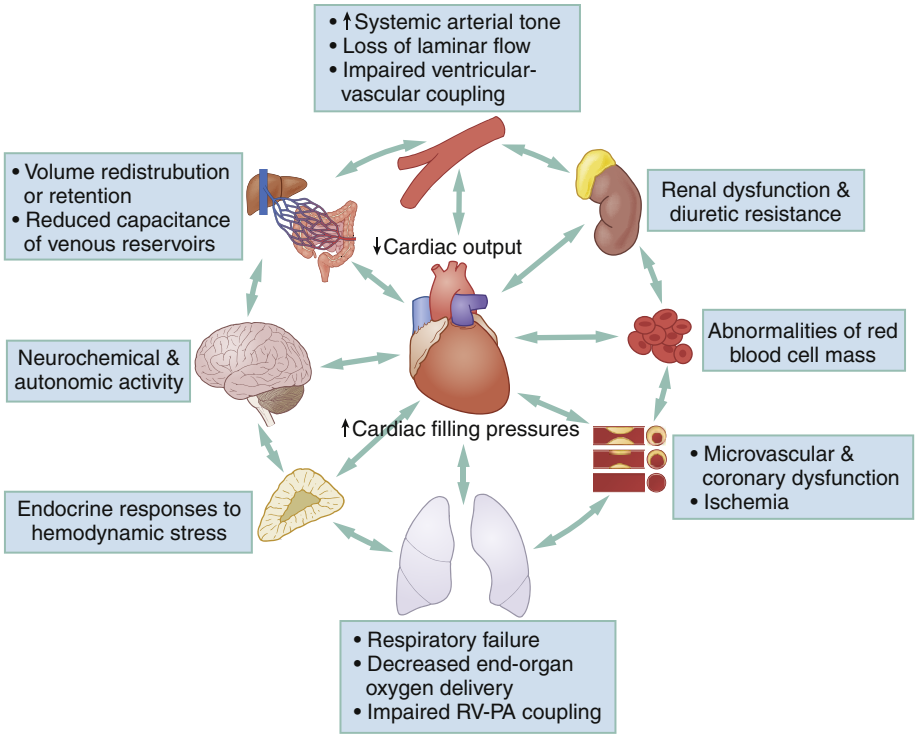

Fig. 67.3 A multiorgan, multidirectional concept chart of AHF. Increased intracardiac pressures or reduced CO (ie, a sine qua non of AHF) can be the result or the cause of other organ system dysfunction. Activation of the sympathetic and RAAS neurohomonal axes, for instance, can be a precipitant of AHF. However, depressed CO also will activate these neurohormonal mechanisms both directly and indirectly. Certain bidirectional relationships have been described as distinct and important syndromes, such as the cardiorenal syndrome. Not every cardiac to end-organ relationship pictured here is a key component of every AHF presentation, underlining the importance of AHF phenotypic heterogeneity and the fact that therapeutic approaches should be tailored to phenotype when possible. Also, many relationships not pictured are likely important in some cases since understanding of AHF physiology is continuously changing. *AHF*, acute heart failure; *CO*, cardiac output; *RAAS*, renin-angiotensin aldosterone system; *RV*, right ventricle; *PA*, pulmonary artery.

of myocardial stretch during future elevations protecting the myocardium from further stretch-induced myocyte death.[15] However, this comes with a tradeoff, because the ensuing diastolic dysfunction prevents accommodation of increased LVEDV, contributing to onset of symptomatic HF. In the early stages, a certain degree of diastolic dysfunction may be subclinical, or only induced upon stress with exercise, acute hypertension, or hypoxia.[16,17] As diastolic dysfunction progresses, demand from activities of daily living may be superimposed on diminishing cardiac reserve associated with other physiologic changes, including decreased myocardial oxygen reserve, abnormalities in nitric oxide signaling, decreased aortic and pulmonary artery compliance, decreased ventricular volume, right ventricular dysfunction, and worsening interventricular and ventricular-circulatory coupling, resulting in depressed tolerance of increased preload and afterload.[8,16-21]

Depressed SV resulting from acute diastolic or systolic dysfunction can be theoretically compensated for by increased chronotropy. However, the time between systolic cycling sets a "hard stop" on the upper limit of cardiac filling time and, at a certain point, further augmentation of CO through increased chronotropy becomes limited by diminished lusitropy (Fig. 67.5). Thus while increasing heart rate has early adaptive benefits, persistent sinus tachycardia in the setting of AHF is generally an ominous sign that CO has been stressed to its limit. This also explains why increased or decreased chronotropy (as in tachy- or brady-arrhythmias) is a relatively common precipitant of AHF.[2]

Abnormal Loading Conditions and Elevated Filling Pressures

Patients with chronic HF (eg, curves IV and V in Fig. 67.4) tend to stay near or beyond the inflection point of the Starling curve (red and yellow zones Fig. 67.4) because of their chronically impaired diastolic and systolic dysfunction. Even subtle increases in loading parameters (rightward shifts on the curves) can lead to fulminant AHF. Additionally, with relatively normal baseline cardiac function (curve III Fig. 67.4, curves I–II Fig. 67.6A), extremes that impede forward flow (eg, hypertensive emergency) can precipitate AHF through a large rightward shift on the curve. Multiple neurohormonal effects result from and contribute to loading conditions and filling pressures.[22,23] Natriuretic peptides (NPs) are especially important in this regard and are upregulated in HF where they result in natriuresis and diuresis, vasodilation, and antifibrotic effects that can reverse remodel the heart.[24-27] Produced directly by the heart, atrial-NP (ANP), B-type NP (BNP), and the N-terminal fragment of BNP's prohormone (NT-proBNP) are clinically useful for diagnosis and prognosis of HF.

Elevated intracardiac pressures are a defining characteristic in AHF (see Fig. 67.1), and even brief episodes can impair the normal cardiac cycle and lead to irreversible systolic or diastolic dysfunction.[12,15] Thus, episodes of AHF negatively impact the long-term prognosis of patients with chronic HF.[28] This is of particular relevance to ED management, with a physiologic justification for a "time-to-treatment" concept in AHF, similar to many other time-sensitive conditions seen in emergency medicine. Given the potential benefit of limiting myocardial

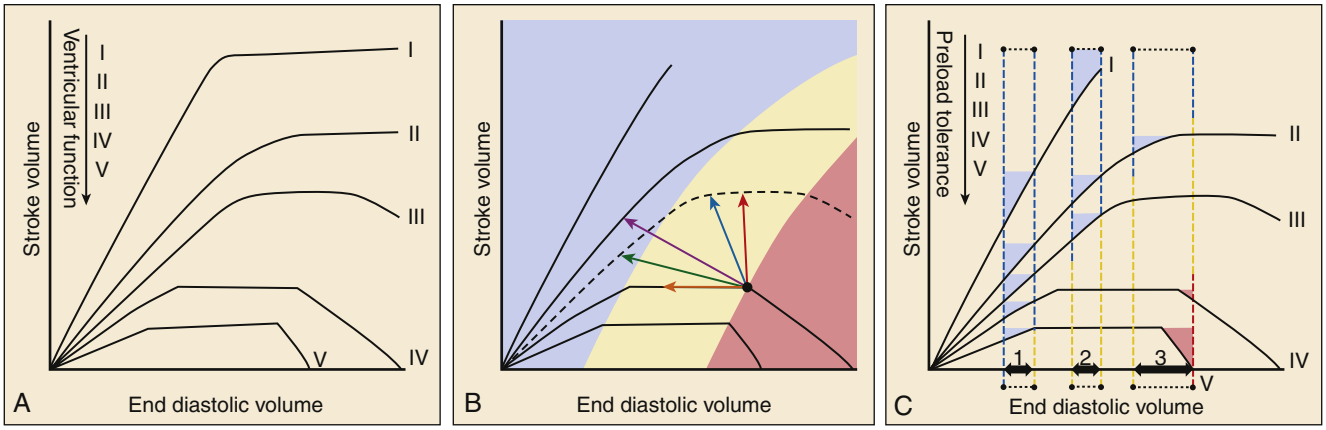

Fig. 67.4 SV versus preload curves describing the Starling mechanism in the context of AHF versus health. (A) Curves I through V represent progressive worsening of baseline cardiac function. Increased preload leads to increased SV early because of more favorable sarcomeric configurations in myocytes. Once all sarcomeres are at a maximal degree of stretch the ability to increase SV by preload is exhausted, and the curve levels off. At severe degrees of stretch, sarcomere configurations become disorganized and stretch-related myocyte injury mechanisms are activated, causing the curve to potentially invert with more preload ("falling off the Starling curve"). The inflection points of leveling off and then of curve inversion occur at less extreme levels of preload as cardiac pump function worsens. (B) For any given preload, patients with cardiac pump dysfunction (IV–V) are more likely to be in the flat or inverted part of the Starling curves (*yellow* and *red zones*, respectively) compared to those with normal or excellent pump function (I–III), and far less likely to be in the preload responsive part of the Starling curve (*blue zone*). Common ED treatment strategies for AHF either push the patient's preload "backwards" to a more favorable zone along the same Starling curve (IV diuretics only, *orange arrow*), move the patient "up" to a curve with improved cardiac performance (inotropes only, *red arrow*), or both (vasodilator only, *blue arrow*; vasodilator plus diuretic, *green arrow*; vasodilator, diuretic, and inotrope, *purple arrow*). (C) Preload tolerance is a conceptualization of whether a patient will benefit, have no change, or sustain harm from a fixed change in preload (intervals/arrows 1, 2, and 3). In AHF, relatively rapid increases in preload occur from intercompartmental fluid shifts, while slower increases occur from progressive volume overload. Interval 1 shows a severely hypovolemic state, in which all 5 patient curves benefit from an increase in preload (eg, a fluid bolus), though SV augmentation is only modest with cardiac dysfunction IV–V. Interval 2 represents a state in which increased central venous volume pushes patients IV–V closer to falling off the Starling curve (while achieving no change in SV), whereas SV is augmented in I–III. In interval 3, further increased central venous volume pushes the patients with myocardial dysfunction "off" the Starling curve, but given the same preload has neutral-to-positive effects for patients I– III. *AHF*, acute heart failure; *SV*, stroke volume.

damage through earlier normalization of intracardiac pressures, organizations such as the Heart Failure Society of America (HFSA), the Society for Academic Emergency Medicine (SAEM), the American Heart Association (AHA), and the American College of Cardiology (ACC) have all recommend that AHF treatment be started as quickly as possible after ED arrival.[28-31] Broadly speaking, the major classes of ED AHF therapies work by targeting the physiology underlying elevated intracardiac pressures either by moving the Starling curve leftward with diuretics or venodilators, moving the curve upward to a higher level of efficiency for a given EDV with inotropes or arterial vasodilators, or both. A simple but useful hemodynamic classification distinguishes between cardiac (ie, primary pump failure predominates) and vascular (ie, acutely increased preload or afterload predominates) phenotypes of AHF.[1] The ED management differs depending on which phenotype predominates.

Congestion and Preload

Congestion in AHF is very specifically the congestion of the central vasculature (ie, the vena cava, great arteries, and proximal organs such as the heart, lungs, and kidneys). Central congestion can occur from true volume overload associated with excessive fluid intake or retention, typical of the cardiac phenotype. Generally, this is an indolent process (Fig. 67.7A). When rapid decompensation occurs in AHF, fluid typically shifts from venous reservoirs to the central circulation in a process largely independent of total body water, more typical of the vascular phenotype. This, in part, explains why classic signs and symptoms of fluid overload may be absent in patients with AHF.[32]

One of the largest and most critical venous reservoirs in the body is the splanchnic circulation, containing 20% to 50% of total blood volume at any given time. The splanchnic vessels dilate or contract in response to central circulation baroreceptors and sympathetic tone, and the renin-angiotensin-aldosterone system (RAAS). Under normal physiologic conditions, regulation of fluid from the splanchnic to central circulation via the hepatic veins acts as a buffer to maintain central volume. In stress situations, volume can be rapidly mobilized from the splanchnic circulation to the central circulation by vasoconstriction. When HF is present, neurohormonal mediators are chronically activated, leading to basal splanchnic vasoconstriction and a reduction in the reservoir's buffering capacity. As a result, rapid fluid shifts can develop in response to any number of AHF precipitants (eg, infection, acute hypertension, ischemia, etc.), leading to central congestion even when total body water is normal (Fig. 67.7B, first curve). Experimentally, denervation of the splanchnic vasculature in AHF patients dramatically lowers intracardiac filling pressures while increasing cardiac output.[33]

In contrast, patients with the cardiac pathophysiology typically have gradual fluid accumulation superimposed on long-standing and intractable hemodynamic derangements. AHF patients with slow

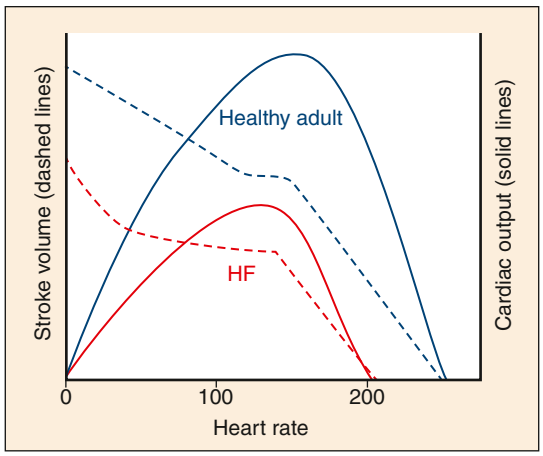

Fig. 67.5 Plot of SV (*dotted line*) or CO (*solid line*) versus HR for healthy and impaired myocardial function (*blue line* vs. *red line*, respectively). Myocardial stimulation in response to physiologic demands (eg, sympathetic drive in response to a physiologic stressor), can compensate by augmenting SV up to a ceiling dictated by the optimization of inotropy and lusitropy. Past this SV ceiling, the only way to augment CO to meet even higher physiologic demand is to increase HR (ie, tachycardia in AHF may signify severe mismatch between myocardial function and metabolic demand). After a certain point of tachycardia, SV will worsen due to insufficient time spent in diastole (ie, de-optimized filling time) and further increases in tachycardia will cause CO to decrease (ie, tachydysrhythmias precipitate hemodynamic instability at extremely high HRs in healthy patients, but at lower HRs in acute or chronic myocardial dysfunction). *SV*, stroke volume; *CO*, cardiac output; *HR*, heart rate; *AHF*, acute heart failure.

onset of symptoms tend to have less pronounced pulmonary edema on arrival and delayed dyspnea relief with worse in-hospital and post-discharge outcomes.[34] Thus, clinicians should not rely entirely on a patient's apparent clinical severity at presentation to determine how much decongestion they may need (Fig. 67.7B).

Afterload

Afterload is the pressure against which the ventricle must contract to eject blood. In practical terms, this means the aortic and pulmonary artery (PA) pressures for the LV and right ventricle (RV), respectively. The coupling of ventricular and vascular function is a dynamic relationship. As afterload rises, SV will gradually decline until extremes in ventricular pressure are reached and a precipitous worsening of ventricular function ensues (Fig. 67.6A). The RV is significantly more pressure-sensitive and volume-tolerant than the LV, though chronic elevated pressure can cause hypertrophic remodeling similar to the LV. The ratio of oxygen consumption to stroke work increases as afterload rises (a phenomenon referred to as ventricular-vascular decoupling), burdening a heart with already diminished oxygen capacity at baseline.[35] Whether intrinsic or exogenous, rises in afterload are often abrupt. Clinical deterioration rapidly follows, resulting in the onset of "flash" pulmonary edema. Though sometimes described as a distinct entity, flash pulmonary edema is the most severe form of afterload-mediated or hypertensive AHF.

Disorganized Contraction

In addition to perturbations in preload and afterload, the heart itself can contribute to AHF through disorganized contraction and relaxation.[20] Each ventricle can be divided into individual myocardial segments (eg, apex to base, anterior/posterior, septal/free wall), which under idealized circumstances all contract and relax simultaneously. In reality, some segments within a single ventricle may contract or relax slightly before others, and even slight asynchrony reduces the mechanical efficiency of contraction. The reasons for segmental asynchrony include relatively fixed myocardial lesions, such as a scar from past MI, and more acute, dynamic causes such as localized demand ischemia, stretch-related myocyte toxicity, coronary microvascular dysfunction, or acute MI. ED treatment of AHF, including noninvasive positive-pressure ventilation (NPPV), diuresis, and vasodilation, can significantly improve segmental contraction synchronization. Failure to improve mechanical synchrony on point-of-care echocardiography (POC echo) after ED AHF treatment is associated with adverse AHF outcomes.[36]

Right Ventricular Dysfunction and Pulmonary Hypertension

Right ventricular dysfunction (RVD) has been increasingly recognized as an important pathologic and prognostic marker in both chronic HF and AHF. RVD identifiable on ultrasound may be present in 28% to 46% of AHF cases and significantly declines in the first 24 hours after initial ED treatment.[36a,37,38] Missed antihypertensive medication within 7 days, ED PPV, COPD history, LVEF, lung ultrasound congestion severity, and right ventricular systolic pressure (RVSP) are significant predictors of RVD. RVD evident on POC echo is rarely recognized despite a high prevalence and potentially greater prognostic implications than LVEF.[36a] RVD in AHF is associated with higher all-cause mortality in AHF even after adjusting for LVEF and other measures of LV function.[39-42] More importantly, the association between RVD and AHF mortality strengthens when pulmonary hypertension is absent. The relationship between acute RV and LV dysfunction is bidirectional and inextricably interdependent (Fig. 67.8). Although the most common cause of right heart failure is left heart failure, RVD can precede, precipitate, or be concurrent with LV dysfunction in AHF. This is evident given that the path through the right heart, pulmonary circulation, left heart, and systemic circulation is a closed circuit and RV CO must equal LV CO. As a consequence, any hemodynamic derangement within the circuit will, on a beat-to-beat basis, adversely impact biventricular functionality. Additionally, the LV and RV share a common wall (the interventricular septum), meaning acute changes on one side do not occur in isolation.

RVD in AHF can result from factors intrinsic and extrinsic to the RV itself (see Fig. 67.8). Some AHF therapies affect the RV as much as or more than the LV, as suggested by the observation that improvement in RV stroke-work (but not LV stroke-work) during an episode of AHF is associated with decreased rates of death, transplantation, ventricular assist device implantation, or HF-related rehospitalization at 6 months.[42] Moreover, RVD independently predicts hyponatremia, worsening renal function after hospitalization, longer hospital length of stay, and higher rates of myocardial fibrosis.[43-47]

Myocardial Infarction Versus Injury

cTn is detectable in 10% to 30% of AHF patients using conventional sensitivity assays and in 80% to 90% of patients with high-sensitivity (hs-cTn) assays.[48-54] cTn is a marker of myocardial damage and can result from both acute and chronic processes.[55] Although acute myocardial infarction (AMI) is often a precipitant or accompanying factor in AHF presentations, an elevated troponin does not by itself indicate AMI. Two criteria must be met to satisfy the universal criterion definition of AMI: the cTn elevation is above the 99th percentile for a given assay, and there is clinical suspicion for ischemia.[56] A cTn value that is elevated but fails to meet one or both criteria for AMI is termed "myocardial injury" and is common in AHF.

Multiple ischemic (ie, infarction) and nonischemic (ie, myocardial injury) mechanisms are clinically relevant to AHF (Table 67.1). A clinical assessment for risk of myocardial injury and ischemia should be undertaken in all AHF patients presenting to the ED. Regardless of the assay or mechanism, an elevated troponin in the setting of AHF

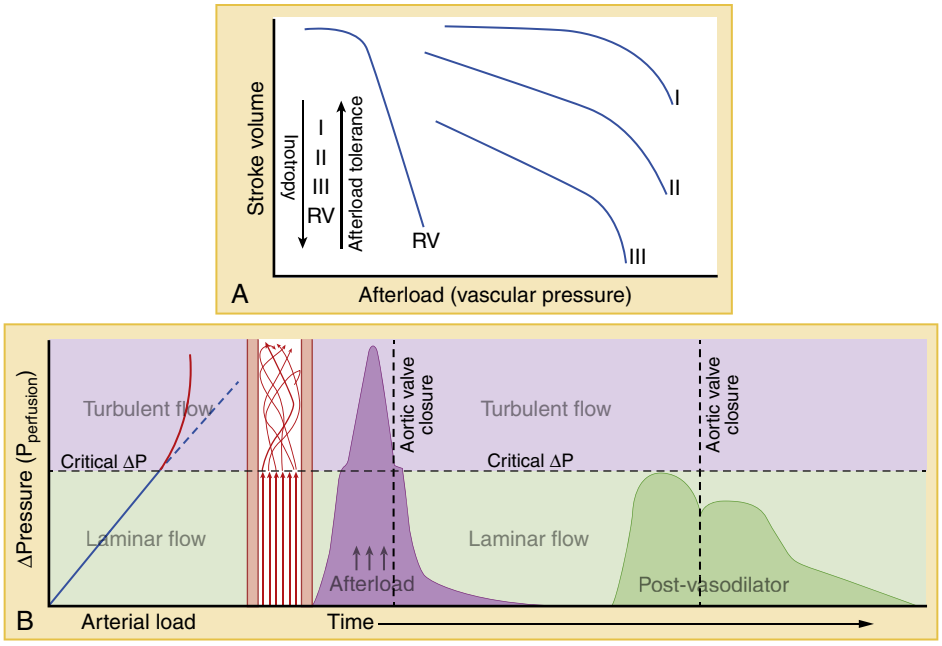

Fig. 67.6 (A) SV versus afterload relationship plotted for 3 levels of decreasing LV function (I–III) and the RV. Increasing afterload for a fixed degree of inotropic and lusitropic function causes a decline in stroke volume. However, resistance to this decline (a flatter slope) is higher with better baseline cardiac pump function. Eventually, regardless of ventricular resilience to afterload, vascular pressure can become high enough to induce a precipitous decline in stroke volume (ie, rapid ventricular-vascular decoupling). The RV is extremely pressure sensitive (but more volume tolerant) compared to the LV. (B) The relationship between the ventricular-vascular pressure difference ("driving pressure" or "delta pressure") and arterial flow rate (*right*) or time (*left*) for a set afterload. In order to overcome high afterload, cardiac driving pressure must increase to maintain arterial flow. This relationship is linear when flow is laminar, but flow becomes turbulent once the pressure difference reaches or exceeds a critical value. Under turbulent flow, further increases in the pressure difference yield decreasing rates of return in arterial flow despite steadily increasing cardiac MVO_2. Flow thus becomes highly inefficient as ventricular-vascular decoupling progresses (eg, in severe hypertension), as in the purple curve of the delta pressure versus time. When blood pressure is lowered (post-vasodilator *green curve*), a larger proportion of flow is laminar and the driving ventricular-vascular pressure difference is spread more evenly over time, leading to more efficient hemodynamics (ie, lower MVO_2 required to produce similar degree of flow). In AHF the "supply" of myocardial oxygen is lowered while the "demand" is increased, so decreasing MVO_2 for a given SV is physiologically beneficial. In the initial resuscitation of the hypertensive/vascular AHF phenotype this typically means IV bolus vasodilators such as nitroglycerin. *SV*, stroke volume; *LV*, left ventricle; *RV*, right ventricle; *MVO_2*, myocardial oxygen consumption rate.

portends a worse prognosis.[57] Even in the absence of critical coronary artery disease (CAD), coronary flow reserve may be decreased due to microvascular dysfunction and exacerbated when the ventricles are subjected to stress, resulting in myocardial ischemia.[14]

Cardiorenal Syndrome

The interaction between cardiac and renal dysfunction plays a critical role in both AHF and chronic HF. Worsening of renal function due to AHF, termed *acute cardiorenal syndrome* (acute CRS, also known as CRS type 1) occurs in approximately 40% of cases and is associated with increased risk for rehospitalization and postdischarge mortality.[58] While underlying chronic kidney disease (CKD) in patients with chronic HF (chronic CRS, also known as CRS type 2) is also a poor prognostic factor, superimposed acute CRS develops in 19% of AHF patients and is associated with a threefold greater risk of mortality.[59]

The kidneys receive approximately 25% of CO despite being relatively distal in the central arterial circulation, almost wholly by virtue of being a very low-resistance circuit.[58] Even a slight elevation in central venous pressure, therefore, causes renal venous hypertension (ie, "renal afterload") that leads to central congestion and acute kidney injury (AKI). Increases in intraabdominal pressure, typically secondary to decreased splanchnic capacitance, cause a similar effect. RVD may also play a role, and is independently associated with renal dysfunction and mortality.[60] AHF therapies that offload central venous congestion and right-sided cardiac pressures may improve renal perfusion and prevent or ameliorate CRS (Fig. 67.9). Requirement of a higher dose of diuretic per amount of urine output (ie, diuretic resistance) is a key clinical sign of CRS. When patients present to the ED in AHF despite a recent increase in their outpatient loop diuretic dose, acute CRS should be highly suspected. When acute CRS is suspected, a higher dose of IV diuretic or combination with a non-loop diuretic should be considered (Fig. 67.9B).

Though clinicians may be wary of giving high doses of IV diuretics when acute CRS is present, increased diuretic dosing in acute CRS is associated with greater fluid loss, better improvement in symptoms, and no significant increase in renal complications.[61,62] Moreover, when creatinine does rise after IV diuresis in AHF, it is not associated with true renal tubular damage and is not associated with short- or long-term adverse outcomes.[63,64] Likewise, vasodilators historically were thought to contribute to CRS by decreasing renal perfusion. However, in the absence of overt shock, renal autoregulation maintains a relatively constant renal blood flow across a wide range of mean arterial pressures (MAPs), making CRS unlikely to result from vasodilators. Moreover, preglomerular vasoconstriction does contribute to CRS

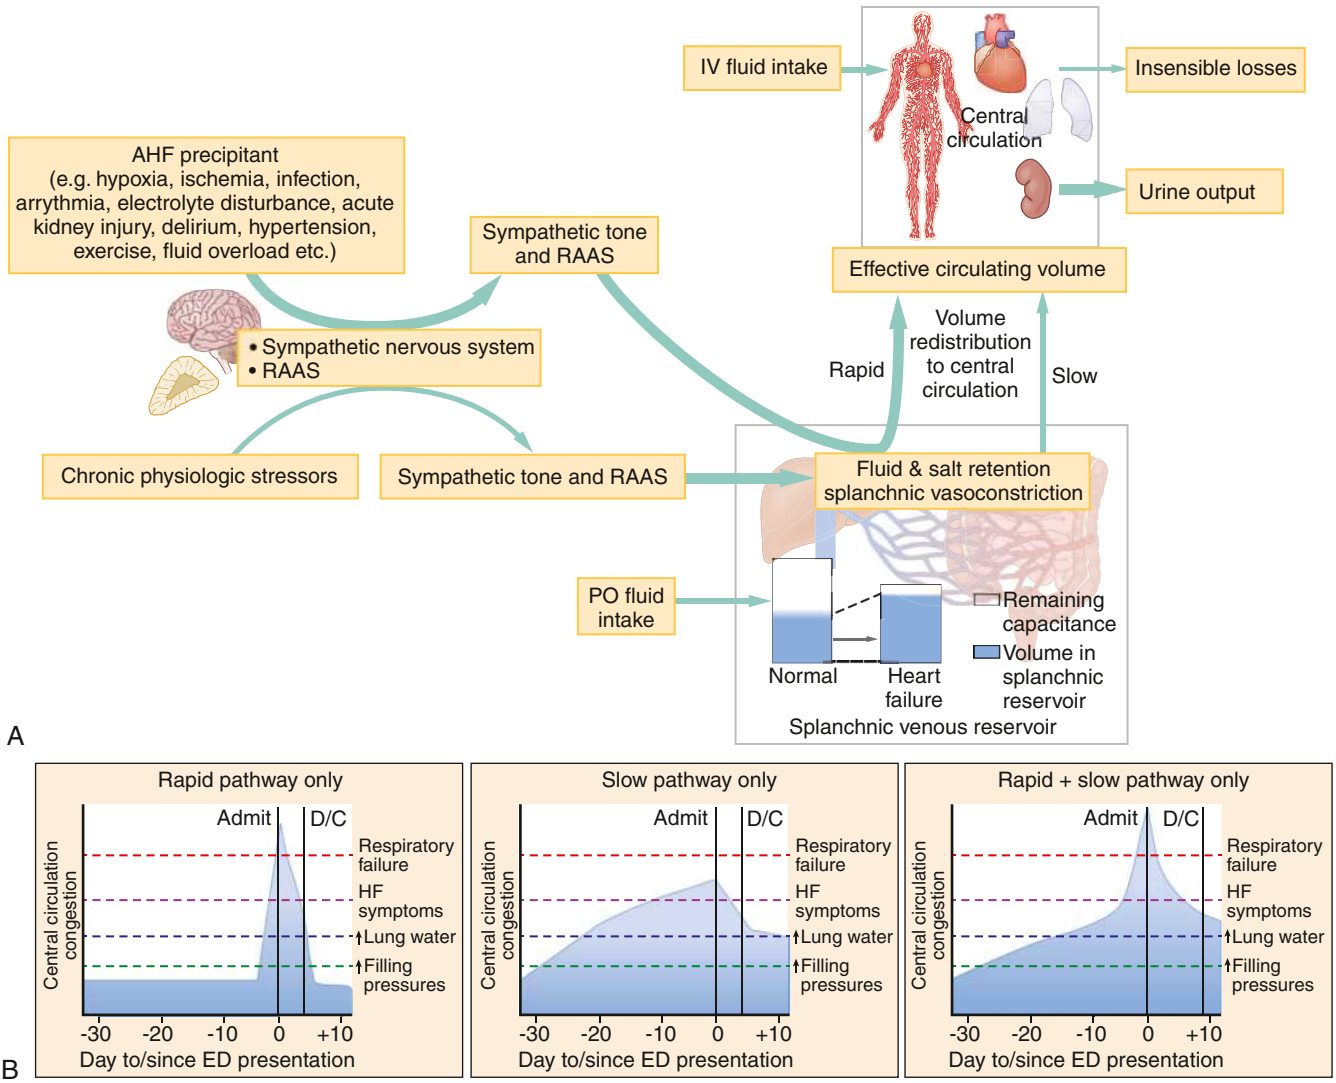

Fig. 67.7 (A) Concept flowchart of central circulation congestion in AHF. The splanchnic circulation under normal physiology holds up to half of total circulating volume, with a large residual capacity to buffer the central circulations against acute increases or decreases in total vascular volume. Neurohormonal activation (eg, alpha-adrenergic, RAAS, etc.) causes progressive splanchnic vasoconstriction that reduces the capacitance of the reservoir and decreases its residual capacity (ie, even without a change in total body water). This impairs the splanchnic buffering capacity, meaning that any increase in oral fluid intake more readily "spills over" to the central circulation while any decreases in central circulation fluid elimination (eg, renal impairment, insensible losses) are unable to be buffered against. The result is the "slow pathway" described in the figure, where progressive central congestion occurs over weeks to months. Left uncompensated, this can result in a slow but progressive descent into AHF. Additionally, if an acute stressor (eg, severe hypertension) rapidly and massively activates sympathetic drive and RAAS, fluid shifts from the splanchnic to central circulation will occur much more rapidly (the rapid pathway). (B) Plots of central congestion versus time, benchmarked by key clinical or physiologic events, to illustrate the ramifications of the rapid versus slow physiologies for AHF clinical presentations. In the rapid pathway only, the abrupt fluid shift produces dramatic and rapid symptoms over only a few days but may resolve quickly with appropriate AHF treatment. These patients, typical of the AHF "vascular phenotype," may present more dramatically by history but ironically have a better prognosis. In the slow pathway only, symptoms develop more indolently but also after significantly more intractable change because symptoms of HF can occur weeks after increases in cardiac pressures and increases in lung water under such conditions. This is typical of a slow decompensation in the "cardiac" AHF phenotype without any overt superimposed physiologic stressor/AHF precipitant to activate the rapid pathway as well. The presentation is less dramatic but prognosis is significantly worse, possibly because lung water and intracardiac pressures have been asymptomatically elevated for a longer period of time and are more intractable. The third curve describes a scenario in which the rapid pathway is superimposed on the slow pathway (in which cardiac and vascular AHF phenotypes are relatively intermixed) such as when a patient with the cardiac phenotype is afflicted by an acute AHF precipitant (infection, hypoxia from other disease, ischemia, etc) activating rapid fluid shifts superimposed on an already chronically reduced splanchnic buffering capacity.

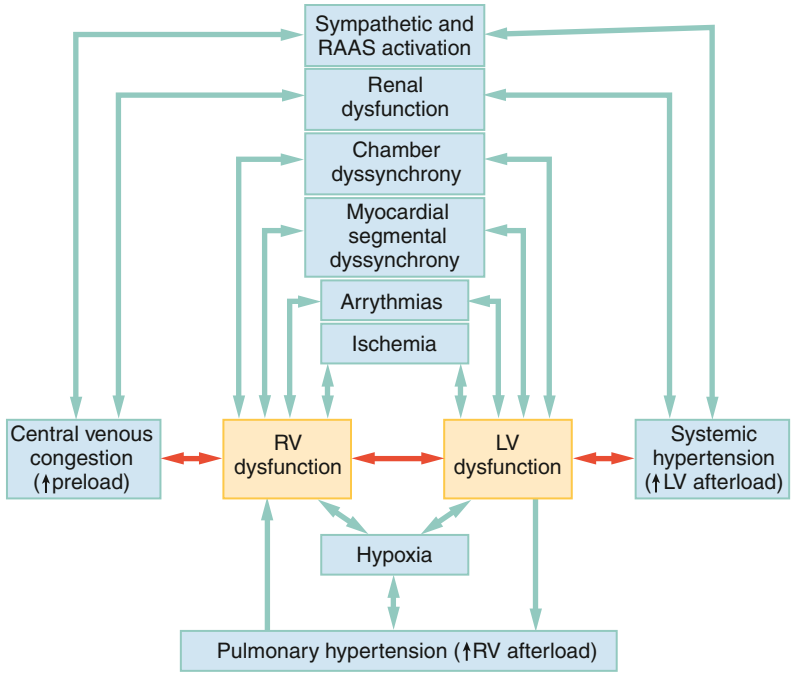

Fig. 67.8 A physiologic flow diagram of the biventricular nature of AHF. Although LVD has long been the focus of an understanding of AHF, it is now recognized that RVD is common, indicates severity of presentation, and predicts poor prognosis. Because both ventricles share (on average, beat to beat) a CO and a wall (ie, the intraventricular septum), forces affecting the RV affect the LV (and vice versa). RV and LV stroke work, however, is not inherently equal and it has been shown that improvement of the former in response to AHF treatment is associated with better outcomes than improvement in the latter. Disorganization of contraction, ischemia, volume overload, acute ventricular-vascular decoupling, or other insults in one ventricle are transmitted to the other ventricle through complex and somewhat unpredictable ways. LVD causing PHTN and subsequent RVD (the classic understanding of "right heart failure") is only one of many ways that RVD develops in AHF (ie, PHTN is neither necessary nor sufficient to produce acute RVD in AHF patients). *AHF*, acute heart failure; *LV*, left ventricle dysfunction; *RVD*, right ventricle; *LVD/RVD*, LV/RV dysfunction; *CO*, cardiac output; *RAAS*, renin-angiotensin-aldosterone-system; *PHTN*, pulmonary hypertension.

(Fig. 67.9A). Thus, vasodilators may even be beneficial in hypertensive/vascular AHF.[64]

Other Factors

Anemia is common in chronic HF and AHF, but represents a true decrease in red blood cell mass (RBCM) only 40% to 75% of the time.[4,5] Thus, outside of severe and life-threatening hemorrhage, transfusion of red blood cells in HF is rarely indicated.

Other factors that are germane to the ED assessment and management of AHF include valvular disease, specific cardiomyopathies, arrhythmias, pericardial disease, high-output heart failure states, and circulatory shunts. These topics are covered in greater depth elsewhere in this text.

CLINICAL FEATURES

History and Physical Exam

The most common symptom in AHF is dyspnea, present in approximately 93% of cases[3,34]; other "classic" HF symptoms are less reliably present (eg, orthopnea in 33%; paroxysmal nocturnal dyspnea in only 15%). A careful history should be obtained because patients may describe dyspnea differently, such as fatigue with exertion rather than shortness of breath. Inquiring about exertional tolerance, weight gain or swelling, syncope or presyncope, chest pain, and increases or decreases in urine output can provide important clues. The duration and rapidity of symptoms are also important, because rapid and severe onset may be indicative of the lower-risk vascular phenotype, as compared to the slow and progressive course of the cardiac phenotype.[34] The presence of a prior diagnosis of HF should be determined, as well as the patient's current medications, any recent changes, and current medication adherence. Inquiry regarding recent increases in diuretic dosing or decreased urine output may raise suspicion for acute CRS. Implanted devices, including a pacemaker, automatic implantable cardioverter-defibrillator (AICD), or implantable pulmonary artery monitor, should be identified in case they need to be interrogated. Comorbidities should be elicited, including an assessment of relative compensation, with particular attention to risk factors such as AMI, CAD, and hypertension.

The most common physical exam sign is peripheral edema (74%).[3] Other findings include jugular venous distention, rales on chest auscultation, the presence of an S3 gallop, or any murmurs. Close attention to vital signs is of particular importance, especially blood pressure and heart rate. Treatment differs significantly among hypertensive, normotensive, and hypotensive AHF presentations. The presence and degree of hypoxemia and any signs of increased work of breathing guide the need for respiratory support. Note any fevers, because infection is both

TABLE 67.1 Ischemic and Nonischemic Causes of cTn Elevation in AHF

Classification	Mechanism(s)	cTn >99th Percentile	Clinical Evidence of Ischemia[a]	Management
Type I MI	Acute thrombosis in epicardial coronary artery (eg, LAD, LCX, LM, RCA or major proximal branches)	Yes	Yes	PCI
Type II MI	Supply and demand mismatch of myocardial oxygenation May occur with obstructive (≥50%) CAD, nonobstructive CAD (<50%), or no CAD	Yes	Yes	1. Optimize myocardial oxygenation: • Address precipitants of O_2 supply/demand mismatch (eg, infection, tachydysrhythmia, hypoxia, vasoconstriction/HTN, etc.) • Directed therapy to ↓ intracardiac pressures (optimize preload, afterload, contractile synchrony with IV diuresis, NPPV, or vasodilators) 2. Consider PCI on urgent basis when optimized if CAD present
Acute Myocardial Injury	Stretch-related injury • Inflammatory or neurohormonal cell toxicity • Cytosolic cTn mobilization	+/-	Uncommon without concomitant MI (type I or type II)	1. Optimize AHF therapies, per clinical condition 2. Consider further investigation for MI if troponin rising despite optimal AHF therapy
Chronic Myocardial Injury	• Structural heart disease (myocardial scar, hibernating myocardium) • CKD	+/–	Uncommon without concomitant MI (type I or type II)	1. Obtain serial cTn to rule out acute injury or ischemia • By definition, troponin level must be stable (≤20% variation from known baseline or prior serial value) to be considered chronic injury 2. Consider acute injury/ischemia if no clinical history to suggest structural cardiac disease or CKD

[a]Defined as more than 1 of the following being present: (1) New ischemic ECG changes, (2) anginal S/Sx's other than dyspnea, (3) pathologic Q waves, (4) new regional wall motion abnormality on imaging (eg, cardiac US).

a common precipitant and poor prognostic factor.[2] Tachycardia may be chronotropic compensation for severe cardiac insufficiency (see Fig. 67.5). Rhythm is similarly important, and atrial fibrillation (AF) with a rapid ventricular response is the most common arrhythmia precipitating AHF.[2]

Unfortunately, virtually no sign or symptom is sufficiently sensitive or specific to make the diagnosis of AHF in isolation (Table 67.2).[32] Physician accuracy in predicting congestion based on physical exam features is also poor (area under receiver operating curve = 0.53).[65] Notably, many physical exam findings for HF, such as peripheral edema and weight gain, are proxies of chronic fluid overload and may not be present in up to half of patients with AHF. Although the combination of signs and symptoms may slightly improve diagnostic certainty, the diagnostic accuracy of emergency physician gestalt is approximately 74% overall.[29,66]

Precipitants

In addition to identifying signs and symptoms, consideration of precipitants for the current AHF episode is important for several reasons.[67] First, acute decompensation is often too quickly attributed to medication and dietary nonadherence, and premature closure on noncompliance as a precipitant can negatively affect patients.[28] Medication nonadherence as an isolated precipitant accounted for only 3.8% of AHF cases in a recent analysis of a large European and Asian registry, and contributed to only 14.1% of cases in a North American registry.[2] Second, the most common precipitants, including ischemia, infection, and arrhythmias, require etiology-specific therapies outside of general HF management. Third, certain precipitants in an AHF episode are associated with a low risk of in-hospital and short-term mortality (hypertension, nonadherence, arrhythmia) compared to others with a higher risk (ischemia, infection, cardiorenal dysfunction). Finally, AHF readmissions within 30 days are high at approximately 20%, yet in most cases, AHF is not the primary diagnosis.[10,29] Rather, common reasons for early readmission mirror some of the most commonly identified precipitants (infection, ACS, renal dysfunction, arrhythmia, etc.), some of which may have been present but unidentified at the index ED visit. However, in up to half of AHF cases, a clear precipitant may never be identified even after retrospective review.[2]

ACS is a particularly important example; it is among the most common precipitants of both AHF and 30-day readmissions and carries a significantly worse prognosis compared to other etiologies.[2] Nevertheless, ACS is significantly underdiagnosed and treated in AHF patients.[67] A thorough assessment of ischemic risk using cTn, electrocardiography (ECG), and clinical history should be undertaken in AHF presentations (see Table 67.1), particularly in those that have not had a prior evaluation for underlying CAD.

DIFFERENTIAL DIAGNOSIS

Common and important differential diagnoses are listed in Box 67.1. Some conditions may coexist with AHF or be a precipitant of AHF. This makes diagnosis more complicated, because ruling in AHF often does not rule out concurrent contributions from other conditions. The converse is also true: ruling in many differentials does not rule out AHF. Thus, rather than taking an "either/or" approach to the AHF differential, it is more useful clinically to determine if AHF is a component of a patient's presentation while also identifying other potentially coexisting diagnoses.

An illustrative example is the relationship between AHF, acute infections, and obstructive airway disease. Wheezing on exam in the ED does not significantly change the likelihood of AHF as a diagnosis compared to COPD, and the likely explanations are myriad.[32] First,

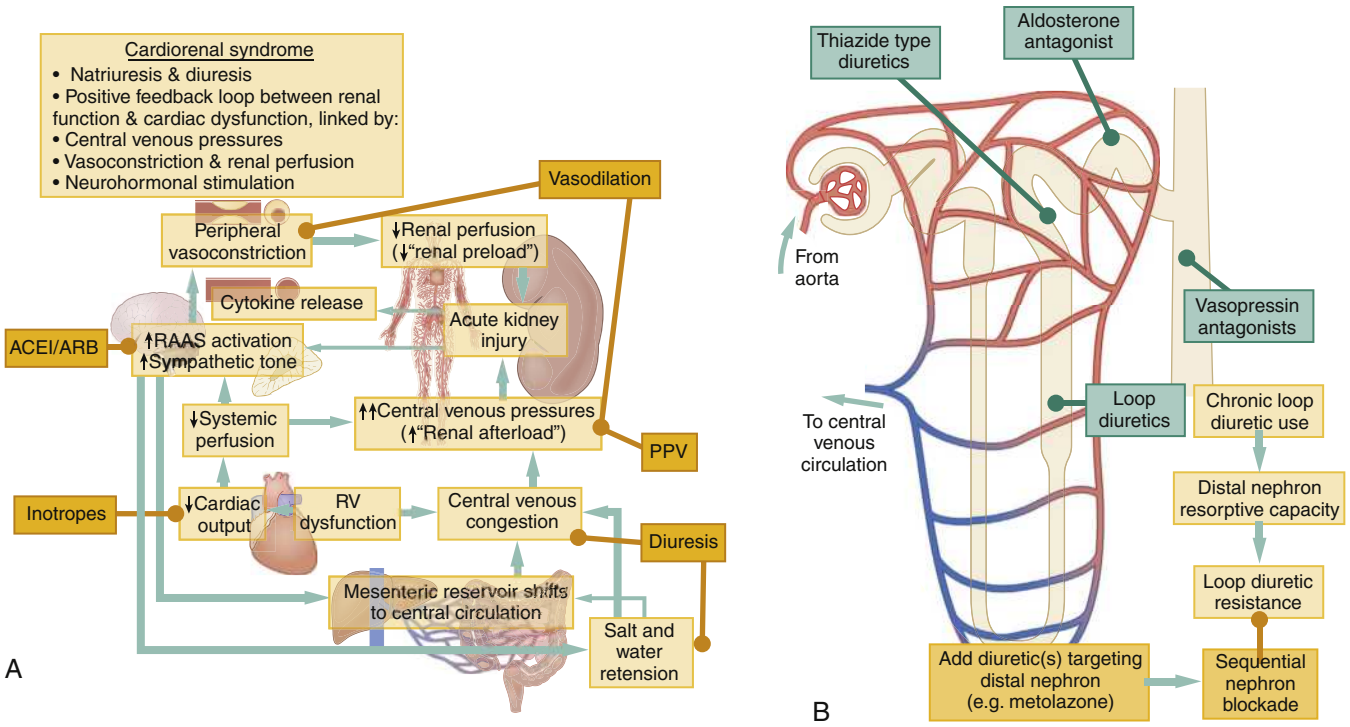

Fig. 67.9 (A) Flow diagram of mechanisms and therapeutic targets in the acute cardiorenal syndrome (CRS type 1) which complicates up to 40% of AHF presentations and predicts increased rehospitalization, mortality, and resistance to IV loop diuretics. Complex factors converge on two primary mechanisms causing CRS: venous hypertension from central circulation congestion and peripheral vasoconstriction limiting arterial flow to the kidneys. A decreased CO has generally been found to not independently correlate with CRS (possibly because autoregulation maintains renal blood flow in most circumstances short of overt cardiogenic shock). This is contrary to classic teaching and has important clinical relevance. Namely, administration of high-dose IV diuretics and IV vasodilators is generally safe in the CRS, potentially provides benefit, and any acute rise in creatinine that may be seen after administration of these drugs is unlikely to be representative of a true AKI. (B) Schematic of mechanisms and treatment targets in loop diuretic resistance, which can occur rapidly with the initiation of new loop diuretics, chronic loop diuretic use, or acute CRS. Diuretic resistance is a poor prognostic factor in AHF, and occurs at least partly due to the downregulation of molecular targets for diuretics in the loop of Henle. To bypass this, one clinical strategy is to simply give an IV loop diuretic dose in the higher range of recommended (see Fig. 67.13). Another, sometimes referred to as the "sequential nephron blockade," is to add a non-loop diuretic to be coadministered (eg, thiazide-type such as metolazone, or AVP antagonist such as tolvaptan) with the IV loop diuretic. *CRS*, cardiorenal syndrome; *CO*, cardiac output; *AKI*, acute kidney injury; *AVP*, arginine vasopressin; *RAAS*, renin-angiotensin-aldosterone system.

39% of AHF patients in the United States have comorbid COPD or asthma.[3] Second, self-report of COPD history is unreliable. One-third of HF patients who report COPD history have no evidence of it on pulmonary function testing (PFT), while as many as two-thirds of who report no COPD history do have PFT evidence of obstructive physiology.[68] Third, the most common precipitant of COPD exacerbation, infection, is also among the most common precipitants of AHF, and hypoxemia caused by either condition can further exacerbate both. Finally, up to a quarter of HF patients may develop obstructive airway physiology from the HF itself.[68] Empiric corticosteroids for presumed COPD exacerbation in which COPD is not present, but AHF is, does not increase 90-day mortality or AHF rehospitalization.[69] Data on the effects of adrenergic or anticholinergic nebulized therapy in AHF patients treated for COPD are lacking.

DIAGNOSTIC TESTING

Electrocardiogram

No ECG findings have a high sensitivity and specificity for AHF diagnosis (see Table 67.2).[32] Nevertheless, the ECG is a critical test because of the need to screen for signs of ischemia and arrhythmias, two of the most common precipitants of AHF.[2] Additional useful information may include signs of electrolyte disturbance or presence of a pacemaker.

Chest Radiography

Chest x-ray (CXR) has long been a mainstay of AHF diagnosis and management. The presence of pulmonary edema, cephalization, or Kerley B-lines strongly suggests a AHF diagnosis in the context of undifferentiated dyspnea (Table 67.2).[32] Unfortunately, the sensitivity of CXR to identify AHF is poor, with cardiomegaly serving as the most reliable finding (74.7% sensitive, negative likelihood ratio 0.43), followed by the presence of pulmonary edema (56.9% sensitive, negative likelihood ratio 0.48). Therefore, a normal CXR will not rule out the diagnosis of AHF unless the pretest probability is extremely low (Fig. 67.10A–C). CXR plus physician gestalt has an area under the receiver operating curve (AUROC) of only 0.62 compared to a reference standard of Doppler echocardiography in determining whether elevated cardiac filling pressures are present.[65] Nevertheless, CXR remains a useful and essential part of the AHF evaluation because it is accessible, inexpensive, relatively quick to perform, has high positive predictive value, and helps assess common differentials.

TABLE 67.2 Characteristics of History, Physical Examination, and Test Results for AHF Diagnosis in ED Patients with Dyspnea

Historical Feature	Sensitivity	Specificity	Positive Likelihood Ratio	Negative Likelihood Ratio
Orthopnea	52.1%	70.5%	1.9	0.74
PND	46.2%	73.9%	1.6	0.79
Dyspnea at rest	54.6%	49.6%	1.1	0.88
Exertional dyspnea	82.4%	36.6%	1.3	0.48
No productive cough	82.0%	25.8%	1.1	0.6

BOX 67.1 Common and Important Differential Diagnoses for AHF

Pneumonia
Acute exacerbation of COPD or asthma
Acute coronary syndrome
Unstable tachy- or brady-arrhythmia
Acute respiratory distress syndrome (ARDS)
Aspiration pneumonitis
Severe anemia presenting with exertional dyspnea and fatigue
Acute renal failure with fluid overload ("acute renocardiac syndrome", ie, cardiorenal syndrome type 3)
Severe metabolic acidosis or toxicologic phenomena presenting as respiratory distress
Noncardiac causes of peripheral edema (eg, cirrhosis, amlodipine, peripheral venous insufficiency, nephrotic syndrome, venous thrombosis, etc.)
Pulmonary embolus
Pneumothorax
COVID-19

Laboratory Testing

Important laboratory tests to consider in the ED assessment of suspected AHF include a complete blood count (CBC), serum electrolytes, blood urea nitrogen (BUN), serum creatinine, glucose, thyroid stimulating hormone (TSH), BNP or NT-proBNP, and cTn.[1,53,67]

A CBC helps to evaluate for evidence of infection and anemia, though anemia in HF is multifactorial and heterogeneous in terms of any actual reduction in RBCM.[4,5,70] Hemoglobin concentration may also provide clues to volume status, especially if changes are evaluated in the context of baseline information, as well as prognostic information. Electrolytes are helpful because disturbances are common and may portend a worse prognosis. Hyponatremia is a significant predictor of all-cause mortality in AHF, and hyponatremia may be related to the degree of sonographic RVD in AHF, with RVD having a strong independent association with mortality.[43] Setting a baseline is important as well, because a rise in serum sodium by day 3 of hospitalization compared to the ED value is suggestive of a 43% lower risk of death, rehospitalization, or transplant at 6 months.[46]

Although TSH is recommended if not previously known,[1,28] the yield of this test in the ED for AHF is relatively unknown. A recent study found that low levels of T3 (<2.3 pg/mL) predicted an 8.5% absolute risk increase in mechanical ventilation, 4 days longer length of hospital stay, and a 14.9% absolute increase in ICU admission.[71] If available promptly, T3 may be reasonable for risk stratification.

cTn should be obtained on ED arrival and trended if elevated or when clinical suspicion of ACS is present. The value, trend, and clinical picture, along with ECG findings, may help distinguish between myocardial ischemia and injury in AHF (see Table 67.1). In HFpEF with AHF, an elevated cTn is associated with a doubling of in-hospital mortality and an increase in 30-day mortality (4.8% vs. 0.6%).[50,57,72] Serial values are important, and increases or decreases correspond to worsened or improved prognosis, respectively.[51,73]

The potential for hs-cTn to identify low-risk AHF patients is still unclear. In one recent multicenter US study, patients with 0- and 3-hour hs-cTnT levels greater than the 99th percentile in the ED did not have a statistically significant lower odds ratio for the primary outcome of 90-day death, hospitalization, or ED revisit.[48] Nevertheless, no patient with serial hs-cTnT levels less than the 99th percentile died within 90 days. A low overall mortality in the cohort (2.7% at 30 days) may have contributed to neutral findings.

Natriuretic peptides have been given a class I recommendation for early AHF diagnosis by the AHA and ESC.[1,67] The two molecules, BNP and NT-proBNP, are related by a common pathway, though clinical assays pick up not only the primary molecule in each but also several precursors and metabolites.[26] As such, there is not a direct one-to-one comparison between the two clinical assays, though in general, both follow similar kinetics and clinical ramifications for their given cutoffs (see Table 67.2). In ED patients with dyspnea, a low level (BNP < 100 ng/L or NT-proBNP < 300 ng/L) is among the strongest tests to rule out the diagnosis of AHF. At high levels (BNP > 500 ng/L or NT-proBNP > 1550 ng/L), AHF is strongly supported though not necessarily confirmed. Intermediate levels (BNP 100–500 ng/L, NT-proBNP 300–1550 ng/L) do less to change pretest probability. Overall, when used by binary or tertile cutoffs, natriuretic peptides are most useful diagnostically when pretest probability is the indeterminate range (20% to 80%) (see Fig. 67.10). Additionally, common causes of elevated NPs in the absence of AHF include several differential diagnoses for AHF, including pulmonary embolus, COPD, and pneumonia, as well as many common HF comorbidities, such as CKD, hypertension, PHTN, AF, and advanced age. Given this, care must be taken in interpreting values. It may be useful to compare values to a known prior, though evidence-based cutoffs for "delta" BNP or NT-proBNP are lacking.

