Lead toxicity rarely presents primarily to the ED. Most patients encountered in the ED have been referred for management of an elevated screening BLL measured in a clinic or workplace surveillance program. Some patients may seek ED care following an ingestion of a leaded foreign body or with worrisome symptoms following a possible environmental exposure. Diagnostic testing should consist of a venous BLL, including those cases referred in for an abnormal screening test. Capillary screens (such as finger or heel sticks) may be falsely elevated. If the patient is symptomatic, other tests include a complete blood cell count, basic metabolic panel, liver and renal function tests, and urinalysis. A peripheral smear classically shows basophilic stippling, but this finding is relatively rare. Because lead-containing objects and paint chips are radiopaque, abdominal radiographs can confirm acute ingestion and determine the need for bowel decontamination. In cases of altered mental status, seizures, or coma, a computed tomography (CT) scan of the head may show cerebral edema associated with acute lead encephalopathy and can assist in ruling out other causes of these neurologic signs. In children, plain radiographs of the wrist and knees classically demonstrate increased metaphyseal activity termed *lead lines* that are characteristic of chronic exposures. However, such x-rays are not routinely obtained in the ED.

Management

Stabilization and Supportive Care

The most important treatment step in lead poisoning is removing the patient from the source. This is the only treatment needed in most cases of lead poisoning. Determining the exact source often requires the collaborative assistance of a primary care physician, social worker, and the

department of public health. Recent data suggest urban patients at risk for lead poisoning are also at risk for asthma; the environmental evaluation for lead and asthma risks is similar, so ensuring follow-up with a primary care provider to assess the risk for both problems is essential.

Decontamination

Oral activated charcoal does not bind lead. If an abdominal radiograph demonstrates lead within the gastrointestinal tract—particularly the stomach and small intestine—then bowel decontamination should be performed. This can be done with WBI or repeated doses of polyethylene glycol (see the Iron section for dosing regimen).

Antidotal Therapy

Children. Treatment for lead toxicity rarely is commenced in the ED, but the decision to admit for chelation or source control may be indicated after consultation with the poison control, a medical toxicologist, or the primary care provider. Regardless of the BLL, eliminating the source of exposure remains the most important priority. Evidence indicates no significant benefit from chelation for children with a BLL lower than 45 µg/dL as long as the source of exposure is controlled. A BLL less than 44 µg/dL in a patient who is asymptomatic or minimally symptomatic requires a medical and environmental evaluation to identify the source, stop further exposure, and have scheduled repeat BLLs done as per current Centers for Disease Control (CDC) and public health guidelines. Caregiver education about concerning symptoms and sources of lead exposure should be coupled with close follow-up with a primary caregiver for all patients with a detectable BLL. An environmental evaluation can often be arranged with the local public health department.

Blood lead levels of 45 to 69 µg/dL in patients without vomiting or CNS symptoms can be managed in the outpatient setting with oral succimer (2,3-dimercaptosuccinic acid [DMSA]; Chemet). The initial dose of succimer is 10 mg/kg every 8 hours for 5 days, then 10 mg/kg every 12 hours for 14 days (maximum 500 mg per dose for children). The most common adverse reactions include nausea, vomiting, diarrhea, and transient elevations in liver transaminase levels. Although succimer has been FDA-approved only for children, it is effective and can be used in adults with lead poisoning. Table 146.5 summarizes available chelating agents with indications and doses. Any patient treated on an outpatient basis should be discharged to a lead-free environment.

Patients with a BLL of 69 µg/dL or higher require hospitalization and parenteral chelation therapy, even if asymptomatic. Evidence of encephalopathy, regardless of BLL, requires admission for parenteral chelation therapy. Consultation with a medical toxicologist, regional poison center, and pediatrician is indicated. Dimercaprol (or British antilewisite [BAL]) is given via a deep intramuscular injection as 4 mg/kg every 4 hours for children and adults. Adverse reactions to BAL include nausea, vomiting, urticaria, pyrexia, hypertension, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Because BAL is diluted in peanut oil, it is contraindicated in patients with peanut allergies. In cases of encephalopathy, intravenous calcium disodium ethylenediaminetetraacetic acid ($CaNa_2EDTA$) should be initiated with the second dose of BAL. Starting treatment with $CaNa_2EDTA$ may paradoxically increase lead transport across the blood-brain barrier. The dosage of $CaNa_2EDTA$ for adult and pediatric patients with acute lead encephalopathy is 1500 mg/m^2/day (approximately 50 to 75 mg/kg/day) given by continuous intravenous infusion for 5 days (maximum of 1000 mg per day for children and 3000 mg per day for adults). Adverse reactions include renal tubular injury and chelation of other metals, especially iron and zinc. $CaNa_2EDTA$ should be given only with adequate urine flow or with hemodialysis in the patient with renal failure. For patients with a BLL more than 69 µg/dL but no signs of encephalopathy, the dosage of $CaNa_2EDTA$ is 50 mg/kg/day or 1000 mg/m^2/day, given in two to four divided doses for up to 5 days without the need for concurrent BAL therapy.

Adults. The treatment of adults with chronic poisoning is based primarily on symptoms and threshold BLLs established by workplace regulatory agencies. In the asymptomatic adult or the patient with only mild clinical symptoms, the only intervention needed is cessation of exposure. According to the Occupational Safety and Health Administration (OSHA) lead standard, workers with serum lead levels above 40 µg/dL should be removed from work. If encephalopathy or severe symptoms are present, then hospitalization and chelation therapy with combined BAL and $CaNa_2EDTA$, as with children described previously, are indicated. Pregnant women should be treated in accordance with adult treatment guidelines. Lead does cross the placenta and can accumulate in the fetus. Newborn infants of exposure mothers may require chelation as well.

Disposition

Families of asymptomatic children with BLLs less than 45 µg/dL and asymptomatic adults should be counseled on how to avoid further exposure and given close follow-up with their primary care provider for a repeat BLL and exposure risk evaluation.

Patients who require oral chelation can be discharged home if they can tolerate succimer and if it can be ensured they do not return to a lead-contaminated environment. The health department should conduct an environmental assessment and testing of other family members so that the primary source of lead exposure can be identified, and further exposure prevented. Follow-up should be arranged with a pediatrician, medical toxicologist, or occupational medicine physician.

Patients who are significantly symptomatic, have worrisome CNS symptoms, and any children with a BLL of 69 µg/dL or higher require hospitalization for environmental exposure evaluation and parenteral chelation therapy.

ARSENIC

Foundations

Arsenic has an infamous history as an agent of homicide and been implicated in mass environmental poisonings.[11] Currently, arsenic exposure is primarily environmental and occupational. Arsenic is found in smelters and electric power plants that burn arsenic-rich coal; in the production of glass and microcircuits; and in rodenticides, fungicides, insecticides, paint, tanning agents, defoliants in the cotton industry, and wood preservatives. Arsenic is also still used for medicinal purposes in the treatment of trypanosomiasis, amebiasis, and leukemia. Importantly, significant concentrations of heavy metals including arsenic, lead, and mercury have been found as contaminants in ayurvedic medications.[12] Arsenic has also been reported in resource challenged countries with large environmental poisonings via well water.

Arsenic exists in different forms: elemental, organic, inorganic, and gaseous. Elemental arsenic (As) is a metal that is poorly water soluble and considered nontoxic. Organic arsenic, found in shellfish, is also generally nontoxic to humans. Of the two inorganic forms, trivalent arsenite (As^{3+}) is more toxic than the pentavalent arsenate (As^{5+}) form.[13] Absorbed arsenic is bound by hemoglobin, leukocytes, and plasma proteins. It is cleared from the intravascular compartment within 24 hours and concentrates in the liver, kidneys, spleen, lungs, and gastrointestinal tract. Arsenic crosses the placenta and can also accumulate in the fetus. Inorganic arsenic interferes with normal cellular metabolic function, energy generation, and induces apoptosis. Arsenic also generates reactive oxygen species and induces oxidative damage in the cell.[13] Gaseous arsenic in the form of arsine (AsH_3) is colorless, almost odorless, and extremely toxic. It is lethal at 250 ppm

TABLE 146.5 Chelators

Chelator	Dosage	Indications	Contraindications	Adverse Effects
Deferoxamine	15 mg/kg/hr up to 24 hours (titrate up slowly because of hypotension)	*Iron* level >500 g/dL or systemic symptoms	Severe renal disease Anuria	Rate-related hypotension Pulmonary complications if given for >24hrs Increased incidence of *Yersinia* and *Mucormycosis* infections
Dimercaprol (BAL)	*Lead encephalopathy:* 4 mg/kg deep IM injection every 4 hours for 5 days in children and adults *Arsenic (severe):* No established regimen; consider 3 mg/kg IM every 4 hours for 48 hours, then twice daily for 7 to 10 days *Mercury:* 5 mg/kg IM first, then 2.5 mg/kg every 12 to 24 hours for 10 days	*Lead* level >70 μg/dL or encephalopathy *Arsenic:* Symptomatic patient with known exposure *Mercury:* Inorganic	Peanut allergy Organic mercury poisoning Hepatic insufficiency	Pain at injection site Hypertension and tachycardia Nausea, vomiting Headache Fever (especially in children) Nephrotoxicity in the setting of an acidic urine
$CaNa_2EDTA$	1500 mg/m^2/day continuous intravenous infusion 50 mg/kg/day or 1000 mg/m^2/day in two to four divided doses for up to 5 days if less severe symptoms	*Lead* level of 70 μg/dL or encephalopathy (given after first dose of BAL)	Severe renal disease Anuria Hepatitis	Nephrotoxicity Transient increase in AST/ALT
Succimer (DMSA)	10 mg/kg every 8 hours for 5 days, then every 12 hours for 14 days (maximum 500 mg per dose for children)	*Lead* level of 45 to 69 μg/dL *Arsenic*: If tolerated orally for subacute and chronic toxicity *Mercury*: Acute and chronic	None	Nausea, vomiting Diarrhea Metallic taste Transient increase in AST/ALT
D-Penicillamine	*Lead*: 1–1.5 g/d (children: 20–30 mg/kg/d), in 3 or 4 divided doses for 1–6 months. To minimize adverse reactions, start at 250 mg/d (children: 10 mg/kg/d) and increase to 50% during week 2 and to a full dose by week 3. The maximum adult daily dose is 2 g. *Elemental or Inorganic Mercury (not effective for Organic)*: 250 mg (5 mg/kg) every 6 hours for 1–2 weeks *Arsenic*: 25 mg/kg every 6 hours for 5 days	*Lead* level of 45 to 69 μg/dL, succimer not tolerated *Arsenic*: Only if BAL and DMSA are unavailable *Mercury*: If BAL and DMSA are unavailable or not tolerated	Penicillin allergy	Leukopenia Thrombocytopenia Enuresis Abdominal pain
DMPS (investigational)	*Oral*: 100–200 mg (50–100 mg in children) every 6–8 hours, tapered over days to weeks *Parenteral (preferred for acute ingestions)*: 5 mg/kg/dose IM or slow IV push every 6–8 hours; day 1, every 8–12 hours; day 2, every 12–24 hours; day 3, until 24-hour urine is <50 mcg/L	*Lead* (chronic) *Arsenic* *Mercury*		Nausea, vomiting Headache Fatigue Rash, pruritis

Note: Indications for chelation and dosing regimens may change. Consult with a medical toxicologist or regional poison center for the most up-to-date recommendations.

BAL, British antilewisite; *$CaNa_2EDTA$,* calcium disodium ethylenediaminetetraacetic acid; *DMPS,* dimercapto-1-propanesulfonic acid, *DMSA,* 2,3-dimercaptosuccinic acid; *IM,* intramuscular; *AST*, alanine transaminase; *ALT*, aspartate transaminase.

and causes massive hemolysis. The excretion of arsenic and its metabolites occurs primarily through the kidneys.

Clinical Features

Acute Arsenic Toxicity

Gastrointestinal effects including nausea, vomiting, abdominal pain, and diarrhea predominate as the initial manifestations of acute exposure to inorganic arsenic. The diarrhea has often been described as "rice water-like" and difficult to differentiate from diarrhea induced by *Vibrio cholerae* infection. These symptoms can be so severe that they progress to hematemesis and hematochezia. The patient can also develop multisystem organ failure and cardiac conduction disturbances (Box 146.1). In cases of severe poisoning, cardiovascular collapse and death ensue. Early arsenic poisoning may be misdiagnosed as gastroenteritis or sepsis. For those who survive the initial gastrointestinal illness, chronic effects of arsenic poisoning appear weeks to months later. These include characteristic white lines that transverse the nailbeds running parallel to the lunula (also known as Aldrich-Mees lines; Fig. 146.2), painful sensorimotor neuropathy, and hyperkeratosis of the palms and soles.

BOX 146.1 Acute Effects of Arsenic Poisoning

Gastrointestinal
Severe gastroenteritis; hematemesis or hematochezia
Jaundice
Pancreatitis
Dysphagia
Hepatomegaly

Cardiovascular
Third spacing with shock
Sinus or ventricular tachycardia
Prolonged QT interval, ST depression, T wave inversion
Torsades de pointes
Pericarditis

Respiratory
Pneumonia
Pulmonary edema
Acute respiratory distress syndrome
Respiratory failure

Renal
Proteinuria
Hematuria
Oliguria
Renal failure

Neurologic
Headache
Drowsiness
Delirium
Coma
Encephalopathy
Seizures

Chronic Arsenic Toxicity

Chronic exposure to arsenic, typically through contaminated drinking water or occupational exposure, is associated with cardiovascular disease, diabetes mellitus, and both benign and malignant dermatologic disease.[14,15] Patients chronically exposed to arsenic have an increased risk of bladder, kidney, liver, and lung cancer.[16]

Arsine Gas

Acute exposure to arsine gas is characterized by severe hemolysis that is also associated with renal tubular injury. Signs of toxicity are usually evident within minutes to hours after exposure. Gastrointestinal symptoms are common, and CNS and liver dysfunction can occur.

Differential Diagnoses

Acute arsenic poisoning is often misdiagnosed as viral or bacterial gastroenteritis or gastrointestinal bleeding. Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicions for caustic ingestions, ethanol, toxic alcohols, colchicine, heavy metals, and iron. Obtaining an environmental and occupational exposure history is important to help discern the etiology of the patient's symptoms.

Diagnostic Testing

To diagnose arsenic poisoning accurately, a 24-hour urine collection should be done. Spot urine samples are inaccurate and should not guide therapy. Normal arsenic concentrations are 5 μg/L or less in blood or less than 50 μg/day in a 24-hour urine collection. Any urine level above

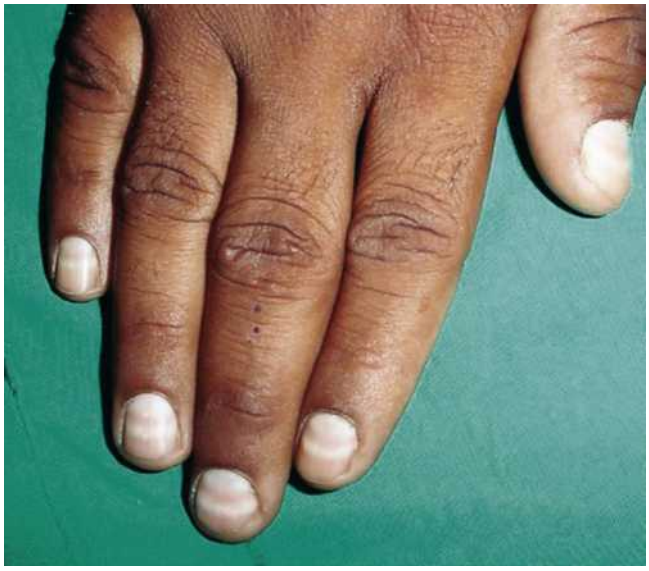

Fig. 146.2 Aldrich-Mees lines seen on the fingernails of a patient. (From: Chauhan S, D'Cruz S, Singh R, et al. Mees' lines. Lancet. 2008;372[9647]:1410.)

100 μg/day or 50 μg/L necessitates treatment. Seafood contains organic arsenic (arsenobetaine), which can significantly increase total urine arsenic concentrations, but arsenobetaine does not result in human toxicity. For this reason, patients should refrain from eating seafood, specifically shellfish, before testing, and the laboratory should be asked to specify the type of arsenic measured. Most patients referred to the ED for management of abnormal urine arsenic tests are not arsenic toxic; their urine tests are falsely abnormal because laboratories do not routinely differentiate between organic and inorganic arsenic. In cases of chronic arsenic poisoning or remote exposure, the serum and urine arsenic levels may no longer detect abnormal concentrations of arsenic.

Other laboratory results may suggest arsenic poisoning. Anemia, leukocytosis or leukopenia, and erythrocyte basophilic stippling may be seen. The results of renal function tests may be abnormal, demonstrating proteinuria, hematuria, and pyuria. Serum alanine transaminase, aspartate transaminase, and bilirubin levels may be elevated.

Arsenic in the gastrointestinal tract is radiopaque and can appear on a radiograph, although sensitivity is limited by its rapid absorption and the ensuing gastroenteritis.

Management

Stabilization and Supportive Care

Initial management of arsenic poisoning should address life-threatening conditions with supportive care of shock, dysrhythmias, and seizures. Fluid resuscitation helps maintain kidney perfusion early after arsine gas exposures.

Decontamination and Enhanced Elimination

As is the case with other metals, oral activated charcoal does not adsorb arsenic and is not recommended. Hemodialysis may remove some arsenic in the setting of acute renal failure. Exchange transfusions or plasma exchange can be done early after a severe arsine exposure. These treatments should be initiated in the intensive care setting for critically ill patients and in consultation with a medical toxicologist and nephrologist.

Antidotal Therapy

Acute Arsenic Poisoning. With a confirmed history of exposure in a symptomatic patient, chelation should start as early as possible without waiting for laboratory confirmation. Intramuscular BAL is

the preferred chelator in patients who are critically ill as described for lead poisoning. Succimer can be given orally, but its use is often limited by the severe gastroenteritis resulting from arsenic poisoning. D-Penicillamine has a high side effect profile and is much less effective than BAL or succimer, so should be used only when BAL or succimer are unavailable. Table 146.5 summarizes available chelating agents with indications and doses. Chelation is not useful for arsine gas exposures. With arsine gas poisoning, exchange transfusion, continuous venovenous hemodialysis, and plasma exchange have been used to remove arsine, which is tightly bound to erythrocytes.[17]

Chronic Arsenic Poisoning. Treatment of chronic arsenic toxicity should begin in a symptomatic patient after confirmation of elevated urinary arsenic levels. Oral chelation with succimer (DMSA) is the treatment of choice. Workers should modify their habits to avoid further exposure, and repeated monthly 24-hour urine collections can follow arsenic excretion dynamics. Prolonged chelation treatment in patients with chronic exposure but no detectable arsenic in blood or urine has not been proven to be effective.

Disposition

Patients who are severely ill and those receiving parenteral chelation for acute arsenic toxicity should be admitted to an intensive care setting. Patients with chronic arsenic exposure who are mildly symptomatic can be discharged home after removal from the source of exposure. Close follow-up with occupational medicine or a medical toxicologist should be arranged. Patients who are asymptomatic with a normal physical examination and vital signs can be discharged home.

MERCURY

Foundations

Mercury is a shimmering silver metal, familiar to most as one of the few metals that is liquid at room temperature in its elemental form. It has a long history of medicinal uses as an antiparasitic, a diuretic, a cathartic, an antiseptic, and a preservative in many older vaccines.

Significant poisoning can occur in the home and in the workplace.[18] Mercury has many industrial uses that include the manufacture of fluorescent lights, batteries, polyvinyl chloride, and in paints as a biocide. Recently, artisanal small-scale gold mining has become a significant source of global mercury pollution and toxicity.[19] For these reasons, mercury is a common environmental pollutant of air and water.[20] This has led to restrictions in the consumption of fish caught in many local waters, especially by pregnant women and children.

Like other metals, mercury exists in different forms: elemental, organic, and inorganic. Toxicity depends on the form of mercury. The most familiar form of mercury is elemental or metallic mercury, also known as *quicksilver.* A common route of exposure to elemental mercury is the inhalation of volatilized vapor during the goldmining extraction process or after vacuuming up a spill. After inhalation, metallic mercury is retained in the lungs and can result in pneumonitis and acute respiratory distress syndrome. Later systemic absorption may also occur leading to CNS and renal toxicities.[21] Subcutaneous and intravenous injections also cause poisoning from systemic absorption.[22] Elemental mercury is not well absorbed by the gastrointestinal tract and toxicity is unlikely by this route.[23]

Inorganic mercury salts have two different valences: Hg^{1+} (mercurous) and Hg^{2+} (mercuric). Ingestion of either salt leads to significant gastrointestinal and renal toxicity. Inorganic salts have a direct corrosive effect on the gastrointestinal tract resulting in third spacing and hemorrhage.

The organic mercury compounds are categorized as either short chain (alkyl) or long chain (aryl). The major route of exposure to organic mercury is through ingestion, but these compounds are also readily absorbed through the skin. Organic forms classically result in delayed neurotoxicity, and most documentation describing this form of toxicity comes from large population exposures.[24] Concerns about mercury poisoning from excessive fish consumption are extrapolations from those exposures.

Like lead, mercury has no known physiologic role in the human body. Mercury binds covalently to sulfhydryl groups, disturbing multiple cellular enzyme functions. Nephrotoxicity results from oxidative damage, cytoskeletal alterations, and increased autophagy in the kidney.[25] Mercury exposure affects both the cardiovascular system and the CNS. Mercury may lead to hypertension and other cardiovascular problems.[26] Mercury also increases reactive oxygen species in the nervous system, leading to cellular damage.[24] Although mercury was previously used as a preservative in various vaccines, it is important to note the dose in those vaccines was relatively low, and mercury has not been proven to be a cause of autistic spectrum disease.

TABLE 146.6 Mercury Poisoning and Clinical Manifestations Based on Route of Exposure and Form of Mercury

Type of Mercury and Route of Exposure	Signs and Symptoms
Inhalation of elemental mercury	Hypoxemia, dyspnea, chest tightness Fever, chills Burning in mouth and throat Nausea, vomiting, bloody diarrhea Renal tubular necrosis
Subacute or chronic inhalation of metallic mercury	Metal fume fever Neuropsychiatric symptoms Renal dysfunction Skin changes
Ingestion of inorganic mercury salts	Severe hemorrhagic gastroenteritis, shock, hypovolemia, third spacing Acute tubular necrosis
Subacute or chronic inhalation of mercury	Neurasthenia, erethism, acrodynia
Organic mercury exposure (methyl-, diethyl-)	Delayed neurologic problems (ataxia, tremor, dysarthria) Visual field constriction Hearing loss Spasticity Hyperreflexia

ARDS, Acute respiratory distress syndrome.

Clinical Features

The clinical manifestations of mercury poisoning depend on the acuity of the exposure, the route of exposure, and the chemical form of mercury (Table 146.6).

Differential Diagnoses

Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicions for caustic ingestion, heavy metals, and iron. Respiratory distress from elemental mercury inhalation can also be mistaken for pneumonia, asthma, or influenza. The vague neurotoxic symptoms of mercury may also be confused with lead-induced neurocognitive deficits and encephalopathy. Obtaining an environmental and occupational exposure history is important to help discern the etiology of the patient's symptoms.

Fig. 146.3 Radiograph of the hand showing elemental mercury deposits in the subcutaneous tissue of a patient who was injecting chronically subcutaneously. (Courtesy Dr. Steven Aks.)

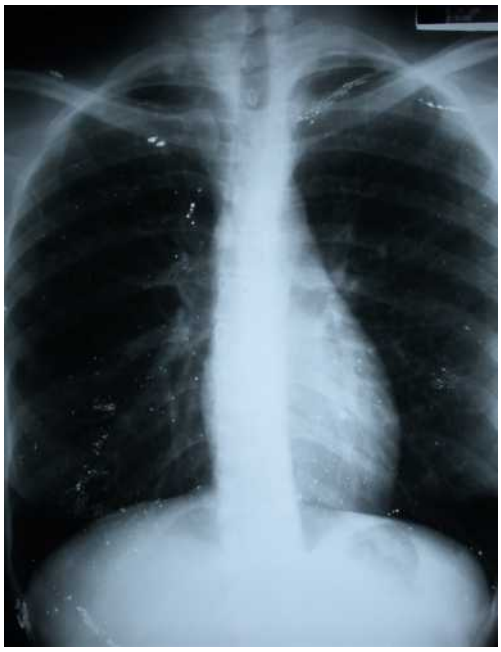

Fig. 146.4 Radiograph of the chest showing elemental mercury deposits in a patient who was chronically injecting the metal subcutaneously. (Courtesy Dr. Steven Aks.)

Diagnostic Testing

Measurement of a 24-hour urine mercury concentration is the most helpful test in confirming exposure and monitoring the effectiveness of chelation therapy. For organic mercury compounds, which undergo little urinary excretion, serum concentration should be used to confirm the diagnosis. A "normal" mercury concentration is considered to be less than 10 µg/L in the blood or less than 20 µg/L in the urine. Blood concentrations above 35 µg/L and urine concentrations above 150 µg/L require intervention. Fish can be contaminated with mercury, especially larger predatory fish and those from certain bodies of water known by local health departments to be most polluted. Individuals eating these locally caught fish may have elevated mercury levels. Elemental (metallic) mercury is radiopaque on plain radiographs, which can be ordered in cases of ingestion or dermal injection of elemental mercury (Figs. 146.3 and 146.4).

Management

Stabilization and Supportive Care

Initial management in the acutely poisoned patient is removal from the source and supportive care regardless of the type of mercury or route of exposure. There is no role for prophylactic antibiotics or steroids.

Decontamination

Oral activated charcoal and other gastrointestinal decontamination strategies are not recommended.

Enhanced Elimination

For acute inhalational exposures, the patient should be removed from the source of exposure and supportive management provided. Suction and postural drainage are indicated in cases of acute aspiration of metallic mercury. Self-injection of metallic mercury may require surgical débridement of infiltrated tissue.[22]

Antidotal Therapy

BAL is used for clinically significant acute inorganic mercury intoxication. BAL is contraindicated for patients poisoned with organic methylmercury compounds because it may increase transport of mercury across the blood-brain barrier.[27] Succimer (DMSA) has been used for both acute and chronic mercury poisoning and may be the best available chelator for methylmercury. D-Penicillamine may also be used but should only be administered if no additional mercury is present in the gastrointestinal tract, because mercury absorption from the intestinal lumen may be enhanced by the penicillamines. Table 146.5 summarizes available chelating agents for mercury poisoning with indications and doses.

Disposition

Ingestion of inorganic mercury in patients with any symptoms warrants admission for further evaluation and supportive treatment. Patients who self-inject metallic mercury may need surgical consultation for surgical débridement; this may be done as an outpatient if no symptoms or signs are evident. Patients with signs of neurotoxicity from organic mercury require admission. Asymptomatic patients with exposure to any form of mercury warrant environmental counseling, and those with exposure from excessive fish consumption need primary care or medical toxicology follow-up as outpatients for dietary counseling and further testing as indicated.

CHAPTER 146: QUESTIONS AND ANSWERS

1. An 18-month-old female presents to the emergency department with her mother after they were informed of an elevated venous blood lead level of 38 mg/dL by their pediatrician. The child is asymptomatic and has a normal physical exam. She is an only child, does not attend daycare, and spends her time in the family home which was built in 1942. Which of the following would be the most appropriate initial management?

a. Admit for parenteral chelation
b. Start oral chelation and discharge home
c. Admit or secure alternative housing to limit exposure
d. Discharge home to follow-up with their pediatrician
e. Obtain an abdominal x-ray to determine if leaded foreign bodies are present

Answer: E. The most important treatment for all heavy metal poisonings is to limit further exposure. The source of lead in this case is likely from leaded paint in the home. Evaluating if the child currently has paint chips or other leaded foreign bodies in her gastrointestinal tract is important. If present, she will require decontamination to prevent absorption. After confirming the absence or presence of leaded foreign bodies, environmental control is paramount. To limit any further exposure, parents should ensure alternative housing (i.e., staying with a relative) or the child should be admitted to the hospital until the local public health entities can inspect and remediate the home. Discharging home with primary care follow-up is not appropriate because the child will continue to be exposed. Parenteral chelation is required for children with a lead level of 69 mg/dL and above or for severely symptomatic patients. Oral chelation is for children with blood lead levels above 44 mg/dL. This asymptomatic child does not meet criteria for chelation with a level of 38 mg/dL.

2. A 20-year-old man presents after an iron overdose. An abdominal radiograph shows many radiopaque objects in his stomach, consistent with iron tablets. You decide to try to decrease the gastrointestinal absorption of the iron. Which of the following methods is most effective?

a. Activated charcoal
b. Gastric lavage
c. Surgical removal
d. Syrup of ipecac
e. Whole bowel irrigation (WBI)

Answer: E. WBI is the preferred method to minimize iron absorption. WBI should not be routinely used in small overdoses or with mild symptoms, but it should be considered when a significant ingestion is suspected or when multiple tablets are identified by radiography. Iron

CHAPTER 146: QUESTIONS AND ANSWERS—cont'd.

is not adsorbed to oral activated charcoal. Gastric lavage and syrup of ipecac do not remove significant amounts of iron. Open surgical removal of tablets has been used in the past and is effective, but it is invasive and has a higher rate of adverse outcomes than WBI.

3. A healthy 26-year-old female was helping her great aunt clean out her home when she spilled a large tray of old mercury thermometers on the floor. She then attempted to vacuum up the mercury. She is now presenting to the emergency department 3 hours later with cough, fever, and shortness of breath. Her oxygen saturation is 93% on room air and her respiratory rate is 24 breaths per minute. A chest x-ray shows bilateral patchy infiltrates. Which of the following would be the most appropriate initial management?
   a. Provide supplemental oxygen and intravenous fluid resuscitation and admit for further monitoring.
   b. Give oral activated charcoal.
   c. Consult nephrology for potential acute kidney injury.
   d. Administer antibiotics and admit for further monitoring.
   e. Call the department of public health to evaluate the home for hazardous material clean-up.

Answer: A. This patient is exhibiting acute inhalation elemental mercury toxicity. After an inhalation exposure where mercury is volatilized and inhaled, patients can have fever, shortness of breath, and cough that can rapidly progress to ARDS. This may occur hours after exposure. Later, as the mercury is absorbed patients are at risk for inorganic mercury poisoning resulting in nephrotoxicity. The best approach to these patients is supportive care and close monitoring of their respiratory status. There are no roles for activated charcoal or antibiotics as activated charcoal does not bind heavy metals and this is a pneumonitis. Nephrology may ultimately need to be consulted but now the focus should be on the patient's cardiorespiratory status. Answer choice E is also reasonable to prevent further exposure at the home given the large amount of elemental mercury spilled, however it is not the most emergent management step.

4. A 5-year-old boy presents with abdominal pain, nausea, vomiting, and bloody diarrhea. The boy was found rummaging through his grandmother's medicine cabinet and says he swallowed some of her medications. His vital signs are significant for hypotension and tachycardia. An electrocardiogram (ECG) shows sinus tachycardia. Laboratory tests are significant for an anion gap acidosis, hyperglycemia, and moderate leukocytosis. Which of the following medications did he most likely ingest?
   a. Digoxin
   b. Diltiazem
   c. Iron
   d. Metformin
   e. Metoprolol

Answer: C. Iron toxicity typically presents with gastrointestinal symptoms including occasional bleeding soon after ingestion. The previously mentioned laboratory findings are also typical. Digoxin toxicity can also be manifested with gastrointestinal symptoms, but there is usually no gastrointestinal bleeding and there are also typically ECG changes. Beta-blocker toxicity, such as with metoprolol, is manifested with hypotension and bradycardia, as well as with hypoglycemia. Calcium channel blocker toxicity, such as with diltiazem, can be manifested with gastrointestinal symptoms, acidosis, and hyperglycemia. However, patients typically have bradycardia, and gastrointestinal bleeding is not expected. Metformin toxicity is manifested with gastrointestinal upset, typically without bleeding. Lactic acidosis can result, but the vital sign abnormalities and other laboratory results are not expected.

5. A 57-year-old woman with hypothyroidism presents to the emergency department with painful, burning circumferential bilateral lower leg pain. She states that over the last 2 weeks the pain has gotten progressively worse so that she feels as though she cannot even wear socks. She lives in a rural community, works part-time at the public library, and denies alcohol use or taking any herbal supplements. Her only medication is levothyroxine. She denies fevers or chills, polyuria, chest pain or shortness of breath. Her exam is remarkable for hyperalgesia in the bilateral lower extremities. Looking through her chart you notice that she was in the ED 2 weeks ago for gastroenteritis, was given IV fluids and then discharged home. As you leave her room, she tells you she is convinced her husband is poisoning her. You then decide to order a complete blood count, a basic metabolic panel, and a:
   a. Neurology consult
   b. Venous blood lead level
   c. Vitamin B_{12}
   d. 24-hour urine collection for arsenic testing
   e. Ethylene glycol level

Answer: D. Acute inorganic arsenic poisoning is characterized by cholera-like diarrhea followed weeks to months later by peripheral neuropathy and nail and skin changes. Arsenic was commonly used as a rodenticide until the mid-19th century when it was no longer produced. It can still be found in rural areas, stored in old barns. A 24-hour speciated urine arsenic test to determine the amount of inorganic and organic arsenic is the gold standard for determining the need for chelation. Although lead poisoning can cause peripheral neuropathy, this is typically motor in nature and not preceded by nausea, vomiting, and diarrhea. Constipation and colicky abdominal pain are characteristic for lead poisoning. Vitamin B_{12} deficiency can lead to a peripheral neuropathy however in this patient it is not the most likely diagnosis.

Hydrocarbons

George Sam Wang and Jennie Alison Buchanan

KEY CONCEPTS

- Aspiration is the major toxic risk of hydrocarbon poisoning.
- Hydrocarbons may cause systemic toxicity, burns, cardiac dysrhythmias, altered mentation, and seizures depending upon the specific agent, dose, and duration of exposure.
- Gastrointestinal decontamination is potentially harmful in cases of hydrocarbon ingestion and is contraindicated.
- Hydrocarbon inhalant abuse can cause central nervous system (CNS) and cardiotoxic effects.
- In most cases of hydrocarbon ingestion or inhalation, symptomatic care with observation and monitoring are the cornerstones of management. There are no specific antidotes for hydrocarbons. Patients with pulmonary symptoms should have a chest radiograph.
- Symptoms of toxicity, especially aspiration, can be delayed, so asymptomatic patients should be observed for 6 hours and given instructions to return if symptoms develop after discharge.

FOUNDATIONS

Overview

Hydrocarbons are a diverse group of organic compounds that contain hydrogen and carbon (Table 147.1). Most hydrocarbons (such as gasoline) are byproducts of crude oil and are therefore called *petroleum distillates.* Essential oils such as turpentine or wormwood are derived from plants. Hydrocarbons are used as solvents and diluents in many products, including household cosmetics and chemicals, pesticides and fuels. The two main categories of hydrocarbons are aliphatic (straight chain structures, such as propane) and aromatic (cyclic structures, such as toluene). Hydrocarbons can also have multiple nonorganic side chains. For example, halogenated hydrocarbons will have at least one bromide, chloride, fluoride, or iodide moiety (e.g., carbon tetrachloride). Finally, hydrocarbons are used as a solvent base for many toxic chemicals, such as insecticides, carburetor cleaner (methanol), and heavy metals, which in turn can cause separate distinct syndromes of poisoning. Although there is a wide variety of toxic hydrocarbons, the majority of human exposures are confined to petroleum distillates.

Human exposure, both intentional and unintentional, to hydrocarbons is a common problem. In 2018, U.S. poison centers reported over 28,500 exposures to hydrocarbons accounting for over 1% of all calls with 121 major outcomes and 20 deaths.[1] Over the prior decade, there were approximately 4000 pediatric exposures to hydrocarbons per year, and almost 10% were hospitalized.[2] It is estimated that nearly 10% of the United States population aged 12 years and older have used an inhalant for its psychoactive properties.[3] Toxic exposure to hydrocarbons is dermal, inhalational, or via ingestion (with potential for aspiration). Inhalational exposures are typically due to either intentional abuse of volatile hydrocarbons (huffing, sniffing, dusting or bagging) or household and workplace exposures. Ingestions are mostly accidental pediatric exposures, which can lead to aspiration pneumonitis. Dermal exposures are from household or workplace use of hydrocarbon-based agents and are rarely intentional.

Pathophysiology

Hydrocarbons are local gastrointestinal irritants, but acute toxicity usually manifests through effects on three main target organs: lungs, heart, and central nervous system (CNS). Most ingestions of hydrocarbons do not lead to serious systemic toxicity but localized gastrointestinal symptoms such as abdominal pain, vomiting, and diarrhea may occur. Exceptions include halogenated or aromatic hydrocarbons, and hydrocarbons containing metals or pesticides, which are capable of causing significant CNS, hepatic, or renal toxicity. Despite the fact that there are thousands of different types of hydrocarbons, their potential for acute toxicity depends on a few physical properties:

- Viscosity is the capacity to resist flow or change. Low-viscosity hydrocarbons, such as gasoline, lamp oil, and furniture polish, spread rapidly into the airway, with high risk of aspiration toxicity. Lubricants and mineral oil, conversely, have high viscosity and low aspiration potential.
- Volatility is a measure of a liquid's ability to evaporate to a gas or vapor. Hydrocarbons with high volatility can displace alveolar oxygen and cause hypoxia. Butane and propane are examples of hydrocarbons with high volatility.
- Surface tension is the capacity for a liquid to adhere to a surface. Low surface tension, like low viscosity, enables a substance (e.g., turpentine) to disperse easily and may lead to pulmonary toxicity.
- Chemical side chains or substitutions often increase potential toxicity. These include metals (e.g., lead), halogens (e.g., the chloride ions in carbon tetrachloride), and those found on aromatic structures (e.g., the CH_3 groups in toluene and xylene). Halogenated hydrocarbons may cause cardiotoxicity.
- Lipophilicity enhances blood brain barrier penetration resulting in CNS effects.

Pulmonary Pathophysiology

The primary target organ for direct toxicity is the lung. Fatalities after ingestion usually occur because of accompanying aspiration. As noted above, hydrocarbons with high volatility, low viscosity, and low surface tension are especially dangerous (Box 147.1).[2-4]

Hydrocarbons penetrate into the lower airways, producing bronchospasm and direct injury to pulmonary alveoli and capillaries leading to an inflammatory response and pneumonitis.[2,4] Hydrocarbons

TABLE 147.1 Spectrum of Hydrocarbon Toxicity

Type	Example	Use	Pathophysiology	Comments
Aliphatic petroleum distillates	Methane, propane, butane, gasoline, kerosene, mineral spirits, mineral oil, naphtha, mineral seal oil, diesel oil, *n*-hexane	Fuels, liquid fuels, solvents, furniture polish, degreasers, multiple uses in chemical industry	Asphyxiants causing hypoxia and CNS depression Abused inhalants Pneumonitis when aspirated CNS depression *n*-Hexane causes peripheral neuropathy	Sudden death from inhalation abuse Viscosity and volatility determine spectrum of toxicity Mineral seal oil has high aspiration potential Poor gastrointestinal absorption
Aromatic petroleum distillates	Toluene, xylene, benzene	Used in plastics, pharmaceutical, rubber, chemical, and solvent industries, degreasers	Highly volatile, lung aspiration Absorbed from gastrointestinal tract Abused inhalants	Inhaled toluene causes renal tubular acidosis Benzene causes aplastic anemia, leukemia
Essential oils	Turpentine, pine oil, oil of wintergreen, pennyroyal	Solvents, household disinfectants, incense	Well absorbed from gastrointestinal tract	Gastrointestinal and CNS toxicity Wintergreen with methylsalycylates Pennyroyal can lead to hepatotoxicity
Halogenated hydrocarbons	Methylene chloride, chloroform, carbon tetrachloride, trichloroethylene, Freon, methylbromide, lindane, DDT	Solvents cleaning fluids, degreasers, fire extinguishers, paint strippers, fumigants	Multisystem toxicity (CNS, renal, hepatic, cardiac) Inhalant abuse Highly lipid soluble	Methylene chloride metabolized to carbon monoxide after ingestion, absorbed through the skin resulting in burns Carbon tetrachloride is radiopaque and can lead to hepatotoxicity Insecticides absorbed through skin
Related chemicals	Phenol, creosols	Disinfectants	Very corrosive	Phenol causes severe skin burns, and systemic toxicity including metabolic acidosis

CNS, Central nervous system; *DDT,* dichlorodiphenyltrichloroethane.

BOX 147.1 Qualities of Hydrocarbon That May Lead to Aspiration and Pneumonitis

- High volatility
- Low viscosity
- Low surface tension

also impair surfactant lipid production and function, leading to alveolar instability and collapse, decreased compliance, and impaired gas exchange. These mechanisms lead to alveolar dysfunction, ventilation-perfusion mismatch, and hypoxemia, which can progress to respiratory failure. Lipoid pneumonia can also develop after hydrocarbons coalesce in alveoli and become encapsulated by fibrous tissue. This has been reported in adults siphoning gasoline and from fire-eating performances and is known as "fire-eater's lung."[5-7]

Central Nervous System Pathophysiology

Most inhalant forms of hydrocarbons cause CNS depression. Products used for recreational mood alteration include glues and adhesives, aerosols, anesthetics, cleaning agents, solvents, and gases. After respiratory exposure, hydrocarbons passively diffuse through the pulmonary alveolus, are absorbed in blood and tissues, and cross the blood-brain barrier. Experimental data suggest that effects occur through binding of hydrocarbons with various neurotransmitter receptors, including glutamate/N-methyl-D-aspartate (NMDA), gamma-aminobutyric acid (GABA), dopamine, and opioids.[3] The inhalation route avoids hepatic first-pass metabolism and generates high CNS concentrations. With an isolated single exposure, these effects usually have a rapid onset of intoxication and short duration of effect. Chronic use of inhaled hydrocarbons can cause severe abnormalities in nervous system function, which include deficits in memory, attention, and judgment, peripheral neuropathy, cerebellar degeneration, neuropsychiatric disorders, chronic encephalopathy, and dementia. More than 50% of patients who abuse toluene for greater than 10 years will have cerebral cortical atrophy (Fig. 147.1) with histologic changes that include loss of neurons, diffuse gliosis, and axonal degeneration.[3] CNS depression can also occur through ingestion of some hydrocarbons, such as tea tree oil.

Cardiac Pathophysiology

Hydrocarbons can precipitate sudden death, usually in the setting of intentional inhalation. These compounds are thought to produce myocardial sensitization to endogenous and exogenous catecholamines by inhibition of calcium signaling, which precipitates ventricular dysrhythmias and myocardial dysfunction. Hypoxemia is also thought to be a contributing factor. Cardiac dysrhythmia occurs disproportionately among those using halogenated and aromatic hydrocarbons (e.g., difluoroethane). Halogenated hydrocarbons can be found in refrigerant propellants and air spray cleaners commonly used for computer keyboard cleaning. Prolonged use can lead to cardiac structural damage and may impede normal cardiac electrical function

Other Organ Systems

Toxicity related to hydrocarbons also has been reported for other organ systems. Recognized syndromes include toluene-induced renal tubular acidosis, benzene-induced bone marrow toxicity and leukemia, delayed methylene chloride–induced carbon monoxide poisoning, and chlorinated hydrocarbon–induced centrilobular hepatic necrosis.[1] Direct skin exposure to certain hydrocarbons can cause defatting dermatitis, contact dermatitis, or chemical burns. Intentional intravenous injection of hydrocarbons such as kerosene has led to both localized caustic and necrotic effects, and systemic effects including renal or

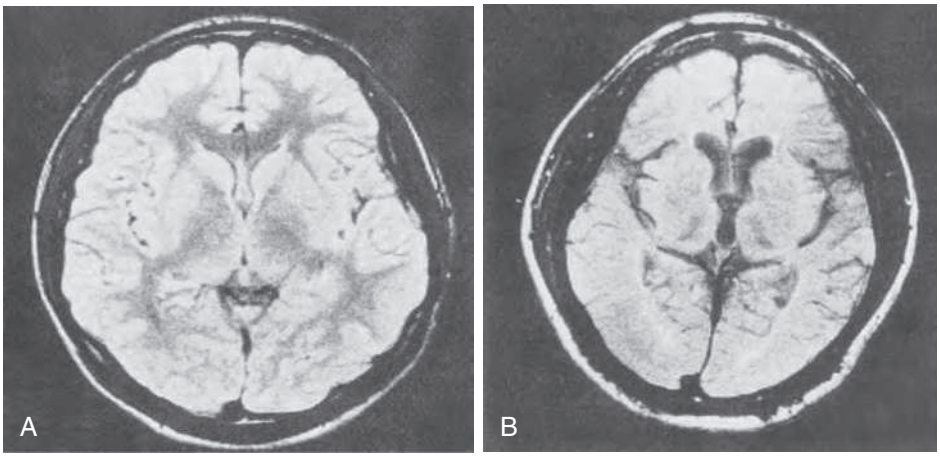

Fig. 147.1 Brain magnetic resonance imaging (MRI) of an individual with no history of inhalant abuse (A) and a patient with a history of chronic toluene abuse (B). (From NIDA Research Report [NIH 05-3818].)

hepatic toxicity, systemic inflammatory response syndrome (SIRS), hemolysis, seizures, pulmonary injury, cardiovascular toxicity, and death.[8] Huffing can lead to localized increased vascular permeability, which can lead to angioedema, or localized frostbite when refrigerants or freon are abused (Fig. 147.2).[9]

CLINICAL FEATURES

After oral ingestion of hydrocarbons, severe poisoning is most often related to aspiration. This manifests with progressive respiratory symptoms, including cyanosis, coughing, grunting, noisy respirations, and increased work of breathing. A patient may initially have mild symptoms and then develop tachypnea, dyspnea, bronchospasm, wheezing, rales, and fever after several hours.[2,4] A change in mental status can be a manifestation of hypoxia or hypercapnia, but it is also a direct effect of the hydrocarbon itself. In extreme cases, respiratory failure can require intubation. Various additives or solutes can produce symptoms independently (e.g., seizures from camphorated hydrocarbons, cyanosis from nitrite-induced methemoglobinemia, or delayed carbon monoxide poisoning from methylene chloride exposure[10]). Pesticides are often dissolved in a hydrocarbon base. With pesticide exposures, it can be difficult to distinguish acute respiratory distress syndrome induced by hydrocarbon aspiration from bronchorrhea induced by organophosphate toxicity (see Chapter 152).

Hydrocarbon solvent abuse is common and associated with various paraphernalia, such as plastic bags used for "bagging" (a method of pouring or spraying hydrocarbons in a bag or container and then inhaling deeply) and hydrocarbon soaked cloth used for "huffing" (a method in which abusers inhale through a saturated cloth).[9] Patients often have the distinctive odor associated with organic hydrocarbons. A characteristic coloration from spray paint (usually silver or gold because these paint colors contain higher concentrations of toluene) may be present over the mouth and nose or localized angioedema may occur, resulting in a "glue-sniffer's rash" (Fig. 147.3). These patients generally present to the emergency department (ED) with CNS intoxication and exhibit euphoria, agitation, hallucinations, confusion, or bizarre behavior. This may progress to CNS depression and seizures. In extreme cases, an individual who has inhaled solvents and then engaged in physical exertion, such as an altercation, may suddenly collapse in cardiac arrest, likely due to cardiac sensitization of endogenous catecholamines by hydrocarbons with ensuing dysrhythmias.[3] Chronic hydrocarbon inhalers may be brought to medical attention for behavioral problems or nonspecific medical symptoms caused by long-term exposure. These patients may share traits with the chronic ethanol user, with peripheral neuropathy (caused by, for example, *n*-hexane), cerebellar degeneration, and encephalopathy.[11]

Fig. 147.2 Angioedema resulting from huffing computer cleaner. (From: Kurniali PC, Henry L. Inhalant abuse of computer cleaner manifested as angioedema. *Am J Emerg Med.* 2012;30:265.e3-5.)

Accidental dermal or inhaled (non-aspiration) respiratory exposure to hydrocarbons may occur in the workplace or home. Such exposures are rarely life-threatening. Most cases do not present for medical care.[1] The few patients who present to the ED typically will be asymptomatic or have transient nonspecific symptoms, such as headache, dizziness, or nausea. Those with significant respiratory exposure may have persistent pulmonary complaints and physical findings, such as coughing, wheezing, and cyanosis. Patients with significant acute dermal exposures may have localized pain and evidence of chemical burns consisting of erythema, swelling, angioedema, blistering, and dermal destruction (e.g., exposure to phenol).[3,9]

In the absence of aspiration, large-volume ingestion, or co-ingestion of another toxic substance, oral ingestion of most commonly available hydrocarbons is not associated with significant morbidity or mortality. Cough or tachypnea may be an early sign of pneumonitis or aspiration.

Fig. 147.3 Presentation of paint sniffer ("huffer") with paint around the face and sedation. (Courtesy Chris Tomaszewski, MD.)

DIFFERENTIAL DIAGNOSES

The history of exposure to a hydrocarbon, and the route or method of that exposure is usually straightforward. Additional history and examination should focus on other ingredients and possible aspiration, especially if the agent is ingested. Symptoms of aspiration include cough, dyspnea, and shortness of breath. Signs of significant pulmonary exposure include tachypnea, tachycardia, wheezing, and hypoxemia. Differential diagnosis depends upon the route of exposure, which primarily includes inhalation and ingestion, and the likelihood of co-intoxicants. CNS depressants such as ethanol and sedative-hypnotics can mimic the altered mental status of hydrocarbon ingestion. For hydrocarbon pneumonitis, pulmonary irritants; organophosphates, salicylates, and paraquat poisonings; and viral or bacterial pneumonia, may all produce a similar clinical presentation, but a focused history usually will lead to the correct diagnosis. In the scenario of the recreational abuser inhaling a particular agent, multiple drugs of abuse are often present, which can confound the clinical evaluation. Furthermore, hydrocarbon products may contain other constituents leading to specific toxicities. Behavioral disorders and confusion can be caused by hypoxia and respiratory compromise, as well as by the drugs themselves. Hypoglycemia, electrolyte abnormalities, and trauma should be considered as an etiology of altered mentation in these patients.

DIAGNOSTIC TESTING

The diagnosis is usually self-evident, and the exposure is often reported by the patient, supported by history of exposure and chemical odor. Ideally, the offending agent and container are brought to the ED. The local poison control center, medical toxicologist or material safety data sheet (MSDS) may identify and verify substances containing hydrocarbons. Hydrocarbons often are vehicles for other chemicals, and other exposures should be investigated.

CHAMP is a long-standing mnemonic used to help identify hydrocarbons and their additives with systemic toxicity (Box 147.2).

We do not recommend laboratory identification of specific hydrocarbons, which is difficult, time-consuming, and does not alter ED management. Other laboratory tests including electrolytes, complete blood count, and liver function tests can be performed to assess for renal tubular acidosis, electrolyte abnormalities (e.g., hypokalemia), bone marrow suppression, or liver injury caused by various hydrocarbons.[3] If essential oils such as oil of wintergreen (salicylates) or pennyroyal (liver toxicity) are ingested, specific relevant testing is performed. We recommend an electrocardiogram (ECG) in patients with a history of halogenated hydrocarbon use, dysrhythmias, syncope, or hemodynamic instability. Abnormal ECG findings may include premature ventricular contractions, QTc interval prolongation, or, in extreme cases, ventricular tachycardia or fibrillation.

Patients with pulmonary symptoms should have a chest radiograph and be observed for at least 6 hours with a repeat chest radiograph if there is worsening of their pulmonary status.[2,3]

BOX 147.2 CHAMP Mnemonic

*C*amphor can cause neurotoxicity and seizures
*H*alogenated hydrocarbons can cause dysrhythmias and hepatotoxicity
*A*romatic hydrocarbons can cause bone marrow suppression and leukemia
*M*etals (e.g., arsenic, mercury, and lead) can cause neurotoxicity
*P*esticides can cause cholinergic crises, seizures, and respiratory depression

MANAGEMENT

Dermal exposures to hydrocarbons can cause extensive burns, and exposed patients require early decontamination. Contaminated clothing should be removed, and the skin should be washed with soap and copious lukewarm water. Thermal injuries and chemical injuries are treated as described in Chapters 54 and 55.

In most cases of hydrocarbon ingestion or inhalation, symptomatic care along with observation and monitoring are the cornerstones of management. Gastrointestinal decontamination with gastric lavage or activated charcoal is not indicated. Most hydrocarbons are much more toxic to the lungs than to the gastrointestinal tract, and emesis or attempts at gastric emptying or decontamination may lead to aspiration and pulmonary toxicity.

Cardiac abnormalities are treated according to standard advanced cardiac life support (ACLS)/pediatric advanced life support (PALS) resuscitation with the exception of epinephrine administration. It is postulated that catecholamines worsen or precipitate cardiac dysrhythmias. This had led to recommendations for using short-acting beta blockers, such as esmolol, for hydrocarbon-induced refractory tachydysrhythmias. We recommend an initial bolus of 1 mg/kg IV over 30 seconds followed by an infusion starting at 50 mcg/kg/min (maximum of 300 mcg/kg/min) until resolution of the tachydysrhythmia. Epinephrine should be avoided in the acutely intoxicated patient for concern of precipitating an arrhythmia.[3] Patients with any history or ECG abnormalities concerning for cardiac involvement should be monitored on cardiac telemetry until symptoms resolve.

Significant hydrocarbon toxicity may lead to early and rapid decompensation of a patient's pulmonary, cardiac, and CNS functions. Monitoring in an intensive care or appropriate ED observation setting is indicated for patients with respiratory distress, significant oxygen requirements, those needing positive-pressure assistance or mechanical ventilation, tachydysrhythmias, cardiac conduction disturbance, or CNS depression. Patients with mild pulmonary symptoms (cough, minimal work of breathing, or low oxygen requirement) may be admitted to an inpatient unit for further observation. All other asymptomatic or minimally symptomatic patients should be observed with cardiac monitoring and pulse oximetry for a minimum of 6 hours and until asymptomatic. Indications for positive-pressure ventilation or mechanical ventilation include hypercarbia, severe respiratory distress, hypoxia unresponsive to noninvasive measures, or CNS depression. There are case reports and animal models using high-frequency jet ventilation, and extracorporeal membrane oxygenation in severe

Fig. 147.4 Chest radiograph of a patient with hydrocarbon ingestion 6 hours after exposure.

cases of pneumonitis, with unproven clinical efficacy. Clinical decisions regarding these novel therapies should be made as in any other case of severe lung disease.[2-4] We recommend consideration of intrapulmonary administration of surfactant for severe hydrocarbon pneumonitis, using elevated oxygenation index, Pao_2/Fio_2 ratios, or poor lung compliance as indicators for use.[12] Consultation with a pulmonologist is advised for surfactant administration. Corticosteroids and antibiotics have not been shown to improve outcomes and are not indicated.[3]

DISPOSITION

Exposures to known, relatively benign hydrocarbons with minimal symptoms should have a 6-hour period of observation. Asymptomatic patients can be discharged home after appropriate psychiatric clearance, if indicated. If signs of pulmonary or systemic toxicity develop during the observation period (such as tachypnea and hypoxia), and a chest radiograph shows evidence of pneumonitis (Fig. 147.4), patients will require observation or hospital admission for at least 24 hours until symptoms have improved. Patients with CNS depression, history of dysrhythmia, significant respiratory distress including cyanosis, coughing, grunting, noisy respirations, and increased work of breathing should be monitored in the intensive care unit (Box 147.3).