Caveats to NP measurement can impact clinical interpretation. Obesity and CKD both affect NP clearance, and their presence either decreases (obesity) or increases (CKD) NP concentrations. As a general rule, the NP concentration should be doubled when measured in an obese patient or halved when measured in a CKD patient. Although the effect of these comorbidities on BNP and NT-proBNP are relatively equal, the same cannot be said for patients on sacubitril-valsartan, which inhibits neprilysin resulting in diminished BNP degradation and increased concentrations. As a result, patients on this drug combination will have higher BNP levels; however, since sacubitril-valsartan is used exclusively in those with chronic HF, this should not affect the diagnostic utility of BNP in the ED. Because NPs are also used for tracking of treatment effectiveness and prognostic purposes, NT-proBNP, which is not altered by sacubitril-valsartan, has become the preferred biomarker in some institutions where the drug combination is commonly prescribed.

The use of NPs as a continuous variable or with interval likelihood ratios has much higher diagnostic utility than as a binary result (see Fig. 67.10D). The recently validated GASP4Ar mathematical model, which includes only age, EP pretest probability, and NT-proBNP concentration, has strong diagnostic utility for AHF in an undifferentiated ED population, with an AUROC of 0.93.[66] Age-adjusted cutoffs have also recently been derived for NT-proBNP, using simplified binary cutoffs while adjusting for a major confounder.[74] The age-adjusted cutoffs improve positive predictive value but reduce the negative predictive value (see Table 67.2). Additionally, the performance of test characteristics overall declines for each increasing age bracket, with age less than 50 years cutoff performing markedly better than the 50 to 75 or greater than 75 years cutoffs (both in terms of positive and negative predictive values).

Finally, as a prognostic factor in AHF, evidence for natriuretic peptides is mixed. Generally speaking, higher levels of BNP and NT-proBNP have been shown to portend worse outcomes,[53,54] though the utility for predicting short to intermediate (e.g., 30–90 day) outcomes from the ED is less clear. NPs have been included in some ED-based disposition decision instruments,[75] and serial measurement has been evaluated throughout a hospital stay to predict need for escalated treatment and readiness for discharge, albeit with no effect on outcomes.[76,77]

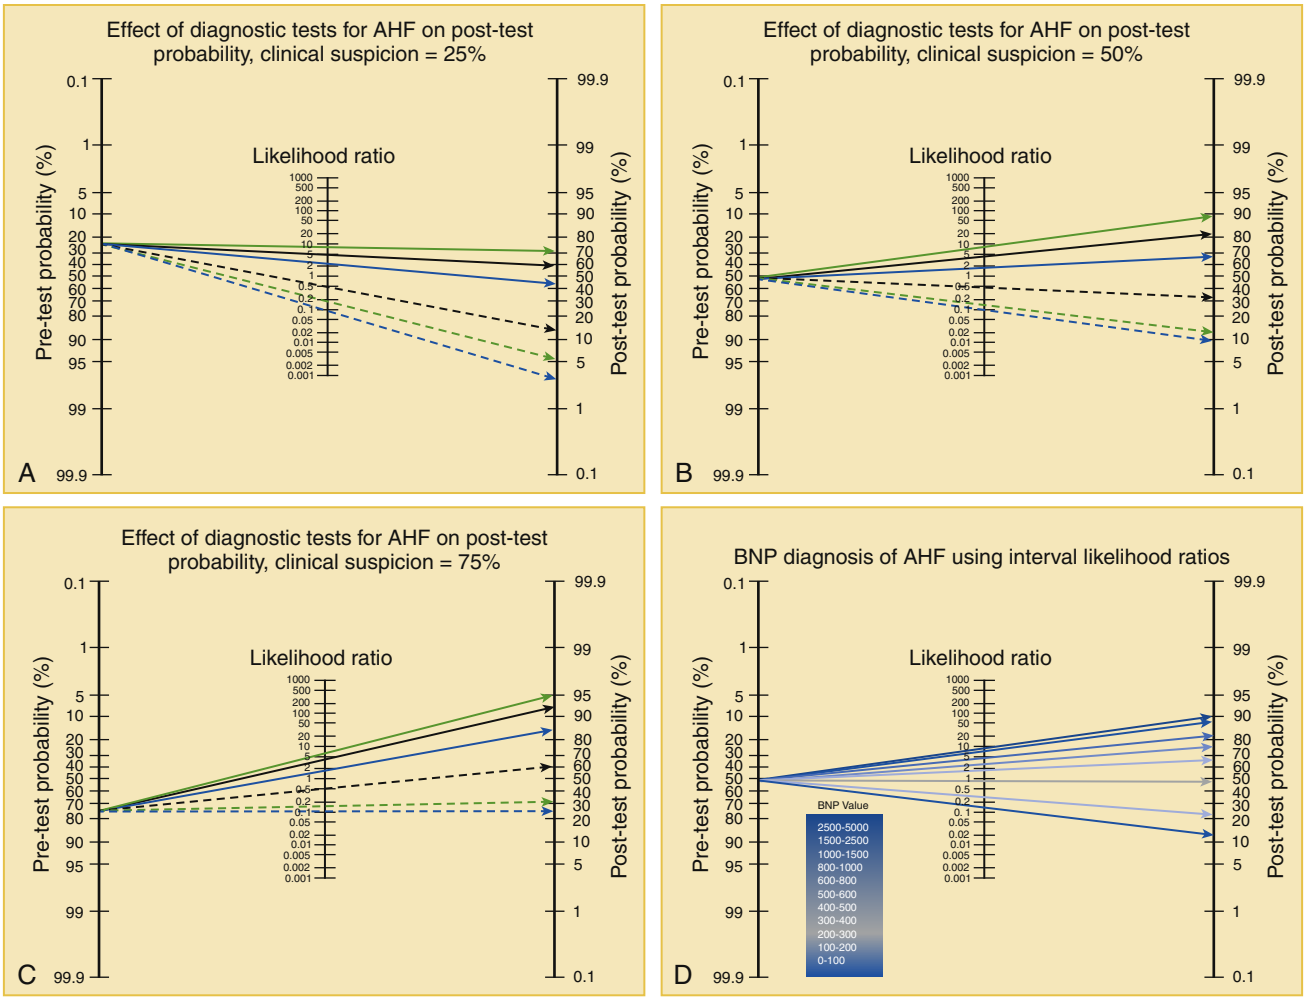

Fig. 67.10 (A–C) Comparative Fagan nomograms illustrating the diagnostic utility of CXR (*black line*), LUS (*green line*), and BNP when each of these tests is positive (*solid lines*) or negative (*dotted lines*) for a given level of clinical suspicion/pretest probability that a patient has AHF (pretest probability A = 25%, B = 50%, C = 75%). CXR, determined positive or negative by clinician or radiologist interpretation, is useful to rule in AHF when positive but ineffective at ruling it out across a wide range of pretest probabilities. BNP at the standard binary cutoff of 100 ng/dL is roughly the opposite: highly effective at ruling out AHF but poor-performing at ruling it in. LUS as an 8-point exam (two anterior and two lateral lung zones per hemithorax, positive if at least 1 lung zone on each side has ≥ 3 B-lines) provides a positive predictive value equal to or exceeding CXR as well as a negative predictive value similar to BNP and thus is the single most effective diagnostic test. LUS may also reduce time to AHF diagnosis (or alternative diagnosis) in the ED setting considerably. (D) Fagan nomogram of BNP distributed as a nonbinary test with interval likelihood ratios. BNP (and NT-proBNP) perform significantly better for "ruling-in" AHF when used as a nonbinary test where at the lowest levels AHF may still be ruled out, but at the highest levels AHF may now be effectively "ruled in" (and intermediate levels do little to change diagnostic suspicion either way). The arrows for each interval or BNP are shaded dark blue to light grey, where shades closer to the former are stronger evidence ruling in/out AHF and shades approaching the latter are more indeterminate results. *CXR*, chest x-ray; *LUS*, lung ultrasound; *BNP*, B-type natriuretic peptide; *NT-proBNP*, amino terminal pro-BNP; *AHF*, acute heart failure; *ED*, emergency department.

Lung Ultrasound

Perhaps the most useful ED-based diagnostic for AHF is lung ultrasound (LUS) (see Table 67.2, Fig. 67.10, and Fig. 67.11).[32,78,79] Lung US techniques and interpretation are well described in the literature.[80] An 8-point lung US exam is defined as viewing two anterior and two lateral intercostal spaces (ICS) in each hemithorax, with a scan considered positive if 3 or more B-lines are present in at least one ICS on each side (Fig. 67.11). This 8-point study maximizes sensitivity while providing a specificity equal to or greater than pulmonary edema on CXR.[32] Overall, the positive and negative likelihood ratios for LUS equal or outperform all other binary diagnostic tests.[32,78] Moreover, LUS speeds ED diagnosis without a loss of accuracy.[79,81] ED discharge change in B-lines, but not initial B-line count in the ED, are associated with higher 30-day death or AHF readmission.[36a,82] A randomized feasibility trial of LUS-guided decongestion showed that ED dosing of diuretics based on B-line count reduced pulmonary edema at 48 hours.[82a] Randomized studies designed to test patient-centered outcomes (i.e., use of LUS-guided therapy from ED arrival through discharge) are needed.

Echocardiography

POC echocardiography may also be used in clinical evaluation of AHF in the ED. The most familiar measure is a visual estimate of reduced versus

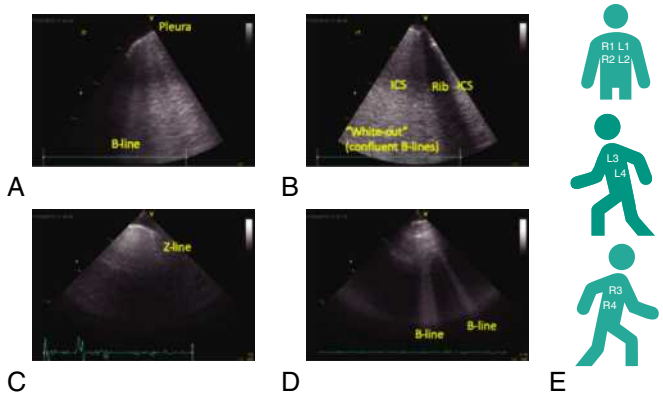

Fig. 67.11 LUS images in A and B are from the same patient prior to ED AHF treatment, and show single ICSs from the right and left hemithoraces, respectively. C and D are the same right and left ICSs on the same patient 72 hours later at hospital discharge. At least 3 B-lines (hyperechoic/bright stripes from pleura to >15 cm in depth) in at least one ICS space (eg, as in A) on each side are required for AHF diagnosis on an 8-point LUS exam. In cases where pulmonary edema is severe, B-lines may appear fused together so as to be indistinguishable (eg, US image B). In such cases of "white-out," counting B-lines is impossible but the number can be assumed to be greater than 3 for that ICS. In C, only a single "Z-line" (a hyperechoic line from the pleura that extends <15 cm and is nondiagnostic for increased lung water) remains as compared to A. In D, there remains at least 3 identifiable B-lines compared to image B, however given that ICS B had a full white-out appearance prior to ED treatment this still represents significant improvement. Panel E shows a diagram of positioning for the components of an 8-point LUS exam. Each hemithorax is divided into 4 quadrants (eg, R1–R4 on right, L1–L4 on left) from the posterior axial line to the sternum. Thus, two views on each side are on the anterior chest (R1–R2 or L1–L2) and two are lateral (R3–R4 or L3–L4). Images are typically obtained with the phased array or curvilinear US probe to achieve the depth required to differentiate B-lines from Z-lines (ie, >15 cm). This approach is the single best test to both rule in and rule out AHF in a dyspneic patient, and can significantly reduce time to diagnosis in the ED. *ICS*, intercostal space; *LUS*, lung ultrasound; *ED*, emergency department; *AHF*, acute heart failure.

preserved EF. However, except for patients with suspected de novo AHF, the utility of determining EF in the ED may be limited. Virtually all patients with chronic HF have a comprehensive echo at some point, and many will have recent echo data available.[28] There may be situations where a change in EF is suspected but, in isolation, this is unlikely to impact ED management. Further, looking at EF alone can be misleading given that nearly half of AHF presentations involve the HFpEF phenotype.[9] Adjusting for RVD and change in LUS congestion severity, LVEF adds virtually no risk-stratification value for 30-day death or AHF-rehospitalization (AUROC = 0.807 for RVD + LUS, 0.807 for RVD + LUS + LVEF).[36a]

As previously mentioned, the heart in HFrEF typically suffers from not only systolic but also diastolic dysfunction.[8,20] Systolic dysfunction in HFpEF may be less intuitive. The traditional definition of HFpEF versus HFrEF is based on two-dimensional echocardiographic (2D echo) EF, which does not accurately capture all forms of systolic dysfunction. Regional irregular or disorganized contraction can lead to the actual EF (ie, what would be measured by invasive volume measurement or 3D imaging) deviating from the EF on 2D echo. Thus, POC echo to determine the presence or absence of systolic dysfunction may not be accurate.

Strain imaging represents a potential adjunct to EF for assessing severity of dysfunction and response to ED treatment. Unlike EF,[3] 2D longitudinal strain on POC echo improves during a patient's AHF treatment in both HFrEF and HFpEF.[36] However, current availability and feasibility of POC echo strain values in the ED is limited to centers and physicians with advanced POC echo expertise.

The discovery that RVD is common in AHF and a strong predictor of numerous adverse AHF outcomes was made possible by improvements in US-based RV assessment over the past two decades. A tricuspid annulus systolic plane excursion (TAPSE) less than 17 mm is indicative of RVD, as are numerous other echo findings described elsewhere.[41,47,83-86] Thirty-day AHF rehospitalization or death is threefold higher for TAPSE <7mm on EP-performed US.[36a]

Although assessment of diastolic function is beyond the scope of most ED physicians, small studies suggest that it can be performed effectively by those with proper training.[32] A recent study tested a 3-minute POC echo protocol at ED arrival combining mitral flow velocity measures (E/e' >15) with lung US. The protocol had a reported 100% sensitivity (95% confidence interval [95% CI:] 91.4–100%) and 95.8% specificity (95% CI: 84.6–99.3%) with a 0.979 AUROC for the diagnosis of AHF.[87] Additionally, unlike EF, cardiac filling pressures, measured by the surrogate of mitral flow parameters, worsen on echo with the precipitation of AHF and improve with treatment. In another small study, a treatment strategy guided by E/e' greater than 15 from ED admission to hospital discharge led to greater decongestion despite a shorter hospital length of stay and lower 6-month mortality or rehospitalization.[88]

MANAGEMENT

Initial Evaluation

Figure 67.12 outlines a pathway for the initial and empiric management of AHF. The most critical initial consideration is whether the patient needs resuscitation for respiratory failure or shock. Signs and symptoms of respiratory failure or any significant increase in work of breathing should be treated with NPPV unless contraindicated. NPPV for the treatment of severe AHF reduces in-hospital mortality (number needed to treat [NNT] = 17), endotracheal intubation (NNT = 13), and does not appear to be associated with an increase in adverse events when compared to standard medical care.[89] If NPPV is contraindicated, but the patient requires immediate stabilization of respiratory failure, options include a trial of high-flow nasal cannula (HFNC) at 40 to 50 liters/minute or endotracheal intubation. The effectiveness of HFNC in AHF has not been sufficiently studied to make a strong recommendation regarding its use. Nevertheless, a randomized ED-based trial showed that HFNC may have benefits in a heterogeneous population with hypoxemic respiratory failure, and the adverse effects of HFNC are few.[90] Thus, it may be considered to prevent intubation, but only if NPPV is not an option. Intubation should be a last resort for the uncommon situation when NPPV has failed or is contraindicated.

Blood Pressure Considerations

Hypotension, with or without accompanying signs of shock, is uncommon in AHF (5–8%).[1] In patients with advanced chronic HF and severe functional impairment, a low BP may be optimal to minimize the resistance to forward flow. True cardiogenic shock (CS) is rare, but when present carries up to a 51% mortality.[91] The AHA and ESC have both proposed definitions of cardiogenic shock, with agreement that clinical and laboratory signs of hypoperfusion (eg, altered mental status, elevated serum lactate, oliguria, cold extremities) are needed for CS to be present. The ESC goes further by specifying an SBP < 90 mm Hg cutoff after adequate fluid resuscitation, while the AHA definition does not specify a blood pressure.[1,91]

For patients with low blood pressure absent true shock, routine use of inotropic agents or vasopressors is associated with worse outcomes and not recommended. When CS is present, ED management is aimed at two parallel goals: stabilizing measures and etiology-directed definitive treatment. Figure 67.13 outlines a strategy for both of these goals

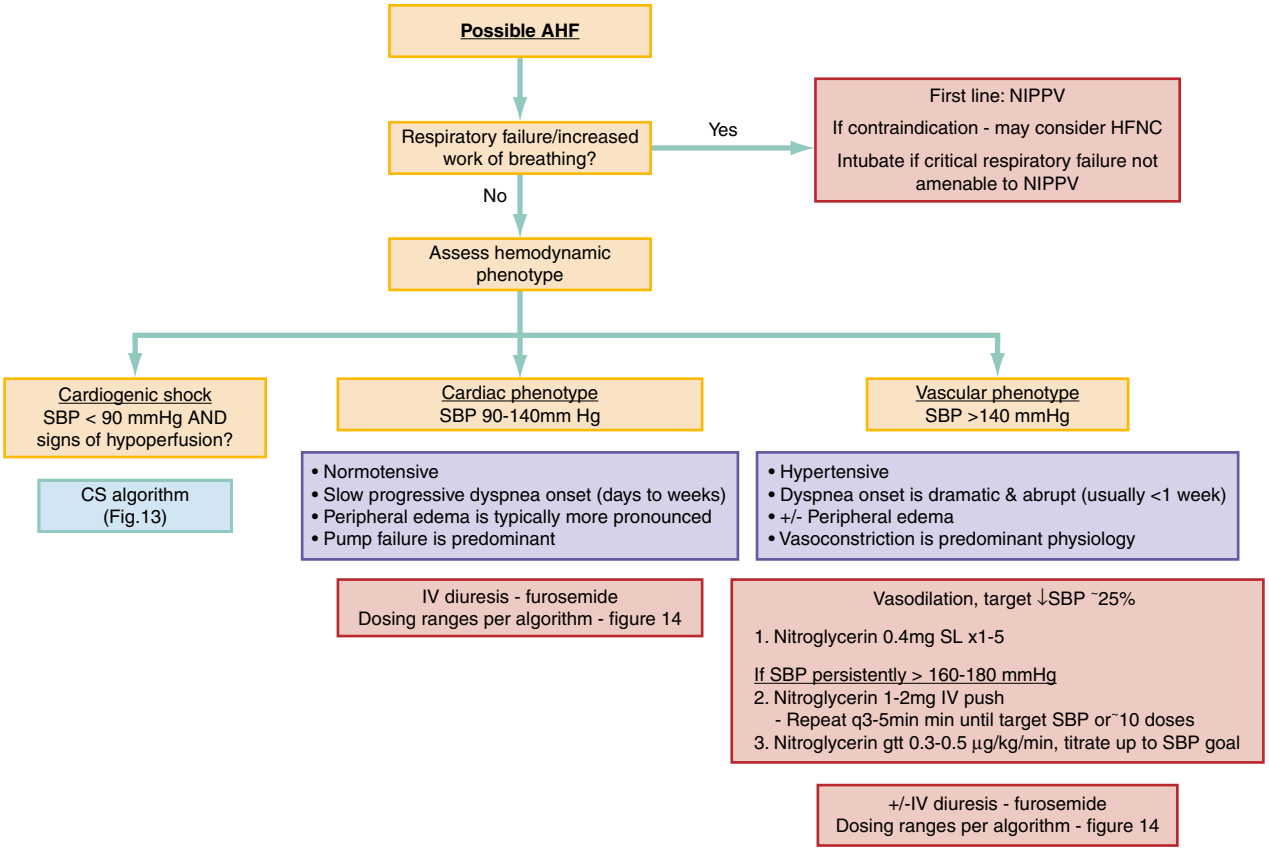

Fig. 67.12 Flowchart management algorithm for AHF in the ED. Respiratory failure is managed early with positive-pressure ventilation. Next, hemodynamic phenotype is assessed. Only a very small proportion of ED AHF patients will present in cardiogenic shock (see Fig. 67.13), and in general this diagnosis should rely on not only blood pressure but also careful assessment of physical signs and elimination of alternative (and more common) causes of shock (eg, septic, obstructive, hypovolemic). For the typical ED AHF patient (who does not show signs of shock), two alternative management strategies are considered, depending on whether the current presentation is predominantly the cardiac or the vascular AHF phenotype (ie, based on clinical history, vital signs, and judgement; see purple boxes). Although both phenotypes can coexist (eg, see Fig. 67.7B, third curve "rapid+slow pathway"), addressing the most highly suspected first and then reassessing the patient for clinical response may allow better discrimination and more targeted therapy because AHF presentations are extremely heterogenous. *AHF*, acute heart failure; *ED*, emergency department; *STEMI*, ST-elevation myocardial infarction; *NPPV*, noninvasive positive-pressure ventilation; *HFNC*, high-flow nasal cannula; *CS*, cardiogenic shock; *PCI*, percutaneous coronary intervention; *SBP*, systolic blood pressure; *MAP*, mean arterial pressure; *SL*, sublingual; *gtt*, continuous infusion.

in detail. Many CS patients need percutaneous coronary intervention, cardiac ICU care, cardiac surgery consultation, and/or mechanical circulatory support (please see Chapter 66). The AHA has proposed the concept of CS "Hub Hospitals" with these capabilities.[91] When such resources are not available at a receiving facility, CS patients should be transferred to an appropriate center as soon as possible. Traditionally, about 80% of CS has been due to STEMI, but in recent estimates, this proportion has been as low as 30%.[92,93] Improvements in PCI capabilities are hypothesized to have led to fewer CS cases due to STEMI, and more due to decompensation of end-stage advanced chronic heart failure (up to 60% of cases).[92] When STEMI is the cause, prompt PCI significantly improves mortality.[93]

In cases of CS not related to STEMI, 9% to 17% are due to mechanical cardiac complications, including papillary muscle rupture, ventricular septal rupture, or free wall rupture, in which prompt surgical intervention is key.[92] When decompensation of end-stage advanced chronic heart failure is the cause, chemical or mechanical circulatory support (eg, percutaneous VAD or intra-aortic balloon pump) may be needed to temporize until sustained hemodynamic recovery can be achieved.

While awaiting definitive treatment with PCI, if CS does not respond to small (250–500 mL) fluid boluses, norepinephrine is the first-line vasopressor therapy. A recent multicenter RCT of norepinephrine and epinephrine in CS showed that the former led to a lower incidence of refractory CS (NNT = 4) with fewer unfavorable effects on cardiac stroke work.[94]

Once the MAP is supported, pharmacologic support for CS involves pure inotropes, also known as inodilators for their effects on the systemic vascular resistance. These include dobutamine, milrinone, and levosimendan (not available in the United States). The degree of vasodilation varies among patients, because patients with extreme pump failure may already be maximally vasodilated in compensation for critically low CO.[93] We recommend titration of norepinephrine to mitigate hypotension from inotropes. All inotropes are associated with increased mortality in AHF, though causality is difficult to establish because only critically ill patients receive these drugs. Generally, inotropes should be initiated in CS for stabilization until definitive treatment or mechanical support can be arranged.[95-97] Many patients will require mechanical circulatory support, even temporarily, and thus urgent interventional cardiac surgery or

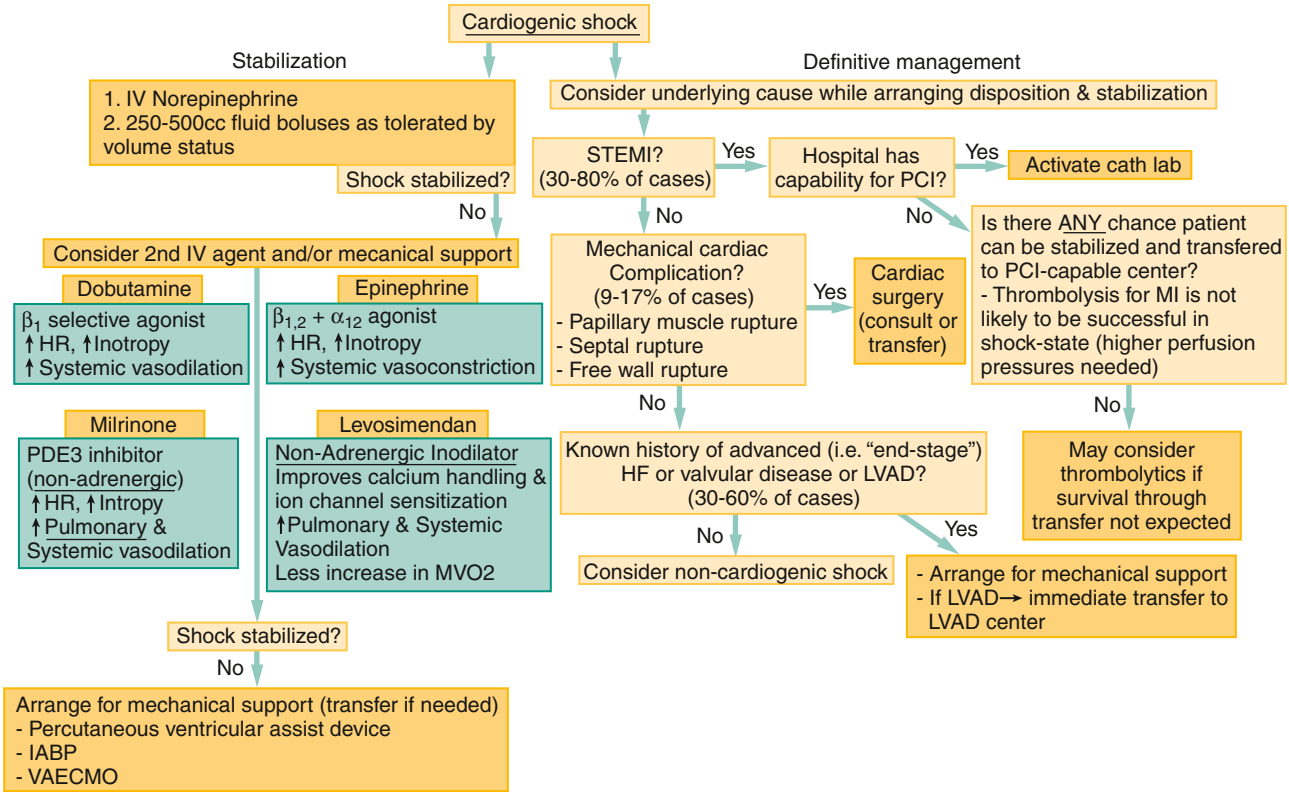

Fig. 67.13 Algorithm for management of CS. The algorithm focuses on two parallel goals: arranging for definitive management (right limb) and stabilization (left limb) until the patient can get there. In the absence of evidence for one of these three most common causes (STEMI, mechanical cardiac complication, or progression of end-stage/advanced pump failure), strong consideration should be given for the patient having an alternative type of shock (eg, distributive, hypovolemic, obstructive) since cardiogenic shock is very uncommon overall and is due to one of these three causes in as many as 99% of presentations. Because these three etiologies all potentially require advanced cardiac surgery or interventional cardiology techniques, definitive management will rarely be achieved in the ED. This means transfer to a center with the required resource for the given etiology (eg, PCI, CABG and valvular surgical capabilities, implantable temporary mechanical support, LVAD, cardiac transplant, IABP, ECMO) is required if not locally available and should be arranged as soon as possible while stabilizing the patient. Note also the wide estimates of prevalence among the three major causes of cardiogenic shock. This reflects apparent changes in etiologic trends over time. Specifically, STEMI as a cause of cardiogenic shock used to be by far the most common, but newer data suggest that PCI techniques and availability may have caused a decrease in STEMI-CS presentations. At the same time, advanced HF patients with near-end-stage disease may be becoming more common, as advanced HF cardiology has become a more robust discipline over time. *CS*, cardiogenic shock; *STEMI*, ST-elevation myocardial infarction; *ED*, emergency department; *HF*, heart failure; *PCI*, percutaneous coronary intervention; *CABG*, coronary artery bypass grafting; *LVAD*, left ventricular assist device; *IABP*, intra-aortic balloon pump; *VA-ECMO*, veno-arterial extracorporeal membrane oxygenation; *PDE3 inhibitor*, phosphodiesterase-3 inhibitor.

interventional cardiology evaluation is indicated. Myosin activators (eg, omecamtiv mecarbil) are an investigational new class of agents that have shown promise in chronic HFrEF and may improve cardiac function in AHF, albeit with no effect on dyspnea or other outcomes.[98] The role of these medications in CS is to be determined.

The vast majority of patients in AHF presenting to the ED are normotensive (SBP 100–140 mm Hg) or hypertensive (SBP > 140 mm Hg). After addressing any further identified or suspected precipitants, the next decision point in AHF therapy is determining whether a vascular or cardiac phenotype predominates (see Fig. 67.12).[1] The vascular type tends to present with moderate to markedly elevated blood pressure (SBP > 160 mm Hg) and abrupt onset of symptoms, and often responds favorably to bolus IV vasodilator therapy even when presenting with severe respiratory distress (see Fig. 67.7B, first curve). In the cardiac type, blood pressure is often in the normal to moderately elevated range (SBP 100–160 mm Hg), onset tends to be subacute (often > 1 week), and symptoms are more likely to have a chronic component with fluid retention and peripheral edema (see Fig. 67.7B, second curve). An assessment to distinguish between the two early in the ED course can have significant impact for both treatment and risk stratification (see Fig. 67.12). Making this distinction can be difficult,[99] given that increases in cardiac filling pressure and lung water accumulation may begin weeks before AHF symptoms develop (see Fig. 67.7B). SBP has a roughly equal correlation with CO (r = 0.30) as it does vascular tone (r = 0.32) in ED AHF patients, while diastolic BP (DBP) has virtually no correlation to CO but a strong one with vascular tone (r = 0.587).[99a] As such, DBP elevation may help identify the vascular phenotype with even higher specificity than SBP.

Vascular Phenotype

In the vascular phenotype of AHF, IV vasodilators can provide rapid offloading of afterload, restore laminar arterial flow, and improve both myocardial oxygen supply and demand, while decreasing the work of

breathing.[96,97] Nitroglycerin provides both venous and arterial dilation at higher doses, providing preload and afterload reduction. In vascular phenotype patients with markedly elevated blood pressure, IV nitroglycerin delivered as a 1- to 2-mg bolus (repeated every 5 min as needed for symptom relief or until 25% SBP reduction) reduces ICU admission (48.4% versus 83% with usual care, NNT = 3), intubation (8.9% versus 16.9%, NNT=13), and hospital length of stay by 1.9 days.[100] The goal is rapid afterload reduction targeting a 25% decrease in SBP.[101,102] Continuous infusion of nitroglycerin may be started concomitantly to maintain blood pressure reduction after bolus therapy, but the continuous infusion in isolation is less efficacious than the bolus strategy.[100] Thus, if a continuous infusion is used as primary therapy, higher initial dosing (50–100 mcg/min) is recommended with up or down titration as needed. Sublingual (SL) nitroglycerin tablets or spray (400 mcg per dose) is rapidly absorbed and 100% bioavailable and may be considered an alternative, but multiple doses of SL nitroglycerin may be needed to achieve similar total dosing to the IV push/bolus strategy. Oral nitrate formulations have limited effectiveness in the ED setting[103] due to slow absorption, decreased bioavailability, and low peak serum concentration and are not recommended in the acute phase of care. Although IV sodium nitroprusside delivered by continuous infusion has historically been used for severe hypertensive AHF patients, it is cumbersome to administer, has the potential for unwanted side effects (eg, cyanide toxicity), and provides no benefit over aggressively dosed nitroglycerin therapy. As such, there is little reason to consider use of this agent.

In addition to IV nitroglycerin, IV enalaprilat (by bolus) may be used, though there is less ED-based evidence.[101] In one case series, enalaprilat given by IV bolus (0.625–1.25 mg repeated every 15 minutes up to 3.75 mg total) significantly reduced blood pressure in hypertensive AHF and was associated with improved respiratory status without adverse effects on renal function. However, data on other outcomes are lacking.[104] Large randomized trials involving other novel vasodilators such as serelaxin, ularitide, TRV027 (a biased ligand of angiotensin II receptor type 1), and nesiritide have shown them to be effective for symptom reduction but of no benefit for the in-hospital course of AHF or postdischarge outcomes including mortality and readmission.[96,105-107] Such data are consistent with systematic reviews of vasodilators in AHF, which show no mortality benefit with any agent including nitroglycerin.[101] Mortality in AHF has a strong inverse relationship with SBP, so reduction of mortality in this phenotype (with an already low risk) is less likely a feasible goal compared to reducing other adverse events like intubation.

To date, few vasodilator studies in AHF have enrolled patients upon ED arrival, making it difficult to know if the lack of benefit reflects specific drugs, timing of administration, or patient heterogeneity. Indeed, nearly all vasodilator studies have included mixed AHF patients rather than those with a hypertensive/vascular phenotype.[108] Importantly, adverse effects such as worsening or precipitation of acute cardiorenal syndrome, symptomatic hypotension, or precipitation of ischemia have not been demonstrated with IV vasodilator use even with large bolus doses of nitroglycerin as described.[100-102] Because vasodilators do result in rapid symptom improvement in respiratory status, a critical aspect of the vascular AHF phenotype,[109,110] they should be utilized early in the management of such patients. Of note, although morphine has historically been used in AHF for its theoretical vasodilatory properties, it increases the risk of respiratory depression and has been associated with higher mortality.[111,112] Given the existence of safer, more effective alternatives, morphine is no longer recommended for ED management of AHF.

Whether IV diuretics should be given in addition to vasodilator therapy depends on the presence or absence of concurrent fluid overload. In the vascular phenotype, central venous congestion occurs primarily due to fluid shifts alone (see Fig. 67.7B, first curve), and so diuresis can remove some of the acute preload and afterload by reducing central circulation congestion. Although there may be little harm in giving a single dose of IV diuretics, not all patients require diuresis.

Cardiac Phenotype

In the cardiac-predominant phenotype, intercompartmental fluid shifts remain important, but patients are more likely to have an increase in total body fluid volume, much of which may be retained in the splanchnic compartment and other reservoirs (see Fig. 67.7B, second and third curves). Thus, diuresis is a core component of ED management. Several days of diuresis may be needed to achieve adequate net fluid removal.[34]

Diuresis should generally involve an IV loop diuretic, with furosemide being the most commonly used. Furosemide by IV bolus is much more rapid-acting, and roughly twice as potent, as the oral formulation.[28,29] This provides rapid decongestion of the central circulation if the diuresis outpaces fluid redistribution from the splanchnic reservoir before the next dose of diuretic. Thus, both the initial dose and dosing interval are important (see Fig. 67.13). Unfortunately, diuresis and natriuresis decrease once an IV dose of loop diuretic has worn off. This process (the so-called "braking-phenomenon") starts within as little as 3 hours of bolus loop diuretic administration due in part to compensatory RAAS activation.[113] It is harder to overcome when diuretic use is chronic due to renal tubular remodeling that produces resistance to loop diuretics. With outpatient loop diuretic use or acute CRS, patients may have significant diuretic resistance on arrival to the ED. Diuretic efficiency (DE), or the amount of urine output per mg dose of diuretic per unit time, is highly associated with worsening heart failure after hospitalization, cardiorenal dysfunction, mortality, and other adverse AHF outcomes.[62,114-116]

Figure 67.13 describes a strategy for initial and possible repeat dosing of IV loop diuretics.[28,61,116] Loop diuretic–naïve patients should receive 40 to 80 mg based on current guidelines. When a patient takes PO loop diuretics at home, the IV dose should be at least 1x the home oral dose in furosemide equivalents (1 mg of bumetanide or 40 mg torsemide is considered equal to 40 mg of PO furosemide). Higher IV doses up to 2.5 times the home PO dose have been shown to be safe and may increase diuresis, though this approach yields no difference in mortality.[28] Continuous IV furosemide infusion, an alternative to bolus therapy, may increase total urine output over bolus therapy but does not improve mortality or hospital length of stay.[117]

No single definition of diuretic resistance has been validated in the ED. Nevertheless, in one ED-based study, a DE of less than 140 mL urine output per 40 mg of IV furosemide in the first 3 hours was associated with increased mortality.[116] While further ED-based studies are needed, these findings correlate with inpatient studies of diuretic resistance. Additionally, low natriuresis in the first hour (<35.4 mmol urine sodium) after ED administration of IV loop diuretic has been associated with worsening heart failure after hospitalization.[118,119] Close attention to urine output in the first 1 to 3 hours after an IV diuretic may allow identification of diuretic resistance and allow the ED clinician to more quickly implement an alternative strategy (Fig. 67.14). This strategy could include a repeated dose at a higher concentration, addition of a non-loop diuretic such as 5 to 10 mg of metolazone, or in the most refractory cases of oliguria, a consideration for ultrafiltration. None of these options has been shown to improve mortality when implemented in the ED, but may improve secondary outcomes such as rehospitalization or the rate of decongestion.[120-123]

Treatment initiation soon after arrival is important, and delays in administering IV diuresis from the ED have been associated with adverse outcomes. One large study found that giving IV furosemide in less than 60 minutes from ED arrival decreased in-hospital mortality for AHF (2.3% versus 6%, NNT = 28).[124] Another found that delays to ED diuresis were associated with an increased hospital length of

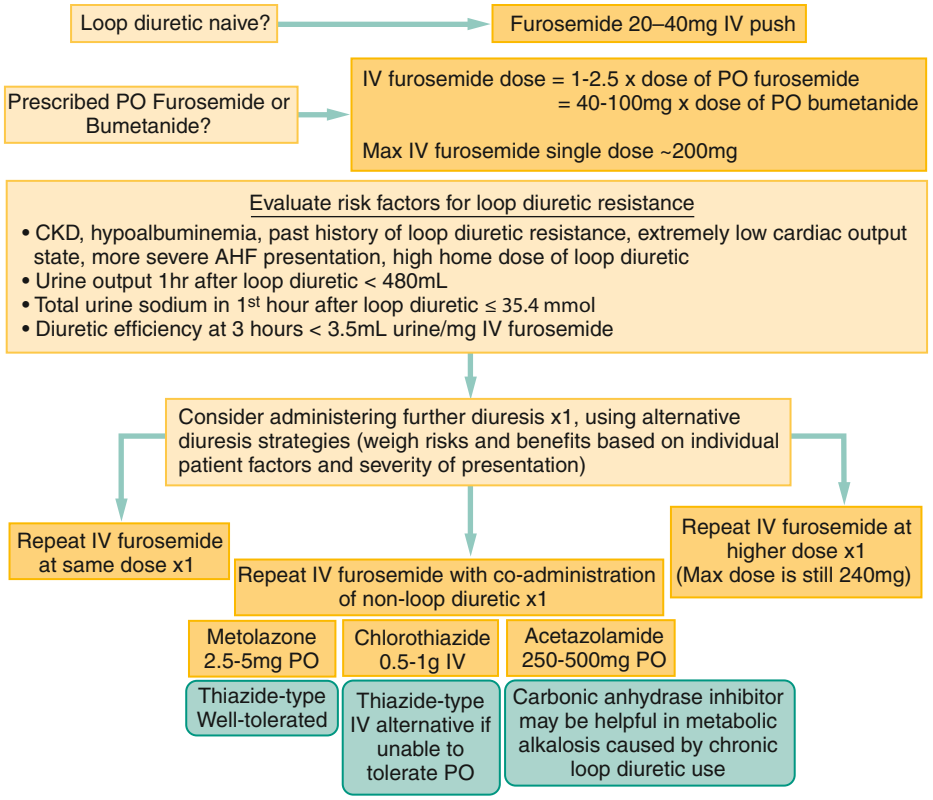

Fig. 67.14 Flowchart algorithm for determining initial IV diuretic dosing, including the management of diuretic resistance when observed or anticipated. IV furosemide, typically by bolus, is the mainstay of AHF treatment, and is preferred over PO treatment because of favorable pharmacokinetics/pharmacodynamics in the face of AHF physiology. IV bolus dosing more quickly offloads central circulation volume/pressure/congestion regardless of whether the patient is hypervolemic, euvolemic, or hypovolemic by clinical assessment of total body water (see Fig. 67.7), and is therefore recommended for both the cardiac and vascular AHF phenotypes (see Fig. 67.12). IV furosemide works over just 1 to 3 hours with a much higher peak concentration, which can help overcome diuretic resistance as well. However, a "braking phenomenon" exists where diuretic resistance can occur or worsen quickly after just a few high-dose IV administrations. Diuretic resistance may be anticipated or expected at time of ED presentation when the patient has a chronic high dose of PO loop diuretics, reports that they have worsening AHF symptoms despite increasing their home diuretic dose within the past few days to weeks, presents with signs of acute or chronic CRS, RVD or PHTN, or have severe baseline renal, cardiac, or hepatic disease. Reassessment after an initial IV furosemide dose in the ED may also suggest diuretic resistance, such as when observing a low diuretic efficiency (urine output/furosemide dose), low urine sodium in the first hour, or unexpectedly low urine output. When diuretic resistance is suspected or anticipated, consideration may be given to adjunct therapy (ie, concomitant non-loop diuretic for "sequential nephron blockade," see Fig. 67.10), using furosemide in doses on the higher end of recommended range (2–2.5 × PO dose), and/or repeat dosing. If concerned for fulminant renal failure (eg, total anuria, or failure of above strategies) arranging for ultrafiltration or renal replacement therapy may warrant consideration. *IV*, intravenous; *PO*, oral; *AHF*, acute heart failure; *ED*, emergency department; *CRS*, cardiorenal syndrome; *RVD*, right ventricular dysfunction; *PHTN*, pulmonary hypertension.

stay, especially among those of lower acuity on arrival.[125] There may be some hesitation to give IV diuresis early based on a fear of worsening a patient's renal function. However, numerous studies have found that increases in creatinine after IV diuresis for AHF are very rarely associated with renal tubular injury.[63,126] Instead, IV diuresis is shown to improve outcomes in acute CRS and AHF. Some trials have even shown paradoxically worsened outcomes when patients have small improvements in creatinine during hospitalization compared to those who have an initial (and transient) worsening in creatinine. This may be because central congestion and RVD play a leading role in the development of acute cardiorenal syndrome. Theoretically, the observed benefits with earlier diuresis could be mediated by an acute reduction of central venous congestion and offloading of the pressure-sensitive RV. Further studies are needed before recommending a specific time to diuretic target for all AHF patients, but current evidence suggests that patients may benefit from early diuresis even prior to lab results in the absence of clear contraindications.[64]

DISPOSITION

Hospital admission rates for AHF from the ED are high, exceeding 80% in the United States, yet as many as half of these may be unnecessary.[29,127] In Canada, ED discharge rates are markedly higher (~50%). The decision to admit a majority of AHF patients reflects both the difficulty in performing risk-stratification from the ED and the low tolerance for adverse outcomes. Emergency physicians tend to paradoxically predict high risk in the lowest-risk AHF patients.[128-130] The converse is also true, as EPs predict low mortality rates in the AHF patients who are actually at the highest risk. Numerous reasons may contribute: uncertainty in diagnosis, a lack of clinical practice

guidelines addressing ED disposition, misunderstanding of factors for low versus high risk in AHF, and others.[1,28,29]

Many studies have looked at ED risk factors for short-term outcomes that may inform disposition, several of which have been discussed throughout this chapter and are listed in Figure 67.15. There is stronger evidence for factors that predict high risk (eg, low blood pressure, elevated troponin, acute cardiorenal syndrome, diuretic resistance, RVD, advanced age, recent missed outpatient visits, number of comorbidities, etc.) than there is for low-risk factors that could predict appropriateness for discharge from the ED.[131-133] Figure 67.15 describes a potential pathway for ED risk-stratification based on assessing high to moderate risk factors that should prompt admission or observation. In the absence of any, consideration should be given to patient-level factors, including adherence to guideline-directed medical therapy, access to follow-up, and response to ED therapy, which could impact discharge appropriateness.

Multiple clinical decision rules (CDRs) have been developed for ED-based risk stratification of AHF. However, many lack external validation in a North American population,[75,134,135] were not derived in an ED population, or were found to perform suboptimally when applied to different populations.[136,137] The Emergency Heart Failure Mortality Risk Grade (EHMRG) is an exception in that it has both been externally validated and accurately predicts 7- and 30-day AHF mortality based on 10 routinely obtained ED clinical variables.[128,138] STRATIFY is another validated CDR, which predicts a ranked composite outcome of mortality and other serious adverse events (mechanical cardiac support, intubation, new or emergent dialysis, coronary intervention or MI) at 30 days. STRATIFY includes 13 clinical variables and demonstrated a negative predictive value of 98% at a risk threshold of 5% for the composite outcome. The use of any AHF CDR in a population other than the one in which it was validated is problematic because the regional heterogeneity of AHF is pronounced. For example, the Multiple Estimation of risk based on the Emergency department Spanish Score (MEESSI) CDR performs excellently for predicting AHF mortality in Spanish EDs where it was derived and validated initially. However, when applied in Switzerland, new cutoffs and calibrations were needed to produce similar results.[139]

Absent CS and a lack of availability of definitive care, few AHF patients need transfer. The exception is for LVAD or cardiac transplant patients, where early discussion with a patient's cardiologist regarding the need for transfer is indicated. If ACS is a possible precipitant and PCI is not available, transfer is appropriate. If ACS is considered (see Table 67.1) and PCI is locally available, cardiology consultation in the ED to discuss prompt PCI is warranted. Ischemic testing (eg, coronary catheterization, stress testing, myocardial perfusion imaging, etc.) is under-utilized in patients with AHF, particularly among de novo presentations and in HFpEF.[140,141] Early discussion with cardiology may facilitate ischemic testing, and AHF patients may have improved outcomes when cardiology is part of an inpatient multidisciplinary team. However, in the absence of these indications, routine consultation with cardiology is not needed during the ED course.[142-144]

When a disposition decision for admission or observation is chosen, home medications should be reinitiated soon after stabilization. Altering or withholding guideline-directed medical therapies for HF during hospitalization is independently associated with increased mortality.[145] A failure to administer guideline-appropriate medical care occurs in over 10% of all AHF hospitalizations.[146]

The absence of high-risk features does not necessarily imply low risk. Thus, in patients without any high-risk features, 24-hour observation or "short-stay unit" disposition is a reasonable option.[127] Proposed criteria for observation appropriateness include SBP greater than 120 mm Hg, respiratory rate less than 32 breaths/min, BUN less than 40 mg/dL, creatinine less than 3.0 mg/dL, a lack of ischemic changes on ECG, and troponin less than the 99th percentile.[29] It should be noted that these criteria are based on an absence of high-risk factors, but validation is pending the results of a prospective multicenter North American trial currently underway.[127]

When a patient lacks any high or moderate risk criteria and discharge is considered, efforts should focus on improving symptoms with ED therapy, ensuring reliability of follow-up, and adherence to guideline-directed medical therapies (see Fig. 67.15).[28,29] Outpatient follow-up within a week of direct discharge from the ED is independently associated with a lower risk of 7-day mortality (relative risk of 0.17 for outpatient visits, 0.32 for email or phone follow-up).[147] Other risk factors for 7-day mortality among patients directly discharged from the ED include age 80 years or greater, baseline SBP less than 100 mm Hg, tachycardia, bradycardia, hypoxia on ED arrival, and hyperkalemia. Although mortality in the month following ED discharge is 3% to 4% overall, there does not appear to be significant differences in the daily rate of death across this timeframe.[147] This may suggest that once high-risk factors of a given ED AHF patient presentation have been ruled out, the remaining mortality risk is primarily based on intractable patient factors at baseline (eg, comorbidities, socioeconomic variables, severity of chronic HF, etc.). Conversely, rehospitalizations and repeat ED visits are far higher in the first 7 days, peaking at 2 days post-discharge, before leveling off during days 8 through 30 after discharge.

For patients with significant fluid overload, admission to the hospital rather than placement in observation status or a short-stay unit should be considered because prolonged diuresis may be needed. When AHF patients are admitted, not all require telemetry. Telemetry should be reserved for those with electrolyte abnormalities, evidence of myocardial injury, prior history or new onset of arrhythmia, or other conditions that predispose to altered electrical signaling in the heart. Likewise, intensive or cardiac care unit admissions should be reserved for those who require ventilatory support or use of IV vasoactive medication, recognizing that institution-specific guidelines may exist for the latter.

Fig. 67.15 Disposition and risk stratification algorithm for ED AHF patients. The algorithm begins with ruling out the presence of moderate- to high-risk features, since the predictive value of these for ruling in a need for hospital admission is much better demonstrated than the value of low-risk features for determining who can be discharged from the ED. This difficulty in identifying low risk is a contributing factor to the fact that 80% of ED AHF patients are brought in to the hospital for admission or observation, but up to 50% of admissions are likely unnecessary. For the purposes of the algorithm, "high" versus "moderate" risk features both indicate a likely benefit to bringing the patient in to the hospital, with the difference being the relative level of care. High-risk features suggest consideration of ICU or step-down unit. Moderate-risk features support bringing the patient into the hospital, but potentially anywhere from observation to step-down depending on symptoms, the presence of low-risk features, and clinical response to ED therapy. De novo HF (ie, AHF without a previous diagnosis of chronic HF) should also prompt hospitalization in most cases, because such patients should undergo urgent evaluation for underlying causes of their HF, and initiation of GDMT. If a patient has no moderate- or high-risk features, history of HF is known, and there is no indication for transfer (eg, LVAD), they may be appropriate for direct ED discharge versus observation. Discharge is favored when the patient is prescribed appropriate GDMT, symptomatically improved with ED treatment (or had only mild/nonlimiting symptoms to begin with), and can obtain close outpatient follow-up (preferably within 1 week). Finally, this algorithm is meant to provide a suggested (and relatively conservative) framework rather than a definitive policy because no single risk-stratification approach is currently available to capture the heterogeneity of all AHF presentations seen in the ED. Thus, hospitalization versus discharge directly from ED may also be considered in the context of individual presentations, patient-specific goals/preferences, clinical judgment, and shared decision making when possible. *ED*, emergency department; *AHF*, acute heart failure; *ADHF*, acute decompensated heart failure; *ICU*, intensive care unit; *GDMT*, guideline-directed medical therapy; *PPV*, positive-pressure ventilation; *ACS*, acute coronary syndrome; *SBP*, systolic blood pressure; *AKI*, acute kidney injury; *CKD*, chronic kidney disease; *HFrEF*, HF with reduced ejection fraction; *HFpEF*, HF with preserved EF; *ACE inhibitor*, angiotensin-converting enzyme inhibitor; *ARB*, angiotensin receptor blocker; *ARNI*, angiotensin receptor-neprilysin inhibitor; *LVEF*, left ventricular ejection fraction; *eGFR*, estimated glomerular filtration rate; *HTN*, hypertension.

CHAPTER 67: QUESTIONS AND ANSWERS

1. A 59-year-old female with a smoking history who has never been to the doctor before presents to the ED with 2 weeks of dyspnea and no known past medical history. Evaluation is notable for BNP 650, creatinine 1.5, wheezing on lung exam, CXR with cardiomegaly but no pulmonary edema, and LUS demonstrating more than 3 B-lines in 2 of 4 lung zones on each hemithorax. Which of the following is the most likely/appropriate diagnosis?
   a. Advanced chronic heart failure
   b. Acute decompensated heart failure
   c. Acute exacerbation of chronic obstructive pulmonary disease
   d. De novo acute heart failure

Answer: D. The patient presents with 3 or more B-lines in 2 of 4 lung zones on each hemithorax, which is highly specific for acute heart failure (AHF). Because the patient does not have a known past history of chronic heart failure, her more specific diagnosis is "de novo acute heart failure," and not "acute decompensated heart failure." "Advanced chronic heart failure" is a subset of chronic heart failure at the end stages of chronic pump dysfunction. Because the patient presented for unscheduled care due to heart failure (ie, true of essentially all patients presenting to the ED for HF symptoms, as opposed to a scheduled outpatient visit), this case is by definition acute heart failure and not chronic heart failure. Finally, although wheezes on exam may lead the clinician to think of COPD exacerbation, auscultated wheezing is common in AHF and neither sensitive nor specific (likelihood ratios positive and negative = 0.6, 1.8) enough to significantly inform a diagnosis of AHF versus COPD on its own.

2. A 68-year-old ED patient with a history of HFrEF presents with 3 weeks progressive edema and exertional dyspnea, pulmonary edema on portable CXR, respiratory rate 35, BP 128/67, and SpO_2 86% on room air. Last week his cardiologist increased his home dose of furosemide from 40 mg PO daily to 40 mg BID, with unchanged urine output and no improvement in symptoms. Which of the following is the best step in management?
   a. Nasal cannula oxygen, 160 mg IV push furosemide now
   b. Nasal cannula oxygen, 60 mg IV push furosemide only if creatinine is not elevated from baseline
   c. BiPAP, 160 mg IV push furosemide now
   d. BiPAP, 60 mg IV push furosemide only if creatinine is not elevated from baseline

Answer: C. This patient presents with hypoxia, tachypnea, and other signs of respiratory failure, and noninvasive positive-pressure ventilation (NPPV) such as CPAP or BiPAP should be the first-line resuscitative therapy. Although nasal cannula may sufficiently reverse the hypoxia, NPPV has beneficial effects on work of breathing and possibly on AHF hemodynamics. IV furosemide dosing should be 1 to 2.5 times the patient's daily home PO dose (or 40–80 mg IV if they do not take furosemide). Because this patient was recently increased to 80 mg, a dose of 80–200 mg IV would be possible. Additionally, since the change resulted in no change in symptoms at home, this would suggest the patient is experiencing some aspect of acute cardiorenal dysfunction, loop diuretic resistance, or both. Thus, a dose at the higher end of the acceptable range is likely advisable. Finally, elevations in creatinine due to acute cardiorenal syndrome are usually due to congestion, and if creatinine rises further after IV loop diuresis this typically represents a transient response not associated with long-term renal dysfunction. In other words, waiting for a creatinine level is not necessary in most cases, because worsening creatinine after furosemide rarely represents a true acute kidney injury. By contrast, delayed administration of furosemide in AHF is associated with adverse outcomes.

3. If the patient in the previous question instead had a BP of 200/125, and was diuretic naïve, which of the following would be the best management approach?
   a. BiPAP, nitroglycerin 1–2 mg IV push repeated until SBP 150 mm Hg, furosemide 40 mg IV push
   b. BiPAP, morphine 4 mg IV push, furosemide 40 mg IV push
   c. BiPAP, isosorbide mononitrate 60 mg PO, furosemide 40 mg PO
   d. BiPAP, nitroglycerin 1–2 mg IV push repeated until SBP <150, furosemide 40 mg PO

Answer: A. In this variation of question two, the patient is diuretic naïve and has features suspicious for the vascular phenotype of AHF. Furosemide should therefore be dosed at 40–80 mg IVP, and a 25% or less reduction in SBP should be targeted with repeated IV push nitroglycerin, 1–2 mg per dose. In patients with less distress or less severe hypertension who still show the vascular phenotype, sublingual nitroglycerin is a useful alternative because absorption and bioavailability are similar to IV. Transdermal and PO nitrates are not currently thought to be useful in AHF, by contrast, because of less favorable kinetics.

4. A 78-year-old patient presents to the ED with hypotension and acute respiratory failure. His daughter states he complained of severe crushing chest pain 7 days ago, but refused to go to the hospital. His ECG shows deep Q waves and T-wave inversions in the inferior leads without ST elevation, and harsh systolic murmur is heard on exam. What is the best next step in management?
   a. Dobutamine, consult cardiac surgery for mechanical hemodynamic support and repair of ruptured papillary muscle
   b. Dobutamine, consult interventional cardiology for PCI
   c. Norepinephrine, consult cardiac surgery for mechanical hemodynamic support and repair of ruptured papillary muscle
   d. Norepinephrine, consult interventional cardiology for PCI

Answer: C. This patient presents with cardiogenic shock, likely due to papillary muscle rupture given the murmur consistent with mitral regurgitation, and an ECG suggesting that a STEMI may have occurred several days ago. Surgical management is the definitive therapy. While arranging for surgical management, norepinephrine is the first-line vasoactive therapy for cardiogenic shock patients. Other inotropic and/or vasoactive medications such as epinephrine, dobutamine, milrinone, or levosimendan are reasonable second-line options.

5. In a patient with AHF and a history of HFrEF whose symptoms have resolved after a single dose of IV furosemide in the ED, which of the following profiles suggests the lowest risk to be discharged from the ED?
   a. No renal or hepatic dysfunction, takes no home medications
   b. SBP 165 mm Hg, compliant with home meds including carvedilol and sacubitril-valsartan
   c. Patient's PCP can see them for follow-up in 21 days from now
   d. No comorbidities, de novo presentation of AHF

CHAPTER 67: QUESTIONS AND ANSWERS—Cont'd

Answer: B. This patient who has resolution of or marked improvement in symptoms after initial ED treatment is a good candidate for discharge from the ED. In option A, a lack of acute renal or hepatic dysfunction would further increase the appropriateness for discharge, but having HFrEF the patient should be on a minimum of a beta-blocker and ACE/ARB/ARNI for guideline-directed medical therapy (GDMT). Discussion with the patient's physician to initiate these therapies and arrange close follow-up could be an appropriate strategy with answer A, but in answer B the patient is already on appropriate GDMT. Elevated BP in option B is also a sign of very low risk for morbidity and mortality. Patients who are able to follow up with their physician within 7 days of ED discharge after AHF therapy have significantly improved outcomes, so answer C is incorrect. Although option D would suggest a similarly low-risk presentation, with de novo AHF it is reasonable to keep a patient for further testing and evaluation for their cardiac dysfunction and its underlying etiology. Of final note, none of the answer options suggest a patient who necessarily requires a full hospital admission. A 24-hour-or-less observation stay would likely be appropriate for A,C, or D.

68

Pericardial and Myocardial Disease

Nicholas J. Jouriles

KEY CONCEPTS

- Pericarditis and myocarditis have chest pain, laboratory results, and ECG findings that can mimic acute myocardial infarction (AMI). When the diagnosis is not clear, early coronary angiography definitively identifies or excludes AMI.
- Acute pericarditis is treated with aspirin or nonsteroidal antiinflammatory drugs. Adding colchicine decreases the rate of recurrence.
- Cardiac tamponade presents many ways. Patients with dyspnea, distended neck veins, hypotension, and muffled heart sounds should have the diagnosis made by bedside ultrasound. Pericardiocentesis is therapeutic and may help establish the etiology.
- Myocarditis should be considered in any patient with viral illness symptoms and chest pain.
- Patients with newly diagnosed hypertrophic cardiomyopathy should avoid strenuous exertion until evaluated by a cardiologist. Beta-blockers are the mainstay of therapy; nitrates should be avoided.
- Dilated cardiomyopathy presents with symptoms of heart failure or rhythm disturbance.
- Many cardiomyopathies have genetic origins. Send patients for both cardiology and genetics follow-up.

MYOCARDIAL DISEASE

Cardiomyopathies are a heterogeneous group of diseases associated with myocyte injury, which leads to ventricular hypertrophy, fibrosis, or dilation. Clinical symptoms result from the underlying pathology.

Myocytes can be injured by genetic and nongenetic factors (Fig. 68.1). More than one thousand mutations in numerous genes have been identified as etiologies.[1] When injury occurs, pathophysiologic pathways are activated that include neurohumoral factors, immune factors, and cytokines. These cause myocyte dysfunction followed by remodeling, involving either hypertrophy or dilation. There is an increase in interstitial fibrosis, which impairs ventricular filling and leads to increased metabolic demand. At a cellular level, these may involve the troponin complex, intracellular concentration of calcium, myocardial subproteins, or the sarcomere. There is an alteration in the myocyte's ability to contract, and the electrophysiology is altered. The correlation between genotype, phenotype, nongenetic factors, and clinical presentation is not known.

Dilated Cardiomyopathy

Foundations

Dilated cardiomyopathy (DCM) is characterized by ventricular dilatation and decreased contractility.[2] Clinical DCM is the final common response to many genetic and non-genetic processes. The incidence of DCM is estimated to be 35 cases per 100,000 persons. The true incidence is probably underestimated because many asymptomatic cases are undiagnosed. DCM occurs in adults and children. Up to one-third of cases are caused by mutation of genes encoding the cytoskeleton, sarcomere, and nuclear envelope proteins. Secondary neurohumoral changes contribute to remodeling and ongoing myocyte damage.[3] Many of the genetic causes are mutations coding for the protein titan, which provides passive force and regulates sarcomere contraction and signaling.[4] The histology is irregular myocyte hypertrophy with fibrosis or necrosis, which leads to muscle changes. The result is impaired myocardial force generation, which initiates a vicious cycle that increases the burden on the remaining cells and leads to increased stress, more work, and more cell death. This results in the clinical symptoms of heart failure or dysrhythmias.

Clinical Features

Symptoms have an insidious onset. Heart failure occurs as the initial manifestation in 75% of adults, with dyspnea (usually with exertion or while supine) being the major symptom. Chest pain, peripheral edema, dysrhythmias, syncope, and sudden death also occur. Rhythm disturbances implicate conduction system involvement. Shortness of breath and fluid overload are the most common presentations in children.

Diagnostic Testing

Abnormal ventricular contractility defines DCM, and an ejection fraction less than 45% is required for diagnosis. Echocardiography shows left ventricular (LV) dilation, reduced systolic function, and variable wall motion abnormalities. End-diastolic and systolic volumes are increased by more than two standard deviations from normal.[3] Pulmonary arterial line placement is often performed, revealing elevated pulmonary capillary wedge pressure and central venous pressures.

Electrocardiogram (ECG) findings are nonspecific and may include poor R wave progression, intraventricular conduction delay, left bundle branch block or left ventricular hypertrophy (Fig. 68.2) with or without repolarization changes. Ectopy is common. Chest x-ray shows cardiomegaly and possible pulmonary congestion. Troponin and BNP may be elevated.

MRI showing delayed gadolinium enhancement can indicate necrosis or scarring.[3] Right-sided failure can develop from primary right-sided disease, persistent volume overload from left-sided disease, or may represent occult atrial septal defect. The echocardiogram or ventricular imaging during coronary angiography evaluate for right-sided pathology as well. For definitive diagnosis, endomyocardial biopsy may be necessary, although histologic abnormalities are nonspecific.

Differential Diagnosis

The most common nongenetic cause of DCM is ischemic cardiomyopathy caused by coronary artery disease. Other etiologies include toxins such as alcohol, cocaine, methamphetamine, chemotherapy with

anthracycline related agents, hemochromatosis, pseudoephedrine, ephedra, phenothiazines, lithium, anabolic steroids, clozapine, and hydroxychloroquine.[2]

Management and Disposition

Treatment is supportive to reduce heart failure, rhythm disturbances, and conduction system issues. Supportive measures include adequate rest, weight control, abstinence from tobacco, moderate salt and ethanol consumption, and structured physical activity.

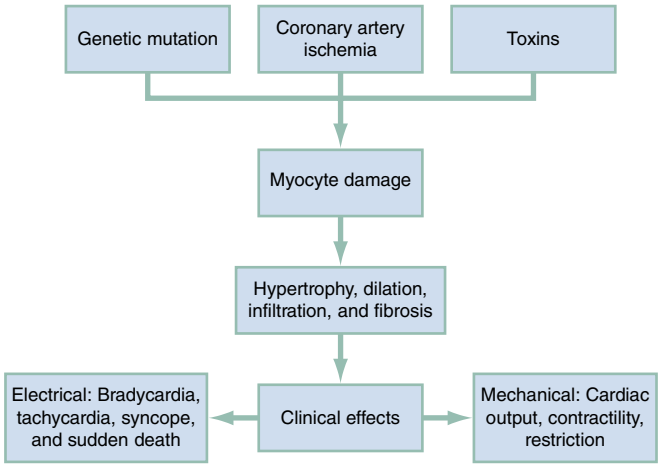

Fig. 68.1 Cardiomyopathy pathogenesis.

Medical treatment includes diuretics and vasodilators for patients who present with dyspnea or hypoxemia. We recommend starting with intravenous furosemide at one to two times the patient's baseline dose, or 10 mg if diuretic naïve. For vasodilators, nitroglycerine can be initiated at 5 mcg/minute and titrated upward, closely monitoring blood pressure and symptoms.

To improve long-term outcomes and reduce heart failure exacerbations, patients should be on a closely monitored heart failure regiment. For patients with mild exacerbations who may be discharged, the emergency clinician might initiate or titrate a medication in coordination with the patient's cardiologist. Angiotensin-converting enzyme inhibitors (ACEIs), beta-blockers, and angiotensin receptor blockers (ARBs) have mortality benefit. Among beta-blockers, carvedilol (starting dose 3.125 mg BID, titrated up to target dose 25 mg BID) is well studied and has proven effective.[3,5] ARB treatment produces beneficial LV remodeling in nonischemic dilated cardiomyopathy. Maximal beneficial remodeling is achieved within 12 to 16 months.[6] Newer treatments include angiotensin receptor-neprilysin inhibitor valsartan/sacubitril, which has shown early promise in the management of dilated cardiomyopathy. Experimental treatments include sinoatrial modulator ivabradine[6] and autologous somatic tissue-derived stem cells transplanted into a DCM heart to stimulate native regeneration.[7] Both have shown limited clinical promise to date.

Biventricular pacing to coordinate both ventricles can help clinical function. ICD therapy reduces all-cause and cardiovascular mortality in patients with nonischemic cardiomyopathy.[8] Current guidelines call for implantable cardioverter-defibrillator (ICD) placement when ejection fraction (EF) is less than 35%. Patients with EF less than 35% who have not had electrophysiologic evaluation should be referred for

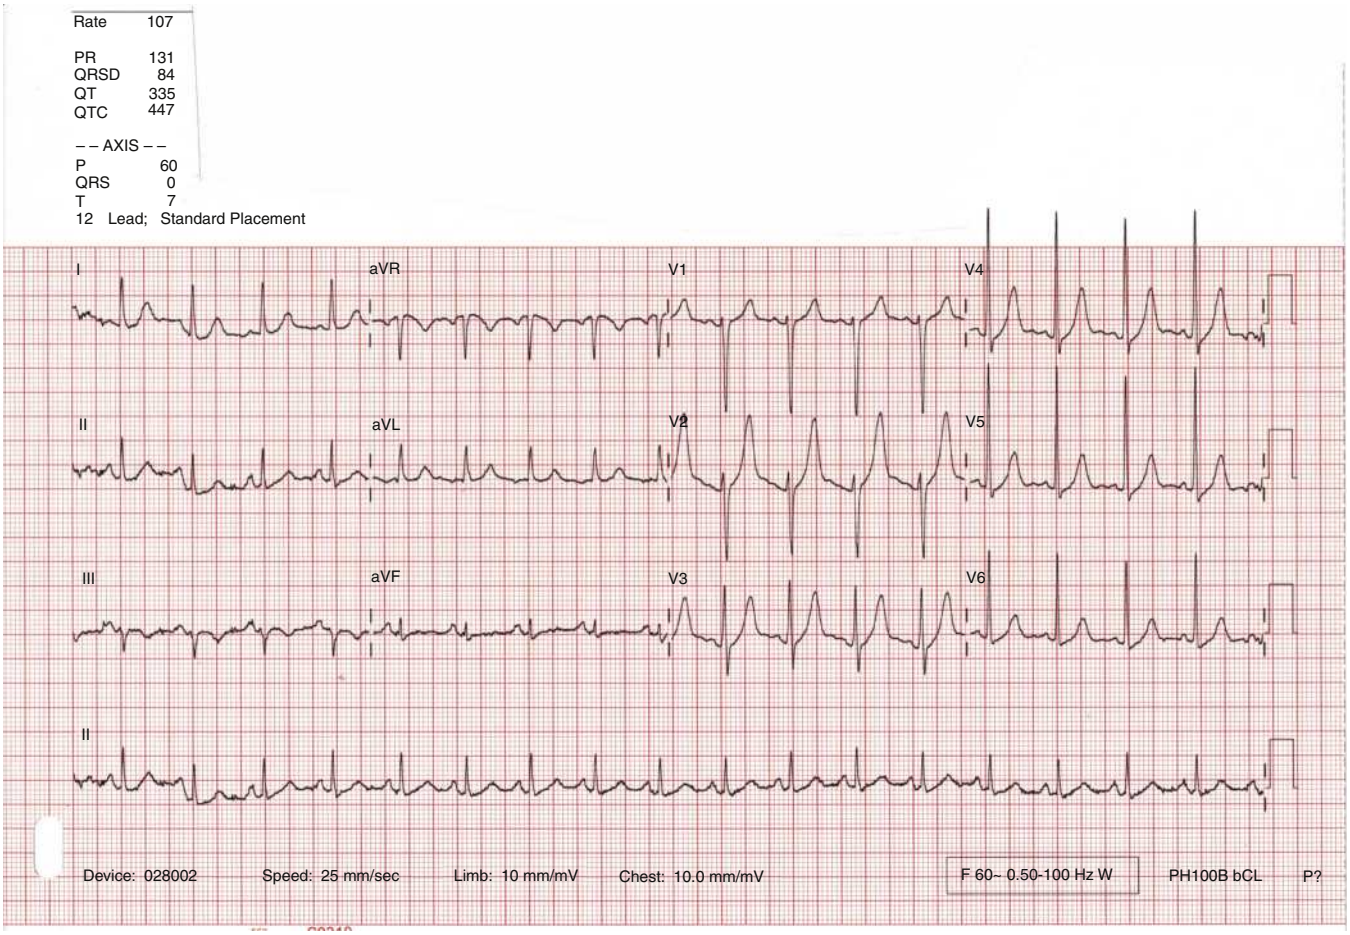

Fig. 68.2 EKG showing left ventricular hypertrophy.

consideration of ventricular synchronization pacing. A search for a more precise way to predict the need for an ICD is ongoing.[9]

Disposition

Patients with DCM show progressive deterioration. There is an increased risk of sudden death, especially with some genetic types. Because medical therapy usually fails, with a mortality of 20% by 3 years, DCM is the leading indication for cardiac transplantation.

Emergency department (ED) patients should be admitted if they have new rhythm disturbances that cannot be adequately controlled with oral medications, deterioration of cardiac function as determined by symptoms or diagnostic data, shock, or significant pulmonary fluid overload that cannot be reversed. Patients whose DCM is first diagnosed in the ED should be hospitalized unless the symptoms are mild and a cardiology consult is available in the ED. If the emergency clinician can control or convert atrial rhythm disturbances, obtain sequential testing for mildly elevated troponin levels, and control symptoms in patients with known DCM, discharge is possible. Medication adjustments, such as increased diuretic dose or adding a beta-blocker or ACEI, should be considered, but follow-up within 48 hours is indicated. Heart failure clinics have been shown to reduce morbidity and mortality, making them an excellent option if available locally. Otherwise, the patient should be referred to a cardiologist.

Hypertrophic Cardiomyopathy

Foundations

Hypertrophic cardiomyopathy (HCM) is one of the first diseases understood at the genetic, anatomic, pathophysiologic, and clinical levels. It is the most commonly inherited cardiac disease. HCM is caused by sarcomere gene mutations that result in left ventricular hypertrophy and scar formation, which then lead to dysrhythmias and heart failure.[10] It is inherited as autosomal dominant, but genotype-phenotype correlations have been inconsistent. More than 200 mutations have been identified.[11] Mutations for beta-myosin heavy chain and myosin binding protein C are the two most common genetic defects, but 40% of cases have no genetic abnormality identified to date. The mutations lead to abnormal cardiac proteins that affect actin-myosin bridging, stroke power, sensitivity to adenosine triphosphate (ATP), and sensitivity of the muscle to calcium. To compensate for abnormal protein, the muscle hypertrophies and fibroses. The combination of myocyte disarray, hypertrophy, and fibrosis leads to the clinical manifestation of dysrhythmias and heart failure. Nongenetic factors such as protein translation and the environment also affect phenotype and clinical outcomes.[12] Specific mutations correlate with sudden cardiac death. Only half of patients with Arg403Gln mutation survive past age 45 years.

The defining anatomic feature of HCM is a hypertrophied left ventricle in the absence of another cause. The ventricular cavities are small or normal, and atrial dilation is common. Hypertrophy is asymmetrical and generally most severe at the base of the intraventricular septum near the aortic valve. Left ventricle (LV) outflow is obstructed in one-third of cases and can be provoked, or dynamic, in one-third more. Histology is myocyte hypertrophy and disarray with interstitial fibrosis. The myocytes are enlarged with bizarre shapes and pleiotropic nuclei. The abnormal cells are widely distributed with a preference for the intraventricular septum.[12]

Clinical Features

Although HCM occurs at all ages, most patients are diagnosed between ages 30 and 40 years. Approximately 2% of cases are diagnosed in children younger than 5 years old, and 7% are diagnosed before 10 years old.

Presentation varies widely. Common symptoms are a result of diastolic dysfunction (exertional dyspnea, orthopnea, peripheral edema), LV outflow obstruction (exertional dyspnea or syncope), imbalance between myocardial oxygen supply and demand (chest pain caused by decreased blood flow into the coronary arteries), and dysrhythmias (palpitations, atrial fibrillation in 20%, ventricular tachycardias, and sudden death). Physical examination shows a displaced left precordial impulse, strong peripheral pulses, a harsh midsystolic grade 3 to 4 over 6 murmur loudest between the apex and the left lower sternal border. The Valsalva maneuver or changing from standing to squatting changes the murmur.[12] Often, the first presentation is sudden death, which most commonly occurs during periods of exertion.

In the ED, the diagnosis should be considered in anyone with a family history, characteristic murmur, and cardiopulmonary symptoms not explained by another condition.

Differential Diagnosis

In individuals with murmurs, HCM may be confused with valvular diseases or a ventricular septal defect. In the absence of a murmur, symptoms may suggest mitral valve prolapse, primary pulmonary hypertension or coronary artery disease.

Diagnostic Testing

The ECG is abnormal in approximately 90% of patients. The most common abnormalities are atrial fibrillation, left ventricular hypertrophy, ST segment alterations, T wave inversion, left atrial enlargement, abnormal Q waves, and diminished or absent R waves in the lateral leads. The chest radiograph may be normal or may show left ventricular or atrial enlargement.

Echocardiography findings include asymmetrical left ventricular hypertrophy, left ventricular outflow tract narrowing, a small left ventricular cavity, and reduced septal motion. Unlike fixed ventricular flow obstructions, the amount of obstruction imaged changes from beat to beat. This dynamic characteristic of HCM distinguishes it from the discrete forms of obstruction. Left ventricle obstruction at rest is an independent predictor of heart failure.

MRI can help with diagnosis and prognosis. It provides an accurate measure of wall thickness and identifies the location and extent of fibrosis. Extensive late gadolinium enhancement, which represents scarring, is associated with sudden death.[13] MRI for HCM is rarely available to the EP and should be used by the cardiologist to manage long-term care.

Management

Beta-blockers and calcium channel blockers are used to control exercise-related symptoms. A beta-blocker such as metoprolol 12.5 mg BID and titrate up to 100 mg BID is the first-line treatment. For those intolerant of beta-blockers, diltiazem 30 mg QID is indicated. Disopyramide (100 to 150 mg Q6H) is often added to reduce resting gradient across the aortic valve. These treatments do not alter the natural history of disease.[11] Spironolactone is not efficacious.[14] ARB agents are being studied.[10] A small model inhibitor of myosin MYK-461 has been effective in preventing HCM in mouse models.[15] Nitroglycerin should be avoided in HCM-associated chest pain because it decreases ventricular volume, exacerbating outflow tract obstruction.

Atrial fibrillation can cause marked hemodynamic compromise and severe CHF. Cardioversion and rate control should be attempted. If the patient is stable, start with diltiazem 0.25 mg/kg (based on weight) or esmolol 50 mcg/kg/min. These doses may be repeated or an infusion started. If not successful at rate control (HR < 100) or the patient is hypotensive (BP < 90 systolic), then electrical cardioversion is indicated. For HCM patients with atrial fibrillation, the risk of stroke is high, and anticoagulation (rivaroxaban 20 mg QD, apixaban 5 mg BID, or dabigatran etexilate 150 mg BID) should be started from the

ED.[12] Amiodarone (600 mg QD divided into 2 or 3 doses) is the drug of choice long term to treat atrial fibrillation as well as ventricular dysrhythmias. Phenylephrine is the vasopressor of choice for persistent hypotension when intravenous fluids have not improved blood pressure. Beta-agonists, such as dobutamine, increase the gradient across the outflow tract obstruction and should be avoided.

Invasive procedures, such as myomectomy or septal alcohol ablation, may be needed to treat severe cases. Dual-chamber pacing decreases outflow gradient and improves symptoms but does not improve mortality.[11]

Implantable cardioverter-defibrillators are indicated for patients who survive sudden cardiac death (SCD) or have certain risk profiles.[11] Risk calculation is based on patient age, family history of one or more first-degree relatives with SCD at age less than 40 years or with confirmed HCM, size of left ventricle and atrium, left ventricle outflow gradient, presence of ventricular tachycardia, and unexplained syncope. These factors all reflect the extent of interstitial fibrosis.[16]

Disposition

A patient with angina, syncope, near-syncope, dysrhythmias, and abrupt hemodynamic changes should be hospitalized. A patient suspected to have HCM should be seen by cardiology in the ED or hospitalized to expedite making the diagnosis.

The natural history of HCM is variable and probably reflects the many different genetic causes. The clinical course is either heart failure, atrial fibrillation, or sudden death. With modern therapy, most patients have low premature mortality.[11]

The evidence for the role of exercise is unclear. Newer evidence shows that the risk of SCD may be lower than previously reported, and moderate or recreational exercise may be beneficial.[17] HCM remains the most frequent cause of nontraumatic sudden death in the young, however, and some still recommend that patients not participate in competitive sports. Current evidence is unclear about which athletes benefit from SCD risk screening.[18] Given the current evidence, emergency physicians should advise their discharged patients to eliminate strenuous exercise until cardiology evaluation.

Restrictive Cardiomyopathy

Foundations

Restrictive cardiomyopathy (RCM) is a gradual and progressive limitation of ventricular filling secondary to myocardial infiltration. There is stiffness of the ventricles with normal diastolic volume and normal ventricular wall thickness.[19] RCM is the least common type of cardiomyopathy, accounting for less than 5% of all cases. The most common etiology in the United States is amyloidosis. Other causes include sarcoidosis, hemochromatosis, scleroderma, neoplastic cardiac infiltration, glycogen storage disorders, Fabry disease, Gaucher disease, and mutations related to myocardial muscle proteins.[20]

Restriction of ventricular filling and compliance results in low ventricular volumes, high end-diastolic ventricular pressures, and decreased cardiac output. Systolic function is maintained. Endomyocardial biopsy shows interstitial fibrosis and myocyte hypertrophy, neither of which is pathognomonic. There are no specific genetic mutations. Grossly, there is atrial enlargement and small ventricles. As the disease progresses, the ventricular cavities may become obliterated by fibrous tissue, scarring, or thrombus.

Clinical Features

Most patients are diagnosed in their 50s. The most common symptom is dyspnea. Signs and symptoms may include exercise intolerance (cardiac output cannot be increased because ventricular filling is compromised), pulmonary congestion, elevated central venous pressure, peripheral edema, pulmonary edema, and S_3 and S_4 gallops. Clues to making the diagnosis in children include trouble eating, lack of weight gain, and difficulty exercising.

Differential Diagnosis

Serum troponin and chemistry panel should be obtained to exclude myocardial infarction or renal and hepatic mimics. Because some causes of RCM can be treated or managed, it is important to search for etiologic causes, which requires extensive serologic testing and cardiac MRI. These can be performed as an inpatient or outpatient. Comprehensive echocardiography should be obtained to confirm the diagnosis.

Diagnostic Testing

ECG findings are not specific. Chest x-ray shows cardiomegaly and often pulmonary congestion.[21] BNP may be elevated. Point of care ultrasound (POCUS) shows thickened ventricles and no change in isovolemic relaxation time with respiration. Central venous pressure tracings show rapid filling causing a sudden dip in pressure and then a sudden plateau, yielding a curve similar to a square root sign. CT can also differentiate RCM from constrictive pericarditis. Pericardial calcification or history of radiation therapy favors constrictive pericarditis over RCM.

Management

Most of the underlying causes of RCM are untreatable, with the exception of hemochromatosis. Patients rely on high filling pressures, making volume management challenging. A trial of beta-blockers (metoprolol 25 mg BID or atenolol 25 mg QD) or calcium channel blockers (diltiazem 30 mg QID) may help increase filling time and thus cardiac output. ACEIs (lisinopril 10 mg QD) and ARBs (losartan 50 mg QD) may also help.[20] Patients with RCM should be maintained in sinus rhythm because they are dependent upon the atrial contribution to cardiac output. RCM is relentless, with 64% of patients dying within 5 years of diagnosis.

Disposition

Patients should be hospitalized for shortness of breath or hypotension that does not respond to ED treatment. Patients with either tricuspid regurgitation or small LV end-diastolic volume have a poor prognosis.[19]

Peripartum Cardiomyopathy

Foundations

Peripartum cardiomyopathy (PPCM) was first described in 1849. It is a rare, often dilated, cardiomyopathy with systolic dysfunction that presents in late pregnancy or the early postpartum period. Although the condition is prevalent worldwide, women with African ancestry seem to be at greatest risk even after confounders are eliminated. Other risk factors include preeclampsia, advanced maternal age, tocolytic use, twins, obesity, and cocaine use.[22] The incidence is thought to be between 1 in 1500 and 1 in 4350 live births and increasing, possibly because of improved detection or rising maternal age. The exact pathogenesis is unknown. Some women have an underlying sarcomere gene mutation.[22]

Clinical Features

PPCM is similar to DCM, with heart failure symptoms predominating on initial presentation. Patients have dyspnea and edema and may also have chest pain or palpitations. Unfortunately, these symptoms can be expected in normal pregnancy, making distinguishing pathology from expected physiologic changes challenging at times. Acute alterations in symptoms, sudden or worsening chest pain or dyspnea, or difficulty performing routine activities are diagnostic clues. Physical

examination often reveals tachycardia, tachypnea, pulmonary rales, and an S3 heart sound.

The ECG may show LV hypertrophy or nonspecific ST-T wave changes. On echocardiography, all four chambers are enlarged, with a reduction in left ventricular systolic function.

Differential Diagnosis

Other causes of symptoms should be evaluated. The differential diagnosis includes preeclampsia, myocardial ischemia including coronary dissection, pulmonary embolism, pneumonia, and primary rhythm disturbance.

Diagnostic Testing

As with any patient presenting with dyspnea, an ECG is a first-line diagnostic test to look for ischemia and rhythm disturbances. Laboratory values can assist in narrowing the differential. A chemistry panel evaluates for electrolyte disarray and renal impairment, while a troponin test assesses for ischemia or RV strain if pulmonary embolism is being considered. A D-dimer is of low utility, because it is elevated in most women from the third trimester until at least a month postpartum. Brain-natriuretic peptide will be elevated in PPCM. A chest radiograph may reveal pulmonary edema, and patients at high risk of PE by the Wells score should undergo CT angiography. Pulse oximetry should be used to monitor oxygenation and cardiac monitoring to assess for dysrhythmias. In cases of maternal instability, fetal monitoring is indicated to follow the pregnancy.

Management

Acutely, patients with PPCM can present with a range of mild symptoms to cardiogenic shock. The management will be titrated to the patient's presentation. Those with mild symptoms will benefit from reduction of preload, but furosemide is pregnancy category C. Afterload reduction with hydralazine (5–10 mg intravenous) is safe and effective. Patients in shock should be managed with vasopressors and inotropes, in consultation with cardiology and obstetrics (see Chapter 3). Delivery within 48 hours may be needed, especially if the patient is unstable. All patients should have obstetrics evaluation of the fetus either in the ED or by transfer to the OB floor.

Long-term treatment of PPCM includes judicious physical activity, beta-blockers, alteration of preload with nitrates and diuretics, increase ventricular contractility, and afterload reduction. Beta-blockers are likely safe but have not been studied. For those women who are still pregnant at presentation, ACE inhibitors and ARBs are contraindicated. The effect of breastfeeding on PPCM is unknown.[2]

Disposition

ED patients first diagnosed with PPCM require obstetrics consultation, often with cardiology consultation as well. Patients with pulmonary embolism or continued dyspnea should be hospitalized. Fetal monitoring for at least 6 hours is indicated if the patient is still pregnant. Recovery of LV function occurs in 45% to 78% of patients. Factors associated with favorable prognosis include small LV diastolic dimension, ejection fraction greater than 35% at the time of diagnosis, absence of troponin elevation, and absence of LV thrombus. Cardiomegaly that persists for more than 6 months has a 50% mortality at 6 years. There is a substantial risk of recurrence with subsequent pregnancies with high morbidity and mortality.[2] Mortality for PPCM in the United States is approximately 2%. Mechanical support or cardiac transplantation may be needed for those who do not fully recover.[22]

Takotsubo Syndrome

Foundations

Takotsubo syndrome (TS) is the preferred name for takotsubo cardiomyopathy because there is rarely significant long-term myocardial damage. Previous names also included stress cardiomyopathy, broken heart syndrome, or tako-tsubo cardiomyopathy.

TS was first reported in Japan in 1991, with hundreds of cases reported subsequently (Box 68.1). In Japanese, *tako-tsubo* means octopus trap, and the condition is so named because the observed shape of the left ventricle resembles the urn-like device used to catch octopi. Physical and emotional stressors can trigger TS. Elevated circulating catecholamines lead to cardiac myocyte dysfunction. The pathophysiology of the unique octopus trap shape is unknown.[23] One theory is that excessive stimulation of excitatory neurotransmitters produces regional cardiac stunning. Serum catecholamines are more than twice as high in TS patients than in those with myocardial infarction.[24]

Clinical Features

In the United States, TS presents most often in women, with 85% being over age 60, often after emotional stress. Risk factors include smoking, alcohol abuse, anxiety, and hyperlipidemia.[23] Symptoms include chest pain, palpations, and dyspnea on exertion. POCUS shows regional wall motion abnormalities that often extend beyond the distribution of a single coronary artery.

BOX 68.1 Published Causes of Takotsubo Syndrome

Achalasia
Addison disease
Anaphylaxis
Anesthesia
Asthma
Chemotherapy
Closed head injury
Depression
Diarrhea
Diving

Pancreatitis
Pheochromocytoma
Pneumopericardium
Pregnancy
Scorpion envenomation
Seizures
Sepsis
Sexual intercourse
Stress testing
Subarachnoid hemorrhage
Surgery or medical procedures
Thrombotic thrombocytopenic purpura
Thyrotoxicosis
Transient ischemic attack
Tricyclic overdose
Vomiting

Differential Diagnosis

Differential diagnosis includes acute myocardial ischemia or any syndrome with an adrenergic surge, be it toxic (cocaine, methamphetamine) or endogenous (stress).

Diagnostic Testing

ECG is often consistent with acute coronary syndrome and may include sinus tachycardia, ST elevations or depressions, and prolonged QT intervals. Chest x-ray is unremarkable. Serum troponin is mildly elevated. Serum natriuretic peptide levels are usually quite elevated, up to 6 times normal, and may be the laboratory test that correlates best with TS. Up to 80% of TS patients have elevated BNP. Though not usually available in the ED, MRI during the acute period shows myocardial edema as high signal intensity with a diffuse or transmural distribution which is not seen in myocarditis or ischemia.[23]

Management

In the ED, TS is usually not distinguishable from AMI, and patients should be treated accordingly, including cardiac catheterization for ST elevations on the ECG. There are no randomized trials for specific treatments. Beyond consulting cardiology for catheterization, the emergency clinician should provide supportive care. Phenylephrine is the vasopressor of choice for hypotensive patients, to reduce the risk of dynamic LV outflow tract obstruction.

After hospital discharge, beta-blockers (atenolol 25 mg QD or metoprolol 25 mg BID) may both help the heart and modulate catecholamine levels, and ACE inhibitors (lisinopril 10 mg QD) may improve one-year survival. There is no evidence for any treatment to prevent recurrence.[23]

Disposition

Patients that do not undergo catheterization should be hospitalized for rhythm monitoring and serial cardiac enzymes. Ninety-five percent of patients show complete resolution of symptoms and normalization of their LV apex ballooning and contractile function. Long-term prognosis matches controls at 4 years. The recurrence rate is 10%.

Arrhythmogenic Right Ventricular Cardiomyopathy

Foundations

This is primarily a genetic disease most commonly seen in Italy. Desmosome proteins provide electromechanical connections between myocytes and play a role in signaling cascades and ion channels. Mutations in genes encoding for cardiac desmosome proteins are found in 60% of cases. There is fibrofatty replacement of the myocardium that leads to diffuse myocardial atrophy, occurring most commonly in the RV. Myocardial replacement predisposes to ventricular dysrhythmias and slowly progresses to systolic dysfunction. Electrical changes occur before there is evidence of pathology on x-ray or echocardiography.[25] Endurance athletes develop AVRCM often. More exercise leads to earlier onset and worse symptoms than in non-endurance athletes. Whether this is causal or an association is under investigation.

Clinical Features

The age distribution is bimodal, with patients in either their teens or their forties. The most common symptom is ventricular dysrhythmia leading to syncope or sudden death.[25]

Differential Diagnosis

The differential diagnosis includes ingestion of toxins such as cocaine and methamphetamine, leading to rhythm disturbances, conduction system defects, and myocardial ischemia.

Diagnostic Testing

Clinical diagnosis is challenging. ED workup should include electrolytes, thyroid testing, family history, and ECG. ECG findings may include left bundle branch pattern, tachydysrhythmias, and T wave inversions in leads V1 to V3. Epsilon waves are the hallmark finding in ARVCM but are found in less than one-third of patients. Echocardiogram shows right ventricular dilation and segmental wall motion abnormalities.[18] The workup after the ED includes MRI, which shows similar findings as echocardiogram but with more diagnostic certainty.[26] Electrophysiologic studies and genetic testing may also be needed.

Management

Management includes anti-dysrhythmics, heart failure medication, catheter ablation, and ICD. Heart transplant may be indicated.[25] Amiodarone (200 mg TID) alone or with a beta-blocker (metoprolol 25 mg BID) is the best medical therapy for controlling symptoms as an adjunct to patients with frequent ICD firings.[27]

Disposition

Patients with LBBB or epsilon waves, ventricular tachycardia, newly diagnosed ventricular dilation, or unexplained syncope should be hospitalized. An ED cardiology consult or observation for consultation should be recommended for the rest. Patients should not participate in sports or exercise until cleared by cardiology.[18] Prognosis in ARVCM is related to ventricular dysrhythmias. Risk factors for SCD include dilated right or left ventricle, young age at diagnosis, amount of scar tissue, and genetic predisposition.[27] Patients and relatives should be sent for genetic testing.

Channelopathies

Several uncommon dysrhythmic diseases are caused by mutations of genes for ion channel proteins, which are cell membrane transport proteins for sodium, potassium, and calcium. Defects alter the action potential, predisposing to dysrhythmias. These include long QT syndrome, short QT syndrome, and Brugada syndrome. All can lead to sudden death.[28] Long QT is the most common channelopathy. There are currently 10 gene mutations identified. Short QT syndrome has an autosomal dominant transmission with three subtypes. Brugada syndrome has a high prevalence in Southeast Asia. The cause is either a decrease in sodium or calcium inflow or an increase in potassium outflow.

Clinical presentation is syncope, near syncope, palpitations or SCD.[29] A strong family history is helpful in making the diagnosis. Short QT syndrome usually presents in patients with a mean age of thirty years.

The ECG shows the characteristic interval changes in long and short QT syndromes. In Brugada syndrome, the ECG shows ST segment elevation in leads V1 to V3, and also often shows increased PR or QRS intervals (see Chapter 65). Electrolytes, chest x-ray, toxicology screen, and thyroid testing should be normal.

Patients should be admitted to monitored settings and undergo cardiology evaluation for ICD placement. After discharge, amiodarone (600 mg QD) may be efficacious for dysrhythmia treatment. Referral to genetics can follow thereafter.

Myocarditis

Foundations

Myocarditis is defined histologically by the presence of mononuclear cell infiltrates in myocardial cells. Up to 5% of patients with viral illness may exhibit a form of myocarditis. Some degree of myocarditis is detected in almost 10% of routine autopsies but is often not recognized clinically. The overall incidence is unknown and likely underdiagnosed.

BOX 68.2 Infectious Causes of Myocarditis

Adenovirus
Chagas disease
Chlamydia
Coxsackie B virus
Cytomegalovirus
Epstein-Barr virus
H1N1 virus
Hepatitis A
Hepatitis B

Mycoplasma
Parainfluenza
Parvovirus 19
Rabies
Rubeola
Rubella
SARS-COV-2
Streptococcus
Toxoplasma gondii
Varicella zoster

Any infectious agent can cause myocarditis (Box 68.2) In the 1980s and 1990s, enterovirus and adenovirus predominated as etiologic agents. Recently, H1N1 influenza virus, coronavirus (SARS-CoV-2), parvovirus 19, human herpes virus 6, Epstein-Barr virus, cytomegalovirus, hepatitis C virus, and HIV predominate.[30] Diphtheria, trichinosis, and Lyme disease all can have associated myocarditis, which is discussed with those diseases. The infectious agent can cause damage by direct injury of cellular integrity, RNA/protein dynamics, transcription, and translation. It also activates host antiviral immune response. Initial immune response limits the viral damage but when prolonged, the immune response leads to inflammation damage.[30] This turning of a normal immune response into one that causes cardiac damage has several predisposing factors and is not always induced by a virus. These include systemic/local primary autoimmunity, viral infection, HLA type, gender, and mimicry.[31] The exact pathogenesis varies by causative agent. Efficient clearing of the causative agent usually results in return to normal function. In some individuals, there is a breakdown of T-cell tolerance, which leads to chronic inflammation.[32]

Three stages of disease have been proposed: (1) acute with cytotoxicity and focal necrosis; (2) subacute, in which there is an increase in humoral factors leading to autoimmune injury; and (3) chronic, in which there is diffuse myocardial fibrosis and cardiac dysfunction that may lead to DCM.

There is a higher concentration of anti-beta-myosin antibodies in patients with myocarditis and DCM than in controls. Because myocarditis is linked to the development of DCM (up to 16% of cases in adults and 46% in children), idiopathic DCM after myocarditis may be predominantly autoimmune in origin, resulting from either shared antigens or molecular mimicry, in which the amino acid sequences of the virus and components of the myocardium are similar.

Clinical Features

The clinical presentation is varied. The first symptoms are usually flu-like, including fever, fatigue, myalgias, vomiting, and diarrhea. The most common presentation in children is dyspnea. In adults, it is dyspnea, chest pain, and dysrhythmias.[18] Toxic appearance or tachycardia disproportionate to the temperature may be the only findings. No symptom or sign is sensitive or specific. Cardiac examination is often unremarkable. Patients who present with severe dyspnea, heart failure, rhythm disturbances, or hemodynamic instability are at greatest risk for poor outcomes.[33]

In children, prominent physical findings include grunting respirations and intercostal retractions. Approximately 10% to 15% have rhonchi. Infants often have a fulminant syndrome characterized by fever, cyanosis, respiratory distress, tachycardia, and cardiac failure. When children have ventricular dysrhythmias, myocarditis and idiopathic DCM are commonly seen on endomyocardial biopsy despite a structurally normal heart by noninvasive studies. Long-term prognosis in children correlates with the severity of their initial presentation.

Differential Diagnosis

Diagnostic considerations include myocardial infarction and any other infectious process. Differentiating cardiac sequelae caused by an infection or inflammation elsewhere from primary myocarditis is often not possible. Patients with myocarditis are usually young and have few risk factors for coronary artery disease. In myocarditis, chest pain continues without evolving ischemic ECG changes. The diagnosis of myocarditis should also be considered in an otherwise healthy patient with symptoms and signs of new CHF or dysrhythmias.

Diagnostic Testing

Common ECG changes include sinus tachycardia, a widened QRS, and low voltages. There may be a prolonged QT interval, AV block, or an AMI pattern. ECG abnormalities may extend beyond the distribution of a single coronary artery. Troponin may be elevated. When the elevation occurs in the course of the disease is unknown. The prognostic significance of elevation is not known. A negative ED or serial troponin does not rule out the diagnosis because the damage could have occurred before ED evaluation. The WBC count, C-reactive protein, and ESR are of no diagnostic value. Echocardiographic features are nonspecific and include reduced left ventricular ejection fraction, global hypokinesis, and regional wall motion abnormalities that do not follow coronary artery anatomy. Coronary angiography usually shows normal arteries.

A formal diagnosis is made by biopsy with immunohistochemical data (Fig. 68.3). Biopsy has variable sensitivity and specificity because of sampling error. Biopsy sensitivity may be increased by MRI guidance to target abnormal regions.[34] Because biopsy is invasive, has variable sensitivity, and is unlikely to change clinical outcome, it is often not used, most often leaving the diagnosis to be made based on clinical findings.

Contrast-enhanced MRI may be diagnostic by showing areas of injury. The MRI pattern on initial diagnosis can predict outcome. Late gadolinium enhancement, especially septal, mid-wall, and patchy distribution, is associated with increased risk of sudden death or ischemia, with greater enhancement indicating greater risk.[34]

Management

Treatment is supportive and aimed at preserving LV function. This may include everything from a simple limitation of activity to rhythm and CHF treatment, extracorporeal membrane oxygenation, ventricular assist devices, and even cardiac transplantation.

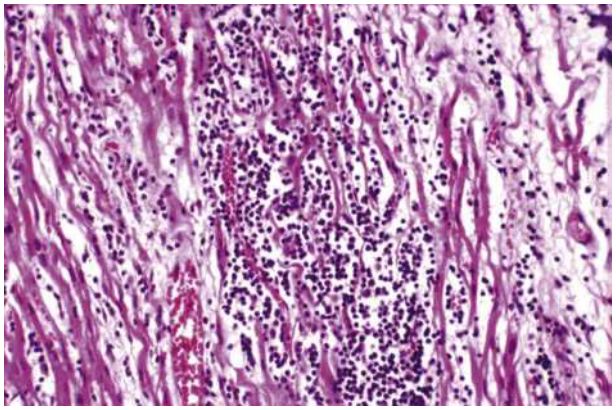

Fig. 68.3 Myocardial biopsy specimen showing myocarditis. Note the lymphocytic infiltrate.

Unfortunately, the majority of studied treatments have failed to improve outcomes.[33] Treatment attempts have been stage-specific. In the viral stage, antiviral agents, such as beta-interferon or ribavirin, are not supported by evidence. For the inflammatory stage, multicenter trials of immunosuppressive therapy with several months of prednisone and azathioprine have shown benefit in only the small subset of patients with heart failure of less than 6 months and no virus on biopsy.[27] Mouse models implicate aspirin and NSAIDs as causing harm.

Symptomatic treatment should be started in the emergency department. Because most patients will be diuretic naïve, start with furosemide 10 mg and add vasodilators, such as nitroglycerine starting at 5 mcg/min for CHF symptom management. In some cases, the deterioration of cardiac function is substantial enough to require inotropic agents, such as dobutamine 2 mcg/kg/min, or even mechanical circulatory support with ventricular assist devices (VADs) (see Chapter 66). Temporary or percutaneous VADs may provide short-term support while awaiting recovery. If the myocardium does not recover, a durable VAD or transplantation may be required.

Disposition

Patients with myocarditis should be hospitalized in a monitored bed. Those with persistent hemodynamic instability require intensive care. Those with mild viral symptoms and slightly elevated troponin may be observed for serial troponins and follow-up echocardiogram. Complications of myocarditis include ventricular dysrhythmias, left ventricular aneurysm, CHF, and DCM.

Given the wide variations in clinical presentations and etiologies, it is difficult to assign a long-term prognosis. The consensus is a 10% to 20% rate of major cardiac adverse events.[35] There is a significant difference in outcome for pediatric patients with fulminant and nonfulminant disease, with fulminant having a higher rate of in-hospital deaths, heart transplantation, and LVEF less than 55% at follow-up.[36] Patients who undergo transplantation because of myocarditis have decreased 1-year survival and higher rejection rates compared with patients who undergo transplantation for other reasons.

Patients with myocarditis, even when asymptomatic, are at higher risk for SCD. Exercise has been shown to worsen myocarditis in animal models. Athletes with myocarditis should not compete until signs of inflammation have resolved, and LV function has normalized.[18]

Chagas Disease

Chagas disease is one of the leading causes of myocardial disease in many countries, particularly in Central and South America. Chagas disease is caused by the protozoan *Trypanosoma cruzi* with transmission by insect vector. Elimination of the vector and improved blood donation screening has decreased the incidence.

Chagas disease should be considered in any patient with new cardiac symptoms and a travel history that includes Mexico, Central America, and South America. Acute infection presents as a nonspecific viral-like illness followed by a latent phase, then a cardiac phase with conduction abnormalities, and then DCM. Most seropositive patients never develop symptoms. Findings include fever, hepatic or splenic enlargement, and unilateral periorbital edema. Cardiac manifestations include angina-like chest pain, dysrhythmias, embolic episodes, heart failure, conduction abnormalities, and multifocal ventricular premature contractions. Syncopal or near-syncopal episodes occur in nearly two-thirds of patients.

The ECG shows ST segment elevation, T wave inversion or increased PR or QRS intervals. Ventricular tachycardia is common and considered a hallmark of the disease. Serum testing for parasites establishes the diagnosis, as does measuring anti-IgG for *T. cruzi*. Echocardiography may show a left ventricular apical aneurysm or scar, which is a reliable marker.

Treatment is with benznidazole for ages 2 to 12 years (5–8 mg/kg/day divided into 2 doses for 60 days) and nifurtimox for ages 12 to 17 years (15 mg/kg/day divided into 3 or 4 doses) and 18 years or over (8–10 mg/kg/day divided into 3 or 4 doses). Amiodarone (200 mg TID) may be useful to treat ventricular tachycardia. ACEIs (lisinopril 10 mg QD) provide a long-term benefit for patients with heart failure.

Up to 30% of patients develop CHF from 5 to 30 years after the initial infection. To whom and why this happens is not understood.

Cocaine Cardiotoxicity

Cocaine has a direct negative inotropic effect on cardiac muscle. Cocaine causes ischemia, myocarditis, and DCM. Myocarditis is a common autopsy finding in patients with cocaine abuse. The mechanism is largely unknown. Theories include increased sympathomimetic effect, severe oxidative stress, and metabolite interaction with ion channels. Patients who die with detectable cocaine levels have myocarditis and myocardial contraction bands more often than controls. The severity correlates with serum and urine concentrations of cocaine. This may supply the anatomic substrate for ventricular dysrhythmias. For further details on cocaine cardiotoxicity, please see Chapter 144.

Sudden Death

Approximately 25% of sudden deaths in patients younger than 21 years old can be attributed to disease of the myocardium. Cardiac causes include myocarditis, congenital abnormalities, HCM, channelopathies, and anomalous coronary artery circulation. Prodromal symptoms are reported in more than half of the patients with cardiac causes, most commonly chest pain in patients older than 20 years, and dizziness in patients younger than 20 years. SCD of coronary artery etiology is decreasing while that of cardiomyopathy etiology is increasing. The risk for SCD increases rapidly at age 25 to 40 and then gradually until age 75 when it decreases. Coronary artery disease is the leading cardiac cause (58%) of sudden death in people older than 30 years old. HCM and anomalous coronary arteries are seen more often in sports-related deaths.[37]

PERICARDIAL DISEASE

Pericarditis

Foundations

Pericarditis is inflammation of the pericardium caused by granulocytic and lymphocytic infiltration. Pericarditis is a relatively common cause of chest pain, accounting for 5% of all nonischemic chest pain.

BOX 68.3 Etiology of Pericarditis

- Infectious
  - Bacterial
  - Fungal
  - Parasite
  - Viral
- Postinjury
  - Blunt trauma
  - Medication
  - Myocardial infarction (MI)
  - Penetrating trauma
  - Radiation
  - Surgery
- Systemic diseases
  - Amyloidosis
  - Metastatic tumor
  - Rheumatoid arthritis
  - Sarcoidosis
  - Scleroderma
  - Systemic lupus erythematosus (SLE)
  - Uremia
- Primary tumors
- Aortic dissection

The pericardium envelops the heart and attaches to the great vessels. It consists of parietal and visceral layers, with a narrow potential space between. Each layer is 1 to 2 mm thick. An ultrafiltrate of plasma, 15 to 35 mL of fluid, is normally present in the pericardial space. The pericardium serves several functions: it maintains the heart's position, lubricates the heart's surface, prevents spread of infection, prevents cardiac overdilation, augments atrial filling, and maintains the normal pressure-volume relationships of the cardiac chambers. Patients with congenital absence (or surgical removal) of the pericardium, however, show few if any problems. Pericardial absence may be associated with other genetic-based issues, however.

In Western countries, 80% to 90% of pericarditis cases are labeled as idiopathic. The etiology may be infectious (viral or bacterial) or noninfectious (systemic inflammatory disease, cancer, post-cardiac injury) (Box 68.3). Tuberculosis is a common etiology in developing countries.[38] In one comprehensive study, pericarditis was diagnosed in 933 patients. No etiology was established in 516 patients (55%), 197 (21%) patients suffered from postinjury syndromes, and 156 (17%) had previously known diseases that were associated with pericarditis.[39]

There is an increase in the number of antibodies in the pericardial fluid of patients with pericarditis. Recent research has focused on the distinction between autoinflammatory and autoimmune pericarditis.[40]

Clinical Findings

The classic findings of pericarditis include chest pain, which can be severe, and pericardial friction rub. A history of fever and myalgias is common. The chest pain of pericarditis is sharp, pleuritic, waxes and wanes, and varies with position. It is relieved by sitting forward and worsened by lying down, deep inspiration, or swallowing. Pericarditis pain is retrosternal, can radiate to the trapezius muscles or back, or can present as isolated shoulder pain.

The classic physical examination finding is a pericardial friction rub. The rub may be caused by friction between inflamed or scarred visceral and parietal pericardium or from friction between the parietal pericardium and adjacent pleura. It may be audible anywhere over the anterior chest wall and is best heard using the stethoscope diaphragm positioned at the lower left sternal border with the patient leaning forward in full expiration. The rub also can be accentuated by a full inspiration, followed by a breath hold. The rub tends to be intermittent, migratory, and difficult to hear, but there can be a characteristic, obvious "scratchiness" and phasic nature of the rub.

Differential Diagnosis

The differential diagnosis includes myocardial infarction, inflammatory or infectious disease of the chest. Rarely pulmonary embolism can mimic pericarditis.

Diagnostic Testing

No single test is diagnostic for pericarditis. The diagnosis is based on chest pain, pericardial rub, ST elevation, and new pericardial effusion. The classic chest pain and ECG patterns are seen in only two-thirds of patients.