BOX 147.3 Disposition

- Observation
  - Patients should be monitored for minimum 6 hours.
  - Discharge criteria: Asymptomatic without chest x-ray findings after 6 hours
- Inpatient admission
  - Mild CNS depression, tachypnea, hypoxia, chest x-ray findings not resolved after 6 hours
- Intensive care monitoring
  - Moderate to severe CNS depression
  - Significant respiratory distress
  - Significant hypoxia or hypercarbia
  - Requiring significant respiratory support (positive-pressure ventilation/mechanical ventilation)
  - History of cardiac dysrhythmias
  - Hemodynamic instability

CNS, Central nervous system.

Recreational inhalational users of hydrocarbons should be observed until clinical symptoms are improving or resolved. In most cases, if asymptomatic without complaints, the patient may be discharged after medical clearance for drug abuse counseling. Patients exposed to hydrocarbons with chemical side chains or substitutions have an increased incidence of systemic toxicity. These include metals (e.g., lead), halogens (e.g., the chloride ions in carbon tetrachloride), those found on aromatic structures (e.g., the CH_3 groups in toluene and xylene) and halogenated hydrocarbons, which can cause cardiotoxicity. These types of hydrocarbon exposures should be managed in conjunction with a poison control center or a medical toxicologist.

CHAPTER 147: QUESTIONS AND ANSWERS

1. Hydrocarbons can affect many organ systems, but derangements in which organ system most commonly lead to death after hydrocarbon exposure?

a. Cardiac
b. Gastrointestinal
c. Nervous
d. Pulmonary
e. Renal

Answer: D. Most fatalities from hydrocarbon ingestion occur because of aspiration. Hydrocarbons cause direct lung injury, as well as displace oxygen and disrupt surfactant. Hydrocarbons can sensitize the myocardium to catecholamines, which can result in ventricular dysrhythmias and sudden death. Although an important consideration, death is more frequently caused by pulmonary complications. Gastrointestinal complications from hydrocarbon exposure are rare unless related to aspiration potential. Chronic hydrocarbon abuse or exposure causes nervous system dysfunction, including peripheral neuropathy, cerebellar degeneration, and neuropsychiatric disorders, but typically does not result in death. Several hydrocarbons cause renal failure, particularly toluene, but rarely result in death.

2. A healthy 20-year-old man presents after accidentally ingesting furniture polish that was stored in a plastic container that he mistook for a beverage. The ingestion occurred approximately 1 hour ago. He has no complaints. His vital signs and physical examination are normal. Which is the most appropriate course of action?

a. Carbon monoxide level
b. Careful gastric decontamination using nasogastric tube
c. Drug screen
d. Observe for 6 hours and discharge if condition does not change
e. Serum electrolytes

Answer: D. Furniture polish is typically a mixture of nontoxic chemicals with a hydrocarbon base. The primary toxicity from hydrocarbon is from aspiration. Gastric decontamination is not recommended. Serum electrolytes and drug screens are rarely helpful in acute asymptomatic hydrocarbon exposures. Wood strippers often contain methylene chloride, which can cause carbon monoxide poisoning, but this chemical is not found in furniture polish.

3. A 4-year-old boy with a history of asthma is brought to the emergency department (ED) following an accidental hydrocarbon ingestion 2 hours ago. He initially was noted to be coughing. His vital signs are normal. His physical examination reveals mild bilateral wheezing but with good air movement. His oxygen saturation is 99% on room air. A chest radiograph is normal. The child is placed on a cardiac monitor and intravenous (IV) access is obtained. What is the most appropriate treatment plan?

a. Admission and observation
b. Endotracheal intubation
c. Intravenous sodium bicarbonate
d. Racemic epinephrine
e. Oral activated charcoal

Answer: A. Patient is symptomatic after a hydrocarbon exposure. Hydrocarbon pneumonitis can worsen over the next 24hours. Typically, they will cause few symptoms when ingested. Any therapy that risks inducing vomiting should be avoided (i.e., gastric lavage and oral activated charcoal). Patient is not ill enough to get intubated. Racemic epinephrine may be helpful if stridor or upper airway swelling is evident. Sodium bicarbonate has no role in hydrocarbon toxicity.

4. A 16-year-old male presents by emergency medical services (EMS) paramedics with sudden cardiopulmonary arrest after being found unresponsive by friends at a high school beach party. In the emergency department (ED), he is unresponsive with no gag reflex. When you attempt to orally intubate the patient, you note gold metallic colorations inside his oral cavity. What else are you immediately concerned about clinically?

a. Airway obstruction from anaphylactic shock
b. Cardiac arrest from ventricular dysrhythmias
c. Sedative hypnotic toxicity and respiratory arrest
d. Toxic alcohol poisoning and acute renal failure
e. Traumatic intracranial hemorrhage

Answer: B. This adolescent has likely abused a hydrocarbon (such as toluene from gold spray paint) for recreational and euphoric reasons. Cardiac arrest could occur from primary asphyxia if they huffed using a bag over their head or possible direct cardiotoxicity from the inhaled hydrocarbon resulting in ventricular dysrhythmias.

Inhaled Toxins

Christopher W. Meaden and Lewis S. Nelson

KEY CONCEPTS

- An asphyxiant is any gas that displaces sufficient oxygen from the breathable air. Treatment consists of removal from exposure, supplemental oxygen, and supportive care.
- Highly water-soluble gases produce rapid irritation and predominantly upper respiratory tract effects, such as airway irritation. Poorly water-soluble gases, like phosgene, often produce delayed lower respiratory tract findings, such as bronchospasm or acute respiratory distress syndrome (ARDS).
- Carbon monoxide (CO) poisoning is confirmed by co-oximetry measurement. Cyanide poisoning is treated empirically when cardiovascular instability (e.g., hypotension), altered mental status, or a serum lactate greater than 10 mmol/L are present in a patient with a concerning history, such as a fire victim.
- Hydroxocobalamin is the preferred antidote for most cyanide-poisoned patients due to its efficacy, ease of use, and safety in patient with concomitant CO poisoning. Sodium thiosulfate may be administered concomitantly and may provide additional benefits.
- Patients with hydrogen sulfide poisoning generally respond to removal from exposure and ventilatory support.
- Normobaric oxygen therapy is sufficient to many patients with CO poisoning, but we recommend consultation with a hyperbaric (HBO) facility, poison control center, or medical toxicologist for consideration of HBO therapy under specific conditions. Indications for consultation and HBO treatment include patients with a carboxyhemoglobin (COHb) greater than 25% in the absence of clinical findings, a COHb greater than 15% or signs of fetal distress in pregnancy, or an elevated COHb level with one or more of the following: syncope, coma, altered mental status, abnormal cerebellar function, or a prolonged CO exposure with minor clinical findings.

Inhalational exposure to systemic toxins can be covert and indolent (as in occupational exposure to irritant photochemical smog) or overt and fulminant. The circumstances of the exposure, the presence of combustion or odors, and the number and condition of victims assist in the management. Despite the array of possible toxic inhalants, identification of a specific inhalant is generally unnecessary because therapy is based primarily on the clinical manifestations (Table 148.1).

SIMPLE ASPHYXIANTS

Foundations

Simple asphyxiants are inert and produce toxicity only by displacement of oxygen and lowering the fraction of inspired oxygen (FiO_2). Exposed patients remain asymptomatic if the FiO_2 is normal. Carbon dioxide and nitrogen are exceptions in that both can produce narcosis at elevated partial pressures, even though their predominant toxicological effect is simple asphyxiation. Since the introduction of catalytic converters, most deaths from the intentional inhalation of automotive exhaust result from simple asphyxiation, due to hypoxia, and not from carbon monoxide (CO) poisoning. Emerging methods of suicide secondary to gas inhalation are the inhalation of helium and charcoal burning.[1]

Clinical Features

Acute effects occur within minutes of the onset of hypoxia and are manifestations of ischemia. A fall in the FiO_2 from normal, 0.21 (i.e., 21%), to 0.15 results in autonomic stimulation (e.g., tachycardia, tachypnea, and dyspnea) and cerebral hypoxia (e.g., ataxia, dizziness, incoordination, and confusion). Dyspnea is not an early finding because hypoxemia is not nearly as potent a stimulus to the medullary respiratory center as are hypercarbia and acidemia. Lethargy from cerebral edema occurs as the FiO_2 falls below 0.1 (10%), and life is difficult to sustain at an FiO_2 below 0.06 (6%). Because removal from exposure terminates the simple asphyxiation and allows restoration of oxygenation and clinical improvement, most patients present with resolving symptoms. Failure to improve suggests complications of ischemia (e.g., seizures, coma, and cardiac arrest) and is associated with a poor prognosis.

Differential Diagnoses

Because the presenting complaints offered by most exposed patients are nonspecific (e.g., dizziness, syncope, and dyspnea), the differential diagnosis is extensive. A consistent history, particularly of a setting in which asphyxia is expected to occur such as in an enclosed space, an appropriate spectrum of complaints and a rapid resolution on removal from exposure are generally sufficient to establish the diagnosis.

Diagnostic Testing

Minimally, symptomatic patients do not require chest radiography or arterial blood gas (ABG) analysis. There is no need for toxicology testing unless the asphyxiation was an act of deliberate self-harm, in which in this case, we recommend selected screening for acetaminophen and any other relevant toxin implicated by history, physical examination, or observation. A definitive diagnosis ultimately requires scene investigation by a trained and suitably outfitted team with personal protective equipment (PPE). Determination of the exact nature of the gas is of limited clinical value but may have important public health implications.

Management

Management rarely requires specific therapy other than removal from exposure, administration of supplemental oxygen, and supportive care. Neurologic injury or cardiorespiratory arrest should be managed with standard advanced cardiac life support (ACLS) resuscitation protocols. Psychiatric consultation is indicated when the exposure was an act of deliberate self-harm.

TABLE 148.1 Common Inhaled Toxins

Inhalant	Source or Use	Predominant Class
Acrolein	Combustion	Irritant, highly soluble
Ammonia	Fertilizer, combustion	Irritant, highly soluble
Carbon dioxide	Fermentation, complete combustion, fire extinguisher	Simple asphyxiant; systemic effects
Carbon monoxide (CO)	Incomplete combustion, methylene chloride	Chemical asphyxiant
Chloramine	Mixed cleaning products (e.g., hypochlorite bleach and ammonia)	Irritant, highly soluble
Chlorine (Cl_2)	Swimming pool disinfectant, cleaning products	Irritant, intermediate solubility
Chlorobenzylidene malononitrile (CS), chloroacetophenone (CN)	Tear gas (Mace)	Pharmacologic irritant
Hydrogen chloride	Tanning and electroplating industry	Irritant, highly soluble
Hydrogen cyanide	Combustion of plastics, acidification of cyanide salts	Chemical asphyxiant
Hydrogen fluoride	Hydrofluoric acid	Irritant, highly soluble; systemic effects
Hydrogen sulfide	Decaying organic matter, oil industry, mines, asphalt	Chemical asphyxiant; irritant, highly soluble
Methane	Natural gas, swamp gas	Simple asphyxiant
Methylbromide	Fumigant	Chemical asphyxiant
Nitrogen	Mines, scuba diving (nitrogen narcosis, decompression sickness)	Simple asphyxiant; systemic effects
Nitrous oxide	Inhalant of abuse, whipping cream, racing fuel booster	Simple asphyxiant
Noble gases (e.g., helium)	Industry, laboratories	Simple asphyxiant
Oxides of nitrogen	Silos, anesthetics, combustion	Irritant, intermediate solubility
Oxygen	Medical use, hyperbaric conditions	Irritant, free radical; systemic effects
Ozone	Electrostatic energy	Irritant, free radical
Phosgene	Combustion of chlorinated hydrocarbons	Irritant, poorly soluble
Phosphine	Hydration of aluminum or zinc phosphide (fumigants)	Chemical asphyxiant
Smoke (varying composition)	Combustion	Variable, but may include all classes
Sulfur dioxide	Photochemical smog (fossil fuels)	Irritant, highly soluble

Disposition

Patients with manifestations of mild asphyxia, who recover after removal from the exposure can be discharged after 6 hours of observation if they are asymptomatic or minimally symptomatic with improvements. Patients at risk for complications of hypoxia, such as those presenting with significant signs or symptoms (e.g., altered mental status, coma, chest pain, electrocardiogram [ECG] changes) or with exacerbating medical conditions (e.g., cardiac disease, asthma), should be observed for 24 to 48 hours for the development or progression of post-hypoxic complications.

PULMONARY IRRITANTS

Foundations

The pulmonary irritant gases are a large and diverse group of agents that produce a common toxicological syndrome when they are inhaled in moderate concentrations. Although many of these gases can be found in the home, significant poisoning from consumer products is uncommon because of restrictions designed to reduce their toxicity. However, catastrophes such as the 1984 release of methyl isocyanate in Bhopal, India, which resulted in more than 2000 fatalities and 250,000 injuries, remain as an environmental risk. On a different scale, industrialization has increased ambient concentrations of sulfur dioxide, ozone, and oxides of nitrogen. These irritant gases frequently exacerbate chronic pulmonary disease.

Irritant gases dissolve in the respiratory tract mucus and alter the air-lung interface by invoking an irritant, or inflammatory response.[2] When these gases are dissolved, most of them produce an acid or alkaline product, but several generate oxygen-derived free radicals that produce direct cellular toxicity (Fig. 148.1). The clinical effects of pulmonary irritants can be predicted by their water solubility (see Table 148.1).

Clinical Features

Highly, water-soluble gases rapidly impact the mucous membranes of the eyes and upper airway causing lacrimation, cough and nasal burning. Although their pungent odor and rapid onset of symptoms tend to limit significant exposure, massive or prolonged exposure can result in life-threatening laryngeal edema, laryngospasm, bronchospasm, or acute respiratory distress syndrome (ARDS). In contrast, because poorly water-soluble gases do not readily irritate the mucous membranes at low concentrations and some have a pleasant odor (e.g., phosgene's odor is similar to that of newly mown hay or freshly cut grass), prolonged breathing in the toxic environment allows time for the gas to reach deep into the alveoli. Even moderate exposure causes delayed irritation of the lower airway, alveoli, and parenchyma 2- to 24-hour after exposure. Initial effects may be mild, only to progress to overt respiratory failure and delayed ARDS during the ensuing 24 to 36 hours.[3] Gases with intermediate water solubility tend to produce syndromes that are a composite of the clinical features manifested with the other gases, depending on the extent of exposure. Massive exposure is most often associated with rapid onset of upper airway irritation and more moderate exposure with delayed onset of lower airway symptoms.

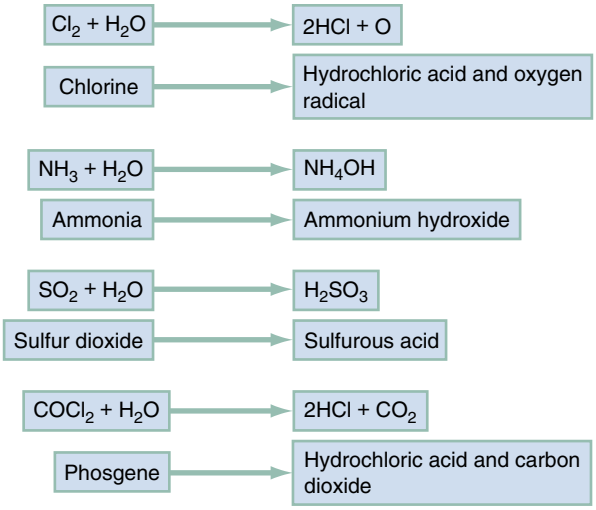

Fig. 148.1 Sample Reactions of Pulmonary Irritants Reacting With Water in the Lung. *Cl_2,* Chlorine; *CO_2,* carbon dioxide; *$CoCl_2$,* cobalt (II) chloride; *H_2O,* water; *H_2SO_3,* sulfurous acid; *HCl,* hydrochloric acid; *NH_3,* ammonia; *NH_4OH,* ammonium hydroxide; *O,* oxygen; *SO_2,* sulfur dioxide.

Differential Diagnoses

The typical symptoms of pulmonary exposure to an irritant gas are bronchospasm, cough, chest tightness, and acute conjunctival irritation. Presentation may mimic non-toxicological causes of pulmonary disease, but the history generally confirms the exposure to the irritant (Box 148.1). History may be particularly important if the patient presents with severe or advanced findings, such as ARDS, which can occur after many physiologic insults, including trauma and sepsis.

Diagnostic Testing

Inhalation of respiratory irritants may affect the upper airway, the lower airways and lungs, or both. Upper airway evaluation proceeds as described in the following Management section. Radiographic and laboratory studies are not useful in the evaluation of upper airway symptoms.

Oxygenation and ventilation are assessed by serial chest auscultation, pulse oximetry, and continuous capnography. Chest radiography is indicated for patients presenting with cough, dyspnea, hypoxia, or abnormal findings, such as rales or wheezes, on pulmonary examination. ABGs are reserved for patients who are more severely symptomatic, have hypoxia, or do not improve readily with oxygen therapy.

In general, it is neither possible nor necessary to test for the specific agent. There are no clinical tests that will differentiate the irritant to which a patient was exposed, although testing at the site by public health authorities may be performed for epidemiologic purposes. Knowing that an agent is highly water soluble will shorten the observation period for symptom development, whereas patients exposed to poorly water-soluble agents will require a more prolonged period of observation.

Management

Patients with no upper airway symptoms, normal voice, and no evidence of irritation (erythema) or burns on examination of the oral pharynx require no further upper airway evaluation but should be reexamined if symptoms or signs develop after the initial evaluation. Those with evidence of tissue irritation, such as oral or tongue edema, altered voice (raspy or muffled), stridor, or significant odynophagia or dysphagia require early examination by laryngoscopy and if severe, should undergo early intubation because rapid progression of these injuries is expected. Laryngoscopy may be performed using a flexible laryngoscope, rigid video, or conventional laryngoscope with appropriate topical anesthesia and sedation as indicated (see Chapter 1). Patients with evidence of mild irritation of the larynx or supralaryngeal area (erythema, no edema, normal glottis) may be observed. Those with more severe findings are considered not to require early intubation, such as erythema with mild edema, should undergo repeat examination from 30 to 90 minutes after the initial examination or earlier, if symptoms or signs are worsening.

Bronchospasm generally respond to inhaled beta-adrenergic agonists. Data regarding the use of corticosteroids are limited and do not support clinical benefits in humans. Therefore, corticosteroids are not recommended unless the patient has underlying reactive airways disease.[3–5]

Patients exposed to chlorine or hydrogen chloride gas receive symptomatic relief from nebulized 2% sodium bicarbonate solution.[6] This solution is prepared by diluting a given volume of standard 8.4% sodium bicarbonate solution with three equivalent volumes of sterile water and administering it in 3 to 5 mL aliquots with standard nebulizer equipment. There are no studies on the recommended dosing regimen, but if successful after its first use, providing it every 30 minutes as needed for symptom relief, for up to 6 hours, is a reasonable approach. Nebulized bicarbonate will not alter the inflammatory cascade so it will not have significant effect on the progression of pulmonary injury. ARDS, if identified, is managed as described in Chapter 2.

BOX 148.1 Differential Diagnoses for Pulmonary Irritant Exposure

1. Acute respiratory distress syndrome
2. Congestive heart failure
3. Pulmonary embolism
4. Pneumonitis (e.g., aspiration, chemical, viral)
5. Asthma exacerbation
6. Metal fume fever
7. Inorganic dust exposure
8. Chronic obstructive pulmonary disease exacerbation
9. Allergic response/hypersensitivity pneumonitis

Disposition

Patients exposed to highly water-soluble gases (see Table 148.1) can be discharged if they are asymptomatic or symptoms are minimal and improving. After exposure to intermediate or poorly water-soluble gases, asymptomatic patients should be observed for increasing dyspnea for 6 hours before final disposition. Regardless of the solubility, patients with prolonged gas exposure, exposure to highly concentrated gases, exposure in a closed space or those with high-risk medical conditions (e.g., underlying pulmonary disease, extremes of age, and poor follow-up) should be observed in an inpatient setting or observation unit for 24 hours. Patients with upper airway findings on examination should be observed in the emergency department (ED) or an intensive care unit (ICU) until there is clear evidence that the process is subsiding. All discharged patients should receive instructions for signs and symptoms of pulmonary deterioration.

SMOKE INHALATION

Foundations

According to a 2019 report by the National Fire Protection Association, an average of 2,620 deaths and 11,220 injuries occur per year in residential fires in the United States.[6] Many of these casualties do not

suffer serious cutaneous burns but rather die of smoke inhalation. This is a variant of irritant injury in which heated particulate matter and adsorbed toxins injure normal mucosa. In addition, CO and cyanide are systemic toxins often considered in conjunction with the smoke inhalation syndrome because of their common origin.

Even at temperatures between 350°C and 500°C, air has such a low heat capacity that it rarely produces lower airway damage. The greater heat capacity of steam (approximately 4000 times than that of air), or heated soot suspended in air (i.e., smoke) can transfer heat and cause injury deep within the respiratory tract.

The nature of the fuel determines the composition of its smoke, and because fires involve variable fuels and burning conditions, the character of fire smoke is often undefined to the emergency clinician. Irritant toxins produced by the fire are adsorbed onto carbonaceous particles that are deposited in the airways and damage the mucosa through mechanisms similar to those of the irritant gases.

Clinical Features

Thermal and irritant-induced laryngeal injury may produce cough, voice alteration, or stridor, but these findings are often delayed. Soot and irritant toxins in the airways can produce early cough, dyspnea, and bronchospasm. Subsequently, a cascade of airway inflammation results in ARDS with failure of pulmonary gas exchange. The time between smoke exposure and the onset of clinical symptoms is highly variable and dependent on the nature of the exposure. Deaths that occur rapidly after exposure are caused by asphyxia, airway compromise, or metabolic poisoning (e.g., CO and cyanide). Singed nasal hairs and soot in the sputum suggest substantial exposure, but significant exposure and injury can occur with neither of these being present.

Differential Diagnoses

With the obvious exposure history to smoke inhalation, the differential diagnosis is limited, however, cyanide and carbon monoxide should always be considered as discussed below. Although it is often unclear whether smoke inhalational injuries are thermal or irritant, the differentiation is clinically irrelevant, as the management approach remains the same. Concomitant physical injuries such as "burns" or trauma may complicate the metabolic picture.

Diagnostic Testing

Airway patency should be evaluated early. Airway management is as described earlier for inhaled pulmonary irritants. If evidence of significant airway exposure is present, such as carbonaceous sputum or a hoarse voice, the airway should be examined by laryngoscopy and secured if signs of injury or compromise are noted. Pulmonary injury is assessed through auscultation and chest radiography for signs of alveolar filling or hyperinflation. Oxygenation should be assessed by co-oximetry, because blood gas analysis and pulse oximetry may be inaccurate in CO-poisoned patients (see discussion in the Carbon Monoxide section later). Co-oximetry will provide a blood carboxyhemoglobin (COHb) level, and we recommend testing for every patient, unless the smoke exposure was brief and in an open space. Metabolic acidosis, particularly when serum lactate concentration is greater than 8 mmol/L and the COHb is not significantly elevated, suggests concomitant cyanide poisoning.[7]

Management

The acute management of a patient with smoke inhalation, is identical to that with other irritant inhalational injuries. Early assessment of the airway and early intubation, as indicated, are critical because deterioration may be occult and rapid. Patients with no upper airway symptoms, normal oropharyngeal, nasopharyngeal examination, no voice alteration, and normal swallowing, may be observed and reevaluated if symptoms develop. Patients with symptoms or findings should be evaluated early stage by laryngoscopy. Simply observing these patients for deterioration can result in airway compromise requiring rapid and potentially difficult airway intervention. Despite a lack of evidence supporting their effectiveness, inhaled beta-adrenergics are widely used for patients with dyspnea or wheezing. Because these agents may provide benefit with little likelihood of harm, we recommend at least one dose of a beta-adrenergic agonist for patients with symptoms of bronchospasm. Both subjective (patient-reported) and objective (respirometry) assessment may be used to determine whether these agents appear to benefit a particular patient, and guide the use of additional doses. Optimal supportive care and maintenance of adequate oxygenation (e.g., suctioning and pulmonary toilet) are the most important aspects of care. Bronchoscopy with bronchoalveolar lavage is frequently recommended to clear debris and toxins from the distal airways. We do not recommend the use of corticosteroids, by inhalation or systemically, because there is no evidence of clinical benefit and they are potentially harmful in patients with cutaneous burns. Ibuprofen, antioxidants, exogenous surfactant, and high-frequency ventilation yield, variably improved survival in experimental and clinical trials but none are considered as standard care.[8] Antibiotics should be used only in patients with suspected bacterial infection.

Disposition

Patients who are intubated should be admitted to the ICU or burn unit, depending on the extent of the cutaneous burns or respiratory tract injury. Patients with upper airway symptoms or signs, but without concerns for airway loss, should undergo repeat airway examination for 6 hours, preferably in an ICU. Patients with prolonged closed-space exposure or lower airway findings, such as rales or carbonaceous sputum, should be admitted to an ICU, and observed for at least 24 hours while assessing for the development of signs of lower respiratory tract injury. Transfer considerations to a higher level of care at another institution or to a burn center should be based on local resources, consultation with the specialty center, an assessment of the risks of transfer, and existing protocols. Patients that should be considered for transfer include those with burns greater than 10 percent body surface area, burns that involve the face, hands, genitalia, perineum, or major joints, and those with third degree burns. See Chapter 54 for further discussion.

CYANIDE AND HYDROGEN SULFIDE

Foundations

Instead of directly affecting the airway and lungs, these poisons cause effects at the cellular level. Hydrogen cyanide is a gas with many commercial uses, particularly in synthetic fiber manufacture and fumigation. Gaseous hydrogen cyanide is occasionally noted to have the odor of bitter almonds. Cyanide in its salt form (e.g., sodium or potassium) is important in metallurgy (e.g., jewelry) and photography and is much safer to work with because of its low volatility. When cyanide salts are dissolved in water, hydrogen cyanide, a gas, can be produced, particularly under acidic conditions. Cyanide is metabolically released *in vivo* from precursors (cyanogens) such as amygdalin, found in apricot and other *Prunus* species pits, and from nitriles, a group of chemicals with many commercial uses.

H_2S poisoning most often occurs in petroleum refinery and sewage storage tank workers. A more recent means of suicide involves generation of H_2S from sulfur-containing products, such as detergent, mixed with acids in an enclosed space, such as an automobile.[9] On occasion, well-intentioned but ill-prepared pre-hospital rescuers become victims

emphasizing the need for proper training and equipment. H_2S has a noxious odor similar to that of a rotten egg, which becomes unnoticeable with extremely high concentrations or prolonged exposure (a process called "olfactory fatigue").

Gaseous cyanide is rapidly absorbed after inhalation and is immediately distributed to the body tissues. Inhibition of oxidative metabolism by binding to cytochrome c oxidase (or Complex IV) of the electron transport chain within the mitochondria which occurs within some seconds. The poisoned tissue rapidly depletes its adenosine triphosphate (ATP) reserves and ceases to function (Fig. 148.2). Cyanide has no evident effect on other oxygen-binding enzyme systems, most notably hemoglobin. This is probably explained by the oxidation state of its iron moiety; cyanide binds only to oxidized iron (Fe^{3+}), whereas deoxyhemoglobin contains reduced iron (Fe^{2+}).

H_2S exerts its toxic effects both as a pulmonary irritant, and as a cellular poison. Its deadly metabolic effects are produced by a mechanism identical to that of cyanide.[10] However, H_2S's spontaneous dissociation from the mitochondria is rapid, allowing most patients to survive after brief exposure.

Clinical Features

Tissue hypoxia occurs within minutes, with the exact onset dependent on the route, dose or concentration, and nature of the exposure. Dysfunction of the heart and the central nervous system that is the organ systems most sensitive to hypoxia and it is a characteristic of cyanide poisoning, manifested as coma, seizures, dysrhythmias, and cardiovascular collapse. Metabolic acidosis develops as a result of diffuse cellular dysfunction and this is associated with an elevated serum lactate concentration. Despite popular belief, cyanosis is not a characteristic clinical finding. Given the extreme toxicity of cyanide, mild acute poisoning is uncommon. Patients with acute H_2S poisoning have similar clinical manifestations, although generally recover by the time of arrival to the ED due to its spontaneous mitochondrial dissociation.

Because cyanide and H_2S prevent tissue extraction of oxygen from the blood, the oxygen content of venous blood remains high, approaching that of arterial blood. Clinically, this may appear as the "arterialization" or brightening of venous blood to resemble arterial blood. A comparison of the measured (by co-oximetry) venous and arterial oxygen contents may assist in the diagnosis of cyanide poisoning. A

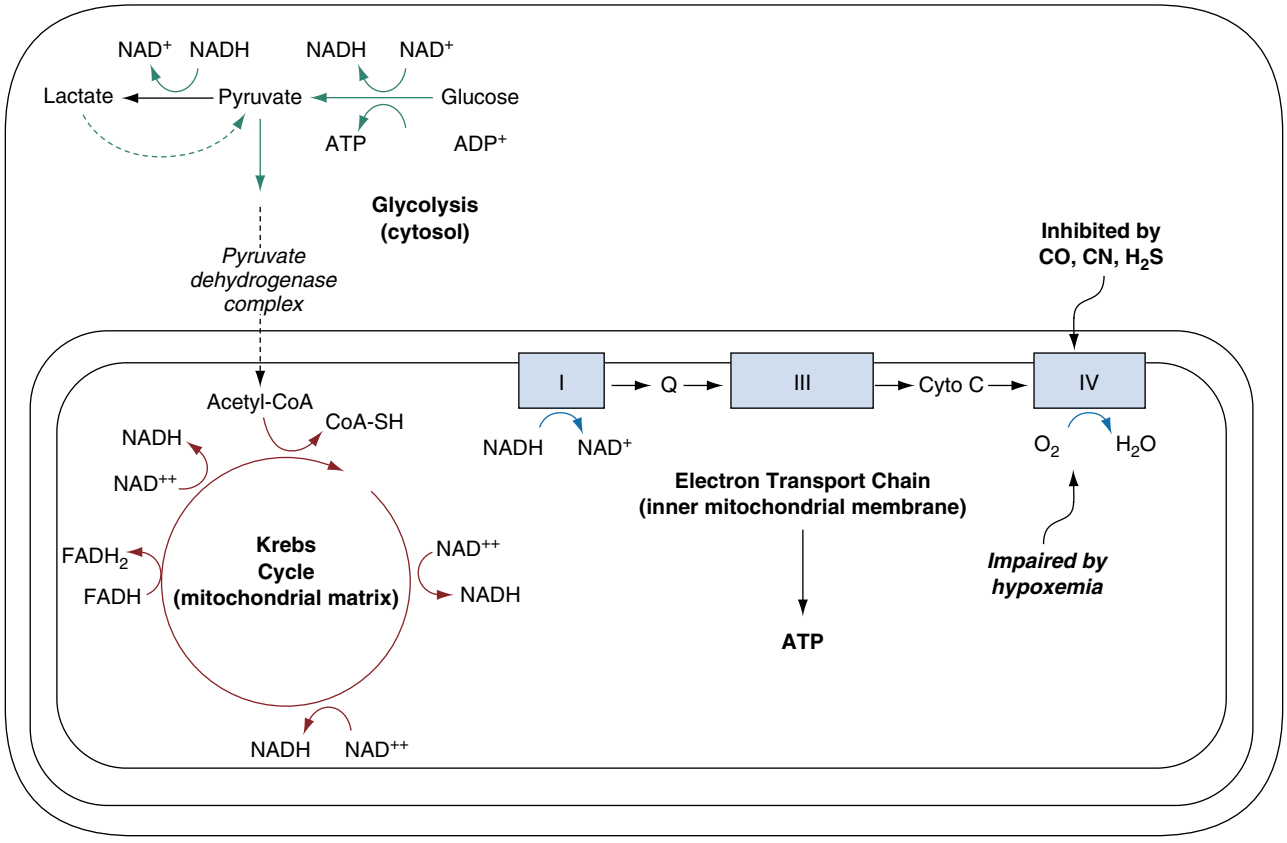

Fig. 148.2 The Complete Metabolism of a Molecule of Glucose to Energy Is Complex but Occurs in Two Broad Steps. The first step, anaerobic glycolysis, which occurs in the absence of oxygen, generates pyruvate, nicotinamide adenine dinucleotide *(NADH),* and adenosine triphosphate *(ATP).* Pyruvate then enters the Krebs cycle to create potential energy in the second step, through the reduction of NAD^+ to NADH and flavin adenine dinucleotide *(FADH)* to $FADH_2$. Fatty acid metabolism and protein metabolism produce $FADH_2$ and NADH, which also requires conversion to ATP. These conversions occur in the mitochondrial membrane, where oxidative phosphorylation is linked to the electron transport chain, the last phase of which involves the transfer of electrons to molecular oxygen to form water. Cyanide *(CN),* hydrogen sulfide *(H_2S),* and carbon monoxide *(CO)* bind to and inhibit the last step, the Fe^{3+}-containing cytochrome-aa_3 oxidase in Complex IV, preventing further oxidation of NADH. This in turn hinders the Krebs cycle because the required regeneration of NAD^+ does not occur, and glucose metabolism is forced to end at pyruvate. For energy production to continue, NADH donates its electrons to pyruvate, creating lactate, and sufficient NAD^+ is regenerated for glycolysis to progress. Ultimately, energy failure and end-organ damage occur. *CoA,* Coenzyme A; *H_2O,* water; *IV,* intravenous; *O_2,* oxygen.

low arterial-venous oxygen difference is suggestive, but not pathognomonic of cyanide poisoning and its absence does not exclude the diagnosis.

Patients surviving cyanide or H_2S poisoning may have persistent or delayed-onset neurologic syndromes identical to those noted in patients with CO poisoning or post-cardiac arrest.

Differential Diagnoses

Rapid cardiovascular collapse, hypotension, bradycardia, ventricular dysrhythmias, and seizures in a fire victim should suggest profound hypoxia, cyanide poisoning, severe CO poisoning, or a combination.[11] In patients without an exposure history, the differential diagnosis is vast and includes CO poisoning, asphyxiants, and other toxicologic and non-toxicologic causes.

Diagnostic Testing

Unlike with CO poisoning, pulse oximetry and ABG analysis are accurate in cases of isolated cyanide or H_2S poisoning. An increased anion gap metabolic acidosis and hyperlactatemia are usually present. A lactate concentration greater than 8 mmol/L is highly predictive of cyanide poisoning in the appropriate clinical context.[6,12] CO and cyanide are fellow travelers, so an elevated COHb level in a fire victim warrants consideration of concomitant cyanide poisoning. The presence of severe clinical findings and metabolic acidosis with a low COHb level is particularly concerning for cyanide poisoning. The result of a blood cyanide determination is usually delayed, to be of use in the ED, but it can be useful for confirmation and documentation purposes. Technology exists for immediate cyanide determination but is not widely available. Testing for H_2S is not clinically available, and support for the diagnosis of H_2S exposure would come primarily from on-scene testing.

Management

The diagnosis of cyanide poisoning usually cannot be confirmed rapidly, and therapy is almost always empirical. Treatment should not be delayed pending the COHb level or other laboratory tests in patients with suspected acute cyanide poisoning. Patients removed from a fire environment who have cardiovascular instability, altered mental status, or a serum lactate greater than 8 mmol/L should receive cyanide treatment regardless of the COHb concentration.

Hydrogen Cyanide

The accepted goal of therapy is to reactivate the cytochrome oxidase system by providing an alternative binding site for the cyanide ion. There are two types of antidotal therapy for cyanide. The preferred antidote is hydroxocobalamin, which takes advantage of the high affinity of cobalt for cyanide. On binding of cyanide, cyanocobalamin, or vitamin B_{12}, is formed. The initial dose is 5 g intravenously (IV) over 15 minutes for adults and 70 mg/kg IV for children, up to an adult dose, and can be repeated once if an incomplete response is noted. Thiosulfate, 12.5 g in adults (250 mg/kg in children), can be considered in combination with hydroxocobalamin (via a separate IV line) in severe cases of cyanide toxicity, but the benefit of this is not well established. The known adverse effects of hydroxocobalamin are mild and include hypertension in those not cyanide poisoned and a bright red discoloration of the patient's skin and urine. Inexperienced clinicians often mistake this side effect as an "allergic" reaction to the drug. The drug's red color can interfere with certain spectrophotometric laboratory tests, including COHb and possibly serum lactate. Therefore, blood samples should be obtained before the administration of the first dose of hydroxocobalamin.

The cyanide antidote kit, an alternative therapy for toxicity, contains three components (amyl nitrite, sodium nitrite, and sodium thiosulfate). The cyanide antidote kit produces a high-affinity source of ferric ions (Fe^{3+}) for cyanide to bind. Its administration can be impractical or dangerous, particularly for nonhospital providers due to the means by which it is administered (i.e., amyl nitrite capsules are crushed between the fingers and placed under the victim's nose and may be inadvertently inhaled by rescuers). Because animal models and clinical evidence in humans demonstrate that sodium thiosulfate alone in combination with oxygen offers substantial protection, this should be the initial therapy administered by paramedics and during mass poisoning events if ample supplies of hydroxocobalamin are not available. Antidotes should not completely replace other resuscitation measures, including high-flow oxygen and removal of the patient from the source of exposure.

Methemoglobin (MetHb) formation results from the nitrites found in the kit. Inhaled amyl nitrite and IV sodium nitrite are both effective, but amyl nitrite should only be administered to patients in the absence of IV access. Caution should be taken to minimize the provider's exposure to the volatile amyl nitrite because dizziness, hypotension, or syncope may occur. The dose of sodium nitrite for a previously healthy adult is 300 mg (10 mL of a 3% solution) given over 2 to 4 minutes. Dosing instructions for anemic patients and children are supplied with the kit. Cyanide has a high affinity for MetHb and readily leaves cytochrome oxidase to form cyanmethemoglobin, which is metabolically inactive. Additionally, the nitrites are vasodilators, and this may be mechanistically important in their therapeutic effect by enhancing blood flow to the liver for clearance. However, hypotension may complicate a rapid infusion.

Both free serum cyanide and cyanmethemoglobin are converted by sulfur transferase (rhodanese) to thiocyanate, which is renally eliminated. Because the rate of rhodanese function increases with the availability of a sulfur donor, the third component of the antidote kit is the sulfur-containing compound sodium thiosulfate. The adult dose is 12.5 g IV, which is provided as 50 mL of a 25% solution (250 mg/kg sodium thiosulfate up to an adult dose in children). In general, few if any adverse effects are associated with proper doses. The nitrite components of the cyanide antidote kit should be avoided in fire victims with known or suspected simultaneous CO and cyanide poisoning because both CO and MetHb reduce oxygen delivery to the tissues. The use of the thiosulfate component alone in this subset of patients is recommended if hydroxocobalamin is not available (Box 148.2).

There are insufficient clinical data to fully support the use of one cyanide antidote over the other. We recommend hydroxocobalamin because of its ease of use and presumed superior safety in CO-poisoned fire victims.[12] Direct comparison to thiosulfate alone in this population has not been and likely never will be performed, but animal models and case reports suggest that hydroxocobalamin is superior.[13] When possible, we recommend administering both hydroxocobalamin and thiosulfate, with the priority given to hydroxocobalamin, and not administering them through the same IV due to incompatibility.[14]

Hydrogen Sulfide

Because the bond between H_2S and cytochrome oxidase is rapidly reversible, removal from exposure and standard resuscitative techniques are usually sufficient to reverse H_2S toxicity. Use of the nitrite portion of the cyanide antidote kit is suggested to create MetHb for patients with severe or prolonged toxicity. Sodium thiosulfate is unnecessary because H_2S is not detoxified by rhodanese. Hydroxocobalamin also binds sulfide, and has been shown to decrease sulfide concentrations, but has not been shown to be clinically effective for H_2S poisoning. There is no defined role for hyperbaric oxygen (HBO) therapy in cases of H_2S toxicity.

BOX 148.2 Cyanide Antidotes

Hydroxocobalamin[a]
Adults: 5 g IV over 15 min[b]
Children: 70 mg/kg up to 5 g[b]

Cyanide Antidote Kit (Two Parts)
1. MetHb inducers[c]
   Amyl nitrite (inhalational, prehospital) *or*
   Sodium nitrite ($NaNO_2$) 3% solution IV over 2–4 min IV
      Adults: 10 mL (300 mg)
      Children: See labeling information with kit
2. Cyanide detoxification
   Sodium thiosulfate ($Na_2S_2O_3$) 25% solution IV
      Adults: 50 mL (12.5 g)
      Children: 250 mg/kg up to 12.5 g

[a] Thiosulfate (see text) can be concomitantly administered for patients with severe clinical effects.
[b] A second dose may be administered in patients with an incomplete response.
[c] Withhold nitrites if an elevated blood carboxyhemoglobin (COHb) is suspected to be present (e.g., fire victims).
IV, Intravenous; *MetHb,* methemoglobin.

Disposition

Patients with symptomatic cyanide or H_2S poisoning should be admitted to a critical care unit and observed for complications of tissue hypoxia. These patients should also be evaluated for delayed neuropsychiatric findings.

CARBON MONOXIDE

Foundations

CO remains a common cause of morbidity and mortality worldwide with an estimated incidence of 137 cases per million annually.[15] CO is generated through incomplete combustion of virtually all carbon-containing products. Structure fires (e.g., wood), clogged vents for home heating units (e.g., methane), and use of gasoline-powered generators indoors are examples of the myriad means through which patients are poisoned by CO. Appropriate public health authorities (e.g., fire department and Department of Health officials) should be informed immediately about any potential public health risks that are identified during the care of a CO-exposed patient.

CO interacts with deoxyhemoglobin to form COHb, which cannot carry oxygen. Hemoglobin binds CO tightly and forms a complex that is only slowly reversible. This allows the exposed individual to accumulate CO, even with exposure to low ambient concentrations. Although binding of hemoglobin is historically described as the mechanism of CO poisoning, it is relevant only in profoundly CO-poisoned patients because a simple reduction in oxygen-carrying capacity due, for example, to anemia would not cause similar symptoms. However, for pregnant patients, the fetus is at increased risk because it is relatively hypoxic compared with the mother. CO shifts the oxyhemoglobin dissociation curve to the left in such a way that even if oxygen is bound to hemoglobin, its unloading to tissues is impaired. In muscle, CO binds myoglobin, preventing its normal function. This likely contributes to the development of atraumatic rhabdomyolysis.

CO affects cellular oxygen use at the tissue level. Similar to cyanide, it inhibits the final cytochrome complex involved in mitochondrial oxidative phosphorylation. This results in a switch to anaerobic metabolism and ultimately in cellular death.

Delayed-onset neurologic complications may be a manifestation of the hypoxic insult, and reperfusion injury and lipid peroxidation related to platelet-induced nitric oxide release may play a significant role.[16] By alteration of the platelet-associated nitric oxide cycle, the microvascular endothelium of the central nervous system undergoes free radical–mediated injury, resulting in localized inflammation and dysfunction. Animal models and human reports suggest that loss of consciousness during CO exposure is a risk factor for the development of delayed neurologic sequelae.

Clinical Features

Severe CO toxicity and cyanide poisoning have identical clinical presentations of chemical asphyxia: altered mental status, including coma and seizures; unstable vital signs, including hypotension and cardiac arrest; and metabolic acidosis. Unlike cyanide poisoning, however, mild CO poisoning occurs frequently, with headache, nausea, vomiting, dizziness, myalgia, and confusion as common presenting complaints. The neurological assessment in these patients may yield normal findings or may demonstrate focal findings or subtle perceptual abnormalities. The often-touted "cherry-red" skin color in patients with cyanide or CO poisoning is a postmortem finding and is not noted in living patients.

Delayed neurologic sequelae is a well-documented phenomenon after CO exposure; the frequency varies from 10% to 30%, depending on the definition and the sensitivity of the test used for their detection. Patients have a variety of neurologic abnormalities after an asymptomatic period, ranging from 3 to 240 days.[17] The delayed neurologic effects can be divided into those with readily identifiable neurologic syndromes (e.g., focal deficits and seizures) and those with primarily psychiatric or cognitive findings (e.g., apathy and memory deficits). Although the delayed neuropsychiatric sequelae require formal neuropsychiatric testing to be detected, the impact of these abnormalities on the patient's daily function may be significant. Risk factors that predict the development of delayed neurologic sequelae include extremes of age and loss of consciousness. Because most CO-poisoned patients reaching the ED survive with minimal intervention, prevention of delayed neurologic and neuropsychiatric sequelae is a major goal of therapy.

Differential Diagnoses

Mild-to-moderate CO poisoning is a difficult diagnosis to establish clinically, and patients are easily misdiagnosed as having a benign headache syndrome or viral illness. CO poisoning should be suspected in patients with persistent or recurrent headache, especially if a group of people have similar symptoms or if the headache improves soon after the person leaves an exposure site.

Patients with severe CO poisoning may present with coma or cardiovascular collapse, both of which have a broad toxicologic, metabolic, infectious, medical, and traumatic differential diagnosis. The medical history, physical examination, and standard laboratory testing are easily able to exclude many of these diagnoses. Given the relatively protean manifestations of CO poisoning and the potentially serious consequences of misdiagnosis, particularly if the patient returns to the contaminated environment, we recommend specific measurement of CO by co-oximetry of an arterial or venous blood sample when the clinician considers CO poisoning as a possible cause for the patient's presentation.

Diagnostic Testing

Suspicion of CO poisoning relies on the history and physical examination findings. Co-oximetry, an inexpensive and readily available spectrophotometric laboratory method that can distinguish between normal hemoglobin, COHb, and MetHb, confirms exposure to CO.

Other laboratory tests only exclude other diagnoses. Severity of poisoning may not correlate with COHb levels because prolonged exposure to low levels can be fatal with a low measured COHb, but a brief, high-concentration exposure can produce a high COHb level with minimal symptoms.

The standard blood gas (ABG or venous blood gas [VBG]) analysis is a poor screening test for CO poisoning other than to identify the presence of a metabolic acidosis and a normal partial pressure of oxygen (Po_2). CO impairs binding of oxygen to hemoglobin but does not affect the amount of oxygen dissolved in blood. Because the Po_2 is a measure of dissolved oxygen, it is normal in patients with CO poisoning. The calculated oxygen saturation will be normal even in the presence of significant CO poisoning. Most pulse oximeters are unable to identify CO poisoning because COHb is misinterpreted as oxyhemoglobin. Newer pulse co-oximeters are capable of noninvasively detecting COHb as well as methemoglobinemia.[18]

Management

Treatment begins with oxygen therapy, which serves two purposes. First, the half-life of COHb is inversely related to the Po_2; it can be reduced from approximately 5 hours at room air to 1 hour by providing supplemental 100% oxygen. HBO therapy (at 3 atmospheres) further reduces the half-life to approximately 30 minutes. Alteration of the kinetics of COHb is relevant only to patients with extremely elevated COHb levels (e.g., over 50%). Even then, only a minority of patients can be treated sufficiently and rapidly enough for HBO to be lifesaving. A sufficient Po_2 can be achieved with HBO to sustain life in the absence of adequately functioning hemoglobin, but this is helpful only when the COHb is extremely elevated. Thus, the primary indication for HBO is not to prevent mortality but rather to prevent delayed neurologic sequelae.

There is controversy regarding the benefit of HBO because the effect is not immediate (as with life and death) and outcome assessment requires close follow-up and sophisticated testing. Several evidence-based reviews have asserted the limited role for HBO, although this conclusion is disputed.[17] Evidence suggests that HBO helps prevent the development of delayed neuropsychiatric and neurologic sequelae after CO poisoning, with a decrease of delayed neurologic sequelae from approximately 12% to less than 1% with its use. When HBO administration is delayed for more than 6 hours after exposure, its efficacy appears to decrease, suggesting the need for rapid implementation. A meta-analysis performed on randomized controlled trials showed a lower risk of impaired memory in patients who received HBO versus those who did not. The meta-analysis also revealed that HBO treated patients had an improvement in their neuropsycholic scores of block design and trail making when compared to patients treated with normobaric oxygen.[19]

Given the implications of poor tissue oxygenation with COHb and the relative safety of HBO, a patient with a neurologic abnormality or cardiovascular instability (e.g., syncope, altered mental status, seizures, myocardial ischemia, and dysrhythmias) is a candidate for HBO (Box 148.3). This should be tempered by the need for transport, often over long distances, for HBO therapy to be obtained. The decision about HBO therapy should not be strictly based on the COHb level, which correlates only weakly with poisoning. Patients with prolonged low-level exposure have a "soaking" phenomenon, in which extremely high tissue concentrations of CO occur with relatively low COHb levels. Thus, patients with consequential clinical findings that are considered to be related to CO poisoning should receive HBO despite relatively low COHb levels.

In addition to the use of HBO in patients with obvious signs of tissue hypoxia or syncope, we recommend referral for HBO for asymptomatic patients with a COHb level of 25% or greater. The decision to perform HBO therapy should be made in the context of transport and other medical requirements, including need for transfer to a burn center which may delay or prevent HBO therapy unless implemented at the burn center. If doubt remains, consultation with a medical toxicologist, poison center, or the HBO treatment specialist will guide decision-making. Because fetal CO poisoning is associated with dysfunction and death and HBO therapy appears to be safe in pregnancy, we recommend HBO therapy in a pregnant woman with a COHb level of 15% or greater regardless of symptoms. Further study is still needed to define the optimal duration, pressure, and frequency, as well as the cost-benefit and risk-benefit relationships of HBO therapy. At this time, discussion with a regional HBO center or poison control center is advisable. Patients with elevated COHb levels who do not require HBO should be treated with normobaric oxygen delivered by a tight-fitting non-rebreather face mask at a flow rate of 15L/min until the symptoms resolve and the COHb levels fall to normal.

BOX 148.3 Recommendations for Hyperbaric Oxygen

Carboxyhemoglobin (COHb) (varies by local standards) independent of clinical findings
- >25% with normal clinical findings
- >15% in pregnancy or fetal distress

or an elevated COHb with one or more of the following findings:
- Syncope
- Coma
- Seizure
- Altered mental status (GCS < 15) or confusion
- Abnormal cerebellar function
- Prolonged CO exposure with minor clinical findings ("soaking")

CO, Carbon monoxide; *GCS,* Glasgow Coma Score.

Simultaneous Carbon Monoxide and Cyanide Poisoning (Fire Victims)

Concurrent toxicity from CO and cyanide is widely reported and a major factor in the mortality associated with smoke inhalation.[20] Victims who present with coma and metabolic acidosis can have severe CO poisoning, cyanide poisoning, or both. Nitrite-induced methemoglobinemia, which further reduces the tissue oxygen delivery, may be detrimental to patients with elevated COHb levels or otherwise impaired oxygen delivery.

Sodium thiosulfate, administered without nitrites, or hydroxocobalamin should be given to all smoke inhalation victims with coma, hypotension, severe acidosis, or cardiovascular collapse in whom cyanide poisoning cannot be rapidly excluded.

Disposition

The decision to transfer a patient to an HBO facility should consider the time delay to therapy, patient issues (e.g., hemodynamic instability, burns, and age), and potential transport-related complications. Patients with minor clinical effects that resolve can be discharged with dedicated follow-up. Those with signs of end organ effects, such as chest pain or altered mental status, if not transferred for HBO, should be admitted for observation. All patients exposed to CO require close follow-up for delayed neurologic sequelae.

CHAPTER 148: QUESTIONS AND ANSWERS

1. A laboratory worker is brought to the emergency department (ED) after being found unconscious. His colleague reports that the patient was found in his vehicle with its windows closed which he was using to transport dry ice. The patient is now awake but reports feeling tired and confused. He has no other complaints. His vital signs and physical examination are normal. What toxin-specific diagnostic test should be ordered for this patient?

a. Carboxyhemoglobin (COHb)
b. Chest radiograph
c. Electrocardiogram
d. Methemoglobin (MetHb)
e. No tests are indicated

Answer: e. Carbon dioxide is primarily a simple asphyxiant, meaning that its major consequential adverse effects stem from its displacement of oxygen in the lungs. Once patients are removed from the source, they generally recover completely. Patients should be observed until this time. COHb measurement would be indicated if there is a suspicion of carbon monoxide (CO) exposure. Chest radiographs should be ordered if patients have pulmonary complaints after an unknown exposure. Electrocardiograms should be ordered if patients are exposed to known cardiac toxins. MetHb levels should be checked when there is suspicion for oxidative stress on the red blood cells.

2. A 32-year-old woman presents following exposure to an irritant gas at her job site. She reports cough, burning eyes, and shortness of breath. She has mild tachypnea, with the remainder of her vital signs within normal limits. Her oxygen saturation is 96% on room air. She is noted to have stridor on physical examination. What is the preferred method to evaluate her upper airway symptoms?

a. Arterial blood gas (ABG)
b. Chest radiograph
c. Computed tomography of the neck
d. Fiberoptic laryngoscopy
e. Soft tissue neck radiograph

Answer: d. Fiberoptic or direct laryngoscopy is the preferred method to evaluate upper airway symptoms after exposures to irritant gases. Radiographs and laboratory tests have no role and should not influence the decision to provide a definitive airway. Symptoms can progress rapidly, so patients with upper airway symptoms require either placement of a definitive airway or close observation with frequent serial examinations.

3. A 52-year-old man is brought to the emergency department (ED) after being rescued from a house fire. He has not suffered any cutaneous burns. He complains of a sore throat, hoarse voice, and cough. Vital signs are normal. Physical examination reveals soot in his oropharynx and carbonaceous sputum. What therapy should be instituted first?

a. Endotracheal intubation
b. Intravenous (IV) methylprednisolone
c. Nebulized albuterol
d. Nebulized sodium bicarbonate
e. Saline bronchoalveolar lavage

Answer: a. Endotracheal intubation should be performed early in patients with signs and symptoms of significant airway burns (as with this patient). Corticosteroids are not beneficial and can worsen associated injuries. Inhaled beta-agonists are commonly used, but there is no evidence of improved outcome. Inhaled sodium bicarbonate plays no role in the management of smoke inhalation. Bronchoalveolar lavage can be performed if there is suspicion of inhaled debris or toxins, but the airway should first be secured.

CHAPTER 148: QUESTIONS AND ANSWERS—cont'd.

4. A 47-year-old woman is brought to the emergency department (ED) after being rescued from a house fire. She was found unconscious at the scene and intubated before arrival. Her vital signs are significant for hypotension and tachycardia. Physical examination is significant for soot in the oropharynx. No cutaneous burns are noted. You suspect that she is suffering from cyanide poisoning. What is the most appropriate immediate therapy?
   a. Hyperbaric oxygen (HBO)
   b. Intravenous (IV) hydroxocobalamin
   c. IV methylene blue
   d. IV sodium nitrite
   e. Observation and supportive care

Answer: b. One of the two major treatments for cyanide poisoning is hydroxocobalamin (the other is the traditional cyanide antidote kit). The nitrite compounds in the cyanide antidote kit convert hemoglobin to methemoglobin (MetHb), which in turn binds to cyanide. However, nitrites produce hypotension and the MetHb prevents proper oxygen deliver, which may compound the reduction in oxygen delivery associated with carbon monoxide (CO) poisoning. HBO has no role in acute cyanide poisoning. Methylene blue has been used for cyanide poisoning in the past but is not as useful as the cyanide kit. Its primary use is in treating methemoglobinemia. General supportive care is not appropriate because there is an effective antidote for this patient's poisoning.

5. A 22-year-old man is brought to the emergency department (ED) after being found unconscious in a car with an intentionally prominent suicide note visible in the window. By the time he arrives in the ED, he has regained consciousness and is complaining of headache and nausea. Paramedics report that the car engine was not running when the patient was discovered. His vital signs and physical examination are normal. Which of the following therapies should be instituted?
   a. Hyperbaric oxygen (HBO)
   b. Intravenous (IV) methylene blue
   c. IV sodium nitrite
   d. IV sodium thiosulfate
   e. Observation and supportive care

Answer: e. This patient has been exposed to hydrogen sulfide (a common form of suicide in some parts of the world), which has similar effects on the mitochondria as cyanide. However, hydrogen sulfide is rapidly removed from the body; and as long as patients are recovering, removal from the source is usually all that is necessary. HBO and methylene blue have no role in hydrogen sulfide poisoning. Sodium nitrite can be used in patients who are not recovering once removed from the source or for severe exposures. Sodium thiosulfate is not necessary because hydrogen sulfide is detoxified by a different pathway than cyanide and does not need a sulfur donor.

6. A worker at a chemical plant was exposed to a cloud of chlorine gas (Cl_2). On examination in the emergency department you note a normal oxygen saturation, increased respiratory rate, and wheezing on lung auscultation. In addition to administration of inhaled beta-adrenergic agonists, which of the following can be administered for symptomatic relief?
   a. Nebulized hypertonic saline
   b. Systemic corticosteroids
   c. Nebulized 2% sodium bicarbonate solution
   d. Antibiotics
   e. Intravenous magnesium sulfate

Answer: c. This patient was exposed to chlorine gas which is an intermediate water-soluble gas that combines with water in the respiratory tract to form hydrochloric acid. Patients may have improvement of their symptoms with the administration of nebulized 2% sodium bicarbonate solution. Systemic corticosteroids have not shown a benefit in these patients. Antibiotics should not be administered routinely in these patients unless an overlying infectious process is suspected.

7. What is the major benefit of hyperbaric oxygen (HBO) therapy for patients suffering from carbon monoxide (CO) poisoning?
   a. Decreased rate of hospitalization
   b. Improvement of 24-hour mortality
   c. Improvement of 30-day mortality
   d. Prevention of delayed cardiovascular complications
   e. Prevention of delayed neuropsychiatric complications

Answer: e. There is controversy regarding the role of HBO therapy for patients with CO poisoning, but the best evidence suggests that it can significantly decrease the incidence of delayed neuropsychiatric complications. There is no change in rate of hospitalization, nor on overall mortality, either short term or long term. There are no delayed cardiovascular symptoms associated with CO poisoning.

8. Assuming that all patients have similar vital signs and complaints of headache and nausea, which of the following patients suffering from carbon monoxide (CO) poisoning should be considered highest priority for hyperbaric oxygen (HBO) therapy?
   a. A 22-year-old otherwise healthy man with a carboxyhemoglobin (COHb) level of 30%
   b. A 25-year-old otherwise healthy pregnant woman with a COHb level of 25%
   c. A 30-year-old otherwise healthy man also suffering from cyanide poisoning with a COHb level of 15%
   d. A 35-year-old otherwise healthy woman with second-degree burns to 20% of her body and with a COHb level of 20%
   e. A 67-year-old asymptomatic woman with coronary artery disease and with a COHb level of 25%

Answer: b. Pregnant patients should be considered for HBO therapy. CO binds more strongly to fetal hemoglobin than to adult hemoglobin and can cause severe hypoxia to the fetus. There is controversy about an absolute level of COHb that requires HBO therapy. HBO does not benefit cyanide victims, nor is it indicated in uncomplicated burn patients or those with stable comorbidities.

9. You successfully treat a patient for cyanide poisoning. Several hours after improvement of the patient's hemodynamics, you are alerted that the patient has developed a bright red skin discoloration. Which of the following is the most likely explanation for this new physical exam finding?
   a. Administration of hydroxocobalamin
   b. Concomitant carbon monoxide toxicity
   c. An anaphylactic reaction
   d. Development of hyperthermia
   e. Peripheral vasodilation

Answer: a. Patient presented with cyanide toxicity for which the antidote, hydroxocobalamin, was given. Hydroxocobalamin has only mild adverse effects, although it can cause hypertension in those without cyanide toxicity and it can cause a bright red discoloration of the patient's skin. This discoloration can often be mistaken as an allergic reaction and it can interfere with spectrophotometric laboratory assays including COHb level. Cherry red skin discoloration in the setting of CN or CO poisoning is a postmortem finding.

149

Lithium

Jillian L. Theobald and Steven E. Aks

KEY CONCEPTS

- The clinical pattern of acute and chronic lithium toxicity is different. Gastrointestinal symptoms occur early, and neurologic toxicity manifests late in acute toxicity. Neurologic findings (e.g., tremors, altered mental status and seizures) often are presenting signs of chronic lithium toxicity, whereas gastrointestinal symptoms often are absent.
- Neither activated charcoal nor whole bowel irrigation (WBI) is indicated in the routine management of acute or chronic lithium toxicity.
- Serial lithium concentrations should be obtained every 2 to 4 hours initially to determine the peak level and the need for hemodialysis.
- Fluid hydration with crystalloid is essential to enhance renal excretion of lithium. Diuretics are contraindicated.
- We recommend hemodialysis for acute lithium concentrations greater than 5 mEq/L or for patients with signs of severe neurologic lithium toxicity, particularly tremor, clonus, altered mental status, and seizure, regardless of the serum concentration.

FOUNDATIONS

Lithium has been used therapeutically since the mid-1800s, when it was initially prescribed to treat gout. Lithium compounds were also historically used therapeutically: lithium bromide as a hypnotic, lithium iodide to treat syphilis, and lithium chloride introduced as a table salt alternative for heart failure patients in the 20th century. Ultimately, multiple deaths led to removal of lithium chloride from the US market. In 1970, lithium was approved for the treatment of bipolar disorder, and it remains one of the most effective agents for both depressive and manic symptoms. Lithium is the only drug treatment for bipolar disorder that is associated with a reduced risk of suicide.[1]

Lithium is a monovalent cation with a narrow therapeutic range, and significant toxicity can result when outside of this range. Lithium largely has no effect when given in therapeutic doses to patients without mood disorders. Despite its long history of therapeutic use, the complex and multimodal mechanism of action of lithium is still not fully understood. Its efficacy in the treatment of psychiatric illnesses is thought to be due to the modulation of neurotransmitters, which has downstream effects through cell signaling and molecular mechanisms.[2]

Lithium is rapidly absorbed from the gastrointestinal tract and peaks in the serum 1 to 2 hours after ingestion of immediate-release preparation and 4 to 5 hours with sustained-release preparations. Absorption and peak concentrations can be delayed in overdose situations, with ingestion of sustained-release formulations, or when concretions form in the gut. Once absorbed, lithium enters the serum followed by a delayed distribution to the tissues. In therapeutic dosing, lithium reaches a steady state within 6 hours after the last dose. Therefore lithium levels must be interpreted in the context of the patient's last dose. Lithium is not metabolized and is excreted unchanged in the urine. Any decreases in renal excretion because of conditions such as dehydration, hyponatremia, or renal dysfunction will lead to increases in serum lithium levels.

CLINICAL FEATURES

Lithium toxicity is categorized into acute, acute on chronic, or chronic toxicity. Evaluation of the potentially lithium toxic patient requires knowledge of whether the patient was previously taking lithium, the timing of the last dose, and the amount of drug ingested. The clinical features of lithium toxicity depend on whether it is acute or chronic in nature (Table 149.1). Acute toxicity usually follows a recent ingestion in a patient who is not therapeutically taking lithium and manifests early with gastrointestinal symptoms such as vomiting and diarrhea. Neurologic consequences of an acute lithium overdose include seizures, altered mental status, tremors, hyperreflexia, clonus, or fasciculations. They occur several hours later, after lithium redistributes to the central nervous system. In some cases with delayed-release lithium, neurologic symptoms may occur 12 or more hours after ingestion. These neurologic consequences are similar to chronic lithium toxicity. Chronic toxicity is caused by a relatively gradual increase in serum lithium level in a patient who is regularly taking lithium. This can either be from reduced excretion, renal insufficiency, or a dose adjustment. Chronic lithium toxicity causes predominantly neurologic symptoms with minimal to no gastrointestinal symptoms. Acute-on-chronic toxicity occurs when a patient with a stable steady-state lithium level takes a substantial additional amount of lithium, intentionally or accidentally. These patients present with signs and symptoms of both acute and chronic toxicity. Either acute or chronic toxicity can result in cardiac conduction abnormalities with T-wave inversions being the most common electrocardiogram (ECG) finding.[3]

Long-term chronic use of lithium can lead to nephrogenic diabetes insipidus and hypothyroidism. Both conditions are reversible with discontinuation of the medication and respond well to conventional management.[4] Hypercalcemia and hyperparathyroidism also can occur and reverse upon discontinuation of lithium.[5] Patients chronically taking lithium can develop the syndrome of irreversible lithium-effectuated neurotoxicity (SILENT). Patients with SILENT will often have persistent cerebellar and brain stem dysfunction, dementia, and extrapyramidal signs even after lithium use has been discontinued for days to weeks. [6] Use of lithium during early pregnancy may increase the risk for cardiovascular abnormalities in the fetus.[7]

DIFFERENTIAL DIAGNOSES

Lithium toxicity is nonspecific and may present in a manner similar to many systemic and neurologic disorders, so obtaining a history of lithium use or ingestion is critical to making the diagnosis. Nausea and vomiting are common with viral or bacterial gastrointestinal

TABLE 149.1 Clinical Features of Lithium Toxicity

Clinical Features	TYPE OF TOXICITY	
	Acute	Chronic
Gastrointestinal[4]	Nausea Vomiting Diarrhea	Mild or nonexistent
Neurologic[8]	Similar to chronic toxicity, occurs several hours after lithium distribution to the brain	Tremors Clonus Hyperreflexia Extrapyramidal symptoms Altered mental status Somnolence Coma Seizures
Cardiac[2]	Sinus node dysfunction AV blockade Brugada pattern on ECG Ischemic changes on ECG QTc prolongation	

AV, Atrioventricular; *ECG,* electrocardiogram.

syndromes, early pregnancy, various abdominal pathologies, acute neurologic events, and other toxic ingestions. The neurologic manifestations of lithium toxicity (tremors, hyperreflexia, altered mental status, and seizures) may prompt consideration of withdrawal syndromes (alcohol or benzodiazepines), sympathomimetic toxicities (cocaine and amphetamines), and serotonin syndrome.

DIAGNOSTIC TESTING

Serum lithium levels should be obtained in all patients who are taking lithium, or have access to lithium, and present with potential toxicity. Because of the insidious and nonspecific nature of chronic lithium toxicity, a serum lithium level is also advisable in any patients who is on lithium maintenance therapy, regardless of their reason for presentation (Box 149.1). Therapeutic serum concentrations of lithium are between 0.6 and 1.2 mEq/L. Serum lithium levels are in a steady state approximately 6 hours after ingestion of a therapeutic dose and should be interpreted in the context of when the last dose was taken. In overdose situations, peak concentrations can occur beyond 6 hours. We recommend obtaining serum lithium concentrations every 2 to 4 hours until two consecutive declining measurements are observed. Serum electrolytes should be obtained because lithium can cause alterations in calcium and sodium, most commonly hypercalcemia and hypernatremia. An assessment of the patient's renal function either by a serum creatinine concentration or a glomerular filtration rate should also be performed. If there is clinical concern for thyroid dysfunction, then thyroid studies should be obtained. In patients presenting with an acute intentional ingestion, both acetaminophen and aspirin levels should be sent to evaluate for possible coingestants. Finally, an ECG

BOX 149.1 Diagnostic Testing for Lithium

Serum lithium level
Serum electrolytes
Creatinine concentration or a glomerular filtration rate (GFR)
Electrocardiogram (ECG)
If the clinical picture dictates:
Acetaminophen/salicylate levels
Thyroid function tests

should be obtained and cardiac monitoring initiated in patients presenting with an acute or chronic overdose. An ECG also should be obtained for patients on chronic lithium therapy, given the propensity of lithium to cause conduction abnormalities.

MANAGEMENT

Stabilization and Supportive Care

No specific antidote exists for lithium toxicity therefore supportive care and enhanced elimination are the mainstays of treatment. Most patients who are lithium-toxic are dehydrated because of gastrointestinal losses in acute toxicity or from underlying dehydration and lithium-induced diabetes insipidus, leading to chronic toxicity. Crystalloid solution (lactated Ringers solution) should be infused as a 1 L bolus followed by a continuous infusion at 150% of the calculated maintenance rate if there are no contraindications, such as congestive heart failure. Volume expansion also enhances renal elimination of lithium. Electrolyte abnormalities, such as hypernatremia and hypercalcemia, if significant, should be corrected (see Chapter 114).

Decontamination

Activated charcoal does not bind lithium. Furthermore, we do not recommend the use of whole bowel irrigation (WBI) in routine lithium ingestions. Although a position paper suggests that WBI can be considered after massive overdose, there is only scant evidence that WBI can decrease the amount of lithium absorbed in nontoxic doses, and there is no clinical evidence of benefit in overdose.[8] Similarly sodium polystyrene resins (e.g., Kayexalate) have been proposed to assist in the elimination of lithium by sodium-lithium exchange; however, due to limited binding capacity, large volumes are needed to have any significant reduction in lithium levels. There are no studies demonstrating an actual impact on clinical outcome, the risks outweigh the benefit, and we do not recommend the use of ion-exchange resins in lithium poisoning.[9]

Enhanced Elimination

Because lithium is primarily excreted unchanged by the kidney, early initiation of intravenous crystalloid solution, as described earlier, enhances elimination. Diuretics are contraindicated, because they can cause worsening dehydration, with further impairment of renal function, and also can enhance renal reabsorption of lithium.

Lithium is highly dialyzable, and hemodialysis is indicated for patients exhibiting signs of severe lithium toxicity (Box 149.2). Patients with severe neurologic toxicity (e.g., altered mental status, clonus, hyperreflexia, and seizures) should undergo hemodialysis to reduce serum lithium levels to less than 1.0 mEq/L.[10] In addition, hemodialysis is indicated for patients with impaired renal function or those who cannot tolerate intravenous fluids. There is little high-quality evidence in favor of dialysis based solely on serum lithium concentration. A Cochrane review concluded that there is insufficient evidence to determine which lithium-intoxicated patients might benefit from hemodialysis.[11] Based on our experience and available evidence, we recommend

BOX 149.2 Indications for H Somnolence

Hemodialysis in Lithium Poisoned Patients

Severely symptomatic patients
Unable to tolerate crystalloid fluid resuscitation
Renal impairment
Acute or chronic toxicity: Levels >5 mEq/L
Neurotoxicity including tremors, clonus, altered mental status, somnolence, seizures

dialysis for serum levels greater than 5 mEq/L[12] or for patients with signs of severe neurologic lithium toxicity, particularly tremor, clonus, altered mental status, and seizure, regardless of the serum concentration. Serum lithium concentrations can rise or rebound after dialysis sessions; therefore a steady state concentration should be determined at 6 hours post procedure.

DISPOSITION

Disposition depends largely on the extent of clinical toxicity and the psychiatric status of the patient. Patients manifesting clinical signs of neurotoxicity such as tremors, altered mental status, and seizures should be admitted. Patients with an acute overdose complicated by significant cardiologic or neurologic symptoms and high (>5 mEq/L) or increasing supratherapeutic serum lithium levels should undergo hemodialysis. Patients with significant altered mental status or seizures, and those requiring dialysis should be monitored in an intensive care which may require early transfer to a hospital with this capability. In these cases, we recommend consultation with a regional poison center or medical toxicologist. Patients with overdoses of sustained-release lithium should also be placed in an observation unit or hospitalized for serial monitoring of lithium concentrations until at least two consecutive declining serum levels are documented. Patients who remain asymptomatic with normal physical examination findings and serum lithium levels in the therapeutic range 6 hours after ingestion of immediate-release lithium preparations or 12 hours after a sustained-release preparation can be discharged or cleared for psychiatric evaluation. Women taking lithium who present to the emergency department with newly diagnosed pregnancy should be referred to an obstetrician for fetal evaluation and monitoring and to discuss the risk benefit profile of lithium use during pregnancy.

CHAPTER 149: QUESTIONS AND ANSWERS

1. What are the two most common electrolyte abnormalities seen in chronic lithium toxicity?

a. Hyperkalemia and hypernatremia
b. Hypernatremia and hypercalcemia
c. Hypokalemia and hypercalcemia
d. Hypomagnesemia and hyponatremia
e. Hyponatremia and hypercalcemia

Answer: b. Chronic lithium use can cause hypernatremia due to the development of diabetes insipidus. Prolonged therapy with lithium alters cellular calcium sensing and leads to elevated parathyroid hormone levels and hypercalcemia. Magnesium and potassium levels are typically normal, and abnormalities are not caused by lithium. Hyponatremia and hypercalcemia are frequently seen in cases of acute lithium overdose.

2. Which of the following conditions is most frequently seen in patients with chronic lithium use?

a. Anticholinergic syndrome
b. Diabetes insipidus
c. Hyperthyroidism
d. Hypoparathyroidism
e. Syndrome of inappropriate antidiuretic hormone

Answer: b. Diabetes insipidus commonly occurs in patients on chronic lithium therapy or with chronic overdose. Diabetes insipidus can cause dehydration and a further increase in lithium concentration and is a frequent contributory cause to chronic lithium toxicity. Rarely, hypothyroidism can also develop. Lithium use is also associated with neuroleptic malignant syndrome and serotonin syndrome but none of the other listed conditions.

3. Which of the following drugs should be used with caution in patients taking lithium?

a. Acetaminophen
b. Hydrochlorothiazide
c. Metformin
d. Metoprolol
e. Penicillin

Answer: b. Hydrochlorothiazide, other diuretics, angiotensin-converting enzyme (ACE) inhibitors, and nonsteroidal antiinflammatory drugs (NSAIDs) can increase lithium levels and consequently cause chronic lithium toxicity by interfering with renal elimination. Lithium has also been implicated in serotonin syndrome when combined with other serotonergic drugs, such as monoamine oxidase (MAO) inhibitors, selective serotonin reuptake inhibitors (SSRIs), and dextromethorphan. None of the other drugs listed causes significant interactions with lithium.

4. A 26-year-old woman presents following a witnessed seizure. She was found with an empty bottle of lithium and a suicide note. Her vital signs reveal hypotension and tachycardia. She is lethargic and her only response is to withdraw from painful stimuli. The remainder of her physical examination is normal. Laboratory tests including a serum lithium level are pending. Which of the following treatments is the most appropriate?

a. Activated charcoal
b. Forced diuresis
c. Hemodialysis
d. Urinary alkalinization
e. Whole bowel irrigation (WBI)

Answer: c. Hemodialysis is the most effective way to remove lithium. It can remove lithium at a rate five to seven times the rate of typical renal elimination. Common indications for dialysis include decreased level of consciousness and seizures. Activated charcoal does not adsorb lithium. Lithium overdose patients are often dehydrated and occasionally hypernatremic and should be fluid resuscitated, but once dehydration is corrected, forced diuresis is of no benefit and can be detrimental. Urinary alkalinization has no role in lithium toxicity. Because this patient has already experienced a seizure, the administration of WBI is not advised. In addition, the seizure suggests that the brain concentration of lithium is already toxic and this is not improved by WBI.

Antipsychotics

Jessica Monas and Aaron B. Skolnik

KEY CONCEPTS

- Antipsychotics are commonly categorized into typical, or first-generation antipsychotics (FGAs) with primary antagonism to dopamine receptors, and atypical, or second-generation antipsychotics (SGAs) which include serotonin receptors as a target. Aripiprazole is an example of a third type of antipsychotic that acts as a partial agonist at dopamine sites.
- Extrapyramidal symptoms are common side effects of antipsychotics. First line treatment is benztropine or diphenhydramine. Lorazepam may be used in refractory cases.
- The most common presentation of an antipsychotic overdose is central nervous system (CNS) depression. Treatment focuses on supportive care, airway management, and cardiac monitoring.
- QT prolongation and *torsades de pointes* are potential complications of antipsychotic overdose but may also occur with therapeutic use.
- Clozapine is associated with potentially life-threatening agranulocytosis. Treatment includes cessation of the medication, treating potential infections, and supportive care.
- Neuroleptic malignant syndrome (NMS) is characterized by altered mental status, hyperthermia, muscle rigidity, and autonomic instability. Treatment includes supportive care with airway management, benzodiazepines, muscular rigidity management, and evaporative cooling methods for hyperthermia.

FOUNDATIONS

Background

In 1950, promethazine was synthesized in an effort to develop antihistamines, but it was also found to potentiate the effects of anesthetics and was widely used. An attempt to derive similar drugs led to the synthesis of chlorpromazine. It was discovered that patients treated with this became sedate and apathetic and it was termed a *neuroleptic*. Chlorpromazine was first used to successfully treat a patient with psychosis in 1952 and helped to pave the way for the modern treatment of mental illness. Prior to the development of antipsychotics, pharmacotherapy for psychosis had focused on tranquilization rather than modification of disease.

In 1956, clozapine was synthesized. It demonstrated that a drug could treat psychosis without significant extrapyramidal effects and became the precursor of the *atypical* antipsychotics. Clozapine was initially removed from market in 1974 due to agranulocytosis but was reintroduced in 1990 with mandatory monitoring because of its clinical efficacy in treatment-resistant schizophrenia.[1]

The term *neuroleptic* has since been replaced with *antipsychotic*, because newer agents are less sedating. Antipsychotic use has expanded beyond schizophrenia and schizoaffective disorders to include supplemental treatment for major depressive disorder, bipolar disorder, anxiety disorders, behavioral changes associated with dementia, and psychoses related to substance use disorders and withdrawal. In the past decade, antipsychotic prescribing has dramatically increased, including off-label and nonpsychosis use.[2–5] In 2018, nearly 50,000 exposures attributable to antipsychotics were reported to poison control centers in the United States. In conjunction with sedatives and hypnotics, antipsychotics comprised the group of drugs with the greatest increase per year in serious adverse outcomes and human ingestions.[6]

Pathophysiology

Antipsychotics have been categorized according to their mechanism of action as well as their clinical effect. All antipsychotics have dopamine receptor antagonism. Typical, or first-generation antipsychotics (FGAs) focused on dopamine blockade as a primary target with subsequent adverse extrapyramidal effects. FGAs are sometimes classified as low-potency or high-potency based on their affinity for the dopamine D_2 receptor subtype (Box 150.1). Atypical, or second-generation antipsychotics (SGAs) were developed to combine with serotonin receptor antagonism (5-hydroxytryptamine type 2A) to decrease neurologic side effects and also treat negative symptoms of thought disorders. More recent development of partial dopamine agonism, such as aripiprazole and brexpiprazole, led to the phrase "third-generation" antipsychotic, but this term has not been readily accepted.[7,8] In 2019, the US Food and Drug Administration (FDA) approved a novel first-in-class antipsychotic, lumateperone, that acts synergistically though serotonergic, dopaminergic, and glutaminergic modulation.[9] Lumateperone has been shown to improve depressive as well as psychotic symptoms.[10] In general, low-potency FGAs are the most sedating. Movement disorders are a significant adverse effect of this class of medication, with SGAs having lower frequency. Although neuroleptic malignant syndrome (NMS) can occur with all antipsychotics, it occurs less often with SGAs.[11]

Antipsychotic medications are widely used for both psychiatric and nonpsychiatric purposes. The antiemetic effects of prochlorperazine, promethazine, and droperidol result from blockade of dopamine receptors in the chemoreceptor trigger zone of the medulla. Prochlorperazine and droperidol are thought to improve migraine headaches by inhibiting dopamine-mediated trigeminovascular activation. Olanzapine has been used for fibromyalgia and the treatment of other chronic pain.[12,13] Chlorpromazine is the historical drug of choice for singultus or intractable hiccups, although other antipsychotics are also used.[14] Although haloperidol, pimozide, and aripiprazole are the only FDA-approved treatments for Tourette syndrome, other SGAs have been recommended.

Toxicity

Toxicity of antipsychotic drugs can be divided into three categories: exaggerated pharmacologic effects seen in acute overdose, undesired clinical effects seen in therapeutic use such as extrapyramidal syndromes, and idiosyncratic effects such as NMS.

BOX 150.1 Classification of US Food and Drug Administration Approved Antipsychotics*

Low Potency (First-Generation Antipsychotics)
Chlorpromazine (Thorazine)
Fluphenazine (Prolixin)
Perphenazine (Trilafon)
Promethazine (Phenergan)
Thioridazine (Mellaril)

High Potency (First-Generation Antipsychotics)
Droperidol (Inapsine)
Haloperidol (Haldol)
Loxapine (Loxitane)
Pimozide (Orap)
Thiothixene (Navane)
Trifluoperazine (Stelazine)

Atypical (Second-Generation Antipsychotics)
Aripiprazole (Abilify)
Asenapine (Saphris)
Brexpiprazole (Rexulti)
Cariprazine (Vraylar)
Clozapine (Clozaril)
Iloperidone (Fanapt)
Lurasidone (Latuda)
Olanzapine (Zyprexa)
Paliperidone (Invega)
Quetiapine (Seroquel)
Risperidone (Risperdal)
Ziprasidone (Geodon)

Atypical (Third-Generation Antipsychotics)
Aripiprazole (Abilify)
Brexpiprazole (Rexulti)
Cariprazine (Vraylar)

Atypical (Other)
Lumateperone (Caplyta)

*Current as of March, 2020.

In addition to D_2 receptor antagonism, most antipsychotics take effect at other receptors and ion channels. These include alpha-1 adrenergic, muscarinic, and histamine H_1 receptor antagonism, as well as fast voltage-gated sodium, and delayed potassium rectifier channel blockade.

Alpha antagonism may result in orthostatic hypotension. Muscarinic antagonism can produce minor side effects in therapeutic use or anticholinergic toxicity in acute overdose including cognitive impairment. Histaminergic blockade can produce sedating effects in both therapeutic use and overdose.

Phenothiazine antipsychotics such as chlorpromazine are structurally related to tricyclic antidepressants (TCAs), exhibiting sodium channel blockade that may lead to wide complex dysrhythmias. Many agents inhibit potassium rectifying currents resulting in QT prolongation and, potentially, torsades de pointes. The degree of prolongation varies between antipsychotics and can increase in a dose-dependent manner, with ziprasidone and iloperidone having the highest risk, and aripiprazole and brexpiprazole the lowest.[15] QT prolonging effects may be worsened in chronically ill patients and with concomitant use of other QT-prolonging drugs.[15,16] Although a direct correlation between degree of QT prolongation and risk of torsades de pointes has not been well established, antipsychotics are associated with increased risk of sudden death that is worsened with comorbid cardiac disease and in elderly patients.[17] In addition, psychotic disorders alone increase the risk of sudden death.[18] Therapeutic use of clozapine has been linked to myocarditis and cardiomyopathy that may be accompanied by eosinophilia.[19]

Antipsychotic drugs block dopamine receptors at multiple regions within the brain. Mesolimbic D_2 blockade produces the desirable effect of reducing positive symptoms of schizophrenia. However, similar degrees of D_2 receptor blockade in the nigrostriatal pathway also produce the undesirable extrapyramidal symptoms (EPSs). This includes dystonia, akathisia, and drug-induced parkinsonism, which may be immediate or delayed in onset. SGAs have lower affinity for the dopamine receptors and add-in serotonin receptor antagonism, both of which are thought to reduce EPSs. The propensity of antipsychotics to produce EPSs is also inversely proportional to the agent's muscarinic receptor antagonism.[20] Rapid dissociation from the D_2 receptor has been hypothesized to reduce the risk of EPS; however, data suggest that association rates may also play a factor.[21,22]

Tardive syndromes (TSs) encompass the hyperkinetic and hypokinetic movements that result after delay from exposure to dopamine-blocking drugs. Tardive dyskinesia (TD) may develop after prolonged use of these medications and has been reported with all antipsychotics. One proposed pathophysiological mechanism is chronic dopamine receptor blockade in the nigrostriatal pathway leading to D_2 receptor upregulation and hypersensitivity to dopamine. Genetic factors are also thought to play a significant role in the development of TD.

NMS is a rare, idiosyncratic reaction to antipsychotic medications, the pathophysiology of which is less understood. It can be severe and, if unrecognized or undertreated, can lead to permanent neurologic sequalae and death. NMS is thought to result from D_2 receptor blockade in the nigrostriatum and hypothalamus, which can lead to rigidity and hyperthermia, with downstream dysregulation of the autonomic nervous system. It has more recently been suggested that NMS may be due to a direct toxic effect of the drug on the musculoskeletal fibers.

Clozapine-associated agranulocytosis is rare, with an incidence of approximately 1%, which drops to 0.38% with routine white blood cell count monitoring.[23] A more recent meta-analysis found that this does not occur more frequently with clozapine than with other antipsychotics.[24] The classic proposed mechanism is a direct cytotoxic effect on bone marrow mesenchymal stromal cells. An alternate suggested etiology is that it may be related to an autoimmune process.

Antipsychotic use has also been associated with weight gain, dyslipidemia, glucose intolerance, metabolic syndrome, and new-onset diabetes mellitus.[23] Numerous observational and case-control studies indicate an increased risk of venous thromboembolism (VTE) with antipsychotic use. Multiple hypotheses regarding the mechanism include drug-induced sedation, weight gain, enhanced platelet aggregation, antiphospholipid antibody level increase, and the possibility that thought disorders may cause a predisposition. The risk of VTE may also be highest within the first 3 months of antipsychotic therapy initiation.

CLINICAL FEATURES

Acute Overdose

In overdose, antipsychotics produce signs and symptoms that are exaggerations of their pharmacologic profile. Most patients develop symptoms within a few hours post ingestion. Paliperidone has a unique delayed-delivery system, and late onset of symptoms has been reported.[25] Central nervous system (CNS) depression is common, ranging from mild sedation to coma. Anticholinergic delirium and agitation may result from drugs with antimuscarinic effects (Box 150.2). Airway reflexes can be impaired and respiratory depression can occur after overdose. Pupils may be of variable size; anticholinergic effects

BOX 150.2 Antipsychotics With Antimuscarinic Effects

Typical Antipsychotics
Chlorpromazine (Thorazine)
Loxapine (Loxitane)
Mesoridazine besylate (Serentil)
Thioridazine (Mellaril)

Atypical Antipsychotics
Clozapine (Clozaril)
Olanzapine (Zyprexa)
Quetiapine (Seroquel)

Data from Levine M, Ruha AM. Overdose of atypical antipsychotics: clinical presentation, mechanisms of toxicity and management. *CNS Drugs*. 2012;26:601–611; Richelson E. New antipsychotic drugs: how do their receptor-binding profiles compare? *J Clin Psychiatry* 2010;71:1243–1244.

promote mydriasis, whereas miosis, resulting from alpha-antagonism, may mimic opioid toxicity. Orthostatic hypotension is also a common finding resulting from alpha-adrenergic blockade. Variable evidence suggests that antipsychotics lower seizure threshold; however, with the exception of clozapine, seizures rarely occur in overdose. Acute EPSs have also been reported in overdose.

Acute Extrapyramidal Syndromes

Acute dystonia presents with involuntary spasms of antagonistic muscle groups most often involving facial, neck, back, or limb muscles. This results in trismus, facial grimacing, dysarthria, tongue and lip distortion, torticollis, or oculogyric crisis. Half of patients who develop acute dystonia do so within 48 hours of receiving the implicated drug. Symptoms may develop rapidly or may be delayed hours to days, although most acute dystonia develops within 5 days of drug administration. Recurrent dystonic reactions may occur, even following a single dose of an antipsychotic. *Laryngeal dystonia,* a rare but life-threatening form of dystonia, manifests as dyspnea, stridor, choking sensation, or respiratory distress and has been reported with both FGAs and SGAs.[26] Increased risk of death due to choking has been reported in patients treated for schizophrenia; both FGAs and SGAs have been associated with dysphagia.

Akathisia (from Greek, *"unable to sit"*) is characterized by subjective feelings of internal restlessness associated with objective motor findings, including repetitive foot shuffling, truncal shifting, or pacing. Akathisia usually develops within hours to days of initiating or increasing the dose of an antipsychotic. Studies of emergency department (ED) patients have demonstrated a lower incidence of akathisia and other EPSs with SGAs. *Rabbit syndrome* is a perioral, tongue-sparing dyskinesia in which rhythmic lip and nose movements resemble the chewing movements of a rabbit. Rabbit syndrome is primarily associated with FGA drugs but has also been case reported with SGAs.

Drug-induced parkinsonism, manifest by bradykinesia, masklike facies, shuffling gait, rigidity, and tremor, may occur in up to 60% of patients treated with antipsychotics and frequently develops 2 to 4 weeks after initiating treatment. Ninety percent of cases develop within 3 months.

Tardive Syndromes

TSs refer to delayed-onset motor and nonmotor syndromes induced by prolonged use of dopamine antagonists, including antipsychotic medications. TSs include dystonia, akathisia, motor, sensory syndromes, and classic TD. TD refers to the repetitive, rapid, involuntary orofacial, limb, trunk, or pelvic movements first described in 1964. The risk of TD with sustained antipsychotic treatment is estimated to be approximately 5% per year and may be higher in the elderly. Prevalence is estimated at approximately 20% of psychiatric patients undergoing long-term treatment. Reduction of the antipsychotic dose or a change to an alternative agent should be considered, in consultation with the patient's psychiatrist. Two drugs, valbenazine and deutetrabenazine, were FDA approved for the treatment of TD in 2017.

Neuroleptic Malignant Syndrome

NMS is a serious idiosyncratic drug reaction that is potentially life threatening. NMS typically develops during the first 2 weeks of therapy but has occurred during long-term drug regimens. The incidence of NMS has been reported to range from less than 1% to 3% among patients exposed to antipsychotics. The unadjusted mortality rate of NMS has been estimated at approximately 5%. Males are approximately 50% more likely to develop NMS, with peak overall incidence between the ages of 20 and 25 years old. Other risk factors include recent dose changes, cumulative drug dosage, high-potency antipsychotics, parenteral formulations, polypharmacy, prolonged physical restraint, dehydration, hyperthermia, prior brain injury, family history of catatonia, muscle channelopathies, and previous episodes of NMS. Cotreatment with two antipsychotics is associated with increased risk for NMS.[27] Although highly potent FGAs are most frequently the culprit in NMS, all antipsychotics have been implicated, including SGAs. NMS caused by SGAs is associated with a lower incidence, decreased severity, and lower mortality than that caused by FGAs.[11] Abrupt withdrawal from dopaminergic agents used to treat Parkinson disease (i.e., levodopa/carbidopa) may cause a potentially fatal syndrome that is clinically indistinguishable from NMS, termed the parkinsonism-hyperpyrexia syndrome.

NMS is characterized by the tetrad of altered mental status, muscular rigidity, hyperthermia, and autonomic instability (Table 150.1). Other features of NMS may include sialorrhea, dysarthria, dysphagia, metabolic acidosis, generalized slowing on electroencephalogram (EEG), coagulopathy, rhabdomyolysis, deep venous thrombosis, pulmonary embolism, and acute kidney injury. Laboratory studies are typically notable for markedly elevated creatinine kinase (>1000 IU/mL), leukocytosis, and nonspecific elevation of inflammatory markers such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR).

Most patients have the cardinal features of NMS within 1 to 2 weeks after starting an antipsychotic or abruptly increasing the dose. Of note, the signs of NMS may develop gradually and in any order. Clinicians should discontinue all antipsychotics, other dopamine antagonists, and other psychotropic drugs in patients with suspected NMS. Acute care in the ED includes airway management as required, intravenous (IV) fluid resuscitation, correction of metabolic disturbances, and supportive care with rapid cooling methods for hyperthermia. Administration of benzodiazepines is also indicated depending on the patient's clinical severity and response to treatment (see dosing recommendations in Management section). Most episodes of NMS resolve with appropriate care within 2 weeks after cessation of the offending medication; however, symptoms may wax and wane for months.

Cardiovascular Toxicity

The most common cardiac effect of these medications is sinus tachycardia with a normal QRS duration. A few FGAs can cause QRS prolongation; however, coingestions should be considered. QT prolongation was once considered a "class effect" of all antipsychotic medications. More recent literature has identified significant differences among the antipsychotics with respect to potential for QTc prolongation and torsades de pointes during therapeutic dosing or in overdose. At therapeutic doses, the highest risk of QT prolongation occurs with pimozide and sertindole. The only antipsychotics without any effect on QT in therapeutic use are brexpiprazole, cariprazine, and lurasidone.[28]

TABLE 150.1 Prevalence of Suggested Diagnostic Criteria for Neuroleptic Malignant Syndrome

Criterion	Prevalence
Exposure to a dopamine antagonist or withdrawal of a dopamine agonist within 72 h:	
Hyperthermia (>38°C) on at least two occasions, measured orally	98%
Rigidity	97%
Mental status alteration	97%
Creatinine kinase elevation (at least 4 times the upper level of normal)	95%
Sympathetic nervous system lability, defined as at least two of the following:	
Blood pressure elevation (SBP or DBP ≥25% above baseline)	61%[a]
Blood pressure fluctuation (≥20% DBP change or ≥25% SBP change in 24 h)	
Diaphoresis	98%
Urinary incontinence	
Hypermetabolic state (heart rate ≥25% and respiratory rate ≥50% above baseline)	88%[b]
Negative evaluation for other toxic, metabolic, infectious, or neurologic causes	

[a]Elevated or labile blood pressure.
[b]Tachycardia.
DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.
Modified from Gurrera RJ, Caroff SN, Cohen A, et al. An international consensus study of neuroleptic malignant syndrome diagnostic criteria using the Delphi method. *J Clin Psychiatry*. 2001;72:1222–1228.

Antipsychotic use has also been associated with an overall increased risk of cardiopulmonary arrest and death.[17]

Myocarditis has been reported in less than 1% of patients taking clozapine. The majority of cases develop in the first 2 months of treatment, with the incidence decreasing 10-fold over 12 months of treatment. A nonspecific, flulike prodrome frequently precedes the onset of myocarditis by days to weeks. The spectrum of disease ranges widely, from subclinical, asymptomatic disease to decompensated heart failure with case-fatality reported between 10% and 30%.

Agranulocytosis

Clozapine can produce life-threatening agranulocytosis in approximately 1% of exposed patients; the highest risk occurs between 1 and 5 months after starting the drug and decreases with subsequent duration of treatment. By 1 year, the risk of agranulocytosis approaches that of chlorpromazine (0.1%). With monitoring and treatment, attributable mortality is approximately 1 in 10,000. Agranulocytosis has not been reported after acute clozapine overdose. Agranulocytosis and neutropenia have been reported with many FGAs and SGAs. A recent meta-analysis of controlled trials suggests that the risk of neutropenia associated with clozapine is not greater than that associated with other antipsychotics.[24] With early recognition, antipsychotic-induced neutropenia typically resolves within 3 to 4 weeks of discontinuing the drug.

Seizures

The risk of new-onset seizures among patients treated with antipsychotics is up to 2.5-fold higher than the background rate in the untreated population, suggesting antipsychotic medications lower the seizure threshold.[29] The prevalence of psychosis in persons with epilepsy may be threefold greater than that of nonepilepsy controls, with a pooled prevalence estimate of 6%. The prescription of antipsychotic drugs to persons with epilepsy is therefore necessary and safe when indicated, even though most antipsychotics may reduce the seizure threshold.

DIFFERENTIAL DIAGNOSES

Antipsychotic toxicity may present similarly to clinical conditions and agents that produce altered mental status, seizures, anticholinergic toxidrome, orthostatic hypotension, QT prolongation, or torsades de pointes, such as TCAs. The differential diagnosis of NMS includes malignant catatonia, serotonin syndrome, heatstroke, sympathomimetic toxicity, acute salicylate poisoning, and other medical conditions (Table 150.2). Consider malignant hyperthermia in patients receiving inhalational anesthetics or succinylcholine.

DIAGNOSTIC TESTING

Quantitative blood levels of antipsychotics are neither readily available nor helpful in the ED setting. As with any patient who presents with suspected drug toxicity, blood glucose concentration, serum acetaminophen level, and directed toxicologic screening are recommended. Aspiration is common among patients with depressed mentation; chest radiography should be performed in hypoxic patients.

An electrocardiogram (ECG) should be obtained in all patients with suspected overdose and in those taking antipsychotics therapeutically with symptoms concerning for cardiotoxicity, because the ECG may predict adverse cardiovascular events.[30] If QT prolongation is present, serum sodium, potassium, calcium, and magnesium levels should be measured.

Patients who have NMS, EPSs with marked muscle rigidity, or prolonged seizures are at risk for rhabdomyolysis. In such patients we recommend serum creatinine kinase, assessment of renal function, and urine myoglobin measurements.

Patients who are severely hyperthermic (>40°C) are at risk for multi-system organ failure and disseminated intravascular coagulation. Because severe salicylate poisoning can cause CNS toxicity and hyperthermia due to uncoupling of oxidative phosphorylation, we recommend a serum salicylate level, in addition to serum transaminases and coagulation studies.

Patients taking antipsychotic medications who present with unusual infections or fever without a source should be evaluated for neutropenia, as the (low) risk appears to be similar for clozapine and other antipsychotics.[24]

Second-generation antipsychotics are associated with new-onset diabetes mellitus (including adult diagnosis of previously latent autoimmune diabetes) and diabetic ketoacidosis (DKA). This typically occurs within 1 year from the onset of treatment and may occur in the absence of weight gain. Most of these patients will subsequently require insulin for long-term blood glucose management.[31] Patients in whom DKA is clinically suspected should have blood glucose and pH, serum electrolytes, and serum or urine ketone testing. Salicylism can also produce a clinical picture that mimics DKA.

Other tests, such as brain computed tomography, lumbar puncture, and drug screens may be helpful in some cases to exclude other diagnoses or establish a comorbid condition but are not indicated when

TABLE 150.2 Differential Diagnoses of Neuroleptic Malignant Syndrome[a]

Disease	Proposed Mechanism	Differentiating Factor	Time Course	Treatment
Neuroleptic malignant syndrome (NMS)	Impaired thermoregulation in hypothalamus and basal ganglia due to due to dopamine blockade Downstream autonomic nervous system dysfunction	Antipsychotic use Muscle rigidity	Gradual over several days Waxing and waning course	Stop offending medication Hydration Active cooling IV benzodiazepines Nondepolarizing neuromuscular blockade Limited evidence: Dantrolene Dopamine agonists (e.g., bromocriptine) Consider ECT for refractory cases
Serotonin syndrome	Excess serotonin levels in CNS	Medications (usually a combination) that increase serotonin levels (e.g., SSRIs, MAOIs, lithium, dextromethorphan, meperidine, tramadol) Muscle rigidity (lower > upper extremities) Muscular or ocular clonus	Usually rapid after introduction of new medication or increase in dose	Stop offending medication Hydration Active cooling IV benzodiazepines Cyproheptadine
Malignant or lethal catatonia	Severe manifestation of schizophrenia, mood disorders, other psychiatric disorders, or neurological conditions Multiple mechanisms proposed	Occurs in absence of antipsychotic administration May be clinically indistinguishable from NMS	Gradual, typically over several days	Hydration Active cooling IV benzodiazepines ECT
Sympathomimetic toxicity	Hyperadrenergic state Extreme psychomotor agitation	Occurs in absence of antipsychotic administration Cardiovascular toxicity may be prominent Muscular hyperactivity in lieu of rigidity	Subacute, typically over hours	Hydration Active cooling IV benzodiazepines Alpha-antagonists Vasodilators
Malignant hyperthermia	Mutations in ryanodine receptors or dihydropyridine receptors allow uncontrolled calcium release from sarcoplasmic reticulum	Occurs after administration of inhalational anesthetic or succinylcholine Muscle rigidity	Sudden Provoked by administration of anesthetic	Stop anesthetic Hyperventilation with 100% oxygen Active cooling Dantrolene
Heatstroke	Impaired physiologic mechanisms for heat dissipation (classical) Environment or exercise elevates body temperature beyond range of cooling mechanisms (exertional)	Environmental exposure History Muscle rigidity rare	Subacute, typically over hours	Hydration Active cooling Prevent shivering

[a]Other clinical entities to consider in the differential diagnosis of NMS include CNS infection, status epilepticus (including nonconvulsive status), alcohol or sedative hypnotic withdrawal, hypocalcemia, hypoglycemia, hyponatremia, intracranial hemorrhage, other poisoning (e.g., anticholinergics, nicotine, salicylates, strychnine, theophylline), sepsis, tetanus, thalamic infarct, thyroid storm, and psychotic agitation.

the historical context and presentation support uncomplicated antipsychotic toxicity as the cause.

MANAGEMENT

General

Treatment of antipsychotic overdose is supportive. Endotracheal intubation and mechanical ventilation may be required in patients with severe CNS depression or respiratory distress. Dextrose should be given to patients with hypoglycemia. Neither gastric emptying nor activated charcoal is indicated for antipsychotic toxicity. See Chapter 135 for a discussion of the roles of activated charcoal and other methods of gastric decontamination.[32]

If sedation and miosis suggest possible opioid intoxication, a trial of intranasal or IV naloxone is warranted. We recommend administering naloxone 0.04 to 0.4 mg intravenous push (IVP) every 2 to 3 minutes in escalating doses and, if effective, titrating to return of normal oxygenation and ventilation. If a naloxone infusion is required, it may be

started at two-thirds of the total dose required to restore respiration per hour and titrated to clinical effect.

Anticholinergic Toxidrome

Physostigmine has been used to treat anticholinergic (antimuscarinic) delirium from antipsychotic overdoses. Contraindications to physostigmine include reactive airway disease and cardiovascular disease (including any intraventricular conduction delay, QRS widening, bradycardia, or heart block). Physostigmine will usually cause a decrease in heart rate through enhanced vagal tone. We recommend avoiding its use in patients who present with seizures, because physostigmine may precipitate additional seizures. In adult patients who have obvious central anticholinergic delirium with agitation, we use physostigmine 1 to 2 mg IV, infused over 5 minutes in the absence of contraindications. In patients in whom agitated delirium is present but the toxidrome is unclear, we recommend lorazepam 1 to 2 mg IV every 10 to 15 minutes titrated to mild sedation. The delirium reversal effect of physostigmine is usually short lived (45 to 60 minutes), with delirium recurring in 30% to 90% of complete responders. The use of physostigmine for reversal of anticholinergic delirium does not preclude the use of benzodiazepines for agitation and vice versa.

Seizures

Antipsychotic-induced seizures may be short and self-limited and may not require pharmacologic treatment. For multiple seizures or status epilepticus, first line treatment is lorazepam 0.1 mg/kg (maximum 4 mg) given intravenously. This dose may be repeated in 5 minutes if seizures have not terminated. Refractory seizures unresponsive to lorazepam can be treated with phenobarbital (10 to 20 mg/kg IV loading dose) or propofol infusion may be administered (80 to 200 mcg/kg/min in healthy adults <55 years old). Use of phenobarbital or propofol in these dosages will likely require endotracheal intubation and initiation of continuous EEG monitoring, if available.

Acute Extrapyramidal Syndromes

Dystonia will often respond within 30 minutes to diphenhydramine (25 to 50 mg) or benztropine (1 to 2 mg) intravenously, intramuscularly, or orally. Lorazepam (1 to 2 mg IV) may also be effective in patients who do not respond within 1 hour to diphenhydramine or benztropine. IV lorazepam may be repeated in 15 to 20 minutes if dystonia is not improved. The first line treatment for akathisia is modification of the antipsychotic regimen. In the acute setting, clinicians may start by giving benztropine (1.5 to 8 mg total daily dose, divided) until symptoms improve. If sufficient improvement in symptoms is not achieved, propranolol (40 to 80 mg total daily dose, divided) or mirtazapine (15 mg/day) can be added.[33] Treatment of drug-induced parkinsonism includes minimizing the effective antipsychotic dose. Acute therapy begins with an anticholinergic agent, dosed as for dystonia and akathisia.

Cardiotoxicity

Cardiac monitoring is recommended in patients who are symptomatic or those with ECG abnormalities until the symptoms are resolving or ECG intervals have normalized. Sinus tachycardia with normal ECG intervals is expected in overdose and does not need to be treated unless secondary cardiac injury is present. Widening of the QRS due to sodium channel blockade is uncommon and is managed similarly to cyclic antidepressant toxicity. We recommend sodium bicarbonate 1 to 2 mEq/kg IVP, which may be repeated every 3 to 5 minutes until QRS narrowing occurs. Boluses may be repeated or an infusion of 150 mEq/L of sodium bicarbonate in 5% dextrose in water may be infused at 1.5 times the calculated maintenance rate and titrated to a goal blood pH of 7.45 to 7.55.

Hypotension is generally mild and typically responds to IV sodium chloride bolus and infusion. We prefer sodium chloride as the crystalloid in these cases because the sodium ion may be beneficial in the context of sodium channel blockade. If hypotension is severe, or persists after 2 L of isotonic crystalloid, a direct-acting vasopressor with alpha-adrenergic agonism should be initiated. We recommend a norepinephrine IV infusion, started at 0.1 mcg/kg/min and titrated to maintain mean arterial pressure greater than 65 mm Hg.

Correction of hypokalemia, hypomagnesemia, and hypocalcemia shortens the QT interval. Adults with a QTc greater than 500 msec or transient torsade de pointes should be given 1 to 2 g of magnesium sulfate IV. Treatment of sustained torsades de pointes includes IV magnesium sulfate up to 4 g total, defibrillation, overdrive pacing, or isoproterenol (see Chapter 65).[34] Any drugs that prolong the QT interval should be avoided.

ED treatment of clozapine-induced myocarditis is supportive. Clozapine treatment should be discontinued when the diagnosis is suspected.

Neuroleptic Malignant Syndrome

Treatment of NMS consists of supportive care and discontinuation of all dopamine-blocking medications. Agitation, psychomotor hyperactivity, and muscle rigidity should be treated with liberal doses of IV benzodiazepines. Lorazepam is administered at a dose of 1 to 2 mg IV every 5 to 10 minutes, until muscle rigidity improves. Refractory cases or patients at risk for aspiration can be managed with intubation and neuromuscular blockade with a nondepolarizing agent (e.g., rocuronium). Hyperthermia should be managed with IV fluids and evaporative cooling. To facilitate evaporative cooling, the patient's bare skin is continually misted with water while a cooling fan blows air continuously across the skin surface. The goal of cooling is a reduction in core temperature to less than 39°C within 30 minutes. If rhabdomyolysis is present, it is treated as described in Chapter 116 with IV fluids, urinary alkalinization, and mannitol depending on the clinical severity.

The dopamine agonists bromocriptine and amantadine (both available only in enteral formulations) have been successfully used in the treatment of NMS, although the quality of evidence is low. Dopamine agonists also carry a theoretical risk of worsening psychosis and are not recommended as a first line treatment. Dantrolene has also been used for the treatment of muscle rigidity. However, as rigidity in NMS is believed to originate in the CNS rather than in myocytes, dantrolene offers no mechanistic advantage over benzodiazepines and nondepolarizing neuromuscular blockade. We do not recommend dantrolene as part of routine treatment of NMS, although it may be administered for refractory, severe rigidity.

Electroconvulsive therapy (ECT) may be used in cases of NMS refractory to pharmacologic treatment. Evidence for efficacy is limited, although it is proposed as a treatment of choice in malignant catatonia, which may be indistinguishable from NMS. One of the primary advantages of ECT is that it may continue to be used when use of antipsychotic drugs is precluded by possible NMS.

Venous thromboembolism (VTE) disease is a prominent cause of morbidity and mortality in NMS. Patients with NMS should receive pharmacologic VTE prophylaxis.

DISPOSITION

Patients with NMS and overdose patients with hemodynamic instability, coma, torsades de pointes, or airway compromise should be admitted to an intensive care unit. Patients with a prolonged QT interval of

any magnitude should have at least 12 hours of cardiac monitoring to ensure that the interval prolongation is resolving and QTc is less than 500 ms. Patients with minimal signs of toxicity should be observed for at least 6 hours from the time of ingestion, with hospitalization for persistent or worsening signs and symptoms. Criteria for hospital discharge include return of baseline mental status and normalization of vital signs with resolution of metabolic and electrocardiographic abnormalities. Psychiatric consultation may be necessary to assess the risk of harm to self or others. Patients with acute dystonia resolved by diphenhydramine or benztropine should continue the drug for 48 hours to prevent recurrence. Patients with drug-induced parkinsonism who must continue antipsychotic medications may need to use anticholinergic agents long term. Such patients should be discharged with benztropine 1 to 2 mg by mouth twice daily for at least 48 hours and should be referred to their treating physician, who may reduce the antipsychotic dose or change treatment regimens as necessary. Patients should be informed that benztropine, diphenhydramine, and other antipsychotic medications have anticholinergic effects, so combination therapy may increase symptoms of dry mouth, blurred vision, and urinary retention.