The ECG is the most reliable diagnostic tool (Fig. 68.4). It evolves through stages over time. The first stage occurs in the early hours to days of illness and includes diffuse ST segment elevation and reciprocal ST segment depression. Most patients with acute pericarditis have concurrent PR segment depression. In the next stages, the ST and PR segments normalize, but the T waves flatten followed by deep, symmetrical T wave inversion. At the last stage, the ECG reverts to normal, although the T wave inversions may become permanent. Ventricular dysrhythmias are rare in pericardial disease. Patients who have ventricular dysrhythmias should be presumed to have concomitant myocarditis, another cardiac disease, or to have been misdiagnosed.

ECG findings of acute pericarditis may be difficult to distinguish from acute myocardial infarction, coronary artery spasm, or benign early repolarization. In contrast to the ECG in AMI, the ST segment elevations in stage 1 acute pericarditis are concave rather than convex upward, simultaneous T wave inversions are not seen, and the findings are not bound to a single coronary artery distribution. Subsequent tracings do not evolve through a typical myocardial infarction pattern, and Q waves do not develop.

Up to 60% of patients have an effusion best seen with POCUS. A normal echocardiogram does not exclude pericarditis. The white blood cell (WBC) count and erythrocyte sedimentation rate are not sensitive or specific. Elevated C reactive protein has been proposed as a marker of inflammation, but the evidence is scant.[38] Other laboratory studies should be directed at determining nonidiopathic causes of pericarditis. Prominent pericardial delayed hyperenhancement on MRI suggests ongoing inflammation.[40]

Management

If a specific etiology of pericarditis is found, therapy should be directed accordingly. Otherwise, therapy for acute pericarditis is symptomatic. NSAID (ibuprofen 600 mg QID or indomethacin 25 mg TID) or aspirin (650 mg TID) for 10 days is the first choice. If the chosen NSAID is not effective within 1 week, a different class of NSAID (such as naproxen 250 mg BID) for 7 days may be tried. Adding colchicine improves treatment success and lowers the recurrence rate by 50%. Colchicine (0.5 mg QD if weight ≥ 70 kg; 0.6 mg BID if weight > 70 kg) should be used with caution in renal failure and pregnancy. It must be used for 3 to 6 months and has frequent side effects. Although the literature supports colchicine, this represents an opportunity for shared decision making with the patient because the side effect rate and recurrence risk are similar. The best choice is to start colchicine in the ED.[41] The second-line treatment is corticosteroids for those unable to take ASA or NSAIDs or those who take an anticoagulant. Low- to moderate-dose prednisone (0.2–0.5 mg/kg/day for 5 days has lower recurrence and complication rates than a higher dose (1.0 mg/kg/day).[38]

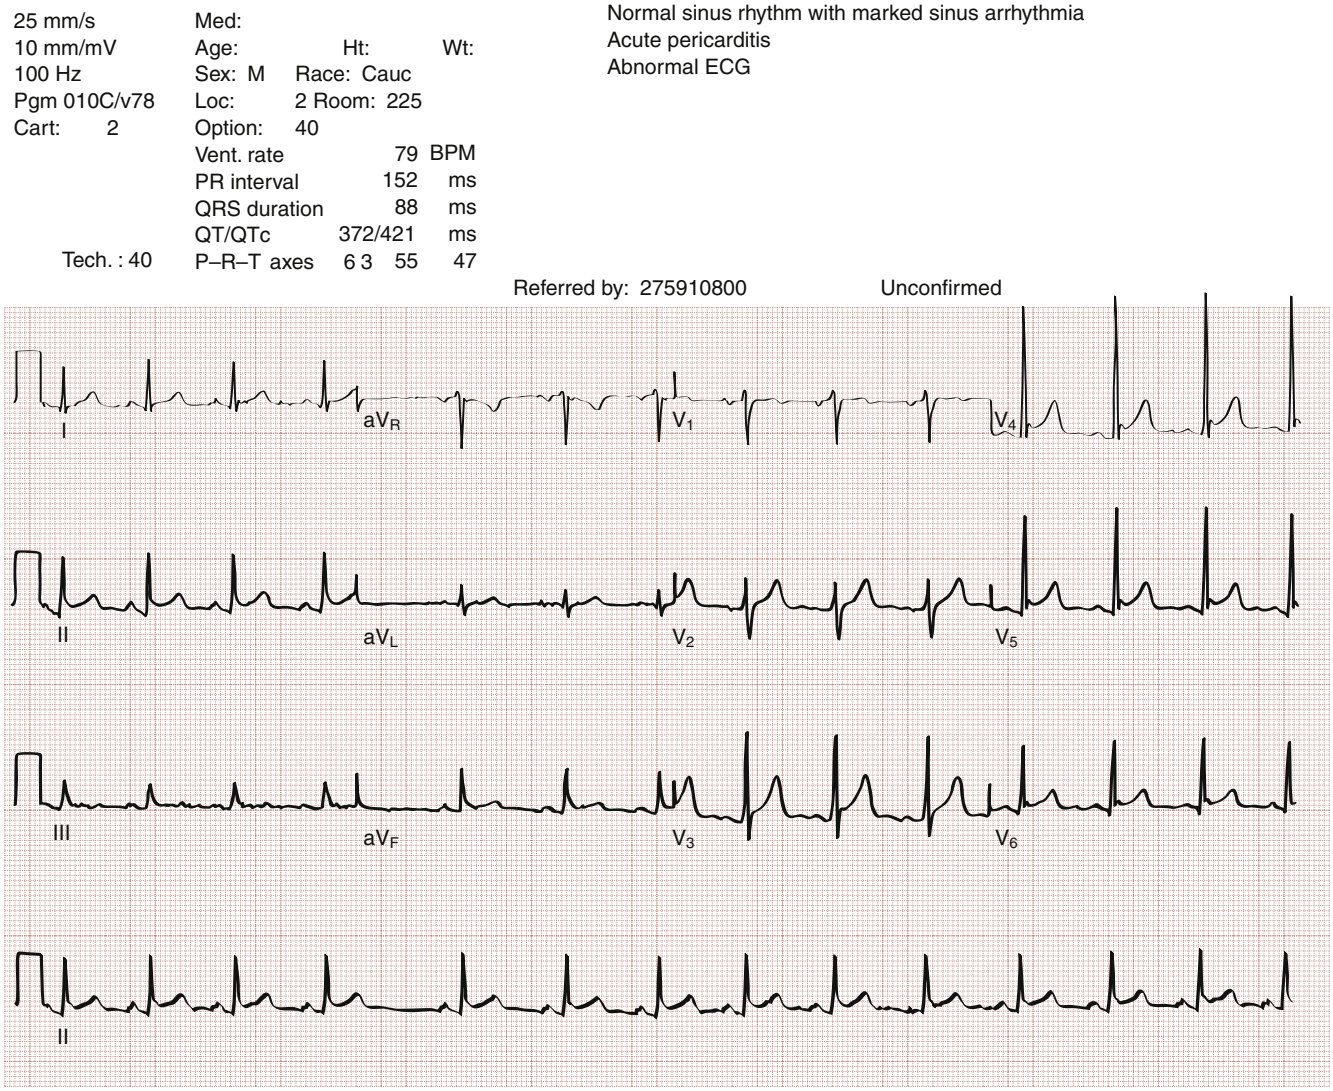

Fig. 68.4 Electrocardiogram (ECG) showing acute pericarditis. (Courtesy Ohio Chapter of the American College of Emergency Physicians.)

Treatment of recurrences that have failed NSAIDs, corticosteroids, and colchicine is difficult. Azathioprine and immunoglobulins have been trialed with little success. Preliminary results using the interleukin-1 beta recombinant receptor agonist anakinra have shown promise in patients whose pericarditis was refractory to colchicine or who could not be weaned from steroids.[42] Pericardiectomy may be needed if all other treatments fail.

Disposition

Most patients can be managed as outpatients unless there are hemodynamic abnormalities or diagnostic uncertainty with acute coronary syndrome. Temperature greater than 38°C/100.4°F, large effusion, and failure of first-round treatment are also indications for hospitalization. Athletes should not compete, though this recommendation is based on expert opinion without evidence to support it.[38]

The clinical course of pericarditis is variable: 60% of patients have complete recovery within 1 week, and almost 80% have complete recovery within 3 weeks. Up to 30% of patients suffer a recurrence, however. Patients with fever, pericardial effusion, a subacute course, or failure of initial NSAID treatment are more likely to have a recurrence. Patients with recurrent pericarditis should have repeat echocardiography to exclude tumor. Nonviral and nonidiopathic pericarditis have higher rates of conversion to constrictive pericarditis.

Uremic Pericardial Disease

Uremic pericarditis occurs secondary to renal failure or dialysis. The etiology is unknown. It occurs with both hemodialysis and peritoneal dialysis. For unclear reasons, it is more frequent with hemodialysis. The number of patients with end-stage renal disease (ESRD) is increasing, resulting in more cases of uremic pericarditis.[43]

Patients with uremic pericarditis have pleuritic chest pain and occasional fever. The ECG is often normal. Cardiac enlargement on chest radiograph in the absence of signs of volume overload or heart failure (HF) should prompt evaluation of pericardial effusion with POCUS. Uremic pericarditis is one of the most common causes of cardiac tamponade.

Patients with ESRD are immunocompromised, and occult infections may be present, including pericardial fluid infection. In considering the differential diagnosis, chest pain may be caused by coronary artery disease or pneumonia. Patients on dialysis frequently have hypotension, and cardiac tamponade must be evaluated in this differential.

Uremic pericarditis is initially treated with intensive dialysis, NSAIDs (indomethacin 25 mg TID), and may occasionally require drainage. Systemic steroids (prednisone 50 mg QD) or intra-pericardial injection of steroids (not an ED procedure) may be used in patients who do not respond to dialysis. If uremic pericarditis evolves into constrictive pericarditis, the patient may need a pericardial window or pericardiectomy.[43]

For patients with a large effusion or continued symptoms of dyspnea or chest pain, the best disposition is dialysis. If symptoms have improved, the vital signs are normal, and the effusion is small, the patient may be discharged home on NSAIDs with dialysis in the next 48 hours.

Post–Myocardial Infarction Pericarditis

Approximately 20% of patients with transmural MI experience chest pain of a different quality 2 to 4 days after infarction, characteristic of post-MI pericarditis. There is frequently low-grade fever and a transient pericardial friction rub. Early post-MI pericarditis is usually short-lived and treated with aspirin. The ECG changes of pericarditis may be masked by the AMI changes, making the diagnosis difficult. Patients with early post-MI pericarditis have more dysrhythmias and heart failure. Pericarditis in AMI may be an indicator of greater myocardial damage and a worse outcome.

Dressler reported a syndrome of delayed fever, pleuritis, leukocytosis, friction rub, and chest radiographic evidence of new pericardial or pleural effusions after MI. The cause of late post-MI pericarditis (Dressler syndrome) is unknown but is thought to be immunologic. This can occur any time, with most presenting 2 to 8 weeks postinfarct. The syndrome may also occur with pulmonary embolus and after pericardiotomy. Consider discontinuing anticoagulants to reduce the risk of hemorrhage. Delayed post-MI pericarditis is treated with NSAIDs (ibuprofen 600 mg QID or indomethacin 25 mg TID).

Postinjury Pericarditis

Postcardiac injury syndrome is defined as pericarditis after MI, cardiac surgery, or trauma. As such, it overlaps with Dressler syndrome. The incidence ranges from approximately 5% after MI to 30% after thoracic surgery or trauma. When it occurs after surgery, it is called postpericardiotomy syndrome. Infection, tamponade, and myocarditis may occur. An immune pathogenesis is suggested by the development of cardiac autoantibodies, although these autoantibodies are common after injury.

Symptoms and signs include pericardial rub, fever, and chest pain. Often there is a pericardial effusion. The interval between injury and the onset of pericarditis ranges from 4 to 12 days. During hospitalization, purulent pericarditis should be considered as a possible source of febrile illness in a patient with multisystem organ failure.

NSAIDs (ibuprofen 600 mg QID or indomethacin 25 mg TID) and colchicine (0.6 mg BID for weight > 70 kg) are the primary treatment choices. Steroids are reserved for refractory cases. Uncomplicated pericarditis secondary to blunt trauma usually resolves.

Since this is a complication of the original injury, these patients should be hospitalized. There is significant morbidity and mortality with the leading complications being constrictive pericarditis and cardiac tamponade.[44]

Neoplastic Pericardial Disease

Please see Chapter 112 for a discussion of neoplastic pericardial disease.

Radiation-Induced Pericarditis

Fewer than 5% of patients treated with radiation therapy develop pericarditis, an incidence that has decreased with improved techniques. The percentage of pericardial volume irradiated and the dosage determine which patients develop pericarditis. It is seen most commonly in patients with lymphoma or breast cancer. If this is the first episode of pericarditis after cure, tumor recurrence should be considered, and an oncologic workup either started or arranged from the ED.

Miscellaneous Causes of Pericarditis

Pericarditis occurs in approximately one-third of patients with rheumatoid arthritis, usually within 3 years of the initial diagnosis. It is rarely clinically significant. Prednisone is the initial treatment. Pericarditis, usually with effusion, is found at autopsy in more than 50% of patients with systemic lupus erythematosus (SLE). SLE pericarditis is treated with corticosteroids or NSAIDs. Patients with Sjögren syndrome, giant cell arteritis, ankylosing spondylitis, Behçet's disease, systemic sclerosis, and polyarteritis can all develop pericarditis. Pericarditis can rarely occur as an extraintestinal complication of inflammatory bowel disease and is independent of the clinical course of the gut disorder. Pericarditis can also occur as a complication of an implantable defibrillator or pacemaker, transbronchial needle aspiration or endoscopic variceal sclerotherapy. Pericarditis can be caused by erosion of a foreign body, such as a sewing needle or toothpick, through the esophagus into the pericardium.

Infectious causes of pericarditis include *Rickettsia conorii,* which causes Mediterranean spotted fever (treated with doxycycline), *Mycoplasma pneumoniae* (treated with a macrolide), *Nocardia asteroides* (treated with pericardiectomy and sulfisoxazole), *Chlamydia trachomatis* (treated with azithromycin or doxycycline), Epstein-Barr virus, cytomegalovirus infection, *Haemophilus actinomycetemcomitans* (treated with chloramphenicol), and coccidioidomycosis (endemic in the southwestern United States). Treatment is as for the systemic illness.

Tuberculous pericarditis is estimated to occur in 1% of patients with pulmonary tuberculosis and is associated with high mortality. In Africa, it is the most common cause of pericarditis. Coexisting HIV should be excluded.

Pericardial Effusion

The most common causes of pericardial effusion are viral or idiopathic pericarditis, malignancy, uremia, trauma, and radiation therapy. Drug reactions and autoimmune diseases are less common.

Pericardial effusion is often asymptomatic. Patients with known associated conditions, especially cancer or renal failure, who present with cough, fever, chest pain, or dyspnea should be considered to have an effusion until proven otherwise.

A minimum of 200 to 250 mL of pericardial fluid is necessary to produce cardiomegaly on chest radiograph. POCUS will confirm the diagnosis (Fig. 68.5) because it easily differentiates pericardial fluid from cardiac chamber enlargement and provides information about myocardial wall motion. CT or MRI may be useful when the echocardiogram is technically unsatisfactory. Nuclear scans may be useful to detect purulent pericardial effusions.

Small effusions may be treated with NSAIDs (ibuprofen 600 mg QID) and close follow-up to ensure no increase in size. Ultrasound-guided pericardiocentesis may be performed for either diagnostic or therapeutic purposes on large effusions.

Patients requiring pericardiocentesis should be hospitalized for serial examinations and determination of the underlying etiology of the pericardial effusion.

Purulent Pericarditis

Purulent pericarditis is a life-threatening process most commonly, but not exclusively, seen in hospitalized patients with systemic illness who

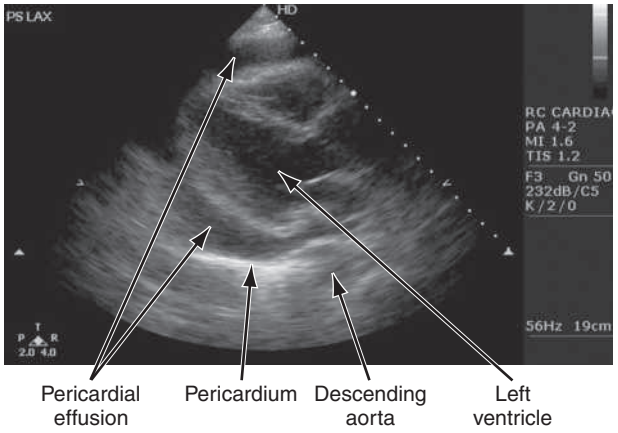

Fig. 68.5 POCUS showing a pericardial effusion. The effusion is best seen superior to the left ventricle at the top of the image. (Courtesy Jessica Resnick, MD.)

develop sepsis. It can occur in any age group and can be caused by any type of infectious agent. *Streptococcus* and *Staphylococcus* are the most common. *Candida* pericarditis is found after cardiac surgery and in patients with impaired host defenses. Purulent pericarditis occurs by several mechanisms: (1) spread from an adjacent infection, such as pneumonia or empyema; (2) hematogenous spread from a distant site; (3) direct inoculation of bacteria (trauma or procedure); and (4) spread from an intracardiac source. The most common mechanism is spread from a distant site.

Purulent pericarditis usually manifests as a febrile illness of several days' duration. Common presenting signs include tachycardia, dyspnea, hepatomegaly, elevated central venous pressure, chest pain, friction rub, and leukocytosis. It is most common in a hospitalized patient with a serious underlying disease who initially improves after treatment of the primary process but later develops fever, dyspnea, chest pain, and a pericardial effusion. Because many patients are discharged home before developing complications, purulent pericarditis is increasingly seen in the ED. A search for the common infection sources, including lungs, urine, and skin, is not successful and the patient gets worse until a pericardial source is considered.

Chest x-ray may show cardiomegaly, and POCUS will show fluid. Pericardiocentesis is necessary to establish the diagnosis, obtain fluid for microbiologic studies, and relieve cardiac tamponade if present.

Pericardiectomy is the traditional treatment of choice. Indwelling catheters, coupled with lavage, antibiotics, and fibrinolytics have been shown to be as effective. Intravenous antibiotics or antifungals and cardiorespiratory monitoring are needed. Fibrinolytic therapy may reduce the rate of constrictive pericarditis when surgery is not needed.

Because treatment requires interventions, ED patients will need hospitalization. The overall survival rate is approximately 30% with antibiotic therapy alone and 50% when combined with early surgical drainage. In addition to complications related to sepsis and tamponade, long-term sequelae include constrictive pericarditis.

Constrictive Pericarditis

Constrictive pericarditis (CP) can be a late consequence of any etiology of acute pericarditis. The incidence has increased as a result of improved survival in patients with chronic renal disease. The key pathophysiologic feature is a thickened pericardium that impairs diastolic filling by external cardiac restriction. Ventricular filling is rapid and completed within the first third of diastole.

Consider CP in any patient with right-sided heart failure symptoms. Dyspnea, fatigue, and weight gain are the most common symptoms. Hepatomegaly, marked pitting lower extremity edema and ascites also occur. The characteristic heart sound is a pericardial knock in early diastole. A friction rub may also be heard.

ECG findings include low voltage, nonspecific ST-T wave abnormalities, and atrial dysrhythmias. Heart size on the chest radiograph is usually normal. Pericardial calcification is suggestive. Liver function tests may be elevated due to passive hepatic congestion. Doppler echocardiography can differentiate constrictive pericarditis from RCM or cardiac tamponade. Cardiac catheterization to measure ventricular end-diastolic pressures or endomyocardial biopsy may be necessary. Pericardiectomy is the therapy of choice. CP is associated with mortality as high as 10%.

Cardiac Tamponade

Foundations

Cardiac tamponade is the result of compression of the myocardium by the contents of the pericardium. This compression is usually caused by fluid. It may also be caused by gas, pus, blood, or a combination of substances.

Cardiac tamponade occurs in a physiologic continuum reflecting the amount of fluid, the rate of accumulation, and the underlying condition of the heart. The most important factor in the development of tamponade is the rate of fluid accumulation. The three stages necessary for tamponade to develop are (1) fluid filling the recesses of the parietal pericardium, (2) fluid accumulating faster than the rate of the parietal pericardium's ability to stretch, and (3) fluid accumulation that exceeds the body's ability to increase blood volume to support the right ventricle filling pressure. The result is increased pericardial pressure, which causes decreased ventricle compliance and decreased flow of blood into the heart. The reduction of blood inflow into the right ventricle results in decreased stroke volume that leads to decreased cardiac output.

The heart initially responds to tamponade by increasing heart rate to maintain cardiac output. This compensatory mechanism is maintained until late in the clinical course, followed by rapid decompensation.

Cardiac tamponade should be suspected in patients with penetrating chest wounds. It is also common in patients with uremic pericarditis and cancer. Etiology includes malignancy (32%), infection (24%), idiopathic (16%), iatrogenic (15%), post-acute MI (7%), uremic (4%), and other causes (2%). The most common associated cancers are lung, breast, lymphoma, and gastrointestinal. Infections include staphylococcus, streptococcus, tuberculosis, and HIV. Iatrogenic causes include post–cardiac catheterization, post–cardiac surgery, and anticoagulant use. Post-MI tamponade is due to cardiac wall rupture 44% of the time.[46]

Clinical Features

Cardiac tamponade symptoms, though often nonspecific, include chest pain, cough, or dyspnea, any of which may be progressive and severe. Dyspnea is most common. The classic triad described by Beck is hypotension, distended neck veins, and muffled heart sounds. These signs may not be present, especially if tamponade develops quickly.

Differential Diagnosis

Cardiac tamponade can be confused with other causes of chest pain such as small pericardial effusion, myocardial ischemia, pericarditis, cardiomegaly, dilated cardiomyopathy, jugular venous distention, superior vena cava syndrome, and heart failure.

Diagnostic Testing

The chest radiograph may show cardiomegaly, but only if there is more than 250 mL of pericardial fluid. The ECG classically shows decreased voltage. Electrical alternans is helpful to make the diagnosis but rarely

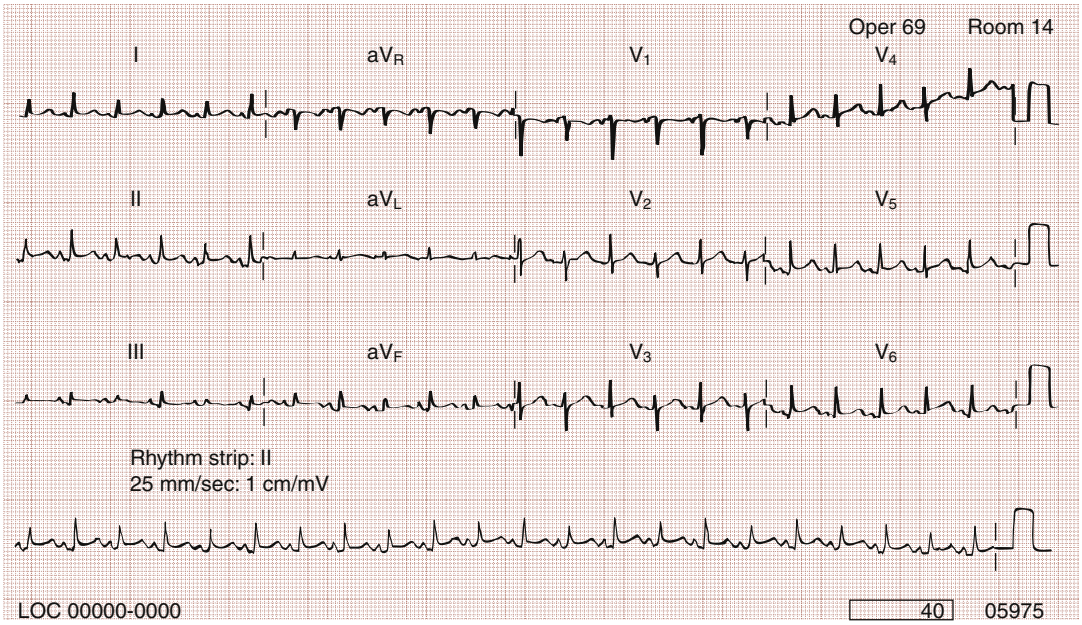

Fig. 68.6 Electrocardiogram (ECG) showing electrical alternans.

occurs (Fig. 68.6). POCUS confirms the diagnosis when effusion and chamber collapse are seen. Cardiac catheterization demonstrates equalization of right and left ventricle pressures (Video 68.1).

Management

Initial treatment is intravenous fluids to increase right-sided filling pressure and overcome pericardial fluid constriction. Pericardiocentesis or pericardial window is the treatment of choice. If tamponade recurs, pericardiocentesis may be repeated, or a drainage catheter may be left in the pericardial space. Pericardiectomy may be necessary.

Disposition

Patients with cardiac tamponade should be hospitalized, usually in a critical care setting. Cardiac tamponade has a high mortality rate, usually related to the underlying disease.

Pneumopericardium

Pneumopericardium is rare. Pneumopericardium is caused by the formation of fistulae between the pericardial and pleural space, bronchial tree, or upper gastrointestinal tract. It may result from bronchial carcinoma or infection with gas-producing microorganisms, or it can be idiopathic. Spontaneous pneumopericardium is caused by an increase in intra-alveolar pressure above atmospheric pressure, resulting in rupture of alveoli. It is associated with many causes including asthma, labor, barotrauma from positive-pressure ventilation, Valsalva maneuvers, weightlifting, and recreational drug inhalation from positive-pressure devices or when augmented by a Valsalva maneuver.

Physical findings depend on the quantity of fluid and gas in the pericardial space. Heart sounds may have a metallic quality accompanied by splashing sounds called the Hamman sign or mediastinal crunch. This is diagnostic. Clinical sequelae of tension pneumopericardium are similar to acute cardiac tamponade. The diagnosis of pneumopericardium is usually confirmed by chest radiograph, POCUS, or cardiac ultrasound, but if not, then CT scan is indicated. Tension pneumopericardium should be treated with emergency pericardiocentesis. Stable patients with uncomplicated spontaneous pneumopericardium may be discharged after all other life-threatening injuries and complications have been excluded. No long-term sequelae are expected.

CHAPTER 68: QUESTIONS AND ANSWERS

1. A 33-year-old man presents with a 4-hour history of left anterior chest pain associated with mild shortness of breath. He is otherwise healthy except for chronic tobacco use. Vital signs are: blood pressure, 142/92 mm Hg; heart rate, 120 beats per minute; respiratory rate, 24 breaths per minute; temperature, 100.4°F (38.0°C) oral; and oxygen saturation, 97%. Physical examination is remarkable for tachycardia and a friction rub. The patient's electrocardiogram (ECG) is shown below. Which of the following would be the most appropriate therapy?
   a. Cardiac catheterization
   b. Ibuprofen 600 mg QID and colchicine
   c. Nitroglycerin, aspirin 324 mg oral, cardiology consultation
   d. Oxygen, serial troponin levels

Answer: b. The ECG shows findings consistent with acute pericarditis. Clinically, diffuse ST elevation is seen in leads I, II, II, aV_L, aV_F, and V_2 to V_6. In contrast to finding an acute myocardial infarction (AMI), ST elevations are concave upward in acute pericarditis rather than convex upward as seen with a myocardial infarction (MI). PR depression is also a frequent finding. As the acute pericarditis resolves, ST changes revert to normal, followed by T wave flattening and later deep symmetrical inversion, which may persist. NSAIDs are the mainstay therapy for uncomplicated pericarditis. Colchicine helps decrease recurrence. Oxygen therapy is not helpful in patients with normal oxygen saturation. Because the ECG, examination, and history point to pericarditis, cardiac catheterization is not needed. There are case reports of thrombolytics use in pericarditis leading to pericardial hemorrhage and major complications.

2. Which of the following statements regarding post–myocardial infarction (MI) pericarditis is true?
   a. Classic pericarditis electrocardiogram (ECG) findings are reliably seen.
   b. It indicates a greater degree of myocardial damage than those without pericarditis.
   c. Large pericardial effusions are common.
   d. The incidence of congestive heart failure (CHF) is unchanged.

Answer: b. Both dysrhythmias and CHF are more common in patients who experience post-MI pericarditis. Large effusions are uncommon, and classic pericarditis ECG findings are often overshadowed by the changes of the recent or evolving MI.

3. A 15-year-old female presents during summer break with fever, cough, and chest pain. She has no history of illnesses or medication use. No street drug use. Her vital signs are BP 110/70, T 38.4, P 122, RR 16, SaO_2 96% on RA. ECG shows sinus tachycardia with normal intervals and low voltage. You order a troponin test and it is slightly above the normal range. Which other test result would you expect?
   a. Cardiomegaly on chest x-ray
   b. Elevated C-reactive protein
   c. Elevated sodium and creatinine
   d. Regional wall motion abnormalities on POCUS

Answer: d. Patients with myocarditis show regional wall motion abnormalities and global hypokinesis on POCUS. Even though there is inflammation, WBC and CRP are neither sensitive nor specific for myocarditis. Electrolyte and renal abnormalities should not occur. Cardiomegaly is a late finding if it occurs at all.

4. A 55-year-old woman presents with progressive dyspnea, chest pain, and cough over 5 days. She has a past history of renal failure and is on dialysis, last 2 days ago. She does not smoke. Vital signs are: temperature, 100.2°F (37.9°C) oral; heart rate, 120 beats per minute; respiratory rate, 26 breaths per minute; blood pressure, 100/60 mm Hg; and oxygen saturation, 96% on room air. Physical examination is remarkable for 3-cm jugular venous distention at 45 degrees, clear lung fields on auscultation, tachycardia without a friction rub, trace pretibial edema, and weak peripheral pulses that disappear during expiration. Chest radiograph shows an enlarged cardiac silhouette and clear lung fields. What would be the most appropriate initial intervention?
   a. Endotracheal intubation with rapid sequence induction
   b. Enoxaparin 1 mg/kg subcutaneous
   c. Computed tomography (CT) scan of the chest
   d. Isotonic fluid bolus and point of care cardiac ultrasound

Answer: d. This patient is presenting with cardiac tamponade, presumably secondary to an uremic pericardial effusion. Pulmonary embolus is a consideration but less likely, given the picture of normal oxygen saturation and an enlarged heart. The initial intervention should be fluid loading to maintain preload and cardiac output, followed by ultrasound confirmation and likely pericardiocentesis. Fluid loading in renal failure may easily result in pulmonary edema, so expeditious relief of tamponade is indicated. It is too early for intubation because the patient is oxygenating adequately.

5. A 44-year-old man complains of swollen legs. He just finished two courses of prednisone for wheezing related to asthma. The first course was prescribed 6 weeks ago in the emergency department (ED), where he was diagnosed with new onset asthma and normal chest radiograph. The second course was prescribed by his family physician 2 weeks ago. The patient denies fever and chest pain and is still mildly short of breath, which is worse at night or with exertion. Examination shows bibasilar rales in his lungs, normal heart sounds, and 1+ edema in both legs up to his knees. What is his diagnosis?
   a. Asthma exacerbation
   b. Idiopathic dilated cardiomyopathy (DCM)
   c. Prednisone-induced edema
   d. Prednisone-induced liver failure

Answer: b. The patient is unlikely to have a new diagnosis of asthma. He most likely had a viral process leading to reactive airway disease initially and viral myocarditis later. He unfortunately now has a DCM and symptoms of heart failure. Treatment is supportive. Prednisone-related end-organ damage usually does not occur this quickly.

69

Infective Endocarditis and Valvular Heart Disease

Bradley W. Frazee and Martha E. Montgomery

KEY CONCEPTS

- Infectious endocarditis (IE) is more often caused by Staphylococcus species than Streptococcus, and increasingly occurs in elderly, recently hospitalized patients, those with prosthetic valves and intra-cardiac devices, and in patients who inject opioids.
- IE should be considered in any patient with a predisposing condition plus fever; IE frequently presents with a complication, including heart failure, embolic stroke, or osteomyelitis.
- At least two sets of blood cultures (obtained before starting antibiotics) and transthoracic echocardiography are the key diagnostic tests to order for patients with suspected IE.
- Empiric antimicrobial treatment for IE should include vancomycin.
- Consultation with a cardiothoracic surgeon is recommended for left-sided vegetations.
- Acute rheumatic fever is a delayed nonsuppurative complication of streptococcal pharyngitis characterized by arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum.
- In a patient with severe mitral stenosis, hypovolemia and tachycardia are poorly tolerated. "Slow and full" are appropriate goals.
- In patients with critical aortic stenosis, avoid excessive preload reduction with vasodilators and diuretics.
- In patients with acute aortic insufficiency, classic physical findings may be absent. Medical stabilization entails the cautious use of vasodilators and diuretics. Intraaortic balloon counterpulsation is contraindicated.
- Complications of prosthetic heart valves range from structural failure and thrombosis to systemic embolization, hemolysis, and endocarditis.

INFECTIVE ENDOCARDITIS

Foundations

Background and Importance

Infective endocarditis (IE) is defined as an infection of a native or prosthetic heart valve, the endocardium, or an indwelling cardiac device. While risk factors and common causative pathogens have shifted in developed countries in recent decades, IE incidence and mortality remain unchanged. IE is a disease with a highly variable and often nonspecific presentation, with the only consistent feature being fever. Early diagnosis and correct initial management remain very challenging, particularly in the emergency department (ED) setting.

Recent changes in the epidemiology of IE in industrialized countries have led to changes in disease presentation. While the overall annual incidence has changed little (9 to 15 cases/100,000), IE has increasingly become a disease of older adults, with the incidence rising dramatically in patients over age 60 and those with multiple comorbidities.[1,2] The incidence of prosthetic valve, intracardiac device (pacemakers and defibrillators), and healthcare-associated infections is increasing. Up to 36% of community onset IE is healthcare-associated, occurring in nursing home residents, patients undergoing dialysis or chemotherapy, or following a recent hospitalization.[1] As opioid addiction has increased in the United States, the proportion of IE cases linked to injection drug use (IDU) has risen nationwide, from 7% in 2000 to 12% in 2013, and exceeds 50% of cases in some communities.[3,4]

The 90-day mortality from IE averages nearly 25%. Predictors of poor outcomes include older age and presence of comorbidities, infection with *Staphylococcus aureus*, heart failure, and perivalvular extension.[1,5] Streptococcal and isolated right-sided infections are associated with better outcomes.

Pathophysiology and Microbiology

Development of IE requires either predisposing valve dysfunction, endothelial damage, or prosthetic material, conditions that all lead to formation of a platelet-fibrin thrombus, which is then seeded with bacteria (Box 69.1). Yet, at the time of presentation, up to 50% of IE patients have no known history of predisposing structural or valvular heart disease or prosthetic device.[6] Occult degenerative heart disease and bicuspid aortic valve are thought to account for many such cases. Rheumatic valvular disease, now uncommon in industrialized countries, remains a common predisposing condition in developing countries. Congenital heart disease predisposes to IE, with the highest infection risk being from cyanotic conditions and repaired lesions with residual prosthetic material, shunt, or valve regurgitation. A prior history of IE confers a high lifelong risk of recurrence, even when the source of endothelial damage remains occult.

IDU carries a high risk of IE, even in patients with normal heart valves. Injection of nonsterile illicit drugs leads to endothelial damage by a poorly understood mechanism, and the resulting thrombus can be seeded by frequent injection-related bacteremia. Though IDU-associated IE may involve any valve, it is much more likely to be right-sided than in non-IDU patients, occurring on the tricuspid valve in approximately 50% of cases.

Prosthetic heart valves and intra-cardiac device leads represent an increasingly common nidus for infection.[7] In community hospital populations, prosthetic valve and cardiac device-related infections now account for roughly 15% and 5% of IE cases, respectively, with even higher proportions in tertiary care centers.[1,8] Prosthetic valve endocarditis (PVE) complicates up to 6% of both bioprosthetic and mechanical valves, with an incidence of 0.3% to 1.2% per patient/year.[5] The highest risk for PVE occurs during the first 6 months after surgery, and these early infections have a worse prognosis. IE associated with pacemaker and defibrillator leads may occur via hematogenous seeding or device pocket infection. It begins as a right-sided infection, usually involving the tricuspid valve.

Bacteremia is also considered requisite for the development of IE, except when contamination occurs perioperatively during valve

BOX 69.1 High-Risk Populations and Predisposing Conditions for Infectious Endocarditis

Prior history of endocarditis
Congenital heart disease (see text for highest risk lesions)
Injection drug use
Prosthetic heart valve
Intracardiac device (pacemaker, defibrillator)
Hemodialysis
Recent hospitalization with central or long-term intravenous access

replacement or device implantation. Poor dentition, dental procedures, and cystoscopy are classically implicated sources of bacteremia. IDU, central and long-term intravenous lines in hospitalized patients and hemodialysis all lead to frequent staphylococcal bacteremia.

The microbiology of IE in industrialized countries has shifted in recent decades, along with the changes in its epidemiology and predisposing conditions. Gram-positive organisms continue to be the leading cause of IE, but Staphylococcus species now predominate, accounting for 30% to 40% of all infections.[1] *S. aureus* is a virulent pathogen, with a predilection for metastatic complications, particularly stroke, relatively acute infections, and high associated mortality. Methicillin-resistant *Staphylococcus aureus* (MRSA) now accounts for almost 15% of IE cases in the United States, and is more common in hemodialysis, IDU, and healthcare-associated infection. The skin commensal coagulase-negative Staphylococcus species, which are often methicillin-resistant and adhere well to prosthetic material, are more common in early PVE and hemodialysis-associated infection. Streptococcus species, including oral commensals belonging to the viridans group, remain the leading IE etiology in developing countries. *Streptococcus bovis* IE is associated with underlying gastrointestinal malignancies. *Enterococcus faecalis* causes both PVE and native valve infection, primarily in elderly and debilitated patients. Streptococcus and Enterococcus infections tend to cause classic, indolent, subacute endocarditis.

The remaining IE etiologies together account for about 15% of cases, and frequently produce initially negative blood cultures. The group of fastidious gram-negative bacteria, termed HACEK—*Haemophilus* spp., *Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae*—can often be isolated within 5 days in modern blood culture systems.[9] Zoonotic etiologies include Coxiella burnetii (Q fever) and Brucella species from livestock, and Bartonella species from body lice and cats. Fungal endocarditis, mostly due to Candida and Aspergillus species, is primarily associated with prosthetic valves, IDU, and immunocompromised states.[10] The above organisms are considered typical of, or consistent with, IE, and blood cultures that grow any of these are a key component of the Duke diagnostic criteria (Box 69.2).

The concept of subacute versus acute infection is no longer used to classify IE. Rather, IE is now classified by the type of valve and by the setting in which it is acquired. Categories include native valve versus prosthetic valve; community-associated versus healthcare-associated (which is sub-classified as nosocomial or community onset); IDU-associated; and intra-cardiac device-associated. PVE is sub-classified as early (≤12 months) or late.

Cardiac and embolic complications develop over time as the infected vegetation grows. Valve leaflet distortion and destruction leads to regurgitant flow and impaired cardiac function. Aortic valve involvement carries the highest risk of clinical heart failure from acute aortic insufficiency. Bacterial invasion of the myocardium can lead to abscess formation and conduction blocks. Friable, infected material

BOX 69.2 Summary of Clinical Duke Criteria for Diagnosis of Infective Endocarditis

Definite Endocarditis
- Two major clinical criteria
- One major and any three minor clinical criteria
- Five minor clinical criteria

Possible Endocarditis
- One major and one or two minor clinical criteria
- Three minor clinical criteria

Major Criteria

Positive Blood Cultures

At least 2 sets positive with typical IE pathogen, including:
- *Staphylococcus aureus*
- Viridans streptococci species of *Streptococcus bovis*
- Enterococcus species
- HACEK group (see text)

Or persistent positive blood cultures with an organism consistent with IE
Or single blood culture or serology positive for *Coxielli burnetii*

Evidence of Endocardial Involvement by Echocardiography
- Pendulum-like vegetation on valve endocardium
- Paravalvular abscess
- Prosthetic valve dehiscence
- New valvular regurgitation

Minor Criteria

Predisposition—predisposing heart condition or intravenous drug use
Fever—temperature greater than 38°C (100.4°F)
Vascular phenomena—arterial emboli, septic pulmonary infarcts, mycotic aneurysm, conjunctival hemorrhages, or Janeway lesions
Immunologic phenomena—glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiologic evidence—positive blood culture not meeting major criteria
Echocardiographic findings—consistent with endocarditis but do not meet major criteria

can embolize from left-sided vegetations, causing downstream tissue infarction, metastatic abscess, mycotic aneurysm, or immune complex deposition. The cerebral circulation is the most frequent site of large vessel embolization, and hemorrhagic transformation of the infarct is common. Right-sided endocarditis produces septic pulmonary emboli.

Clinical Features and Differential Diagnosis

Symptoms of IE are nonspecific and diverse (Box 69.3). Patients often appear relatively well. However, depending on host factors, location of the vegetation, and microbial virulence, some present acutely ill with sepsis and multi-organ failure. The most common symptom is fever (90%). The list of additional possible symptoms includes chills, malaise, weight loss, cough, dyspnea, chest pain, headache, myalgias, arthritis, back or neck pain, altered mental status, or a focal neurologic complaint. A measured fever is present in the ED in about 80% of patients with IE. Since a new murmur, or worsening of a preexisting murmur, is present in only 68% of patients, often no murmur will be heard in the ED. In approximately 30% of cases, the primary presenting syndrome represents a complication of IE, including acute heart failure, stroke, septic pulmonary emboli, and vertebral osteomyelitis.[5]

With such a broad range of possible presentations, IE can easily be mistaken for another infection, such as a viral syndrome, meningitis, or pneumonia, particularly common with right-sided IE and septic

BOX 69.3 Presenting Clinical Syndromes and Findings in Infectious Endocarditis

Syndromes

- Mild and nonspecific febrile illness
- Acute heart failure
- Focal neurological deficit from septic cerebral embolus
- Altered mental status
- Axial spine pain from osteomyelitis
- Pneumonia from septic pulmonary emboli

Findings

- Heart murmur
- Splinter hemorrhages
- Cardiac device pocket inflammation
- Janeway lesions, Osler's nodes
- Roth spots
- Splenomegaly
- Anemia
- Glomerulonephritis

pulmonary emboli. It can also present similarly to a non-infectious problem, such as acute coronary syndrome, primary heart failure, or stroke. In these cases, fever may be the key sign prompting consideration of IE.

The most important clue to the diagnosis of IE is the presence of a predisposing condition (see Box 69.1). If IE is suspected, a core temperature should be correctly measured to assess for fever, multiple times if necessary, and a particularly careful cardiac auscultatory exam performed. Peripheral embolic and vasculitic stigmata should be sought (see Box 69.2), although each is found in only about 5% of cases, with splinter hemorrhages being the most commonly seen (Fig. 69.1).

Diagnostic Testing

Findings on standard laboratory tests in IE are nonspecific. Clinicians must consider IE when faced with a constellation of suggestive findings rather than looking for a single definitive test. Normocytic anemia and hematuria and proteinuria, suggesting glomerulonephritis, are classic findings in indolent infections. An elevated erythrocyte sedimentation rate and C-reactive protein are expected in roughly 60% of cases. A chest x-ray may show signs of heart failure or septic pulmonary emboli, and an electrocardiogram (ECG) may display conduction abnormalities related to a myocardial abscess.

When IE is suspected, it is the responsibility of the emergency clinician to ensure that blood cultures are obtained prior to administering antibiotics. Blood culture results are key to both definitive diagnosis and tailored antimicrobial therapy. At least two sets, each containing 10 cc of blood, should be drawn from separate sites and, if possible, separated in time by at least one hour. Three sets of blood cultures are required in suspected PVE or cardiac device-related infection because one of the most common pathogens in prosthetic device infections, coagulase-negative *S. aureus*, is also the most common blood culture contaminant.

Echocardiography is the other key diagnostic test in IE. Transthoracic echocardiography (TTE) should be performed as soon as possible whenever IE is suspected. While the diagnostic sensitivity of TTE for one of the definitive endocardial findings of IE (see Box 69.2) is no more than 70%, its specificity is very high. Hence, this noninvasive test stands to make the correct diagnosis very rapidly while the patient is still in the ED. More importantly, echocardiography can identify endocardial complications that may require urgent surgery, including acute

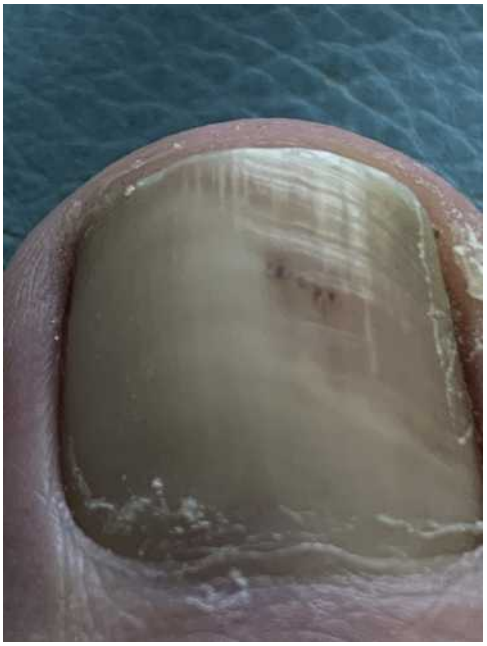

Fig. 69.1 Splinter hemorrhage on the great toe in a patient with aortic valve *Streptococcus bovis* infectious endocarditis. (Courtesy of Gene Hern, MD.)

BOX 69.4 Summary of Indications for Surgical Treatment for Infective Endocarditis

Aortic or mitral insufficiency with ventricular failure
Valve perforation or rupture
Perivalvular extension, abscess, fistula, associated heart block
Prosthetic valve dehiscence
Less than 10 mm vegetation on the anterior mitral leaflet
Recurrent embolization or persistent bacteremia on therapy

valvular insufficiency or perforation with heart failure, perivalvular extension, prosthetic valve dehiscence, and vegetation size greater than 10 mm, which presents an elevated embolic risk (Box 69.4).[5,11] The sensitivity of transesophageal echocardiography (TEE) is significantly higher than that of TTE, both for identifying vegetations and assessing for complications, particularly in PVE.

TEE is now recommended after TTE in all cases, though this invasive modality will usually be performed after hospital admission. The value of point of care TTE, performed immediately by experienced emergency clinicians in the setting of suspected IE, has been demonstrated in numerous case reports, although its role has yet to be evaluated in a large study (Fig. 69.2).[12]

Additional advanced imaging in patients with suspected IE should generally be driven by symptoms. Some advocate routine brain magnetic resonance imaging (MRI) in uncertain cases, even without neurological symptoms, because asymptomatic cerebral emboli are found in up to 60% of those with left-sided infection, and this finding constitutes a Duke minor criteria.

Management

In the sickest subset of IE patients, ED management begins with stabilization, including evidence-based therapy for sepsis, hemodynamic support, and positive pressure ventilation. Patients with suspected IE and acute heart failure require immediate consultation by a cardiothoracic surgeon, and emergency clinicians need to be

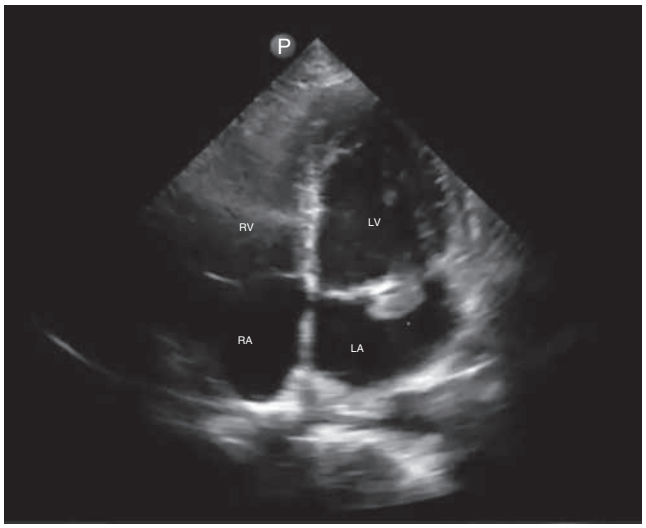

Fig. 69.2 Large mitral valve vegetation as seen on ED point of care ultrasound, apical 4 chamber view. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Courtesy of Highland Emergency Ultrasound Division.)

aware of additional echocardiographic findings that are indications for surgical therapy (see Box 69.4). In general, there has been a shift toward earlier surgical treatment in IE, with approximately one-half of patients with left-sided infection undergoing surgery during the index admission.[9] If possible, patients with left-sided IE should be managed by a multidisciplinary team at a center capable of cardiothoracic surgery.

In the ED, initial antimicrobial treatment of IE is almost always empiric. Occasionally, patients present because previously drawn blood cultures have returned positive; in such cases, isolate susceptibility-directed antibiotics should be selected in consultation with an infectious disease specialist. Consensus guidelines on IE treatment tend to focus on pathogen-specific therapy, with limited discussion or recommendations regarding empiric treatment.[5,13] Patient characteristics to consider in choosing the empiric regimen include whether there is a prosthetic valve, history of IDU, or recent health care exposure, as well as disease severity. If available, hospital-specific empiric treatment recommendations, which account for local susceptibility patterns and are updated regularly, supersede published guidelines, which are updated infrequently.

In most cases, empiric therapy in the ED should include vancomycin (20 to 35 mg/kg actual body weight loading dose, then 15 to 20 mg/kg every 8 to 12 hours not to exceed 3000 mg). Vancomycin alone for one or two doses is a reasonable approach for native valve and prosthetic valve infection and in IDUs. Addition of ceftriaxone (2 g/day) can be considered to cover HACEK and other gram-negative organisms, responsible for less than 6% of infections.[1,5] As soon as blood culture results return, pathogen and susceptibility-directed therapy is selected by an infectious disease specialist. Because of the complex pathology of bacterial growth within vegetations, 4 to 6 weeks of parenteral antibiotic therapy is generally required to eliminate infection. For selected stable patients who respond well to initial therapy in the hospital, IV treatment can be completed as an outpatient. Protocols that include partial oral therapy have recently proven effective and safe.[14]

Disposition

All patients with suspected IE, in whom blood culture results are pending, should be hospitalized. Increasingly, for selected stable patients who respond well to initial treatment in the hospital, IV antibiotic therapy can be completed at home.

Prophylaxis

The American Heart Association and European Society of Cardiology recommend antibiotic prophylaxis to prevent IE for individuals with very high-risk predisposing conditions before undergoing procedures that produce heavy bacteremia with potential IE pathogens. These primarily consist of dental procedures. High-risk predisposing conditions include a prior history of IE, certain forms of congenital heart disease (see previous) and the presence of a prosthetic valve. This issue is of limited relevance to emergency practice, since most commonly performed ED procedures do not produce the kind of bacteremia that requires prophylaxis—including local anesthesia injection into uninfected tissue, laceration repair, endotracheal intubation, and foley catheter placement in the absence of infection. Prophylaxis should be administered prior to cutaneous abscess drainage, however. A reasonable approach is to administer IV vancomycin (15 mg/kg) one hour before incision and drainage.

RHEUMATIC FEVER

Foundations

Background and Importance

From 1920 to 1950, acute rheumatic fever (ARF) was the leading cause of death in United States children and the most common cause of heart disease in individuals younger than age 40 years. During the 1960s and 1970s, the incidence of ARF in the United States and other developed countries declined dramatically because of widespread antibiotic treatment of streptococcal infections, the declining prevalence of the more virulent strains of group A streptococci, and improved hygiene and living conditions. In many developing nations, however, ARF continues to be a leading cause of childhood mortality. Children 4 to 9 years of age remain at greatest risk, with an annual incidence of ARF of 2 to 14 cases/100,000. Chronic rheumatic heart disease (RHD), a consequence of ARF, peaks in adults between the ages of 25 and 34 years. There are an estimated 34 million people worldwide living with RHD.[15]

Pathophysiology

ARF is a delayed nonsuppurative complication of streptococcal pharyngitis. ARF is thought to result from an exaggerated immunologic response to group A beta-hemolytic streptococci—antibodies cross-reacting with tissues in the heart, joints, skin, and central nervous system. Patients with a history of ARF are predisposed to recurrent Strep infections, and repeated infections lead to progressive heart damage.

Clinical Features and Differential Diagnosis

ARF occurs 1 to 5 weeks after the initial bout of pharyngitis. Up to one-third of patients with documented ARF do not remember having had pharyngitis in the preceding month. Fever is generally present during the acute phase of rheumatic fever, rarely lasting more than 2 weeks. Additional manifestations include arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum (see Box 69.4).

A syndrome of mono- or poly-articular arthralgias and arthritis is the most common finding in ARF. Arthritis tends to occur early in the course of ARF and often coincides with a rising titer of streptococcal antibodies. It classically affects large joints, such as the knee, ankle, elbow, and wrist. The pain may be more severe than physical findings suggest (severe arthralgias). Synovial fluid analysis generally reveals a sterile inflammatory fluid.

Cardiac manifestations of ARF may be subtle and can include symptoms and signs of pericarditis, myocarditis, and endocarditis. The mitral valve is the most commonly affected, causing acute mitral regurgitation (MR). Inflammation of the valvular endocardium may result in permanent deformity and impairment of one or more valves over

Fig. 69.3 Erythema Marginatum. This is one form of annular erythema seen in 10% of cases of children with acute rheumatic fever but is rare in adults with the disease. (From Cohen J, Powderly WG. *Infectious Diseases*. 2nd ed. New York: Mosby; 2004.)

the course of decades. Stenotic lesions of the mitral and/or aortic valve are common late manifestations of RHD (Fig. 69.3).

Chorea is a random, rapid, purposeless movement, usually of the upper extremities and face. Chorea is a relatively rare manifestation of ARF that tends to emerge after a long latency period. Subcutaneous nodules and erythema marginatum are found in fewer than 10% of cases of ARF. Their presence, however, should suggest the diagnosis. Subcutaneous nodules are pea-sized and nontender. They typically appear over the extensor surfaces of the wrists, elbows, knees and, occasionally, the spine. Erythema marginatum is a nonpruritic, painless, evanescent ring of erythema that commonly appears on the trunk and proximal extremities (see Fig. 69.3).