CHAPTER 150: QUESTIONS AND ANSWERS

1. Which of the following is a second-generation atypical antipsychotic?
   a. Aripiprazole
   b. Haloperidol
   c. Lumateperone
   d. Olanzapine

Answer: d. Olanzapine is an atypical second-generation antipsychotic. Aripiprazole is an atypical psychotic but would be considered a third generation. Haloperidol is a first-generation, high-potency antipsychotic. Lumateperone is a newer unique antipsychotic that affects multiple systems including serotonergic, dopaminergic, and glutamatergic.

2. A 19-year-old woman presents with urinary frequency, urgency, and dysuria. She had a urinalysis which demonstrated 20 to 40 white blood cells per high-power field. She has schizophrenia for which she takes haloperidol. You diagnose her with an uncomplicated urinary tract infection. Which of the following antibiotics could cause a life-threatening arrhythmia if administered to this patient?
   a. Amoxicillin/clavulanic acid
   b. Ciprofloxacin
   c. Cephalexin
   d. Nitrofurantoin

Answer: b. Antipsychotics can cause QT prolongation, so other drugs that cause QT prolongation should be avoided. Macrolides, fluoroquinolones, and trimethoprim-sulfamethoxazole are common antibiotics that can all cause QT prolongation.

3. A 32-year-old man presents complaining of neck pain. His neck is turned to the right and he states that he has difficulty moving it. He denies any trauma and has not had a fever. He has no previous similar episodes. He has schizophrenia but cannot recall the names of his medications. His vital signs are normal and his examination reveals a palpable spasm of the right trapezius and sternocleidomastoid muscles. What is the most appropriate treatment?
   a. Bromocriptine
   b. Cyclobenzaprine
   c. Diphenhydramine
   d. Morphine

Answer: c. This patient has an acute dystonic reaction to an antipsychotic medication best treated with an anticholinergic medication, such as diphenhydramine or benztropine. Bromocriptine is a dopamine agonist used to treat pituitary disorders and can worsen psychosis. Cyclobenzaprine can be used for typical muscle spasms but will not significantly improve acute dystonia. Morphine may help but does not resolve the underlying problem.

4. A 52-year-old man presents to the emergency department with a cough. He is tachycardic with a temperature of 38.6°C. His chest x-ray has a left lower lobe infiltrate. His lab work is significant for a leukopenia with an absolute neutrophil count of 250 cells/μL. His past medical history is significant for psychiatric illness. Which of the following medications is he most likely to be taking?
   a. Clonidine
   b. Clozapine
   c. Fluoxetine
   d. Lithium

Answer: b. Clozapine is an antipsychotic associated with agranulocytosis and neutropenia. Clonidine is an alpha-adrenergic agonist with no known association with this condition. Fluoxetine is a selective serotonin reuptake inhibitor commonly used in the treatment of depression and is not known to cause neutropenia. Lithium is used as a mood stabilizing medication such as in bipolar disorder and not known to cause an alteration in cell counts.

5. A 23-year-old woman is brought to the emergency department by her boyfriend with a change in mental status. He reports that the patient had her psychiatric medications adjusted 3 days ago and has been confused since then. The patient's vital signs are: blood pressure: 162/100 mm Hg; heart rate: 140 beats/min; respiratory rate: 22 breaths per minute; and temperature: 40.2°C. On physical examination, the patient is noted to have muscle rigidity. Laboratory tests are pending. Intravenous (IV) access is obtained, and balanced crystalloid fluids are started. Cool mist and fans are applied to the patient. What therapy is indicated next?
   a. Acetaminophen
   b. Cyproheptadine
   c. Dantrolene
   d. Lorazepam

Answer: d. The patient has neuroleptic malignant syndrome (NMS) and the best first line treatment option is a benzodiazepine, such as lorazepam. Acetaminophen is ineffective in treating the hyperthermia, which should be treated with active cooling measures. Cyproheptadine can be used in serotonin syndrome but does not improve NMS. Dantrolene can be used in malignant hyperthermia and for refractory, severe muscle rigidity but has no mechanistic indication in NMS, and evidence for its use is of low quality. Diphenhydramine is used for acute dystonia and does not affect the course of NMS.

Opioids

Jenna Karagianis Nikolaides and Trevonne M. Thompson

KEY CONCEPTS

- The opioid toxidrome includes three prominent findings—central nervous system depression, miosis, and, most importantly, respiratory depression—but presentations may be variable.
- A negative urine screen is often unreliable, and absence of detection should not deter a diagnosis of opioid intoxication when clinical findings support it.
- Airway protection, oxygenation, ventilation, and early administration of the reversal agent naloxone are the cornerstones for management of patients with opioid toxicity.
- The duration of action of many opioids, especially after overdose, is significantly longer than that of naloxone. Patients responsive to naloxone should be observed for recurrence of respiratory depression because they may require additional doses of naloxone.
- Naloxone distribution, prescription drug monitoring programs, and initiation of buprenorphine with a referral to addiction treatment programs are ways in which the medical profession is trying to combat the epidemic of opioid-related deaths.
- Opioid withdrawal syndrome does not include altered cognition. Patients with known or suspected opioid withdrawal who also have altered mental status should be evaluated for an alternative cause of altered cognition.

PRINCIPLES OF TOXICITY

Opiate is the term for natural agents derived from the poppy plant that have morphine-like pharmacological effects. Examples of opiates include morphine and codeine. Opioid is the more inclusive term, which refers to any synthetic, semisynthetic, or natural agent that has morphine-like properties. Some common semisynthetic opioids are heroin, hydrocodone, oxycodone, hydromorphone, oxymorphone, and buprenorphine. Some common synthetic opioids are fentanyl, methadone, and meperidine. Both "opiate" and "opioid" are terms derived from "opium," which was the Greek word for the juice of the poppy plant (Papaver somniferum).

Opioids are among the world's oldest known drugs. The therapeutic use of opioids has been a practice since ancient times, with the primary goals being sedation and analgesia. Opioids act on receptors in the central nervous, cardiovascular, pulmonary, and gastrointestinal systems and can also be used therapeutically for their antitussive and antidiarrheal effects.

Pain is a common reason why patients present to the emergency department (ED). Since the Joint Commission placed increased attention on pain management and hospitals increased their emphasis on patient satisfaction, there has been a proliferation in the number of opioid prescriptions written by physicians, including emergency providers. This trend did not lead to an actual improvement in overall patient satisfaction, but rather led to a flood of available opioids into the wider population.[1] According to the Centers for Disease Control and Prevention (CDC), there was a 300% increase in the sale of opioid analgesics from 1999 to 2011. As the medical profession recognized the severity of the subsequent epidemic of deaths due to opioids, the CDC issued new opioid prescribing guidelines[2] in 2016 and prescription rates began to decline.[3]

Opioid-related fatalities continued, however, because of a concomitant rise in illicit heroin use, and a heroin supply that has been mixed with a family of synthetic opioids such as fentanyl. According to the CDC, the death rate from heroin overdose increased five-fold from 2010 to 2017.[4] There has also been a change in demographics of heroin use. Formerly involving primarily inner-city minority populations, in recent years, the use of heroin has spread geographically beyond urban areas[5] and has increased among men and women, in most age groups and at all income levels. Some of the greatest increases have occurred in women, the privately insured, and people with higher incomes.[6] It is now believed that prescription analgesics can be a gateway to heroin use. During 2000 to 2013, approximately three out of four new heroin users reported having misused prescription opioids prior to using heroin.[5]

The wider availability of opioids has affected each population group. This has been especially concerning for pediatric patients, because analgesic prescriptions written for adults can end up in the hands of children and adolescents. From 1999 to 2016, there was an approximate threefold rise in the mortality rate of pediatric opioid poisonings, resulting in the deaths of nearly 9000 children and adolescents.[7] Unintentional opioid overdose is also a growing concern among chronic pain patients, geriatric patients, and obese patients because risk is increased by polypharmacy, medical comorbidities, and sleep apnea.

Opioids come in three forms: synthetic, semisynthetic, and natural opiates. There are prescription versions of all three forms, which are available in many different preparations, including tablets, liquids, patches, and even lollipops. Prescription opioids are commonly packaged as combination preparations with acetaminophen, ibuprofen, and aspirin, and have historically existed in combination with atropine and camphor. Other prescription oral preparations are formulated with opioid-receptor antagonists, such as naloxone, which has little oral bioavailability to prevent illicit use and intentional alteration for intravenous (IV) misuse. There are also prescription drugs that are not chemically classified as opioids, but which have opioid receptor agonist properties, such as tramadol and tapentadol.

Illicit opioids also exist in all three forms. Table 151.1 details some of the known street names for opioids sold illicitly.[8,9] Street names are often unreliable, however, because they tend to be regional and are subject to dealers who attempt to market or rebrand their product to cater to their target population. Heroin (diacetylmorphine), a semisynthetic opioid, is the most widespread street preparation, but recent years have seen a rise in synthetics, such as fentanyl, fentanyl analogues, and other novel substances such as U-47700, often mixed with or mislabeled as heroin. Synthetic opioids have also proliferated in the form of counterfeit pills due to increased demand for prescription opioids on the illicit

TABLE 151.1 Street Names for Illicitly Obtained Opioids

Opioid	Street Names
Heroin	Dope, Smack, H, Horse, Junk, Skag, Skunk, Brown Sugar, White Horse, China White
Heroin + acetaminophen and diphenhydramine	Cheese
Codeine ± acetaminophen	Captain Cody, Cody, Lean, Schoolboy, T-threes, cough syrup
Codeine + promethazine + soft drinks and hard candy	Purple Drank, Sizzurp
Codeine + glutethimide	Doors & Fours, Loads, Pancakes and Syrup
Fentanyl	China White, China Girl, Apache, Dance Fever, Friend, Goodfella, Jackpot, Murder 8, Tango and Cash, TNT
Hydrocodone ± acetaminophen	Vike, Watson-387
Hydromorphone	D, Dillies, Footballs, Juice, Smack
Meperidine	Demmies, Pain Killer
Methadone	Dollies, Amidone, Fizzies
Methadone + MDMA	Chocolate Chip Cookies
Morphine	M, Morph, Miss Emma, Monkey, White Stuff
Oxycodone ± acetaminophen	O.C., Oxycet, Oxycotton, Oxy, Hillbilly Heroin, Percs
Oxymorphone	Biscuits, Blue Heaven, Blues, Mrs. O, O Bomb, Octagons, Stop Signs
Pentazocine	Yellow Footballs

MDMA, N-methyl-3,4-methylenedioxyamphetamine.

drug market.[10] Consequently, the U.S. Drug Enforcement Administration (DEA) added "Fentanyl-Related Substances" to the list of Schedule I drugs in 2018, making it illegal to manufacture, distribute, or possess fentanyl analogs.[11]

Illicit opioid preparations can be contaminated by the byproducts from the manufacturing process, adulterated with additives to change the preparation's pharmacological effects, and diluted with inert substances to increase bulk. The most commonly found additional substances are sugars and starches, talcum powder, caffeine, over-the-counter medications (such as diphenhydramine), prescription medications (including other opioids, quinine, benzodiazepines, and other psychoactive medications such as antipsychotics),[12,13] other illicit drugs (such as cocaine), heavy metals, and spore-forming infectious agents.[14,15] Toxicity can occur as a consequence of intentional overdose, recreational misuse, or as an adverse effect of therapeutic use. Although different opioids have receptor preferences in therapeutic doses, this specificity is lost at higher doses.

Opioids are well absorbed via gastrointestinal, IV, intramuscular (IM), mucocutaneous, and subcutaneous routes of administration. Depending on the lipid solubility of the specific opioid, they can also be absorbed through nasal, buccal, pulmonary, or a specifically formulated transdermal delivery system.[16] In general, toxicity is less pronounced but more prolonged when ingested than with parenteral administration. In therapeutic doses, an ingested opioid is absorbed in the small intestine within 1 to 2 hours. In toxic doses, delayed gastric emptying prolongs the absorption and clinical effects of the opioid.

Most opioids have a large volume of distribution. Different opioids and their metabolites cross into the blood-brain barrier due to variations in lipid solubility. All opioids undergo hepatic metabolism and renal elimination. Thus, changes in hepatic or renal function will alter drug clearance, which could prolong clinical and toxic effects of the specific opioid.

CLINICAL FEATURES

The hallmarks of the opioid toxidrome are central nervous system (CNS) depression, respiratory depression, and miosis. Miosis is caused by stimulation of μ receptors in the Edinger-Westphal nuclei of the third cranial nerve. This effect may be unreliable or masked by coingestants and, thus, respiratory depression is the essential feature of opioid intoxication. Respiratory depression is caused by opioids' effect on the medullary respiratory center via suppressing its sensitivity to hypercapnia and overriding the hypoxic drive. When combined with CNS depression, prolonged hypopnea can lead to hypoxia, causing further neurologic complications and death. Long-term opioid use is known to cause dependence and appears to contribute to central sleep apnea, as well as structural and functional changes in the brain.

Acute lung injury can be seen in opioid overdose, and pulmonary edema can cause further hypoxia. This manifests as desaturations on pulse oximetry, despite an adequate respiratory rate, with rales auscultated on lung examination. The cause of acute lung injury in opioid overdose is not clearly elucidated but may be related to a capillary leak phenomenon.

Other signs and symptoms commonly associated with opioids include relative bradycardia, mild hypotension, pruritus, skin flushing, nausea, vomiting, and bowel dysfunction. Hypotension, pruritus, and flushing are caused by nonallergic histamine release—an effect more pronounced with morphine. Nausea and vomiting are frequently seen, even in therapeutic doses of opioids, and are responsive to antiemetics and more potent opioids. Decreased gastrointestinal motility, delayed gastric emptying, constipation, and ileus are all commonly described with the spectrum of opioid-induced bowel dysfunction.

The skin should be examined in a patient exhibiting the opioid toxidrome because it may give diagnostic clues as to which opioids have been used. Look for the presence of fentanyl patches over the entire body, including in the oropharynx and other bodily orifices. If IV puncture sites or scars from "skin popping" (a process where opioids are injected subcutaneously) are detected, these findings could be signs of illicit opioid use.

Certain opioids have unique clinical findings due to their chemical structure or to their route of exposure (Table 151.2). Propoxyphene is associated with sodium channel blockade properties, causing QRS widening, in addition to PR and QT interval prolongation, which led to its withdrawal from the market. Methadone is known to block the human ether-a-go-go-related gene (hERG) as well as potassium channels, causing QTc prolongation. Propoxyphene, meperidine, and tramadol have been associated with hypertonicity, myoclonus, and seizures. Meperidine, methadone, tramadol, and fentanyl inhibit serotonin reuptake and are associated with serotonin syndrome. Sensorineural hearing loss has been reported with both acute and chronic use of heroin, methadone, and hydrocodone, thought to be due to direct ototoxicity. Heroin has also been found to be associated with Parkinsonian-like symptoms. A practice known as "chasing the dragon," where heroin is heated in aluminum foil and the vapor inhaled, has been found to be associated with spongiform leukoencephalopathy, with symptoms including psychomotor retardation, dysarthria, ataxia, and tremor.

Patients who hastily ingest loosely packaged bags of illicit drugs are known as "body stuffers." Patients who internally conceal dense and meticulously packaged packets of illicit drugs for the purpose of trafficking across international borders are known as "body packers." Heroin is a common drug seen in both stuffers and packers. Both populations are at risk for severe and prolonged opioid toxicity if the

TABLE 151.2 Special Clinical Properties of Certain Opioids

Effect	Opioid
QRS widening, sodium channel blockade	Propoxyphene
QT widening, potassium channel blockade	Methadone
Seizures	Propoxyphene, meperidine
Serotonin syndrome	Meperidine, methadone, tramadol, fentanyl
Hearing loss, ototoxicity	Methadone, hydrocodone, heroin
Spongiform leukoencephalopathy Parkinsonism	Heroin via "chasing the dragon" or inhalation of heroin vapor

packets leak or rupture. Heroin "stuffers" however, generally do not ingest enough to cause serious effects when compared to "packers," who may have several-fold lethal amounts of concentrated product in their gastrointestinal tract.

DIFFERENTIAL DIAGNOSES

The diagnosis of opioid intoxication is usually based on history, vital signs, and physical examination, with recognition of its characteristic toxidrome: hypopnea, stupor, and miosis. All of these findings are not consistently present, and the clinical picture may be complicated by cointoxicants. The essential finding in opioid intoxication is respiratory depression. Other intoxications may present similarly, such as clonidine, guanfacine, tetrahydrozoline, valproic acid, gamma-hydroxybutyrate, ethanol, sedative hypnotics, and atypical antipsychotics. Nontoxicologic considerations include pontine stroke or hemorrhage.

DIAGNOSTIC TESTING

No laboratory test or drug screen should be relied upon by the emergency clinician to make the diagnosis of opioid toxicity. The presence of the toxidrome and rapid response to naloxone are the two most important diagnostic clues. End-tidal carbon dioxide and oxygen saturation monitoring may be helpful for recognition of respiratory depression and hypoxia but are not as necessary as observation of the patient's respiratory rate.

A 12-lead electrocardiogram is a useful diagnostic for identifying QRS widening, as seen in propoxyphene use, or for QTc prolongation, as seen in methadone use. If the patient exhibits audible pulmonary rales on examination, then a chest radiograph is useful to evaluate for the presence of acute lung injury. If the opioid preparation is unknown, then acetaminophen and salicylate levels should be measured, because many prescription opioids are sold as combination preparations with these pain relievers. Hypoglycemia is the only consistent laboratory abnormality found in opioid toxicity. It is generally mild but can contribute to the decreased level of consciousness seen in opioid overdose. In addition, a serum ethanol level should be measured.

If needed for confirmation, a urine drug screen can be obtained once the patient has been stabilized. Nonetheless, a negative urine screen can be unreliable, and absence of detection should not deter a diagnosis of opioid intoxication when clinical findings support it. Opiates or opioids that metabolize to opiates, such as morphine, codeine, and heroin, are reliably detected on most qualitative antibody-based enzymatic immunoassay urine toxicology screens. Some semisynthetic and synthetic opioids, such as oxycodone, methadone, and fentanyl, however, are often missed on typical urine drug screens unless they are specifically measured. A urine test result can remain positive for up to 72 hours after last use, depending on the half-life of the drug used. A large poppy seed ingestion can lead to a positive opiate screen, although federal workplace testing guidelines have raised the confirmatory morphine concentration threshold to 2000 ng/mL to avoid positive screens for commonplace poppy seed ingestions in food sources. Advanced screening methods detecting for 6-monoacetylmorphine, a specific metabolite of heroin, can be used to confirm heroin use, although this test is generally not available in the ED setting.

MANAGEMENT

Stabilization and Supportive Care

The ED clinician should direct efforts at stabilizing the patient's airway, oxygenation, and ventilation. This can be accomplished with a combination of basic supportive measures and titrated use of naloxone. Patients with acute lung injury may require oxygen and positive-pressure modalities, such as bi-level positive airway pressure (BiPAP), continuous positive airway pressure (CPAP), or mechanical ventilation with positive end-expiratory pressure (PEEP).

Decontamination

Because many opioids are extended-release preparations and can also delay gastric motility, activated charcoal has been used in the past but there are no data to support or refute the effectiveness of this practice. Additionally, naloxone is a highly effective antidote for opioid overdose, and sedation from opioid intoxication could conceivably lead to charcoal aspiration. Hence, activated charcoal administration should be considered on a patient-specific basis, but we generally discourage its use in patients with opioid intoxication. Gastric lavage similarly is not recommended because the risks outweigh the benefits. Whole bowel irrigation is not generally useful, but it can be considered for body packers (see Chapter 135).

Enhanced Elimination

As mentioned previously, most opioids have a large volume of distribution. There are no clinically effective techniques for enhanced or extracorporeal elimination of opioids.

Antidote Therapy

Naloxone is a competitive opioid antagonist that rapidly reverses the effects of opioid intoxication. Because of the rapid clinical response, it can also aid in the diagnosis of opioid overdose. Naloxone is ineffective orally because its bioavailability is minimal due to first-pass hepatic metabolism. It is effective via IV, subcutaneous, intramuscular (IM), intranasal (IN), inhalational, and endotracheal routes. It is indicated when an opioid-intoxicated patient has significant CNS or respiratory depression.

In the ED, naloxone is usually administered intravenously with empirical dosing. The dose widely ranges from 0.04 to 15 mg, depending on the amount and formulation of the opioid taken, the patient's weight, and whether the patient is opioid dependent. In general, it is best to start with low doses and to increase each subsequent dose as needed to alleviate respiratory depression. The exception to this rule is the arrest or near-arrest situation where opioids are the suspected cause. In this scenario, recommended starting doses are 0.4 to 4.0 mg IV. In chronic opioid users, the minimal effective naloxone dose should be used so as not to precipitate acute withdrawal. In this population, when respiratory status is adequate, we recommend starting with doses of 0.04 mg of naloxone, followed by titration of subsequent doses. Acute opioid withdrawal can be unpleasant for the habituated patient, but it is not considered life-threatening. Furthermore, naloxone has an excellent safety profile. The clinician should not be reluctant to dose

naloxone as needed, even if opioid withdrawal symptoms develop, in order to ensure adequate patient oxygenation and ventilation.

Naloxone's onset of action, when administered intravenously, is less than 2 minutes, and the duration of action is anywhere between 20 minutes and 2 hours, which is shorter than the duration of action of most opioids. Reversal of respiratory depression usually occurs at low doses, but dosing may be repeated until the desired effect is achieved. If respiratory depression is not reversed after the administration of high doses of naloxone (10 to 15 mg), then it is unlikely that opioid intoxication is the cause of the symptoms. If naloxone does reverse the symptoms but the patient later develops recurrent respiratory depression, then repeated naloxone doses, a continuous naloxone infusion, or endotracheal intubation should be considered. When starting a naloxone infusion, one-half to two-thirds of the bolus dose that effectively reversed intoxication is given hourly, although individual patient responses may vary depending on dose, tolerance, and dependency. This is usually enough to maintain an adequate respiratory effort without producing withdrawal.

In situations where IV access is not easily obtained, naloxone can also be given via IM, IN, IO, or nebulized routes. IN naloxone has proved a viable alternative to IV administration, especially for prehospital providers and nonmedical bystanders. It is available as 0.4 mg/mL and 1 mg/mL solutions, in vials or prefilled syringes, delivered into each nostril using an atomizer device, or as a 4 mg/0.1 mL prepackaged nasal spray.[17] Nebulized naloxone—2 mg of naloxone is mixed with 3 mL of saline—has also been shown to be a safe, effective, and gradual way to reverse opioid intoxication in both the ED and prehospital settings. Care must be taken in selecting the optimal patient for nebulized naloxone. A patient with profound respiratory depression, such as a respiratory rate of less than six breaths per minute or cyanosis, will not receive enough naloxone via a nebulizer to obtain the desired clinical effect.

Nalmefene and naltrexone are opioid antagonists with longer half-lives and duration than naloxone. Nalmefene's duration of action is 4 to 10 hours. Naltrexone is available in an oral preparation, with a duration of action between 24 to 72 hours, and as an extended-release injectable solution, with a duration of action of up to 30 days. We do not recommend their use in the ED because of concern for inducing a prolonged withdrawal state. Naloxone bolus and titration remains the treatment of choice for opioid reversal in the acutely intoxicated patient.

DISPOSITION

Patients who present with heroin toxicity can be successfully treated in the ED. Opioid intoxicated patients who use longer-acting opioids may require an admission to an observation unit. Body stuffers who remain asymptomatic after 6 hours of observation may be discharged. Asymptomatic body packers, however, require admission until all packets have been successfully passed or retrieved. If an overdose is severe, involves multiple drugs, or requires multiple doses of naloxone, naloxone infusion, or endotracheal intubation, then intensive care unit (ICU) admission is appropriate.

The observation period following the administration of naloxone is dependent on the opioid implicated in the poisoning. Overdoses of long-acting opioids or sustained-released opioid preparations will require longer observation periods. In cases of heroin-only overdose, an observation period of up to 4 hours is generally sufficient. After an appropriate observation period, if there are no signs of recurrent toxicity and no concerns for longer-acting coingestants, the patient may be discharged. When indicated, the patient may require a psychiatric evaluation or be referred for substance misuse counseling and an appropriate treatment program.

In recent years, as the opioid overdose epidemic has grown, there have been increased efforts to expand access to naloxone as a public health measure intended to save lives. Most states have passed laws to widen the availability of naloxone to family, friends, and other potential bystanders of an overdose.[18] Community and hospital-based initiatives have worked to educate opioid users and bystanders on signs of overdose, train them for out-of-hospital naloxone use, and then distribute or prescribe naloxone directly to patients or bystanders.[19,20] Both IN and IM auto-injector delivery methods have been used.[21] The number of naloxone prescriptions dispensed from retail pharmacies increased substantially from 2012 to 2018.[22] These programs are showing that providing overdose education and naloxone distribution has decreased opioid overdose mortality.[19,23] Prescribing take-home naloxone is one intervention that the emergency provider can provide to reduce the harm caused by opioids.

Another evolving public health effort is the use of prescription drug monitoring programs (PDMPs), which are currently available in 49 U.S. states, the District of Columbia, and Guam.[24] To decrease the opioid burden in the community, the emergency provider can use these programs to access a patient's prescription opioid history prior to prescribing a new opioid upon discharge. However, while there is some evidence to suggest that states with more robust PDMPs have less overdose deaths,[25] inconsistent implementation has resulted in mixed results regarding the impact PDMPs have on prescribing[26] and on overdose deaths.[27] There have been several proposed solutions, such as improving the technology and its integration into electronic medical records, which may make PDMPs a more useful public health tool in the ED setting.[28]

WITHDRAWAL

Withdrawal occurs in tolerant patients when opioids are abruptly withheld or an antagonist is administered. In withdrawal, the patient goes into a hyperadrenergic state. The symptoms include yawning, piloerection, CNS excitation, tachypnea, mydriasis, tachycardia, hypertension, nausea, vomiting, diarrhea, abdominal cramps, and myalgias. CNS excitation takes the form of restlessness, agitation, dysphoria, and insomnia. Cognition and mental status are usually unaffected. In general, opioid withdrawal is uncomfortable but not life-threatening. As with opioid toxicity, no diagnostic test exists for acute opioid withdrawal. It is diagnosed based on the patient's symptoms, signs, and a history of prior opioid use.

Treatment for the withdrawing patient in the ED has historically been supportive and symptom-based: IV fluids, electrolyte replacement, and antiemetics. Clonidine, an alpha$_2$-agonist, can be used to suppress sympathetic hyperactivity and shorten the duration of withdrawal. However, there are now increased efforts by EDs to use buprenorphine, a long-acting partial opioid agonist approved by the U.S. Food and Drug Administration (FDA) for opioid use disorder, to not only control withdrawal, but to also initiate as a maintenance therapy in the ED as a bridge to long-term addiction treatment.[29] For an emergency provider to be able to prescribe buprenorphine at discharge, additional training to get an X-waiver applied to his or her DEA license is required. Methadone, a full opioid agonist, can also palliate withdrawal and has federal prescribing restrictions, as well. Even without a waiver, emergency providers are permitted to initiate the administration of either buprenorphine or methadone for 72 hours to patients under their care for the purposes of transitioning patients to outpatient treatment through an opioid treatment program or addiction medicine specialist.[30] Opioid withdrawal alone typically does not require inpatient treatment, but some patients with severe symptoms and other comorbidities may require admission. It has been documented that patients who ultimately die from an opioid overdose sharply increase their ED utilization prior to their death.[31] Therefore, treating withdrawal in the ED setting gives emergency providers a sentinel opportunity to engage patients in treatment and long-term recovery.[32]

CHAPTER 151: QUESTIONS AND ANSWERS

1. Most opioids cause mild hypotension related to histamine release and bradycardia. Which of the following opioids can also cause sodium channel blockade and QRS widening?
   a. Hydromorphone
   b. Hydrocodone
   c. Morphine
   d. Oxycodone
   e. Propoxyphene

Answer: e. Propoxyphene and its metabolite norpropoxyphene can cause QRS widening. None of the other listed opioids has significant effects on the cardiac conduction system.

2. Which of the following laboratory abnormalities is most commonly seen in opioid overdose?
   a. Hypocalcemia
   b. Hypochloremia
   c. Hypoglycemia
   d. Hypokalemia
   e. Hyponatremia

Answer: c. Hypoglycemia is the only consistent laboratory abnormality found in opioid overdose. It is generally mild but can contribute to the decreased level of consciousness seen in opioid overdose.

3. A 32-year-old man presents with confusion, nausea, vomiting, diarrhea, and abdominal pain. His friends report that he is withdrawing from heroin. Vital signs reveal mild hypertension, tachycardia, and tachypnea. Physical examination is significant for confusion, mydriasis, diaphoresis, lacrimation, piloerection, and mild diffuse abdominal tenderness. Which of the following signs and symptoms makes you concerned that this may not be a simple opioid withdrawal case?
   a. Confusion
   b. Diarrhea
   c. Mydriasis
   d. Piloerection
   e. Tachycardia

Answer: a. Opioid withdrawal almost always causes restlessness, agitation, and anxiety. Cognition and mental status are not affected in simple opioid withdrawal and, if present, should prompt the clinician to search for other causes instead of, or in addition to, withdrawal.

4. A 20-year-old woman is brought to the emergency department (ED) after being found with decreased mental status at a club. Vital signs indicate mild hypotension and bradycardia. She is drowsy but arousable, and she has an otherwise normal physical examination. Upon receiving naloxone 2 mg IV, her mental status immediately improves and soon thereafter she vomits. She now reports nausea but has no other complaints. She states that she took some "pain pills" to get high but does not know what they were. What diagnostic tests should be performed?
   a. Acetaminophen
   b. Arterial blood gas
   c. Chest radiograph
   d. Lactate
   e. Urine drug screen

Answer: a. Because many prescription opioid medications are combinations of an opioid and acetaminophen, ibuprofen, or salicylate, concentrations of acetaminophen and salicylate should also be ordered. Acetaminophen overdose might otherwise remain undiagnosed but, if identified, can be treated with an existing antidote, *N* acetylcysteine. The chest radiograph is not indicated unless a pulmonary complication is suspected. Lactate and a urine drug screen would not change patient management.

5. Which of the following medications can be used to treat opioid withdrawal?
   a. Clonidine
   b. Dextromethorphan
   c. Diphenhydramine
   d. Nalmefene
   e. Valproic acid

Answer: a. Clonidine suppresses the sympathetic hyperactivity of opioid withdrawal. Dextromethorphan is an opioid derivative used as a cough suppressant, but it does not treat the symptoms of opioid withdrawal. Diphenhydramine is not the most commonly used antihistamine for a patient in withdrawal. Valproic acid has no role in opioid withdrawal. Nalmefene is an opioid antagonist similar to naloxone but with a longer duration of action. Administration of nalmefene is longer-acting than naloxone and would worsen opioid withdrawal symptoms.

6. A 14-month-old child is brought to the emergency department (ED) 4 hours after he was found with his grandmother's antidiarrheal medication bottle. A pill count identifies that only one Lomotil tablet is missing. The child is playful, has a normal respiratory rate and pattern, and has a soft abdomen with normal bowel sounds. Appropriate management includes which of the following?
   a. Administration of activated charcoal
   b. Administration of naloxone
   c. Admission to a monitored unit
   d. Discharge home
   e. Gastric lavage

Answer: c. Activated charcoal and gastric lavage are means of gastrointestinal decontamination and are not routinely recommended in opioid toxicity. Opioid intoxicated patients with central nervous system (CNS) and respiratory depression should be treated with naloxone, but asymptomatic patients do not require antidote administration. Asymptomatic patients with known or suspected Lomotil (diphenoxylate/atropine) ingestion should be observed in a monitored setting for delayed onset of toxicity from the metabolite of diphenoxylate.

7. An 18-year-old male is driven to the emergency department (ED) by friends and carried into the triage area. He has agonal respirations and is cyanotic. Immediate resuscitative measures include bag-valve-mask (BVM) ventilation, establishment of an intravenous (IV) line, and administration of 0.4 mg of naloxone. The patient's respiratory status improves and, although sleepy, he is able to answer some questions. During subsequent monitoring, the patient's respiratory status again declines, and he requires two additional doses of naloxone. Additional treatment should include which of the following?
   a. Nalmefene
   b. Naloxone infusion
   c. Hemodialysis
   d. Naltrexone
   e. Narcan nasal spray

Answer: b. This patient likely has toxicity from a long-acting opioid agent, and a continuous infusion of naloxone will be necessary for ongoing reversal of toxicity. Nalmefene and Naltrexone are a longer-acting opioid antagonists but are not preferred over naloxone infusion because naloxone allows for dose titration. Once multiple doses of IV narcan are given, there is no role for narcan nasal spray. Opioids are not dialyzable due to large volumes of distribution.

CHAPTER 151: QUESTIONS AND ANSWERS—cont'd

8. A 26-year-old female is brought to the emergency department (ED) from the local airport by law enforcement. She is sleepy, with small pupils, and mumbles incoherently in a foreign language. Vital signs include the following: blood pressure, 104/66; respiratory rate, 14 breaths/min; and temperature, 98.6°F. Which of the following tests might identify the cause of this patient's symptoms?

a. Abdominal radiograph
b. Electrocardiogram (ECG)
c. Electroencephalogram (EEG)
d. Head computed tomography (CT)
e. Urine drug screen

Answer: a. An abdominal radiograph would likely reveal multiple packets of illicit opioid in the gastrointestinal tract of this body packer. One or more of the packets has leaked, producing the opioid toxicity. A urine drug screen may not identify an opioid but would not identify the internal packets. A head computed tomography (CT) scan would not be helpful unless associated head trauma is suspected. An EEG and ECG would not provide specific information to identify the internal packets.

Pesticides

Katherine Louise Welker and Trevonne M. Thompson

KEY CONCEPTS

- Organophosphates cause symptoms by accumulation of acetylcholine.
  - Treat cholinergic symptoms with atropine.
  - Reverse the inhibition of acetylcholinesterase with oximes.
- Aging, which results in prolonged toxicity, occurs with organophosphate poisoning, but not with carbamates.
- Chlorinated hydrocarbons can present with seizures and cardiac toxicity.
- Substituted phenols are found in weight loss products and exert their toxicity by uncoupling oxidative phosphorylation. These products can cause cardiac, liver, and renal injury.
- Chlorophenoxy compounds cause muscular injury. Measure creatinine kinase; assess for acute rhabdomyolysis, kidney injury, and liver injury.
- Bipyridyl compounds (paraquat and diquat) cause pulmonary and renal injury.
  - Paraquat concentrates in lungs; supplemental oxygen therapy should be limited, since this will exacerbate pulmonary toxicity.
  - Diquat causes renal injury.
- Pyrethrins and pyrethroids cause local dermatologic symptoms.
- Acute toxicity with glyphosate is likely related to the surfactant included in the product.
- DEET (N, N-Diethyl-meta-toluamide) should not be used in infants younger than 2 months old. DEET in concentrations of more than 30% should not be used in children and may result in neurotoxicity and self-limited seizure activity if used in excessive amounts.
- Most rodenticide exposures will be superwarfarin compounds.
  - For large exposures, International Normalized Ratio (INR) should be checked at a minimum of 2 days after ingestion.
  - Vitamin K should be used for reversal; blood products should be used for active bleeding.

Pesticide is a general term that refers to all pest-killing agents. It includes insecticides, herbicides, rodenticides, and fungicides. In this chapter, several classes of pesticides will be discussed, as well as their importance in the emergency department (ED) setting (Table 152.1).

ORGANOPHOSPHATE INSECTICIDES

Foundations

Organophosphates are a class of insecticide that work by inhibiting cholinesterases, including acetylcholinesterase and pseudocholinesterase. This is both the mechanism of their efficacy as insecticides, as well as their toxicity in humans. Inhibition of cholinesterases results in accumulation of acetylcholine at multiple receptors within the autonomic nervous system, such as the sympathetic and parasympathetic ganglionic nicotinic sites, postganglionic cholinergic sympathetic and parasympathetic muscarinic sites, skeletal muscle nicotinic sites, and central nervous system sites (Fig. 152.1).[1]

Organophosphates are lipid soluble and are absorbed through dermal, gastrointestinal, and respiratory routes. This can lead to deposition in fat tissues, allowing for possible toxicity from acute and chronic, low-level exposures. Some organophosphates have active metabolites that can result in delayed toxicity.

For a discussion of chemical warfare nerve agents (e.g., sarin gas and novel "*Novichok*" agents), see Chapter 55.

Clinical Features

Organophosphate toxicity is represented by the "SLUDGE" or "DUMBELS" syndrome (these are acronyms, which are explained in Box 152.1) manifested by accumulation of acetylcholine at receptor sites. The clinical features in any given case are attributable to the location of the receptors affected, the properties of the specific organophosphate product (predominance of nicotinic versus muscarinic effects), and the dose of the exposure. Muscarinic acetylcholine accumulation leads to salivation, lacrimation, urinary incontinence, defecation, emesis, bronchospasm, bronchorrhea, and bradycardia. Nicotinic acetylcholine accumulation leads to tachycardia, tachydysrhythmias, and skeletal muscle fasciculations.

At the neuromuscular junction, excess acetylcholine causes hyperstimulation of the muscles with secondary paralysis, and when the diaphragm is affected, cholinesterase poisoning leads to respiratory arrest. Sympathetic stimulation can lead to diaphoresis. A combination of sympathetic stimulation, involvement of the *N*-methyl-D-aspartate (NMDA) receptor, and enhanced acetylcholine concentrations can induce seizures.[2,3]

Pulmonary edema can occur in organophosphate poisoning and should not be confused with bronchorrhea or bronchospasm. Pulmonary edema results from many factors, including the release of inflammatory mediators and increased vascular permeability. Bronchospasm and bronchorrhea are mediated by both central and local mechanisms involving acetylcholine. Pulmonary edema, bronchospasm, bronchorrhea, and the aforementioned respiratory muscle paralysis all contribute to respiratory failure.

Although the classic clinical picture of acute organophosphate poisoning is more apparent, toxicity from gradual, cumulative exposure may be subtle. These patients commonly exhibit vague confusion or other central nervous system complaints; mild visual disturbances; or chronic abdominal cramping, nausea, and diarrhea.

A unique feature of organophosphate insecticides is the process called *aging,* the irreversible conformational change that occurs when the organophosphate is bound to the cholinesterase enzyme for a prolonged time. This causes the clinical effects to persist for periods of days to weeks. The time to aging varies by the specific product involved. Once an enzyme has aged, an oxime antidote (as discussed under Antidote Therapy) cannot regenerate the cholinesterase.

Differential Diagnoses

Differential diagnoses for acetylcholinesterase inhibitor poisoning are limited. Carbamate pesticides, carbamate medications (e.g., rivastigmine), nicotine and other nicotine alkaloids, and cholinomimetics (e.g., pilocarpine) are xenobiotics that can cause a similar constellation of symptoms. There are few medical conditions included in the differential diagnosis: viral and bacterial gastroenteritis, as well as conditions causing exaggerated vagal response (e.g., inferior wall myocardial infarction with pulmonary edema) and conditions that cause exaggerated sympathetic responses (e.g., thyroid storm or pheochromocytoma).

Diagnostic Testing

Patients who present with the classic cholinergic toxidrome should be treated empirically without waiting for laboratory confirmation of decreased cholinesterase activity. Known or suspected exposures to organophosphates can be evaluated by assessing plasma and erythrocyte (red blood cell [RBC]) cholinesterase concentrations. These concentrations are not generally available in real-time clinical settings and are usually sent out to regional reference laboratories for analysis.

In acute toxicity, plasma cholinesterase levels decrease first. In chronic, low-level exposure, however, plasma enzyme levels may be normal, but RBC cholinesterase may still be decreased. This is because plasma cholinesterases can recover in 4 to 6 weeks, whereas RBC cholinesterases can take as long as 12 weeks to recover. Other laboratory studies should focus on the evaluation of pulmonary, cardiovascular, and renal function, as well as fluid and electrolyte balance. A measurement of acid-base status should be performed, because patients with metabolic acidosis have higher mortality rates.[1] Both initial hyperglycemia and hypoglycemia in organophosphate-poisoned patients have been shown to be associated with increased mortality and severity of toxicity.[3] Other prognostic tools such as the Glasgow Coma Scale or the Poison Severity Score vary by type of organophosphate and are generally of little clinical utility.[2]

Management

Treatment of organophosphate poisoning is directed toward four goals: (1) decontamination, (2) supportive care with an emphasis on respiratory stabilization, (3) reversal of acetylcholine excess, and (4) reversal

TABLE 152.1 Pesticide Classes and Examples

Pesticide Class	Example(s)
Organophosphates	Parathion, malathion
Carbamates	Aldicarb, carbaryl
Chlorinated hydrocarbons	Dichlorodiphenyltrichloroethane (DDT), gamma-hexachlorocyclohexane (lindane)
Substituted phenols	2,4-dinitrophenol (DNP)
Chlorophenoxy pesticides	2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 2,4-dichlorophenoxyacetic acid (2,4-D)
Bipyridyl pesticides	N, N′-dimethyl-4,4′-bipyridinum dichloride (paraquat), 1,1′-ethylene-2,2′-bipyridyldiylium dibromide (diquat)
Pyrethrins/pyrethroids	Permethrin
Glyphosate	N-(phosphonomethyl)glycine
Insect repellent	N, N-Diethyl-meta-toluamide (DEET)

of toxin binding at receptor sites on the cholinesterase molecule. The severity of the patient's signs and symptoms, as well as antidote availability, will guide management.

Decontamination

Decontamination begins in the out-of-hospital setting to prevent further absorption and to protect care providers. Because dermal absorption is likely, removal and destruction of clothing and thorough flushing of exposed skin limits absorption and toxicity. Alternatively, dermal decontamination can be done with dry agents, such as military resins, flour, sand, or bentonite. Due to availability and ease of flushing with water, we recommend this as the primary method of decontamination. Caregivers are at risk for contamination from splashes or handling of contaminated clothing. Personnel may be rotated to limit their exposure to either multiple contaminated patients or patients extensively contaminated (or contaminated with a high concentration product). Caregivers should use universal precautions (level C PPE), which includes a full-face air purifier cartridge mask, eye shield, and protective clothing including a chemical-resistant suit, boots, and nitrile or butyl rubber gloves. In the case of ingestion, neither gastrointestinal decontamination procedures (such as gastric lavage) nor activated charcoal are of benefit. Cholinergic agents are rapidly absorbed and profuse vomiting and diarrhea are seen early in ingestion, negating any beneficial effect of additional gastrointestinal decontamination. Equipment, but not skin, may be washed with a 5% hypochlorite solution.

Stabilization and Supportive Care

Because death is a result of airway and respiratory failure, supportive care should be directed primarily toward airway management and should include suctioning of secretions and vomitus, oxygenation, and ventilatory support. Succinylcholine, 1.5 mg/kg, is commonly used as a paralytic drug for rapid-sequence orotracheal intubation. Succinylcholine, however, is metabolized by cholinesterases and may have a prolonged duration of effect (4 to 6 hours) in the setting of organophosphate poisoning. If succinylcholine is used as a paralytic drug, anticipate the need for prolonged sedation and ventilatory support. We prefer a nondepolarizing paralytic drug not metabolized by cholinesterases (e.g., rocuronium, 1 mg/kg). Tachycardia and tachydysrhythmia generally resolve by treating the underlying cholinergic excess and should not be treated symptomatically (e.g., with beta blockers). Patients with agitation, seizures, and coma should be treated with adequate doses of a benzodiazepine after the airway has been secured and ventilatory support established.

Enhanced Elimination

There is no role for enhanced elimination or extracorporeal techniques of removal, such as hemodialysis, in organophosphate poisoning.

Antidote Therapy

Definitive treatment for organophosphate poisoning is focused on decreasing the amount and effect of acetylcholine at its various receptor sites. This begins with atropine, which is a competitive inhibitor of acetylcholine at muscarinic receptors. The atropine dose for the treatment of organophosphate poisoning is 1 to 3 mg (0.05 mg/kg in children) intravenously with doubling of each subsequent dose every 5 minutes until there is control of the muscarinic effects, particularly reduction in airway secretions. Atropine may initially be administered intramuscularly until intravenous or intraosseous access is obtained. Depending on the specific organophosphate product involved and the degree of poisoning, patients may require as much as 200 to 500 mg of atropine during the first hour. Once the patient has been stabilized with appropriate "atropinization," an infusion is initiated to provide 10% to 20% of the total cumulative dose needed to obtain symptom control per hour. Tachycardia and mydriasis may occur at these atropine doses but are not an indication to discontinue therapy. However, excessive administration of atropine may cause the typical symptoms of the anticholinergic toxidrome. The endpoint of atropinization is drying of respiratory secretions, easing of respiratory effort, and normalization of respiratory rate. Early and rapid atropinization is associated with better control of seizures and reduced mortality in animal models. The recommended atropine dosing regimen can easily exhaust available hospital supplies, and arrangements for alternative sources should be discussed with the appropriate hospital personnel early in the case of an organophosphate poisoning. Other anticholinergic medications, such as diphenhydramine and anticholinergic ophthalmic drugs, have been studied in rodents and may be considered a "last resort" alternative in humans if intravenous atropine is scarce or exhausted. Atropine is not active at nicotinic receptor sites and will not reverse skeletal muscle effects, such as respiratory muscle paralysis.

The second part of the treatment of organophosphate poisoning is the use of an oxime to regenerate acetylcholinesterase function. Oximes bind to the organophosphate-cholinesterase complex, causing a conformational change that allows for the cholinesterase to resume normal function. There are currently five oximes in common use worldwide: pralidoxime (2-PAM), trimedoxime (TMB-4), obidoxime chloride (Toxogonin), methoxime, and asoxime chloride (HI-6). Pralidoxime is the product commonly available in the United States. There are controversies regarding the use of oximes related to dosing, duration of treatment, time to therapy initiation, and effectiveness in treating neurologic symptoms. Despite these controversies, we recommend oximes for the treatment of moderate or severely poisoned patients, defined as those who require multiple, large doses of atropine. Indications for oxime treatment include respiratory depression or failure, muscle fasciculations, seizures, dysrhythmias, hemodynamic instability, or the use of large amounts or repeated doses of atropine to completely control signs and symptoms of organophosphate intoxication. We recommend administering pralidoxime as a 1 to 2 g bolus (25 to 50 mg/kg in pediatric patients) over 30 minutes, which can be repeated as needed (up to hourly) based on response (improved mental status and respiratory and heart rate, as well as decreased secretion). Even higher doses may be required. Alternative dosing options are 2 g bolus over 20 minutes followed by an infusion of 500 mg/h for up to 7 days; 1 g/h every 4 hours; or 30 mg/kg followed by infusion of 8 mg/kg/h (Table 152.2). Oximes can be given intravenously or intramuscularly (as with standard military autoinjectors).

Novel treatments for organophosphate and nerve agent poisoning are under investigation. At present, pyridostigmine is the most commonly used prophylactic drug. Other prophylactics include tablets containing pyridostigmine, trihexyphenidyl and benactyzine, as well as a transdermal patch containing H-series oximes (HI-6).

Disposition

Most patients who present to the ED after significant organophosphate exposure should be admitted to a monitored setting. The effects of organophosphate intoxication can be prolonged. If plasma cholinesterase levels are available, they may be useful for treatment and disposition decisions. Asymptomatic or minimally symptomatic patients with normal or minimally depressed cholinesterase levels may be discharged after 6 hours with close outpatient follow-up to ensure that progressive toxicity does not occur. Patients who present with significant symptoms (e.g., seizures, acute respiratory compromise associated with depressed cholinesterase levels) require admission and continuous monitoring, usually to an intensive care unit (ICU). Patients may have rebound toxicity several days after apparently

TABLE 152.2 Specific Treatment Dosing

Agent	Indication	Adult Dose	Pediatric Dose	Route	Comments
Atropine	Organophosphate toxicity	1–3 mg	0.05 mg/kg	IV, IM	Double dose every 5 min until effect
Pralidoxime	Organophosphate toxicity	1–2 g bolus	25–50 mg/kg	IV, IM	Given over 30 min Dose can be repeated based on response

IM, Intramuscular; *IV,* intravenous.

satisfactory response to initial treatment. This may occur for many reasons, including persistent release of organophosphates from lipid stores. Poisoning with fenthion is of particular concern because initial symptoms could be mild and progress to life-threatening intoxication over time.

The intermediate syndrome (IMS) can occur after the acute intoxication from organophosphates has resolved. IMS manifests with delayed muscle paralysis, including in respiratory muscles, which can occur 24 to 96 hours after the resolution of the cholinergic crisis. The precise cause of IMS is not well documented. Delayed peripheral neuropathy may occur 7 to 21 days after acute organophosphate intoxication.[4] Therefore, close patient follow-up, including a neurological evaluation, is important after stabilization. Finally, those patients with acts of self-harm or suicidal intent require psychiatric consultation once medically stabilized.

Carbamate Insecticides

Carbamates are acetylcholinesterase inhibitors whose toxicological picture is similar to organophosphates. There are two important differences: (1) short duration of effect (minutes to 48 hours) and (2) the process of aging does not occur. Decontamination, supportive care, airway management, and atropinization are usually adequate for treating patients poisoned with these compounds. Severe toxicity, including respiratory depression and seizures, can occur. Because carbamates do not cross the blood-brain barrier as readily as organophosphates, neurotoxicity is less likely. Dosing of atropine is the same as for organophosphates, but the duration of treatment is usually less. There is controversy regarding the use of oximes in carbamate poisoning. We recommend the use of oximes only when the poisoning is severe (as defined for organophosphates) or if the provider cannot differentiate carbamate from organophosphate poisoning.

Chlorinated Hydrocarbons Insecticides

Foundations

Dichlorodiphenyltrichloroethane (DDT) is the best-known example of chlorinated hydrocarbon insecticides. This class is also known as *organochlorine insecticides.* DDT was developed in the late 1800s and first used widely in World War II to reduce mosquito populations in an attempt to prevent transmission of typhus and malaria. It was found to be effective and stable and led to the development of other similar insecticides that were used in agricultural, industrial, and residential settings. Their widespread and indiscriminate use, long half-life, and persistence in the environment resulted in adverse ecologic effects that lead to a ban on most chlorinated hydrocarbons. In the United States, gamma-hexachlorocyclohexane (also known as *lindane*) is a chlorinated hydrocarbon insecticide available as a pharmaceutical drug for the second-line treatment of head lice and scabies. Many U.S. states have banned lindane and restricted its use to physician prescription only.

Principles of Toxicity

Chlorinated hydrocarbon insecticides are highly lipid soluble. They are readily absorbed via dermal, respiratory, and gastrointestinal routes and are stored in fatty tissues. This storage allows for toxicity from repeated, low-level exposure. Lindane toxicity often occurs from excessive dermal exposure or accidental oral exposure.

Chlorinated hydrocarbon insecticides affect neuronal voltage-gated sodium channels. They are also gamma-aminobutyric acid (GABA) antagonists. This results in hyperexcitability and irritability of both central and peripheral neurons. Chlorinated hydrocarbons increase susceptibility to ventricular tachydysrhythmias, as well, because of increased myocardial sensitivity to circulating catecholamines.

Clinical Features

The primary clinical feature of chlorinated hydrocarbon insecticide toxicity is neurologic excitation. This includes muscle fasciculations, ataxia, tremors, delirium, weakness, paresthesias, and, in severe toxicity, paralysis, seizures, and death. Mild premonitory symptoms are not always present prior to serious neurological manifestations; patients can present initially with seizure activity. Hyperthermia can result from muscle fasciculations and seizures. Metabolic acidosis, respiratory failure, and acute renal failure can also occur. Chronic exposure can cause liver toxicity, arrhythmias, menstrual changes, and neuropsychological effects. The most important clue to diagnosing exposure to chlorinated hydrocarbons is a detailed history because there is no specific clinical toxidrome.

Differential Diagnoses

The defining features of chlorinated hydrocarbon insecticide toxicity are neuro-excitation and seizure. Differential diagnoses are broad, including any disorder or toxic exposure that can lead to seizures (e.g., organophosphates, isoniazid, theophylline, sympathomimetic agents, lead, ethanol, and benzodiazepine or alcohol withdrawal).

Diagnostic Testing

The diagnosis of chlorinated hydrocarbon insecticide poisoning is determined by history and clinical features. Some reference laboratories can measure chlorinated hydrocarbons from fat or plasma samples, but this will not be readily available during emergency treatment. An electrolyte panel, creatinine kinase, and blood gas should be measured on patients with known or suspected acute poisoning.

Management

Decontamination

The first step in chlorinated hydrocarbon insecticide toxicity is decontamination. Remove all clothing and wash the skin and hair with soap and water. Ingested chlorinated hydrocarbons are rapidly absorbed by the gastrointestinal tract; therefore, decontamination with activated charcoal has no clinical effectiveness.

Stabilization and Supportive Care

The main objective in treating chlorinated hydrocarbon toxicity is cessation of seizures. Benzodiazepines and barbiturates are the mainstays of therapy to treat seizures. Chlorinated hydrocarbons can cause myocardial sensitization that can lead to ventricular

tachydysrhythmias, which are most commonly seen around the time of seizure activity due to a catecholamine surge. Beta-adrenergic antagonists (e.g., intravenous metoprolol, 5 mg boluses every 5 minutes) are recommended for treating any life-threatening tachydysrhythmias (e.g., ventricular tachycardia and fibrillation). Prolonged seizures can lead to hyperthermia. Seizure control with benzodiazepines and external cooling with evaporative cooling methods should be implemented if severe hyperthermia is present. Other complications such as metabolic acidosis, rhabdomyolysis, and acute kidney injury are treated with intravenous crystalloid hydration and, in the case of rhabdomyolysis, alkalinization, as described in Chapter 116.

Enhanced Elimination

There is no role for enhanced elimination of chlorinated hydrocarbon insecticides in the ED.

Antidote Therapy

There is no known antidotal therapy for chlorinated hydrocarbon insecticides.

Disposition

Patients who present symptomatic with chlorinated hydrocarbon insecticide poisoning require admission for evaluation, monitoring, and treatment of neurologic and metabolic derangements.

SUBSTITUTED PHENOLS

Foundations

Dinitrophenol (DNP), pentachlorophenol, and dinitrocresol belong to a class of compounds called *substituted phenols* and have been used as dyes, wood preservatives, photograph developers, and insecticides. DNP was previously used as a weight loss medication but has not been available by prescription since the 1930s because of fatalities associated with its use. DNP is currently used as a weight loss supplement and is readily available over the internet. It can be easily obtained from online nutritional supplement retailers and is available in powder, capsule, and crystalline form. The most common route of exposure is oral, but substituted phenols can also be absorbed dermally or inhaled.

Principles of Toxicity

Substituted phenols uncouple oxidative phosphorylation. This results in decreased adenosine triphosphate (ATP) formation and increased heat generation, which is the mechanism of action for DNP in weight loss because calories are burned excessively. DNP also stimulates glycolysis, which, along with the uncoupling of oxidative phosphorylation, increases lactic acid production.

Clinical Features

Patients with acute toxicity from substituted phenols present with hyperthermia, tachycardia, diaphoresis, and tachypnea. Neurologic signs and symptoms include confusion, agitation, seizures, and coma. Rhabdomyolysis, myocardial injury, acute kidney injury, and hepatic damage can occur in acute toxicity. These patients can progress to cardiovascular collapse and death. Dermal exposure can cause a yellow discoloration of the skin and corrosive injury.

Differential Diagnoses

Patients suffering from the toxic effects of substituted phenols will appear to have sympathomimetic excess. This leads to a broad differential diagnosis that includes toxicologic, infectious, and environmental considerations, such as cocaine and amphetamine toxicity, encephalitis, and heat stroke (Table 152.3). Since substituted phenols act by uncoupling oxidative phosphorylation, salicylate toxicity should also be considered in the differential diagnosis. An accurate history is important to the diagnosis of substituted phenol intoxication.

TABLE 152.3 Differential Diagnoses for Substituted Phenol Poisoning

Toxicological	Infectious	Environmental
Cocaine	Meningitis	Hyperthermia
Salicylates	Encephalitis	Heat stroke
Amphetamines/MDMA	Sepsis	
Caffeine		
Other sympathomimetics		

MDMA, N-methyl-3,4-methylenedioxyamphetamine.

Diagnostic Testing

Diagnostic testing focuses on the metabolic disturbances and potential organ damage associated with acute substituted phenol toxicity. Serum electrolytes and renal function are to be assessed. Liver studies should be performed, and creatinine kinase is measured to assess for rhabdomyolysis. An electrocardiogram (ECG) and laboratory assessment for myocardial injury with serial cardiac markers (troponin) is advised for any patient with symptoms consistent with myocardial ischemia.

Management

Decontamination

Patients who present with dermal exposure should have their clothing removed and skin washed with soap and water. Because of the potential lethality of phenol-containing compounds with no effective antidote, a patient presenting within 1 hour of an acute oral ingestion who is alert and cooperative should be given oral activated charcoal (at least 100 g in adults).

Stabilization and Supportive Care

Supportive care is the mainstay of treatment for substituted phenol toxicity. Patients with hyperthermia (temperature >102.5°F) should be cooled with evaporative cooling, a cooling blanket, cold intravenous fluids, and strategically placed ice packs. Patients should be given adequate crystalloid fluid resuscitation and electrolyte derangements should be corrected. This is especially important in hyperthermic patients. Agitation and seizures should be treated with benzodiazepines, such as lorazepam (1 to 2 mg intravenous push [IVP]) or diazepam (5 to 10 mg IVP).

Enhanced Elimination

There is no known role for enhanced elimination in substituted phenol toxicity.

Antidote Therapy

There is no known antidote for acute phenol poisoning.

Disposition

Patients who manifest symptoms after substituted phenol exposure should be admitted for intensive cardiac and neurologic monitoring and treatment. A patient who presents asymptomatically after an exposure should be observed for 8 to 12 hours and may be safely discharged if they remain asymptomatic over that period of time.

CHLOROPHENOXY HERBICIDES

Foundations and Principles of Toxicity

Chlorophenoxy compounds are effective herbicides for broad-leaved weeds. This class of herbicides includes 2-methyl-4-chlorophenoxyacetic acid (MCPA), methylchlorophenoxypropionic acid (MCPP), and 2,4-dichlorophenoxyacetic acid (2,4-D). Chlorophenoxy herbicides are widely used in both commercial and residential settings.

Chlorophenoxy herbicides are absorbed through the gastrointestinal tract, skin, and respiratory tract. Most cases of toxicity, however, result from ingestion. Skeletal muscle is the primary organ of toxicity, although the exact mechanism of action is not well defined. Proposed mechanisms of action include direct cell membrane damage, forming analogues of acetyl-CoA and acting as false cholinergic messengers, and at high doses, uncoupling of oxidative phosphorylation.[5]

Clinical Features

Ingestion of chlorophenoxy herbicides can result in gastrointestinal symptoms that include vomiting, abdominal pain, diarrhea, oropharyngeal burning, and gastrointestinal hemorrhage. Other symptoms include muscle fasciculations, weakness, myotonia, and decreased tendon reflexes. Myotonia and fasciculations may lead to rhabdomyolysis and metabolic acidosis.[5]

Differential Diagnoses

Severe toxicity from chlorophenoxy herbicides is rare. When symptoms are present, other possible diagnoses include other causes of acute myopathy. When gastrointestinal symptoms are present, viral and bacterial gastroenteritis, ingestion of caustic substances, organophosphate, and carbamate exposure are other considerations.

Diagnostic Testing

Testing for chlorophenoxy herbicides is not available in the emergency setting. Diagnostic testing should focus on assessing skeletal muscle damage and its consequences. Measurement of creatinine kinase, electrolyte profile, renal function, liver function, and acid base status are indicated.

Management

Decontamination

In the case of a dermal exposure, remove the clothing and wash the skin with soapy water. Because chlorophenoxy herbicides are rapidly absorbed via the gastrointestinal tract and vomiting may occur early, activated charcoal is not indicated.

Stabilization and Supportive Care

Supportive care with fluid resuscitation is the mainstay of treatment for patients symptomatic after chlorophenoxy herbicides.

Enhanced Elimination

In the rare event of a critically ill patient (patients requiring ventilator, hemodynamic support, and those with seizures, hyperthermia, or significant metabolic derangements) who presents after chlorophenoxy herbicide poisoning, urinary alkalinization or hemodialysis can be used to enhance elimination.

Antidote Therapy

There is no known antidote for chlorophenoxy herbicide toxicity.

Disposition

A patient who presents with muscular symptoms after chlorophenoxy herbicide toxicity should be admitted and carefully monitored for progression of symptoms. A patient who is asymptomatic at presentation should be monitored for 6 hours. If no symptoms develop, the patient can be safely discharged home.

BIPYRIDYL HERBICIDES

The bipyridyl (also called *dipyridyl*) herbicides paraquat and diquat are extremely effective contact herbicides that are widely used throughout the world. Paraquat is particularly toxic to humans and is under strict regulation in the United States. Diquat is less toxic and is subject to less regulation.

Foundations and Principles of Toxicity

Paraquat causes the production of superoxides created during cyclic oxidation-reduction reactions in tissues. This causes oxygen radical damage that results in cell death.[6] Paraquat selectively concentrates in the lungs, regardless of the route of exposure, because of an uptake mechanism in alveolar cells. High concentration of oxygen in the pulmonary system increases the extent of paraquat-induced oxygen radical injury; therefore, the lungs are the major target in paraquat poisoning. Paraquat exposure can lead to adult respiratory distress syndrome, progressive pulmonary fibrosis, and respiratory failure. Paraquat damages other organ systems by the same oxygen radical injury effect, including the liver, kidneys, heart, and central nervous system. Diquat has a similar mechanism of action but does not accumulate in the lungs as does paraquat. Diquat concentrates in the kidneys and often results in renal failure. Paraquat is absorbed through the skin, gastrointestinal tract, and respiratory tract. Diquat is poorly absorbed through intact dermis.

Clinical Features

Paraquat and diquat are corrosive and can cause vomiting and caustic injury to the oropharynx, esophagus, and gastrointestinal tract. Dermal exposure can cause corrosive injury to the skin. Systemic toxicity from both paraquat and diquat poisoning will often progress to multiorgan failure and death. This is especially true for paraquat, which can be fatal in small amounts. Patients who survive systemic toxicity from paraquat often develop a progressive pulmonary fibrosis 1 to 3 weeks after the exposure. The clinical course, however, is dependent on the dose of the exposure.

Differential Diagnoses

Bipyridyl herbicides are corrosive and the differential diagnosis encompasses other caustic agents (e.g., acids and alkalis), insecticides (organophosphates and carbamates), and pulmonary toxic chemotherapy agents (e.g., bleomycin). The subsequent systemic toxicity and multiorgan failure with bipyridyl herbicide poisoning could be attributable to other sources of similar symptoms, such as sepsis and acute respiratory distress syndrome (ARDS).

Diagnostic Testing

The cornerstone of diagnosing bipyridyl herbicide poisoning lies in the history of exposure. There is a colorimetric test to detect diquat and paraquat in urine that can be useful but is not readily available in the United States. Serum concentrations of bipyridyl herbicides can be measured but are generally not available in a time frame useful in the ED; however, the concentration paired with the time of ingestion can be used for mortality prognostication.

Multiorgan failure is possible after bipyridyl herbicide poisoning. Laboratory evaluation for respiratory, renal, hepatic, metabolic, and cardiovascular toxicity is indicated. Serial chest radiographs and arterial blood gases are recommended for symptomatic patients.

Management

Decontamination

Dermal exposure should be treated by removing soiled clothing and washing the skin with water. In general, gastrointestinal decontamination is not indicated in the case of caustic ingestions. Because bipyridyl herbicides, particularly paraquat, can cause systemic toxicity in small amounts, gastrointestinal decontamination may be warranted in these cases of ingestion. We recommend at least 100 g activated charcoal or Fuller's earth (in certain international settings) if an alert patient presents early, within 1 hour of the ingestion, because this toxicity has high morbidity and mortality without any antidotal therapy.

Stabilization and Supportive Care

Upper airway corrosive injury can lead to an obstructed airway. Orotracheal intubation is necessary when there is any concern for pending obstruction. Because of the oxygen radical damage, supplemental oxygenation should be targeted to an oxyhemoglobin saturation of 90% to 95%, and excessive supplemental oxygen should be avoided. Supportive care for multiorgan failure is indicated based on the clinical circumstances.

Enhanced Elimination

The use of hemodialysis to increase the elimination of paraquat or diquat is controversial. If renal failure, metabolic acidosis, or electrolyte imbalance develops as a result of the poisoning, hemodialysis is indicated.

Antidote Therapy

There is currently no specific antidotal therapy for bipyridyl herbicide poisoning. Antioxidants, immune modulators, and corticosteroids have been incompletely evaluated as options for therapy to prevent the delayed pulmonary fibrosis. There is currently insufficient data to recommend specific antidotal treatment in the ED.

Disposition

Due to potential high lethality, patients presenting with bipyridyl poisoning require admission to an ICU setting. As with any pesticide or herbicide exposure, those patients with acts of self-harm or suicidal intent require psychiatric consultation once medically stabilized.

PYRETHRIN AND PYRETHROID INSECTICIDES

Pyrethrins are naturally occurring insecticides derived from the chrysanthemum plant. Pyrethroids are synthetic derivatives of pyrethrins that are more stable in the environment.

Foundations and Principles of Toxicity

In humans, pyrethrins block voltage-gated sodium channels, voltage-gated calcium channels, and the chloride channels on GABA receptors. Toxicity in humans, however, is not common. Pyrethrins and pyrethroids are used both as commercial insecticides and pharmaceutically to treat human infestations of scabies and lice (e.g., permethrin). Pyrethrins and pyrethroids are poorly absorbed dermally but are well absorbed via gastrointestinal and respiratory routes.

Clinical Features

Toxicity from pyrethrins and pyrethroids is rare. Allergic and sensitivity reactions can be seen with exposure. Skin exposure can result in erythema. Inhalation can result in rhinitis, sneezing, oral mucosa irritation, cough, dyspnea, wheezing, and chest pain. Nausea, vomiting, abdominal pain, and diarrhea can occur after ingestion; in severe cases, this can contribute to metabolic acidosis.[7] With massive ingestions, the patient is at risk for neurological symptoms, such as numbness, tremors, ataxia, paralysis, seizures, and cerebral infarction.[8]

Differential Diagnoses

Sensitivity reactions seen with exposure to pyrethrins and pyrethroids can mimic allergic reactions or contact dermatitis from other etiologies.

Diagnostic Testing

There are no laboratory or diagnostic tests specific to poisoning from pyrethrins and pyrethroids in the ED setting.

Management

Decontamination

In the case of dermal exposure, clothing should be removed and skin washed with water.

Stabilization and Supportive Care

Skin reactions should be treated symptomatically with histamine blockers, such as diphenhydramine. Wheezing should be treated with beta agonists. Neurologic symptoms can be treated with benzodiazepines as needed (lorazepam, 1 to 2 mg IVP; diazepam, 5 to 10 mg IVP).

Enhanced Elimination

There is no role for enhanced elimination in pyrethrin and pyrethroid poisoning.

Antidote Therapy

There is no known antidotal therapy for pyrethrin and pyrethroid poisoning.

Disposition

Most cases of pyrethrin and pyrethroid exposure will not demonstrate signs of toxicity and can be safely discharged from the ED. Patients with massive ingestions should be observed for 24 hours for the development of neurologic symptoms. Any patient with neurologic symptoms should be admitted to a monitored setting.

GLYPHOSATE

Glyphosate is one of the most commonly used pesticides in the United States. It is a nonselective, contact herbicide that interferes with amino acid synthesis in plants. Recent in vitro studies have shown that glyphosate causes DNA damage and mitochondrial-driven apoptosis, resulting in potential human toxicity.[9] There is much controversy regarding whether glyphosate is associated with cancer in humans; however, this issue is less pertinent to the ED management in an acute exposure.[10,11]

Foundations and Principles of Toxicity

Glyphosate is poorly absorbed dermally. It is absorbed through the gastrointestinal tract. Concentrated solutions (40%) can cause mucosal injury. The residential concentration is 1%. Human acute toxicity is thought to be due to the surfactant included in the glyphosate preparation. Unintentional ingestion of glyphosate generally results in mild

gastrointestinal symptoms. Hypotension, renal failure, respiratory distress, and death can occur from intentional, massive ingestions.

Clinical Features

Patients who present with dermal exposure to glyphosate will likely have no signs of toxicity. However, one case of a large exposure (unclear if inhalational or dermal) resulted in vasculitic peripheral neuropathy.[12] Most ingestions of dilute preparations cause only mild gastrointestinal symptoms. Patients ingesting large volumes of dilute solutions or moderate volumes of concentrated solutions may develop sore throat, nausea, vomiting, abdominal pain, hyperthermia, respiratory distress, acute lung injury, renal failure, and coma. Metabolic acidosis may develop as a result of cardiovascular compromise. Poor prognostic features include altered mental status, hyperkalemia, and renal failure.

Differential Diagnoses

The differential diagnosis of glyphosate poisoning includes caustic ingestions and other causes of respiratory distress or cardiovascular compromise from other pesticides (e.g., organophosphates and carbamates) and herbicides (e.g., paraquat and diquat).

Diagnostic Testing

The key to the diagnosis of glyphosate poisoning is to obtain an accurate history of exposure. An electrolyte profile is recommended to assess for hyperkalemia. A creatinine concentration assesses for renal injury. If respiratory distress is present, a chest radiograph should be performed. We recommend measuring acid-base status with a venous or arterial blood gas to assess extent of respiratory compromise and for comparison with serial measurements to ascertain whether the patient is clinically improving or deteriorating.

Management

Decontamination

With dermal exposure, remove the clothing and wash the skin with water. Gastrointestinal symptoms are generally present with significant ingestions, and activated charcoal is not indicated.

Stabilization and Supportive Care

The mainstay of management of acute glyphosate exposure is supportive care. Provide airway management and cardiovascular support as indicated by the symptom profile. Hyperkalemia can be managed by standard measures.

Enhanced Elimination

There is no role for enhanced elimination in the management of glyphosate poisoning.

Antidote Therapy

There is no known antidote for glyphosate poisoning.

Disposition

Patients who demonstrate symptoms after glyphosate ingestion should be admitted for further management. Patients who present after unintentional exposures of small amounts or low concentrations of glyphosate can be discharged from the ED after a 6-hour observation period.

DEET

N, N-diethyl-m-toluamide, or DEET, is not technically a pesticide. It is the most widely used insect repellant used throughout the world. DEET is available in concentrations ranging from 5% to 100%, and it primarily repels mosquitoes and ticks. The American Academy of Pediatrics recommends 30% as the maximum concentration for use in children and does not recommend use of DEET in infants younger than 2 months old. It is available as lotions, aerosols, pump sprays, roll-on applicators, and impregnated towelettes. Concentrated DEET solutions (up to 100%) can cause plastic products, such as sunglasses and water bottles, to melt with contact.

Foundations and Principles of Toxicology

DEET is lipid soluble and is well absorbed when applied to the skin or ingested. Repeated exposure, skin wounds or abrasions, sweating, and elevated skin temperature increase absorption. DEET affects the central nervous system at the GABA receptors in humans.

Clinical Features

Most exposures to DEET result in minimal or no symptoms. Prolonged skin contact may lead to contact dermatitis, and prolonged contact with higher concentrations can lead to skin blisters. Ingestion of DEET can result in nausea, vomiting, and oral mucosal irritation. Ingestion or excessive skin exposure can lead to headache, liver injury, lethargy, respiratory depression, seizures, and coma.

Differential Diagnoses

The differential diagnosis for DEET poisoning includes any infectious (malaria, encephalitis) toxicological (pesticides, organophosphates, carbamates), metabolic, or neurologic abnormality that could cause seizures and depressed mental status.

Diagnostic Testing

There is no specific test for DEET poisoning that is useful in the ED.

Management

Decontamination

In patients with excessive or prolonged skin exposure to DEET, wash the skin with water. Gastrointestinal decontamination has no role in DEET ingestions because of rapid absorption and the potential for seizure activity.

Stabilization and Supportive Care

Supportive care is the mainstay of treatment for a DEET-poisoned patient. Seizures should be treated with benzodiazepines (lorazepam, 1 to 2 mg IVP; diazepam, 5 to 10 mg IVP) and are generally self-limited.

Enhanced Elimination

There is no role for enhanced elimination with DEET exposure.

Antidote Therapy

There is no known antidote for DEET poisoning.

Disposition

Any patient with acute neurologic symptoms after DEET exposure should be admitted. An asymptomatic patient after an oral ingestion or a patient with localized skin reaction can be discharged after a 6-hour observation period.

RODENTICIDES

Foundations

There are hundreds of rodenticides available throughout the world with variable toxicity (Table 152.4). Rodenticides are implicated in self-harm attempts, malicious poisonings, and accidental ingestions. In the United States, anticoagulants, or superwarfarin-type, are the most common rodenticides, accounting for over 90% of exposures. They are

TABLE 152.4 Rodenticides (Acronym: RATS PANIC)

R SUPER WARFARINS	AT FLUORACETAMIDE	S STRYCHNINE	P PHOSPHORUS	A ALUMINUM[1]	NIC NICOTINAMIDE
Rodenticide	SMFA, fluoroacetamide 1080–1972; banned in 1972 Today: Sheep collars	Moles, gophers, pigeons Adulterant in heroin and cocaine	Yellow (white) phosphorus	Aluminum and zinc phosphide ("rice tablet")	Vacor: 2% PNU banned in 1979
Mechanism	Irreversible TCA cycle inhibitor (fluorocitrate is "suicide inhibitor")	Competitive inhibitor of glycine binding (increased neuronal excitability)	Corrosive, cellular poison Combusts at room temp	Unknown (inhibit electron transport chain, release phosphine gas with moisture and gastric acid)	Unknown (antagonizes nicotinamide axons and injures pancreatic cells)
Effects	GI: Nausea/vomiting/diarrhea/pain Respiratory distress Seizures Cardiotoxicity Hypotension	"Awake seizure" Risus sardonicus Opisthotonus Hyperthermia, rhabdomyolysis	Respiratory "Phossy jaw" GI ("smoking" stool), liver failure Neuro, cardio Eye Skin (burns)	Delayed pulmonary edema, ARDS, GI, neurologic, cardio, hepatic, adrenal Refractory hypotension Metabolic acidosis	Nausea/vomiting Orthostatic hypotension Diabetes mellitus Neuropathy, coma
Diagnosis	Electrolytes, BUN/Cr, calcium, LFTs ECG, MRI Levels not helpful acutely	Cramps, awake seizure, electrolytes, BUN/Cr, CPK, ABG, serum levels do not correlate with toxicity	Garlic odor Burns (skin fluoresces) BUN/Cr, calcium, LFTs UA ABG, chest x-ray, ECG	Fishy/garlic odor BUN/Cr, electrolytes, LFTs ABG, chest x-ray	History Sudden orthostatic hypotension or DM Electrolytes, glucose, BUN/Cr
Treatment	Decontaminate Activated charcoal Supportive care	Stabilization and supportive care Limit stimulation Benzodiazepines for seizures, analgesia	PPE Decontaminate Sand or water over solid phosphorus	Benzodiazepines for seizures, steroids for adrenal dysfunction, magnesium for refractory arrhythmia	IVFs, activated charcoal Nicotinamide Insulin Steroids
Disposition	ICU for CNS, CV symptoms—more than rapid death	ICU if symptomatic Symptoms several hours (supportive care)	Likely ICU admission if significant exposure Isolation (patient and secretions)	Observe at least 72 hours for delayed effects	Admit for delayed neurologic symptoms Neuropathy/DM after several days

Modified from the original acronym created by Jack Snyder, MD.

ABG, Arterial blood gas; *ARDS,* acute respiratory distress syndrome; *BUN/Cr,* blood urea nitrogen/creatinine; *CNS,* central nervous system; *CPK,* creatine phosphokinase; *CV,* cardiovascular; *DM,* diabetes mellitus; *ECG,* electrocardiogram; *GI,* gastrointestinal; *ICU,* intensive care unit; *IVF,* intravenous fluids; *LFT,* liver function test; *MRI,* magnetic resonance imaging; *PNU,* N-3-pyridylmethyl-N′-*p*-nitrophenyl urea; *PPE,* personal protective equipment; *SMFA,* sodium monofluoroacetate; *TCA,* tricarboxylic acid; *UA,* urine analysis.

Hassan NAM, Madboly AG. Correlation between serum creatine phosphokinase and severity of acute organophosphorus poisoning: a prospective clinical study (2012–2013). *IOSR J Environ Sci Toxicol Food Tech*. 4(5):18–29, 2013.

long-acting, anti-vitamin K anticoagulants. Examples are brodifacoum, diphacinone, bromadiolone, chlorophacinone, and difenacoum.

Principles of Toxicology

Superwarfarins competitively inhibit vitamin K and the hepatic synthesis of vitamin K-dependent coagulation factors II, VII, IX, and X. These anticoagulants can also damage capillary walls, increasing permeability and fragility and exacerbating bleeding. Effects are prolonged in these long-acting anticoagulants—half-life of 150 hours versus 15 hours in first generation warfarins, leading to toxic effects that can last for months. All significant toxicological exposures are via ingestion, and all warfarins are well absorbed orally.

Clinical Features

Initially, patients can by asymptomatic and remain so for as long as 72 hours after ingestion, even with large ingestions. Alternatively, signs of gastrointestinal irritation can predominate early in the course of poisoning, and symptoms appear as early as 8 hours after exposure. They can then present with bleeding anywhere in the body, as evidenced by ecchymosis, epistaxis, hemarthrosis, gingival bleeding, menorrhagia, and hematuria. Life-threatening effects are massive gastrointestinal bleeding and intracranial hemorrhage.

Differential Diagnoses

The differential diagnosis includes supratherapeutic doses of warfarin, advanced stages of hepatic failure, disseminated intravascular coagulation, hemophilia, oncological diseases, and other hematological disorders that can present with similar bleeding symptoms.

Diagnostic Testing

Measure hemoglobin/hematocrit, platelets, prothrombin time (PT)/international normalized ratio (INR), and partial thromboplastin time (PTT). Additionally, obtain blood type and screen as well as crossmatch (if actively bleeding). PT/INR might not be abnormal until 48 hours after ingestion; a normal INR at 48 hours essentially excludes a significant ingestion. Although most rodenticides are not commonly

measurable, brodifacoum level is available at many reference labs (<4 to 10 ng/mL is normal and generally does not cause coagulopathy).

Management

Decontamination

If a patient presents within 1 hour after reported massive ingestion of superwarfarin, we recommend oral activated charcoal in a 10:1 activated charcoal to poison ratio. If the dose ingested is unknown, 100 g is an appropriate dose. Do not perform gastric lavage, because, in addition to a lack of clinical efficacy, it adds the additional risk of inducing gastrointestinal bleeding with insertion of a large orogastric tube.

Stabilization and Supportive Care

With massive blood loss, fluid resuscitation and transfusion are necessary. Packed RBCs to replace blood loss, fresh frozen plasma to improve coagulation profile, and four-factor prothrombin complex concentrate (PCC) are proven to be beneficial and are considered first-line treatments. Another option shown to be beneficial is recombinant activated factor VII.

Enhanced Elimination

There is no role for enhanced elimination in superwarfarin toxicity.

Antidote Therapy

Vitamin K_1, (as opposed to K_3 or K_4), is the preferred antidote, or reversal agent, because other forms are not effective and have potential for toxicity. Although vitamin K_1 will reliably reverse anticoagulation, it should not be given prophylactically; toxicity is determined by derangement in INR. This therapy requires 6 hours to take effect and, therefore, is not used for immediate reversal. This pharmacokinetic principle explains the usual vitamin K dosing regimen of every 6 hours. Prolonged treatment with doses as high as 800 mg daily has been required in massive overdoses.

Disposition

The majority of patients with small warfarin-based rodenticide ingestions (e.g., children tasting two to three pellets) can be discharged home with outpatient follow-up in 48 to 72 hours. Patients presenting with reported large intentional ingestion of superwarfarins (i.e., an entire box or bait tray) should be admitted for at least 48 hours, at which time an INR should be checked (minimum time after ingestion to check INR is 48 hours). In patients with coagulopathy, admission is required until all bleeding has subsided, and the patient is maintained on a vitamin K regimen for desired INR. On an outpatient basis, these patients may require monitoring of their coagulation profile for 4 to 6 weeks with the longer-acting superwarfarin products. Patients with acts of self-harm or suicidal intent require psychiatric consultation once medically stabilized.

CHAPTER 152: QUESTIONS AND ANSWERS

1. A 37-year-old man arrives at the emergency department (ED) after exposure to an organophosphate. He is severely symptomatic, and atropine is given. When should atropine treatment be discontinued?

a. After 100 mg has been given
b. When fasciculations stop
c. When mydriasis occurs
d. When secretions have stopped
e. When tachycardia occurs

Answer: d. Patients with organophosphate poisoning may require very large doses of atropine (up to 500 mg). Proper dosing is 1 or 2 mg intravenously, with doubling of the dose every 5 minutes until the drying of secretions. Atropine has no effect at the neuromuscular junction. Mydriasis may occur before secretions have dried. Tachycardia is likely, but it is not a contraindication for continued atropine treatment. The tachycardia often improves as the pulmonary status improves.

2. A 30-year-old agricultural worker arrives at the emergency department (ED) with confusion, abdominal pain, nausea, vomiting, and shortness of breath. His coworkers report that he was spraying plants with an insecticide. The patient's vital signs are significant for hypotension, bradycardia, and tachypnea. Physical examination reveals miosis, wheezing, vomiting, diarrhea, and urinary incontinence. Which clinical finding is associated with higher mortality?

a. Hyperglycemia
b. Hypoglycemia
c. Glasgow Coma Scale (GCS) ≤3
d. Acidosis
e. Poison Severity Score (PSS) 4

Answer: d. This patient has symptoms of the cholinergic syndrome (SLUDGE symptoms) and was likely exposed to an organophosphate or carbamate pesticide. Patients poisoned with organophosphate or carbamate pesticides that are acidotic have a higher mortality than those with normal acid-base status. Elevated and decreased glucose concentrations have both been associated with increased morbidity and mortality. As for PSS and GCS, these vary by type of poisoning and cannot reliably be used to determine risk of fatality.

3. A 4-year-old boy arrives at the emergency department (ED) after drinking a medication that was being used to treat his sister's head lice. An unknown amount was consumed, and the bottle is not available. The patient's only complaint is of nausea. Vital signs and physical examination findings are normal. Which of the following symptoms should be anticipated?

a. Gastrointestinal hemorrhage
b. Hallucinations
c. Hypotension
d. Paralysis
e. Seizure

Answer: e. Lindane is a chlorinated hydrocarbon insecticide that is used for the topical treatment of head lice and scabies. It is rapidly absorbed and can result in difficult-to-control seizures requiring high doses of benzodiazepines or barbiturates and that may require sedation, paralysis, and intubation. Because lindane is a hydrocarbon, it can sensitize the cardiac membrane and predispose to ventricular dysrhythmias. It can also cause pulmonary compromise if it is aspirated.

4. An 18-year-old woman arrives at the emergency department (ED) complaining of feeling generally weak. She reports reading online about a pesticide that can help in weight loss, and she has recently tried this. Her vital signs are blood pressure, 110/70 mm Hg; heart rate, 121 bpm; respiratory rate, 22 rpm; and temperature, 104°F (40.0°C). Her physical examination reveals dry mucous membranes and yellow staining on her abdomen. Which of the following laboratory findings can you anticipate?

a. Hypoglycemia
b. Hypokalemia
c. Hyponatremia
d. Hypoxia
e. Methemoglobinemia

Answer: a. Substituted phenols, such as dinitrophenol, are pesticides that uncouple oxidative phosphorylation. This causes an increased metabolism, which in turn consumes glucose and generates heat, often causing an increased body temperature. For this reason, they have been used as diet aids. They can be applied topically, and the yellow skin staining is considered pathognomonic for nitrogen compounds. Treatment is supportive and should be aimed at stopping further exposure; providing the needed substrates of oxygen, water, and glucose; and applying active cooling measures.

5. What organ system is most affected by paraquat ingestion?

a. Cardiac
b. Gastrointestinal
c. Nervous
d. Pulmonary
e. Renal

CHAPTER 152: QUESTIONS AND ANSWERS—cont'd.

Answer: d. Paraquat is concentrated in the lungs and directly damages the alveolar capillary membrane. This results in surfactant loss, adult respiratory distress syndrome, pulmonary fibrosis, and respiratory failure and is accelerated with supplemental oxygen. All the other organ systems listed are affected but to a much lesser degree.

6. A patient arrives at the emergency department (ED) after an intentional paraquat ingestion complaining of severe mouth, throat, and chest pain. What potentially fatal complication of paraquat ingestion should be suspected?
- **a.** Aortic dissection
- **b.** Esophageal rupture
- **c.** Myocardial infarction
- **d.** Pneumothorax
- **e.** Pulmonary embolism

Answer: b. Paraquat is extremely corrosive and can cause severe burns to the oropharynx, as well as to the esophagus. Frequently, esophageal rupture occurs, leading to mediastinitis and death. None of the other listed conditions occurs with any frequency in paraquat poisoning.

7. How do pyrethrins cause toxicity?
- **a.** Sensitivity or allergic reactions
- **b.** Bone marrow suppression
- **c.** Cardiovascular instability
- **d.** Inhibition of coagulation
- **e.** Uncoupling of oxidative phosphorylation

Answer: a. Pyrethrins are naturally occurring substances from the yellow chrysanthemum and commonly cause allergic reactions in humans. These reactions can be mild or life-threatening, with bronchoconstriction and laryngeal edema. They also affect gamma-aminobutyric acid (GABA)-mediated chloride channels in the nervous system, but this typically results in only a mild headache and paresthesias.

8. DEET is a commonly used insect repellant that can cause contact dermatitis and more severe neurologic complications, including seizures with high doses that are absorbed through the skin. Which of the following methods will minimize DEET absorption through the skin?
- **a.** Apply to skin at night
- **b.** Cover skin with clothing
- **c.** Expose skin to direct sunlight
- **d.** Keep skin dry
- **e.** Remove from skin with oil-based products

Answer: d. DEET absorption and toxicity increase with repeated applications, with increased ambient temperatures, with sweating, when it is applied to abraded or thin skin, and when it is covered with tight-fitting clothing. Oils or lipophilic substances applied to the skin also increase absorption of DEET.

9. A patient has long-standing depression that was exacerbated by the recent COVID-19 pandemic. During the isolation of the pandemic, the patient was cleaning their attic and found an old box of rat poison. During a particularly challenging time, the patient attempted suicide by consuming the contents of the rat poison container. The patient woke up the next day and was asymptomatic. Two days later, the patient noted bruising and hematuria. Which class of pesticides likely represents the overdose in this situation?
- **a.** Bipyridal compounds
- **b.** Organophosphates
- **c.** Pyrethrins
- **d.** Superwarfarins
- **e.** Chlorophenoxy compounds

Answer: d. Superwarfarins were developed from warfarin for rodenticides, after increasing numbers of rats developed resistance to warfarin. They act by inhibiting vitamin K, which is a cofactor in the synthesis of clotting factors II, VII, IX, and X. The therapeutic and toxic effects require significant reduction of these clotting factor concentrations, thus taking at least 15 hours to present. While warfarin has a half-life of 35 hours, the duration of action can be up to 5 days. Superwarfarins are 100 times more potent than warfarin, leading to increased and prolonged toxicity, which can manifest as superficial, as well as internal, bleeding (such as bruising and hematuria). Bipyridal compounds, such as paraquat and diquat, are pesticides that are not used in the United States. Organophosphates are insecticides that are highly regulated in the United States. Pyrethrins are insecticides derived from chrysanthemums, commonly used to treat scabies. Chlorophenoxy compounds are herbicides, and not used as rodenticides.

153

Plants, Herbal Medications, and Mushrooms

Christopher S. Lim and Steven E. Aks

KEY CONCEPTS

- Most botanical exposures result in minimal toxicity and management is largely supportive.
- Most serious toxicities result from exposure to plants with anticholinergic, antimitotic, cardiovascular or convulsive properties.
- Most cases of mushroom ingestion in which gastrointestinal (GI) symptoms begin within the first 2 h will prove to involve a non–life-threatening substance.
- Delayed GI symptoms with an onset of more than 6–8 h after exposure suggest a potentially life-threatening ingestion, such as the cyclopeptide and gyromitrin mushroom groups.
- Regional poison control centers, mycologists, and botanists can assist in identifying potentially toxic plants and mushrooms. We recommend smart phone digital photography with expert consultation.
- Herbal medications are largely unregulated and may have inherent toxicity, herb-drug interactions, or contaminants. Clinicians should advise against the routine use of herbal medications.

PLANTS

FOUNDATIONS

The nutritional, therapeutic, psychoactive and toxic properties of botanicals have made their usage pervasive since antiquity. The earliest documented use of plants for medicinal purposes can be found in Sumerian clay tablets that describe the use of over 200 different plants in the treatment of various maladies. Ancient Greeks recognized the lethal effects of botanicals, sentencing Socrates to death by ingestion of a poison hemlock-based liquid. The recreational abuse and medicinal use of opium poppies highlight the wide-ranging role plants have played throughout history.

Exposures to plants comprise over 42,000 calls nationally to US poison centers, with over half of cases involving pediatric patients less than 6 years of age. Over 85% of plant exposures are accidental ingestions. The overwhelming majority of plant exposures result in minimal toxicity and death is exceedingly rare.[1] Plant exposures reported to US poison centers have been decreasing over the past three decades, ranking 3rd and comprising 9% of all exposures in 1983, but ranking 22nd and making up only 2% of all exposures in 2018. The most common plant exposures resulting in severe and occasionally fatal poisonings involve those with anticholinergic, antimitotic, cardiotoxic or convulsive properties.[1]

CLINICAL FEATURES

The vast majority of plants are considered non-toxic (Table 153.1). However, serious toxicity can result from certain plant exposure (Table 153.2). Toxicity does not correlate well with taxonomy, and plants within the same genera may have varying toxic profiles. Further complicating matters, the severity of exposure may depend on the method of exposure (chewed, swallowed, smoked or injected) and which part of the plant was ingested (berries, leaves, or stems). For example, although all parts of the water hemlock plant are considered toxic, cicutoxin is most concentrated in the root of the plant. The majority of serious or fatal outcomes occur when adults intentionally consume botanicals for suicidal or recreational intent. A focused history and physical exam should be aimed at identifying the etiology of the present illness and to identify any toxidrome common to botanical exposures.

DIFFERENTIAL DIAGNOSES

Patients with plant ingestions present with vomiting and diarrhea and should be differentiated from food poisoning, viral or bacterial gastroenteritis, and pesticide poisoning (often sprayed on plants). Those patients presenting with altered mental status should be differentiated from patients co-ingesting hallucinogenic, stimulant, or opioid drugs of abuse.

DIAGNOSTIC TESTING

Although specific concentrations of botanical toxins are not routinely available at most institutions, evaluation of electrolytes, renal and liver functions, transaminases, and complete blood count should be performed in patients with potentially toxic exposures. An electrocardiogram (ECG) and cardiac monitoring should be performed to identify any dysrhythmias. Efforts at botanical identification should be made to determine the potential toxicity of any exposure. Patients should not be routinely relied upon for botanical identification. Mistaken identification by patients and family members is a frequent cause of accidental ingestion of toxic botanicals and can lead to toxicity and inappropriate disposition from the emergency department (ED).[2–4] Most emergency medical staff struggle to correctly identify even common house plants. Instead, family members or friends should be asked to bring in or send digital photographs of the involved plant, which can then be compared to reliable reference photographs or sent to local botanical experts or regional poison centers for proper identification.

MANAGEMENT

Ipecac for forced emesis and gastric lavage in botanical poisoning is not indicated. There is little evidence of clinical benefit of activated charcoal, and we do not recommend its routine use in botanical poisoning. A few exceptions can be made in patients who present within 1 hour of ingestion of a potentially life-threatening exposure (see Table 139.12).

TABLE 153.1 Non-toxic Plants

Common Name	*Botanical Name*
Abelia	*Abelia spp.*
African daisy	*Gerbera jamesonii*
African violet	*Saintpaulia ionantha*
Aglaonema	*Aglaonema spp.*
Aluminum plant	*Pilea cadierei*
Alyssum	*Slyssum spp.*
Aralia	*Dizygotheca elegantissima*
Areca palm	*Chrysalidocarpus lutescens*
Artillery plant	*Pilea spp.*
Asparagus fern	*Asparagus setaceus*
Aspidistra	*Aspidistra spp.*
Aster	*Callistephus chinensis, Townsendia sericea*
Astilbe	*Astilbe japonica*
Baby's breath	*Gysophila paniculate*
Baby's tears	*Hypoestes phyllostachya, Soleirolia soleirolii*
Baby's toes	*Centaurea cyanus*
Bachelor's buttons	*Centaurea cyanus*
Balsam	*Impatients spp.*
Bamboo	*Phyllostachys aurea*
Basket vine	*Aeschynanthus spp.*
Beauty bush	*Kolkwitzia amabilis*
Begonia	*Begonia goegoensis, Cissus spp.*
Bird's nest fern	*Asplenium nidus*
Bleeding heart vine	*Clerodendrum spp.*
Blood leaf plant	*Iresine spp.*
Boston fern	*Nephrolepis spp.*
Bromeliad	*Vriesea hieroglyphica*
Brunch berry	*Cornus canadensis*
Butterfly bush	*Buddleia davidii*
Button fern	*Pellaea rotundifolia*
Calathea	*Calathea spp.*
Camellia	*Camellia japonica, Thea japonica*
Candle plant	*Plectranthus oetendahlii*
Cape primrose	*Streptocarpus spp.*
Cast iron plant	*Aspidistra elatior*
Cattail	*Typha latifolia*
China doll	*Leea spp.*
Chinese evergreen	*Aglaonema modestum*
Christmas cactus	*Cactaceae*
Coleus	*Coleus spp.*
Columbine	*Aquilegia spp.*
Coral bells	*Kalanchoe uniflora*
Cordyline	*Cordyline spp.*
Corn plant or cornstalk plant	*Dracaena fragrans*
Creeping Charlie (houseplant)	*Pilea nummulariifolia, Plectranthus australis*
Creeping Jennie	*Lysimachia nummularia*
Crocus (Spring ONLY)	*Crocus spp.*
Dahlia	*Dahlia spp.*
Dandelion	*Taraxacum officinale*
Day lily	*Hermocallis spp.*
Donkey's tail	*Sedum morganianum*
Dracaena	*Dracaena spp., Cordyline spp.*
Dragon tree	*Dracaena draco*
Easter lily	*Lilium longiflorum*
Echeveria	*Echeveria spp.*
Emerald feather	*Asparagus densiflorus sprengeri*
Eugenia	*Eugenia cyanocarpa, Syzgium cuminii*
False aralia	*Dizygotheca elegantissima*
Fatsia	*Fatsia japonica*
Ferns	*Davallia canariensis, Davallia fejeensis, Rumohra adiantiformis, Asplenium spp.*
Ficus	*Ficus benjamina*
Fig	*Ficus carica*
Fingernail plant	*Aregelia spp.*
Firecracker flower	*Crossandra spp.*
Firecracker vine	*Menettia bicolor*
Fittonia	*Fittonia spp.*
Florida beauty	*Dracaena spp.*
Flowering quince	*Chaenomeles spp.*
Forsythia	*Forsythia spp.*
Friendship plant	*Billbergia spp., Pilea involucrate*
Fuchsia	*Fuchsia spp.*
Gardenia	*Gardenia jasminoides*
Gazania	*Gazania spp.*
Geranium	*Pelargonium spp.*
Glory tree	*Clerodendrum thomsoniae*
Gloxinia	*Gloxinia perennis, Sinningia speciosa*
Golddust plant	*Alyssum spp., Aucuba japonica*
Goldfish plant	*Hypocyrta spp.*
Hawthorn	*Crataegus spp.*
Hemlock tree	*Tsuga spp. (not to be confused with Conium or Cicuta spp.)*
Hens and chicks	*Echeveria spp., Sempervivum tectorum*
Hibiscus	*Hibiscus spp.*
Honey locust	*Gleditsia triacanthos*
Honeysuckle	*Lonicera fragrantissima*
Hosta	*Hosta spp.*
Hoya	*Hoya spp.*

[a]Cardioactive steroid.

of the plant is not immediately known and treatment should be focused on symptom-based, supportive care. This includes maintenance of a patent airway, intravenous fluids and vasopressors for hypotension, active cooling for hyperthermia, and benzodiazepines for agitation and seizures. Management of specific categories of botanicals is outlined in the following sections.

DISPOSITION

Any patient with signs of severe toxicity, especially those involving the cardiovascular and neurologic systems, should be managed in the ED until symptoms and signs are resolving, or they are admitted to an intensive care setting. Patients with exposure to unknown plants can be discharged after 6 hours of cardiac monitoring if they are hemodynamically stable and otherwise asymptomatic. This period of observation should be extended to 24 hours if pre-existing cardiovascular or other concerning medical problems exist or an exposure to a plant of serious toxicity is suspected.

PLANT CATEGORIES

Anticholinergics

Foundations

Principles of toxicity. *Datura stramonium* (Jimson weed, angel's trumpet) (Fig. 153.1) and *Atropa belladonna* (deadly nightshade) are the most frequently encountered plants with anticholinergic toxins. They contain scopolamine, hyocyamine and atropine. All parts of the plant contain toxic alkaloids, but they are most concentrated in the seeds of *D. stramonium* and the fruit and leaves of *A. belladonna*.

Clinical features. Ingestion can cause the antimuscarinic syndrome of agitation, diminished gastrointestinal (GI) motility, dry skin, flushing, hallucinations, hyperthermia, mydriasis, tachycardia, and urinary retention.[5,6] *D. stramonium* is commonly abused for its hallucinogenic properties, whereas berries from *A. belladonna* have been mistaken for the common blueberry *(Vaccinium arctostaphylos)* resulting in poisonings.

Differential diagnoses. The differential diagnosis of antimuscarinic toxicity includes toxicity from pharmaceutical agents such as diphenhydramine, benztropine, cyclic antidepressants, antipsychotics, and antiparkinson medications. Sympathomimetic drugs such as cocaine and amphetamines will also cause similar toxic symptoms but typically present with diaphoresis instead of dry skin, which is typical of the antimuscarinic toxidrome.

Diagnostic testing. Symptomatic patients with altered mental status or abnormal vital signs should have a screening ECG to assess corrected QT (QTc) and QRS intervals, serum electrolytes, glucose, creatinine phosphokinase (CPK) and renal function.

Management. Management should be focused on supportive care, including active cooling for hyperthermia and benzodiazepines for agitation. Recommended agents include diazepam, 5 to 10 mg IV, or lorazepam, 1 to 2 mg IV. Additional doses can be administered every 10 minutes until the patient is calm and able to cooperate with care. The use of a cholinesterase inhibitor, such as physostigmine (0.5 to 2 mg in adults; 0.02 mg/kg in children), is recommended for severe anticholinergic toxicity (see Chapter 140).[6]

Disposition. Mildly symptomatic patients can be observed in the ED for 6 to 8 hours and discharged from the ED. Severely poisoned patients with refractory antimuscarinic symptoms should be admitted to a monitored setting for 24 hours.

Antimitotic Toxins

Foundations

Principles of toxicity. *Colchicum autumnale* is also known as autumn crocus, meadow saffron, or wild saffron, and contains the toxic alkaloid colchicine. Colchicine inhibits microtubule formation, leading to disruption of mitosis, intracellular transport mechanisms and cell structure. *C. autumnale* is often mistaken for *Allium ursinum* (wild garlic), leading to fatal, unintentional ingestions. Pharmaceutical colchicine is most commonly used to treat acute gouty arthritis. Serious

toxicity from pharmaceutical colchicine is seen at doses greater than 0.5 mg/kg, and it is invariably lethal at doses of 0.8 mg/kg.

Clinical features. The clinical course of colchicine poisoning is typically divided into three phases of illness.[7] The first phase is marked by GI symptoms, such as severe vomiting, diarrhea, abdominal pain, hypovolemia, and electrolyte disturbances. Multi-organ failure ensues in the second phase, with manifestations of cardiac dysrhythmia, adult respiratory distress syndrome (ARDS), pancytopenia, liver failure, rhabdomyolysis, and sepsis. Death usually occurs during this second phase. The third phase is recovery from the poisoning.

Differential diagnoses. Patients presenting in the first phase of illness may be misdiagnosed as having gastroenteritis or food poisoning. In the second phase, colchicine poisoning mimics many serious disorders and is treated similarly with supportive interventions based on the type and severity of the patient's presentation. Obtaining a history of ingestion is critical to making the correct diagnosis but will not significantly alter the treatment plan. Patients with pancytopenia should be differentiated from patients with sepsis, leukemia, or oncological disorders—obtaining the history of ingestion may avoid invasive testing, such as a bone marrow biopsy.

Diagnostic testing. Laboratory data should include a complete blood count to assess for pancytopenia. Additional labs include serum electrolytes, renal and liver function tests as well as a screening ECG. Serum colchicine levels can be sent out to reference laboratories for analysis, but the results are time consuming and should not alter or delay emergency care.

Management. There is no specific therapy for colchicine poisoning, and management consists primarily of supportive care. There is no commercially available antidote for colchicine poisoning in the United States, and supportive care is ineffective in those who ingest a lethal dose. Thus, efforts to prevent gastric absorption by administration of activated charcoal should be made for those who ingest a potentially lethal dose of colchicine and present within 1 hour of ingestion.

Disposition. Patients presenting with GI symptoms but normal laboratory testing may be discharged home after 6 to 8 hours of hydration and observation in the ED. Patients with cardiac dysrhythmias, pancytopenia, liver dysfunction or renal failure require admission to a monitored setting. Patients with pancytopenia require admission and isolation precautions to avoid sepsis and secondary nosocomial infections.

Cardiac Glycosides

Foundations

Principles of toxicity. Cardiac glycosides bind to cell transmembrane Na^+-K^+-ATPases, which, in turn leads to a rise in intracellular Ca^{2+} concentrations, causing decreased automaticity and increased contractility. Common plants that contain cardiac glycosides include *Convallaria maalis* (lily of the valley), *Digitalis* spp. (foxglove) (Fig. 153.2), *Nerium oleander* (common, pink or white oleander) (Fig. 153.3), and *Thevetia peruviana* (yellow oleander).

Clinical features. Similar to digoxin poisoning, patients with exposure to cardiac glycosides can present with GI symptoms, generalized weakness, altered mental status, bradydysrhythmias, tachydysrhythmias, and hypotension. Toxicity and treatment of cardiac glycosides are also discussed in Chapter 142.

Differential diagnoses. The differential diagnoses of cardiac glycoside plant poisoning is broad and includes pharmaceutical toxicity with digoxin, calcium channel blockers, beta blockers, and clonidine. Additionally, other cardiogenic bradydysrhythmias (atrioventricular [AV] blocks and sick sinus syndromes) should be considered.

No sign or symptom, including dysrhythmia, is unique to digoxin poisoning, so the differential diagnosis is broad. Intrinsic cardiac disease, as well as other cardiotoxic drugs, should be considered. Cardioactive steroid poisoning from plants is rare but presents similarly to digoxin toxicity. Common examples include oleander (*N. oleander*, see Fig. 147.2) and lily of the valley (*Convallaria majalis*, see Fig. 147.3). Aconitine, a sodium-channel opening xenobiotic found in common monkshood *(Aconitum napellus)*, may also mimic digoxin poisoning. Central nervous system (CNS) depression or confusion may be due to various depressant drugs (opioids, major tranquilizers, sedative hypnotic agents) and toxins, as well as infection, trauma, inflammation, and metabolic derangements. Visual disturbances caused by digoxin are binocular and are often not reported by the patient; unfortunately,

Fig. 153.2 *Digitalis purpurea* (foxglove). (Courtesy Christopher Lim.)

Fig. 153.3 Nerium oleander. (Courtesy Steven Setzer.)

they are not specific to digoxin poisoning. Methanol, metformin, ethambutol, ethyl chloride, quinine, and other anti-malarial medications are all capable of producing visual disturbances. GI disturbances are common and nonspecific and may be misdiagnosed as gastritis, enteritis, or colitis.

Diagnostic testing. Patients should have an ECG performed, and serum electrolytes should be evaluated with attention to potassium because cardiac glycoside-poisoned patients are susceptible to hyperkalemia. A serum digoxin concentration can be measured, but correlates poorly with the degree of toxicity and should be used only to confirm exposure.

Management. The cornerstone of therapy is digoxin-specific antibody fragments (Fab) and should be administered in any patient displaying serious toxicity (heart rate <40 beats/min, sinus arrest or exit block, atrial tachydysrhythmia, ventricular dysrhythmia, second- or third-degree AV block, hypotension, and/or serum potassium level >5.0 mEq/L).[8] The optimal dose is not established and may be dependent on several variables (e.g., plant species, amount, route of exposure, and part of plant ingested).[8,9] Studies from yellow oleander poisoning suggest higher dose requirements of digoxin immune Fab with plant cardiac glycoside poisoning than with pharmaceutical digoxin poisoning. A reasonable approach considers the patient's clinical status. If the patient is in cardiac arrest or unstable, we suggest an initial 20 vials IV of Fab fragment. For stable patients, we recommend an initial 10 vials IV. Patients should be re-evaluated every hour for the need of additional doses. Cardiac pacing, atropine, beta-adrenergic agents are without demonstrated benefit and should only be considered adjunctive therapies.

Disposition. Symptomatic patients with bradycardia, hypotension, altered mental status, or hyperkalemia are admitted to a monitored setting. Those requiring digoxin-specific Fab should be admitted to an intensive care setting with cardiology and medical toxicology consultation.

OTHER CARDIOTOXIC PLANTS

Rhododendron species contain grayanotoxin, which can be found in concentrated levels in the honey that is produced from the nectar. Often referred to as "mad honey," poisonings can result in GI symptoms, hypersalivation, diaphoresis, and cardiac effects. Grayanotoxin binds to cell membrane sodium channels, preventing voltage-dependent inactivation, thereby holding cells in a depolarized state. This is thought to increase the vagal tone. The cardiac manifestations mainly consist of bradydysrhythmias (including sinus bradycardia, AV blocks, and atrial fibrillation with slow ventricular response) and hypotension, leading to symptoms of dizziness and syncope.[10,11] It has even been implicated as a cause of myocardial infarction.[12] In addition to IV fluids for hypotension, atropine and cardiac pacing have been used successfully in the treatment of mad honey toxicity.[10,11]

Taxus species (Fig. 153.4), commonly known as yew, are coniferous trees and shrubs that are often cultivated for ornamental landscaping. They contain several toxic components, including taxine pseudoalkaloids that cause sodium and calcium channel blockade. The most serious effects are on the cardiovascular system, and manifestations include hypotension, dysrhythmias, and cardiac arrest.[13,14] Management of toxicity is largely supportive. The successful use of extracorporeal membrane oxygenation (ECMO) for severe and refractory cardiotoxicity and hypotension has been reported.[13,15]

Aconitium spp. (monkshood, wolfsbane) contain aconitine and other related alkaloids. Similar to grayanotoxins, aconitine binds and prevents inactivation of voltage-gated sodium channels of myocardial and neural cells. Thus, the main features of poisoning are neurological (paresthesias, weakness) and cardiovascular (hypotension, dysrhythmias).[16] Management includes supportive care and standard therapy for dysrhythmias.[17]

Cicutoxin

Principles of Toxicity

Both *Cicuta* spp. (Fig. 153.5) and *Oenanthe crocata* are commonly known as water hemlock and contain toxins responsible for the hallmark presentation of intractable and life-threatening seizure activity. Seizures are thought to occur from non-competitive gamma-aminobutyric acid (GABA) antagonism.

Clinical Features

Initial features of poisoning may include vomiting, abdominal pain, confusion, weakness, and dizziness. Prolonged seizures can further complicate the clinical course, leading to rhabdomyolysis, hyperthermia, acidosis, hypoxia, cerebral edema, and eventual cardiopulmonary arrest.

Fig. 153.4 *Taxus media* (yew). (Courtesy Christopher Lim.)

Fig. 153.5 *Cicuta maculata* (water hemlock). (Courtesy Steven Setzer.)

Differential Diagnoses

Water hemlock is often confused for edible plants (e.g., carrots, parsnips, turnips), leading to unintentional poisonings. Other neurotoxic agents should be considered including organophosphates, isoniazid (INH), cyclic antidepressants, methyl xanthines, tramadol, sympathomimetic toxicity, and ethanol and benzodiazepine withdrawal. Seizure disorders, hypoglycemia, head trauma, and brain lesions are also diagnostic considerations.