Diagnostic Testing

Diagnosis of ARF is clinical, based on the presence of the characteristic manifestations plus evidence of antecedent streptococcal infection. In 1944, Jones formulated major and minor criteria for the diagnosis of ARF, which, in revised form, remain the basis for making the diagnosis (Box 69.5).[16] Throat cultures are usually negative at the time of clinical onset of ARF, but antistreptolysin antibody titers remain positive for 4 to 6 weeks from the time of infection. The erythrocyte sedimentation rate and C-reactive protein levels are typically elevated, and a prolonged PR interval is common and suggestive in ARF.

Management and Disposition

All patients with ARF should receive antibiotic therapy, regardless of the clinical history of pharyngitis. Penicillin can be administered orally (250 mg for patients less than 28 kg, 500 mg for patients 28 kg and above, BID or TID for 10 days) or intramuscularly (600,000 units of penicillin B for patients less than 28 kg, 1.2 million units for patients 28 kg and above, as a one-time dose).

Treatment for arthritis consists of anti-inflammatory agents, usually aspirin, administered until symptoms resolve and the erythrocyte sedimentation rate and C-reactive protein concentration normalize. Patients with severe carditis are often treated with corticosteroids, but no evidence supports this treatment. Patients with congestive heart failure should be managed accordingly. Treatment is aimed at symptom relief and unfortunately does not decrease the likelihood of progression to RHD. Primary prevention involves treating those with group A streptococcal pharyngitis within nine days of the onset of symptoms, which decreases the risk of ARF. Following ARF, patients should receive prophylactic antibiotics (generally, penicillin) for up to 10 years, depending on the severity of carditis, to prevent recurrences.

BOX 69.5 Jones Criteria (Revised) for the Diagnosis of Acute Rheumatic Fever

Major Manifestations
Carditis
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules

Minor Manifestations
Arthralgias
Fever
Increased erythrocyte sedimentation rate or C-reactive protein level
Prolonged PR interval

Evidence of Preceding Streptococcal Infection
Positive throat culture for group A beta-hemolytic streptococci or positive rapid streptococcal antigen test
Elevated or rising streptococcal antibody titer, usually antistreptolysin O

VALVULAR HEART DISEASE

Foundations

Anatomy and Physiology

There are four heart valves, three of which (tricuspid, pulmonic and aortic) are tricuspid, while the mitral valve is bicuspid. Each cusp is formed from a double layer of endocardium attached at its base to the fibrous skeleton of the heart. For the tricuspid and mitral valves, muscular projections from the ventricles (papillary muscles) merge with tendinous cords (chordae tendineae) which extend from the edges of the cusps. Contraction of the ventricle leads to contraction of the papillary muscles, resulting in the opening or closing of the valve.

Mitral Stenosis

The most common cause of mitral stenosis (MS) worldwide is RHD, a decades-delayed complication of ARF and carditis of the mitral valve. In the developed world, mitral annular calcification leading to degenerative valvular disease in the elderly is the most common etiology of MS.[17] Though uncommon, MS can also be a congenital condition.

Pathophysiology

The normal cross-sectional area of the mitral valve orifice is 4 to 6 cm^2. Stenosis becomes clinically significant when the area decreases to below 1.5 cm^2, or 1 cm^2/m^2 body surface area in larger patients. As the valve narrows, impeded inflow from the left atrium to the left ventricle results in decreased preload, decreased cardiac output, left atrial hypertension and, ultimately, pulmonary congestion. As the disease progresses, patients may develop pulmonary hypertension, right ventricular hypertrophy, and right ventricular failure.

The most common complication of MS is atrial fibrillation due to left atrial dilation. Atrial fibrillation leads to decreased atrial contraction and decreased diastolic filling with subsequently decreased cardiac output. Patients with underlying MS may also decompensate in the setting of pregnancy, anemia, infection, and hyperthyroidism, conditions that increase cardiac demand and decrease ventricular filling. Finally, right ventricular failure may cause left ventricular dysfunction due to chronic preload reduction and impaired contractility over time.

Clinical Features

Early symptoms of MS include decreased exercise tolerance and dyspnea on exertion. Patients with more advanced disease may have orthopnea and peripheral edema. Embolic events from atrial fibrillation may be the initial presenting feature. Hemoptysis from rupture of a bronchial vein, and hoarseness, caused by compression of the recurrent laryngeal nerve, are classic but uncommon presentations. Chest pain or discomfort is not a typical feature of MS.

Aside from the typical signs of heart failure, findings that suggest the presence of MS include a loud S1 and an opening snap in early diastole, accompanied by a low-pitched, rumbling, decrescendo diastolic murmur, best heard at the apex.

The chest x-ray may be normal, or cephalization of pulmonary vascular flow or pulmonary vascular congestion may be observed. Left atrial enlargement may be suggested by straightening of the left heart border in more advanced cases. ECG may demonstrate atrial fibrillation along with signs of left atrial enlargement or right ventricular hypertrophy. Echocardiography is the preferred method of diagnosis and assessment of disease severity[18,19] (Fig. 69.4). TTE is often sufficient for routine care,[20] however TEE typically provides more detailed information on valve morphology and evaluates for concomitant left atrial thrombus.

Management

Acute stabilization in the ED begins with identification and treatment of underlying precipitants, such as anemia or infection. Symptoms of vascular congestion (pulmonary and peripheral) are treated with diuresis. Rate control and anticoagulation are important if secondary atrial fibrillation is present. With long term medical management alone, 5-year survival rates with MS are 47%.[21]

Definitive surgical interventions include percutaneous and open approaches. Symptomatic severe MS is most commonly treated with percutaneous transvenous mitral commissurotomy, also known as percutaneous balloon valvulotomy, when valve anatomy is favorable, and when there is an absence of left atrial thrombus and moderate-severe regurgitation.[18,19] Surgical mitral valve replacement is considered based on surgical expertise, specific valve characteristics and patient comorbidities.

(From Marijon E, Mirabel M, Celermajer DS, Jouven X. Rheumatic heart disease. *Lancet*. 2012;379:953–964.)

Mitral Regurgitation

MR is the most prevalent valvular disease worldwide.[22] Primary MR is caused by degenerative disease, RHD, IE, mitral valve prolapse (MVP) in connective tissue disease, and acute papillary muscle rupture, all leading to direct dysfunction of the valve leaflets or support structures (the annulus, chordae or papillary muscles) themselves. Secondary MR is caused by left ventricular enlargement and remodeling due to coronary artery disease or other cardiomyopathy, which over time distorts the architecture of the support structures and leads to secondary valve dysfunction.

Pathophysiology

MR causes retrograde flow of blood from the left ventricle to the left atrium during systole. Pathophysiology differs between acute and chronic presentations. Acute MR, as results from papillary muscle rupture secondary to myocardial infarction, is characterized by a sudden decrease in afterload, low left atrial compliance and sharply elevated left atrial pressure, resulting in acute pulmonary vascular congestion. Chronic MR, as results from cardiomyopathy, is characterized by stable afterload in the setting of cardiac remodeling, progressively increased left atrial compliance and near-normal left atrial pressures, resulting in preserved cardiac output—until the point at which decompensation ensues. Acute MR is a true cardiac emergency, whereas chronic MR may be occult and go undetected for many years.

Clinical Features

Acute Mitral Regurgitation

Acute MR presents as severe dyspnea, acute pulmonary edema, or cardiogenic shock, typically in a patient with no prior history of heart failure. Classically a harsh, high pitched midsystolic murmur can be heard, loudest at the apex. Radiation is usually to the axilla but depends on the direction of the regurgitant jet. In severe acute MR, there may be an S3 and a short diastolic rumble.

The chest x-ray usually demonstrates unilateral or bilateral pulmonary edema. The ECG may show signs of ischemia or infarction, including Q waves, ST-T changes and left bundle branch morphology. ED point of care TTE establishes a cardiogenic cause of acute dyspnea with high sensitivity/specificity,[23] and experienced ED sonographers can identify an MR jet (Fig. 69.5). Comprehensive echo will identify the incompetent valve, regurgitant flow, and papillary muscle rupture, if present, in addition to decompensated heart failure.

Chronic Mitral Regurgitation

The presentation of chronic MR is similar to that of chronic systolic heart failure, with clinical symptoms and signs of vascular congestion. The chronic MR murmur is classically described as holosystolic, heard best at the apex and radiating to the axilla. There may be a S3 present.

The chest radiograph may suggest left atrial enlargement. Atrial fibrillation is common, and the ECG often demonstrates left atrial and

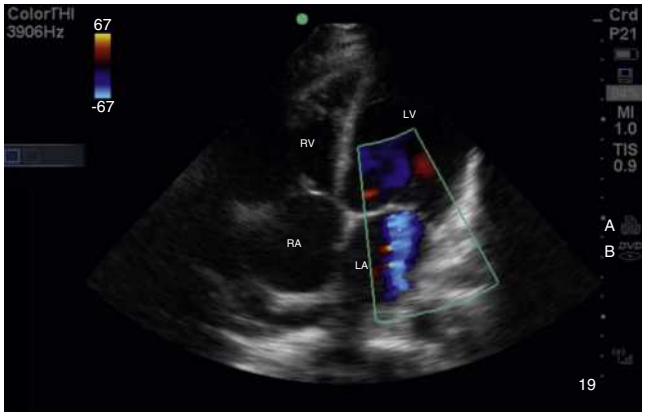

Fig. 69.5 Transthoracic echocardiography (apical four chamber view) of mitral regurgitation (*represents mitral regurgitant jet). *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Courtesy of Highland Emergency Ultrasound Division.)

ventricular hypertrophy. Echocardiography may show a normal or above-normal ejection fraction, but some portion of systolic flow is retrograde. TEE is the preferred diagnostic modality to evaluate valve anatomy and size and direction of the regurgitant jet. Increasingly, 3D TEE is being used to grade disease severity and guide valve replacement.[24]

Management

When the diagnosis of acute MR is suspected, emergency echocardiography and right heart cardiac catheterization should be pursued to assess the degree of regurgitation and urgency for surgery. Initial stabilization in the ED includes treatment of pulmonary edema with intravenous nitrates, diuretics and noninvasive positive pressure ventilation (CPAP or BiPAP). Norepinephrine is the first-line vasopressor for hypotensive patients, and once the blood pressure is supported with a mean arterial pressure of at least 65 mm Hg, inotropic support with dobutamine can be added for patients with persistent hypoperfusion. In a persistently hypotensive patient who does not respond to vasopressor and inotropic therapy, an intraaortic balloon pump (IABP) may stabilize the patient and provide a bridge to valve replacement surgery. A small subset of patients may improve and stabilize without surgical intervention, however rates of secondary pulmonary hypertension in this population are high. In cases of acute MR from inferolateral myocardial infarction, coronary artery revascularization can lead to complete resolution of MR.

Chronic symptomatic MR is managed with afterload reducing agents angiotensin-converting enzyme [ACE] inhibitors and angiotensin II receptor blockers [ARB], and beta blocking agents are first-line therapy), and diuretics to prevent progression of left ventricular (LV) failure.[19] A long period of medical therapy and annual echocardiographic monitoring is the norm, with 15-year survival approaching 70% with medical therapy alone. Once the left ventricular ejection fraction (LVEF) falls below 60%, valve repair or replacement is recommended to avoid irreversible left ventricular dysfunction. Open valve repair or replacement remains the surgical treatment of choice in most cases. Recent studies support the use of transcutaneous mitral valve repair (MitraClip) for carefully selected patients with primary MR.[19]

Mitral Valve Prolapse

MVP is a form of abnormal mitral valve leaflet movement during systole. It may be inherited or sporadic. Epidemiological studies report a prevalence of approximately 2% to 3% worldwide.[25] While usually a benign condition, MVP can result in MR and rarely other complications.

Pathophysiology

MVP is characterized by myxomatous proliferation of the middle spongiosa layer of the valve leaflet, resulting in abnormal billowing of one or both leaflets into the left atrium during systole. MVP is usually an isolated primary disorder, but may be associated with connective tissue disorders, particularly Marfan and Ehlers-Danlos syndromes. Most patients with MVP have no or mild MR, however severe MR occurs in up to 10% of patients with MVP.[26] The most frequent complications of MVP are progressive MR (resulting in need for valve replacement), atrial fibrillation, heart failure and endocarditis.

Clinical Features

MVP is associated with a wide variety of clinical symptoms, from asymptomatic to palpitations, chest pain, dyspnea, lightheadedness, fatigue, and anxiety. A midsystolic click may be heard, caused by snapping of the chordae tendineae with prolapse of the valve. Occasionally a mid to late systolic murmur can be heard over the left lower sternal border. Echocardiography is the primary diagnostic modality.

Management

Patients with MVP should be reassured about the typically benign natural history of the disease. Beta-blockers may be used to control symptoms such as palpitations, chest pain, and anxiety. Lifestyle modifications, such as exercise, relaxation techniques, and avoidance of ethanol, caffeine, and other stimulants may also be helpful.

AORTIC STENOSIS

The most common cause of aortic stenosis is calcific degeneration, which is prevalent in older adults with atherosclerotic disease. Aortic stenosis also occurs in younger individuals with a bicuspid aortic valve and calcific changes. RHD can lead to atrial stenosis (AS), in which case it may coexist with MS.

Pathophysiology

The normal aortic valve area (AVA) is approximately 3 to 4 cm^2. Stenosis occurs through an active process of calcification, inflammation, oxidative stress and remodeling. Clinically significant obstruction of outflow from the left ventricle occurs when the AVA decreases by more than 50%.[27] As the valve narrows, increased left ventricular afterload leads to compensatory left ventricular hypertrophy (LVH) to maintain cardiac output. Left ventricular hypertrophy and increased wall tension predispose the patient to cardiac ischemia, even in the absence of significant coronary artery disease. Further progression of disease is associated with left ventricular dysfunction, left atrial enlargement, and atrial fibrillation. In advanced stages, cardiac output decreases while left atrial and pulmonary artery pressures increase, leading to pulmonary hypertension and right heart failure.

Severe aortic stenosis is defined by a peak velocity of ≥4 m/s, a mean pressure gradient (MPG) of ≥40 mm Hg, or a valve area of less than 1 cm^2.[18] Up to one-third of patients with severe AS have a preserved ejection fraction.[28] Individuals with severe AS are preload-dependent and have very little cardiovascular reserve. Any disruption of the delicate balance between myocardial oxygen supply and demand (e.g., rapid atrial fibrillation, dehydration, acute blood loss) can result in acute decompensation.

Clinical Features

AS is most commonly diagnosed incidentally on routine physical exam, or on echocardiography as part of a broader cardiology work-up. Symptomatic AS gradually progresses from fatigue, exertional dyspnea, and angina to lightheadedness and exertional syncope, to overt heart

failure. In an older patient with chest pain who appears preload dependent in the ED, the possibility of AS, with or without coronary artery disease, should be considered. In addition to the gradual progression of symptoms, patients may also experience acute decompensation due to triggers such as sepsis, anemia, or endocarditis.

The classic AS murmur is a crescendo-decrescendo systolic murmur, heard best at the right upper sternal border, radiating into the carotids. An S4 gallop may be present at the apex. As the severity of disease increases, the murmur peaks later and becomes less audible. Carotid pulses may be delayed (tardus) and diminished in intensity (parvus).

The chest radiograph is frequently normal except in cases of acute decompensation. In elderly patients with calcific degeneration, valve calcification may be visible and is often associated with a tortuous aorta. ECG typically reveals LVH. Evidence of left atrial enlargement, left axis deviation, left bundle branch block, and atrial fibrillation (in the late stage) may also be present. Echocardiography is the main modality used to diagnose AS and stage severity and can be reliably done in the ED setting.[23,29] AS severity is categorized using three echocardiographic parameters: aortic peak jet velocity (PVel), MPG, and calculated AVA.[18]

Management

The natural history of AS is one of slow asymptomatic progression over years to decades. If identified during this latent phase, AS can be managed medically or surgically based on patient preference. Antihypertensives are the only medical therapy recommended by the current American and European guidelines.[27] Statins may slow the rate of aortic calcification, but do not affect the rate of valve narrowing. Once symptoms develop, medical management has a limited role, and survival is markedly reduced unless the valve is replaced. The choice of surgical aortic valve replacement (SAVR) versus transcatheter aortic valve replacement (TAVR) is based on multiple factors, including surgical risk, patient frailty and comorbidity, and patient preference.[30] In high-risk patients, balloon valvuloplasty is feasible and safe as a bridge to valve replacement, but long-term survival is poor with valvuloplasty alone.[31]

In the ED setting, management of decompensated AS includes judicious fluid resuscitation, blood transfusion and restoration of sinus rhythm, if indicated. Vasodilators, diuretics and inotropic agents should be avoided, if possible. When required, first-line vasopressor support is with phenylephrine or norepinephrine. When there is no response to medical therapy and the patient is a candidate for valve replacement, an IABP may provide a bridge to surgery.

AORTIC REGURGITATION

Aortic regurgitation (AR) can be caused by disease of the aortic valve leaflets, or by distortion of the anatomy of the aortic root and ascending aorta. Aortic valve leaflet abnormalities are caused by calcific degeneration, a congenital bicuspid valve, infectious endocarditis, or RHD. Processes that affect the aortic root include idiopathic root dilation (ectasia), connective tissue disorders, syphilis, aortic aneurysm and aortic dissection. AR has an estimated prevalence of 4.9% in the Framingham data, with moderate or severe AR found in 0.5%.[32]

Pathophysiology

In acute AR, sudden development of AR leads to increased left ventricular end-diastolic pressure, reduced cardiac output, and subsequent acute pulmonary vascular congestion. In contrast, in chronic AR, progressive left ventricle remodeling and dilation allows the heart to maintain near-normal cardiac output despite significant regurgitation. The increased LV volume leads to increased stroke volume, allowing for the maintenance of cardiac output despite regurgitation.

Clinical Features

The clinical presentations of acute and chronic AR are clinically distinct.

Acute Aortic Regurgitation

Patients with acute AR can present with severe respiratory distress and cardiogenic shock, due to rapidly increased end-diastolic volume in the setting of low left ventricular compliance and acute pulmonary vascular congestion.

Patients are typically tachycardic, hypotensive, and hypoxic. The pulse pressure may be normal or only slightly widened. A short, soft, diastolic murmur may be present, but often is difficult to detect in the ED setting.

Chest x-ray may show pulmonary vascular congestion. The ECG is typically normal, but may show signs of demand ischemia. Emergent echocardiography is required to confirm the diagnosis. Point-of-care ultrasound in the ED using a parasternal long (PSL) axis view can rapidly identify valve failure using color doppler over the valve area to observe the regurgitant jet (Fig. 69.6).[23] The PSL axis view may also demonstrate a dilated aortic outflow tract suggesting a problem with the aortic root, and the apical four-chamber view may demonstrate a vegetation suggesting endocarditis as the primary etiology (see Fig. 69.2). Additionally, the suprasternal notch view is easily and rapidly obtainable view of the thoracic aorta which allows accurate visualization of a dissection flap if present.[33]

Chronic Aortic Regurgitation

Chronic AF tends to have a prolonged asymptomatic period, after which a patient develops dyspnea on exertion due to increased LV end-diastolic pressures and anginal symptoms due to decreased aortic diastolic pressure and increased oxygen demand.

Chronic AR is characterized by a wide pulse pressure. The point of maximal impulse is typically displaced and sustained. A high-pitched, blowing, diastolic murmur at the left lower sternal border is usually present. Classic physical findings of severe AR include a rapidly rising and falling carotid pulse (water hammer, or Corrigan's, pulse), head bobbing due to exaggerated carotid pulsations

Fig. 69.6 Transthoracic echocardiography (parasternal long axis view) of aortic regurgitation (*represents aortic regurgitant jet). *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle. (Courtesy of Highland Emergency Ultrasound Division.)

(Musset's sign), spontaneous nail bed pulsations (Quincke's sign), or a bruit over the femoral artery (Duroziez's sign). An Austin-Flint murmur—a soft mid-diastolic rumble caused by a regurgitant stream against the anterior leaflet of the mitral valve—may also be present when auscultating the apex.

The chest radiograph may show cardiomegaly, and pulmonary vascular congestion in advanced or decompensated AR. The ECG usually demonstrates LVH. Echocardiography provides a definitive diagnosis, and is used to evaluate valve anatomy, and aortic root and ascending aortic dimensions, as well as LV size and function. Echocardiography can also determine the feasibility of valve or root repair.

Management

Acute AR is a surgical emergency necessitating urgent valve replacement, along with repair of any underlying aortic root pathology. Medical stabilization involves the cautious use of short-acting vasodilators (nitroprusside, nicardipine, or clevidipine) and diuretics. Use of an IABP is contraindicated in the setting of an incompetent aortic valve. Often, diagnosis and management of the underlying aortic dissection or IE must be undertaken simultaneously. For aortic dissection complicated by AR, beta-blocker therapy should be used with caution.

Chronic AR is managed like other types of decompensated heart failure, with emphasis on diuresis, as well as preload and afterload reduction, to prevent worsening left ventricular function and avoid aortic complications if an aneurysm is present. Ideally, valve repair or replacement should be performed before the development of left ventricular systolic dysfunction. Chronic severe AR has a yearly mortality of 10% to 20% without surgical treatment.

Complications of Prosthetic Valves

Prosthetic heart valves may be mechanical or biologic. Biologic valves include whole valve transplants (human or porcine) as well as bioprosthetic valves, typically manufactured from bovine pericardium. All prosthetic heart valves are associated with complications, ranging from structural failure and thrombosis to systemic embolization, hemolysis, and endocarditis (Box 69.6). In the acute setting, the diagnosis of a prosthetic valve complication can be challenging because symptoms and signs are often subtle.

Structural Failure

Primary structural failure is extremely uncommon with modern mechanical valves. When it does occur, the presentation is one of acute severe regurgitation and shock, and emergent valve replacement is required. With biologic valves, structural failure is more common but less dramatic. At 10 years, 20% to 30% of bioprosthetic valves exhibit some evidence of structural failure, and most are replaced electively. Symptoms are characteristically insidious in onset and are similar to those of native valvular disease.

BOX 69.6 Prosthetic Valve Complications

- Structural failure
- Valve thrombosis
- Systemic embolization
- Hemolysis
- Endocarditis

Valve Thrombosis

Prosthetic valve thrombosis occurs with both mechanical and biologic valves. When appropriately anticoagulated, mechanical valves have thrombotic complications at a similar rate (~2%/year) as biologic valves. Patient compliance with oral anticoagulation therapy therefore is an important consideration when evaluating for thrombotic and embolic complications. Symptoms of prosthetic valve thrombosis are generally subacute and may have characteristics of stenotic disease, regurgitant disease, or both. On physical examination, the diagnosis is suggested by a decreased or absent valve click, new regurgitant murmur, or louder than expected stenotic murmur. Echocardiography may demonstrate the thrombus or restricted leaflet motion. Treatment options include fibrinolytic therapy and surgery.

Systemic Embolization

The incidence of systemic embolization from a prosthetic valve is approximately 1%/year. Compared with aortic valve prostheses, mitral valve prostheses are associated with twice the risk of systemic embolization, with rates roughly equal for an appropriately anticoagulated mechanical mitral valve and a bioprosthetic valve. The vast majority of diagnosed embolic events (85%) involve the central nervous system and roughly 50% of these result in permanent impairment.

Hemolysis

Mild hemolytic anemia resulting from sheer forces across the prosthetic valve is common but usually subclinical. In more severe cases, presenting features include dyspnea, fatigue, and even jaundice. Iron replacement is effective therapy for most patients but transfusion may be required. Worsening hemolysis may be the result of a new periprosthetic leak or other structural failure, which should be evaluated by echocardiography.

Endocarditis

The incidence of PVE is highest during the initial months after surgery and is similar for mechanical and bioprosthetic valves. Early PVE, within 60 days of surgery, is presumed to be caused by a pathogen acquired perioperatively and is associated with relatively high morbidity and mortality, whereas late PVE is more likely due to transient bacteremia and generally has a better prognosis. As with other forms of IE, fever is the most common symptom and systemic embolization is a common presentation. A normal TTE does not rule out PVE, and a TEE is generally required for diagnosis and complete evaluation of the valve. Three sets of blood cultures are recommended to evaluate for PVE. The ED diagnosis of PVE is usually presumptive because definitive diagnosis requires positive blood cultures. Vancomycin is a reasonable initial empiric antibiotic choice, although gentamicin and rifampin are often added for definitive therapy in Staphylococcal PVE. Early consultation with both an infectious disease specialist and cardiothoracic surgeon should be obtained, and transfer to a center with cardiothoracic surgical capabilities should be considered.

Disposition

Patients with acute symptoms related to valvular heart disease should be admitted to the hospital until their condition has stabilized and the cause for their decompensation has been addressed. For patients with stable valvular disease, outpatient cardiology follow-up is recommended.

CHAPTER 69: QUESTIONS AND ANSWERS

1. What is the most common manifestation of acute rheumatic fever (ARF)?
   a. Carditis
   b. Chorea
   c. Erythema marginatum
   d. Polyarthritis

Answer: d. Arthritis occurs early in the course of ARF. The knees, ankles, elbows, and wrists are commonly affected, and pain can be out of proportion to physical findings. Cardiac manifestations are subtle and may reflect endocarditis, myocarditis, or pericarditis. Chorea and erythema marginatum are rare. Chorea is typically a late finding.

2. A 49-year-old woman presents with progressive dyspnea on exertion and orthopnea. Vital signs are temperature 36.7°C (98.1°F; oral), heart rate, 110 beats/min, blood pressure, 135/80 mm Hg, respiratory rate, 22 breaths/min, and oxygen (O_2) saturation, 97% on room air. The physical examination is remarkable for clear lung fields and an irregularly irregular rhythm with a 4/6 diastolic murmur in the left anterior axillary line. She has no peripheral edema. Which of the following would be appropriate hemodynamic management of her cardiac pathophysiology?
   a. Aggressive diuresis
   b. β_1-Agonist to increase chronotropy
   c. Beta blocker
   d. Selective arterial vasodilator

Answer: c. This patient has a picture consistent with atrial fibrillation and mitral stenosis. The apical diastolic murmur and left atrial enlargement, along with progressive dyspnea, all support the diagnosis. Tachycardia is poorly tolerated because of the need for higher left atrial pressures and a longer time during diastole to perfuse across the stenotic valve. Slow and full are appropriate goals. Diuresis might decrease venous return. Any agent producing tachycardia would decrease diastole time and left ventricular preload. An arterial vasodilator would have little effect, given the normal blood pressure and the fact that systemic vascular dilation would not be seen at the mitral valve level as long as the aortic valve was competent.

3. A 32-year-old woman with a history of injection drug use presents with persistent fevers, night sweats, and shortness of breath. Vital signs are temperature 38.2°C (100.8°F; oral), heart rate, 123 beats/min, blood pressure, 105/60 mm Hg, respiratory rate, 26 breaths/min, and oxygen (O_2) saturation, 93% on room air. The physical examination is remarkable for scattered rhonchi and a 2/6 systolic murmur in the left lower sternal border. Which of the following is the most appropriate antibiotic to start?
   a. Clindamycin
   b. Vancomycin
   c. Ceftriaxone
   d. Cefepime

Answer: b. In most cases, empiric therapy in the ED should include vancomycin, and vancomycin alone for one or two doses is a reasonable approach for native valve and prosthetic valve infection and in IDUs. Ceftriaxone can be added to vancomycin to cover HACEK and other gram-negative organisms, but these are responsible for less than 6% of infections. There is no role at this time for empiric use of clindamycin or cefepime.

4. A 62-year-old man with presents 3 days after being admitted for an inferior ST-segment elevation myocardial infarction (STEMI). He underwent a successful percutaneous coronary intervention (PCI) and was just discharged earlier in the day. He developed sudden onset shortness of breath at home, and he arrives in extremis. Vital signs are temperature 37.2°C (98.8°F; oral), heart rate, 112 beats/min, blood pressure, 85/68 mm Hg, respiratory rate, 24 breaths/min, and oxygen (O_2) saturation, 90% on room air. The physical examination is remarkable for severe respiratory distress, diffuse crackles, and a 2/6 systolic murmur in the left lower sternal border. Which of the following is the most appropriate intervention?
   a. Give 2L of crystalloid over an hour.
   b. Start dobutamine.
   c. Initiation of dialysis for volume overload.
   d. Initiate continuous positive airway pressure (CPAP) therapy.

Answer: d. This patient presents with likely acute mitral regurgitation (MR) from a papillary muscle rupture after an myocardial infarction (MI). Giving additional fluid will likely make his pulmonary edema worse. Starting dobutamine without a vasopressor while he is hypotensive could make the hypotension worse. When the diagnosis of acute MR is suspected, initial stabilization in the ED includes treatment of pulmonary edema with intravenous nitrates, diuretics, and noninvasive positive pressure ventilation.

5. A 38-year-old man with presents with progressive dyspnea over a day, starting 2 hours before arrival. Vital signs are temperature 38.9°C (102.0°F; oral), heart rate, 115 beats/min, blood pressure, 120/72 mm Hg, respiratory rate, 26 breaths/min, and oxygen (O_2) saturation, 92% on room air. The physical examination is remarkable for diffuse crackles and a 2/6 systolic murmur in the left lower sternal border. His echocardiogram demonstrates a large, mass on the mitral valve with severe mitral regurgitation (MR). In addition to managing his pulmonary edema, which of the following is the most appropriate intervention?
   a. Administer beta-blockade to reduce the risk of embolization.
   b. Consult Cardiac Surgery.
   c. Start a heparin infusion.
   d. Start digoxin for heart rate control.

Answer: b. Patients with suspected infectious endocarditis (IE) and acute heart failure require immediate consultation by a cardiothoracic surgeon. In general, there has been a shift toward earlier surgical treatment in IE, with approximately one-half of patients with left-sided infection undergoing surgery during the index admission. If possible, patients with left-sided IE should be managed by a multidisciplinary team at a center capable of cardiothoracic surgery. There is no role for addition of beta-blockade in this patient in heart failure. Heparin and digoxin are not indicated for IE.

70

Hypertension

Phillip D. Levy and Aaron Brody

KEY CONCEPTS

- Elevated blood pressure with or without associated symptoms is exceedingly common in the emergency department (ED).
- A true hypertensive emergency is defined by the presence of acute target organ damage (TOD) and is distinct from other clinical presentations.
- Commonly encountered hypertensive emergencies include ischemic and hemorrhagic stroke, myocardial infarction, acute heart failure, aortic dissection, and pre-eclampsia.
- Management strategies regarding target blood pressure reduction, rate of reduction, and agent choice vary widely among the discrete conditions defined as hypertensive emergencies. Thus, clinical decision making in this context requires knowledge of the physiology and an evidence-based approach to each condition.
- For patients without acute TOD, immediate antihypertensive therapy is not needed. However, emergency clinicians play an essential role in the care of this group, providing screening, ongoing surveillance, and linkage to care to prevent secondary complications of this disease.
- Initiation of long-term oral antihypertensive therapy in the ED for those with elevated blood pressure but no established history of hypertension is not recommended; however, emergency clinicians are encouraged to refill, reinitiate, or up-titrate antihypertensive medications in patients with elevated blood pressure who are known to have chronic hypertension.

FOUNDATIONS

Background and Importance

Hypertension (HTN) is an important but largely treatable risk factor for cardiovascular disease that affects almost half of Americans and approximately 1 billion people worldwide.[1,2] Recent society guidelines have lowered the diagnostic criteria and treatment threshold for HTN,[3] thus increasing the prevalence of HTN from 31% to 45%.[4] Under these definitions, the proportion of patients with controlled HTN has increased from 25% to 43% over the last two decades,[5] reflecting the partial success of awareness campaigns and new classes of antihypertensive medications. This has clear implications on the practice of emergency medicine. According to data from a nationwide emergency department (ED) sample between 2006 and 2012, one patient of every four in the ED was diagnosed with HTN,[6] and this number is steadily increasing. Hypertensive emergencies, while still rare (2 to 6 per 1000 visits), are also rising in prevalence.[7] Patients presenting to the ED for hypertensive events bear a four-fold increase in risk for long-term adverse cardiovascular outcomes, but this risk is attenuated by outpatient follow-up.[8]

Despite this understanding, there is a critical divide between what constitutes a true emergency condition and what does not when it comes to elevated BP in the ED. When associated with acute target organ damage (TOD), HTN represents a component of a truly critical condition that warrants emergent intervention. However, this is relatively rare, and, for the vast majority, acute TOD will not be present, even in the setting of markedly elevated BP. Although such patients have a low likelihood of near-term adverse events and are not classified as acute emergencies, interventions to control BP if chronically elevated can decrease their overall cardiovascular risk. Thus, this distinction is a key aspect of the approach to HTN in the ED and a core feature of emergency medicine practice.

Importance

HTN is a major modifiable risk factor for the development of cardiovascular, cerebrovascular, and renovascular disease. Uncontrolled BP is strongly associated with heart failure, myocardial infarction, stroke, vascular dementia, and chronic kidney disease. The risk of developing these conditions increases with the degree of BP elevation, and it has been estimated that the risk of cardiovascular disease doubles for each elevation of 20 mm Hg systolic and 10 mm Hg diastolic BP, starting at 115/75 mm Hg. Conversely, antihypertensive treatment can lower the risk for stroke by as much as 40%, myocardial infarction by 25%, and heart failure by 50%.

The distribution of HTN and the benefits of intervention are not uniform. According to data from the National Health and Nutrition Examination Survey (NHANES), African Americans have higher age adjusted rates of diagnosed HTN (males, 57.6%, females 53.2%) than whites (males, 46.7%, females 38.8%) or Hispanics (males, 44.4%, females 37.9%), and conversely, worse rates of BP control (22% for blacks, and 19.3% for Hispanics vs. 26.8% for whites), leading to an increased risk of adverse outcome.[2] This disparity, in combination with other economic, social, and lifestyle determinants, leads to a dramatically increased morbidity from cardiovascular disease in the African American population. HTN is by far the single most important contributor to racial differences in life-years lost from cardiovascular disease, accounting for 50% of the excess risk within the African American community.

Definition of Hypertension and Relevant Terminology

Although BP below 120/80 mm Hg is considered normal, an understanding of what constitutes HTN has been evolving. The most recent

TABLE 70.1 ACC/AHA 2017 Guidelines Definition of Hypertension Compared to Classic (JNC 7)

Systolic and Diastolic BP	JNC 7	ACC/AHA 2017 Guidelines
<120 SBP *and* <80 DBP	Normal	Normal
120–129 SBP *or* <80 DBP	Prehypertension	Elevated blood pressure
130–139 SBP *or* 80–89 DBP	Prehypertension	Stage I HTN
140–159 SBP *or* 90–99 DBP	Stage I HTN	Stage II HTN
>160 SBP *or* >100 SBP	Stage II HTN	Stage II HTN

ACC, American College of Cardiology; *AHA*, American Heart Association; JNC 7.

guideline from the American Heart Association (AHA)/American College of Cardiology (ACC) reduces the diagnostic cut-off for HTN from 140/90 to 130/80 mm Hg.[9] Additionally, these guidelines drastically change the classic categorical definitions as defined in the Seventh Report of the Joint National Commission on Prevention, Detection, Evaluation, and treatment of High Blood Pressure. Table 70.1 displays the change in diagnostic categories of HTN. These changes reflect an increasing awareness of the long-term cardiovascular risk associated with modest elevations in BP,[10] and de-emphasize the significance of severely elevated BP (i.e., stage II HTN) as a discrete clinical category.

Historically, the approach to BP measurement has been office-based, with a diagnosis of HTN considered to be present when BP of 140/90 mm Hg (now 130/80 mm Hg) or higher is detected on properly measured, seated readings on two or more occasions. Recent data have suggested that the 24-hour ambulatory BP measurement (ABPM) may be a better method to diagnose HTN.[11] ABPM enables the evaluation of BP over a range of conditions, minimizing the potential for so-called white coat effects while increasing the likelihood of detecting masked HTN. ABPM is recommended (class I, level of evidence A) in the AHA/ACC guideline to confirm a suspected HTN based on clinic measurement and to optimize antihypertensive therapy in those with uncontrolled BP. Importantly, ABPM provides a more accurate estimate of true BP compared with clinic-derived measurements. As a result, correction factors have been proposed with clinic BP values of 130/80, 140/90, and 160/100 mm Hg corresponding to ABPM measurements of 125/75, 130/80, and 145/90 mm Hg, respectively.[12]

How ED-measured BPs fit into this paradigm is not clear. Many ED patients with elevated BP will have an established history of HTN, but a sizeable proportion will not, presenting an opportunity to establish the diagnosis. Although this should be approached with caution based on a single ED measurement, a persistently elevated BP over several prior ED visits may be a reasonable indicator of true underlying HTN. Prior studies have shown that as many as 70% of patients with elevated BP in the ED will also have an abnormal BP at primary care follow-up, and this proportion increases with the ED BP value. Approximately half of a cohort of ED patients with elevated BP, but no diagnosis of HTN who were given devices for home BP measurements, were found to have persistent BP elevations.[13] Newer BP devices that perform automated, unattended serial measurements, discarding the first reading and averaging subsequent values, have been shown to improve the accuracy of clinic-based BP assessment and may be a useful adjunct in the ED for patients with suspected chronic HTN.[14]

More important in the ED setting than diagnosing chronic HTN is understanding the need for acute intervention among patients with marked BP elevations (i.e., ≥180/100 mm Hg). Although terms such as *hypertensive crisis*, *hypertensive urgency*, and *accelerated* or *malignant HTN*, are liberally applied to such patients, they are poorly defined and are often used interchangeably and incorrectly by emergency clinicians. A more contemporary term, "diffuse microvascular injury" denoting a group of vascular pathologies that may not produce clinical symptoms has been proposed to replace "malignant hypertension."[15] However, this clinical entity has not been well delineated or studied in large cohorts, and an association with short or long-term cardiovascular outcomes has not been demonstrated. A better approach focuses on the presence (or absence) of signs or symptoms attributable to acute TOD within the context of established or potentially new-onset HTN, thus distinguishing patients with active vasculopathy from those without.

Based on this conceptual model, there are three distinct subgroups of patients with elevated BP that are relevant to emergency medicine practice:

1. Hypertensive emergency—a disease state defined by acute TOD, manifest by newly developed clinical sequelae or diagnostic test abnormalities. A hypertensive emergency can exist in patients with or without underlying chronic HTN. Although it has been estimated that 1% to 2% of patients with chronic HTN will experience a hypertensive emergency in their lifetime, hospitalization for this condition is relatively rare, occurring in only 2 of every 1000 ED presentations and 6 per 1000 HTN-related ED visits in the United States.[7]
2. Poorly controlled chronic HTN—a presentation in which patients with established HTN are found to have elevated BP without specific attributable symptoms or evidence of acute TOD. Such presentations often result from inadequate medical management or nonadherence to treatment regimens, but may also reflect refractory disease. Concurrent use of seemingly innocuous medications, including nonsteroidal antiinflammatory drugs (NSAIDs), steroids, decongestants, appetite suppressants, over-the-counter stimulants, oral contraceptives, and tricyclic antidepressants or rebound from short-acting antihypertensives, such as clonidine, may be contributory.
3. Elevated BP without prior history of HTN—a relatively frequent occurrence in which routine ED vital signs identify an elevated BP. Such individuals also may visit the ED after an outpatient physical examination, community health screening event, or self-performed, automated BP measurement identifies elevated BP. Whether or not this truly represents HTN can be difficult to determine in the ED, and all such patients should have a repeat measurement of BP, ideally 1 hour or more after arrival and after analgesic treatment for those with acute pain. Depending on the circumstance, an evaluation for potential TOD may be warranted, along with referral for subsequent follow-up in an outpatient setting. As noted above, ABPM may be useful for confirming chronic HTN, but initiation of such testing is generally outside the purview of emergency clinicians.

An approach to elevated BP in the ED based on this understanding is presented in Fig. 70.1.

Physiology of Hypertension

Whereas BP is known to rise with increasing age, onset of HTN in non–older adults represent a complex interplay of multiple inciting factors including neurohormonal dysregulation, vascular modulation, sodium intake, psychosocial stress, and obesity. Alterations in cardiac and renal function are also important, serving as contributors to and consequences of ongoing BP elevation. Despite an advanced understanding of the pathophysiology of HTN, the definitive cause of elevated BP remains unknown in more than 90% of patients. These individuals are labeled as having primary or essential HTN, and the cause is considered idiopathic. In the subset of patients for whom an identifiable cause can be ascertained, the term *secondary HTN* applies (Table 70.2). Although it may not be possible to diagnose and treat

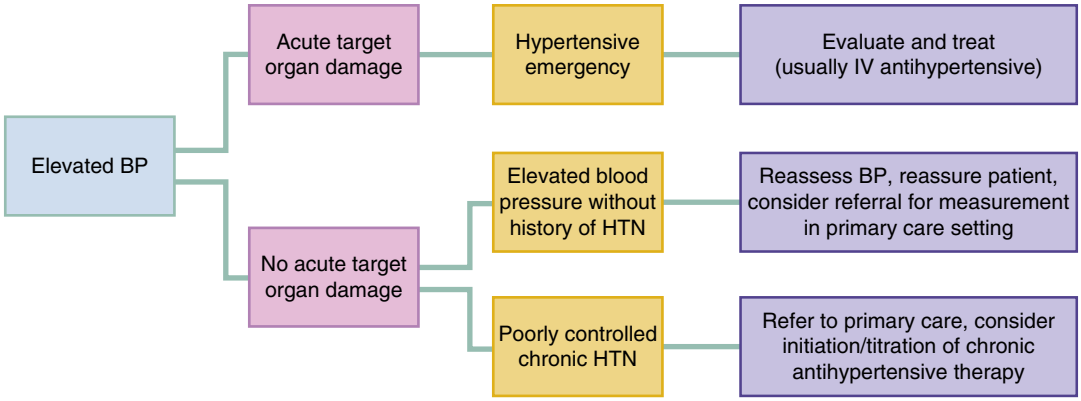

Fig. 70.1 Schematic for the approach to elevated blood pressure *(BP)* in the emergency department. *HTN,* Hypertension; *IV*, intravenous.

TABLE 70.2 Secondary Causes of Hypertension

Cause	Diagnostic Test	Clinical Clues
Endocrine		
Cushing's syndrome and other glucocorticoid excess states	History; dexamethasone suppression test	Glucose intolerance; purple striae
Hyperaldosteronism and other mineralocorticoid excess states	24-h urinary aldosterone level or other mineralocorticoids	Unexplained hypokalemia
Oral contraceptive use	History	
Pheochromocytoma	24-h urinary metanephrine and normetanephrine	Labile or paroxysmal HTN with palpitations, pallor, perspiration
Thyroid disease	Serum TSH	Temperature intolerance, weight loss, tachycardia; hypercalcemia
Parathyroid disease	Serum PTH	
Pulmonary		
Obstructive sleep apnea	Sleep study with O_2 saturation	Obesity; narcolepsy
Renal		
Chronic pyelonephritis	History; urinalysis, urine culture	
Diabetic nephropathy and other chronic kidney disease	Estimated GFR; urine albumin/creatinine ratio	
Nephritic and nephrotic syndromes	Urinalysis; renal biopsy	
Polycystic kidney disease	Renal ultrasound	
Renovascular conditions (e.g., renal artery stenosis)	Doppler flow study; magnetic resonance angiography	HTN onset before the age of 30 years or after 55 years; abdominal bruit; refractory HTN control; recurrent pulmonary edema; unexplained renal failure
Toxic or Metabolic		
Chronic alcohol abuse	History; ETOH level	
Sympathomimetic drug use	History; drug screen	
Tyramine-containing foods	History	Paroxysms of HTN, especially in those taking monoamine oxidase inhibitors
Vascular		
Atherosclerosis		
Coarctation of the aorta	CT angiography	Decreased lower extremity pulses

CT, Computed tomography; *ETOH,* ethyl alcohol; *GFR,* glomerular filtration rate; *HTN,* hypertension; O_2, oxygen; *PTH,* parathyroid hormone; *TSH,* thyroid-stimulating hormone.

such causes of secondary HTN in the ED, when suspected, early referral for outpatient evaluation or, in some cases, hospital admission to expedite evaluation, may be warranted.

Neurohormonal Dysregulation

The sympathetic nervous system (SNS) has a pivotal role in the development of HTN. Norepinephrine, the principal sympathetic neurotransmitter, is a potent stimulator of vasoconstriction. This effect is mediated through peripheral α_1-adrenergic receptor activation in vascular smooth muscle cells and occurs predominantly in small-diameter arterioles. Although individually, these vessels contribute a minuscule amount to BP, in aggregate, they serve as the primary driver of systemic vascular resistance (SVR) and constitute the main force that amplifies afterload in HTN. The SNS also stimulates β_1-adrenergic receptors in the heart, leading to an increase in CO through augmentation of stroke volume and heart rate, but these are considered lesser contributors to the pathologic process of high BP. Sympathoactivation exerts additional direct effects on the kidney that promote sodium reabsorption, leading to an increase in circulating blood volume, and trigger renin release, resulting in angiotensin II production and further vasoconstriction.

In addition to activation by the SNS, the renin-angiotensin-aldosterone system exerts critical, independent effects on BP. Renin is an enzyme produced by the juxtaglomerular cells in the kidney in response to several factors beyond adrenergic stimulation, including sodium load in the distal tubule and renal perfusion status. Renin cleaves angiotensin I from its plasma globulin precursor angiotensinogen. Angiotensin I is then converted to angiotensin II by circulating and tissue-bound (especially in the lung) angiotensin-converting enzyme (ACE). Angiotensin II exerts systemic and renal effects by binding to angiotensin II type I (AT_1) receptors, which results in arterial vasoconstriction, sodium reabsorption, and modulation of the glomerular filtration rate (GFR). Through AT_1 receptor binding in the adrenal gland, angiotensin II also serves as a potent stimulator of aldosterone release, promoting further sodium reabsorption and potassium excretion.

Vascular Modulation

Continued vascular stimulation by the SNS and renin-angiotensin-aldosterone system, coupled with an increase in wall tension caused by HTN itself, leads to ongoing remodeling throughout the arterial tree. In large vessels such as the aorta or carotid arteries, this results in increasing intima-media thickness, with minimal luminal narrowing—unless there is unrelated plaque buildup. In contrast, small-vessel and arteriolar remodeling reduce the lumen diameter. Although both forms of remodeling work to normalize wall stress associated with HTN, they reduce vasodilatory capacity and enhance the vasoconstrictor response when faced with a hypertensive stimulus.

Sodium Intake

The average American has a daily sodium intake of close to 3500 mg (150 mEq)—more than double the recommended level of 1500 mg (≈65 mEq) as recommended by the AHA/ACC in the 2017 HTN guidelines. Randomized trials have demonstrated a reduction in systolic BP with diminished daily sodium intake (up to 7 mm Hg/1200 mg, or a 52-mEq decrease in hypertensive individuals)[16]; however, the impact of this intervention on long-term cardiovascular outcomes is unclear.[15,17] Salt sensitivity is defined by an increase in BP with intake of a high-sodium diet. It is linked to obesity but may be more directly related to defects in renal ion transport mechanisms that lead to ongoing sodium retention and potassium depletion. Although not fully defined, the latter plays a critical role, because the entire effect of salt sensitivity on BP can be mitigated with high-dose (e.g., 100 mEq/day) potassium supplementation.[18]

Psychosocial Stress

Life stressors, especially socioeconomic status, are known to adversely affect health and wellness. Through its effects on the SNS function and the hypothalamic-pituitary axis, stress modulates BP and is a specific contributor to disparities in HTN. Although episodic stress reactions can lead to transient sympathetic surges, sustained stimulation related to ongoing concern over life circumstances (e.g., financial security, crime and safety, racism) triggers a chronic adaptive response and has emerged as an important consideration in patients with seemingly idiopathic HTN.

Obesity

Obesity is a known risk factor for the development of HTN. For every increase of body mass index by 5 kg/m^2, the relative risk of HTN increases by 1.5.[19] Elevated BP in obese individuals correlates with high circulating aldosterone and cortisol levels, which in turn may be related to salt sensitivity. Obesity, especially truncal, is also strongly associated with diabetes and obstructive sleep apnea, contributing to poor BP control. Conversely, weight loss is correlated with a modest reduction in BP, though long term mortality benefits are not clear.[20] Physical activity, which is closely linked to obesity, can mitigate the risk related and unrelated to weight loss.

Pathophysiology of Target-Organ Damage

Uninterrupted by treatment, continued vasoconstriction in chronic HTN leads to several deleterious consequences that culminate in TOD. On a macrocirculatory level, the central components of the cardiovascular system (e.g., heart, large blood vessels) are most affected. Sustained elevations in the SVR cause significant augmentation of the pressure wave reflected from the periphery back to the central circulation (termed the *augmentation index*), thus driving up left ventricular (LV) afterload; this increase manifests with a rise in the central aortic pressure and change in the morphology of its waveform. This results in increasing impedance to forward flow from the heart, which necessitates a greater contractile force to maintain the aortic valve opening and the duration of ventricular ejection. Active contraction against this resistance also increases intraventricular wall tension, which, together with ongoing stimulation from, among other things, the SNS and renin-angiotensin-aldosterone system, triggers cardiomyocyte hypertrophy and myocardial fibrosis. Initially, this leads to an increase in LV mass, enhancing the heart's pumping against excessive afterload. However, when progressive, the net result is LV stiffening and impaired diastolic function, with an increase in LV filling pressure and diminished flow from the left atrium to the left ventricle.

If the increase in afterload is sudden, an abrupt decrease in stroke volume occurs, precipitating backflow of fluid into the lungs and rapid onset of so-called flash pulmonary edema (see Chapter 67). If excess afterload is more gradual or even chronic, a subacute rise in LV end-diastolic pressure may cause increased wall tension, with compression of the subendocardial microvasculature and myocardial ischemia. Over time, this contributes to LV wall thinning, chamber dilation, and eventually systolic dysfunction.

On a microcirculatory level, the initial beneficial effect of vascular remodeling gradually gives way to critical luminal narrowing and the potential for regional ischemia from occlusion or loss of vessel wall integrity with leakage or rupture. Autoregulation, the intrinsic capacity of resistance vessels to dilate or constrict rapidly in response to dynamic perfusion pressure changes, works to maintain a relatively constant blood flow and is protective with moderate fluctuations.

Small-vessel ischemic episodes, many of which are silent, are the primary cause of chronic TOD, including progressive white matter (i.e., multi-infarct) disease in the brain and hypertensive nephropathy. Cerebral microbleeds identified on brain magnetic resonance imaging (MRI) scans as hemosiderin deposits, are a relatively new class of subclinical brain injury associated with chronic HTN and portend more rapid cognitive decline in older adults.[21]

Unlike the pattern of TOD that occurs with poorly controlled chronic HTN, a hypertensive emergency results from acute endothelial injury triggered by an abrupt rise in vascular pressure that overwhelms autoregulatory mechanisms. A subsequent drop in nitric oxide (NO)–mediated vascular smooth muscle relaxation and excess release of endothelin further increase SVR, which functionally maintains BP at severely elevated levels. Unchecked wall tension ensues, and terminal arterioles dilate and eventually rupture, leading to a proinflammatory hypercoagulable state, with fibrin deposition and diffuse ischemia. Rising pressure in the proximal capillary beds causes fluid leakage and tissue edema, which, combined with the process of fibrinoid necrosis, produces acute TOD along with microangiopathic hemolytic anemia and other signs of small vessel injury.

CLINICAL FEATURES

Although BP elevation alone does not define any particular clinical syndrome, acute TOD generally does not occur in the absence of moderate to severe HTN (≥180/110 mm Hg). Conversely, in the absence of symptoms, the mere presence of an excessively high BP in the ED (regardless of the level) does not herald imminent development of TOD.

Hypertensive Emergency

Most hypertensive emergencies occur in patients with chronic HTN; perhaps the most important exception is in pregnancy where abrupt rises in BP in previously normotensive women can lead to catastrophic acute consequences. Organ system involvement is relatively consistent and is dominated by vascular injury leading to impaired function of the heart, brain, or kidneys (Table 70.3). True hypertensive emergencies are defined by the target organ acutely involved. Focal neurologic deficit or altered mentation point to brain injury, whereas chest pain or shortness of breath may indicate cardiac or vascular involvement. Although frequently accompanied by an elevated BP, symptoms such as headache,[22] epistaxis,[23] and dizziness are not, in and of themselves, evidence of acute TOD and, in isolation, do not constitute a hypertensive emergency, nor do they indicate the need for acute BP reduction.