Diagnostic Testing

History is essential to identify the toxin as the cause of the new onset seizure, thus obviating the need for further diagnostic testing. Serum electrolytes exclude hypernatremia, hyponatremia, hypocalcemia, or hypoglycemia as a cause of the confusion or seizures and hypokalemia as a cause of the weakness. Serum CPK and creatinine evaluate for rhabdomyolysis and renal impairment. A toxicology screen, especially a serum ethanol level, help identify or exclude alternate causes of the confusion. An ECG should be performed to assess intervals if an electrolyte disturbance or overdose is suspected.

Management

The mainstay of management is seizure control with benzodiazepines (lorazepam, 1 to 2 mg IV, or diazepam, 5 to 10 mg IV, repeated every few minutes until seizure activity ceases). If seizure activity is not controlled with benzodiazepines, treatment is similar to that of other toxicologic causes of status epilepticus (see Chapter 88).

Disposition

Patient with altered mental status and seizures should be admitted to an intensive care setting. Those who are asymptomatic after 6 to 8 hours of observation in the ED may be discharged home.

OTHER TOXIC PLANTS

Nicotinic toxin

Conium maculatum (poison hemlock) (Fig. 153.6), *Nicotian tabacum* (Fig. 153.7), and *Nicotiana glauca* (wild or tree tobacco) contain alkaloids capable of producing nicotinic-cholinergic poisoning. They contain the toxins coniine and coniceine (*C. maculatum*), and anabasine (*N. glauca*) that stimulate nicotinic acetylcholine receptors on the autonomic nervous system and neuromuscular junction. Clinical effects can include hypersalivation, vomiting, diarrhea, muscle fasciculation, and agitation; toxicity can progress to profound weakness, paralysis, respiratory failure, hypotension, rhabdomyolysis, and renal failure.

Fig. 153.6 *Conium maculatum* (poison hemlock). (Courtesy Steven Setzer.)

There is no specific antidote, and treatment should be aimed at ventilatory support for those with respiratory distress or muscle fatigue and those who cannot adequately oxygenate. Treatment should be continued until resolution of respiratory muscle fatigue and airway stabilization.[18,19]

Raphides

Raphides are needle-shaped, calcium oxalate crystals and have been observed in over 200 plants. Common plants that contain calcium oxalate crystals include the species from the genera *Dieffenbachia* (dumb cane, mother-in-law plant) (Fig. 153.8), *Philodendron*, *Spathiphyllum*, and *Brassaia* spp. Dieffenbachia plants are commonly found in homes and offices due to their attractive appearance, low cost and resistance to neglect. Ingestions can result in vomiting, and mucosal irritation,

Fig. 153.7 *Nicotiana tabacum* (tobacco). (Courtesy Christopher Lim.)

Fig. 153.8 *Dieffenbachia amoena* (dumb cane). (Courtesy Christopher Lim.)

ulceration and edema that can lead to compromise of the airway in severe ingestions. Dermal exposures may lead to contact dermatitis.[20]

Treatment is supportive including maintenance of a patent airway. The use of corticosteroids and antihistamines are considered adjunctive therapies, but they have not been shown to improve outcomes in mild cases of exposure. However, we recommend the administration of diphenhydramine (25 to 50 mg intravenous push [IVP]) and dexamethasone (4 to 8 mg IVP) for the rare cases of respiratory distress with significant airway edema following ingestion of specific raphide plants.

Toxalbumins

Abrus precatorius (jequirity pea, rosary, or prayer bead) (Fig. 153.9) and *Ricinus communis* (castor oil plant) contain the toxins abrin and ricin, respectively, that inhibit ribosomal protein synthesis, leading to cell death. Seeds of *A. precatorius* are distinctive, bright red or orange seeds with black caps that are often used in jewelry or rosaries. Castor beans are light brown and mottled, with dark brown spots. Seeds or beans swallowed whole with the hard outer shell intact typically prevent absorption of significant toxin. Chewed or crushed seeds or beans may release the toxin and cause local toxicity in the GI tract, leading to gastroenteritis, abdominal pain, dehydration, and electrolyte disturbances.[21,22]

Rarely, abrin or ricin is absorbed systemically, and symptoms may progress to severe neurologic toxicity (seizure, coma, cerebral edema, demyelinating encephalitis), multi-organ failure, and death. Purified ricin derived from the castor bean is highly toxic and lethal in small doses. It has been used historically as a biologic weapon, implicated in the assassination of Bulgarian journalist Georgi Markov in the 1970s, and discovered at a Washington DC postal service facility in 2001. There is no effective antidote, vaccine, or other therapy for the treatment of prevention of abrin or ricin poisoning. Treatment consists of fluid resuscitation, vasopressor agents for hypotension, and correction of electrolyte imbalances with neurotoxic symptom precautions.

MUSHROOMS

FOUNDATIONS

Mushrooms represent a wide range of species with regional variation. In this section, we will consider the mushrooms of toxicologic significance. The categories of poisonous mushrooms are grouped according to the types of illness or organ-specific toxicity. Another important perspective is that the most common species of toxic mushrooms belong to the GI irritant group and generally do not cause life-threatening illness. Distinguishing the GI irritant group from the more serious groups is the challenge for the treating emergency clinician.

According to data from 2018 as reported by the American Association of Poison control centers, there were a total of 6318 mushrooms exposures. The majority of the ingested mushrooms were never identified (5138). Four mushrooms from the cyclopeptide group, nine from the hallucinogenic group, one from the muscimol-containing group, and one from the orellarine group resulted in major effects. There were five fatalities from mushroom exposures in this database.[1]

CLINICAL FEATURES

An important clinical consideration is the onset of symptoms after a mushroom ingestion. In general, the GI irritants will develop symptoms in the first 2 to 3 hours after ingestion. Some of the most lethal mushrooms will cause symptoms on a delayed basis, such as *Amanita phalloides*, or *Gyromitria esculenta,* at 6 to 8 hours after ingestion.[23] There are some exceptions that are highlighted later in the chapter.

DIFFERENTIAL DIAGNOSES

Many mushrooms are edible and considered delicacies, such as puffballs or morels. However, there are many look-alikes, and foragers must be certain that they identify correct species to avoid morbidity and mortality. The differential diagnosis with mushroom poisoning includes gastroenteritis, pancreatitis, hepatitis, acute renal failure, hallucinogenic poisonings, anticholinergic and cholinergic poisonings, disulfiram toxicity, and food poisoning.

DIAGNOSTIC TESTING

Identifying the mushroom ingested is extremely helpful to the treating team. It is beyond a realistic scope for emergency clinicians to be able to identify mushrooms, and it is wise to coordinate with poison control centers and local mycologists to identify mushrooms in real time. Smart phone digital identification by sending images to mycologists via a poison control center model has been shown to be accurate in identifying mushrooms. Attempts at mushroom identification should be made, particularly if a patient presents with a delayed onset of symptoms.

Routine testing includes complete blood count, urinalysis, and basic metabolic profile with specific attention to renal function and measures of dehydration. Liver enzyme and tests of liver function should be obtained if cyclopeptide or gyromitrin poisoning is suspected.

MANAGEMENT

The general management of mushroom poisoning focuses on symptom-based supportive care. There is no proven outcome benefit from administration of activated charcoal for patients with mushroom ingestion. We recommend activated charcoal only if it can be administered within 1 hour of the ingestion and the clinician suspects

ingestion of a potentially life-threatening mushroom (e.g., cyclopeptide- or gyromitrin-containing species). We do not recommend gastric emptying by any method. Because many toxic mushrooms can cause vomiting or diarrhea, it is important that these patients are fluid resuscitated and rehydrated until they can tolerate oral liquids.

DISPOSITION

Patients should be admitted for 24 hours when the ingestion of a potentially life-threatening mushroom has occurred. For hepatotoxic mushrooms, transferring the patient to a tertiary care center with liver transplantation capabilities should be considered. For suspected or confirmed GI irritant mushroom ingestion the patient can be safely discharged after the GI symptoms are controlled and oral fluids are tolerated.

MUSHROOM CATEGORIES

Hepatotoxic Mushrooms

Principles of Toxicity

The two major categories of mushrooms that can cause life-threatening hepatotoxicity include cyclopeptide-containing mushrooms such as *A. phalloides*, or certain *Lepiota* species of mushrooms. The *Gyromitra* species also cause hepatotoxicity but have other symptoms distinct from the cyclopeptide-containing mushrooms.

Clinical Features

The cyclopeptide-containing mushrooms will cause an onset of GI symptoms 6 to 8 hours after ingestion. This includes nausea, vomiting, diarrhea, and abdominal pain. Over the next 1 to 2 days, the patient will develop increasingly severe hepatic injury and encephalopathy.

Differential Diagnoses

In patients with cyclopeptide-containing mushroom toxicity with elevations in liver aminotransferases, bilirubin, partial thromboplastin time (PTT)/international normalized ratio (INR), or creatinine, other sources of injury should be considered, including acute tubular necrosis, rhabdomyolysis, ischemic hepatitis, alcoholic hepatic disease, viral hepatitis, and Wilson's disease. Other hepatotoxic considerations include poisoning with acetaminophen, valproic acid, INH, statins, herbal medications (e.g., pennyroyal oil, pyrrolizidine alkaloids), vinyl chloride, and polychlorinated biphenyls.

Diagnostic Testing

Poisoning is evidenced by rising liver enzymes and worsening measures of liver function (rising bilirubin and increased INR). Hyperammonemia can also be seen in severe toxicity. These markers should be followed serially during the hospital course. Also, because patients may develop a hepatorenal syndrome, creatinine and blood urea nitrogen should be measured.

Management

Many therapies have been tried for cyclopeptide-containing mushrooms. Initial decontamination measures with oral activated charcoal are recommended if the patient presents within 1 hour of ingestion and has not already vomited. Suggested therapies in the literature that may be immediately available include *N*-acetylcysteine (NAC), high dose IV penicillin, and early hemodialysis or hemoperfusion.[23] NAC is thought to work via hepatoprotective effects, and animal studies indicate that amatoxins deplete glutathione stores. IV NAC dosing regimens are similar to those administered to acetaminophen poisoned patients (see Chapter 138). High dose penicillin is thought to work by displacing amatoxin uptake by the hepatocytes. Experimental antidotes such as thioctic acid, silibinin, and *polymyxin* B, have been more commonly used in Europe. Silibinin, the main isomer of silymarin, found in milk thistle, is currently available as an investigational agent. It works as an antioxidant, free radical scavenger, and can restore glutathione stores.[24] If a cyclopeptide-containing mushroom has been ingested, we suggest mobilizing silibinin by calling the regional poison control center to coordinate management and prioritization of agents. The use of oral milk thistle extract, a common health supplement product, has been reported in areas where the IV formulation is not available. However, its use has not been adequately studied to be routinely recommended as a therapeutic option. Patients who progress to fulminant hepatic failure despite appropriate supportive care may ultimately require liver transplantation.[25] Consultation with a transplant center should be initiated early in the course of management.

Disposition

Patients showing evidence of severe hepatotoxicity and those at risk for fulminant hepatic failure should be admitted to an intensive care unit. These patients require frequent neurological checks, continuous vital sign monitoring, and serial laboratory studies. If a patient presents with established hepatotoxicity, transferring to a tertiary-care center that specializes in the management of patients with hepatic failure with liver transplant capabilities is recommended.

Gyromitrin-containing Mushrooms

Principles of Toxicity

Gyromitrin-containing species are also known as the *false morel*. Like the cyclopeptide-containing mushrooms, these can also cause significant hepatotoxicity[26] but may also cause neurotoxicity, particularly seizures and altered mental status. The mechanism for seizures is similar to INH by causing deficiency of pyridoxine and inhibiting the action of glutamic acid decarboxylase. This prevents the formation of GABA, an inhibitory neurotransmitter.[27] These mushrooms can also induce some degree of oxidant stress, which can clinically manifest as methemoglobinemia.

Clinical Features

Similar to the cyclopeptide-containing group, gyromitrin mushrooms can cause delayed nausea, vomiting, diarrhea, and hepatotoxicity, but most notably manifest with generalized seizure activity.

Differential Diagnoses

The highly sought-after *true morel* is an edible delicacy and is considered nontoxic. The *false morel* has a close resemblance and can be found in similar regions. Other causes of seizures and neurotoxicity should be considered, including INH poisoning, sympathomimetic toxicity, intracranial bleeds, brain mass lesions, and underlying seizure disorders. Other causes of methemoglobinemia include ingestion of nitrate and nitrate-containing compounds, local anesthetic agents, dapsone, and inborn errors in metabolism.

Diagnostic Testing

In patients presenting with seizure activity, obtaining a history of toxic ingestion obviates the need for most diagnostic testing. Because there is potential for hepatoxicity, serial liver transaminases should be monitored. Serum electrolytes should be monitored for protracted vomiting or diarrhea. A screening methemoglobin level is also recommended.

Management

Management of gyromitrin-induced seizures should include IV pyridoxine, as recommended for INH poisoning, with 5 g as an empirical dose (see

Chapter 124). Clinically significant methemoglobinemia can be managed with methylene blue, although this is a rare occurrence. Methylene blue dosing is typically 2 mg/kg IV, which can be repeated within 30 to 60 minutes as needed. (See Chapters 55 and 148 for dosing of methylene blue.)

Disposition

Patients with altered mental status and seizures requiring pyridoxine therapy should be admitted to an intensive care setting. Those who are asymptomatic after 6 to 8 hours observation the ED may be discharged home.

OTHER MUSHROOM CLASSES

Cholinergic Agonists

True cholinergic agonists are rarely encountered in the clinical setting. *Clitocybe dealbata*, also known as "the sweater," is one of these mushrooms. If ingested, clinical symptoms of cholinergic excess may be seen. Muscarinic effects recalled by the mnemonic SLUGBAM, can be useful. **SLUGBAM** stands for **S**alivation, **L**acrimation, **U**rination (excessive), **G**astrointestinal effects (nausea, vomiting, and diarrhea), **B**radycardia/bronchorrhea/**b**ronchospam, **A**bdominal cramps, and **M**iosis. Treatment is supportive, but atropine can be used for excessive cholinergic symptoms, as described in Chapter 152. Unlike organophosphates, there is no role for oxime therapy.

Disulfiram Reaction-Inducing Mushrooms

Coprinus atramentarius and other *Coprinus* species contain the toxin coprine that can inhibit aldehyde dehydrogenase similar to disulfiram. If ingested along with ethanol, it can lead to a disulfiram-like reaction including nausea, vomiting, diarrhea and flushing. Treatment is generally supportive, including IV hydration and antiemetics, such as prochlorperazine, or ondansetron (Fig. 153.10).

Hallucinogenic Mushrooms

There are a wide variety of mushrooms that can lead to hallucinations. Some common examples include the *Psilocybe* and *Conocybe* species. These are direct hallucinogens and contain psilocybin and related compounds. Psilocybin is found in a wide range of mushrooms. These are well known to be available for purchase online and in "grow at home" kits.[28] Possession of these types of mushrooms has recently been decriminalized in the State of Colorado.

Fig. 153.10 Coprinus atramentarius (Courtesy Joe McFarland.)

The ibotenic acid and muscimol containing mushrooms can also lead to hallucinations. *Amanita muscaria* is an important example of this class. Others include *Amanita pantherina* and *Gemmata* species. Ibotenic acid acts similarly to glutamate and can have excitatory effects. Muscimol has inhibitory effects and works as a GABA agonist. These mushrooms are used for their hallucinogenic effect and both CNS excitation and depression can be seen.

Overdose of these mushrooms can lead to nausea, vomiting, diarrhea, abdominal pain, dry mouth, dilated pupils, tachycardia, agitation, delirium, coma and seizures.[29] The mainstay of treatment of hallucinogenic mushrooms is providing a low-stimulus environment where the effects can dissipate. Benzodiazepines are generally effective in treating the agitation and tachycardia (lorazepam, 1 to 2 mg IVP; diazepam, 5 to 10 mg IVP). Antipsychotic agents can be used for prolonged hallucinations not improved with benzodiazepines (e.g., haloperidol, 2 to 5 mg IM or droperidol, 1.25 to 2.5 mg IM).

Gastrointestinal Irritants

There are hundreds of species of mushrooms that are GI irritants. These mushrooms will cause irritation to the GI tract within 2 to 3 hours of ingestion. Some commonly encountered species of GI irritants include *Boletus* sp., *Chlorophyllum molybdites, Lactarius* sp, and *Omphalotus* sp. Nausea, vomiting, diarrhea, and crampy abdominal pain will be the typical presenting symptoms. The course is generally self-limited, but care should be taken to monitor patients with prolonged symptoms or with significant fluid losses.

Another consideration with mushrooms ingested that cause GI symptoms is that the mushroom will be contaminated with pesticides or metals. Therefore, the symptoms may not be from the mushroom itself but from the chemical contaminant.

Renal Insufficiency

Two species of mushrooms can potentially lead to direct renal toxicity. In Europe, the *Cortinarius* species of mushrooms have been associated with renal failure.[30] Similar to the deadly cyclopeptide and gyromitirin-containing mushrooms, symptoms commonly occur on a delayed basis and as long as 2 weeks after ingestion. This mushroom is not generally found in the US.

A more problematic mushroom that is found in the Pacific Northwest is the *Amanita smithiana* mushroom. The toxin contained in this mushroom is allenic norleucine, which can have serious nephrotoxic effects. This mushroom leads to GI symptoms early after ingestion, and thus violates the general rule that serious poisoning follows delayed onset of GI symptoms. GI symptoms can begin between 2 and 12 hours after ingestion. Treatment is generally supportive, including fluid bolus followed by maintenance. However, with acute renal failure, metabolic acidosis, and electrolyte imbalances, hemodialysis may be required.

Rhabdomyolysis-Inducing Mushrooms

Another mushroom that can cause toxicity on a delayed basis is *Tricholoma equestre* (commonly referred to as the "man on horseback" or "yellow knight" mushroom). It can cause weakness, fatigue, and muscle pain 24 to 72 hours after ingestion. This mushroom can cause clinically significant rhabdomyolysis. Serial serum CPK levels should be followed to monitor for rhabdomyolysis and development of renal failure. Treatment is supportive with IV hydration and alkalinization therapy.

HERBAL MEDICATIONS

Although much of the world's population has used herbal products as medicine for centuries, its growing popularity in the United States has

been a relatively recent trend. Since the passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994, the number of herbal products on the market has sharply increased from 4000 to 90,000 in 2014.[31] It is estimated that nearly 40 million US adults use herbal products with sales exceeding $5 billion annually.

PRINCIPLES OF TOXICITY

The DSHEA established herbal products as food, and unlike pharmaceuticals, they are not subject to rigorous regulations and do not need to demonstrate efficacy or safety for commercial sale. As a result, ingredients and their concentrations are often unknown, and controlled clinical trials and toxicologic testing are not routinely performed. The consumer may believe that herbal medications undergo strict regulation and testing, and are safer and more efficacious than pharmaceuticals. This misperception, combined with a lack of proper dosing and scheduling regimen, may lead to misuse and over-use of herbal medications. Factors that further contribute to adverse events include inherent toxicity, contamination and adulteration of products, and herb-drug interaction.[32] Studies show that most people who use herbal medications in addition to prescribed medications will do so without consulting or notifying their health care providers.

Clinical research in the area of herb-drug interaction is lacking.[33] Most pharmaceutical drugs undergo hepatic biotransformation and inactivation via the cytochrome P_{450} enzymes. Herb-drug interactions typically stem from alteration of this system, leading to increased or decreased drug concentration. Herbal medications may also affect drug transporters, such a p-glycoprotein, and further modify pharmacodynamics. Herb-drug interactions are best documented in the use of St. John's Wort *(Hypericum perforatum)* (Fig. 153.11).[34] It induces cytochrome P_{450}, family 3, subfamily A (CYP3A), which metabolizes approximately 50% of available US pharmaceuticals, leading to decreased drug concentrations.

CLINICAL FEATURES

Many herbal medications possess toxicity inherent to the botanical from which they are derived (Table 153.3). Adverse effects can range from allergic reactions to cardiovascular and hepatic toxicity.[35–39] The Food and Drug Administration (FDA) banned the sale of Ma Huang *(Ephedra sinica)* in 2004 after reports of serious cardiovascular events and death related to its sympathomimetic effects. Many herbal medications, including Germander *(Teucrium chamaedrys)*, Pennyroyal oil (*Mentha pulegium*

Fig. 153.11 *Hypericum perforatum* (St. John's wort). (Courtesy Christopher Lim.)

TABLE 153.3 Mushrooms

Early Onset Symptoms (First 2–3 h)

Clinical Category	Symptoms	Treatment
Gastrointestinal irritants (*Boletus* sp., *Chlorophyllum* sp., *Lactarius* sp.)	Nausea, vomiting, diarrhea	Supportive care
Hallucinogens (*Psilocybe* and *Conocybe* sp., *Amanita muscaria, Amanita pantherina*)	Agitation, hallucinations	Benzodiazepines Low stimulus environment
Disulfiram (*Coprinus* sp.)	Nausea, vomiting, diarrhea, abdominal cramping, flushing	Supportive
Cholinergic (*Clitocybe* sp.)	SLUGBAM (Salivation, lacrimation, Urination, GI Distress, Bronchorrhea, Bradycardia, Bronchospasm, Abdominal cramps, Miosis)	Atropine
Renal *(Amanita smithiana)*	Renal insufficiency (GI symptoms early)	Supportive Hemodialysis

Late Onset Symptoms (>4–5 h)

Mushroom Group Hepatotoxic	Symptoms	Treatment
Cyclopeptide-containing (*Amanita phalloides, Amanita bisporigera, Lepiota* sp.,*Galerina* sp.)	Hepatic failure, symptoms begin 6–8 h post-ingestion	Supportive, NAC, Dialysis, Penicillin, Thioctic acid Silibinin, Liver transplant
Gyromitrin *(Gyromitra esculenta)*	Hepatic failure, Seizures, Supportive, Vitamin B6, Methylene blue	Methemoglobinemia
Renal (*Cortinarius* sp.)	Delayed onset renal failure	Supportive, Dialysis
Rhabodomyolysis *(Tricholoma equestre, Russula subnigricans)*	Muscle pain, weakness, fatigue	Supportive, hydration, Hemodialysis

and *Hedeoma pulegoides*), and those containing pyrrolizidine alkaloids are associated with hepatotoxicity.[39] Most herbal medications that possess inherent toxicity can have adverse maternal-fetal effects, and we advise against the routine use of herbal medications during pregnancy.

Some herbal medications increase bleeding risk by altering the pharmacokinetics of anticoagulants, such as warfarin, or having a synergistic effect with antiplatelet agents and anticoagulants.[40] The concurrent use of several herbal medications, such as St. John's wort, with other serotonergic drugs can potentially contribute to the development of serotonin syndrome. Kava Kava *(Piper methisticum)* and Valerian *(Valerian officinalis)* have been shown to potentiate the GABA-mediated CNS depression from alcohol consumption.

DIFFERENTIAL DIAGNOSES

Due to the unregulated nature of herbal medications, contaminants and adulterants are often present and sometimes result in toxicity. In addition to fillers and substituents, contamination with heavy metals, pesticides and other harmful materials has been found in herbal medications. Certain metals are believed to have therapeutic properties. Lead is the most commonly reported heavy metal contaminant, but arsenic, cadmium, and mercury poisoning after herbal medication use have been described as well.[32] Additionally, there are many examples reported in the literature of toxicity from herbal medications adulterated with pharmaceuticals.

DIAGNOSTIC TESTING

Diagnostic studies in patients presenting with herbal medication toxicity include a complete blood count, coagulation profile, serum electrolytes, glucose, hepatic, and renal function tests. In addition, acetaminophen and salicylate levels should be measured along with urinary heavy metal screens, targeting lead, arsenic, and mercury.

MANAGEMENT

Treatment is largely supportive, with hydration, bleeding control if coagulopathic, cardiac dysrhythmia treatment, and targeted antidote therapy (e.g., NAC, heavy metal chelation therapy; see Chapter 146).

DISPOSITION

The majority of patients with herbal medication toxicity will be mildly symptomatic with GI symptoms and normal diagnostic testing. These patients can be observed and hydrated in the ED and safely discharged home. Patients with systemic toxicity including hepatic, renal, cardiac or multi-organ failure require admission for monitoring and consultation from appropriate services.

CHAPTER 153: QUESTIONS AND ANSWERS

1. A 52-year-old man presents after ingestion of water hemlock complaining of nausea but no other symptoms. He reports that he ate the water hemlock in a suicide attempt but has since changed his mind. His vital signs and physical examination are normal. What is the most appropriate initial treatment of this patient?
   a. General seizure precautions
   b. Hemodialysis
   c. Neutralization with milk
   d. Supportive care only
   e. Whole bowel irrigation

Answer: a. Water hemlock is very toxic, with fatality rates as high as 70%. Because this patient is at risk for seizures, oral activated charcoal and gastric lavage are contraindicated. Hemodialysis, whole bowel irrigation, and milk are not beneficial. Supportive care is not adequate with water hemlock ingestion. Most deaths are caused by intractable seizures, so this complication should be anticipated.

2. A family of four presents to the emergency department feeling ill after consuming a homemade stew containing Datura stramonium (Jimsonweed). Which of the following can be expected upon physical examination?
   a. Bradycardia
   b. Confusion
   c. Diaphoresis
   d. Miosis
   e. Respiratory depression

Answer: b. Jimsonweed contains atropine, hyoscyamine, and scopolamine, all of which have anticholinergic properties. Anticholinergic signs include confusion, dry skin and mucous membranes, mydriasis, tachycardia, urinary retention, confusion. In severe cases, physostigmine can be used to reverse effects.

3. Oleander contains cardiac glycosides similar to digoxin. Which of the following should be considered when treating oleander ingestion?
   a. Activated charcoal should be avoided.
   b. Serum digoxin levels correlate with degree of toxicity.
   c. Treatment is supportive.
   d. Treatment with digoxin-specific Fab fragments is beneficial, but a higher dose may be necessary.
   e. Treatment with digoxin-specific Fab fragments is not beneficial.

Answer: d. Treatment is with digoxin-specific Fab fragments, but much higher doses are necessary compared with those needed to treat digoxin toxicity. Activated charcoal is useful if the ingestion was recent. A serum digoxin level should be measured, but it is not a reliable indicator of level of toxicity. An elevated level confirms oleander ingestion, but a negative level cannot rule out ingestion.

4. A husband and wife present to the emergency department (ED) complaining of nausea and vomiting after eating mushrooms that they picked while hiking. They report eating the mushrooms on a salad approximately 1 hour ago. Each is complaining of severe nausea, vomiting, and diffuse abdominal pain. There is no hematemesis. Vitals signs and physical examination are normal. You inform them that they will be symptomatically treated and observed, but there is likely nothing to worry about. Why are you not concerned about their ingestion?
   a. Early onset of gastrointestinal symptoms
   b. No hematemesis
   c. No right upper quadrant tenderness
   d. Normal mental status
   e. Normal vital signs

Answer: a. The vast majority of severely toxic mushrooms have delayed onset of symptoms (>6 hours from ingestion). Occasionally, people will ingest two different types of mushrooms—one benign and causing early onset of symptoms and one more toxic. Therefore, patients should be observed and rechecked.

5. What is the most common cause of death after mushroom ingestion?
   a. Gastrointestinal hemorrhage
   b. Heart failure
   c. Liver failure
   d. Renal failure
   e. Respiratory failure

Answer: c. The *Amanita* species of mushrooms are very toxic and cause fulminant liver failure often necessitating liver transplant. Hepatotoxic mushrooms account for about 90% of all mushroom fatalities. Although certain mushrooms (*Cortinarius* spp. and *Amanita smithiana*) can cause renal failure, death is uncommon with these mushrooms. Mushrooms generally do not affect the other listed organ systems.

6. A 46-year-old man presents after waking in the night with headache and severe nausea and vomiting. For dinner the night before, he consumed some mushrooms that he had gathered from a nearby forest. He felt fine immediately after dinner. His vital signs are normal. While conducting your physical examination, he begins to seize. Benzodiazepines are administered without improvement. What treatment is indicated?
   a. Phenobarbital
   b. Phenytoin
   c. Propofol
   d. Pyridoxine
   e. Vecuronium

Answer: d. Most mushrooms do not cause seizures, but gyromitrin-containing mushrooms are an exception. They are commonly mistaken for edible morels because they look quite similar. They contain an isoniazid-like toxin that causes seizures. Traditional seizure medications can be used (because they are typically more readily available), but seizures can be intractable until pyridoxine is given.

7. A 54-year-old male with a history of depression presents to the emergency department with confusion. He is prescribed nortriptyline only, but his wife reports that he has recently started taking an herbal supplement. His vital signs are temperature 100.3°F, blood pressure 130/75, pulse 124, respiratory rate 20, oxygen saturation 96%, You note spontaneous clonus to his lower extremities and diagnose him with serotonin syndrome. Which of the following herbal supplements did he most likely start taking?
   a. Ephedra
   b. *Hypericum perforatum*
   c. *Gingko biloba*
   d. *Piper methisticum*
   e. Saw palmetto

Answer: b. *Hypericum peforatum* (St. John's wort) is a non-selective serotonin reuptake inhibitor and is thought to also upregulate post-synaptic serotonin receptors. Combination therapy with other anti-depressants that increase serotonin has been reported to cause serotonin syndrome. Ephedra is no longer commercially available as it was banned by the FDA for its association with cardiovascular disease. *Gingko biloba* may have antioxidant properties and inhibit platelet aggregation. *Piper methisticum* can increases GABA-mediated CNS depression when combined with alcohol. Saw palmetto is a remedy for benign prostatic hypertrophy and is thought to work by inhibiting 5-α-reductase.

Sedative-Hypnotics

Daniel L. Overbeek and Timothy B. Erickson

KEY CONCEPTS

- Supportive care, with a focus on respiratory depression, is the foundation of management of all sedative-hypnotic ingestions.
- Benzodiazepines are commonly used medications both medically and recreationally. Coingestions with other sedative-hypnotic agents can potentiate their neurologic and respiratory effects.
- Barbiturate medications are less commonly prescribed, and intoxications are infrequent. Most patients recover with supportive care alone.
- A positive urine toxicology screen for benzodiazepines or barbiturates does not prove a causal linkage between the drug and the current clinical condition.
- We do not recommend routine use of flumazenil for benzodiazepine toxicity, particularly in chronic benzodiazepine users in whom flumazenil can precipitate seizures. Due to the short duration of action of flumazenil, when administered, patients should be monitored closely for recurrence of respiratory depression.
- Chloral hydrate toxicity may result in sedation and cardiotoxicity, principally in the form of supraventricular tachycardias, which are best treated with a short-acting beta blocker.
- Withdrawal from sedative-hypnotic use, including benzodiazepines, barbiturates and gamma hydroxybutyrate (GHB), can be life threatening. Management often requires high doses of benzodiazepines or barbiturates.

FOUNDATIONS

The sedative-hypnotic toxidrome encompasses depressed mental status, decreased respiratory rate, and suppressed response to stimuli. Within this chapter, we will discuss a variety of medications and agents that can induce a sedative-hypnotic toxidrome at therapeutic or toxic doses. Also, the general treatment recommendations and specific considerations for individual agents will be presented.

Most sedative-hypnotics have effects mediated through the gamma-aminobutyric acid (GABA) neurotransmitter system. GABA is the primary inhibitory neurotransmitter, and the GABA-A receptor is a protein complex found on postsynaptic membranes in the CNS. Structurally, it consists of several distinct receptor sites surrounding a chloride ion (Cl^-) channel (Fig. 154.1), which is opened by GABA binding. The resulting flow of Cl^- into the cell increases the negative resting potential, hyperpolarizing and stabilizing of the membrane. The net effect is a diminished ability of the nerve cell to initiate an action potential, inhibiting neural transmission. There are separate receptor sites for barbiturates and for benzodiazepines and a third site that binds GABA, ethanol, and meprobamate. Increasing either the frequency or duration of GABA stimulation in the nervous system causes most of the effects seen in the sedative-hypnotic toxidrome, including blunted responses to stimuli and sedation.

Sedative-hypnotic drugs, especially benzodiazepines, are among the most widely prescribed classes of drugs[1] (Table 154.1) and are the most commonly prescribed drugs used in suicide attempts. Pediatric patients comprise 10% of benzodiazepine overdose cases. With the significant proliferation of opioid usage, prevalence of combined benzodiazepine and opioid toxicity with significant risk of respiratory compromise has increased significantly.[2]

BENZODIAZEPINES

Clinical Features

Benzodiazepines are widely used medically for their antiepileptic, sedative, and anxiolytic properties. Prior to benzodiazepines, barbiturates were the primary sedative-hypnotics used, but they have been overwhelmingly supplanted by benzodiazepines and other, newer agents.

Benzodiazepines produce sedative, hypnotic, anxiolytic, and anticonvulsant effects by potentiating the GABA-A receptor in the presence of GABA.[3–5] In contrast, barbiturates can directly increase Cl^- conductance. This may account for the relative safety of benzodiazepines in comparison with barbiturates.

At therapeutic dosage, the GABA effects of benzodiazepines cause euphoria, anxiolysis, and drowsiness. Mild toxicity includes CNS depression, ataxia, slurred speech, nystagmus, and impaired cognition. Most benzodiazepine overdoses follow a relatively benign clinical course. Larger overdoses may cause respiratory depression, which may require intervention. The respiratory depression is less severe than with barbiturates, especially if benzodiazepines are the only substance ingested. Coingestants with sedative properties, particularly ethanol or opioids, can markedly potentiate the respiratory depression caused by benzodiazepines.[6] Loss of muscle tone leads to upper airway obstruction and increased airway resistance. Hypoventilation is often the first sign of severe respiratory depression, and may be masked by oxygen supplementation, which can maintain adequate oxyhemoglobin saturation. Capnography can be useful in detecting early signs of hypoventilation.

Cardiac toxicity or hypotension from pure benzodiazepine overdose is rare. Other potential complications include aspiration pneumonia and pressure necrosis of skin and muscles. Intravenous solutions of diazepam and lorazepam contain the diluent propylene glycol, which is metabolized to lactate, and prolonged or high-dose infusions of these preparations can cause lactic acidosis. Patients with renal or hepatic insufficiency are at increased risk for this complication.

Most pediatric patients have symptoms within four hours of benzodiazepine ingestion. Ataxia is the most common sign of toxicity, occurring in 90% of pediatric patients. Respiratory depression occurs in fewer than 10% of pediatric cases, and hypotension is rarely reported in children.

Benzodiazepines were previously identified as pregnancy category D, noting some risk, but that they should be used when indicated based on a risk-benefit analysis (see Chapter 175 regarding drug therapy for the pregnant patient). There are some studies showing risks, but these are difficult to analyze as most patients involved were also exposed to other psychiatric medications.[7] In the acute setting, when needed for management of emergent conditions including seizures, the benefits of short term acute use likely outweigh the complications to the mother and fetus.[8,9] Management of seizures during pregnancy is discussed in Chapter 173. The management of benzodiazepine toxicity during pregnancy follows the standard approach, including supportive care and respiratory support, with the recognition of an increased risk of respiratory and mental status depression in the fetus if delivery is required.

Novel synthetic benzodiazepines are procured from a variety of internet sites or other illicit sources, and the true content of the product received is unknown to the user. Limited information is available about many of these agents. Management should be similar to the known pharmaceutical benzodiazepines, recognizing the increased likelihood of coingestants, as discussed in the following.[10,11]

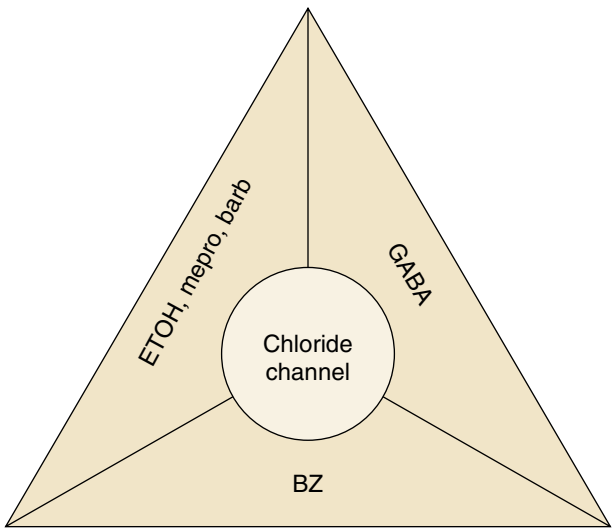

Fig. 154.1 The gamma-aminobutyric acid (GABA) receptor complex. *BZ,* Benzodiazepine binding site; *GABA,* GABA binding site; *ETOH, mepro, barb,* binding sites for ethanol, meprobamate, and barbiturates, respectively.

Pharmacokinetics

Benzodiazepines are rapidly absorbed orally. Intramuscular use of chlordiazepoxide and diazepam is limited by erratic absorption, but lorazepam and midazolam are predictably absorbed after intramuscular injection. Parenteral and rectal administration of benzodiazepines provide faster time to onset than oral ingestion and can be used for antiepileptic and sedative indications. After absorption, benzodiazepines distribute readily, and rapidly penetrate the blood-brain barrier. In plasma, benzodiazepines are highly protein bound.[12,13]

Benzodiazepines are metabolized in the liver. Lorazepam, oxazepam, and temazepam are directly conjugated to an inactive, water-soluble glucuronide metabolite that is excreted by the kidney. Other benzodiazepines must first be converted by the hepatic cytochrome P450 system. Many benzodiazepines, including chlordiazepoxide and diazepam, are metabolized to active compounds that are then conjugated and excreted. The long elimination half-lives of up to 120 hours of these intermediates can cause accumulation in the body with repeated dosing and prolong the sedative effects of these benzodiazepines.[13] Alprazolam and midazolam are converted to hydroxylated intermediates that are rapidly conjugated and excreted, but do not contribute significantly to the overall effect of the drug.[12]

Cytochrome P450 metabolism may be significantly impaired in elderly patients or those with liver disease, leading to prolonged elimination of benzodiazepines. Coingestion of drugs that inhibit P450 metabolism (e.g., cimetidine, ethanol) also prolongs the half-lives of benzodiazepines.[12]

Differential Diagnoses

Benzodiazepine overdose is usually suspected or diagnosed by clinical presentation. Many patients are able to interact appropriately with providers and can provide supporting information. Atypical or focal neurological findings suggest the presence of other conditions, such as intracranial events (e.g., intracerebral hemorrhage, cerebral ischemia). Profound coma or cardiopulmonary instability is rare with pure benzodiazepine overdose and should prompt the search for coingestants, such as opioids, ethanol, phenobarbital, choral hydrate, or a cyclic antidepressant. Non-toxicologic metabolic causes of CNS depression,

TABLE 154.1 Benzodiazepines

Name	Usual Dose	Oral Peak (Hours)	Half-Life (Hours)	Parent Metabolite Activity
Alprazolam (Xanax)	0.25–0.5 mg	1–2	6–27	Inactive
Chlordiazepoxide(Librium)	5–25 mg	0.5–4	5–30	Active
Clonazepam (Klonopin)	0.25–0.5 mg	1–2	18–50	Inactive
Clorazepate (Tranxene)	7.5–15 mg	1–2	1–3	Active
Diazepam (Valium)	2–10 mg	0.5–1	20–50	Active
Estazolam (Prosom)	1–2 mg	2	8–28	Inactive
Flurazepam (Dalmane)	15–30 mg	0.5–1	2–3	Active
Halazepam (Paxipam)	20–40 mg	1–3	14	Active
Lorazepam (Ativan)	0.5–2 mg	2–4	10–20	Inactive
Midazolam (Versed)	10–20 mg	1–2	1.5–3	Active
Oxazepam (Serax)	10–30 mg	2–4	5–20	Inactive
Quazepam (Doral)	7.5–15 mg	2	39–41	Active
Temazepam (Restoril)	7.5–30 mg	1–2	3–19	Inactive
Triazolam (Halcion)	0.125–0.25 mg	1–2	1.5–5.5	Inactive

such as hypoglycemia or hyponatremia should also be considered. The broader differential of CNS depression includes conditions described in Chapters 12 and 13.

Diagnostic Testing

Sedative-hypnotic toxidromes are clinical diagnoses, and most laboratory testing will not be helpful in determining the appropriate care for the patient. Any patient with altered mental status should have a blood glucose level rapidly determined. Qualitative immunoassays for benzodiazepines in urine are available, but do not aid management decisions and cannot provide definitive information regarding the cause of the altered mental status. Because most screening tests detect a specific benzodiazepine metabolite, including nordiazepam or oxazepam glucuronide, some benzodiazepines (including clonazepam, lorazepam, midazolam, and alprazolam) will not be detected on many standard urine drug tests. A positive urine drug screen for benzodiazepines indicates exposure or use but does not identify intoxication or indicate a specific agent and does not confirm benzodiazepine exposure as the cause of the clinical presentation. The positive screen also does not provide information regarding the timing of the benzodiazepine exposure. Serum drug concentrations are not routinely available and do not correlate with clinical severity.[14]

Adjunct testing should be used as clinically indicated, including computerized topography (CT) imaging when concerned for head trauma or intracranial hemorrhage. The benzodiazepine antagonist flumazenil should not be routinely administered to patients with suspected benzodiazepine overdose or coma of unknown origin solely for diagnostic purposes.[15]

MANAGEMENT

Stabilization and Supportive Care

Initial stabilization, including endotracheal intubation when necessary, should not be delayed by the administration of an antidote. Most benzodiazepine overdoses can be managed expectantly with observation and supportive care alone. Neither gastrointestinal (GI) decontamination or administration of activated charcoal is indicated in benzodiazepine ingestion. Close respiratory monitoring is indicated to guide respiratory interventions and end tidal carbon dioxide (CO_2) monitoring can be a useful adjunct. Naloxone should be administered in cases of suspected opioid coingestion (see further discussion of opioid overdoses in Chapter 151).

Antidote Therapy

Flumazenil, a nonspecific competitive antagonist at the benzodiazepine receptor, can reverse benzodiazepine-induced sedation after general anesthesia, procedural sedation, and confirmed benzodiazepine overdose. However, the risks of flumazenil usually outweigh the benefits in patients with benzodiazepine toxicity. Therefore, flumazenil is not recommended for the routine reversal of sedative overdose in the ED.[15] Theoretic benefits of flumazenil use include cost savings and avoidance of procedures and tests (such as endotracheal intubation and CT scans). However, several clinical studies have failed to demonstrate these benefits in practice.[15] Benzodiazepine toxicity has a low mortality rate with supportive care, shifting the risk benefit analysis away from the use of flumazenil in routine cases.

There are also risks associated with flumazenil; it can precipitate acute withdrawal in patients who are chronically dependent on benzodiazepines, leading to significant complications including status epilepticus. Similarly, this antidote is hazardous when it is given to patients who have coingested seizure-inducing drugs (such as cocaine or a tricyclic antidepressant) because of loss of the benzodiazepine's protective anticonvulsant properties and the subsequent ineffectiveness of benzodiazepines to abort a seizure if one occurs. Seizures after the administration of flumazenil should be treated with the administration of barbiturates or propofol. Cardiac dysrhythmias (principally paroxysmal supraventricular tachycardia [PSVT]) can occur after flumazenil administration. Coingestants that cause dysrhythmias, such as carbamazepine or chloral hydrate, may increase the likelihood of cardiac effects. Fatalities after flumazenil administration have been reported.[15] Other risk factors are summarized in Box 154.1.

BOX 154.1 Use of Flumazenil

Indications

Isolated benzodiazepine overdose in non-habituated user (e.g., accidental pediatric exposure)

Reversal of conscious sedation

Absolute Contraindications

Suspected coingestant that lowers seizure threshold (e.g., tricyclic antidepressants, cocaine, lithium, methylxanthines, isoniazid, propoxyphene, monoamine oxidase inhibitors, bupropion, diphenhydramine, carbamazepine, cyclosporine, chloral hydrate)

Patient taking benzodiazepine for control of a potentially life-threatening condition (e.g., seizures)

Concurrent sedative-hypnotic withdrawal

Seizure activity or myoclonus

Hypersensitivity to flumazenil or benzodiazepines

Patient with neuromuscular blockade

Relative Contraindications

Chronic benzodiazepine use, not taken for control of life-threatening condition

Known seizure disorder not treated with benzodiazepines

Head injury

Chronic alcoholism

When benzodiazepine-naive patients ingest benzodiazepines alone in overdose (as occurs in young children), the risks associated with flumazenil are lower.[15] In cases of benzodiazepine overdose by a non-benzodiazepine habituated patient, flumazenil use combined with close monitoring and repeated or infusion-based dosing, may obviate the need for intubation and mechanical ventilation. We recommend basing this decision on a balance of risks/benefits for the particular patient and the reliability that the patient is a novice benzodiazepine user. This approach extends to the setting of unintended over-sedation by benzodiazepines for procedural sedation. In these cases, as patients are often nonbenzodiazepine-dependent, flumazenil would likely have a lower risk of complications.

The initial adult dose of flumazenil is 0.2 mg given intravenously over 30 seconds. A second dose of 0.2 mg may be given, followed by 0.2 mg dose at 1-minute intervals to a total of 1 mg. In children, the initial dose is 0.01 mg/kg (up to 0.2 mg). Because the duration of action of flumazenil is short (45 to 75 minutes), re-sedation occurs in up to 65% of patients and requires either re-dosing or continuous infusion (0.25 to 1.0 mg/h). It is important to note that flumazenil reverses the CNS depressant effects of benzodiazepines more than it reverses the respiratory depression.

In summary, benzodiazepine overdose requires primarily supportive care, assisted ventilation, and if severe, intubation. Flumazenil may precipitate seizures or acute withdrawal and should be used only in highly selected cases (such as to reverse procedural sedation, or to treat young children with a clear history of inadvertent benzodiazepine ingestion). When flumazenil is used, close monitoring of

oxy-hemoglobin saturation and overall ventilatory status (ideally including end-tidal CO_2) is necessary because of the risk for recurrent respiratory depression or resedation.[15]

Disposition

Patients remaining asymptomatic after 4 to 6 hours of ED observation following benzodiazepine ingestion may be medically cleared. For cases of deliberate overdose, appropriate psychiatric consultation should be obtained. Patients presenting with respiratory depression and coma should be given oxygen, ventilatory support, and admission to a monitored setting, such as an ED Observation Unit, or monitored inpatient unit.

Benzodiazepine Withdrawal Syndrome

Abrupt discontinuation of a benzodiazepine in a chronic user results in a characteristic constellation of symptoms similar to ethanol withdrawal (Box 154.2). Risk for withdrawal is a function of both the dose of benzodiazepine and the duration of its use. Continuous treatment for more than 3 to 4 months is generally required before a patient is at risk for withdrawal. With abrupt discontinuation of a benzodiazepine, the most severe withdrawal symptoms occur within several days to a week. Treatment of withdrawal consists of restarting benzodiazepines in the acute setting and, if refractory, phenobarbital or propofol administration to treat withdrawal symptoms. Patients who have experienced withdrawal symptoms after cessation of benzodiazepine use may require benzodiazepine tapers to avoid symptomatic withdrawal.

BARBITURATES

Clinical Features

Barbiturates, once commonly prescribed as sedative-hypnotic agents, are generally used now only for management of some seizure disorders and withdrawal states. Mortality from barbiturate poisoning declined from approximately 1500 deaths per year in the 1950s to fewer than five fatalities in 2017.[16]

Barbiturates are addictive, producing physical dependence and a potentially life-threatening withdrawal syndrome similar to that of benzodiazepines. Whereas tolerance to the mood-altering effects of barbiturates develops rapidly with repeated use, tolerance to the lethal effects including respiratory depression develops more slowly, and the risk of severe toxicity increases with the dose escalation that often accompanies continued use.

Barbiturates depress the activity of excitable cells, especially those in the central nervous system (CNS), by enhancing the activity of GABA. In acute overdose, barbiturates decrease neural transmission in autonomic ganglia, the myocardium, and the GI tract, also inhibiting the response to acetylcholine at the neuromuscular junction.

Barbiturates produce dose-related depressive effects ranging from mild sedation to coma and respiratory arrest. Mild barbiturate toxicity manifests with drowsiness, slurred speech, ataxia, unsteady gait, nystagmus, emotional lability, and impaired cognition. In severe acute intoxication, CNS depression progresses from stupor to deep coma and respiratory arrest. The life threat in severe barbiturate toxicity is respiratory depression, from direct barbiturate action on the respiratory centers in the medulla. Because respirations can be rapid but shallow, the degree of hypoventilation may not be apparent on clinical examination, and pulse oximetry or capnography may be needed to detect the ventilation compromise. Barbiturate-induced respiratory depression can be significantly potentiated by the addition of other respiratory depressants, particularly opioids. High barbiturate levels depress GI motility, delaying drug absorption. As the drug is metabolized and blood levels drop, peristalsis and drug absorption may increase, causing drug levels to rise again.

Therapeutic doses cause anxiolysis and euphoria, and mild decreases in pulse rate and blood pressure, similar to sleep. With toxic doses, more significant hypotension occurs from direct depression of the myocardium along with pooling of blood in a dilated venous system. Peripheral vascular resistance is usually normal or increased, but barbiturates interfere with autonomic reflexes, which then do not adequately compensate for the myocardial depression and decreased venous return. Barbiturates can precipitate severe hypotension in patients whose compensatory reflexes are already maximally stimulated, such as those with heart failure or hypovolemic shock. Barbiturates also decrease cerebral blood flow and intracerebral pressure. Although hypnotic doses of barbiturates do not affect gastric emptying, higher doses can decrease GI smooth muscle tone and peristaltic contractions, delaying gastric emptying.

Hypotension is common in patients with severe intoxication, along with a normal or increased heart rate. Barbiturate overdose is also associated with noncardiogenic pulmonary edema or acute lung injury. Altered pulmonary capillary permeability can be caused by hypoperfusion, hypoxia, or a direct effect of the drug.

Barbiturates are classified according to their onset and duration of action (Box 154.3). Only long-acting preparations have anticonvulsant effects in doses that do not cause sedation. Short- and intermediate-acting preparations are almost completely metabolized to inactive metabolites in the liver, whereas 25% of a phenobarbital (long-acting) dose is excreted unchanged through the kidney.

Barbiturates cross the placenta with fetal levels approaching those of the mother. They are also excreted in low concentration in breast milk. Use during pregnancy is associated with birth defects (category D).

Barbiturate withdrawal syndrome includes tremors, hallucinations, seizures, and delirium, which is similar to the delirium tremens of ethanol withdrawal or benzodiazepine withdrawal discussed previously. However, severe withdrawal occurs only after dependence on short- or intermediate-acting barbiturates (e.g., pentobarbital, secobarbital, amobarbital, or butalbital). Because these drugs are less commonly used, this syndrome is now rare.

Differential Diagnoses

Mild barbiturate toxicity mimics ethanol intoxication and that of other sedative-hypnotic agents such as benzodiazepines. Barbiturate intoxication causes relatively more respiratory depression and hypotension than ethanol compared to benzodiazepine toxicities. Chloral hydrate overdose is marked by greater cardiotoxicity (discussed later in this chapter). Gamma-hydroxybutyrate (GHB) produces coma just like barbiturates, but resolution of the coma occurs much more rapidly. Opioids cause similar sedation with a greater degree of respiratory depression, which reverses rapidly with the administration of naloxone. Other common antiepileptic agents (such as, carbamazepine, phenytoin, and valproic acid) will cause sedation similar to barbiturates with acute overdose. As with any patient exhibiting depressed mental status, metabolic causes (such as, hypoglycemia or hyponatremia) and intracranial events (such as, cerebral ischemia or hemorrhage) should be excluded.

BOX 154.2 Benzodiazepine Withdrawal Symptoms

Nonspecific
Anxiety, depression, insomnia, tremor, tachycardia, sweating

Severe (Rare)
Visual hallucinations, delirium, seizures

BOX 154.3 Barbiturates

Ultrashort Acting
Methohexital (Brevital)
Thiopental (Pentothal)

Short and Intermediate Acting
Pentobarbital (Nembutal)
Secobarbital (Seconal)
Amobarbital (Amytal)
Aprobarbital (Alurate)
Butabarbital (Butisol)
Butalbital (Fiorinal)

Long Acting
Phenobarbital (Solfoton, Luminal)
Mephobarbital (Mebaral)

Diagnostic Testing

Generally, laboratory testing is not helpful in the acute management of barbiturate toxicity, except to exclude metabolic or electrolyte disorder. A positive urine screen establishes only qualitative exposure to a barbiturate but does not prove that the drug is present in toxic amounts and should not be relied on to explain decreased mental status. A quantitative serum phenobarbital level can be obtained to document toxicity (therapeutic levels range 10 to 40 mcg/mL) but rarely guide management. Other than phenobarbital, barbiturates have high volumes of distribution, so serum levels do not accurately reflect CNS concentrations or correlate with clinical severity and these levels are not rapidly available.

A chest radiograph can detect noncardiogenic pulmonary edema, acute lung injury or aspiration pneumonia. Computed tomography (CT) of the head may be helpful in comatose patients with evidence of trauma, focal neurologic signs, papilledema, or no otherwise identifiable cause of stupor and coma.

Because the electroencephalogram may be silent as a result of barbiturate overdose, in patients with coma, brain death should not be determined if phenobarbital is present in the serum at therapeutic levels or higher.[17]

MANAGEMENT

Supportive Care and Stabilization

Barbiturates have no specific antidote, and management is supportive care, particularly with respect to the cardiovascular and respiratory systems. Severely intoxicated patients are unable to protect their airway and have a decreased ventilatory drive. Supplemental oxygen may suffice for patients with mild to moderate overdose, but intubation and mechanical ventilation is often required. Fluid replacement should be limited to maintain a systolic blood pressure above 90 mm Hg and adequate urine output as patients may be at risk of pulmonary edema.

Gastrointestinal Decontamination

Gastric emptying by lavage is not indicated. High barbiturate levels depress GI motility, delaying drug absorption. As the drug is metabolized and blood levels drop, peristalsis and drug absorption may increase, causing drug levels to again rise. Although multidose activated charcoal increases clearance of phenobarbital via hepato-enteric circulation and may shorten the duration of clinical toxicity, there is no convincing evidence it results in improved outcome over supportive care alone and we do not recommend its routine use.

Enhanced Elimination

Because phenobarbital is a weak acid (pKa 7.2), alkalinization of the urine will increase the amount of drug present in ionized form, minimizing tubular reabsorption and increasing drug clearance. Short- and intermediate-acting barbiturates are not significantly affected by pH changes in this range. Alkalinization may interfere with the ability of the drug to diffuse across intestinal mucosa from the gut into the blood. There is limited evidence, regarding the clinical benefits of alkalinization in the setting of barbiturate toxicity,[18] and we do not recommend its routine use.