TABLE 70.3 Hypertensive Emergencies by Organ System

Injury Pattern by Target Organ	Approximate Incidence[a] (%)
Heart (cumulative)	27–49
• Acute heart failure	14–37
• Acute coronary syndrome	11–12
Brain (cumulative)	37–45
• Acute ischemic stroke	6–25
• Spontaneous intracranial hemorrhage	5–23
• Hypertensive encephalopathy	8–16
Kidney	
• Acute renal risk	15
• Acute kidney injury	8
Vascular	
• Aortic dissection	1–2
Other	
• Eclampsia	2
• Acute hypertensive retinopathy	1

Hypertensive Encephalopathy

Hypertensive encephalopathy is the prime example of a hypertensive emergency. Resulting from diffuse, vasogenic cerebral edema, it is caused by a failure of autoregulation in the brain, with vasospasm, ischemia, increased vascular permeability, punctate hemorrhages, and interstitial edema. Severe headaches, vomiting, and altered mental status are common features that may progress to seizures or coma. Retinal involvement may cause blurred vision progressing to complete blindness. When present, focal neurologic deficits do not follow a singular anatomic pattern and may occur on opposite sides of the body, indicating diffuse cerebral dysfunction rather than an anatomically localized stroke syndrome or space-occupying lesions. Papilledema, which may be difficult to recognize with absent pupillary dilation, is often present, along with significant hypertensive retinopathy. Computed tomography (CT) may not show acute hemorrhage or other acute pathology. Diffuse or regional cerebral edema and small hemorrhages have been reported. The combination of altered mentation or diffuse neurological dysfunction on clinical examination, normal or nonspecific CT scan, and markedly elevated systemic BP, particularly if supported by objective findings such as papilledema or retinal hemorrhage, is sufficient to make a presumptive diagnosis of hypertensive encephalopathy and necessitates the initiation of acute antihypertensive therapy. Hypertensive encephalopathy is fully reversible with early, prompt BP reduction (30% to 40% decrease). Recently published data from the Nationwide Inpatient Sample have suggested that the overall in-hospital mortality rate is less than 1%.[24]

First defined in 1996, posterior reversible encephalopathy syndrome (PRES) has a neurologic presentation similar to that of hypertensive encephalopathy, albeit with less global and more region-specific features. Also caused by increased vascular permeability secondary to endothelial damage with vasogenic edema, PRES is characterized by a constellation of symptoms related to posterior cerebral impairment, including visual changes, headache, altered mental status, and seizures.[25] It is diagnosed by the visualization of white matter edema in the posterior parietal-temporal-occipital regions on MRI. As the name suggests, PRES is reversible by treating the underlying cause. HTN is the most common condition associated with PRES, although it may also be seen with kidney disease, malignancies, cytotoxic therapy, and autoimmune disease.

Other Hypertension-Related Emergencies

The clinical features of other HTN-related emergencies cross over with non-hypertensive manifestations, and they are described in greater detail elsewhere in this text. Moreover, these conditions are defined by more than just HTN and, in many cases, their onset is incidental to, not caused by, elevated BP. In specific conditions such as intracranial hemorrhage (ICH), the BP elevation may be compensatory to the associated pathology. However, long-standing HTN is often a contributor to the underlying problem and, when elevated BP is causal, effective treatment can have a dramatic impact on the clinical course. Elevated BP frequently accompanies acute ICH, and the rapid initiation of antihypertensive therapy is a routine component of ED care (see Chapter 87). HTN is the primary population-attributable risk factor for developing chronic cardiac dysfunction, and more than 50% of ED patients with acute heart failure have

elevated BP on presentation (see Chapter 67). Patients with acute heart failure and HTN respond well to vasodilatory agents and afterload reduction. Nitroglycerin has long been used in the setting of acute coronary syndrome (ACS) and demand ischemia (see Chapter 64), and antihypertensive therapy is a key component of ED management of acute aortic dissection (see Chapter 71). Acute kidney injury (AKI) in the setting of elevated BP may be a consequence of associated TOD, especially acute heart failure, particularly when these patients are on baseline diuretic or calcium channel blocker therapy. Recent or chronic NSAID or newly initiated ACE inhibitor therapy may also contribute, but the effect of these agents is usually transient (see Chapter 83). Preeclampsia and eclampsia are discussed in Chapter 173.

Acute Target Organ Damage in the Context of Systemic Illness

Any medical condition that leads to a hypermetabolic state can impair electrolyte homeostasis and trigger an intrinsic vasomotor response, causing the BP to rise acutely. Depending on the circumstance, this may also be associated with clinical or diagnostic evidence of acute TOD. Distinguishing this from a true hypertensive emergency necessitates demonstration that the elevated BP does not contribute directly to the pathologic condition. Treatment of the underlying disorder will often resolve the BP elevation, although BP reduction may play a role in supportive management.

Absence of Target Organ Dysfunction

Most patients who are found to have significantly elevated BP on intake vital signs measurement or who come to the ED because the BP was found to be elevated in an outpatient setting or by self-measurement do not have an acute hypertensive emergency. For such patients, acute reduction of BP is not indicated and offers no tangible outcome benefit. Although many patients who fall into this group have poorly controlled chronic HTN, some lack such a history. To connote an absence of acute TOD, these patients are often described by the term *asymptomatic*, but this is potentially misleading because nonspecific symptoms (e.g., low-grade or recurrent headache, chest pain, dyspnea, dizziness, generalized weakness, focal but anatomically uncorrelated weakness or numbness, vague visual disturbances) are frequently present. However, with the exception of dyspnea, the occurrence of these symptoms appears to be unrelated to the degree of BP elevation. In addition, despite widespread belief among the lay community and some members of the health care profession that acute severe HTN contributes to epistaxis, there is no evidence to support a causal relationship.

As a general rule, acute BP reduction is not indicated in patients with elevated BP who lack acute TOD, even when vague symptoms are present. BP will spontaneously improve with time or with treatment for concurrent pain or anxiety in many cases, and there is no need to hasten this with antihypertensive therapy. If chronic oral medications have been missed, these should be restarted; the first dose may be administered in the ED to reinforce the importance of future compliance, although this is in no way required and will not change any outcome. Regardless, no data support a threshold BP that warrants such treatment or a target BP to be achieved before discharge. Notably, the administration of a short-acting, potent antihypertensive agent such as clonidine or hydralazine simply to improve BP values lacks rationale or evidence of benefit and may be associated with an increased likelihood of subsequent ED visit for issues related to HTN. As previous experience with sublingual nifedipine has shown, BP reduction in the absence of acute TOD is also potentially dangerous, inducing relative hypoperfusion with increased related morbidity, especially in the cerebrovascular circulation. Therefore, we recommend not to administer medication in the ED solely to improve BP values.

DIFFERENTIAL DIAGNOSES

Differential considerations are based on patient subtype. For those with a suspected hypertensive emergency, the decision point centers on the potential causal relationship between patient presentation and acutely elevated BP. Clinical entities within this broader heading, such as stroke syndromes and acute heart failure, carry their own differentials, and a full discussion of each is beyond the scope of this chapter. Depending on the clinical scenario, ancillary testing may be needed to rule out alternatives to a hypertensive cause, particularly in patients with systemic illness.

For those with poorly controlled chronic HTN, a consideration of cause (primary vs. secondary) may be warranted. A related diagnostic evaluation (see Table 70.1) can usually be pursued on an outpatient basis. However, for some (e.g., individuals with multiple episodes of flash pulmonary edema, symptomatic paroxysmal episodes of labile BP, or suspected poor follow-up), initiation of treatment from the ED or admission to the hospital is needed.

The final factor to consider is whether a newly detected BP elevation is caused by true HTN. Although the diagnostic accuracy of BP can be enhanced by a second repeat measurement in the ED, the ideal approach may be to average several measurements taken over a brief period of observation. For those without a previous history of HTN, definitive diagnosis will typically require reassessment in an outpatient setting and may involve ABPM. This discussion is summarized in Box 70.1.

DIAGNOSTIC TESTING

The diagnostic evaluation of hypertensive emergency is guided by symptoms and signs identified on clinical examination but will often involve a number of tests. In selected cases, laboratory testing to look for acute or worsening renal dysfunction (e.g., basic metabolic panel, urinalysis) and microangiopathic hemolytic anemia (e.g., complete blood count with manual differential, peripheral smear) may be needed. Individuals with chest pain or shortness of breath generally require a chest radiograph, electrocardiogram, and cardiac biomarker (e.g., troponin, natriuretic peptide [NP]) measurement. Additional cardiovascular imaging by CT, transesophageal echocardiography, or MRI should be considered if there is clinical suspicion for aortic dissection. When focal neurologic deficits or altered mentation are present, brain imaging by CT and, in many cases, MRI, will be needed, along with laboratory tests to evaluate for potential toxic, metabolic, or infectious causes.

Hypertensive retinopathy identified on funduscopic examination signifies underlying TOD and, when present, is strongly associated with an enhanced risk of stroke in patients with HTN. Findings of acute hypertensive retinopathy include focal intraretinal periarteriolar transudates (whitish ovoid lesions deep in the retina), focal retinal

BOX 70.1 Differential Diagnoses for Elevated Blood Pressure in the Emergency Department

- Elevated blood secondary to pain, anxiety, transient physiological conditions, and medications
- Inaccurate measurement

pigment epithelial lesions (evidence of choroidal injury), macular and optic disk edema, and cotton wool spots (fluffy white lesions that consist of swollen ischemic axons caused by small vessel occlusion). Hard exudates, which consist of lipid deposits located deep in the retina, are also a common but late occurrence. When identified, such fundoscopic abnormalities are considered diagnostic; however, they may be absent in more than 30% of patients with a clinically evident hypertensive emergency. Lesions of acute retinopathy are distinct from more chronic changes, including arterial narrowing, copper or silver wiring of the arterioles, arteriovenous nicking, and retinal hemorrhages. The spectrum of retinal findings in HTN can be graded on a five-point scale (Box 70.2). Despite such value, fundoscopy is infrequently performed adequately to evaluate severely elevated BP in ED patients. Technical challenges and a lack of experience likely contribute to this. Nonmydriatic digital fundus photography can help overcome these issues and has shown promise as an adjunct to detect chronic and acute changes associated with hypertensive retinopathy in the ED setting.[22]

Although fundoscopy provides useful information, whether this or any other form of diagnostic evaluation is needed in the ED as a routine screening tool for those without overt TOD is a matter of debate. Although recommendations on routine testing in the primary care setting exist, there is no similar guidance for the ED. In the only prospective multicenter study of recommended routine tests (e.g., basic metabolic panel, urinalysis, electrocardiography, chest x-ray) performed in the ED, clinically meaningful abnormalities were detected in only 6% of patients, none of which were definitively attributable to HTN. However, in settings where HTN-related kidney disease is prevalent (e.g., predominantly Black American communities), evaluation of renal function by a basic metabolic panel may be a reasonable consideration. Although such information is highly unlikely to affect emergent management, there is value in knowing baseline renal function and electrolyte levels, particularly if the initiation of chronic antihypertensive therapy is planned. Urine testing, especially spot measurement of the urine albumin-to-creatinine (Cr) ratio, is a reasonable alternative to detect subclinical kidney disease, although it does not provide information on electrolyte levels.

Unlike renal function, there is no simple, efficient test for detecting subclinical cardiac disease in the ED, and symptoms guide evaluation in this setting. Although chest x-ray and electrocardiography are often used, they have poor sensitivity for TOD (especially LV hypertrophy), and abnormalities, when identified, are unlikely to alter clinical management. Serum NP levels (e.g., B-type NP [BNP] and N-terminal pro-BNP [NT-proBNP]) have yielded conflicting results and are not optimal screening tests, nor are they indicated for the emergent evaluation of HTN unless there is suspected cardiac TOD. Based on findings from a study in which echocardiography was used as the criterion standard, the prevalence of subclinical hypertensive heart disease in select populations appears to be substantial (≈90%), suggesting the need to develop a more effective screening strategy. Bedside cardiac ultrasound in the ED focused on identifying LV hypertrophy and perhaps diastolic dysfunction has shown potential for this purpose[23–27]; however, validation of such an approach in large prospective trials will be needed before widespread adoption can be endorsed.

BOX 70.2 Funduscopic Grading of Suspected Hypertensive Retinopathy

Grade 0—normal
Grade 1—minimal arterial narrowing
Grade 2—obvious arterial narrowing with focal irregularities
Grade 3—arterial narrowing with retinal hemorrhages and/or exudate
Grade 4—grade 3 plus disk swelling

MANAGEMENT

Acute Blood Pressure Control

Antihypertensive Therapy

Immediate BP reduction using antihypertensive therapy is indicated when an acute hypertensive emergency is present. In such cases, the goal of acute antihypertensive therapy is to lower BP safely and effectively in a relatively rapid fashion while maintaining peripheral perfusion. Although some oral (e.g., clonidine) or sublingual (e.g., captopril, nitroglycerin) medications are capable of this, patients who truly require acute lowering of BP benefit from the predictable, controlled effects of a parenteral agent by titrated intravenous (IV) boluses or by adjustable infusion.

Mean arterial pressure (MAP), a summary measure representing the average arterial pressure during one cardiac cycle, is a composite of circulatory inputs. The relationship is defined by the following equation:

$$MAP = (CO \times SVR) + CVP$$

where SVR reflects vasogenic tone in the arterioles (afterload), CO reflects the pumping force of the heart, and central venous pressure (CVP) represents intravascular volume (preload) and the effective hydrostatic force in the circulatory system. The hemodynamic response to a specific medication or class of medications is a function of how they interact with this equation, and, as shown in Table 70.4, effects can differ substantially. Existing IV antihypertensive agents directly exert their effects through receptor-mediated actions (largely agonist or antagonist properties) or indirectly through a decrease in the production or release of endogenous vasoconstrictors. The magnitude of BP reduction reflects the mechanism of action as well as the pharmacokinetic and pharmacodynamic activity, with some variability in the latter based on aging.

Labetalol and nitroglycerin are the most common IV antihypertensive medications used in the ED setting, but outcome data related to different agents are lacking. Thus, although some studies have suggested more favorable effects on BP reduction with nicardipine, a dihydropyridine calcium channel blocker, as compared to labetalol, clear superiority of one drug over another has yet to be demonstrated. A general guide to IV antihypertensive therapy is provided in Table 70.5. However, certain agents may be more appropriate than others for a specific indication depending on the desired response profile.

Blood Pressure Goals

Optimal treatment of a true hypertensive emergency involves therapy that is directed toward the precipitant of specific TOD and the acute consequences of elevated BP rather than the BP itself. The longstanding approach to acute antihypertensive therapy has targeted a maximal reduction in MAP of 20% to 25% within the first hour and a goal BP of 160/100 mm Hg by 2 to 6 hours.[28] This arises from an understanding of the cerebral autoregulation curve, which maintains stable blood flow within a range of pressures (MAP of 60 to 160 mm Hg) under normal circumstances but resets in chronic HTN with a shift of the lower limit toward the right. This shift tends to settle approximately 25% below baseline MAP, resulting in concern for decreased cerebral blood flow with BP reduction beyond this.

Although this consideration is relevant for patients who have poorly controlled chronic HTN, BP is often well above baseline when a hypertensive emergency is present and far in excess of the lower limit of their individual autoregulation curve. Consequently, a margin of

TABLE 70.4 Hemodynamic Effect Profile of Common Intravenous Antihypertensive Medications

Classification	Agent(s)	HEMODYNAMIC EFFECT		
		Cardiac Output	Systemic Vascular Resistance	Central Venous Pressure
Adrenergic inhibitors				
• α 1-Blockers	Phentolamine, urapidil[a]	↑	↓	↑
• β1-Blockers	Esmolol, metoprolol	↓	↑↓	↑↓
• Mixed α1–β1 blockers	Labetalol	↓	↓	↑↓
Angiotensin-converting enzyme inhibitors	Enalaprilat	↑↓	↓	↑↓
Calcium channel blockers

TABLE 70.5 Guide to Intravenous Antihypertensive Therapy

Medication by Class	Bolus or Loading Dose	Infusion Rate	Time to Onset	Duration of Action	Comments
Adrenergic Inhibitors					
Phentolamine	5–15 mg q5min	0.2–0.5 mg/min	1–2 min	10–30 min	Avoid with coronary artery disease
Urapidil	12.5–50 mg q5min	9–30 mg/h	1–2 min	2.5 h	Not FDA approved
Esmolol	0.5–1 mg/kg × 1	50–300 μg/kg/min	1–2 min	20 min	
Metoprolol	5 mg q5min	None	10–30 min	5–8 h	
Labetalol	20–80 mg q10min	1–2 mg/min	2–5 min	3–6 h	Beta blocker effects predominate (1:7)
ACE Inhibitor					
Enalaprilat	0.625–1.25 mg q15min	1–2 mg/h	15–30 min	6–12 h	May produce prolonged hypotension; avoid in pregnancy
Calcium Channel Blockers					
Clevidipine	None	2–32 mg/h	1–2 min	1–5 min	
Nicardipine	None	5–15 mg/h	5–15 min	4–6 h	Avoid with aortic stenosis and liver failure (hepatic metabolism)
Diltiazem	0.25–0.35 mg/kg q15min	5–15 mg/h	5–15 min	6 h	Will decrease blood pressure but not often used for this indication
Verapamil	2.5–5 mg IV q15min	None	5–15 min	6 h	
Direct-Acting Vasodilator					
Hydralazine	5–20 mg q30min		10–20 min	2–4 h	Causes reflex activation of the sympathetic nervous system
Dopamine Antagonist					
Fenoldopam	None	0.1–0.3 μg/kg/min; titrate by 0.1 μg/kg	<5 min	30 min	Increases intraocular pressure; contains sodium metabisulfate—avoid in patient with sulfa allergy
Loop Diuretics					
Furosemide	40–240 mg q12h	10–40 mg/h	30–60 min	2–4 h	Limited antihypertensive effect compared with other agents listed
Bumetanide	0.5–4 mg q12h	None	30–60 min	2–4 h	
Torsemide	10–20 mg q12h	None	30–60 min	2–4 h	
Natriuretic Peptide					
Nesiritide	2 μg/kg × 1	0.01 μg/kg/min	15 min	18 min	Indicated only for use in acute heart failure
Nitric Oxide Donors					
Sodium nitroprusside	None	0.25–10 μg/kg/min	Immediate	1–2 min	May cause precipitous drop in blood pressure with right ventricular ischemia or renal artery stenosis; bolus administration controversial; risk of cyanide toxicity with nitroprusside; avoid entire class in patients taking phosphodiesterase–5 inhibitors (eg, sildenafil)
Nitroglycerin	1–2 mg q5min	5–200 μg/min	2–5 min	5–10 min	

ACE, Angiotensin-converting enzyme; *FDA,* US Food and Drug Administration; *IV,* intravenously.

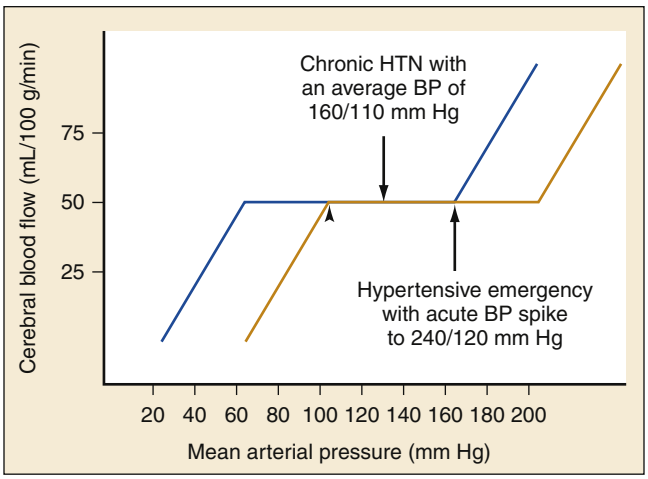

Fig. 70.2 Cerebral blood pressure *(BP)* autoregulation curve *(black line)* and its right shift response to chronic hypertension (HTN; *red line*). Data shown are for a hypothetical patient with chronic hypertension and poor blood pressure control at baseline *(blue arrow)* with a hypertensive emergency *(black arrow)*. As indicated by the *arrowhead*, the lower limit of the shifted autoregulation curve in this scenario sits well beyond a 25% reduction in mean arterial pressure.

safety exists in this case, with antihypertensive therapy serving to bring BP down to (rather than along) the perfusion plateau from the ascending portion of the autoregulation curve (Fig. 70.2). Use of a single BP goal for all hypertensive emergencies fails to account for this and may preclude the ability to interrupt the pathophysiology causing acute TOD effectively. Therefore, the best approach is to focus on condition-specific targets. An overview of respective treatment goals and relevant caveats for differing indications is found in Table 70.6.

Acute Coronary Syndrome and Acute Heart Failure

In ACS complicated by HTN, the primary goal (beyond expeditious reperfusion) is a decrease in cardiac work and improved coronary artery perfusion, each of which can be dramatically affected by changes in afterload (see Chapter 64). Similarly, in patients with acute hypertensive heart failure in which a rise in SVR—more specifically the augmentation index—impedes forward flow and exacerbates ventricular stiffness, intervention aimed at reducing afterload can offset resistive forces, enabling more effective contraction (see Chapter 67).

Medications that exert their effect by providing an exogenous nitric oxide (NO) source are known as NO donors, including nitroglycerin and sodium nitroprusside. Nitroglycerin can be highly beneficial in both ACS and heart failure because it produces small-vessel dilation, yielding a dose-dependent decrease in overall vascular resistance and

TABLE 70.6 Indication-Specific Approach to Management of Hypertensive Emergencies

Indication	Goals of Treatment	Optimal Agents	Alternative Therapy	Caveats
Acute coronary syndromes	Diminish cardiac workload and improve coronary artery perfusion	*Primary*—nitroglycerin *Secondary*—metoprolol, labetalol	Esmolol, nicardipine	Routine use of intravenous beta blocker therapy is controversial.
Acute heart failure syndromes	Reduce impedance to forward flow and diminish cardiac workload	*Primary*—nitroglycerin, furosemide *Secondary*—enalaprilat	Clevidipine, nicardipine, sodium nitroprusside	Intubation or noninvasive ventilatory support decreases preload and may drop BP. Enalaprilat may cause sustained hypotension. Although FDA-approved, use of nesiritide is controversial.
Aortic dissection	Reduce shear force and *dP/dt*	*Primary*—esmolol plus sodium nitroprusside *Secondary*—labetalol	Esmolol plus (clevidipine or nicardipine), diltiazem, verapamil	Avoid beta blockers if aortic regurgitation is present.
Acute ischemic stroke[a]	Reduce hemorrhagic conversion and edema while avoiding regional hypoperfusion	*Primary*—nicardipine or clevidipine *Secondary*—labetalol	Esmolol	Acute BP reduction is indicated only with planned fibrinolytic administration or when secondary target organ dysfunction is involved.
Acute intracerebral hemorrhage[a]	Reduce hematoma expansion and perihematomal edema	*Primary*—nicardipine *Secondary*—labetalol	Esmolol	BP may decrease with pain management alone. Clevidipine is currently under investigation.
Hypertensive encephalopathy[a]	Decrease brain edema, reduce intracranial pressure, improve autoregulatory control	*Primary*—nicardipine *Secondary*—labetalol	Esmolol, enalaprilat	Other causes of altered mental status should be considered in the evaluation.
Acute kidney injury	Decrease pressure in renal parenchyma and glomerular apparatus	*Primary*—*Secondary*—clevidipine, nicardipine	Labetalol, sodium nitroprusside	Angiotensin-converting enzyme inhibitors and diuretics should be avoided.
Preeclampsia and eclampsia	Decrease intracranial pressure while maintaining placental perfusion	*Primary*—hydralazine *Secondary*—labetalol	Nicardipine	Intravenous magnesium (4 g initially) is administered in all cases. Emergent cesarean section is definitive treatment.
Sympathetic crisis	Reduce alpha1-adrenergic receptor–mediated vasoconstriction	*Primary*—phentolamine *Secondary*—nitroglycerin	Fenoldopam, clevidipine, nicardipine, sodium nitroprusside	Benzodiazepines are first-line therapy when sympathetic crisis is caused by cocaine or amphetamines. Beta-blocker monotherapy (including labetalol) is relatively contraindicated.

[a]Nitric oxide donors and hydralazine should be avoided with these indications.
BP, Blood pressure; *dP/dt,* change in pressure/change in time; *FDA,* US Food and Drug Administration.

diminishing arterial waveform reflection intensity, thus improving systolic ejection time and diastolic coronary artery filling.

Rapid reduction in MAP, typically utilizing nitrates, has been associated with profound symptom resolution and improved short-term outcomes among patients with severe, acute hypertensive heart failure[29] and is recommended as first-line therapy.[30,31] As shown in Fig. 70.3, this may be due to improved coronary perfusion and decreased subendocardial ischemia. Achieving this may require high doses of nitroglycerin (e.g., 1 to 2 mg by IV bolus or infusion rates greater than 250 µg/min), but this approach is generally well tolerated, with no adverse effects, even at MAP reductions of 30% to 40%.

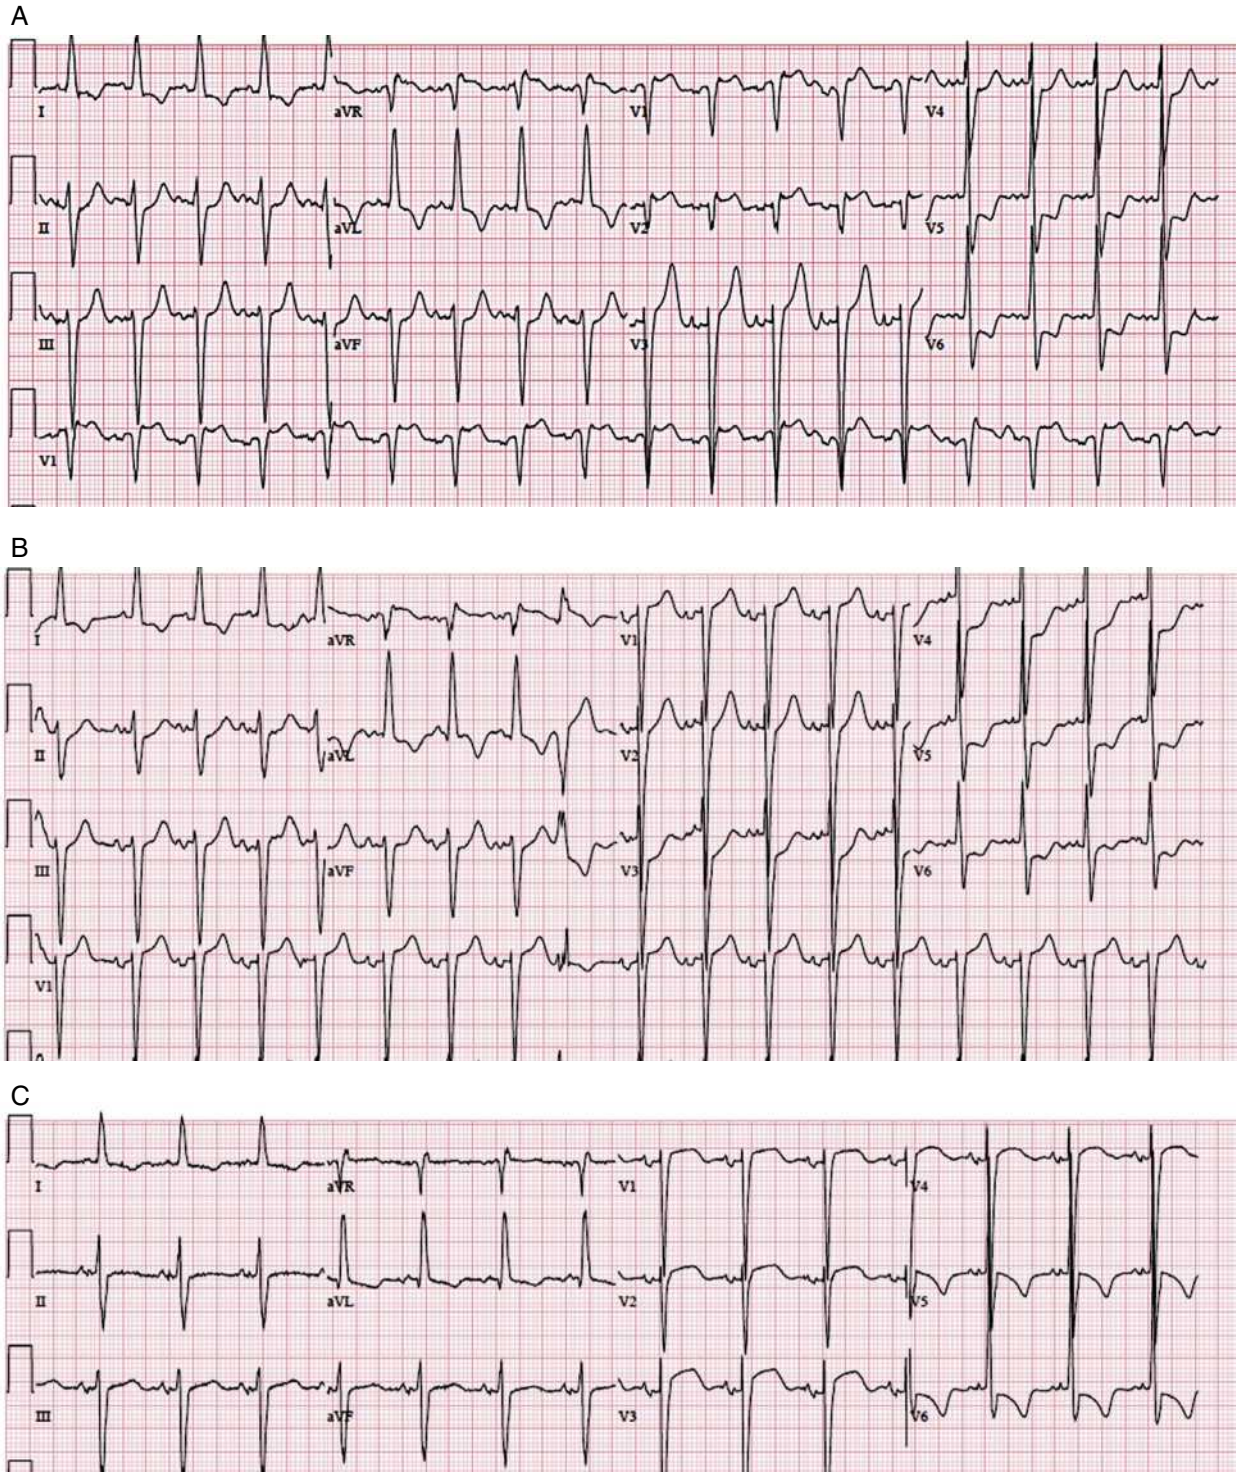

Fig. 70.3 Serial electrocardiograms demonstrating resolution of relative myocardial ischemia in a profoundly hypertensive patient with acute heart failure after treatment with high-dose intravenous nitroglycerin. (A) BP, 241/122 mm Hg. Anterior leads (V1–3) show ST segment elevation and lateral leads (V5–6) show ST depression. (B) BP, 192/103 mm Hg. Anterior lead ST elevation has resolved, but lateral lead ST depressions persist. (C) BP, 150/92 mm Hg. ST segment deviations have largely resolved.

Moreover, using nitroglycerin avoids the challenges associated with alternatives such as sodium nitroprusside, including the need for arterial line monitoring, risk of cyanide toxicity, and potential for compound photodegradation. The most important caveat is that NO donors should be avoided in patients who have taken a phosphodiesterase-5 (PDE5) inhibitor such as sildenafil or tadalafil within the preceding 24 to 48 hours because this can result in a more profound BP decrease and persistent hypotension.

ACE inhibitors are also well-tolerated and associated with rapid symptom improvement in patients with hypertensive heart failure. Enalaprilat can be administered by IV bolus or infusion and is the preferred ACE inhibitor in the setting of acute heart failure, but cautious dosages (0.625 to 1.25 mg/dose IV, up to a maximum of 2.5 mg over 30 minutes) are recommended because the drug is long-acting and can precipitate a sustained drop in BP.

Given their short half-life, third- and fourth-generation IV dihydropyridine calcium channel blockers (e.g., nicardipine [5 to 15 mg/hour IV], clevidipine [1 to 6 mg/hour]) are potential alternatives, with at least one prospective trial suggesting that this class can safely and effectively reduce BP while improving dyspnea more rapidly than standard therapy in those with acute hypertensive heart failure.

Labetalol and other IV agents with inhibitory β-adrenergic effects, such as metoprolol, should be avoided in the early stages of treatment because they produce a decrease in CO and, in ACS, may increase the risk of developing cardiogenic shock.

Although BP reduction drives symptom improvement in acute hypertensive heart failure, adverse events are more likely to occur when BP is rapidly normalized (i.e., decreased to ≤120/80 mm Hg), particularly in the setting of compromised cardiac function. Therefore, antihypertensive therapy for ACS or acute heart failure should be titrated to symptom resolution rather than a specific MAP, with short-term tolerance of persistently elevated BP in a clinically improving patient.

Aortic Dissection

With aortic dissection, unlike other hypertensive emergencies, BP control to a specific target (systolic BP <110 mm Hg) is essential because it decreases ongoing injury and reduces the likelihood of perioperative adverse events (see Chapter 71).[28] The immediate goal is to reduce intimal shear forces by driving down the pressure that results from LV ejection with each cardiac cycle (termed *dP/dt*). This is best accomplished by decreasing the heart rate and stroke volume through the administration of a rapid-acting IV beta-blocker, such as esmolol (bolus 500 mcg/kg IV, followed by maintenance 0.05 to 0.2 mcg/kg/min). Although a direct reduction in BP is also critical, beta-blocker therapy should be initiated before vasodilation because the latter can lead to reflex tachycardia and worsening of *dP/dt*. Once beta blockers have been initiated, and a heart rate of less than 60 beats/min has been achieved, agents such as sodium nitroprusside, nicardipine, or clevidipine can be rapidly titrated to reduce systolic BP as low as can be tolerated (and, ideally to <120 mm Hg) within 30 minutes. Because labetalol has both alpha and beta blocker properties, it may be an acceptable alternative. Note that labetalol has a long half-life, of about 4 to 6 hours, and is therefore not easily titratable as a continuous infusion. Diltiazem and verapamil, mixed calcium channel blockers (agents with cardiac and vascular effects), may also be used, although neither is ideal as monotherapy. For patients with persistently elevated BP, despite initial therapy, the use of multiple agents from different classes may be needed.

Acute Ischemic Stroke

Understanding the nuances of elevated BP in acute ischemic stroke is critical (see Chapter 87). A U-shaped relationship exists between mortality and BP, with worse outcomes at high and low extremes. Ischemic stroke is thought to impair cerebral autoregulation mechanisms, and thus cerebral perfusion is dependent on systemic BP. The elevated BP seen in the acute phase is likely a compensatory mechanism to achieve perfusion of the brain within low flow areas distal to occluded arteries. Disrupting this process is deleterious and can lead to worse outcomes. The 2018 AHA/American Stroke Association (ASA) guidelines call for a BP reduction to below 185/110 mm Hg only when thrombolysis is planned, with maintenance of BP at below 180/110 in such cases.[32] Otherwise, antihypertensive therapy is not indicated unless BP exceeds 220/120 mm Hg and, even in such cases, the goal is to decrease BP by approximately 15% gradually, over the first 24 hours after symptom onset. The AHA/ASA guidelines are supported by a meta-analysis that fails to show a mortality benefit associated with rapid BP reduction.

Based on these recommendations, and considering data from two large randomized studies[33] showing no benefit with BP reduction over the first 24 hours, there appears to be a limited role for ED management of elevated BP in patients with acute ischemic stroke who will not undergo thrombolysis. However, a subanalysis of one study showed a trend toward reduced vascular events (but not functional outcomes) among those treated within 6 hours of symptom onset, as well as those with large vessel occlusions,[34] suggesting a possible time-dependent component, with increased susceptibility to the adverse effects of sustained BP elevation earlier in the disease course.

For patients who need IV antihypertensive therapy, labetalol (bolus 20 mg IV q 10 minutes), and nicardipine (5 to 15 mg/hour IV) have emerged as the agents of choice because they maintain adequate cerebral perfusion while producing generalized reductions in vascular resistance. Nicardipine may offer some advantage over labetalol because it results in a more rapid and sustained achievement of BP goals with reduced BP variability, a potentially important determinant of patient outcome. As a fourth-generation calcium channel blocker, clevidipine offers similar benefits to nicardipine with the added advantage of being shorter-acting, making it easier to recover quickly if BP is lowered too much. Esmolol may also be used, although it reduces BP by reducing CO than SVR. While sodium nitroprusside is a highly effective antihypertensive option, it and other NO donors should be avoided because they can cause an increase in intracranial pressure.

Spontaneous Intracranial Hemorrhage

Spontaneous ICH is strongly associated with HTN, and persistently elevated BP contributes to hematoma expansion, vasogenic edema, and rebleeding (see Chapter 87). A large systematic review and several multicenter trials have shown improved outcomes with BP reductions to 140 to 150 mm Hg. In contrast to ischemic stroke, there is little evidence to suggest adverse outcomes from hypotension in ICH. The 2015 AHA/ASA guidelines recommend rapid reduction via continuous IV agents when the systolic BP exceeds 220 mm Hg and state that a target systolic BP of 140 mm Hg is safe for such patients. When more modest elevations are present (systolic BP >150 but <220 mm Hg), BP should be lowered, possibly more gradually, to 140 mm Hg—a strategy that has been shown to improve functional outcomes.[35]

Results from the Second Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT2) add to the AHA/ASA guidelines suggesting functional outcome but no mortality benefit with intensive antihypertensive therapy targeting a reduction of systolic BP to 140 mm Hg within 1 hour of diagnosis. However, in a post hoc analysis of INTERACT2, patients who achieved a reduction in systolic BP of 20 mm Hg or more within the first hour of treatment were 35% less likely to experience a poor outcome, suggesting that optimal recovery from acute ICH may be dependent on early, profound reductions in BP with antihypertensive therapy.

As with ischemic stroke, labetalol and nicardipine (or clevidipine) are the preferred agents for acute BP reduction. In INTERACT2, urapidil, an α-adrenergic antagonist not approved in the US, was the most commonly used agent (32.5%) in the intensive treatment arm, followed by nitroglycerin or nitroprusside (27.0%), nicardipine (16.2%), and labetalol (14.4%). However, in the ATACH-II study, in which nicardipine was used exclusively, no outcome benefit was associated with the lower BP target.[36] Nimodipine, an oral dihydropyridine calcium channel blocker, is specifically indicated for patients with subarachnoid hemorrhage, although its benefit appears to be related more to a reduction in intracranial arterial vasospasm than to an effect on SVR.

Hypertensive Encephalopathy

Unlike acute stroke syndromes, in which HTN may be reactive rather than causative, a direct association exists between the degree of BP elevation and neurologic symptoms in patients with hypertensive encephalopathy. Once alternative causes of altered mentation have been ruled out, therapy should be directed toward the initiation of rapid BP reduction. The goal is to return BP to a point at which autoregulation can regain control of cerebral blood flow, and the process leading to cerebral edema can be reversed, requiring the MAP to be brought back down to the pressure curve plateau. To achieve this, reductions in MAP of 30% to 40% may be needed. Whereas MAP targets should still be kept in mind, symptom resolution is the best gauge of therapeutic effectiveness, with treatment explicitly directed toward improvement of encephalopathy.

The agents of choice for BP reduction in hypertensive encephalopathy are labetalol (20 mg IV q 10 minutes), nicardipine (5 to 15 mg/hour IV), and clevidipine (1 to 6 mg/hour IV) because they produce an even decrease in resistance across vascular beds in different organ systems. In contrast, NO donors (nitroglycerin and nitroprusside), although widely used for this indication, have a differential effect on the cerebral and systemic circulations, resulting in a relative increase in cerebral BP and a shunt effect to the peripheral circulation. This decreases the cerebral blood flow and may produce a greater than anticipated reduction in cerebral perfusion, thereby increasing the risk of ischemia in watershed areas of the brain. This may be worsened by the relative increase in intracranial pressure known to occur with sodium nitroprusside therapy. Several case reports have described neurologic deterioration with administration of nitroglycerin in PRES, supporting this as an actual rather than theoretical concern. Similar differential circulatory effects may also occur with hydralazine (a direct-acting vasodilator that inhibits calcium release from the sarcoplasmic reticulum) and, unless BP is entirely refractory for other therapy, it is best to avoid use of these agents.

Acute Kidney Injury

Defined by an increase in serum creatinine level of 0.3 mg/dL or more in 48 hours, 1.5 or more times baseline in 7 days, or a urine volume of less than 0.5 mL/kg/hour over 6 hours, AKI represents an abrupt worsening of renal function (see Chapter 83). Although often a manifestation of ongoing glomerular injury from chronic poor BP control, deterioration of kidney function in the setting of severe HTN may be precipitated by prerenal causes, including volume depletion (often related to concurrent diuretic therapy), extrinsic alterations in the GFR (often triggered by drug-mediated, afferent arteriolar vasoconstriction and ACE inhibitor–induced autoregulatory modulation) or intrinsic nephron destruction caused by acute pressure overload. Consequently, some patients require fluid administration to augment volume, whereas others need antihypertensive therapy to mitigate pressure-mediated nephrogenic damage.

Laboratory testing is useful to differentiate which approach should be initiated. A blood urea nitrogen (BUN)/Cr ratio higher than 20 and a fractional excretion of sodium (FENa) calculated as

$$\frac{\text{Urine Na} \times \text{Serum Cr} \times 100}{\text{Serum Na} \times \text{Urine Cr}}$$

below 1% indicates a prerenal cause. Because diuretics alter sodium excretion, for those on chronic diuretic therapy, a fractional excretion of urea (FEurea), calculated as

$$\frac{\text{Serum Cr} \times \text{Urine Na} \times 100}{\text{Serum urea} \times \text{Urine Cr}}$$

below 35% indicates a prerenal state.

When antihypertensive therapy is indicated, fenoldopam, a potent dopamine 1A receptor agonist, is preferred because it leads to improved perfusion of the corticomedullary region and has been associated with a reduction in the need for subsequent dialysis and rate of in-hospital death. Enalaprilat should be avoided because it produces differential effects on the precapillary and postcapillary glomerular vascular bed (i.e., more significant vasodilation in efferent than afferent arterioles), which increases the risk of further deterioration in estimated GFR. Peripheral-acting calcium channel blockers such as nicardipine and clevidipine have no adverse effect on the glomerular autoregulation and are acceptable first-line alternatives to fenoldopam. Other agents, including labetalol and sodium nitroprusside, may also be used.

Preeclampsia and Eclampsia

Although delivery is the definitive treatment, BP control is a critical part of early management (see Chapter 173).[37] Similar to hypertensive encephalopathy, preeclampsia and, to a greater degree, eclampsia, represent an overwhelming of the cerebral autoregulation, and rapid BP reduction is essential. Because they are acute (rather than chronic) complications in a relatively healthy young population, there is generally no resetting of the autoregulation curve in preeclampsia or eclampsia, and adverse consequences can develop at seemingly "low" (but relatively high) pressures. Therefore, the threshold for intervention is set lower than with other hypertensive emergencies (e.g., systolic BP >160 mm Hg).

Magnesium sulfate (4 g IV loading dose, followed by 1 to 2 g/hour) is considered first-line therapy for all cases of preeclampsia and eclampsia. It relaxes the smooth muscle (partly through calcium antagonism), leading to some decrease in peripheral and cerebral vascular resistance, limiting cerebral edema formation by protecting the blood-brain barrier, and has central anticonvulsant activity. However, its antihypertensive effects are modest, and additional treatment is typically needed to control BP. Hydralazine (10 mg IV) and labetalol (20 mg IV) by IV bolus are equally useful for this purpose and have a limited impact on placental blood flow. Nicardipine (5 to 15 mg/hour) or clevidipine (1 to 6 mg/hour) are reasonable alternatives and may produce a more profound decrease in BP than labetalol.

Sympathetic Crises

Hyperadrenergic states can result from endogenous sources of catecholamine excess (e.g., pheochromocytoma) but, more commonly, they are triggered by the intake of exogenous substances that interfere with norepinephrine—and to a lesser degree, epinephrine—metabolism, such as cocaine, amphetamines, and tyramine-containing foods, especially in patients on monoamine oxidase inhibitors. The net result is a cardiostimulatory and vasopressor response that manifests clinically as tachycardia and marked HTN. In patients with cocaine or amphetamine intoxication, such peripheral effects are compounded by central sympathetic activation, and the hemodynamic derangements

can often be improved by the administration of benzodiazepines and other sedative medications.

When BP is persistently elevated, and target organ compromise is present, antihypertensive treatment is needed. Phentolamine (5 to 15 mg IV), a reversible pure alpha blocker, is considered first-line therapy, producing a reliable decrease in peripheral and coronary vasoconstriction, with few adverse effects. Nitroglycerin (1 to 2 mg IV bolus, or 50 to 200 mcg/min maintenance infusion) can also be used and is specifically indicated for patients with associated chest pain and suspected coronary artery vasospasm. Other agents, including fenoldopam, nicardipine, clevidipine, and sodium nitroprusside, are acceptable alternatives.

Heart rate control may also be needed, especially in patients with pheochromocytoma, in whom adrenal release of epinephrine may be exceptionally high, and a short-acting beta blocker such as esmolol is ideal for this purpose. However, to avoid precipitation of unopposed alpha receptor activity and a worsening of HTN, beta blocker therapy should be paired with a vasodilator. Although labetalol has combined alpha and beta blocker properties, beta receptor effects strongly predominate when the drug is administered in IV form (alpha/beta ratio of 1:7). Consequently, IV labetalol is susceptible to a similar differential response and should not be used in isolation in the setting of catecholamine excess.

Chronic Antihypertensive Therapy

Poorly controlled chronic HTN on a single visit or a clear trend toward persistently elevated BP over time requires a referral for timely follow-up, with reinforcement of goal BP recommendations and emphasis on the need for lifelong dietary and medication compliance. Initiation of oral antihypertensive therapy for those in whom a new diagnosis of HTN is suspected should be approached with caution. However, reinitiation or up-titration of medication for patients with chronic HTN is appropriate from the ED, especially when outpatient follow-up cannot be ensured. Although it is unclear whether this practice impacts long-term outcomes, it is associated with a substantial reduction in BP at follow-up and appears to be safe.

Although there are multiple medication options, a standardized approach to prescribing chronic antihypertensive therapy has been proposed by the AHA/ACC, starting with a thiazide diuretic for most patients. Calcium channel blockers, ACE inhibitors, and angiotensin receptor blockers (ARBs) are included as acceptable first-line alternatives and recommended as add-ons for patients with persistent, poorly controlled BP. Because most patients with stage II HTN ultimately require multiple agents to control their BP, initiation of two-drug therapy when the systolic BP is higher than 160 mm Hg or diastolic BP higher than 100 mm Hg is recommended. There is increasing evidence that improved compliance with reduced side effects and outcome benefits can be achieved using low-dose combination tablets, especially combined ACE inhibitors and thiazide-like diuretics.

Preferential use of ACE inhibitors or ARBs in diabetic patients is no longer recommended, and lower BP targets (i.e., <130/80 mm Hg) for diabetics and those with chronic kidney disease are no longer endorsed. Moreover, the use of beta blockers as primary therapy has been greatly deemphasized, with inadequate BP control despite other maximum dosed agents or the presence of underlying coronary artery disease or heart failure serving as the main indications. A simplified algorithm to guide the initiation and escalation of antihypertensive therapy from the ED for patients without significant comorbidity is presented in Fig. 70.4.

As emphasized throughout this chapter, acute BP reduction in the ED provides absolutely no benefit to patients with chronic HTN without acute TOD and exposes them to unnecessary risk of potential hypoperfusion in regions in which blood flow has been governed by long-standing autoregulation. When these patients have symptoms such as headache or chest pain, and there is no suspicion of acute TOD, treatment should be directed toward the symptoms, not the BP. Anxiolytic or analgesic medication administration accompanied by resumption of chronic oral antihypertensive therapy is more rational and beneficial than the initiation of short-acting antihypertensive therapy. However, care should be taken to avoid prescribing NSAIDs and other medications that can have a negative impact on BP control and result in the development of cardiovascular complications.

Disposition

Individuals without evidence of acute TOD can be discharged home, but hypertensive emergency patients warrant admission, usually to an intensive care unit. Clinical features such as chest pain, dyspnea on exertion, or worsening renal function may confuse the picture, and short-term evaluation in an observation unit can be useful to determine whether the acute presentation represents a true emergency.

Outcomes associated with a given hypertensive emergency are largely a function of underlying TOD. However, data suggest that when severe HTN is present and IV antihypertensives are administered, risks are considerable with in-hospital and 30-day mortality rates of

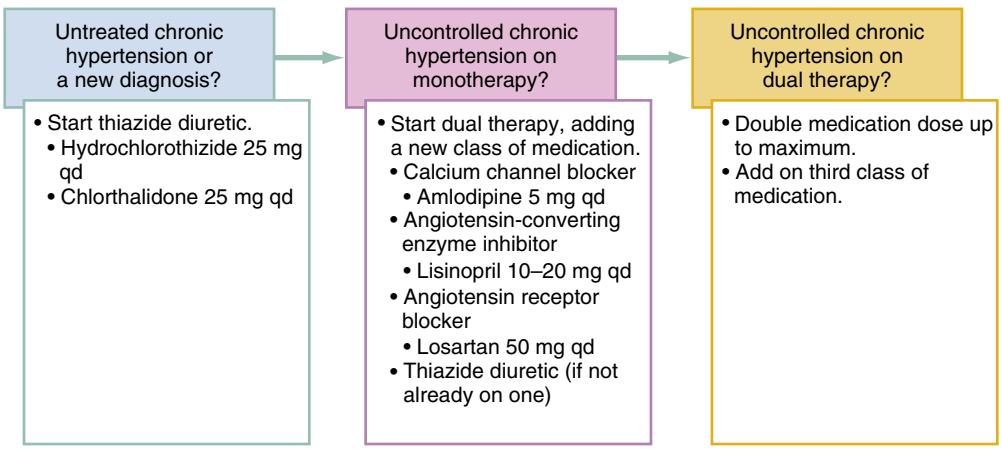

Fig. 70.4 Modified approach to the initiation and escalation of antihypertensive therapy for use in ED patients. Note that the proposed medications are representative of listed classes and may be substituted with equally dosed alternatives agents in the same class, as needed.

6.9% and 11%, respectively, and a 90-day readmission rate of nearly 40%. When associated with AKI, the relative mortality is even greater, with an odds ratio of 1.05 for each 10 mL/min estimated GFR decline. Although the risk for short-term deterioration is minimal in patients with elevated BP who lack evidence of acute TOD, the long-term risk of cardiovascular, cerebrovascular, and renovascular disease is relatively high, underscoring the need for the development of effective, patient-centric models of chronic HTN care at the system level.[38]

CHAPTER 70: QUESTIONS AND ANSWERS

1. An 85-year-old man presents with acute onset of right-sided weakness that began 1 hour before arrival. His family states that he was recently diagnosed with dementia and has refused to take any of his medications for more than 1 week but had otherwise been relatively healthy. Emergency medical services (EMS) report a prehospital blood pressure of 240/110 mm Hg. On examination, the patient has clear evidence of an acute stroke with severe deficit (National Institutes of Health [NIH] Stroke Scale = 24), but his gag reflex is intact. His initial blood pressure is 230/110 mm Hg. A head computed tomography (CT) scan shows diffuse white matter ischemic disease but no evidence of acute infarct or hemorrhage. The most appropriate next step is which of the following?

a. Repeat the blood pressure and, if 185/110 mm Hg or higher, start a nicardipine infusion at 5 mg/hour.
b. Contact neurosurgery for intracranial pressure monitoring.
c. Give a dose of tissue plasminogen activator (tPA) immediately.
d. Give sublingual nifedipine.

Answer: a. Despite his advanced age, this is a relatively high-functioning individual with acute onset of a severe stroke. He is within the time window for administration of tPA, but his blood pressure is excessively elevated. According to the American Heart Association/American Stroke Association guidelines, efforts should be made to reduce his blood pressure to less than 185/110 mm Hg before tPA administration. Other agents, such as labetalol, would also be appropriate to use.

2. A 27-year-old woman presents with lower back pain for 1 week. She recently moved into the community and has been busy unpacking and moving furniture. She denies any neurologic symptoms and has no medical history. Her triage blood pressure is 170/110 mm Hg, but vital signs are otherwise normal. With the exception of appreciable muscle spasm in her lower back, the physical examination is normal. You give her 10 mg of diazepam and observe her for 1 hour. She is feeling better but her blood pressure is still elevated, at 165/90 mm Hg. At this point you should do which of the following?

a. Give her 0.2 mg of clonidine.
b. Take a more extensive history to see if she is taking oral contraceptives
c. Ignore the blood pressure and discharge her without follow-up.
d. Order a 24-hour urine metanephrine and normetanephrine test.

Answer: b. This patient's blood pressure elevation is clearly not a reaction to her pain, and some further questioning is needed to identify a potential cause. In young women, oral contraceptive agents are a treatable cause of hypertension and should be considered when elevated blood pressure is encountered in these patients. Of note, the likelihood of contraceptive-related hypertension increases with the duration of use. It would not be unreasonable to discharge the patient without further exploring the potential cause of her elevated blood pressure, provided some provision of follow-up was sought. The clinical picture is inconsistent with renal artery stenosis or pheochromocytoma, and an evaluation for these conditions would be inappropriate at this point.

3. A 50-year-old man complains of dull chest pain that began 4 hours before arrival. The patient states he awoke this morning feeling well and that the pain began while shoveling his driveway. He has a 20-year history of hypertension and diabetes but has always been compliant with his medications, which include metformin, Norvasc, and Diovan. His initial blood pressure is 215/120 mm Hg, and his heart rate is 100 beats/min. On examination, his lungs are clear, heart sounds are normal, pulses are bounding and symmetric, and there are no neurologic deficits. An electrocardiogram shows nonspecific T wave inversions in the lateral leads, with no evidence of ST segment elevation or depression and normal intervals. The serum troponin level is elevated. Which of the following is the most likely explanation for his clinical presentation?

a. He has a ruptured dissecting aortic aneurysm that is leaking blood into the retroperitoneal space.
b. He is suffering from a massive pulmonary embolism.
c. He strained an intercostal muscle while shoveling.
d. He is suffering from subendocardial ischemia triggered by a cycle of increased afterload that began while he was shoveling.

Answer: d. Increased afterload can be triggered by exertional activation of the sympathetic nervous system. In the presence of long-standing hypertension, ventricular and aortic stiffness are likely to develop, increasing the potential for afterload-mediated effects on the heart. When suddenly faced with increased resistance, the left ventricular pressure may rise, leading to intrinsic compression of subendocardial myocytes and ischemia. Coupled with earlier transmission of the reflected arterial wave form, the diastolic coronary filling time may also be diminished, producing a clinical picture of acute coronary syndrome. He may also have a coronary artery lesion on which this is superimposed but, as described, the likelihood of his clinical presentation being caused by a complete right coronary occlusion is quite low.

4. Which of the following fundoscopic findings would be the earliest indicator of acute hypertensive retinopathy in a comatose patient whose blood pressure is 260/140 mm Hg?

a. Copper and silver wiring appearance to the retinal arterioles
b. Focal intraretinal periarteriolar transudates
c. Cotton wool spots
d. Diffuse atrioventricular (AV) nicking

Answer: b. Focal intraretinal periarteriolar transudates are the first abnormality to appear with acute hypertensive retinopathy, preceding all other findings, including cotton wool spots and disk edema. Other findings that are listed may also be seen, but they are indicative of chronic, not acute, retinal involvement. It is important to remember that acute retinal abnormalities may be absent in hypertensive emergency patients and, although fundoscopy is an important tool,

CHAPTER 70: QUESTIONS AND ANSWERS—cont'd

the diagnosis should be based primarily on the results of the clinical examination.

5. A 65-year-old woman presents to the emergency department (ED) with chief complaint of elevated blood pressure, which was discovered at her dentist's office prior to a routine dental procedure. Her blood pressure upon admission is 187/101 mm Hg. Otherwise, the patient has no acute complaints, however, she does note chronic low grade chronic headaches and intermittent blurry vision. She has had previous readings of mildly elevated blood pressure at church health fairs, although was never formally diagnosed, and does take medication. Which of the following steps would be appropriate in the context of and ED visit?
   - **a.** Obtain a CT of the head to rule out intracranial pathology.
   - **b.** Administer a short-acting antihypertensive to reduce her blood pressure prior to discharge.
   - **c.** Prescribe a diuretic such as chlothalidone or hydrochlorothiazide, and refer to outpatient follow up with a hospital affiliated primary care provider.
   - **d.** Discharge home with instructions to follow up with a primary care provider.

Answer: d. Most patients who are found to have significantly elevated BP on intake vital signs measurement or who come to the ED because BP was found to be elevated in an outpatient setting or by self-measurement do not have an acute hypertensive emergency. While many patients have vague symptoms, such as headache or mild blurry vision, these symptoms do not correlate with the degree of hypertension. For such patients, a head CT or acute reduction of BP is not indicated and offers no tangible outcome benefit. This patient has a physician and is already on medication. As such, there is no indication to start a new medication or make a new referral at this time.

71

Aortic Dissection

Keith A. Marill

KEY CONCEPTS

- Aortic dissection most commonly presents as abrupt, sharp, severe pain maximally intense at onset in the chest or back. There may be various seemingly unconnected associated symptoms due to altered blood pressure or insufficiency of disparate vascular beds.
- Definitive diagnosis is most commonly made with an imaging study such as computed tomography of the aorta with intravenous contrast. A combination of standardized clinical assessment, chest x-ray, and serum D-dimer testing can effectively rule out the condition in low-risk patients.
- The critical immediate therapeutic actions are medical therapy to decrease aortic sheer force and blood pressure control. Immediate surgical consultation is indicated.
- Surgical treatments, including endovascular stent placement, are advancing, leading to decreased mortality. This increases the importance and benefit of early diagnosis in the emergency department setting.

FOUNDATIONS

Background and Importance

Aortic dissection is a lethal disease that can be difficult to diagnose. The majority of patients present with abrupt, severe pain of the chest or back, but a significant minority of patients present with different symptoms that can mimic a variety of other more common conditions. The average age of presentation is about 64 years and 65% are male.[1] Approximately 5000 to 10,000 cases of aortic dissection are diagnosed annually in the United States. Consequently, an individual emergency physician can generally expect to see fewer than 1 case per year.

Anatomy, Physiology, and Pathophysiology

The aorta is composed of three layers: the inner endothelial intima, the smooth muscle media, and the connective tissue outer adventitia. In the media, elastic fibers composed of elastin and fibrillin intertwine with collagen and smooth muscle cells, providing the viscoelastic properties that enable the aorta to distend, storing a portion of the stroke volume and elastic potential energy during ventricular systole. The aorta then recoils during diastole so that blood continues to be propelled to peripheral end organs.

The aorta emanates from the left ventricular outflow tract of the heart, makes an approximate 180-degree curve, and travels posteriorly within the mediastinum of the chest until it crosses through the diaphragm. It assumes a retroperitoneal position within the abdomen and continues inferiorly until it bisects into the common iliac arteries at approximately the level of the umbilicus. Major arterial branches include the brachiocephalic, left common carotid, and left subclavian in the chest, and the celiac, superior mesenteric, bilateral renal and gonadal, and inferior mesenteric arteries in the abdomen. It provides the major supply to the anterior spinal artery and lumbar spinal cord via the artery of Adamkiewicz.

Aortic dissection is defined by separation of the media layer of the aortic wall, generally with formation of a hematoma or false lumen. This commonly occurs in the setting of degeneration of the medial layer with associated inflammation. Aortic dissection is classified as acute if it is diagnosed within 2 weeks of symptom onset, subacute if diagnosed with 2 weeks to 3 months of onset, or chronic if greater than 3 months from onset.

Aortic dissection is commonly described with the Stanford classification. Type A describes dissection involving the ascending aorta with or without descending involvement, and Type B dissection is limited to the descending aorta commencing distal to the left subclavian artery. The less commonly used DeBakey classification separates dissections into: type I, involving the ascending and descending aorta; type II, involving only the ascending aorta; and type III, limited to the descending aorta (Fig. 71.1). These classification systems were proposed in part to differentiate patients who required surgical or pharmacologic therapy, though these delineations have blurred with modern therapeutic advances including endovascular treatments.

Aortic dissection most commonly occurs due to a tear in the intimal layer subsequent to a process that has weakened the aortic media. Blood passes through the tear separating the intima from the media or adventitia, creating a false lumen that can propagate in an anterograde or retrograde fashion. Propagation of aortic dissection can cause complications such as visceral or neurologic malperfusion syndromes due to compromise of branch vessels, pericardial tamponade, or acute aortic insufficiency.

Intramural hematoma refers to hematoma formation within the wall of the aorta without evidence of intimal aortic tear. The hematoma may be localized or dissect along the plane of the aortic media. The risk factors, presentation, and natural course of this variant generally mirror those of typical aortic dissection due to intimal tear. However, over half of intramural hematomas occur in the descending aorta as a result of atherosclerotic disease or iatrogenic intravascular catheter manipulation trauma.[2] Intramural hematoma is most easily diagnosed with CT angiography and may be missed with conventional angiography.

Penetrating atherosclerotic ulcer results from erosion of an intimal atherosclerotic lesion. It is an alternative mechanism to intimal tear, allowing blood to dissect into the media of the aortic wall or beyond. This process develops gradually in elderly patients with extensive atherosclerosis and often is heralded by chest or back pain and hypertension. Ulceration may lead to hematoma formation in the dissected media, or it can extend into the adventitia with pseudoaneurysm formation and potential rupture. It is usually a localized process most commonly occurring in the descending aorta without retrograde aortic

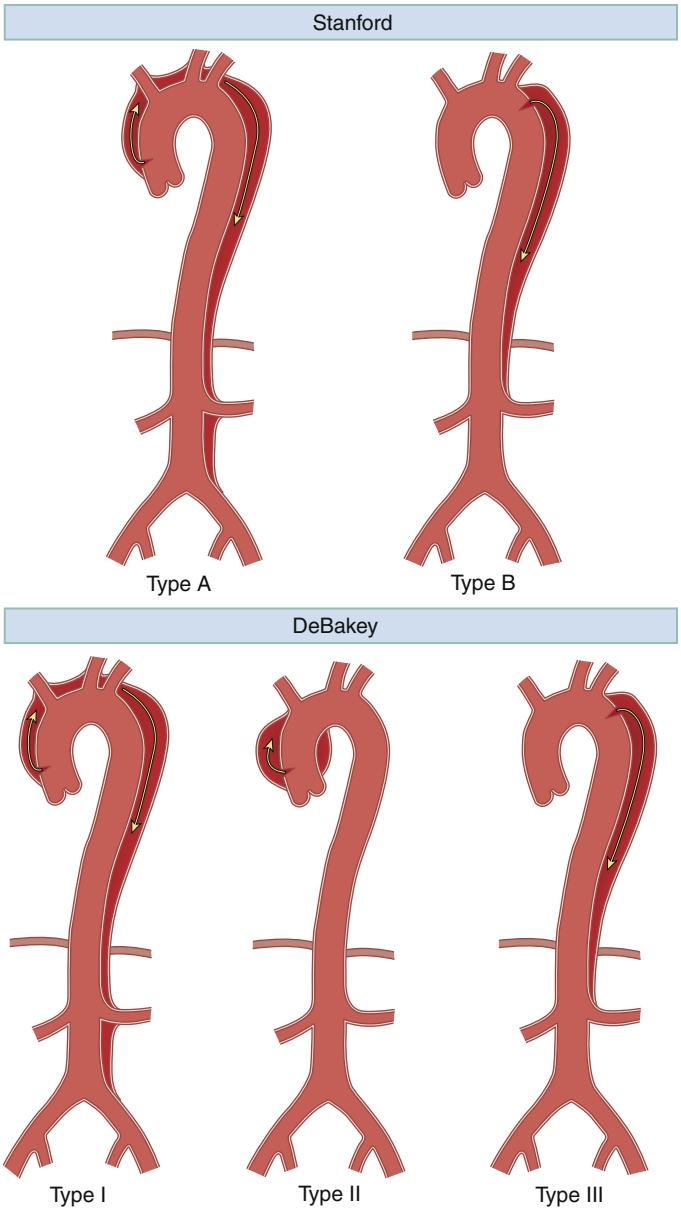

Fig. 71.1 Acute aortic dissection classifications. The Stanford classification divides dissections into those involving the ascending aorta from dissection originating there or proximal dissection of a more distal origin (Type A), or those limited to the descending aorta (Type B). The DeBakey classification divides dissections into those arising in the ascending aorta and extending distally beyond the innominate artery (Type I), arising in the ascending aorta with extension limited to the level of the innominate artery take-off (Type II), and arising at or distal to the left subclavian artery take-off with extension distally (Type III).

valve, pericardial, or branch vessel involvement and associated diffuse symptoms and signs (Fig. 71.2).

About two-thirds of aortic dissections are classified as type A, and the remainder as type B. Hypertension is the most common risk factor, present in a majority of patients.[1] Both type A and B patients may have a history of cardiac surgery, including aortic valve replacement. Patients may have a history of aortic aneurysm or a prior aortic dissection. Marfan syndrome is the connective tissue disease most commonly associated with acute aortic dissection. Other associated conditions include: atherosclerosis, a family history of thoracic aortic disease with or without a defined genetic syndrome, bicuspid aortic valve, coarctation of the aorta, a bovine-type aortic arch, when the brachiocephalic artery shares a common origin with the left common carotid artery, and infectious disease such as syphilis. Activities and events associated with increased aortic sheer force including crack cocaine use, weight lifting, the peripartum period,[3] and deceleration trauma can rarely cause aortic dissection. Traumatic aortic dissection most commonly occurs at the level of the left subclavian artery in the proximal descending aorta because the aorta is tethered at this point by the ligamentum arteriosum. Other causative genetic syndromes include Turner, type 4 Ehlers-Danlos, and Loeys-Dietz. Fluoroquinolones interfere with collagen synthesis and increase the risk of aortic dissection during treatment.[4]

CLINICAL FEATURES

Aortic dissection is classically characterized by an acute severe, sharp, ripping or tearing, painful sensation in the chest or central upper back

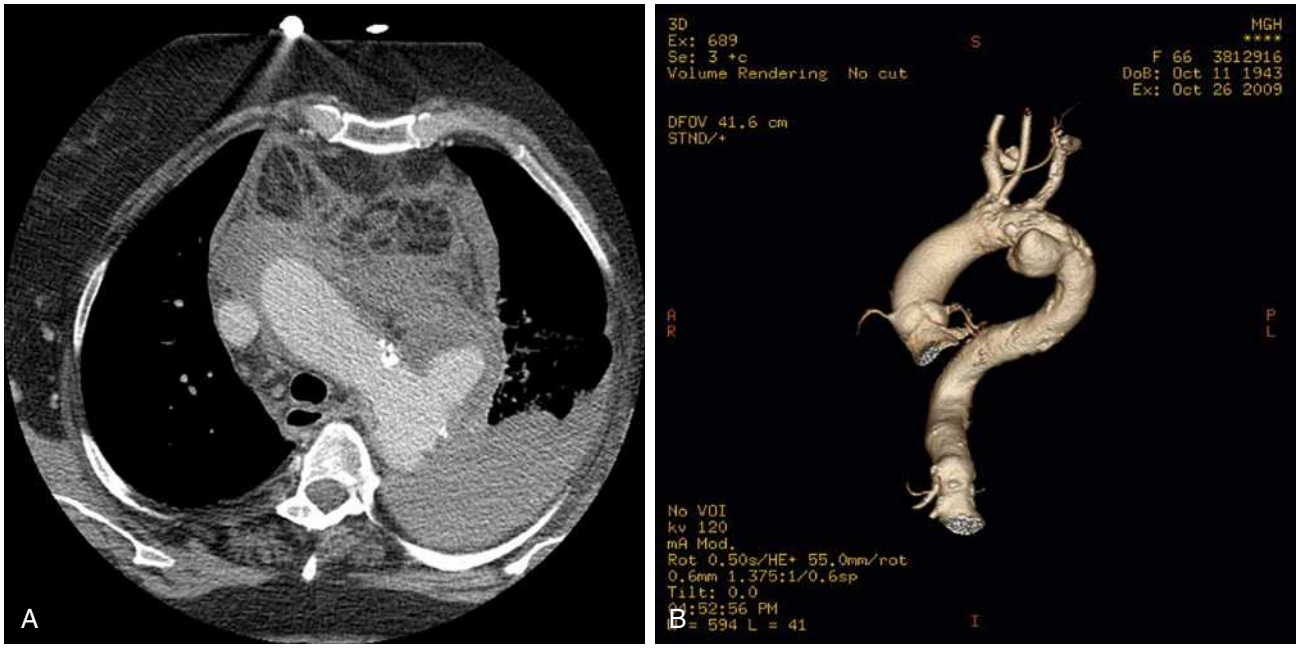

Fig. 71.2 Pseudoaneurysm due to penetrating ulcer. A 66-year-old female presented with sharp chest pain radiating to the interscapular area and was found to have a penetrating ulcer of her descending thoracic aorta just beyond the left subclavian artery with a contained hematoma and blood in the mediastinum and left chest. The patient was treated with emergent endovascular repair. (A) Cross-sectional computed tomography (CT) with contained hematoma (pseudoaneurysm) and left hemothorax, and (B) three-dimensional CT angiogram rendering of aorta with pseudoaneurysm.

with maximal intensity from onset, and associated apprehension.[5] When present, the pain generally radiates to the anterior chest or neck when the ascending aorta is involved, and to the back, abdomen, or down the legs when the pathology is in the descending thoracic aorta. Migratory pain is described in about one-third of cases. The radiation and migration of pain often reflect the anatomic extension of the dissection. Emergency physicians may have little difficulty diagnosing patients with a classic presentation. The challenge is that patients can present with a spectrum of pain, and some patients have no pain at all (Fig. 71.3). Additionally, many other symptoms may be present.

Other symptoms of type A dissection include lightheaded sensation or syncope, and less commonly, dyspnea related to congestive heart failure. Patients with either type A or B dissection may complain of neurologic deficits related to cerebral or spinal cord compromise. Type B dissection is considered complicated in the setting of refractory pain, rapid aortic expansion or rupture, uncontrollable hypertension, or insufficient perfusion of the renal, splanchnic, spinal, or lower extremity vasculature.

Signs of type A dissection include asymmetric pulse deficits,[6] and patients may present with hypertension, normotension, or hypotension. Pseudohypotension may occur when the blood pressure in one arm is lowered due to subclavian artery compromise. Syncope occurs in a minority of patients and is associated with increased mortality. It is classically due to pericardial tamponade from retrograde dissection into the pericardial sac, but other causes include cerebrovascular insufficiency, internal hemorrhage with hypovolemia, or dysrhythmia. Tamponade may be evidenced by dilated neck veins, diminished heart sounds, and decreased pulse or pulse pressure. A new diastolic murmur in the lower left sternal border suggestive of aortic regurgitation can occur when the dissection spans the aortic valve. All three components of the classic triad—abrupt tearing pain, pulse deficits, and aortic insufficiency—are seldom observed in a single patient.

Acute myocardial infarction due to coronary ostium compromise may occur in type A dissection, with the majority of these cases involving the right coronary artery ostium with infarction of the corresponding inferior coronary territory. Left main occlusion is the second most common site (Fig 71.4). Rarely, patients may present with isolated congestive heart failure when the dissection compromises aortic valve function.

The majority of patients with type B dissection have elevated blood pressure greater than 150 mm Hg. Syncope and pulse deficits can occur but are less common than with type A disease.

Neurologic symptoms and signs can occur in either type A or B dissection.[7] These include ischemic stroke, spinal ischemia leading to temporary or permanent paralysis in 1% to 3% of patients, and ischemic peripheral neuropathy. Up to one-third of patients who complain of neurologic symptoms at dissection onset have no complaint of pain.

Gastrointestinal complications can also occur in either type A or B disease. These can be due to fixed or dynamic arterial branch occlusion or global hypoperfusion. Mesenteric ischemia is the most common cause of death in type B disease. Gastrointestinal hemorrhage is less common and can be due to ischemic bowel or fistula formation. Nausea, vomiting, diaphoresis, and apprehension can be seen with all acute dissections.

Information from the history and physical exam can be combined systematically to estimate a combined risk of disease. The aortic dissection detection risk score (ADD) is a tool combining three domains of clinical information to assess for the risk of acute dissection: high risk conditions, pain features, and exam features (Table 71.1). Patients are classified on a score of one to three, scoring one point if any items in each of the three domains is positive. An ADD score of one or more is 95% sensitive for aortic dissection. Among patients with none of the identified clinical risk factors on the ADD, half had a widened mediastinum on chest x-ray. This suggests the ADD score and chest x-ray provide complementary information.

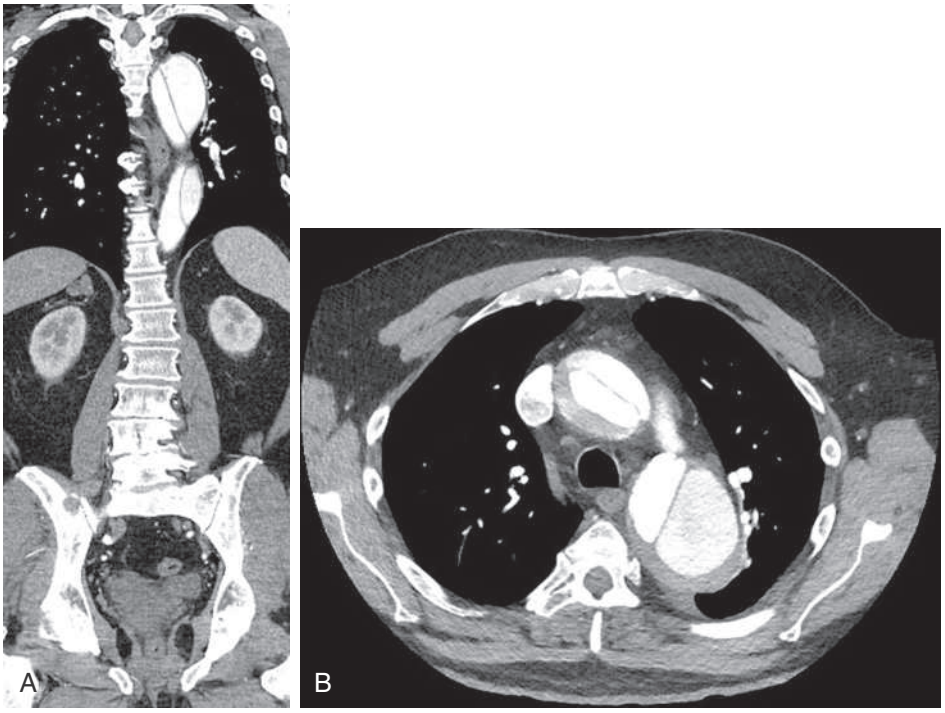

Fig. 71.3 Painless dissection presentation. A 64-year-old man with a history of atrial fibrillation on warfarin presented with transient blurred vision without pain or complaints in his chest or elsewhere. Magnetic resonance angiogram (MRA) imaging revealed dissection involving the carotid artery. Subsequent computed tomography angiogram (CTA) of the chest revealed a type B aortic dissection (A). Endovascular stenting was performed without event. The patient re-presented with chest pain 6 years later with an ascending dissection requiring operative repair. (B) Computed tomography angiogram (CTA) demonstrating original type B dissection and new type A dissection.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for acute aortic dissection is broad and includes many conditions more common than dissection. It is perhaps most important to always consider the possibility of aortic dissection when diagnosing these other conditions. Dissection may coincide with or cause another condition on the differential. Some factors associated with a delay in diagnosis include fever, normal blood pressure, female sex, non-white race, and previous cardiac surgery.

Acute myocardial ischemia or infarction is an alternative, more common cause of chest pain or discomfort. In contrast to aortic dissection where pain is often at high intensity at onset, pain due to coronary ischemia may be provoked by exertion and crescendo with subsequent waxing and waning. It can sometimes be relieved by rest or nitroglycerin. Myocardial ischemia may be associated with suggestive ECG changes. Unfortunately, as noted, type A dissection can cause coronary ostial compromise and subsequent myocardial infarction, leading to misdiagnosis. Approximately one in every 1000 STEMIs is caused by a type A dissection. Acute pericarditis presents with chest pain, which is often positional, and evidence of pericardial effusion. Aortic dissection should be considered in any patient with pericardial effusion, with or without tamponade physiology, or new aortic regurgitation.

Pulmonary embolism can cause chest pain and syncope like aortic dissection, but commonly associated pulmonary symptoms such as shortness of breath or cough are absent in dissection. Patients with aortic dissection and neurologic symptoms may appear to be suffering from a primary central nervous system event such as ischemic or hemorrhagic stroke. Among patients with ischemic stroke, approximately 1% are suffering from acute aortic dissection.[8] Severe hypertension associated with dissection may further suggest intracranial hemorrhage.

Patients with mesenteric ischemia classically present with a soft abdomen and abdominal pain out of proportion to tenderness. This can also be observed with acute type A or B dissection. Mesenteric ischemia may present with bloody bowel movements, which is an uncommon finding in acute dissection. Other intestinal conditions can cause acute abdominal pain, but often with localized abdominal exam findings.

Other vascular emergencies such as renal artery aneurysm can present similarly to aortic dissection with severe pain and hypertension. These are important differentials, particularly in predisposed patients such as those with type 4 Ehlers-Danlos syndrome. Lumbar spinal disc disease can cause back pain radiating to one or both legs and associated neurologic compromise. These symptoms and signs are usually more geographically constrained to this portion of the body as compared to dissection.

DIAGNOSTIC TESTING

Diagnostic testing begins with bedside ultrasonography, which is indispensable to assess for reversible catastrophic conditions such as pericardial tamponade. Using a small footprint probe to allow access between the ribs, the exam should focus on the heart, and thoracic and abdominal aorta. The initial assessment should determine if there is a pericardial effusion, and if so, if there evidence of right ventricular free wall scalloping during diastole suggestive of tamponade physiology. The aortic root should be assessed for dilatation, dissection, and visible flap using the left parasternal long-axis view. The descending aorta is also inspected for dissection, flap, or dilatation.

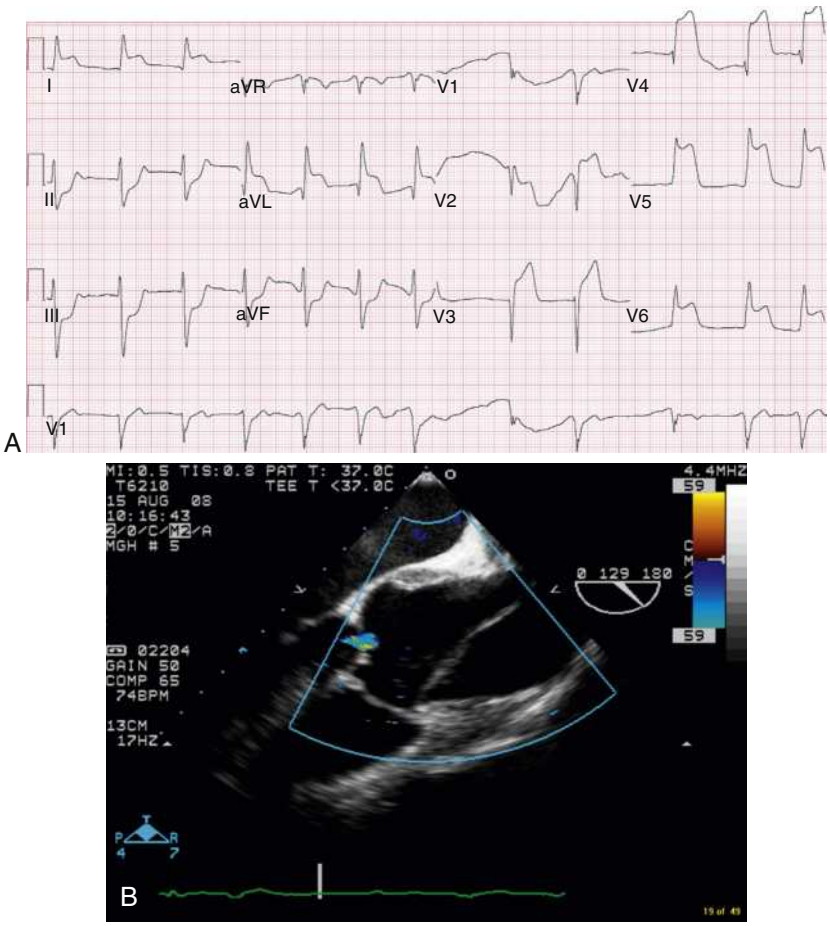

Fig. 71.4 Acute dissection complicated by left main STEMI. A 46-year-old man presented with acute, severe chest pain with vomiting and diaphoresis while lifting weights at the gym. Initial ECG (A) indicated acute antero-septal STEMI with reciprocal inferior ST depression. The patient was taken emergently to the cardiac catheterization lab. After temporizing stenting of his left main coronary as well as the left anterior descending and left circumflex arteries, he was taken to the operating room for aortic root graft replacement with CABG. Intraoperative transesophageal echocardiogram (TEE) (B) reveals type A dissection of the ascending aortic root extending to the aortic valve.

TABLE 71.1 Aortic Dissection Detection Risk Score

High-Risk Conditions	High-Risk Pain Features	High-Risk Examination Features
Marfan Syndrome	Chest, back, or abdominal pain described as any of the following:	Evidence of perfusion deficit:
Family history of aortic disease		Pulse deficit
Known aortic valve disease	Abrupt onset	Systolic BP differential
Recent aortic manipulation	Severe intensity	Focal neurologic deficit (in
Known thoracic aortic aneurysm	Ripping or tearing	conjunction with pain)
		Murmur of aortic insufficiency
		(new and with pain)
		Hypotension or shock state

Any positive attributes in each column yields a score of 1 for that column. Each column can have a score of 1 or 0. The total ADD score is the sum of the 3 columns (on a scale of 0 to 3).

Laboratory studies should be sent, including complete blood count, serum chemistry and renal function, coagulation profile, and blood typing. Additionally, clinicians should send serial troponin for patients with pain suggestive of coronary ischemia, B-type natriuretic peptide if there are signs of heart failure, and urinalysis if there is any concern for renal arterial involvement. None of these studies diagnose dissection, but they help to rule out other etiologies and define the extent of complications.

ECG may demonstrate STEMI due to coronary ostial compromise by the dissection or associated flap. Voltage may be decreased due to pericardial effusion. Left ventricular hypertrophy due to longstanding hypertension may be present in 20% of cases. Nonspecific ST-T

changes may be observed, and these can delay the correct diagnosis of dissection.[9] There is no ECG finding highly accurate for dissection.

Chest x-ray has a sensitivity of 67% for acute dissection. The most sensitive chest x-ray findings are a widened aortic silhouette or mediastinum where mediastinal widening was defined as a width of at least 8 cm at the level of the aortic knob or a mediastinal to chest width ratio exceeding 0.25.[7] Separation of aortic intimal calcification from the external aortic wall and pleural effusion have sensitivities of 9% to 16% and 16% to 37%, respectively. Two-view versus one-view chest x-ray technique does not improve sensitivity. Given the only fair sensitivity of this test, it is crucial that emergency physicians not let a normal chest x-ray defer or delay further evaluation when dissection is suspected.

A variety of serologic tests have been investigated to diagnose aortic dissection. Serum D-dimer is the most useful at present. It is rapidly performed and readily available due to its use to assess for pulmonary embolism. At a test threshold of 500 ng/ml, the test is approximately 96% sensitive and 70% specific with a negative likelihood ratio of 0.05 for acute dissection.[5] D-dimer alone is insufficient to rule out acute dissection confidently, but in concert with other information, it is useful to assess the need for CT imaging.[10,11] The combined strategy of ADD=0 and negative D-dimer was 99.7% sensitive for acute dissection.[10] Specificity was 18%. Applied in practice, this means CT imaging or equivalent could be avoided in 18% of the patients in whom dissection is considered, but not present. Conversely, in patients with an ADD score of 2 or above, 4% of patients had an acute aortic syndrome even if the d-dimer was negative. This suggests that D-dimer should not be used in patients with a high clinical probability of dissection; rather, these patients must receive an advanced imaging test.

Investigations of other candidate biomarkers for acute dissection continue. These include smooth muscle myosin components, soluble elastin fragments, microfibril fragments including fibrillin-1, fibrin degradation products, and an interleukin receptor, ST2.[12] None have demonstrated sufficient sensitivity to rule out acute dissection adequately.

The diagnosis of aortic dissection ultimately rests on diagnostic imaging. Techniques with acceptable test characteristics include multidetector CT angiogram of the aorta (MDCTA), conventional angiography, magnetic resonance angiography (MRA), and transesophageal echocardiography (TEE). The choice of test used is based on multiple factors, including accuracy, safety, contraindications, availability, speed, convenience, ability to identify alternative diagnoses, and cost. MDCTA is the initial imaging study in about three-quarters of patients today, followed by TEE.[1] Often multiple tests are used. Goals of imaging are to confirm the diagnosis, localize the tear, display the anatomy and extent of the dissection flap, and determine whether prompt lifesaving intervention is needed.

MDCTA is generally preferred throughout the United States because it is readily available, fast, both sensitive and specific, and usually meets the previously stated goals. In the event of serious contrast allergy requiring a prolonged pretreatment regimen, or inability to tolerate or fit on the CT scanner, then another modality must be used. TEE may generally be the preferred alternative choice if it can be performed expeditiously by a qualified specialist.

TEE offers some advantages over MDCTA. The TEE probe and procedure are portable. In addition to being highly sensitive for the identification of type A dissection, TEE is also useful when involvement of the aortic valve and the status of the left ventricle, pericardial space, and right and left coronary artery ostia are unknown. Transthoracic echocardiography (TTE) is useful if it demonstrates disease but is insufficiently sensitive to rule out dissection.

MRA is rarely used for diagnosis of dissection because it takes longer to perform than MDCTA or TEE. Additionally, clinical staff must maintain a distance from the potentially unstable patient during the study, leading to safety issues. When used, it demonstrates excellent spatial resolution and anatomic detail. Aortography is the historical gold standard, but it is seldom the initial test for aortic dissection today due to the ease and rapid acquisition of MDCTA in most instances. The reported false-negative rate for aortography ranges from 5% to 15%. Aortography is valuable for the patient with STEMI but some presentation characteristics suggestive of dissection. As time is essential for percutaneous transluminal coronary angioplasty (PTCA) or stenting for STEMI patients, the patient can be brought to the cardiac catheterization lab and aortography performed at the initiation of the procedure in lieu of other imaging. The emergency physician must share his or her concerns with the interventional cardiologist to plan this diagnostic approach.

"Triple rule out" imaging refers to MDCTA protocol to assess simultaneously for acute aortic dissection, myocardial infarction, and pulmonary embolism. ECG gating freezes cardiac motion allowing evaluation of the perivalvular area and coronary arteries. A broad spectrum of other chest and upper abdominal diseases also may be identified with this study. However, EPs seriously consider and test for all three diagnoses in only about 3% of chest pain evaluations. There are a host of limitations to this test including coronary calcifications or stents, renal insufficiency, atrial fibrillation, inadequate heart rate control, contrast allergy, obesity, cost, and concern for radiation exposure.

MANAGEMENT

The initial primary goal of care in the emergency department setting is to minimize dissection extension. This is accomplished by decreasing the force of cardiac contraction and resulting aortic sheer forces, and driving the heart rate down to 60 beats per minute or less. Acceleration of aortic blood flow, dP/dt, is minimized while maintaining blood pressure in the low normal range. Beta-1 adrenergic blockade therapy is the preferred treatment (Table 71.2). Favored agents include esmolol infusion due to its short 9-minute half-life and titratability, or metoprolol or labetalol if esmolol is not readily available. Labetalol also provides alpha-1 adrenergic blockade decreasing vascular tone and blood pressure. A selective beta-1 receptor blocker such as esmolol or metoprolol may be preferred for patients with chronic obstructive pulmonary disease (COPD) at risk for bronchospasm. Decreased cardiac contractility can also be achieved with infusion of the calcium channel blockers diltiazem or verapamil if beta blockers are contraindicated due to allergy or severe pulmonary disease, or unavailable.

Blood pressure control is critical in the setting of dissection. Hypotension should elicit an immediate search for potentially reversible causes such as pericardial tamponade or internal hemorrhage. In addition to any temporizing interventions such as pericardiocentesis, blood pressure may be supported with crystalloid infusion and vasopressors to provide adequate perfusion of vital organs, targeting a mean arterial pressure of 65 mm Hg. Norepinephrine or phenylephrine infusions are preferred to maximize peripheral vasoconstriction and minimize myocardial stimulation with resulting sheer stress. Antiadrenergic infusions should be stopped.

Hypertension is commonly encountered in type B dissections and must be treated with a target of 100 to 120 mm Hg systolic. Vasodilating agents such as nitroprusside can be infused, but only after initiation of antiadrenergic therapy to blunt the force of myocardial contraction. An ACE inhibitor such as enalaprilat may be beneficial, particularly if there is renal artery compromise. An arterial catheter should be placed in an uninvolved extremity to monitor and titrate therapy closely.

Analgesia is essential for patient comfort and to decrease pain-induced sympathetic discharge. Parenteral narcotics such as morphine,

TABLE 71.2 Acute Aortic Dissection Medications

Medications	Dosages (IV)
Contractile force and BP control	
Antiadrenergic	
Esmolol	0.5 mg/kg over 1 minute, then 50 μg/kg/min infusion
	Increase by 50 μg/kg/min every 4 min to max. 300 μg/kg/min
	Repeat 0.5 mg/kg boluses with each increase in dosing
Labetalol	10–20 mg up to every 10 minutes, or 0.5-2 mg/min infusion
Metoprolol	2.5–5 mg every few minutes
Vasodilation	
Nitroprusside	Begin 0.25–0.5 μg/kg/min and increase to max. 10 μg/kg/min
Enalaprilat	Begin 1.25 mg over 5 minutes, repeat up to 5 mg every 6 hours
Calcium channel blockade	
Diltiazem	Begin 10–20 mg, then 5 mg/hr infusion
	Infusion can be increased in 5 mg/hr increments up to 15 mg/hr
Verapamil	Begin 5 mg over 5 minutes, then repeat 5–10 mg up to every 15 minutes
	Or infuse 5 mg/hr with adjustment as needed
Analgesia (opioids)	
Fentanyl	0.5–1 mcg/kg every 30 min as needed
Morphine	0.1 mg/kg every 1 hr as needed
Vasopressor	
Norepinephrine	Begin 5 μg/min and titrate up to mean arterial blood pressure goal of 65 mm Hg
Phenylephrine	Begin 50 μg/min and titrate up to mean arterial blood pressure goal of 65 mm Hg

fentanyl, or hydromorphone are reasonable choices. Fentanyl benefits from a short half-life allowing titratability and relatively minimal secondary decrease in blood pressure. These characteristics are particularly valuable in the setting of hypotension.

Cardiac tamponade complicates up to approximately one-fifth of acute aortic dissections and carries a 50% mortality. Controlled catheter drainage with a pigtail catheter can be performed with ED ultrasound guidance to temporize and allow time to prepare for definitive operative care. We recommend insertion of an 8F pigtail catheter at the fourth or fifth intercostal space at or just medial to the left midclavicular line aiming for the pericardial effusion visualized beyond the apex of the heart. Once the catheter is inserted, 5 to 10 mL of hemopericardium can be aspirated with close observation of the resulting hemodynamics. Aspiration can be repeated as needed to attain a systolic blood pressure of 80 to 90 mm Hg.

Definitive therapy of acute aortic dissection has been defined by the type of dissection and continues to evolve, particularly due to advancing endovascular therapies. It is critical to consult surgical services as soon as dissection is identified to develop a coordinated plan. Type A dissection generally requires expeditious surgical repair due to progressive increasing risk of multiple complications, including rupture into the pericardial space, development of coronary or cerebral ischemia, aortic regurgitation, congestive heart failure, or free rupture of the aorta into the thorax.

For patients with type A dissection complicated by malperfusion, medical therapy, along with temporizing percutaneous reperfusion using aortic stenting or fenestration, and selective branch stenting may allow stabilization and reduce the risk of the operation. Repair of the patient's ascending aorta may proceed after a period of recovery.

Definitive aortic repair includes resection of the dissected aorta segment and insertion of an aortic graft. Restoration of aortic valve competence is paramount in patients who develop aortic insufficiency. This is usually achieved by resuspension of the native aortic valve or by aortic valve replacement, depending on the size of the aortic root and the condition of the aortic valve leaflets. Reimplantation of the coronary arteries to the new graft may also be necessary. Surgical mortality has slowly decreased but remains substantial at 18% overall in major centers.[1]

The cornerstone of type B dissection treatment is blood pressure control. Surgical intervention has been reserved for life-threatening complications such as ischemia of both kidneys leading to reversible renal failure, intestinal ischemia, limb ischemia, progressive aneurysm extension, impending or frank rupture, or intractable pain. However, modern endovascular therapy using stent grafts and fenestration is evolving this paradigm. The goals of this therapy include reconstruction of the thoracic aorta segment containing the entry tear, induction of thrombosis of the false lumen, and reestablishment of the true aortic lumen and side-branch flow. Aortic fenestration is indicated for carefully selected patients with malperfusion syndrome due to branch artery occlusion, and to provide a reentry tear for a dead-end false lumen. A less invasive strategy using stents may be preferable to surgery in higher-risk candidates. Endovascular aortic repair may even be employed for uncomplicated type B dissections to prevent subsequent aneurysm formation, which is otherwise common.[13]

Surgery and endovascular interventions require coordinated teams with expertise and experience to achieve success. Outcomes for type A dissection patients are generally better at high-volume centers. However, patient transfer incurs a delay in time-sensitive care. Recent data suggest regionalization of care with transfer a mean of 50 miles to high-volume centers is associated with lower operative mortality.[14]

DISPOSITION

Patients with acute aortic dissection generally require emergent surgical consultation and admission to the intensive care unit or operating room for further care. Consultation with surgical subspecialties could include cardiovascular surgery for type A dissections and vascular surgery for type B dissections but may vary based on local practice and resources.

The patient and family should be informed of the diagnosis and gravity of the situation. Type A acute aortic dissection carries a mortality of 1% to 2% per hour immediately after the onset of symptoms. The risk of death is increased in patients presenting with pericardial tamponade, coronary artery involvement leading to myocardial ischemia or infarction, or carotid artery involvement causing cerebral hypoperfusion. The most common causes of death are aortic rupture, stroke, visceral ischemia, cardiac tamponade, and circulatory failure. The long-term 1- and 3-year survival reported in the IRAD in the surgically treated patients surviving to hospital discharge are 96 ± 2.4% and 91 ± 3.9%, respectively, reflecting the timely surgical repair of the ascending aortic dissection. Patients with type B acute aortic dissection without

associated complications have a 30-day mortality of 10%. However, patients who develop ischemic complications with associated organ malperfusion syndrome, renal failure, visceral ischemia, or contained rupture often require urgent aortic repair, which carries a mortality of 20% by day 2 and 25% by day 30.

Survivors of aortic dissection require vigilant long-term surveillance with strict blood pressure control and monitoring. Patients who retain patency in the false channel of the aorta after either medical treatment or surgical repair have a significant risk of aneurysm formation and rupture of the false channel, especially in the first 6 months after initial therapy. Expansion, rupture, or both are more common in patients who are older and have poorly controlled hypertension and COPD. Other potential complications include redissection and progressive aortic insufficiency. The emergency physician should have a heightened level of concern and low threshold for definitive imaging for patients who return to the ED with relevant complaints after prior treatment for aortic dissection.

CHAPTER 71: QUESTIONS AND ANSWERS

1. The single most important agent to treat acute aortic dissection is:
- **a** Nitroprusside.
- **b** Aspirin.
- **c** Antiadrenergic.
- **d** Enalaprilat.

Answer: C. The initial primary goal of care for a patient with an aortic dissection in the emergency department setting is to minimize extension of the dissection. This is accomplished by decreasing the force of cardiac contraction and resulting aortic sheer forces, and driving the heart rate down to 60 beats per minute or less. Acceleration of aortic blood flow, dP/dt, is minimized while maintaining blood pressure in the low normal range. Beta-1 adrenergic blockade therapy is the preferred treatment.

2. A 70-year-old man with a history of poorly controlled hypertension presents with sharp central severe chest pain. ECG, chest x-ray, and serum D-dimer are normal. The next appropriate step is:
- **a** Transthoracic echocardiography in the radiology suite.
- **b** CT angiogram of the aorta.
- **c** Check serial troponin, and discharge with close follow up if negative.
- **d** Consult surgical service.

Answer: B. This patient had a presentation very concerning for an aortic dissection. In high-risk cases, chest x-ray and D-dimer cannot not be used to rule out a dissection. These patients must receive an advanced imaging test.

3. You are working in a small rural hospital when you diagnose a type A aortic dissection based on CT angiogram of the aorta. Vital signs are heart rate 85 beats per minute and blood pressure 130/85 mm Hg. The high-volume referral center is 25 minutes away by ambulance ride.
- **a** Arrange for immediate transfer to high-volume center.
- **b** Stabilize with arterial and central lines and intubation, then arrange transfer.
- **c** Call the intensivist to arrange medical ICU admission on labetalol infusion.
- **d** Call the general surgeon on duty to organize emergent surgery at your facility.

Answer: A. Surgery and endovascular interventions for aortic dissection require coordinated teams with expertise and experience to achieve success. Outcomes for type A dissection patients are generally better at high-volume centers. However, patient transfer incurs a delay in time-sensitive care. Recent data suggest regionalization of care with transfer a mean of 50 miles to high-volume centers is associated with lower operative mortality.

4. A 60-year-old woman presents with chest pain radiating to the back with onset while lifting a 50-lb pot in her garden, and her ECG demonstrates an inferior STEMI. The next appropriate step is:
- **a** MR angiogram of the chest.
- **b** Aspirin and TPA.
- **c** Diltiazem infusion.
- **d** Immediate cardiac catheterization with recommendation to interventional cardiologist for initial aortogram.

Answer: D. Aortography is valuable for the patient with STEMI but some presentation characteristics suggestive of dissection. As time is essential for percutaneous transluminal coronary angioplasty (PTCA) or stenting for STEMI patients, the patient can be brought to the cardiac catheterization lab and aortography performed at the initiation of the procedure in lieu of other imaging. The emergency physician must share his or her concerns with the interventional cardiologist to plan this diagnostic approach.

5. The connective tissue disorder responsible for the most cases of acute aortic dissection is:
- **a** Ehlers-Danlos, type I.
- **b** Ehlers-Danlos, type IV.
- **c** Marfan syndrome.
- **d** Loeys-Dietz syndrome.

Answer: C. Marfan syndrome is the connective tissue disease most commonly associated with acute aortic dissection.

6. There are about 150 million annual ED visits in the United States. An emergency physician who sees 3000 patients per year can expect to see an acute aortic dissection about every:
- **a** 6 months.
- **b** 1 year.
- **c** 5 years.
- **d** 15 years.

Answer: C. Aortic dissection is a rare condition, with only about 10,000 cases a year in the United States. If an emergency physician sees 3000 patients, and the rate of aortic dissection is 10,000 per 150,000,000 ED visits, this results in seeing 0.20 per year, or about 1 every 5 years.

Abdominal Aortic Aneurysm

Christopher B. Colwell

KEY CONCEPTS

- A ruptured abdominal aortic aneurysm (AAA) should be considered in any patient with otherwise unexplained abdominal or back pain. The complete triad of pain, hypotension, and a pulsatile mass may not be present.
- In a patient with an AAA and acute symptoms such as severe abdominal or back pain or hypotension, rupture is imminent or has already occurred.
- A patient with a ruptured AAA and initially normal vital signs can suddenly deteriorate at any time.
- The risk of rupture increases substantially with increased aneurysm size, and most ruptured AAAs have diameters greater than 5 cm.
- Bedside ultrasound may be used to document an AAA or free fluid and assist in the rapid diagnosis of a ruptured AAA.
- The abdominal CT scan is the diagnostic test of choice in the evaluation of the stable patient with suspected ruptured AAA; intravenous contrast is not essential in emergencies.
- The patient who has had endovascular repair of an AAA remains at risk for aneurysm rupture.

PRINCIPLES

An abdominal aortic aneurysm (AAA) is a true aneurysm, meaning a localized dilation of the aorta involving all three layers (intima, media, and adventitia) of the arterial wall (Fig. 72.1). A false aneurysm, or pseudoaneurysm, is a collection of flowing blood that communicates with the arterial lumen but is not enclosed by the normal vessel wall and is contained only by the adventitia or surrounding soft tissue. Pseudoaneurysms can arise from a defect in the arterial wall or a leaking anastomosis after AAA repair.

AAA is distinct from aortic dissection, which is sometimes incorrectly referred to as a *dissecting aortic aneurysm*. In aortic dissection, blood enters the media of the aorta and splits (dissects) the layers of the aortic wall. Aortic aneurysm and aortic dissection are different disease processes with different clinical presentations, complications, diagnostic methods, and treatments.

An aneurysm can develop in any segment of the aorta, but most are infrarenal. The diameter of the normal adult infrarenal aorta is approximately 2 cm, and a diameter of 3 cm or more defines an AAA.

Epidemiology

The prevalence of AAA increases with advancing age and is found in 2% to 5% of men older than 50 years. Men are affected more often than women, although recent research suggests AAA may be more common in women than previously suspected, particularly among women who smoke.[1] The patient often has concomitant atherosclerotic occlusive disease, including coronary, carotid, or peripheral vessels, which may influence the clinical presentations, complications, and management.

Several risk factors for the development of an AAA have been established, but risk factors are epidemiologic, not individual characteristics. Age is the most significant risk factor for the development of an AAA.[2] An AAA can be found in 5% to 10% of all older men who are screened with ultrasonography with increasing prevalence in those who have concomitant coronary artery disease or peripheral vascular disease. A family history of an AAA is a powerful risk factor; those with an affected first-degree relative have a markedly increased risk of developing an AAA. Although awareness of high-risk groups can speed the recognition of AAA, the consideration of AAA should not be restricted to patients in these groups. Some evidence suggests that women may experience delays in diagnosis and worse operative mortality after ruptured AAA. Up to half of AAAs in the United States occur in women, nonsmokers, or those younger than 65 (Table 72.1).

Pathophysiology

AAAs have traditionally been attributed to atherosclerosis, but patients with advanced atherosclerosis have occlusive disease, not aneurysms. Patients with AAA have biochemical abnormalities leading to the loss of elastin and collagen, which are the major structural components of the aortic wall. The propensity to form aneurysms may have a genetic basis, but the exact mode of inheritance is uncertain. The Society for Vascular Surgery has recommended labeling the typical degenerative AAA as "nonspecific," rather than "atherosclerotic," to reflect this uncertainty surrounding the etiology.

AAAs may also have specific etiologies, such as infection, trauma, connective tissue diseases, and arteritis. Such aneurysms are rare, however, compared with nonspecific degenerative aneurysms.

Natural History

AAAs progressively enlarge, ultimately resulting in rupture of the aneurysm and potentially fatal hemorrhage. Although other complications are possible, by far the most common and most clinically significant is rupture.

The most important factor determining the risk of rupture is the size of the aneurysm. The risk of rupture increases substantially with increased aneurysm size, and most ruptured AAAs have diameters greater than 5 cm. The growth rate of the AAA, in addition to other anatomic factors, may also be important in determining the risk of rupture. Although rupture of aneurysms smaller than 4 cm is rare, no aneurysm is completely "safe." Any aneurysm can rupture and cause significant consequences.

AAA most commonly ruptures into the retroperitoneum, where hemorrhage may be temporarily limited by clotting and tamponade at the rupture site, but 10% to 30% involve free intraperitoneal rupture, which is often rapidly fatal. Occasionally, rupture occurs into the gastrointestinal tract or the inferior vena cava.

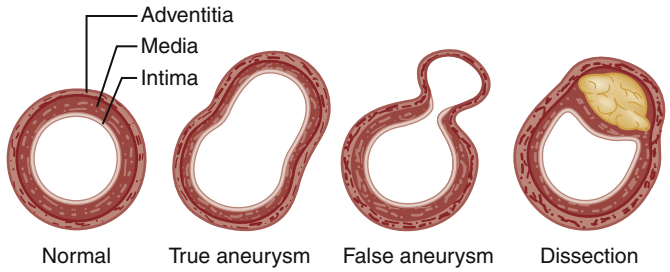

Fig. 72.1 Types of aortic aneurysms. (Adapted from LaRoy LL, et al. Imaging of abdominal aortic aneurysms. *Am J Roentgenol.* 1989;152:785.)

TABLE 72.1 Prevalence of Abdominal Aortic Aneurysms in Selected Risk Groups

Group	Incidence
Men aged 65 years or older	5% to 10%
Patients with coronary artery disease or occlusive peripheral vascular disease	10% to 15%
Brothers of patients with abdominal aortic aneurysms (AAAs)	20% to 30%

Complications can also arise from an intact AAA. The walls of an AAA are often lined with clot and atheromatous material, which can embolize and occlude distal vessels. Sequelae of occlusion and embolization may be the only diagnostic clues to AAA. Aortic thrombosis may occur rarely and patients can also have complications caused by impingement of the aneurysm on adjacent structures.

In approximately 5% of AAAs, a dense inflammatory and fibrotic reaction develops in the aneurysm wall and adjacent retroperitoneal tissue. In these "inflammatory" AAAs, periaortic fibrosis may incorporate and obstruct adjacent structures, such as the ureters or duodenum.

The principal concern in the patient with an AAA is the potential for rupture of the aneurysm, which can be prevented only by timely repair.

CLINICAL FEATURES

Unruptured Aneurysms

Because most AAAs do not cause symptoms until they expand or rupture, the prevalence of symptoms in patients with unruptured AAAs is difficult to determine. Patients may have symptoms that lead to the aneurysm's discovery before rupture. These symptoms can include pain in the abdomen, back, or flank; an awareness of an abdominal mass or fullness; or a sensation of abdominal pulsations. Clinical suspicion of AAA, which includes both the patient's history and physical examination findings, warrants further investigation with imaging.

The pain associated with stable, intact aneurysms often has a gradual onset and a vague, dull quality. It is usually constant but may be described as throbbing or colicky. Acute or severe pain is an ominous symptom that suggests imminent or actual aortic rupture.

In most cases, an AAA is asymptomatic and is discovered incidentally on physical examination, on a radiologic study done for unrelated issues, or by ultrasonography as part of an aneurysm screening program. Symptoms may not develop until the aneurysm ruptures, and the finding of an AAA may or may not be related to the patient's current visit. If determined not to be related, follow-up will be necessary even when found incidentally.

The most prominent physical finding is a pulsatile, expansile abdominal mass above the level of the aortic bifurcation. If the iliac arteries are also aneurysmal, the mass may extend below the umbilicus. The right border of an AAA may be palpable to the right of midline, whereas a normal or tortuous aorta is usually not. Most intact AAAs are nontender; tenderness suggests aneurysm expansion or rupture.

Symptomatic aneurysms are usually relatively large and are often palpable with a careful abdominal examination. However, an AAA may be challenging to palpate if the aneurysm is small or the patient is obese. Published reports indicate that 30% to 60% of unruptured aneurysms measuring 3.0 to 3.9 cm on ultrasonography can be detected by abdominal palpation; 50% to 70% of aneurysms measuring 4.0 to 4.9 cm and 75% to 85% of aneurysms 5 cm or larger can be palpated. These reports are based on the examination of patients with intact, asymptomatic aneurysms, with the examination specifically directed at sizing the aorta. The sensitivity is likely much lower when the abdomen is not palpated deeply, in hypotensive patients, or in those with significant abdominal guarding. There is virtually no risk of causing aneurysm rupture by abdominal palpation.

Physical examination may reveal findings consistent with an AAA even when the aorta is of normal size. A tortuous aorta may feel enlarged, and prominent aortic pulsations, especially in a thin patient, may simulate an aneurysm. Pulsations from a normal aorta may be transmitted to an adjacent abdominal mass.

An abdominal bruit is an uncommon finding in patients with AAAs. The presence of a bruit is also nonspecific, because bruits can originate from a stenotic renal, iliac, or mesenteric artery. A loud continuous bruit suggests the diagnosis of arteriovenous fistula, a rare complication of AAAs.

Perfusion distal to an AAA is usually well maintained, and most patients have normal femoral pulses. Diminished femoral pulses may result from iliofemoral occlusive disease or hypotension related to hemorrhagic shock in the patient bleeding from a ruptured aneurysm.