Despite a lack of compelling data demonstrating, its benefit in acute phenobarbital overdose, hemodialysis is a legitimate option for severe phenobarbital toxicity.[19,20] Phenobarbital is 40% to 60% protein bound, and newer, high-efficiency dialyzers using high blood flow rates provide drug clearance greater than that achieved by hemoperfusion. Cases with pharmacokinetic data have documented significant elimination of barbiturates with hemodialysis. Although rarely indicated, we recommend hemodialysis for acute phenobarbital toxicity (persistent serum levels over 100 mcg/mL) in the presence of prolonged coma, refractory hypotension, renal or cardiac failure, metabolic acidosis, or inadequate response to less invasive measures (such as supportive care and mechanical ventilation).[19] Although potentially efficacious with severe toxicity, we are not aware of studies assessing the role of extracorporeal membrane oxygenation (ECMO) in cases of refractory barbiturate poisoning, and until further studied, would not recommend its use over hemodialysis.

Disposition

Asymptomatic patients presenting after barbiturate ingestion should be observed for 6 hours for mental status changes, slurred speech, ataxia, hypotension, and respiratory depression. Symptoms generally occur within 1 hour of ingestion. Patients who remain asymptomatic and have no significant complicating coingestants can be discharged or referred for psychiatric evaluation. Patients who are symptomatic after 6 hours should be admitted to a monitored setting in hospital or an ED observation unit for respiratory monitoring and supportive care. Those with persistent hypotension, severe depression of mental status, or respiratory depression requiring intubation and ventilator support will need intensive care monitoring. Psychiatry or social services consultation is undertaken when the patient with intentional ingestion is medically cleared.

INDIVIDUAL MEDICATIONS

Zolpidem, Zaleplon, and Zopiclone

Zolpidem (Ambien), zaleplon (Sonata), and zopiclone (Imovane) differ in structure from the benzodiazepines and act selectively at the benzodiazepine receptor, producing sedation without many of the side effects seen with benzodiazepines. They have modest anxiolytic, muscle relaxant, and anticonvulsant properties. Significant drug interactions are rare.[21] Transient visual disturbances, transient global amnesia, hallucinations, and somnambulism can occur in patients with normal levels of consciousness with both zolpidem and zaleplon. Over ingestion of zolpidem is limited by vomiting, which may occur after a supratherapeutic dose. Both zolpidem and zaleplon are rapidly eliminated and lack active metabolites. A controlled-release formulation of zolpidem (Ambien CR) is also available. The dual-layered tablet releases an immediate dose of zolpidem, followed by a slow, extended release from the inner layer to maintain plasma zolpidem concentrations. Overdoses with the controlled-release formulation mirror those of the immediate-release preparation, with only small differences in the likelihood of drowsiness, hallucinations, and ataxia. Of the three "Z-drugs," zopiclone has the longest duration of action, and may have longer duration of symptoms in toxic ingestions.

Zolpidem overdose is managed by supportive care. Fatalities from isolated zolpidem overdose are rare[21] and are associated with coingestants, particularly other sedative-hypnotics or antipsychotics. Drowsiness is the most common symptom; coma and respiratory failure are rare, despite overdoses of up to 40 times the normal dose. Intubation may be required for airway protection or ventilatory support, particularly if there are coingestants that exacerbate respiratory depression. Zolpidem overdose in children which generally follows a similarly benign course. Drowsiness, ataxia, and hallucinations generally resolve within eight hours. Patients who remain asymptomatic after six hours can be discharged.

Adverse effects with therapeutic zaleplon use include headache, anterograde amnesia, and transient visual hallucinations. Overdose information is limited, but patients generally experience CNS depression and mild hypotension. Flumazenil administration is not advised.[21] The blue-green discoloration of gastric contents, oral cavity, and urine after zaleplon overdose is attributed to the indigo carmine dye present in zaleplon's capsule shell.

Minimal data are available on the toxicity of zopiclone, which is not currently available as a commercial product in the United States. There have been multiple reported deaths with zopiclone ingestion;[23] however most of these have associated coingestants. Zopiclone has a notably high prevalence of toxicity in areas where its prescription is uncontrolled. General principles should follow the sedative-hypnotics discussed previously, including supportive care with respiratory intervention when indicated.

Eszopiclone

Eszopiclone (Lunesta) has been marketed in the United States for treatment of insomnia. It is the S-isomer of racemic zopiclone, which has been used for decades outside the United States. Eszopiclone has a structure unrelated to that of benzodiazepines or barbiturates.

The mechanism of eszopiclone's action involves a specific GABA-A receptor close to or coupled with the benzodiazepine receptor. Eszopiclone is rapidly absorbed, with a peak serum level at 1 hour and a half-life of 6 hours. It is metabolized in the liver to minimally active metabolites. The maximum hypnotic dose is 3 mg. It is recommended that elderly patients and those with hepatic insufficiency be treated with a lower (1 mg) dose.

Adverse effects with therapeutic use of eszopiclone include drowsiness, dizziness, dry mouth, unpleasant taste, nausea, and vomiting. Auditory and visual hallucinations have been reported. Experience with eszopiclone overdose is limited. Treatment is supportive. CNS depression may be prolonged and pronounced in elderly patients. Most reported eszopiclone ingestions had mild to moderate symptoms.

Buspirone

Buspirone (BuSpar) is often prescribed for generalized anxiety disorder because of its lack of sedative effect. Even when combined with ethanol, CNS depression is minimal. Buspirone acts on the serotonin (5HT-1A) receptor and antagonizes dopamine (D2) receptors, unlike the mechanism of action of benzodiazepines discussed above. There are rare case reports of toxicity in overdose, including a death reported in single-drug buspirone overdose.[16] A withdrawal state after discontinuation has not been reported. Due to the low toxicity in most situations, supportive care is sufficient for buspirone overdose.

Flunitrazepam

Flunitrazepam (Rohypnol) has been used in Europe, Asia, and Latin America for insomnia and preoperative sedation. Although it has never been manufactured or sold commercially in the United States, flunitrazepam has been documented in many sexual assaults or "date rape" incidents. Flunitrazepam has been an active agent in the illicit drug market, where it is used to alter the effects of other drugs, including ethanol, heroin, and cocaine.

Flunitrazepam has 10 times more affinity than diazepam for benzodiazepine receptors. CNS depression occurs within 30 minutes. The drug is most frequently ingested with alcohol, producing additional disinhibition and amnesia. Despite marked CNS depression, patients can usually be aroused with noxious stimuli. The half-life of the drug is 16 to 36 hours, but coma can be prolonged for up to 48 hours. Management should include monitoring for hypoxia, hypoventilation, and aspiration; airway protection and ventilatory support can be provided when indicated. Flunitrazepam is easily obtained outside the United States and on the Internet. The drug is not detected on routine urine drug screens, but if needed as evidence, a urine sample should be obtained and the local or state police crime laboratory contacted to arrange specific testing. Metabolites of flunitrazepam can be detected in the urine up to 72 hours after exposure.

Chloral Hydrate

Clinical Features

Chloral hydrate has a low therapeutic ratio and can produce significant, potentially fatal toxicity. It is used in rare cases, but chloral hydrate is occasionally prescribed as a sedative in the elderly and for children undergoing hospital and outpatient procedures.[24,25] The use has decreased significantly with the availability of other procedural sedation medications with wider therapeutic indices. The oral hypnotic in adult is of dose 0.5 to 1.0 g. The pediatric sedation dose is 25 to 50 mg/kg orally 30 minutes prior to the procedure, with a maximum dose of 1000 mg.

The toxic oral dose is approximately 10 g in adults and may be as little as 1.5 g in children. The toxic effects of chloral hydrate include CNS and respiratory depression, GI irritation, cardiovascular instability, hepatitis, and proteinuria.[24] The combination of deep coma and cardiac dysrhythmia without hypoxia is characteristic of severe cases. Chloral hydrate decreases myocardial contractility, shortens the cardiac refractory period, and increases the sensitivity of myocardium to catecholamines. Dysrhythmias can be fatal, and include atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, multifocal premature ventricular contractions, torsades de pointes, ventricular fibrillation, and asystole.

A citrus or pear-like odor to the patient's breath or gastric contents may suggest the diagnosis. Findings consistent with chloral hydrate toxicity include miosis, muscle flaccidity, diminished deep tendon reflexes, hypoventilation, hypotension, and hypothermia. Chloral hydrate is a GI irritant and causes nausea, vomiting, esophagitis, hemorrhagic gastritis, and, rarely, GI perforation or necrosis. Transient hepatic or renal dysfunction can also occur.

Chloral hydrate is rapidly absorbed from the GI tract. The primary active metabolite of chloral hydrate, trichloroethanol, has a barbiturate-like effect on GABA-A receptors and is responsible for most of the CNS depression seen with significant overdose. Metabolism to trichloroethanol occurs via the enzyme alcohol dehydrogenase with an onset of action of 20 to 30 minutes. Trichloroethanol is long acting, and its half-life can be significantly prolonged after overdose as the metabolic pathways become saturated.

Chloral hydrate and ethanol in combination (historically referred to as a "Mickey Finn") potentiate each other's effects to produce rapid loss of consciousness. Chloral hydrate increases the half-life of ethanol by competitively inhibiting the enzyme alcohol dehydrogenase, and the metabolism of ethanol generates nicotinamide adenine dinucleotide (NADH), a cofactor for the conversion of chloral hydrate to trichloroethanol.

Differential Diagnoses

Mild chloral hydrate toxicity can mimic many other sedative-hypnotics, including ethanol, benzodiazepines or barbiturates, with drowsiness, ataxia, and lethargy. More severe toxicity can mimic other cardiotoxic agents, including tricyclic antidepressants and cocaine. Hypomagnesemia can also induce torsades de pointes, as can QTc prolonging agents such as antipsychotics or methadone.

Management

The key to management is support of cardiorespiratory functions. Intubation may be required for airway protection, or to support ventilation, and oxygenation if there is significant depression of respiratory function. Avoid naloxone or flumazenil, which may precipitate ventricular dysrhythmias and will not have reversal effects. Because chloral hydrate, like other chlorinated hydrocarbons, sensitizes myocardium to catecholamines, epinephrine and norepinephrine should also be avoided. Standard type I antidysrhythmic agents, such as quinidine (1a) and lidocaine (1b), do not appear effective against chloral hydrate–induced cardiac ectopy. The treatment of choice for chloral hydrate-induced tachydysrhythmias is a beta-blocker. A short-acting agent, such as esmolol, can be used with an initial bolus of 1 mg/kg IV over 30 seconds followed by an infusion starting at 50 mcg/kg/min (maximum of 300 mcg/kg/min) as an intravenous infusion until resolution of the tachydysrhythmia. Torsades de pointes should be treated with intravenous magnesium or overdrive pacing, as described in Chapter 65. Patients with refractory hypotension or persistent unstable dysrhythmia despite supportive therapy can be treated with hemodialysis.

Disposition

Patients with acute chloral hydrate overdose should be observed in the ED until clinically stable, alert, oriented, and ambulatory. In cases of prolonged altered mental status, respiratory depression, hypoxia, or evidence of cardiotoxicity (e.g., PSVT, QRS widening, QTc prolongation, torsades de pointes), the patient should be admitted to a monitored setting. If the intent of the overdose was self-harm, psychiatric consultation is indicated once the patient is medically stabilized.

OVER-THE-COUNTER SLEEP AIDS

Over-the-counter (OTC) sleep aids, currently available in the United States, contain either diphenhydramine or doxylamine. Many preparations also contain acetaminophen or aspirin, added to achieve nighttime pain relief. The availability and frequent use of these agents may explain why overdose is so common. Diphenhydramine and doxylamine are first generation H-1 antihistamines that also have hypnotic, antimuscarinic, and weak local anesthetic properties. They act as competitive antagonists of H-1 histamine receptors and cause sedation by inhibiting the actions of acetylcholine on muscarinic receptors in the CNS. They also have sodium channel blocking effects which can cause QRS prolongation. Patients generally experience anticholinergic toxidromes, including tachycardia, dilated pupils, red and dry skin, and delirium. Further discussion of antimuscarinic toxicity is found in Chapter 140.

GAMMA-HYDROXYBUTYRATE

Clinical Features

Originally synthesized in the 1960s as an anesthetic, GHB was later discovered to be a naturally occurring metabolite of GABA. GHB had been used clinically to treat narcolepsy, alcohol addiction, opioid withdrawal, and depression.[26] GHB quickly distributes across the blood-brain barrier where it exerts its main toxic effects.[27]

The FDA approved GHB for the treatment of narcolepsy under the trade name Xyrem (sodium oxybate, 0.5 mg/mL) as a schedule III drug. The sale and manufacture of GHB is otherwise banned in the United States yet illicit use of GHB has increased, along with its precursors gamma-butyrolactone (GBL) and 1,4-butanediol (1,4-BD). There is a wide variety of "street names" that have been associated with GHB (Box 154.4).

GHB remains a popular drug of abuse. Some individuals take GHB for its purported muscle-building and fat-burning actions, others for its psychoactive effects. The drug's euphoria-producing properties make it popular at "raves" (large, crowded parties with energetic dancing to rhythmic music). Self-treatment of insomnia with GHB has been reported and can cause dependence. CNS depression, amnesia, and disinhibition caused by mixing of GHB with ethanol make this combination a potential agent in "date rape" situations. After overdose, a call for medical assistance is often delayed because of the false belief that victims need only to "sleep off" their intoxications. Death occurs most often in the prehospital setting, both from direct effects of the drug and increased the risk for fatal traumatic accidents. Combined intoxication with ethanol occurs in most fatal cases.

GHB binds to specific GHB receptors and at high concentrations to GABA-B receptors. The complex interaction between these two receptors may explain the paradoxical manifestations of GHB toxicity with somnolence alternating with agitation.

GHB is lipophilic and rapidly absorbed. Onset of symptoms occurs within 15 to 30 minutes, and peak plasma levels are reached within 20 to 60 minutes. Unlike GABA, GHB readily crosses the blood-brain barrier. The half-life of GHB is 30 minutes but may increase at high doses.

As underground clandestine laboratories often synthesize liquid GHB by mixing and heating butyrolactone and sodium hydroxide, careless preparation can result in residual unreacted alkali, causing significant caustic injury when the liquid is ingested.

Chemical precursors to GHB are also commonly abused with similar toxic effects. GBL is an industrial solvent that is rapidly absorbed after ingestion and it is metabolized within minutes to GHB by peripheral and hepatic lactonases. Before conversion to GHB, GBL itself is inactive and has no sedating effects. It produces a clinical syndrome similar to that of GHB ingestion, but its effects are more pronounced and prolonged.

1,4-BD is converted after ingestion to GHB by the enzyme alcohol dehydrogenase. Like GBL, it is used as an industrial solvent. Clinical findings are similar to those of GHB. When 1,4-BD and ethanol are ingested together, ethanol acts as a competitive inhibitor of alcohol dehydrogenase, so the toxic effects of 1,4-BD are delayed and prolonged, and the risk of death is increased.

BOX 154.4 Gamma-Hydroxybutyrate Street Names

Grievous bodily harm (GHB)	Liquid G
Georgia home boy (GBH)	Somatomax
Gib	Soap
Natural sleep-500	Salty water
Gamma-OH	Scoop
Gamma hydrate	Sodium oxybate
Liquid X	Easy lay
Organic Quaalude	Cherry menth
Liquid E	Fantasy
Liquid ecstasy	G-Riffick

Differential Diagnoses

The differential diagnoses of GHB intoxication is broad including other sedative-hypnotics (such as barbiturates or benzodiazepines), OTC sleep aids, antimuscarinic agents, opioids, ethanol, ketamine, chloral hydrate, and designer amphetamines.

Poisoning with other sedative-hypnotics can produce a similar clinical picture. Unique to GHB, however, is the relatively rapid resolution of symptoms. In the absence of a coingestant such as ethanol, most patients will be functionally awake within 3 to 4 hours. Nearly all patients recover fully within 8 hours. Prolonged coma should prompt a search for another toxicological or non-toxicological cause. Cardiac effects and refractory seizures are rare and suggest the presence of other agents or etiologies.

Diagnosis of GHB intoxication is based on the history and clinical course, as clinical laboratory testing is not readily available. Rapid recovery from coma or periods of agitation alternating with periods of decreased level of consciousness is its characteristic. Hypothermia may occur with prolonged coma. In the presence of coma, bradycardia with or without hypotension can occur and may respond to auditory or tactile stimulation alone. Miosis with or without nystagmus may be seen. Because emesis occurs in about 50% of cases, obtunded patients are at risk for aspiration pneumonitis. Apparent seizure activity may actually represent random myoclonic movements of the face and extremities. Severity is dependent on the dose and the concurrent use of alcohol or other psychoactive drugs.

Diagnostic Testing

GHB is not detected on routine urine toxicology screens. If laboratory confirmation is required, specimens must be collected early in the clinical course, and sent for gas chromatography–mass spectroscopy. The drug may be detected in urine up to 12 hours after ingestion. In most cases, the toxicology laboratory test is not available for patient management. Pulse oximetry and end-tidal capnometry can be used to monitor respiratory status, and adjunct testing can be used to rule out alternative diagnoses.

Management

The management strategy for GHB toxicity follows the same principles as the other sedative-hypnotics discussed previously. Supportive care including respiratory and ventilatory support is critical. Because of rapid absorption and the high incidence of emesis with GHB overdose, there is no indication for gastric decontamination. Intubation for airway protection may be required by patients with significant CNS depression or hypoxia. There is a high prevalence of coingestants with recreational use of GHB. Physostigmine should not be used for GHB intoxication, based on reported adverse events, particularly in the setting of polydrug use.

Disposition

Because of GHB's short half-life, symptoms of intoxication generally resolve while the patient is still in the ED. The patient generally regains consciousness spontaneously within 3 to 4 hours. No delayed toxicity is expected unless there are coingestants. Patients should be counseled about the seriousness of GHB intoxication, withdrawal potential with chronic use, and discharged home with reliable caretakers.

Additional monitoring and observation for up to 12 to 24 hours should be provided in the setting of ingestions of either GBL or 1,4-BD as toxicity can be prolonged and more severe, as well as less predictable.

Withdrawal

Patients who abruptly stop GHB or its precursors after chronic frequent use can experience a severe and potentially life-threatening withdrawal syndrome. Because of the short half-life of GHB, symptoms of withdrawal begin within several hours of the last dose. The typical patient will have been using these products for weeks or months, in frequent repetitive doses, to avoid withdrawal symptoms.[28]

Withdrawal symptoms are similar to withdrawal from other sedative-hypnotics, including benzodiazepines. Mild withdrawal is manifested with anxiety, tremor, and insomnia. This can progress to confusion, delirium, overt psychosis, paranoid ideation, hallucinations (visual, aural, or tactile), and autonomic instability. Diagnosis relies on a history of symptoms beginning after abrupt cessation of use of these products. The differential diagnosis includes withdrawal from other sedative-hypnotic agents, delirium tremens, sympathomimetic toxicity, serotonin syndrome, neuroleptic malignant syndrome, CNS infection, and thyroid storm.

Initial treatment begins with high-dose benzodiazepines with doses escalated as required for agitation. However, GHB withdrawal may involve depleted levels of GABA. Because the effect of benzodiazepines requires the presence of GABA, they may be less effective in control of GHB withdrawal. Barbiturates, such as pentobarbital or phenobarbital, which do not need GABA to be effective, are often required in cases of severe withdrawal. These patients often require admission to an intensive care unit for titrated sedation, as well as to observe for development of seizures, rhabdomyolysis or hyperthermia.

CHAPTER 154: QUESTIONS AND ANSWERS

1. All of the following patients have depressed mental status, decreased respiratory drive, and mild hypotension. Supportive care has been initiated. All of the patients have a confirmed benzodiazepine overdose by a reliable historian. For which patient is it most reasonable to consider the use of flumazenil?

- **a.** A 5-year-old boy with no known medical problems who took his mother's medication
- **b.** A 22-year-old woman with no known medical problems
- **c.** A 30-year-old man who is known to abuse cocaine
- **d.** A 43-year-old man with depression and anxiety
- **e.** A 79-year-old woman with congestive heart failure, coronary artery disease, and diabetes who takes benzodiazepines for insomnia

Answer: a. Flumazenil variably reverses the effects of benzodiazepines but can cause dysrhythmias and intractable seizures. Contraindications for flumazenil include history or suspected chronic benzodiazepine use (which are the vast majority of benzodiazepine overdose patients), coingestants that lower the seizure threshold, tricyclic antidepressants, cocaine, history of seizure disorder, chronic alcoholism, and head trauma. Its use should be for a known non-habituated patient (e.g., the pediatric patient described here). Because flumazenil's duration of action is short compared with the benzodiazepine and it has variability to reverse respiratory depression, patients require close, monitored observation, repeated dosing or continuous infusion, and preparations to manage the airway. Because benzodiazepine overdose is rarely lethal and patients recover with supportive care, using an antidote requires a careful benefit/risk analysis.

CHAPTER 154: QUESTIONS AND ANSWERS—cont'd.

2. How do barbiturates affect peripheral and cerebral blood flow?
   - **a.** Decrease peripheral pressure and have no effect on intracranial pressure
   - **b.** Decrease peripheral pressure and increase intracranial pressure
   - **c.** Decrease peripheral and intracranial pressure
   - **d.** Increase peripheral and intracranial pressure
   - **e.** Increase peripheral pressure and decrease intracranial pressure

Answer: c. Barbiturates cause direct cardiac depression with decreased cardiac output. In addition, they cause venous pooling and blunt the normal compensatory increase in system vascular resistance that would occur with decreased cardiac output. They also decrease cerebral blood flow and lower intracranial pressure. These effects are particularly pronounced in individuals with an already low cardiac output, such as in congestive heart failure or hypovolemic shock.

3. Other than general supportive care, which of the following is most useful in the management of a severe phenobarbital overdose with hemodynamic instability?
   - **a.** Flumazenil
   - **b.** Hemodialysis
   - **c.** Multidose activated charcoal
   - **d.** Urinary alkalinization
   - **e.** Whole bowel irrigation

Answer: b. Although rarely indicated, hemodialysis is effective for acute phenobarbital toxicity (persistent serum levels over 100 mcg/mL) in the presence of prolonged coma, refractory hypotension, renal or cardiac failure, metabolic acidosis, or inadequate response to conventional measures and ventilatory support. These patients often require mechanical ventilation, so the patient's airway should be secured prior. Although there is evidence that multi-dose activated charcoal (MDAC) increases clearance of phenobarbital and may shorten duration of clinical toxicity, there is no evidence it results in improved outcomes over supportive care alone. Flumazenil will reverse the effect of benzodiazepines but has no effect on barbiturates. Urinary alkalinization has traditionally been used to "trap" the acidic barbiturates in the urine to increase excretion, However, a recent comprehensive review concluded that there is little clinical role for urine alkalinization in acute barbiturate poisoning. Whole bowel irrigation is not beneficial.

4. Which of the following sedative-hypnotics is most likely to cause fatal cardiac dysrhythmias in overdose?
   - **a.** Buspirone
   - **b.** Chloral hydrate
   - **c.** Eszopiclone
   - **d.** Flunitrazepam
   - **e.** Zolpidem

Answer: b. Chloral hydrate sensitizes the myocardium to catecholamines and also independently induces dysrhythmias. Treatment of choice of dysrhythmias from chloral hydrate is beta-blockers. None of the other listed medications cause significant cardiac toxicity.

5. A 53-year-old woman presents with decreased mental status and mild hypotension. She is arousable to pain. Her husband reports that approximately 4 hours ago she had been complaining of insomnia and said she was going to take something to help her sleep. He then found her in her present state with an empty bottle of "sleeping pills" on the counter. He does not remember the name of the sleeping pills. Supportive care is initiated. Which of the following laboratory tests would be the most helpful to manage this patient?
   - **a.** Acetaminophen level
   - **b.** Arterial blood gas
   - **c.** Serum chemistry
   - **d.** Serum myoglobin
   - **e.** Urine drug screen

Answer: a. Many over-the-counter (OTC) sleep aids contain acetaminophen or salicylates. The active ingredient in OTC sleep aids is an antihistamine, typically diphenhydramine or doxylamine. Both have anticholinergic effects in addition to causing sedation. Toxicity is typically mild and can be successfully managed with supportive care. It is rare that an antihistamine overdose results in rhabdomyolysis, and a serum creatine phosphokinase level, urinalysis, and urinary myoglobin level can be checked if there is concern. Myoglobin is cleared rapidly from the serum and is not a useful diagnostic test. Arterial blood gases, serum chemistries, and urine drug screens can be ordered if there is a complicated clinical course—but only rarely alter treatment.

6. A 21-year-old woman is brought to the emergency department (ED) by her friends after they found her unconscious in the bathroom of a local bar. The friends report that she had only had one or two alcoholic drinks. The patient's vital signs show bradycardia, hypotension, and bradypnea. Physical examination reveals short periods of apnea with hypoxia. She wakens briefly to noxious stimuli. You suspect that she may be suffering from gamma-hydroxybutyrate (GHB) poisoning. What is the most appropriate next step in management?
   - **a.** Atropine
   - **b.** Electrocardiogram
   - **c.** Endotracheal intubation
   - **d.** Flumazenil
   - **e.** Naloxone

Answer: c. GHB frequently causes emesis and aspiration because patients are unable to protect their airways. Patients with significant GHB overdose should be intubated, but supportive care alone is all that is required for most GHB overdoses. The half-life is short, and many patients will return to baseline mental status in several hours. Bradycardia is common, usually mild, and does not typically require atropine, but this can be used if bradycardia is severe. GHB does not generally cause dysrhythmias. Neither flumazenil nor naloxone has any effect on GHB.

7. A 30-year-old man presents with anxiety and insomnia. He is agitated and has a tremor on physical examination. His vital signs are as follows: blood pressure, 200/124 mm Hg; heart rate, 123 beats/min; respiratory rate, 22 breaths/min; and temperature, 37.5°C. On further questioning, he reports that he chronically uses gamma-hydroxybutyrate (GHB) for muscle building but has not been able to take any for approximately 24 hours. Lorazepam is given in two escalating doses without response. Which of the following should be given next?
   - **a.** A barbiturate
   - **b.** Additional lorazepam
   - **c.** Clonidine
   - **d.** GHB
   - **e.** Labetalol

Answer: a. GHB withdrawal is severe, and deaths have been reported. GHB acts as a central nervous system (CNS) depressant, so withdrawal causes CNS excitement and autonomic instability. Chronic GHB abuse can lead to GABA depletion in the CNS. Because benzodiazepines require the presence of GABA, they may not be effective. Barbiturates act independently of GABA and are therefore more effective in GHB withdrawal. Clonidine can be used in opioid withdrawal but is not useful in GHB withdrawal. Labetalol would improve the vital signs but would have no effect on the underlying cause of the autonomic instability.

155

Care of the Pediatric Patient

Stephen John Cico and Derya Caglar

KEY CONCEPTS

- Patterns of illness and injury vary by age, and a number of anatomic and physiologic characteristics affect the presentation and management of pediatric emergencies.
- A basic understanding of normal development will aid the emergency clinician in assessment of the pediatric patient.
- The pediatric assessment triangle (PAT) can be used as a tool for rapid evaluation of the patient's overall status.
- Tachypnea in children should be evaluated relative to age norms and is often a sign of increased metabolic demands. A child with tachypnea despite normothermia should be evaluated for respiratory and nonrespiratory causes (e.g., hypoperfusion, acidemia).
- Maintenance of a neutral thermal environment is necessary for critically ill infants.
- Child abuse should be considered when injuries are inconsistent with history, when details of the history change, or with certain injury patterns.
- A joint guideline of the American College of Emergency Physicians, American Academy of Pediatrics, and Emergency Nurses Association summarizes the role of pediatric emergency care coordinators, development of pediatric policies, and recommended equipment, supplies, and medications for emergency departments (EDs).
- EDs that comply with the national guidelines for pediatric readiness have improved outcomes for care of critically ill children.
- The family's presence should be encouraged for pediatric procedures and resuscitations.
- A variety of pharmacologic and nonpharmacologic techniques are available to decrease procedural pain and anxiety.

FOUNDATIONS

Emergency clinicians assess and manage pediatric patients from newborns to adolescents. Of the 146 million annual US emergency department (ED) visits, 27.4 million (19%) are for children younger than 15 years.[1] Twenty-two percent of children have at least one ED visit per year. Infants have higher per capita ED utilization than other age groups, with 98.7 visits/100 infants.[1] More than 80% of pediatric patients are seen in general EDs, requiring all emergency clinicians to be skilled in the assessment, treatment, and stabilization of pediatric illnesses and injuries.[2]

Children can present diagnostic and management challenges due to their anatomic, physiologic, and developmental differences from adult patients. Understanding these differences is crucial to the recognition and appropriate treatment of many pediatric emergencies. In addition, caring for the pediatric patient also involves active participation from caregivers.

Pathophysiology

Children exhibit different patterns of illness and injury because of their unique physiologic and anatomic characteristics. Illness and injury patterns not only differ between pediatric and adult patients, but also vary in children by age. In addition to changes in cognitive and behavioral development, temperature regulation, airway anatomy, cardiovascular physiology, immune function, and the musculoskeletal system all change as children grow. Furthermore, pediatric patients may present to the ED with previously undiagnosed congenital disorders. Drug dosing and choice of medications also depend on patient size and physiology.

Assessment should begin with a review of vital signs, evaluating for early signs of physiologic decompensation. Normal heart rate and respiratory rate vary by age (Table 155.1). Normal blood pressure also varies by age, height, and gender (Box 155.1; Table 155.2). Abnormal vital signs should be repeated and persistently abnormal vital signs quickly addressed.

Temperature Regulation

Infants and young children have a larger surface area–to–mass ratio, resulting in more heat loss to the environment than in adolescents and adults. Maintenance of a stable body temperature can be a significant metabolic demand for young infants, especially those stressed by injury or illness. Maintain a neutral thermal environment for children during the physical examination and while performing procedures. Patients exposed briefly for examinations and interventions should be covered as soon as possible to avoid excessive heat loss. Critically ill young infants should be placed under radiant warmers. Overhead warming lights are useful for older infants and children who require prolonged exposure for resuscitation and procedures.

Airway

The pediatric airway differs in a number of ways from an adult airway.[3,4] Compared to the adult airway, the pediatric larynx is more

15	110/65	113/64	127/83	131/83

[a]For children at the 50th percentile for height.
Modified from The National High Blood Pressure Education Program Working Group on Children and Adolescents: The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4074640/ and https://www.nhlbi.nih.gov/files/docs/resources/heart/hbp_ped.pdf

anterior and cephalad, and the epiglottis is composed of more flexible cartilage, making it floppy. The relatively larger occiput in infants and young children can cause neck flexion in the supine position, leading to potential airway obstruction. To open the airway, particularly during intubation attempts, a towel roll placed under the shoulders may be needed to align the laryngeal, pharyngeal, and oral airway axes (Fig. 155.1). Infants and young children also have relatively large tongues, which may lead to airway obstruction during periods of changes in muscle tone, such as during a seizure. Use of a nasopharyngeal airway can alleviate the obstruction by allowing a clear passage of inhaled gases. In addition, airways in children are much smaller in diameter and much more easily obstructed with secretions. Because young infants preferentially breathe through their noses, respiratory distress can develop from copious nasal secretions. Thus, suctioning the nose and upper airway can dramatically diminish an infant's work of breathing.

Cardiovascular System

Healthy children have compensatory mechanisms to maintain blood pressure, even when cardiac output is decreasing. Children have the ability to increase their heart rate and vasoconstrict peripherally to shunt blood centrally, while very young children have limited ability to increase their cardiac contractility. Hypotension is a late finding of shock in previously healthy children, and interventions should ideally occur before the onset of hypotension.[5] The earliest sign of cardiovascular compromise in most patients is tachycardia. Unfortunately, tachycardia is nonspecific and may be due to fever, pain, or anxiety. Repeated assessment of the heart rate can be helpful. In a crying child, a true resting heart rate can be obtained by leaving the pulse oximeter on until the child is calm. Unexplained tachycardia in a calm or sleeping child should be investigated for the cause of the tachycardia. The quality of the pulse is also helpful. A thready peripheral pulse associated with tachycardia should be considered a sign of shock. Bradycardia in ill children is especially ominous and may signal impending cardiopulmonary failure.

Musculoskeletal System

Growing children have musculoskeletal injury patterns different from those of adults. Ligaments are stronger relative to the immature bone, so children are more likely to fracture bones than sprain ligaments. The weakest part of a growing child's bone is the physis, or growth plate. If tenderness is present on examination, physeal injuries should be considered in children with normal radiographs. Treatment of fractures in children should consider future growth potential. For example, certain physeal injuries can lead to long-term growth disturbances, whereas greater degrees of angulation are acceptable in many fractures due to the increased potential for bone remodeling.

Immunologic System

Due to their immature immune system, young infants are at increased risk of serious bacterial infections. Febrile infants younger than 1 month are a particularly high-risk group and have a 10% or higher rate of serious bacterial infection.[5] For this reason, the evaluation of infants with fever differs from the evaluation of older children and adults; the evaluation varies by age and vaccination status (see Chapter 161).

Pharmacologic Considerations

Medications for children are calculated using weight-based dosing, with attention to the maximum medication dose. Suggested safeguards to prevent calculation-based dosing errors in children include pharmacy review of medication orders, computerized order entry, use of templated order forms, and length-based resuscitation tapes to reduce calculation errors.[6] One easily remedied potential error is the inadvertent calculation of a drug dose on the basis of weight in pounds, not kilograms, leading to a more than twofold overdose. Therefore, ED scales and electronic charts should be programmed to report weight only in kilograms.[7]

In addition to potential dosing errors, certain frequently used medications in older children and adolescents should not be given to young infants. For example, ceftriaxone is not recommended for infants younger than 28 days because it can displace bilirubin from albumin, leading to kernicterus or bilirubin-induced neurologic dysfunction (BIND). Although not well studied, the use of ibuprofen in infants younger than 6 months has not been approved by the US Food

Fig. 155.1 Infant With Neck in Flexed Position (A) and After Placement of a Shoulder Roll (B). (From Santillanes G, Gausche-Hill M. Pediatric airway management. *Emerg Med Clin North Am.* 2008;26:961–975.)

and Drug Administration because of the theoretical risk of kidney and liver injury.

Developmental Considerations

Assessment of pediatric patients requires an understanding of normal developmental milestones. Table 155.3 lists basic developmental milestones in the first 2 years of life. Variation in the rate at which children develop can be normal or may signal neurodevelopmental delays. Therefore, the parent's report of the child's developmental history and normal behavior is extremely important. Injuries identified should also fit the developmental milestones of a child. Injuries that fall outside of the normal developmental patterns should raise the consideration of non-accidental trauma/child abuse.[8]

Young Infants

Infants younger than 2 months are especially challenging to assess because they have a limited behavioral repertoire. They may not make eye contact nor have a social smile. Normal behavior includes sleeping, crying, quiet alert time, feeding, and stooling. A change in any of these activities may indicate serious disease. Increased sleeping or crying or decreased interest in feeding may herald a serious illness, such as sepsis or an underlying cardiac or metabolic disorder.

Infants (<12 Months)

Infants typically develop a social smile and track close objects by 2 to 3 months of age. After 6 months, infants may develop significant stranger anxiety, making the physical examination challenging. Whenever possible, examining the infant in the parent's lap, with the infant initially facing away from the examiner, can mitigate anxiety and facilitate physical examination. Bubbles or interactive toys can distract infants and may help keep them calm.

Toddlers (1- to 2-Year-Olds)

Toddlers have variable reactions to a physical examination. A toddler may provide a limited history due to their narrow expressive language skills (e.g., only pointing to the location of pain). Some are fearful and will not cooperate, whereas others are curious and cooperate more easily with the examination. In a stable patient, begin the encounter standing or sitting at a distance from the child while taking the history. Speaking in a soothing voice and distracting the child with toys or other interesting objects can facilitate the examination. Emergency clinicians should interact with the parents, because this will be perceived by the child as a sign of endorsement and indicate that the parents are involved with the emergency care. Conversely, toddlers will often negatively react to parental anxiety.

TABLE 155.3 Developmental Milestones in Typically Developing Children Up To 2 Years of Age

Age (Months)	Gross Motor	Visual-Motor, Social, and Language
1	Raises head from prone position	Visually follows to midline, alerts to sound, regards face
2	Lifts chest off table	Smiles socially, recognizes parent, follows object past midline
4	Rolls over	Laughs, orients to voice
6	Sits unsupported	Babbles
9	Pulls to stand, cruises	Says "mama" and "dada" indiscriminately, plays games such as pat-a-cake
12	Walks alone	Two words other than "mama" and "dada"
15	Creeps upstairs, walks backward	Uses 4–6 words
18	Runs	Uses 7–10 words, knows five body parts
24	Walks up and down stairs independently	50-word vocabulary, two-word sentences

Adapted from Engorn B, Flerlage J. *The Harriet Lane Handbook*. 20th ed. Philadelphia: Elsevier Saunders; 2015.

Preschoolers (3- to 5-Year-Olds)

Preschool-age children have increasing language skills. Like toddlers, their receptive language skills exceed their expressive language skills, and they often understand more than is realized. Preschoolers should be included in the conversation when possible. Emergency clinicians should be cautious about talking to the parents about procedures or diagnoses in front of the preschool child, even if the child seems not to be paying attention or not to understand. Like toddlers, preschool children vary greatly in their cooperation with the physical examination. Providing limited options, such as sitting with the parent or on the gurney, or choosing which ear should be examined first, may give the child a sense of control and improve cooperation. Distraction with stories, videos, or games on a smartphone or other devices can also facilitate the physical examination. The young child will build up anxiety awaiting a procedure. For this reason, clinicians should provide

children with simple concrete explanations of procedures only immediately before and during the procedure. Preschool children may perceive illness or painful procedures as punishment for their actions, making simple explanations of what and why it is occurring even more important.

School-Age Children

Some questions during the history should be directed at the school-age child, because many can provide much of the history themselves. At this age, children are often cooperative with the examination, but may regress when they are frightened or in pain. Additionally, children at this age become increasingly modest, and conscious attempts should be made to provide privacy.

School-age children may develop anxiety and attempt to negotiate or stall when a painful or unpleasant examination or procedure is planned, particularly if there is a long delay between the explanation and procedure. Firm but reassuring explanations of what will happen are important. Appropriate concrete explanations include the sequence of events and what physical sensations the patient will experience. It is also crucial to involve parents in the process to provide not only a candid explanation of the procedure itself, but also anticipated reactions from their child. When available, child life specialists are particularly helpful with this age population, using play and education to prepare children for anxiety-provoking procedures.

Adolescents

Adolescents will be able to provide much, if not all, of the history. However, despite desired independence from their parents, adolescents may regress in times of stress. It is therefore important to elicit the concerns of the adolescent and parent, and to ensure that both understand the diagnosis and plan. The adolescent should be given a chance to speak to the emergency clinician without the parent in the room. Any sensitive questions, such as those about drug use, alcohol consumption, tobacco and vaping, and sexual activity should be asked privately. State laws vary on confidentiality and ages of consent, so it is important for emergency clinicians to know those specifics which may be applicable to their patients.

Adolescents can generally be examined in a manner similar to that for adults. They may or may not prefer to have a parent present during the physical examination, and providers should clarify the patient's preference. Adolescents are often extremely modest, and attempts should be made to preserve privacy with the examination in a private room, when possible, with exposure of only the body part being examined.

EVALUATION

Triage

Pediatric-specific triage systems are important to avoid overtriage and undertriage of children. The application of adult-specific vital signs to children will lead to an inappropriate triage level classification or inadvertently trigger inappropriate sepsis alerts. In addition, signs and symptoms of serious illness may be subtle in infants and very young children, requiring those providing the initial triage assessment to be familiar with normal pediatric physiology and development.

Triage systems with pediatric modifications include the Emergency Severity Index, Paediatric Canadian Triage and Acuity Scale, Manchester Triage System, and Australasian Triage Scale. No triage system has been clearly demonstrated to be superior, and data on reliability and validity are limited for all triage systems. The Emergency Severity Index, Manchester Triage System, and Paediatric Canadian Triage and Acuity Scale have been demonstrated to be valid for pediatric patients.

BOX 155.2 Focused Sample History

Signs and symptoms
Allergies
Medications
Past medical problems
Last food or liquid
Events leading to injury or illness

Modified from Dieckmann R, Brownstein D, Gausche-Hill M, eds. *Pediatric Education for Prehospital Professionals*. Sudbury, MA: Jones & Bartlett; 2013.

The Emergency Severity Index has been updated by the Emergency Nurses Association and has pediatric specific resources.[9]

History

In critically ill or injured patients, the SAMPLE history can be used to obtain a focused history quickly (Box 155.2). The SAMPLE history reminds providers to ask for ***S***igns and symptoms, ***A***llergies, ***Me***dications, ***P***ast medical history, ***L***ast meal, and ***E***vents surrounding the illness or injury.

A more detailed history will be guided by the patient's presenting complaint. In preverbal children, symptoms will often be inferred by the caregiver based on the child's behavior. Parents are often very perceptive and may notice subtle changes in behavior that are not immediately evident to a healthcare provider.

Additional age-specific questions may be indicated. In neonates, pregnancy and birth history will help identify risk factors for conditions such as hyperbilirubinemia (e.g., prematurity, ABO incompatibility), infection (e.g., maternal fever during labor, early or prolonged rupture of membranes, maternal group B streptococcus [GBS] status), and respiratory illnesses (e.g., prematurity, meconium aspiration, need for supplemental oxygen or mechanical ventilation). The emergency clinician should also inquire about results of the newborn screen if available. Each state screens for a different panel of disorders determined by their public health board. Most of the conditions included in newborn screening can lead to serious health problems if not recognized and treated shortly after birth. Prompt identification and management of these conditions may be able to prevent life-threatening complications.

In infants and toddlers, urine output, quantified by the number of wet diapers, helps determine hydration status. This can be especially helpful in breast-feeding newborns, whose intake is difficult to quantify. Vaccination status is important in infants and children presenting with symptoms such as fever (e.g., risk of bacteremia) and rash (e.g., risk of varicella, measles). Drug, alcohol, and e-cigarette use, as well as the sexual history, become important in adolescents who have increased risk-taking behaviors and should be questioned in a private setting, not in front of the caregiver.

Pediatric Assessment Triangle

Rapid recognition of the critically ill child is a crucial skill. The pediatric assessment triangle (PAT) assists emergency clinicians in assessing children quickly and is an orderly approach for formulating an initial impression of the child's overall status from the door of the examination room (Fig. 155.2). The three components of the PAT are (1) appearance, (2) work of breathing, and (3) circulation to the skin. On the basis of the initial PAT, the emergency clinician can distinguish the "sick" from the "well" child rapidly. Table 155.4 summarizes the findings that may be noted on each of the three sides of the triangle, and Table 155.5 summarizes interpretation of the PAT.

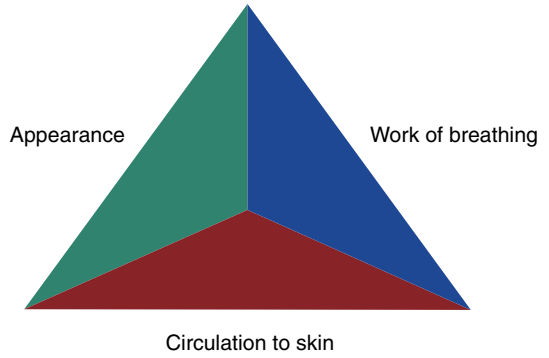

Fig. 155.2 Pediatric Assessment Triangle.

TABLE 155.4 Pediatric Assessment Triangle Abnormal Findings

Appearance	Work of Breathing	Circulation to the Skin
Tone—poor tone, floppy infant	Abnormal sounds—stridor, grunting, snoring, wheezing	Pallor
Interactiveness—irritability, poor responsiveness to surroundings	Abnormal positioning—sniffing, tripoding, refusal to lie down	Delayed capillary refill time (>2 s) Mottling
Consolable—inability to be consoled by parent	Retractions	Cyanosis
Look, gaze—poor attention, lack of normal tracking	Head bobbing	Petechiae
Speech, cry—weak cry, or no cry with environmental stimuli	Nasal flaring	

Adapted from Dieckmann R, Brownstein D, Gausche-Hill M, eds. *Pediatric Education for Prehospital Professionals*. Sudbury, MA: Jones & Bartlett; 2013.

Appearance

Observation of the child from a distance allows the provider to assess the patient's overall status without upsetting the child. The mnemonic TICLS (***t***one, ***i***nteractiveness, ***c***onsolability, ***l***ook and gaze, ***s***peech and cry) summarizes the components of the assessment of overall appearance. Observation of the infant or child interacting with his or her parents provides many clues about the child's overall status. An ill infant with a vacant or glazed look can be distinguished from an alert infant who responds to environmental stimuli. An infant who is awake but lying motionless on a gurney is much more concerning than an active infant who moves all the extremities. Irritability is an early sign of inadequate brain perfusion. This may be followed by lethargy and then coma as perfusion is further compromised.

The quality of the cry is another helpful clue. A persistently high-pitched or irritable cry is concerning for central nervous system disease, such as meningitis. A normal overall appearance suggests that oxygenation, ventilation, and perfusion are adequate.

TABLE 155.5 Interpretation of the Pediatric Assessment Triangle General Impression of Condition

Physiologic State	Appearance	Work of Breathing	Circulation to the Skin
Respiratory distress	Normal	Abnormal	Normal
Respiratory failure	Abnormal	Abnormal	Normal-abnormal
Compensated shock	Normal	Normal	Abnormal
Decompensated shock	Abnormal	Normal-abnormal	Abnormal
Brain injury or dysfunction	Abnormal	Normal	Normal
Cardiopulmonary failure	Abnormal	Abnormal	Abnormal

Adapted from Dieckmann R, Brownstein D, Gausche-Hill M, eds. *Pediatric Education for Prehospital Professionals*. Sudbury, MA: Jones & Bartlett; 2013.

Work of Breathing

The work of breathing should be observed ideally when the child is calm. Children may have increased work of breathing with retractions without facial signs of respiratory distress, therefore, the emergency clinician should ask the parent to remove the clothing so the chest wall can be observed for retractions. Infants and children with respiratory distress may assume the sniffing position in an attempt to decrease their work of breathing. The tripod position is an ominous sign of severe respiratory distress.

The quality of the voice or cry may be a clue to airway and respiratory disease or compromise. For example, children with croup have a hoarse voice, and children with peritonsillar abscesses may have a have muffled or so-called "hot potato" voice. Abnormal breath sounds may be audible without a stethoscope.

Signs of respiratory compromise include stridor, audible wheezing, retractions, grunting, and snoring respirations. Retractions may be seen in the suprasternal, supraclavicular, intercostal, and subcostal areas (Fig. 155.3). Nasal flaring is an attempt to decrease airway resistance (Fig. 155.4). Head bobbing (the use of neck muscles to assist respiration) and seesaw breathing (ineffective breathing pattern, in which the abdomen moves outward while the chest moves inward during inspiration) are signs of impending respiratory failure. As the child tires and nears complete respiratory failure, the respiratory rate falls and the work of breathing may diminish.

Normal pediatric respiratory rates are inversely related to age due to younger children's increased metabolic rates and lower tidal volume reserves. Because children normally function near their maximum tidal volume capacity, relatively small increases in metabolic demands (e.g., fever) can result in an elevated respiratory rate. As a result, abnormal respiratory patterns may provide clues about a nonrespiratory illness. Effortless tachypnea may be a sign of shock from any cause, whereas deep rapid breathing without other auscultative findings may be compensation for a metabolic acidosis. Children who are tachypneic despite normothermia should be evaluated for respiratory and nonrespiratory causes. Neurologic disorders may also lead to abnormal respiratory patterns (e.g., bradypnea and irregular respiration in the setting of increased intracranial pressure).

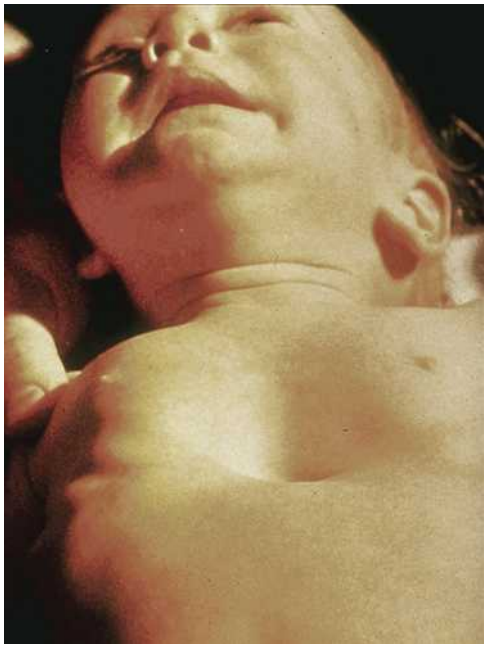

Fig. 155.3 Intercostal Retractions in a Child With Respiratory Distress.

Fig. 155.4 Nasal Flaring in a Child With Respiratory Distress From Lower Airway Obstruction.

Circulation to the Skin

Visual inspection of the skin can provide clues to overall cardiovascular status. Early compensated shock is characterized by peripheral vasoconstriction and shunting of blood to the brain and other vital organs. At this stage, skin appears pale but remains warm to the touch with delayed capillary refill time (>2 seconds). If the shock state is not corrected, the patient may become mottled, with cold extremities (Fig. 155.5A). Mottling is a random pattern of vasoconstriction in adjacent capillary beds in the skin. This is not to be confused with cutis marmorata, a regular lacy pattern on the skin caused by vascular instability (see Fig. 155.5B). Cutis marmorata is a normal finding in young infants in a cool environment. In contrast to infants with mottling, infants with cutis marmorata will be otherwise well-appearing, and the skin findings will diminish or disappear if the infant is placed in a warm environment. Cyanosis may be present normally in children with congenital heart disease but, if cyanosis is a new finding for the patient, it is almost always indicative of respiratory failure or decompensated shock.

Fig. 155.5 Infant with skin mottling (A) and cutis marmorata (B).

Length-Based Resuscitation Tape

Ideally an actual body weight in kilograms should be used for determination of medication dosing in children. An accurate weight may not be available for critically ill children especially for those that require immediate resuscitation. Use of a color-coded, length-based resuscitation tape gives an estimate of the child's weight. Each color on the tape corresponds to a weight range that corresponds to an ideal body weight for length. Medication doses and appropriate equipment are listed on the tape for each weight range. Use of the length-based resuscitation tape avoids error-prone calculations of medication dosages and equipment sizes in the high-stress setting of a pediatric resuscitation. In addition, pediatric resuscitation equipment organized by weight ranges minimizes the need to search for appropriately sized equipment.

Physical Examination

As in adults, the physical examination in critically ill or injured children will focus initially on airway, breathing, and circulation, with abnormalities in these systems corrected before a complete physical examination is performed. In any infant or toddler with respiratory complaints, observing the child breathing with the shirt removed will allow the most reliable assessment of the work of breathing. The respiratory rate should be manually counted for a minimum of 30 seconds, due to periodic breathing, and also because the rate on the monitor

Fig. 155.6 Toddler Being Held for Otoscopic Examination of the Ears.

can be unreliable. In infants and young children with some degree of respiratory distress, observation of respiratory status and pulse oximetry during feeding or sleeping can be helpful when deciding on further observation and admission.

In infants and young children, the physical examination should not be performed in a head-to-toe fashion. Auscultation of the heart and lungs and palpation of the abdomen should be performed before other more frightening or uncomfortable parts of the examination. Although, ideally, the emergency clinician should palpate the child's abdomen, occasionally a fearful child will cry so much it is impossible to determine if the child has abdominal tenderness or guarding. In these cases, observing the parent palpate the abdomen may be helpful. Although parents cannot be relied on to examine for masses or organomegaly, they can elicit pain with palpation and feel for guarding.

Examination of the ears, oropharynx, or area of injury should occur toward the end of the physical examination. Providers can try to ease a child's fear by first demonstrating the examination on a parent, older sibling, or stuffed animal. For the ear examination, the parent can hold the young child in his or her lap, with one arm around the head and one arm around the child's body and arms (Fig. 155.6). Young children can often be coaxed into opening the mouth wide enough for examination of the oropharynx without use of a tongue depressor. The examination can be turned into a game by asking the child to open his mouth and pant "like a puppy" or see if she or he can touch the tongue to the chin. The exam of the groin in young girls or boys can be facilitated by having them sit in a frog leg position in the parent's lap. Children should be reassured of the safe environment with the provider and caregiver but also should be counseled to understand the difference between the examination and inappropriate touching by others.

SPECIFIC DISORDERS

The most common reasons for infants and children to present to EDs are respiratory illness, fever, and injury. Causes of serious illness and injury vary by age. Respiratory illnesses are the most common reason for infant hospitalization after the immediate neonatal period. Asthma and appendicitis are the most common reasons for hospitalization of school-age children, and affective disorders are the most common cause of adolescent hospitalizations.

This section focuses on complaints specific to the pediatric population and complaints in which the differential and approach vary significantly from those in adult populations.

Common Neonatal Complaints

Neonates may present with a variety of previously undiagnosed genetic, anatomic, and metabolic conditions. In addition to the very limited behavioral cues displayed by newborns, parents of newborns are frequently anxious and may not know what behaviors or patterns are normal.

Concerns about feeding are common. Neonates typically feed every 2 to 3 hours. Bottle-fed neonates take about 2 to 3 ounces per feed, whereas breast-feeding neonates typically spend 10 to 15 minutes on each breast each feed. Newborns, especially those who are exclusively breast-fed, can lose up to 10% of their birth weight during the first 7 days of life. Birth weight should be regained by day 10, with a subsequent weight gain of 20 to 30 g/day for the first 3 months of life. Providers should clarify feeding routines with caregivers. Infants with excessive weight loss or failure to gain weight may have underlying metabolic, cardiac, or infectious causes or be victims of abuse or neglect.

Small amounts of regurgitation of breast milk or formula are normal in infants and generally are not concerning if the amount is stable, the infant is gaining weight, and emesis is not bilious. Larger volume emesis should be evaluated. Common benign causes include overfeeding and inadequate burping, but providers should consider other serious causes, such as pyloric stenosis, malrotation with volvulus, intussusception, and nonaccidental trauma (head or abdominal). Bilious emesis in a neonate should always prompt further investigation with imaging.

Another common concern is the frequency and consistency of bowel movements. Although infants typically have soft stools multiple times a day, it can be normal for exclusively breast-fed infants to stool as infrequently as once every 5 to 7 days. Straining during a bowel movement is also commonly seen and may occur after transition from breast milk to formula. In infants presenting with constipation, a history of failure to stool in the first 24 hours of life is concerning for Hirschsprung's disease—aganglionic segments of the colon that fail to relax.