Thromboembolic complications can occur spontaneously or when atheromatous plaques are disrupted during invasive intravascular procedures. Large emboli can acutely occlude major vessels, such as the iliac, femoral, or popliteal artery, causing painful lower extremity ischemia with absent distal pulses. Rarely, the aneurysm itself can thrombose, rendering both lower extremities acutely ischemic. More commonly, microemboli consisting of cholesterol crystals or clot obstruct small distal vessels, such as the digital arteries of the toes and arterioles and capillaries of the skin. These patients can present with livedo reticularis; one or more cool, painful, cyanotic toes; and palpable pedal pulses. This constellation of findings, often called the *blue toe syndrome,* is highly suggestive of a proximal source of emboli. When an AAA is the source, the aneurysm is often too small to palpate and only recognized with radiologic investigation.

In rare instances, an intact AAA can cause symptoms by compressing adjacent structures, with symptoms arising from those structures involved. Large, long-standing aneurysms can cause vertebral body erosion and severe back pain. Compression of the duodenum between the superior mesenteric artery and an AAA can cause duodenal obstruction, vomiting, and weight loss. Obstruction of the ureters in the patient with an inflammatory aneurysm can cause symptoms suggestive of ureteral colic.

Ruptured Aneurysms

Pain-Hypotension-Mass Triad

Although the classic description of a ruptured AAA is the triad of pain, hypotension, and a pulsatile abdominal mass, many patients have only one or two components of this triad, and occasionally none of these classic features.

Acute rupture is often the first presentation of an AAA. Not infrequently, however, patients may have a previously diagnosed AAA that has not been repaired because the aneurysm was small or the patient was considered too high risk. Any new or acute symptoms in these patients should be considered acute aneurysmal rupture.

Most patients with a ruptured AAA experience pain in the abdomen, back, or flank. The pain is classically acute, severe, and constant. Although it may be difficult to localize, the pain can radiate to the chest, thigh, inguinal area, or scrotum. A history of pain may be more difficult to elicit if the patient's mental status is compromised by severe hypotension.

The source of the pain associated with aneurysm rupture is not clearly understood. It may be caused by the expansion of the aortic wall or by stimulation of visceral sensory nerves in the retroperitoneum. Identical pain can occur with intact but acutely expanding aneurysms, which may be impossible to differentiate clinically from ruptured aneurysms.

In patients with a ruptured aneurysm, the duration of symptoms before presentation can vary dramatically. Some patients present immediately after rupture because the pain is severe, sudden in onset, and may be accompanied by hypotension. In others, the rupture is initially contained in the retroperitoneum and blood loss is minimal. In these cases, the pain may be minor, waxing and waning, and the presentation delayed. Rare patients with a ruptured AAA may have symptoms for several days or even weeks before seeking medical attention; therefore, a long duration of symptoms does not exclude the diagnosis of ruptured AAA.

Rupture of an AAA may be accompanied by nausea and vomiting in addition to pain or, rarely, absent significant pain. Sudden hemorrhage may present as syncope or near-syncope. Compensatory hemodynamic mechanisms may restore blood pressure and cerebral perfusion to normal. Transient improvement in symptoms is common but will be followed by hemodynamic deterioration if the diagnosis and treatment are delayed. Ruptured AAAs are often large, and non-obese patients will have a palpable abdominal mass. The examination may be difficult if abdominal guarding is present or if an ileus causes significant distention. Aortic pulsations may not be prominent if the blood pressure is low.

Hypotension is the least consistent part of the triad, occurring in approximately half of patients, and is often a late finding. When the initial blood loss is minimal, vital signs may be normal. Patients with initially normal vital signs are more likely to be misdiagnosed and may quickly and unpredictably deteriorate and become hypotensive.

Occasionally, rupture into the retroperitoneum is contained for many weeks or months. When this occurs, patients develop abdominal or back pain, presumably at the time of aneurysm leakage, which subsequently diminishes or resolves completely. If the diagnosis is made, chronic rupture (organized hematoma) is found at surgery. These patients can have chronic pain and may progress to free rupture and massive hemorrhage at any time.

Aortoenteric Fistula

A primary aortoenteric fistula (AEF) is formed when an unrepaired AAA erodes into the gastrointestinal tract, most commonly in the third or fourth portion of the duodenum. A secondary AEF, a communication between the site of previous aortic surgery and the gastrointestinal tract, can occur as a late complication of AAA repair and should be considered in any patient with a severe gastrointestinal bleed and a history of aortic graft placement. An AAA can rupture into the gastrointestinal tract (AEF) or inferior vena cava (aortocaval fistula).

Early in the formation of a primary AEF, the adjacent AAA erodes through the bowel wall from the outside. This can lead to the leakage of intestinal contents, with local infection and abscess formation. Eventually, breakdown of the aortic wall leads to an AEF and may lead to gastrointestinal bleeding. A patient with an AEF may have abdominal or back pain, fever and other signs of intra-abdominal infection, or gastrointestinal bleeding. Because most of these fistulae are into the duodenum, hemorrhage usually manifests as hematemesis or melena. The initial bleeding results from erosion of vessels in the bowel wall and is often occult or minor. Massive bleeding from rupture into the intestinal lumen can occur days or even weeks after the initial bleeding. Primary AEF, although rare, should be considered in any patient older than 50 years with unexplained severe gastrointestinal bleeding. A patient with an AAA diagnosed by history, physical examination, or other modality, presenting with gastrointestinal bleeding should raise the concern for AEF.

Arteriovenous (Aortocaval) Fistula

An arteriovenous (usually aortocaval) fistula arises when periaortic inflammation causes adherence of the aorta to an adjacent vein, with pressure on the vessel walls causing the development of an arteriovenous communication. If concomitant extravasation of blood into the retroperitoneum occurs, the clinical presentation is similar to that of other patients with ruptured AAAs. More commonly, however, the aneurysm ruptures into the vena cava without leaking externally, and the signs and symptoms of a large arteriovenous fistula dominate the clinical picture.

As in other patients with AAAs, a patient with an arteriovenous fistula may have abdominal or back pain. An aneurysm that becomes fistulous with the vena cava is usually large, and 80% to 90% are palpable. A continuous abdominal bruit can be auscultated in approximately 75% of patients with arteriovenous fistulae, and 25% of patients have a palpable abdominal thrill.

Shunting of blood from the arterial to the venous system increases venous pressure, venous volume, and venous return to the heart. Signs and symptoms of high-output congestive heart failure (dyspnea, jugular venous distention, pulmonary edema) are often present. The increased venous volume and pressure can cause lower extremity edema or cyanosis, and dilated superficial veins can be seen on the legs or abdominal wall. Distention and rupture of veins in the bladder mucosa can cause gross or microscopic hematuria, and rectal bleeding can occur for similar reasons. Because of shunting of arterial blood into the venous system, the lower extremities may be cool with diminished pulses.

The patient with an arteriovenous fistula often has renal insufficiency caused by a decrease in renal perfusion as a result of high-output congestive heart failure and increased renal venous pressure. Such patients may exhibit hematuria, which is common when an arteriovenous fistula is present but not in other patients with AAAs. Computed tomography (CT), and preferably computed tomographic angiography (CTA), is essential for diagnosing or ruling out arteriovenous fistula formation.

DIFFERENTIAL DIAGNOSES

Symptoms consistent with ruptured AAA—abdominal, back, or flank pain, with or without hypotension—are seen in other conditions as well, which can lead to delayed or missed diagnoses (Box 72.1). The most common misdiagnosis is renal colic, followed by pancreatitis, intestinal ischemia, other nonspecific intra-abdominal disorders, and musculoskeletal back pain.

Presentation of epigastric pain and hypotension may lead to a presumptive diagnosis of acute myocardial infarction because patients with a ruptured AAA often have concomitant coronary artery disease,

and blood loss from a ruptured aneurysm may diminish coronary perfusion and cause chest pain or electrocardiographic changes consistent with cardiac ischemia. In the setting of abdominal or back pain, these findings do not exclude the presence of a ruptured AAA.

Ruptured AAA should be considered in patients with any part of the classic triad pain (abdomen, back, or flank), and hypotension. The diagnosis of ruptured AAA should also be considered in making the diagnoses listed in Box 72.1, especially when the diagnosis is not clear-cut or the patient is at risk for an AAA.

DIAGNOSTIC TESTING

Abdominal Radiography

Plain film radiography is not indicated in the evaluation of a patient for suspected AAA. A normal plain abdominal radiograph does not exclude the presence of an AAA and rarely identifies alternative pathology. Even if an aneurysm is identified on plain film because it is calcified, imaging with CT is necessary to determine whether the aneurysm is an incidental or culprit lesion in the patient's presentation (Fig. 72.2).

Ultrasonography

Ultrasonography is virtually 100% sensitive in detecting AAAs (Fig. 72.3) when a technically adequate study can be obtained. Measurements of aortic diameter are very accurate and reproducible. Because it is relatively inexpensive and requires no contrast agents or radiation exposure, ultrasonography is also used for aneurysm screening and to follow patients with known aneurysms after they have been characterized with CTA.

Point of care ultrasonography has distinct advantages in the emergency evaluation of a patient with a suspected ruptured AAA. It can be performed rapidly at the patient's bedside, obviating the need to take a potentially unstable patient to the radiology suite. If an aorta with a normal diameter throughout its abdominal course is visualized, the patient does not have an AAA. In addition, ultrasonography occasionally provides alternative explanations for the patient's pain by revealing other conditions, such as acute cholecystitis. Emergency clinicians can accurately identify the etiology of acute nontraumatic abdominal pain, including AAAs, using bedside ultrasound.[3]

Point of care ultrasonography does have limitations, including being more operator-dependent compared to other modalities, and therefore may be more prone to technical or interpretive error. In the emergency department (ED) the aorta may not be well visualized because of obesity or excess bowel gas. Although ultrasonography is extremely

BOX 72.1 Common Misdiagnoses in Patients with Ruptured Abdominal Aortic Aneurysms

- Renal colic
- Acute abdomen
- Pancreatitis
- Intestinal ischemia
- Diverticulitis
- Cholecystitis
- Appendicitis
- Perforated viscus
- Bowel obstruction
- Musculoskeletal back pain
- Acute myocardial infarction

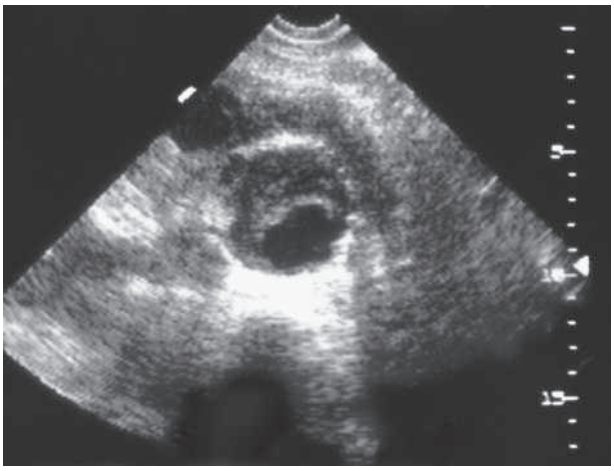

Fig. 72.3 Transverse sonogram of an abdominal aortic aneurysm (AAA). The central patent lumen is surrounded by an echogenic mural thrombus. (Courtesy Richard Rensio, MD.)

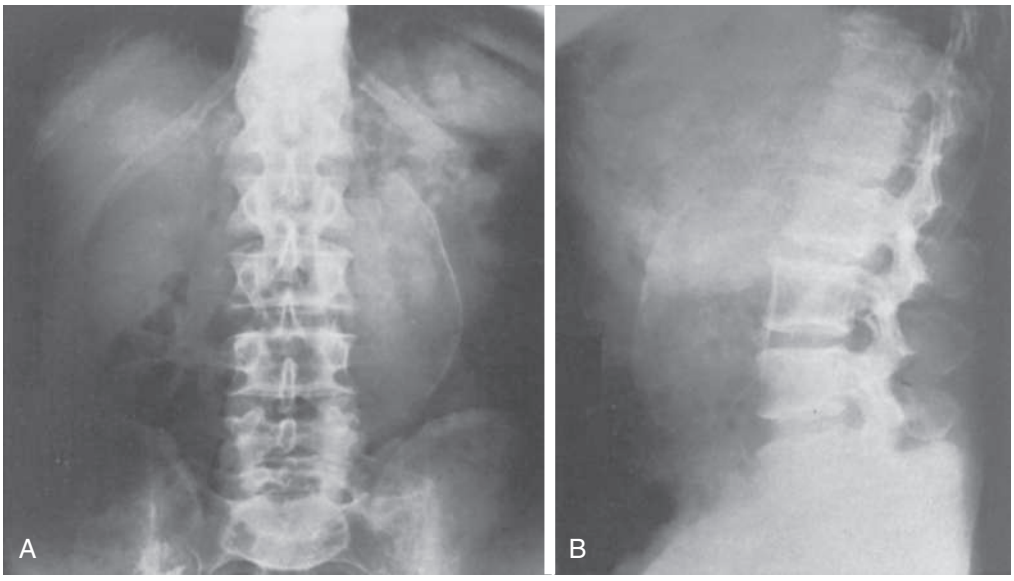

Fig. 72.2 Anteroposterior (A) and lateral (B) views of large abdominal aortic aneurysms (AAAs) with calcification of aortic wall. (From Juergens JL, et al. *Peripheral Vascular Diseases*, ed 5. Philadelphia: WB Saunders; 1980. By permission of the Mayo Foundation.)

sensitive in detecting an AAA, it cannot be relied on to reveal whether an AAA has ruptured.

Free intraperitoneal or retroperitoneal blood, seen in the presence of an AAA, confirms a rupture. However, the sensitivity of point of care ultrasonography in detecting extraluminal blood is very low. The purpose of the study is to confirm or exclude the presence of an aneurysm; clinical information (or a CT scan) must be used to determine the likelihood of rupture. Ultrasonography with the use of contrast agents may aid in the detection of leaking blood, but the clinical utility of this modality has not been determined. If ultrasonography reveals an AAA in an unstable patient, aneurysm rupture should be presumed, and prompt surgical evaluation for consideration of aneurysm repair should be initiated.

Computed Tomography

The abdominal CT scan is the diagnostic test of choice to evaluate the stable patient with suspected ruptured AAA. It is virtually 100% accurate in determining the presence or absence of an AAA and the presence of bleeding. CT also provides detailed anatomic information about the aneurysm.

An intravenous contrast agent is desirable, but not essential, in emergencies. Intravenous contrast will opacify the aortic lumen and distinguish the patent lumen from mural thrombus. It can also demonstrate peri-aortic fibrosis, because the soft tissue surrounding an inflammatory AAA will often enhance. Although intravenous contrast is not necessary to identify the aneurysm or acute hemorrhage, contrast will be helpful for accurate sizing and planning if an endovascular approach is being considered.

CT is more sensitive than ultrasonography in detecting retroperitoneal hemorrhage associated with aneurysm rupture. The reported sensitivity approaches 100% with current-generation scanning technology, with falsely negative studies sometimes occurring with very small ruptures. Blood is seen as a retroperitoneal fluid collection adjacent to the aneurysm, often tracking into the perinephric space or along the psoas muscle (Fig. 72.4).

Although a CT scan sometimes reveals signs of impending aneurysm rupture, such as hyperattenuation of the wall, peri-aortic hematoma, penetrating ulcer, or pseudoaneurysm cannot reliably determine whether an AAA is the cause of the patient's pain or whether rupture of the aneurysm is imminent. An alternative cause of pain can be diagnosed only if the CT scan shows no aneurysm or shows an intact aneurysm and clearly demonstrates an alternative explanation for the patient's symptoms.

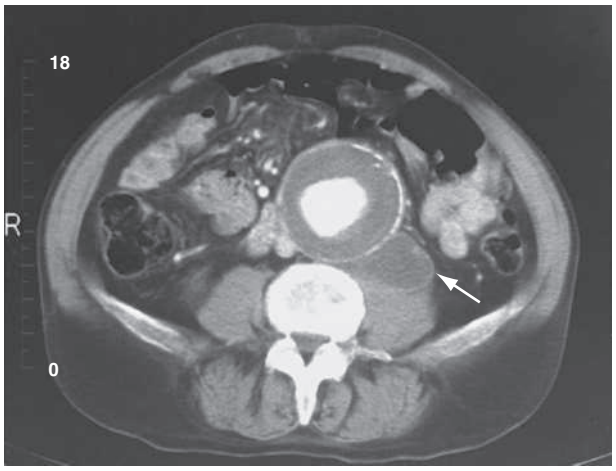

Fig. 72.4 Computed tomography (CT) scan of ruptured abdominal aortic aneurysm (AAA), with calcification of the aortic wall and intraluminal thrombus. The patent lumen enhances with the administration of contrast material, but the periaortic hematoma *(arrow)* does not. (Courtesy Richard Rensio, MD.)

Other Diagnostic Modalities

Conventional angiography has no place in the emergency evaluation of the suspected ruptured AAA. Because contrast opacifies only the patent lumen and not mural thrombus, angiography often underestimates aneurysm size and can miss an aneurysm entirely. In addition, angiography is time-consuming and performed away from the ED. If detailed information is needed about the anatomy of the aneurysm or its relationship to nearby vessels, a CT angiogram is the strongly preferred imaging choice.

Magnetic resonance imaging and magnetic resonance angiography can be very time-consuming, logistically challenging, and provide no benefit over CT scan. Magnetic resonance scanning is not indicated in the evaluation of a patient with suspected AAA in the ED.

MANAGEMENT

Ruptured Aneurysms

No patient with a known or suspected aortic rupture should be considered stable, regardless of the vital signs or initial hemoglobin level, until the aorta is cross-clamped in the operating room or stabilized with endovascular techniques. Ruptured AAA is a time-dependent disease, and patients taken to the operating room soon after ED arrival have a significantly higher survival rate than those in whom surgical care is delayed.

When the patient arrives in the ED, large-bore redundant intravenous access should be established and blood sent for type and crossmatch. At least 6 units of blood should be made available initially, with notification to the blood bank of the potential need for massive transfusion. The surgical and anesthesia teams should be notified emergently. If surgery is not available, transfer arrangements should be initiated as soon as possible. Further management will depend on the hemodynamic status and level of diagnostic certainty.

The hemodynamically unstable patient in whom a ruptured AAA has been diagnosed or is strongly suspected should be taken to the operating room as soon as possible (in this context, the term "operating room" includes other locations that may be used for endovascular aneurysm repair) and diagnostic testing should be kept to a minimum. The diagnosis can often be made on clinical grounds, and point of care ultrasonography can quickly confirm or exclude the presence of an aneurysm. A thin-sliced CT scan of the abdomen and pelvis with intravenous contrast is appropriate only if it can be obtained immediately. Time-consuming tests can lead to avoidable delay of definitive therapy and increase the risk of exsanguination. Hypotensive patients may have to be taken to the operating room based on a strong clinical presumption of the diagnosis, without definitive diagnostic imaging. Some of these patients will not have ruptured aneurysms, but they often have other acute abdominal conditions requiring laparotomy.

Attempts to resuscitate these patients to normalize vital signs in the ED can waste valuable time and should be avoided. Hypotensive patients need to be taken to the operating room so that the aorta can be clamped or occluded with a balloon and hemorrhage stopped.

Fluid Resuscitation

The right amount of preoperative volume resuscitation remains controversial. Preoperative hypotension is the strongest predictor of mortality in the patient with a ruptured AAA. Correction of hypotension before the aorta is clamped may not improve mortality and may even be harmful because hypotension slows bleeding in patients with AAA and allows local clot formation and tamponade of the rupture site.

Raising the intravascular volume and blood pressure before occluding the aorta may dislodge clots and cause further bleeding. Similar to trauma patients with uncontrolled hemorrhage, large volumes of crystalloid solution may contribute to bleeding by worsening acidosis and causing a dilutional coagulopathy.

However, delaying resuscitation of hypotensive patients until they reach the operating room may also have deleterious effects. The patient with a ruptured AAA often survives the surgery but dies in the early postoperative period. These deaths are caused by complications of prolonged hypotension, such as myocardial infarction, respiratory failure, and renal failure. The patient with a ruptured AAA is usually elderly, often has coexisting conditions, and tolerates hypovolemia and hypotension poorly.

No prospective studies have compared different preoperative fluid regimens in hypotensive patients with ruptured AAAs, and the optimal resuscitation strategy has not been determined. The priority in these patients is expeditious transportation to the operating room for definitive control of aortic hemorrhage. In the prehospital setting and the ED, the blood pressure should be raised with crystalloid, or preferably blood products, only to a level that maintains adequate cerebral and myocardial perfusion to prevent irreversible end-organ damage. An arbitrary blood pressure goal cannot be specified because the blood pressure necessary for vital organ perfusion varies among patients, but a reasonable target for this permissive hypotension is a systolic blood pressure of 70 to 90 mm Hg.[2]

If blood products are to be given in large amounts, fresh frozen plasma (FFP) and packed red blood cells (PRBCs) should be administered in patients with ruptured AAAs. As with trauma patients, a PRBC:FFP ratio of less than 2:1 may result in improved mortality.

Rarely, patients with a ruptured AAA may be hypertensive on presentation because of pain or underlying chronic hypertension. Unlike with aortic dissection, no evidence exists that lowering the blood pressure is beneficial in the patient with a ruptured AAA, and these patients are at risk of developing precipitous hypotension.

Diagnostic Confirmation

If an AAA can be diagnosed with bedside testing (abdominal examination or point of care ultrasonography), the surgeon will often proceed immediately to the operating room with a clinical diagnosis of aneurysm rupture, because a delay in surgery places the patient with a ruptured AAA at risk for sudden and unpredictable hemodynamic deterioration. If the patient remains hemodynamically stable and an AAA cannot be identified with bedside testing, or if anatomic detail is needed for endovascular repair, an abdominal CT scan should be obtained. This will confirm or exclude the presence of an aneurysm, define the aortic anatomy, and determine the patient's suitability for endovascular repair. The patient who is sent for a CT scan should be monitored closely and taken to the operating room emergently if hemodynamic deterioration occurs.

CT may provide confirmation of rupture or may show no evidence of rupture, potentially allowing the surgeon to avoid the complications of emergency surgery in a patient with an intact aneurysm. Emergency surgery may not allow detailed anatomic evaluation and careful preoperative evaluation and optimization of the patient's cardiopulmonary and renal function. Therefore, patients who are taken for emergency surgery and are found to have intact, symptomatic aneurysms have a higher mortality rate than patients undergoing elective aneurysm repair. Establishing a protocol for urgent or emergent management of a patient with a ruptured AAA based on available resources is essential for optimizing outcomes. A goal of door-to-intervention time of less than 90 minutes is recommended by the Society for Vascular Surgery, with time zero defined as the initial contact by an emergency physician and intervention defined as placement of an aortic occlusion balloon.[2]

Surgery and Mortality

Ruptured AAA is uniformly fatal unless treated surgically. Thus once this diagnosis has been made, repair should be attempted in almost all patients. Attempts have been made to identify patients with a very low likelihood of survival, and it has been suggested that surgery can be withheld in patients with prehospital or ED cardiac arrest. However, no variables assessed in the ED, including cardiac arrest, are universally predictive of a fatal outcome. Repair is indicated unless the patient has comorbidities such as severe renal, myocardial (in particular uncontrolled congestive heart failure or a recent myocardial infarction), or cerebrovascular disease, making surgery unreasonable, or if surgery is not within the patient's goals of care.

In part because patients with ruptured AAAs have a mortality of 30% to 40% with open repair, endovascular repair of ruptured aneurysms is becoming increasingly common, even in unstable patients. There is evidence that high-volume centers experienced with endovascular repair have a lower operative morbidity and mortality rate than open repair.

Not all patients with ruptured aneurysms will have an aorta that is anatomically suitable for endovascular repair. The method of repair will depend on the preference and skill set of the surgeon, as well as institutional capability and suitability for an endovascular approach. Planning for the care of such patients should include the development of a protocol or pathway that advises the ED staff about which services to mobilize and which diagnostic tests to perform in patients with suspected ruptured AAA.

Intact Asymptomatic Aneurysms

An incidental diagnosis of AAA may sometimes be made in the ED. The decision to repair an asymptomatic aneurysm depends on the risk of aneurysm rupture, comorbidities, and surgical risk. Surgical risk is determined by the patient's age and comorbidities, whereas the risk of rupture is largely a function of aneurysm size.

In two clinical trials, one of which has long-term follow-up, patients with small (<5.5 cm) aneurysms were randomized to early surgery or close follow-up. In the latter group, aneurysms were followed with serial ultrasounds or CT scans, and surgery was performed only if any symptoms developed, rapid expansion was documented, or a diameter of 5.5 cm was reached. Both studies showed equivalent survival rates in the two groups. As a result, fewer small aneurysms are now repaired electively, potentially leaving a larger group of patients who may come to the ED with complications of an AAA.

Traditional Repair

The conventional technique for repair of AAAs is an open approach with a laparotomy. The aneurysm is opened longitudinally and repaired from within (Fig. 72.5). A graft is inserted inside the aneurysm and anastomosed to uninvolved vessels above and below once lumbar vessels are ligated and the mural thrombus evacuated. When possible, a straight graft is used between the infrarenal and distal aorta, but if the aneurysm involves the aortic bifurcation or if iliac artery aneurysmal or occlusive disease is present, a bifurcation graft is used, with the distal anastomosis to the iliac or femoral arteries. Coagulopathy is addressed and the aneurysm wall is then closed around the graft to help separate it from adjacent structures in the retroperitoneum. The bowel is re-inspected, and the abdominal wall is frequently managed with temporary abdominal closure using negative pressure wound therapy when managing ruptured aneurysms.

Endovascular Repair

More than half of all AAA repairs are now performed without laparotomy, with use of endovascular techniques.[4] Perioperative mortality is lower than that with open repair, but it is unclear whether this mortality benefit is sustained in the long-term. More recent studies suggest the

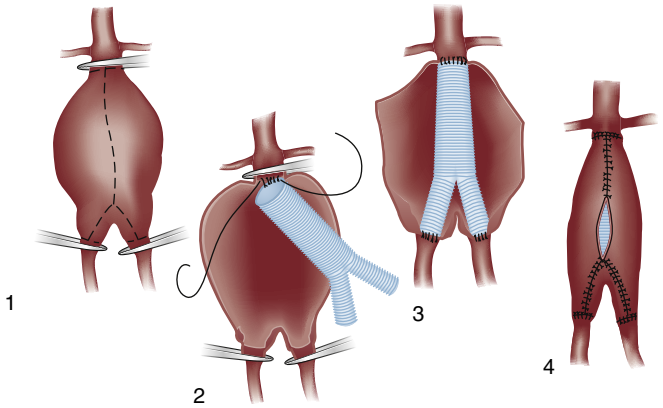

Fig. 72.5 Steps in repair of an abdominal aortic aneurysm (AAA). See text for details. (From Kent KC, et al. Surgical principles for operative treatment of aortic aneurysms. In Lindsay J Jr, ed. *Diseases of the Aorta*. Philadelphia: Lea & Febiger;1994: 287.)

survival advantage is maintained for 3 years.[5] Numerous studies have cited a clear reduction in early mortality associated with endovascular aneurysm repair (EVAR) but continue to emphasize the importance of an organized algorithmic approach with a specialized team.[6] Recent guidelines recommend EVAR when anatomically feasible and expertise is sufficient.[2] Although many hospitals have hybrid operating rooms, EVAR can be done with portable fluoroscopy in the operating room.

Stable patients can undergo bilateral femoral artery cut-downs to place sheaths and wires once in the operating room. Unstable patients, however, may require transfemoral access with a 12 French sheath followed by aortic balloon occlusion in the ED. Once an arteriogram is performed with a marking flush catheter, the endovascular plan is formulated unless a contrast-enhanced CT scan is available for stent graft sizing.

A stent graft (a fabric graft supported by a nitinol wire frame) is placed into the femoral artery percutaneously or through a groin incision and is advanced under fluoroscopic guidance to a position that spans the infrarenal aneurysm (Fig. 72.6A). The contralateral iliac limb is placed to form a bifurcated graft (see Fig. 72.6B). Once in position, the graft is deployed and expanded to fit tightly against the walls of the aorta. These self-expanding devices have radial forces but are also oversized 10% to 20% to ensure proper sealing. There are several devices approved by the US Food and Drug Administration (FDA) and all have unique features. Standard criteria for use include an aortic transverse diameter between 18 to 32 mm, angulation less than 60 degrees, and neck (lowest renal artery to start of aneurysm) length more than 10 mm, iliac landing zone diameter of 10 to 22 mm, and femoral access diameter more than 8 mm

Endovascular repair results in more frequent reinterventions for graft-related complications. Because not all aneurysms are anatomically suitable for endovascular repair, detailed preoperative imaging and planning are required to make this determination. In addition, patients who have had an endovascular aneurysm repair remain at risk for several complications—most importantly, rupture of the aneurysm. Some authors now suggest that endovascular repair has become the first choice of AAA treatment in almost all patients, with anatomic location remaining the most common indication for open repair.[7] Lack experience with endovascular operations remains the greatest barrier to the widespread application of evolving endovascular technologies for emergency use. Percutaneous endovascular repair is becoming more common and may represent a suitable alternative to open endovascular repair in some patients.[8]

Survival

The operative mortality rate for elective AAA repair is approximately 1% to 2% for endovascular repair and 3% to 5% for open repair, in contrast to the much higher operative mortality with ruptured aneurysms. Patients who survive the operation have an excellent prognosis, with a long-term survival close to that of the general population. After repair of the aneurysm, long-term survival is primarily limited by associated cardiac disease.

LATE COMPLICATIONS OF REPAIR

Graft infection, AEF formation, and anastomotic aneurysm (pseudoaneurysm) formation can occur at any time from weeks to years after the surgery. These complications can occur concurrently or sequentially and are diagnosed by similar mechanisms. In addition, endovascular aneurysm repair has several unique complications, the most important of which is endoleak.

Graft Infection

Graft infection can result from contamination of the graft at surgery, spread of a contiguous infection, or hematogenous seeding. Infection can disrupt the anastomosis between the native artery and graft, leading to leakage of blood from the anastomosis and pseudoaneurysm formation. The infection can be localized to a portion of the graft, most often the inguinal portion of an aortofemoral graft, or can involve the entire graft.

Infection of the distal limb of an aortofemoral graft may cause local signs of infection or a palpable false aneurysm. Intra-abdominal graft infection is often subtle, with low-grade fever and vague abdominal or back pain. Abdominal tenderness or a palpable mass may be present if there is a leaking anastomosis. Collections of fluid or gas around the graft on CT provide evidence of infection, although CT scans can be falsely negative.

Aortoenteric Fistula

As discussed earlier in this chapter, an AEF should be considered in any patient with gastrointestinal bleeding and a history of abdominal aortic surgery. Most of these patients, however, ultimately prove to have other, more common causes of gastrointestinal bleeding. The diagnostic approach depends on the patient's hemodynamic stability.

If the patient with a suspected AEF is unstable with massive bleeding, diagnostic testing may be dangerously time-consuming. In these patients, emergency laparotomy may be necessary to control hemorrhage and diagnose or exclude the presence of an AEF. Stable patients can be evaluated with endoscopy or a CT scan. Some patients with AEF may be treated endovascularly, which may result in improved perioperative morbidity and mortality.

Upper gastrointestinal endoscopy is recommended as the initial diagnostic test in the stable patient when available. Direct visualization of the fistula into the distal duodenum is sometimes possible. Endoscopy cannot be relied on to identify an AEF, however, and its main value is in establishing another diagnosis. Emergency surgery can be avoided if an active bleeding site that is not an AEF is clearly seen.

An abdominal CT scan can also be used to evaluate a suspected AEF. Although imaging of the fistula may not be possible, graft infection is almost invariably present in patients with secondary AEFs, and the CT scan will demonstrate the associated infection. Radiographically distinguishing an AEF from intra-abdominal graft infection alone may not be possible.

Pseudoaneurysm (Anastomotic Aneurysm)

Pseudoaneurysms can arise at the site of a leaking anastomosis. They may be associated with graft infection or AEF formation but more often result from degeneration of the native vessel.

The patient with an anastomotic aneurysm may have pain or a pulsatile mass in the abdomen or groin. The aneurysm may give rise to distal emboli or may rupture and cause life-threatening hemorrhage. Suspected pseudoaneurysms can be evaluated with angiography, CT scan, or ultrasonography.

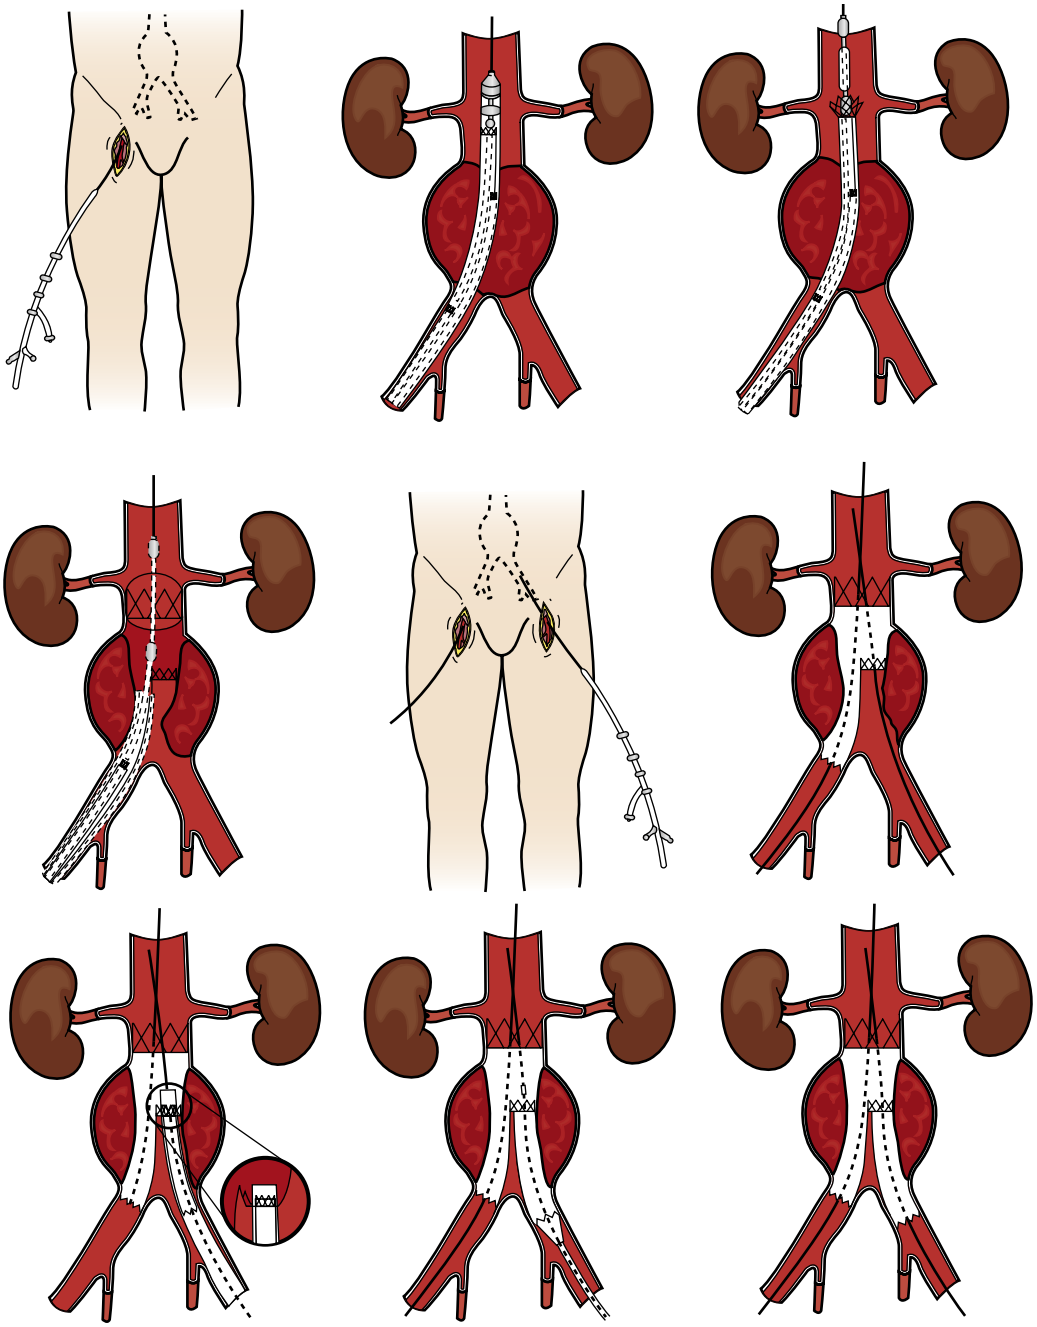

Fig. 72.6 Endovascular repair (ipsilateral and contralateral) of abdominal aortic aneurysm with a modular endograft. (From Hornacky A, Phillips N. Vascular surgery. In: Hornacky A, Phillips N, eds. *Berry & Kohn's Operating Room Technique*, 14th ed. Elsevier; 2021. Fig. 44.21.)

Complications of Endovascular Aneurysm Repair

An increasing percentage of elective AAA repairs are done with endovascular techniques, and these patients may come to the ED with postoperative complications. The most serious of these is endoleak—blood flow outside of the graft lumen but within the aneurysm sac, potentially allowing enlargement of the aneurysm. Endoleaks may be caused by separation of the proximal or distal end of the graft from the aortic wall (type I), back-bleeding into the aneurysm sac from branch vessels such as lumbar arteries (type II), leakage between the modular components of the graft (type III), leakage through the graft fabric itself (type IV), or in rarer cases when the sac enlarges without an identifiable leak, otherwise known as *endotension* (type V) (Fig. 72.7). Patients with persistent leakage of blood into the aneurysm sac are at risk for rupture of the aneurysm.

Endoleaks may develop soon after the procedure or much later. They have been reported in as many as 20% of patients who have had endovascular aneurysm repair. Because many type II endoleaks resolve spontaneously, patients are sometimes observed for months before repair of the leak with secondary endovascular procedures or surgical intervention.

Patients sometimes sustain other complications, such as graft migration, stenosis or thrombosis, and structural failure of various elements of the graft. These complications often lead to endoleak and the risk of rupture.

In the ED, CT with intravenous contrast should be used to evaluate for possible complications of endovascular repair. A specific CT imaging protocol may be desired; this should be discussed with the radiologist or vascular surgeon. Prompt surgical consultation should

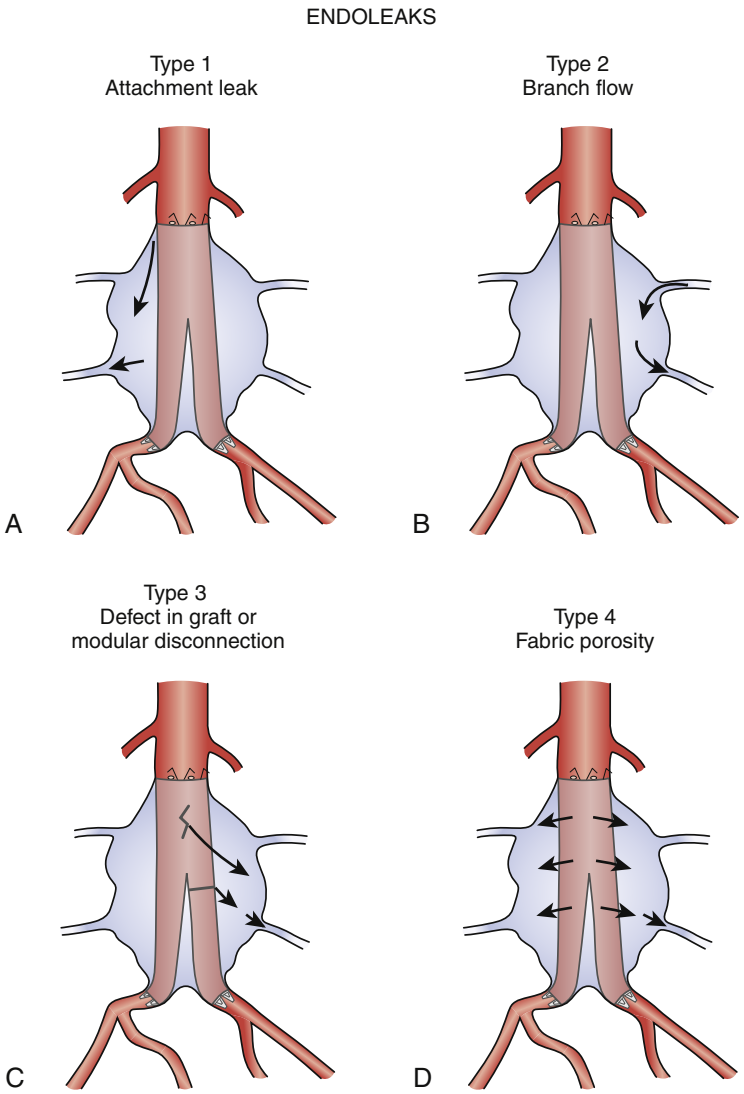

Fig. 72.7 Endoleaks of abdominal aortic aneurysm after endovascular aneurysm repair. (A) Type 1 leak (attachment leak). Blood continues to enter the aneurysm sac at one of the three ends of the bifurcated stent graft, the points where the stent graft should be tightly affixed to the arterial wall. Egress, as with all endoleaks, is through branches of the aorta that remain patent. Treament of type 1 leaks is indicated. (B) Type 2 leak (branch artery leak). Blood enters the aneurysm sace through a patent branch artery. This type of leak can be self-limited and may be just observed. Treatment is indicated if the aneurysm enlarges. (C) Type 3 leak (loss of integrity of stent graft). Either the modules of the stent graft have become separated or a rent has formed in the fabric of the stent graft. Blood enters the sac from the stent graft lumen through the site of loss of stent graft integrity. Treatment is indicated. (D) Type 4 leak (fabric porosity). Blood enters the sac from the stent graft lumen through intact cloth of the stent graft. This is self-limited and present only at surgery. The pore of the fabric quickly become occluded by blood products. (From Mustafaraj E, Bertino RE. The retroperitoneum. In: Rumack CM, Levine D, eds. *Diagnostic Ultrasound*, 5th ed. Elsevier; 2018. Fig. 12.9.)

be obtained for patients with any symptoms that could be related to device malfunction, and the potential for aneurysm rupture should always be considered.

DISPOSITION

A patient with an acutely symptomatic AAA requires emergency surgical evaluation and repair. A patient whose aneurysm is asymptomatic and discovered incidentally should be referred for consideration of elective repair. The patient with an AAA should be referred for an outpatient evaluation only if it is clear that the symptoms prompting the ED visit are unrelated to the aneurysm. Although the incidental detection of AAA is common, such patients may suffer from poor subsequent follow-up and monitoring. If the patient is discharged, appropriate referral for follow-up is crucial, and instructions should be given to seek immediate medical attention if abdominal, back, or flank pain develops.

In the patient who has a history of a repaired AAA, unexplained fever, abdominal pain, or gastrointestinal bleeding suggests the presence of a graft-related complication and the need for inpatient evaluation.

CHAPTER 72: QUESTIONS AND ANSWERS

1. What is the most common complication of abdominal aortic aneurysms (AAAs)?
- **a.** Renal artery infarction
- **b.** Rupture
- **c.** Development of an aortoenteric fistula
- **d.** Ureteral obstruction

Answer: B. Although all of the options are potential complications of AAAs, rupture is by far the most common. Rupture typically occurs into the retroperitoneum, allowing possible tamponade of the rupture site. Only between 10 and 30% of ruptures are freely into the peritoneum, which is often rapidly fatal.

2. An 82-year-old male presents after a syncopal episode, which occurred 1 hour prior to arrival and was without preceding symptoms. He has a past medical history significant for hypertension and a surgical repair of an abdominal aortic aneurysm (AAA) 15 years ago. Physical examination reveals a pale man with a heart rate of 112 beats per minute, a blood pressure of 86/54 mm Hg, and a respiratory rate of 24 beats per minute. There is melena on rectal examination and there is no palpable mass on abdominal palpation. Along with appropriate volume resuscitation, what is the most appropriate next step in the management of this patient?
- **a.** CT scan of the abdomen with contrast enhancement
- **b.** Abdominal x-rays
- **c.** Immediate vascular surgery consultation
- **d.** Addition of albumin to crystalloid infusion

Answer: C. The presence of gastrointestinal bleeding with evidence of an AAA or a history of aortic surgery is an aortoenteric fistula until proven otherwise. The most common site of vascular erosion is the third or fourth portion of the duodenum, causing hematemesis or melena. Initial bleeding may be minor, followed days to weeks later by massive bleeding. Surgical intervention is necessary. Unstable patients may need to be taken directly to the OR based on a strong clinical presumption.

3. Which of the following is true regarding the management of a patient with a suspected abdominal aortic aneurysm (AAA)?
- **a.** Aggressive crystalloid resuscitation to normalize the blood pressure is warranted.
- **b.** Permissive hypotension with a goal of a systolic blood pressure of 70 to 90 mm Hg is a reasonable target.
- **c.** Lowering the blood pressure in hypertensive patients has been shown to improve outcomes.
- **d.** Bedside ultrasound should always be followed by a CT scan to better define the aneurysm.

Answer: B. Permissive hypotension with a goal of a systolic blood pressure of greater than 70 mm Hg but not necessarily more than 90 mm Hg is a reasonable target. Aggressive crystalloid resuscitation may be harmful. Lowering the blood pressure in hypertensive patients has not been shown to improve outcomes in patients with abdominal aortic aneurysms as it has in patients with dissecting thoracic aortic aneurysms. Although a CT scan can be useful to better define the aneurysm prior to surgery in stable patients, bedside ultrasound may be the only imaging necessary in unstable patients.

4. What is the strongest predictor of mortality in patients with a ruptured abdominal aortic aneurysm (AAA)?
- **a.** Hypotension
- **b.** Presentation more than 12 hours after symptom onset
- **c.** Age older than 70
- **d.** Anemia on arrival

Answer: A. Although all of the options are predictors of higher mortality, preoperative hypotension is the strongest predictor. That said, there is little data guiding volume resuscitation, fluid choices, and target blood pressures in hypotensive patients with a ruptured AAA. Crystalloid resuscitation before surgical repair can cause dilutional coagulopathy and clot dislodgement by raising the intravascular volume. Judicious volume resuscitation with early use of blood products and a target systolic pressure of 70 to 90 mm Hg is reasonable.

5. Which of the following is most common in the patient with an intact (non-ruptured) 6-cm abdominal aortic aneurysm?
- **a.** Back pain
- **b.** Abdominal pain
- **c.** Sensation of abdominal distention
- **d.** Absence of any symptoms

Answer: D. Most intact AAAs are asymptomatic. They may be discovered incidentally on physical examination or a radiologic study done for other reasons or may be found in an ultrasonographic aneurysm screening program. Pain in the abdomen or back does not usually develop until the aneurysm ruptures.

Continued

CHAPTER 72: QUESTIONS AND ANSWERS—cont'd

6. A 67-year-old man presents with a several-day history of intermittent periumbilical abdominal pain. Physical examination and vital signs are unremarkable except for supraumbilical tenderness. Hemoglobin is 12 g/dL. Contrast-enhanced computed tomography (CT) scan of the abdomen details a 4.2-cm infrarenal abdominal aortic aneurysm (AAA) with an apparent old contained rupture with no obvious new or acute blood. All of his discomfort is relieved by a single dose of morphine sulfate. Which of the following would be the most appropriate course of action?

a. Vascular surgery clinic follow-up in 1 or 2 days
b. Emergency department (ED) observation for 6 to 8 hours with serial abdominal examinations
c. Gastrointestinal consultation for early follow-up and upper or lower endoscopy
d. Surgical consultation

Answer: D. Watchful waiting is indicated only for asymptomatic aneurysms, regardless of the size (up to 5.5 cm). The majority of "stable" AAAs are neither painful nor tender, and the presence of both in this patient suggests imminent rupture. Although the CT scan did not detect acute blood, the safest course of action would be surgical consultation, with early or imminent rupture as the presumed source of this patient's symptoms

73

Peripheral Arteriovascular Disease

Tom P. Aufderheide

KEY CONCEPTS

- Acute arterial occlusion is a limb-threatening emergency requiring early anticoagulation and Fogarty catheter embolectomy. The clinical diagnosis is based on some variant of the five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Confirmatory tests are unnecessary and increase the limb's ischemic time.
- Atheroembolism (blue toe syndrome) is associated with cool, painful cyanotic toes in the presence of palpable distal pulses. A proximal source should be localized, most often an atherosclerotic aneurysm in the aorta or the iliac, femoral, or popliteal artery.
- Popliteal aneurysms are bilateral in 60% of patients and often coexist with an abdominal aortic aneurysm.
- The classic Raynaud attack is triphasic: the fingers become pale, blue, and then red. Raynaud disease has no detectable underlying cause and usually has a benign course. Conversely, Raynaud phenomenon has an underlying disorder, usually connective tissue disease.
- The only reliable clinical test for the detection of thoracic outlet syndrome is the elevated arm stress test (EAST).
- Partial arterial lacerations continue to bleed, resulting in an expanding hematoma. Complete arterial transections initially have only moderate bleeding but can result in delayed hemorrhage. Blunt arterial injury may produce intimal disruption resulting in dissection, thrombosis, or obstruction. Arterial vasospasm can accompany injuries adjacent to the blood vessel, but spontaneous resolution always occurs in the absence of arterial disruption or intimal injury.
- Aneurysms and arterial stenoses are characterized by a systolic murmur. Pseudoaneurysms, associated with prior surgical or trauma sites, are characterized by a loud systolic and possibly a separate, faint diastolic murmur. Arteriovenous fistulae are characterized by a harsh "to and fro" murmur associated with a palpable thrill.
- Intra-arterial injection of illicit drugs into the brachial or radial artery is associated with immediate onset of severe, burning pain, and emergency department presentation with patchy blue-purple skin discoloration. Identifying the injection site helps confirm this syndrome, which can be associated with persistent ischemia and tissue loss.

FOUNDATIONS

Arteries are classified into three categories based on their size and histologic features: (1) large or elastic arteries (the aorta and its immediate proximal, larger branches, including the innominate, subclavian, and common carotid, as well as the pulmonary arteries); (2) medium-sized or muscular arteries (located just distal to elastic arteries, including the common femoral, axillary, and internal carotid arteries); and (3) small arteries (usually <2 mm in diameter) that course in the substance of tissues and organs. This chapter considers diseases of medium and small arteries.

BACKGROUND

Arterial Anatomy

All arteries possess three layers: the tunica intima, tunica media, and tunica adventitia. As peripheral arteries diminish in caliber, these three layers become progressively indistinct and are no longer identifiable at the level of the arteriole, the precapillary vessel containing smooth muscle.

The tunica intima has an inner lining of endothelial cells surrounded by subendothelial connective tissue. The single layer of continuous endothelium is a unique thromboresistant layer between blood and the potentially thrombogenic subendothelial tissues. The integrity of the endothelium is fundamental for the normal structure and function of the vessel wall. Endothelial injury results in intraluminal thrombosis and contributes to atherosclerosis.

The tunica media is made up primarily of circular or spiral smooth muscle cells arranged in concentric layers. The outer limit of this layer is marked by a well-defined, external elastic membrane. The elastic content of the tunica media gives resilience to medium-sized arteries. With age, elastic fibers deteriorate, replaced by fibrous tissue. This loss of elasticity results in stretching and elongation and accounts for the progressive tortuosity and development of arterial aneurysms with aging. In addition, vascular smooth muscle cells may contribute to lipid accumulation in the vessel wall during atherosclerosis, which precipitates vasoconstriction and dilation.

The tunica adventitia is a layer of connective tissue in which nerve fibers and small, thin-walled nutrient vessels (vasa vasorum) are dispersed. Medium-sized arteries contain more nerve fibers than larger vessels, reflecting their role in the autonomic regulation of blood flow.

The peripheral arterial vascular system can be considered as a single end-organ subject to eight basic pathophysiologic processes: (1) atherosclerosis, (2) aneurysm, (3) embolism, (4) thrombosis, (5) inflammation, (6) trauma, (7) vasospasm, and (8) arteriovenous fistula. Two of these—atherosclerosis and thrombosis—are responsible for most cases of the disease.

Pathophysiology

Atherosclerosis

Atherosclerosis is a disease of large- and medium-sized muscular arteries. The basic lesion, the atheroma, or fibrofatty plaque, is a raised focal plaque within the intima; it has a lipid core covered by a fibrous cap. As the plaques increase in size and number, they progressively encroach on the lumen of the artery and the adjacent media. Atheromas compromise arterial blood flow and weaken the walls of the affected arteries.

The distribution of atherosclerotic plaques is relatively constant. The abdominal aorta typically is susceptible to more atherosclerotic disease than the thoracic aorta, and aortic lesions are much more common and prominent around the ostia of major branches. Other vessels

affected by atherosclerosis are the aortoiliac, femoral, and popliteal arteries; the descending thoracic aorta; the coronary arteries; the internal carotid arteries; and the circle of Willis. Upper extremity vessels are usually spared.

As atherosclerosis progresses, atheromas calcify, resulting in hard, brittle vessels. Rupture of the atheromatous plaques discharge debris, producing atheroemboli (cholesterol emboli). Ulcerated lesions produce in situ thrombosis, causing intraluminal occlusion. Hemorrhage into the plaque may further compromise the arterial lumen. Although atherosclerosis primarily affects the intima, in severe cases, the tunica media undergoes pressure atrophy and loss of elastic tissue, with sufficient weakening to create aneurysmal dilation.

Arterial Embolism

An embolus, by definition, is a foreign body, most commonly a blood clot, carried by the blood to a site distant from its point of origin. Most emboli are detached thrombus formations or thromboembolism. Less common emboli include debris from ruptured atherosclerotic plaques, tumor debris, or foreign bodies. Unless otherwise specified, the term *embolus* in this chapter is defined as thromboembolus.