Urate crystals may also form in the first week of life. Families often come to the ED with concerns for neonatal hematuria upon seeing these reddish "brick stained" deposits in the diaper. Though benign, these are most commonly seen in babies who have some degree of dehydration, especially in mothers who are breastfeeding and have not quite established a good milk supply.

Neonatal Intensive Care Unit Graduate

Gestational rather than chronologic age is typically used for premature infants in whom development is often delayed. Due to their immature immune function relative to infants of the same chronologic age, premature infants are at increased risk for recurrent respiratory infections. Chronic lung disease is a common complication in extremely premature infants (gestational age <28 weeks). Such infants frequently have a baseline tachypnea and increased work of breathing and may

require supplemental home oxygen. Parental report of changes in work of breathing, activity, feeding pattern, and level of alertness can be clues to serious illness, such as sepsis or underlying metabolic abnormalities.

Respiratory syncytial virus (RSV) immunoglobulin (palivizumab) prophylaxis is recommended for certain high-risk infants during peak season.[10] During RSV season, the timing of the last RSV immunoglobulin injection given should be ascertained when a premature infant presents with fever, cough, or rhinorrhea. Palivizumab is administered monthly and, if a dose has been missed, the physician should have a higher level of suspicion for RSV infection.

Children With Special Health Care Needs

The assessment of children with chronic illnesses and other special health care needs is especially challenging. Although specialty care is often provided at pediatric EDs affiliated with tertiary children's hospitals, a greater absolute number of the most complex pediatric patients are cared for within general EDs, likely due to regional proximity and easier access to care. This emphasizes the need for general EDs to be prepared to care for this vulnerable population[3,11]. Parents or other daily caregivers can provide helpful information on baseline behavior and mental status, and the caregiver's input should be sought.

However, a parent's knowledge and recollection of detailed medical information may be limited, especially during times of high stress. Parents may forget medication names or concentrations, details of previous hospital admissions, and current treatment plans. An Emergency Information Form (EIF) that summarizes chronic medical conditions, medications, medical devices, and other critical information can be used for children with special health care needs.[12] These forms can quickly provide critical information to the ED provider, assisting in the early management and stabilization of the child until more detailed records are obtained. ED staff can request that specialists affiliated with their hospitals provide EIFs for complex patients to facilitate rapid and appropriate emergency treatment.

Children with autism or sensory processing disorders may have a particularly difficult time in the loud and unpredictable environment of the ED. Day-to-day life for a child with an autism spectrum disorder can become extremely regimented, and knowing what is going to happen may help the encounter go more smoothly and decrease patient and family stress. Asking what sensory sensitivities the child experiences with touch, noise, and lighting will help guide the best approach to evaluating and treating the patient.[13]

Child Abuse

Nonaccidental trauma should be in all patients presenting with injuries and complaints, such as altered mental status and apparent life-threatening events. Unfortunately, abusive injuries are frequently not recognized at the initial health care encounter, leaving children at high risk for future and more serious injuries and death. Historical clues to nonaccidental trauma include mechanisms inconsistent with the injury pattern or a history inconsistent with the developmental level of the child (Box 155.3). Physical examination clues for abuse include presence of bruises in young precruising or nonambulatory infants and unusual locations of bruises, such as the trunk, ear(s), and neck (the so-called TEN regions) (Box 155.4). The TEN-4 Rule for bruising states that bruising in children under the age of four in any of the TEN regions, or any bruising under 4 months of age, should raise suspicion for non-accidental trauma. Fractures in children younger than 12 months without a significant witnessed trauma mechanism are especially concerning (see Chapter 172).

BOX 155.3 Historical Features Causing Concern for Child Abuse

- History lacking in details
- Inconsistency—details change with repeated questioning
- History inconsistent with child's developmental status
- Reported mechanism inconsistent with injury

BOX 155.4 Physical Examination and Radiologic Findings Concerning for Abuse

- Any bruises in young precruising infants
- Patterned ecchymosis, burns, or skin marks (abrasions, lacerations)
- Bruises on the ears, trunk, inner thighs, neck, or groin
- Posterior oropharynx bruising or lacerations
- Posterior rib fractures
- Classic metaphyseal fractures
- Any fracture in a nonambulatory child
- Fractures in different stages of healing

OTHER CONSIDERATIONS

Consent for Emergency Care

In general, parent or guardian consent is required for the evaluation and treatment of minors, and emergency clinicians should attempt to notify parents or guardians and obtain consent. However, in emergency situations, evaluation and stabilization cannot be delayed while awaiting consent. The Emergency Medical Treatment and Active Labor Act has mandated that patients presenting for emergency care receive a medical screening examination and, if an emergency medical condition is identified, patients should receive the care required to stabilize the condition (see Chapter e7). Thus, all minors presenting to the ED require an examination to determine if an emergency medical condition exists. If a condition that is threatening to life or health exists, treatment should be provided under the doctrine of implied consent. If an emergency medical condition is not suspected after a screening examination, nonemergent care should be delayed until guardian consent is obtained, unless the minor is legally able to consent for care. Patients in foster care or who are in child protective services custody should have a medical screening examination, but consent for treatment beyond emergency medical conditions may need to be obtained from a state representative.

The circumstances under which minors can consent for their own care vary from state to state, but minors can generally consent if they are emancipated or if they are seeking treatment for mental health issues, drug or alcohol abuse, contraception, pregnancy, or testing for or treatment of sexually transmitted infections. Minors are generally considered emancipated if married, on active duty in the military, or living independently and economically independent from their parents. Some states recognize minors as emancipated if they are pregnant or a parent. Many states recognize that a mature minor, generally 14 years or older, can consent for care if sufficient intelligence and maturity is displayed to make a reasonable and voluntary choice. The process for determining mature minor status varies from state to state.

Pediatric-Ready Emergency Department

Preparation to care for infants and children of all ages involves not only ED staff training but also stocking pediatric medication formulations, equipment, and supplies in appropriate sizes for the premature neonate

to the adult-sized adolescent. The American College of Emergency Physicians, American Academy of Pediatrics, and Emergency Nurses Association have developed joint guidelines for the care of children in the ED.[14–16] The guidelines include recommendations for necessary personnel, protocols, medications, equipment, and supplies. Surveys have found that EDs frequently lack the items recommended in the guidelines.[3] One strong recommendation in the guidelines is the appointment of physician and nurse coordinators for pediatric emergency care.[14–16]

Pediatric emergency readiness also requires a plan for continuing care of critically ill and injured children. Small community hospitals often do not have pediatric intensive care units or access to pediatric subspecialists. Therefore, a plan for transfer of patients whose needs exceed available resources is necessary. Receiving hospitals and a mechanism for transporting critically ill pediatric patients should be identified in advance. Overall mortality for critically ill children is reduced in pediatric ready facilities.[17]

Pediatric-Friendly Emergency Department

One topic that has received increasing attention is pain and anxiety management in pediatric patients. Procedural pain is frequently undertreated in infants. Appropriate use of sedation, anesthesia, analgesia, and nonpharmacologic methods of pain management can increase the patient's cooperation and increase visit satisfaction for the child and parent. Children have significant anxiety and fear surrounding medical procedures, leading to additional challenges in performing procedures successfully. In addition to reducing pain and anxiety during the acute visit, adequate pain control is likely to have long-term benefits. Multiple studies have demonstrated that inadequate procedural pain control can lead to increased pain perception with future painful procedures.

A variety of options are available to minimize pain associated with blood draws and intravenous line starts, including vapocoolants, topical anesthetics, and needle-free jet injection of anesthetics.[18] Topical anesthetics can also decrease the pain of an anesthetic injection before a lumbar puncture and other procedures. Topical application of a lidocaine, epinephrine, and tetracaine mixture has been shown to have comparable efficacy to injected anesthesia for facial and scalp lacerations. The combination of sucrose and radiant warmth can provide effective analgesia to newborns.[19] Child life specialists are particularly helpful and, when available, should be used to provide play therapy and education to frightened children, allowing the provider to focus on the procedure. Child life providers are trained in the developmentally appropriate use of nonpharmacologic distraction techniques such as bubbles, songs, books, videos, and video games to decrease anxiety, tools that can also be adopted by department staff.[18] In young children, the use of anxiolytic medications or procedural sedation may be appropriate for procedures that could be accomplished with local anesthesia in older patients.

Providers should encourage and support the family's presence during pediatric procedures and resuscitations.[20] Children are stressed when separated from their parents and their presence can reassure and calm the child. Studies have shown that a family's presence also decreases anxiety levels in family members.[20] Their presence during unsuccessful cardiopulmonary resuscitation is perceived by families as beneficial in the grieving process. Studies have shown that with well-implemented policies, a family's presence does not interfere with resuscitation.[20]

Families present during resuscitations should have a family support person assigned who can explain procedures and answer questions. Ideally, families are briefed on what to expect before entering the resuscitation room. Social workers and Child Life specialists can provide expertise and support, helping families understand what is happening to their child, guide them through procedures, and support them through critical illness and death. Guidelines have been developed to assist emergency clinicians in implementing family presence protocols at their institutions.[21]

CHAPTER 155: QUESTIONS AND ANSWERS

1. Which of the following respiratory signs is characteristic of a child in compensated or decompensated shock?

a. Grunting with abnormal breath sounds
b. Tachypnea with nasal flaring
c. Tachypnea with clear breath sounds on auscultation
d. Tripoding with stridor
e. Wheezing with retractions

Answer: c. Effortless tachypnea, or rapid respirations with clear breath sounds, is characteristic of a child in compensated or decompensated shock. Grunting, nasal flaring, tripoding, stridor, wheezing, and retractions are all signs of increased work of breathing and would be more indicative of pulmonary or airway disease.

2. As the pediatric physician coordinator for your emergency department, you decide to institute new policies to prevent pediatric medication errors. Which of the following strategies will be most effective in decreasing risk of dosing errors?

a. Pharmacy review of medication orders
b. Use of length-based resuscitation tapes
c. Use of resuscitation calculators
d. Weighing and recording the weight in kilograms

Answer: d. Weights should be measured and recorded in kilograms, not pounds, to avoid inadvertent dosing calculations using pounds instead of kilograms. The use of length-based resuscitation tapes and resuscitation calculators and pharmacy review of medication orders have also been suggested to reduce medication dosing errors, but the most effective measure is to weigh and record the weight in kilograms.

3. You have written an order for a blood draw and placement of an intravenous line in a nervous 3-year-old boy. Which of the following is least likely to be helpful in decreasing the patient's procedure-related distress?

a. Application of a lidocaine-epinephrine-tetracaine mixture
b. Having the patient blow bubbles prior to the needle stick
c. Needle-free jet injection of local anesthetic
d. Use of a vapocoolant

Answer: a. The formulation of lidocaine-epinephrine-tetracaine only works on broken skin (i.e., lacerations). Unlike eutectic mixture of local anesthetic (EMLA) and 4% liposomal lidocaine preparations which are effective on intact skin, it will not work on intact skin. The use of vapocoolants and a needle-free jet infection of local anesthetic may decrease the patient's pain. Distraction techniques such as blowing bubbles, singing a song, or watching a video may relieve procedure-related anxiety.

Pediatric Airway Management

Joshua Nagler and Nathan W. Mick

KEY CONCEPTS

- Pediatric advanced airway management is a relatively rare skill to perform in most emergency departments (EDs), and skill maintenance is difficult based solely on clinical practice.
- There are several anatomic differences that impact pediatric airway management, and these occur mostly in the very young child (<2 years of age). Infants have a large occiput and a high, anterior airway, which impacts positioning during intubation. The narrowest portion of the pediatric airway is at the level of the cricothyroid membrane which means a foreign body could be lodged below the cords. They are also more dependent on diaphragmatic excursion for ventilation, thus gastric insufflation can result in difficulty with rescue ventilation.
- Children are prone to desaturation due to their high metabolic rate and their lungs' small functional residual capacity, making preoxygenation and maintenance of oxygenation during intubation attempts crucial.
- The cognitive burden inherent in dealing with the large age/size spectrum in pediatrics can be overcome with reference aids that organize equipment selection and drug dosing based on length/age/size. Formulas have been developed to aid in selection of the correct endotracheal tube (ETT) size and determine appropriate depth of ETT insertion. For estimation of uncuffed tube sizes in children older than 1 year old: ETT size = 4 + (age in years/4). Subtract 0.5 in size for cuffed tubes. To estimate the depth of ETT insertion (the so-called "lip to tip" distance), multiply the ETT size × 3 (e.g., a 5.0 ETT would be inserted to 15 cm at the lip).
- Rapid sequence intubation (RSI) is the preferred method of airway management in the vast majority of pediatric cases in the ED.
- Compared to adults, children are more prone to desaturation over the time it takes for a neuromuscular blocking agent (NMBA) to take effect. Use of high-flow nasal cannula during the apneic period of RSI has not been well studied in children in the emergency setting, but we recommend its use at 1 to 2 L/min/year of age to a maximum of 15 Lpm. Because children desaturate more rapidly than adults, we recommend that assisted ventilation (coordinated with the child's respiratory efforts if not yet fully paralyzed) be initiated if oxygen saturation drops below 95%.
- Video laryngoscopy is an evolving technology for use in pediatrics and assists in visualization of the airway but may prolong time to intubation.
- Surgical airway techniques differ in infants and young children, necessitating a needle technique that is different from the older child or adult. This technique provides a mechanism to oxygenate the "can't intubate, can't ventilate" child, but should not be relied on as a definitive airway.

FOUNDATIONS

Background and Importance

Pediatric airway management is an uncommon, but critical resuscitation skill. Acquisition and retention of necessary skills is difficult when relying solely on clinical practice. Although the skills required to perform advanced airway management between adults and children are similar, there are anatomic and physiologic nuances of pediatric patients. These differences are most prevalent in the first 2 years of life and necessitate modifications to the "typical" intubation approach in older adolescents and adults. Additionally, because of the size and weight spectrum inherent in the pediatric patient population, there is a large spectrum of equipment and medication dosages.

Even in large children's hospitals, there are few opportunities to perform endotracheal intubation as part of clinical practice. Of 1000 pediatric emergency department (ED) patients, 1 to 3 will require intubation, compared to 1 out of 100 adults. Many providers will leave residency training with fewer than 10 pediatric intubations and will not routinely intubate children as part of their clinical practice after training. At the same time, pediatric intubation success and skill mastery improves with increasing experience. Operating room studies demonstrate first-pass intubation success rates are less than 50% after 10 airways but rise to more than 90% after 50 intubation attempts. Fortunately, through experience with older patients, most emergency clinicians can recognize critical illness and have the skills necessary to manage the pediatric airway. These translational skills can be augmented using a simulated environment or with dedicated training in the operating room. Developing a systematic approach to pediatric airway management, while recognizing the anatomic and physiologic differences in the young child, is critical to success and will help to eliminate much of the anxiety associated with performing a time-dependent, infrequent critical procedure.

ANATOMY

There are several anatomic differences in pediatric patients that directly impact airway management (Table 156.1). These differences are most notable in the first 2 years of life; children 2 to 8 years old represent a transitional stage where the anatomy becomes more adult-like, yet there remains variability with medication dosing and equipment size selection.

By correctly positioning the patient, the oral, pharyngeal, and laryngeal axes can be aligned to visualize the glottis during direct laryngoscopy. The small infant has a relatively large head and occiput in relation to their body size. This can cause slight flexion at the neck when the patient is lying supine, impeding the ability to visualize the glottis. The patient should be positioned so that a line drawn through the external auditory canal and the anterior shoulder is horizontal and parallel to the bed (Fig. 156.1). In the infant (younger than 6 months old), this is accomplished by placing a towel roll under the patient's shoulders, elevating the body, and overcoming the neck flexion associated with their large occiput. In the small child (6 months to 5 years old), correct positioning can likely be achieved without the need for support. In the older child/adolescent, the head is smaller in relation to the size of the body, and the head may need to be elevated. As long as cervical spine

TABLE 156.1 Anatomic Differences in Pediatric Airway Management

Anatomic Difference	Implications for Airway Management	Solution
Large occiput and head	Neck position flexed when lying supine and flat on stretcher	Shoulder roll required for optimal positioning of young infant
Large tongue	May occlude airway in the unconscious or obtunded patient	Jaw thrust and oral or nasopharyngeal airway useful adjuncts during airway management
High, anterior airway	Visualization of the vocal cords may be difficult	Correct positioning prior to laryngoscopy critical
Upper airway anatomy and narrow subglottic region	Upper airway prone to dynamic collapse and inflammation (e.g., croup)	Cuffed tubes safe, and sometimes preferred, as long as cuff pressure monitored
Large tonsils and adenoids	Prone to bleeding with manipulation	Blind nasotracheal intubation relatively contraindicated younger than 10 years old
Small cricothyroid membrane	Surgical cricothyrotomy difficult	Needle cricothyrotomy recommended in infants and young children
Large stomach, dependence on diaphragmatic excursion for ventilation	Insufflation of the stomach during BMV can compromise ventilation	Use orogastric or nasogastric tube for decompression

BMV, Bag-mask ventilation.

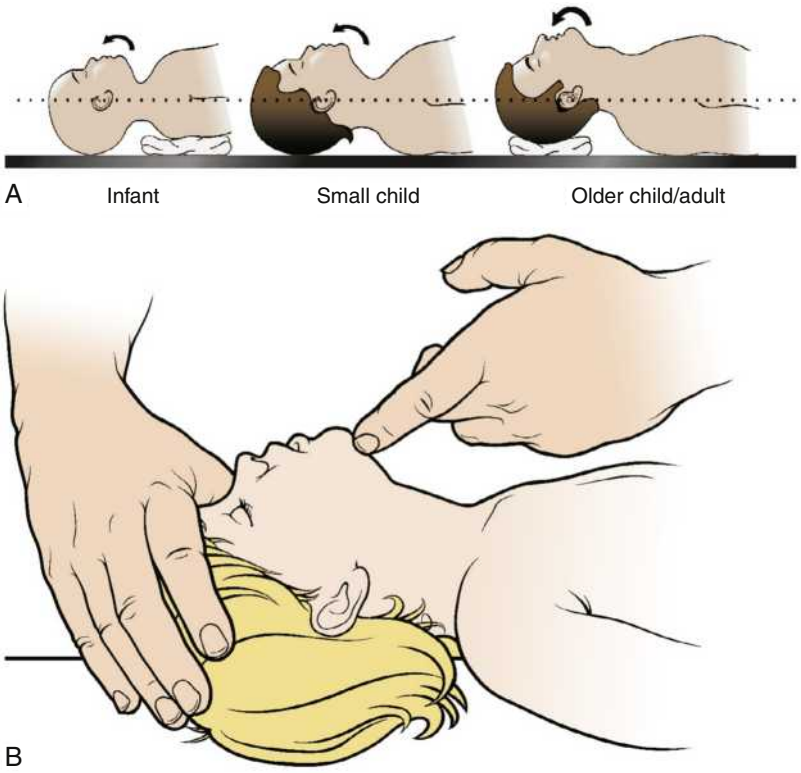

Fig. 156.1 Correct positioning of a pediatric patient to ensure optimal airway alignment utilizing a line passing through the external auditory canal and the anterior shoulder. (A) The small infant requires a shoulder roll to achieve optimal positioning, the small child typically requires neither a shoulder roll nor head support, and the older child/adolescent may require head support. (B) In this small child, a line drawn through the external auditory canal and the anterior shoulder reveals the child to be in good position without support. Slight extension of the head results in the achievement of the sniffing position. (Used with permission: Walls R, Murphy M. *Manual of Emergency Airway Management*, ed 4. Philadelphia: Lippincott Williams & Wilkins; 2012.)

injury is not suspected, correct positioning combined with slight head extension will optimize conditions for direct laryngoscopy.

Infants and children have large tongues relative to the size of their mouths and tend to have a large, floppy epiglottis. Because of these differences in anatomy, they are prone to obstruction when sedated or obtunded, and manipulation of the epiglottis during direct laryngoscopy is frequently required to achieve intubation. Practically, these differences may necessitate the use of an oral or nasopharyngeal airway during bag-mask ventilation (BMV) to bypass the large tongue. Furthermore, a straight (Miller) laryngoscope blade may better manipulate the floppy epiglottis.

The vocal cords and glottic opening are situated at the level of the first cervical vertebrae in infants, gradually dropping to the C3 to C4 level by age 7, and further descending to the C6 level by late

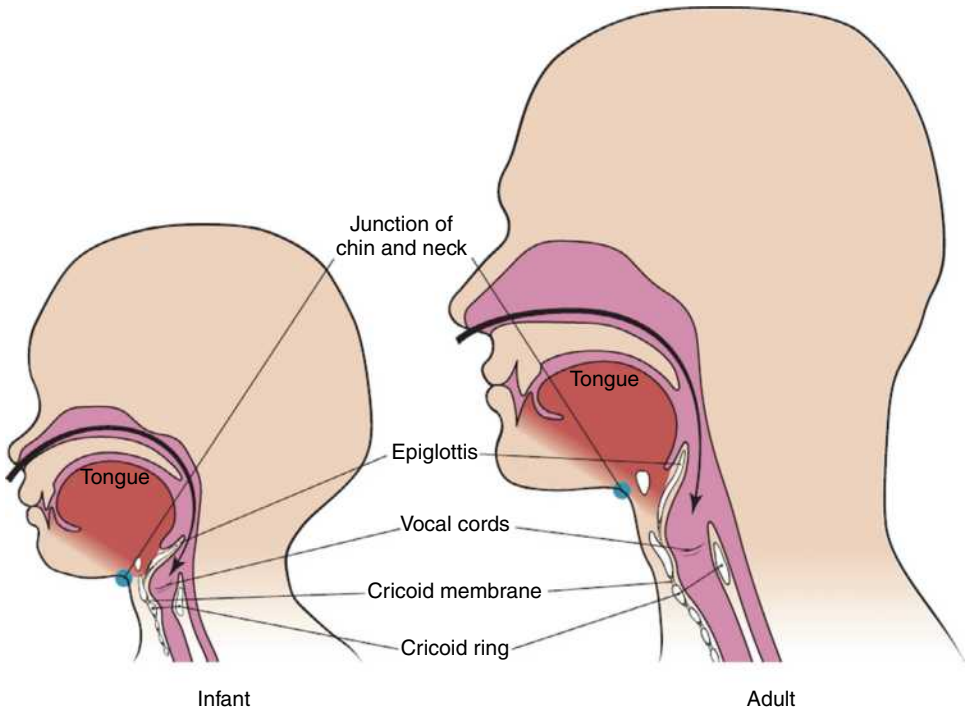

Fig. 156.2 High, anterior airway of the small child. Anatomic difference in the relation of the glottis in the small child compared with the adult.

adolescence. Therefore, the airway is higher and more anterior in small infants than what is encountered in adults, making correct positioning prior to direct laryngoscopy critical to ensure success of intubation (Fig. 156.2).

Historically the narrowest portion of the pediatric trachea was felt to be subglottic at the cricoid ring. However, recent studies using airway CT in anesthetized pediatric patients have confirmed prior MRI and bronchoscopy findings demonstrating anatomic narrowing at the level of the vocal cords and an elliptical-shaped subglottic region.[1,2] Because of the non-distensible nature of the cricoid cartilage, the subglottic region functionally remains the narrowest in the spontaneously breathing child.

The unique anatomy of the pediatric upper airway has traditionally led to the use of uncuffed endotracheal tubes (ETTs) in the small child. Support for uncuffed tubes came at a time when the cuffs were relatively stiff and there was not a reliable, easy way to identify high cuff pressures that can lead to subglottic tracheal injury. Current cuff technology can accurately measure cuff inflation pressures, and we recommend using cuffed tubes for intubation of children, particularly in instances of high airway pressures or poor compliance (e.g., asthma, pneumonia, and acute respiratory distress syndrome [ARDS]).[3-5] Utilizing a cuffed ETT may obviate the need to replace and upsize a tube when there is significant air leak that impacts ventilation, avoiding the risk of losing an already secured airway.

The pediatric trachea is more flexible and prone to dynamic collapse. In addition to implications with positioning during assisted BMV and intubation, the trachea can narrow due to upper airway pathology (e.g., croup, bacterial tracheitis). In cases of upper airway pathology, keeping the patient in a calm and quiet environment is important. Children with "complete" upper airway obstruction often respond well to positive pressure via BMV, which can act to stent open the upper airway. Heliox, typically a 70% to 30% mixture of helium to oxygen, can help decrease a child's work of breathing by increasing laminar flow in partially obstructed airways. Where available, a trial of heliox may be considered in cases of partial upper airway obstruction (e.g., croup), although it has been found no more effective than racemic epinephrine or humidified oxygen in reducing the level of distress in these patients.[6]

The anatomic variations in children impact recommendations in pediatric airway management. Children have relatively prominent tonsillar and adenoidal tissue that is prone to bleeding with even minor trauma. Thus, blind nasotracheal intubation is relatively contraindicated and not routinely recommended in pediatric patients younger than 10 years old. Anatomic landmarks in the neck may be difficult to identify in young infants and children with short necks, and the cricothyroid membrane is small. Thus, needle cricothyrotomy is the recommended invasive airway of choice rather than surgical cricothyrotomy in emergency department settings when the airway cannot otherwise be managed with BMV, intubation or supraglottic device.

Finally, small children are dependent on diaphragmatic excursion for ventilation and have relatively large stomachs and low gastroesophageal sphincter tone. They are predisposed to gastric insufflation during BMV, which can impede diaphragmatic motion and compromise ventilation. Use of cricoid pressure in infants and young children is controversial and not well supported in the literature. If gentle cricoid pressure is used during BMV to reduce gastric insufflation and chest rise is poor, we recommend release of cricoid pressure to see if effective ventilation can then be maintained. We recommend placement of a nasogastric or orogastric tube and aspiration of air immediately following endotracheal intubation, or before intubation attempts if the abdomen is becoming distended and impeding ventilation during BMV.

PHYSIOLOGY

Owing to a high metabolic rate and low functional residual lung capacity, young children are prone to quick desaturation once apneic, even with adequate preoxygenation. Whereas a fully preoxygenated adult with healthy lungs may not desaturate below 90% for a full 6 minutes, a

normal healthy 10-kg child may fall below 90% in half that time and a sick infant may desaturate in less than 1 minute. Thus, careful attention to preoxygenation is crucial. Additionally, use of nasal cannula (1–2 L/min/year of age to a maximum of 15 L/min) during the apneic period may help support oxygenation until intubation can be achieved. BMV should be provided between intubation attempts when oxygen saturation levels start to decline below 95%.

Children have a large extracellular fluid volume compared with adults. Many of the drugs used to facilitate endotracheal intubation (sedatives and paralytics) need higher per kilogram doses and their duration of action may also be shorter when compared with adults.

EQUIPMENT

The cognitive burden that occurs when caring for a critically ill child is significant. Equipment selection and medication dosing should be calculated based on weight and size, which can vary tremendously across the spectrum of pediatric patients, from the 3 kg newborn to the 100 kg adolescent. Every ED that cares for pediatric patients should have airway equipment stocked, accessible, and organized by age and size to facilitate easy use. There are numerous mobile device and computer applications, as well as color-coded length-based systems, which can be utilized to simplify medication and equipment selection (Fig. 156.3). Regardless of method, elimination of the reliance on rote memorization lessens the cognitive burden of caring for pediatric patients across the age/size spectrum, particularly during periods of high stress.

There are several "formulas" that are useful in selecting the appropriate equipment for pediatric patients. To determine ETT size, a number of methods are used. Measure the length of the child with a length-based resuscitation tape that has tube sizes based on length and weight recorded on the tape, or use of age-based formulas for a child older than 1 year old:

$$4 + (\text{age in years}/4)$$

Example: 4-year-old patient

$$4 + (4\ \text{years}/4) = 5.0\ \text{uncuffed ETT}$$

or

4.5 *cuffed* ETT (subtract 0.5 from above formula for cuffed tube sizing)

ETT depth of insertion (lip to tip distance) can be visualized during intubation by watching the vocal cord marker go past the vocal cords, or estimated by use of the Broselow-Luten tape or by the following formula:

$$3 \times \text{uncuffed tube size} = \text{lip to tip distance (midtrachea)}$$

Example: 5.0 ETT

$$3 \times 5.0 = 15\ \text{cm depth of insertion}$$

MANAGEMENT

Decision Making

For a child who is effectively stabilized using noninvasive means (such as BMV), the additional benefit of a secure airway needs to be weighed against the risk of potential difficulty or complications. Failure to successfully oxygenate or ventilate a child by other means forces immediate action, whereas other conditions allow medical interventions and recurrent assessments over time to determine if advanced airway management is required.

Overall, an equal number of pediatric intubations in the ED are performed on trauma and nontrauma patients.[7] Indications for pediatric intubation can be placed into four categories: (1) inability to oxygenate and ventilate; (2) inability to maintain or protect the airway; (3) potential for clinical deterioration; and (4) facilitation of necessary diagnostic studies, procedures, or for safe patient transport (e.g., high risk of decompensation on route).

Respiratory compromise is a leading contributor to morbidity and mortality in the pediatric population, and more likely than a primary cardiac disease to be the cause of arrest. Respiratory failure can result from intrinsic pulmonary disease or from conditions with infectious, neuromuscular, traumatic, toxicologic, or environmental etiologies. Respiratory failure is a clinical diagnosis, identified by characteristic examination findings and supported by noninvasive measurement of oxygenation (pulse oximetry) and ventilation (capnography). Blood gas analysis can also be informative but should not be relied upon to determine need to perform necessary advanced airway management.

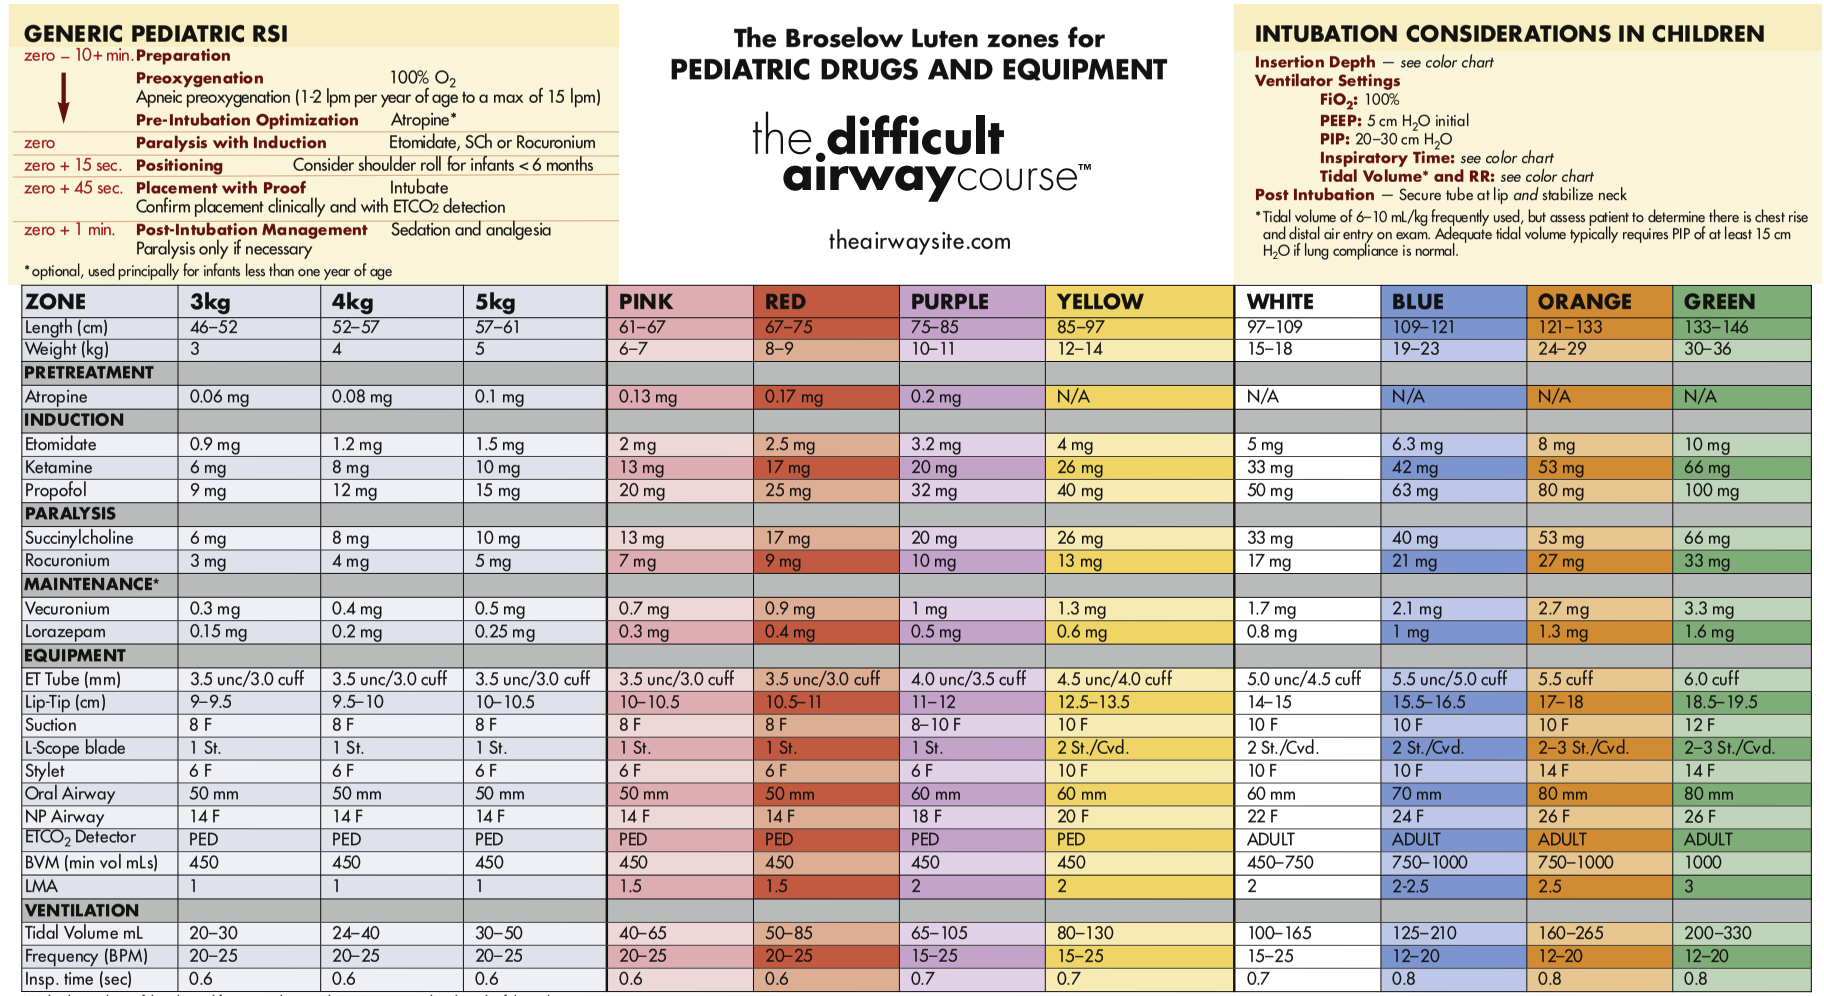
Signs of partial obstruction (sonorous or stridulous airway noises) or complete obstruction (inability to phonate or produce audible breath sounds in a patient with adequate respiratory effort) suggest an inability to maintain the airway and should prompt immediate basic airway maneuvers, including airway repositioning or insertion of oral and nasal airways to help stent open the upper airways. Suctioning and removal of any foreign material might also be required. When these efforts are ineffective, patients may require an advanced airway. For patients with severely depressed mental status, the loss of protective airway reflexes may necessitate airway control, regardless of the ability to maintain the airway. For example, the use of a Glasgow Coma Score (GCS) of 8 or less is often cited as an indication for intubation in head-injured patients. Systemic illness, toxicologic exposure, and other etiologies of central nervous system (CNS) depression may also increase risk of aspiration; the presence of a gag reflex correlates poorly with GCS and the risk of aspiration. Thus, testing for a gag is not recommended, because it may increase the risk of vomiting and subsequent aspiration.

When airway compromise is progressive (e.g., from acute thermal injury), airway management should be initiated early to avoid increased difficulty later in securing the airway. Similarly, patients with systemic illnesses (e.g., sepsis) may require intubation to maximize oxygen delivery and decrease the metabolic demands of increased work of breathing.

Children often require sedation to perform diagnostic testing, such as computed tomography (CT), magnetic resonance imaging (MRI), or invasive procedures. The risk of airway compromise during procedural sedation is greater in patients with significant illness or medical instability. Therefore, securing the child's airway may be necessary to ensure safety during the procedure, particularly in circumstances where accessibility for assessment and intervention may be compromised (e.g., a patient under surgical drapes or tunneled into a CT or MRI scanner). Because many acutely ill and injured children will require transfer to a pediatric tertiary care center, the stability of the patient's overall condition and risk of airway compromise should be carefully considered. Securing the airway prior to transfer can obviate the need for emergent advanced airway management in a less controlled setting.

Rapid Sequence Intubation

Rapid sequence intubation (RSI) is the preferred method to perform endotracheal intubation in children, provided no contraindications exist. We do not recommend attempting emergency pediatric endotracheal intubation with sedation only as studies have demonstrated higher success and lower complications rates with RSI. A small number of medications are used for pretreatment, sedation/induction, and neuromuscular blockade during ED pediatric RSI (Table 156.2).



ZONE	3kg	4kg	5kg	PINK	RED	PURPLE	YELLOW	WHITE	BLUE	ORANGE	GREEN

TABLE 156.2 Common Rapid-Sequence Intubation Medications in Children[a]

Medication	Dosage	Comments
Premedications		
Atropine	0.02 mg/kg	Not routinely used in RSI. Consider use in young infants (<1 year of age) Should be given for preexisting or periprocedure bradycardia not responsive to oxygenation and ventilation
Lidocaine	1.5 mg/kg	Not routinely used in RSI. Very limited pediatric-specific data to support use in increased ICP Needs to be given 3 minutes prior to laryngoscopy No data for bronchodilatory effect in children
Induction Agents		
Etomidate	0.3 mg/kg	Rapid and reliable sedation Preserves hemodynamics Known to cause adrenal suppression even with single dose, although limited data on impact on clinical outcome Consider stress dose hydrocortisone with use No analgesic properties
Ketamine	1 to 2 mg/kg	Causes release of endogenous catecholamines May support hemodynamics in hypotensive patients Beta-agonist effect may help with bronchodilatation, favoring its use in asthma Preserves airway reflexes and respiratory drive Can be used without NMBA for "awake sedated look" in suspected difficult airways
Propofol	3 mg/kg	Rapid onset, short acting May cause hypotension Apnea possible Higher dose recommended in infants No analgesic properties
Midazolam	0.3 mg/kg	Higher dosing required than used for antiepileptic dosing or anxiolysis At induction dosing, may cause hypotension Often used concomitantly with opioids No analgesic properties
Fentanyl	1 to 5 mcg/kg	Often used with midazolam Lower dosing (1–2 mcg/kg) recommended for shock or hemodynamic concerns
Paralytics		
Rocuronium	1 to 1.2 mg/kg	Nondepolarizing agent Equivalent onset as succinylcholine but longer duration of action No specific contraindications in patients suitable for RSI
Vecuronium	0.1 mg/kg	Nondepolarizing agent Slower onset of action than rocuronium Suitable alternative for rocuronium if more readily available
Succinylcholine	0–11 years: 2 mg/kg >11 years: 1.5 mg/kg Double the dose when given IM	Fasciculations without clinical relevance in children Shorter duration than rocuronium Very low risk of bradycardia with IV induction agents used in ED (see earlier) Risk of hyperkalemia and arrest in patients with known and undiagnosed myopathies and neuromuscular disease
Sugammadex	16 mg/kg (full reversal dose)	Rapid reversal agent for rocuronium or vecuronium Neuromuscular blockade generally reversed within 3 minutes

[a]RSI medications can be given intraosseous (IO) when IV access cannot be obtained.
ED, Emergency department; *ICP,* intracranial pressure; *IM,* intramuscular; *IV,* intravenous; *NMBA,* neuromuscular blocking agent; *RSI,* rapid sequence intubation.

Pretreatment

The goal of pretreatment medications is to attenuate the physiologic responses to laryngoscopy and intubation, or to mitigate the adverse effect of pharmacologic agents used for sedation or neuromuscular blockade; however, data are limited with regard to the benefit of pretreatment medications in children. Use of these agents needs to be weighed against the potential for procedural delays and drug errors that can occur with the administration of medications requiring weight-based dosing. This is particularly relevant during high stress situations, such as the management of critically ill children. Two drugs

have been used for pretreatment in pediatrics: (1) atropine to prevent bradycardia related to vagal tone, and (2) lidocaine to attenuate the reflex sympathetic response in patients with concern for increased intracranial pressure (ICP); however, their use today is not routinely recommended.

Infants, particularly younger than 1 year old, have higher intrinsic vagal tone than older children or adults. Atropine serves as a vagolytic and can reduce the risk of bradycardia resulting from laryngoscopy in this age group. There is an association between the use of succinylcholine and bradycardia. Data suggest that this risk may be tied to use with select inhaled anesthetics (e.g., halothane) and with newer induction agents the incidence of succinylcholine-related bradycardia is very low.[8] Given the limited available evidence, routine use of atropine for patients receiving succinylcholine during RSI is not necessary.[9] Atropine may be helpful for bradycardia that exists prior to intubation, but it should only be considered once hypoxia-induced bradycardia is excluded and maximal oxygenation achieved.

Data on the effectiveness of lidocaine in blunting the sympathetic response to laryngoscopy in patients with suspected elevated ICP are limited to case series and extrapolated from adult experience. Literature reviews have failed to identify a benefit in adult head injured patients, and no supporting data exist in pediatric populations. Therefore, we do not recommend the routine use of lidocaine.

Sedatives

Sedatives rapidly induce unconsciousness and facilitate intubation. Providers should choose sedatives based on their efficacy, adverse effect profile, and clinical situation. In particular, providers should pay careful attention to the hemodynamic profile of these agents, to minimize the risk of clinical deterioration during RSI.

Etomidate is a common sedative used for pediatric RSI. It has reliable efficacy and pharmacokinetics and a stable hemodynamic profile. Etomidate may suppress adrenal corticosteroid synthesis transiently. However, no convincing data exist to suggest that administration of a single dose during intubation influences clinical outcome. Pediatric advanced life support (PALS) guidelines have included precautions against "routine use" in septic shock, and suggest consideration of stress dose hydrocortisone when etomidate is used.

Ketamine is a dissociative anesthetic with reliable and rapid onset. Its use is well established for procedural sedation and analgesia in pediatrics. It causes an endogenous release of catecholamines, making it appealing for patients with hypotension or shock. Adverse reactions to ketamine include vomiting, laryngospasm, myoclonus, and emergence phenomenon. Although ketamine is a known sialagogue, the coadministration of atropine is unlikely to be of help during RSI given that the onset of action for the drying effects of atropine may take up to 20 minutes. Ketamine has been shown to increase ICP, although the significance of this on clinical outcome is unclear, as it can also support cerebral perfusion pressure.[10,11] The catecholamine release with ketamine may lead to the beta-agonist effect of bronchodilation, making it an ideal drug for patients with bronchoconstriction. This same benefit may not apply to conditions such as bronchiolitis, in which airway edema and debris are the primary etiology of airway obstruction. Ketamine is the preferred sedative for children in septic shock requiring RSI because of its ability to maintain mean arterial pressure.[12]

Propofol has rapid and profound sedative properties, that when combined with its short duration of action, make it an ideal induction agent. However, as a vasodilator and myocardial depressant, propofol is not recommended in patients with tenuous hemodynamics, including hypovolemia or shock. Propofol may also compromise cerebral perfusion if mean arterial pressure is rapidly reduced.

Benzodiazepine dosing is higher for RSI induction than when used as an anticonvulsant or during procedural sedation. For example, 0.3 to 0.4 mg/kg of midazolam may be required to achieve sufficient sedation. Alternatively, benzodiazepines may be used in conjunction with opioids, such a fentanyl, but the combination can compromise hemodynamics.

Neuromuscular Blocking Agents

Neuromuscular blocking agents (NMBAs) are used to relax airway musculature and block airway protective reflexes during laryngoscopy to facilitate the passage of an ETT. The aim is rapid onset of action to limit the time without spontaneous or assisted ventilation. Succinylcholine and rocuronium are the most commonly used NMBAs for emergent pediatric RSI.[13] Understanding the specific benefits and risks of each is helpful in creating an airway management plan.

Succinylcholine has a rapid onset of action of 30 to 60 seconds and duration of action of 3 to 8 minutes. It is the oldest, and often the most familiar, NMBA for emergency clinicians, and has a long track record of safe and effective use. Higher doses (2 mg/kg) are recommended in neonates and infants compared to 1.5 mg/kg for adolescents. Providers should be aware of several side effects and potential risks of succinylcholine. Muscle fasciculations result from the depolarizing effect of this agent, although young children may not have large enough muscle mass to result in clinically observable effects. Succinylcholine can cause hyperkalemia, which can be fatal in a number of clinical conditions (see Table 156.2). In many patients, high-risk diagnoses are known or suspected; however, published case series have described succinylcholine use in infants with undiagnosed myopathies leading to hyperkalemia arrest. As a result, a US Food and Drug Administration (FDA) black box warning exists for the use of succinylcholine in children, although given the rarity of these conditions, exception has been allowed for emergency use. Given this waiver, succinylcholine is still the most commonly used NMBA in pediatric emergency airway management.[7] Other serious but rare adverse effects of succinylcholine use in children include masseter spasm and malignant hyperthermia, which are most commonly associated with concurrent halothane use. Masseter spasm is a rare side effect of succinylcholine administration in children and can be terminated by the administration of a competitive neuromuscular blocking agent (NMBA).

Rocuronium is the most common nondepolarizing NMBA used in emergency pediatric airway management. Pediatric data suggest that rocuronium at a dose of 1.2 mg/kg has equivalent efficacy in time to intubation conditions as succinylcholine. The duration of action, however, is much longer with a time to return of spontaneous respirations of anywhere from 20 to 90 minutes. The primary advantage of nondepolarizing agents is the absence of the risks (e.g., hyperkalemia) associated with depolarizing agents. The longer duration of action can be of concern if the airway cannot be secured or in patients in whom rapid return of examination findings (e.g., neurologic examination) is important. However, it may also have advantages if subsequent management may include imaging, additional vascular access, initial ventilator management, or other procedures. A reversal agent (sugammadex) for rocuronium exists that can limit its duration of action to less than that of succinylcholine.

DEVICES AND TECHNIQUES

Basic Airway Management

The priority in pediatric airway management is establishing effective oxygenation and ventilation. For children with hypoxemia but effective ventilation and without concern for increased work of breathing, passive supplemental oxygen delivery may be sufficient. For

mild hypoxemia in children who will not tolerate a nasal cannula or face mask, "blow-by" oxygen using a mask, shovel, or plastic funnel attached to oxygen tubing aimed toward the face are options. Nasal cannula can provide more consistent oxygen delivery, particularly in infants who are preferential nasal breathers. High-flow nasal cannula is increasingly being used to deliver supplementary oxygen to pediatric patients. The heated and humidified delivery allows higher flow rates without discomfort, and the absence of a need for a tight seal makes application easier than other forms of noninvasive ventilation.[14] Simple face masks can be used, whereas non-rebreather masks provide maximal passive oxygen delivery in spontaneously breathing patients.

When ventilation is of concern or a child's work of breathing is excessive, assisted ventilation may be required with a bag and mask. Effective assisted ventilation requires: (1) a patent airway and (2) an effective mask seal. Opening the airway is accomplished with positioning of the child, avoiding flexion of the neck from a large occiput or from downward pressure on the face when applying the mask. Application of basic airway maneuvers including a head tilt–chin lift maneuver or a jaw thrust can be of further help. Placement of nasopharyngeal and oral airways can be of value when the airway is being partially or completely obstructed, often by the tongue or soft palate. Oral airways are only tolerated in patients with depressed mental status, either pharmacologically induced or related to underlying pathophysiology. To create an effective mask seal, the provider first needs to select the appropriate size mask. An ideal fitting mask is large enough to cover the nose and open mouth but should not allow air leak across the bridge of the nose or off the base of the chin. Emergency clinicians should deliver appropriate volume and pressure breaths. There may be a tendency in an acute situation to deliver a much larger tidal volume than is appropriate for the size of the child, which may result in barotrauma. Gentle rise of the chest accompanied by clinical improvement are key clinical features of effective BMV. The bag-mask device should be squeezed just until chest rise is initiated and then released. The emergency clinician may time ventilation by stating "squeeze, release, release" which slows ventilation rate and may reduce complications from hyperventilation and gastric insufflation during rescue ventilation. Cricoid pressure has limited utility, primarily in reducing gastric insufflation, and should be used with caution in children. Too much cricoid pressure can compress the pliable pediatric trachea, leading to iatrogenic upper airway obstruction. Cricoid pressure should be lightened or released if felt to impede BMV.

Advanced Airway Management

Chapter 1 covers a detailed approach to RSI. The general approach to the procedure is identical to that of an adult, although there are several pediatric considerations worthy of mention.

Preparation

Passive oxygen delivery devices, self-inflating bags and masks, oral and nasal airways, laryngoscope blades, ETTs, stylets, and rescue devices all come in varying sizes to match the anatomy of the child. Generally having at least two sizes of ETTs (estimated size as well as a half size smaller) available during the procedure is prudent. Having a systematic approach to identifying the correct equipment prior to initiating the procedure can eliminate errors and failed attempts in critical situations. Potential resources include a length-based resuscitation system, pediatric resuscitation cards (Fig. 156.3), print or online textbooks, and mobile device applications.

Preoxygenation

As described earlier, young children desaturate much more quickly than adolescents or adults. In a patient with sufficient respiratory effort, preoxygenation with maximal passive oxygen delivery (i.e., a non-rebreather mask) for 2 to 3 minutes may be sufficient in healthy children. However, patients requiring emergency intubation often have compromised pulmonary function or respiratory effort and may benefit from a more prolonged preoxygenation time. A technique of using vital capacity breaths for more rapid preoxygenation will be difficult to accomplish in children who may not be cooperative with this technique. Even with appropriate preoxygenation, a significant percentage of young children will desaturate during intubation attempts, particularly those with underlying respiratory illness or when intubation attempts are prolonged (Fig. 156.4).[15] Due to children's propensity to quickly drop oxygen saturations during intubation attempts, we recommend utilizing apneic oxygenation using nasal cannula during RSI. A number of nasal cannula flow rates for apneic oxygenation in children have been proposed.[8] As a simplified approach in infants and children, we recommend 1 to 2 L/min/year of age to a maximum of 15 L/min for children to help prevent the drop in oxygen saturation during the apneic period of RSI. Positive-pressure ventilation with bag-mask device should be considered at the first sign of desaturation, and we recommend it be initiated when oxygen saturation drops below 95%. Once oxygen saturation has improved, additional attempts can begin.

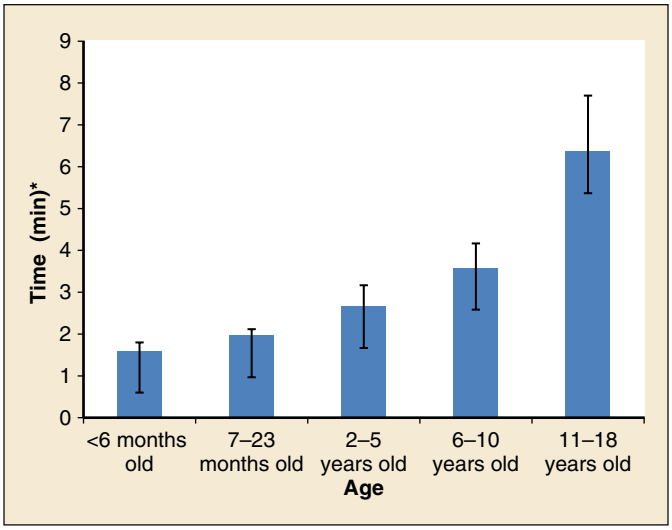

Fig. 156.4 Time to desaturation in preoxygenated healthy children. (American Society of Anesthesiologists Classification 1 [ASA 1] patients undergoing elective surgery.) *Time from administration of neuromuscular blocking agent (NMBA) to desaturation to 90%, with no ongoing supplemental oxygen or respiratory support. (Adapted from: Patel R, Lenczyk M, Hannallah RS, et al. Age and the onset of desaturation in apnoeic children. *Can J Anaesth*. 1994;41:771-774.)

Positioning

As described previously, age-appropriate positioning is required during laryngoscopy and endotracheal intubation. Alignment of the oral, pharyngeal, and tracheal axes greatly facilitates visualization. In neonates and infants, a shoulder roll is often required; toddlers and school-age children are usually best aligned in the neutral recumbent position; and adolescents will often require elevation of the head similar to adults.

Placement of Tube

When performing direct laryngoscopy, straight blades placed beneath the epiglottis are preferred in infants and younger children to lift the larger pediatric epiglottis and bring the vocal cords into line of sight. Alternatively, an appropriately sized laryngoscope blade placed into the

TABLE 156.3 Common Post-Intubation Sedation/Analgesia in Children

Medication	Bolus Dosing	Drip	Comments
Lorazepam	0.05 to 0.1 mg/kg		Long-acting sedative/amnesic Often used in combination with analgesic
Midazolam	0.5 to 2 mg/kg	0.05 to 0.1 mg/kg/h	Short-acting sedative/amnestic Often used in combination with analgesic
Fentanyl	1 to 2 mcg/kg	1 to 3 mcg/kg/h	Short-acting analgesia Preserves hemodynamic stability
Morphine	0.05 to 0.1 mg/kg	0.05 to 0.1 mg/kg/h	Longer-acting analgesic May cause histamine release
Ketamine		0.1 to 1 mg/kg/h	Bolus dosing not recommended for prolonged ongoing sedation May be helpful in status asthmaticus
Propofol	0.5 to 1 mg/kg	25 to 250 mcg/kg/min	No analgesic properties Prolonged infusion in children can lead to profound acidosis and rhabdomyolysis
Dexmedetomidine		0.2 to 0.7 mcg/kg/h	Associated with significant cardiovascular effects (including bradycardia, hypotension, AND hypertension) Limited data on safety in infants (<5 kg)

vallecula can engage the hyoepiglottic ligament to elevate the epiglottis in most pediatric patients.[7] In younger children, emergency clinicians may tend to insert the laryngoscope blade too deeply, resulting in retroglottic or esophageal placement and unnecessary airway trauma. With this in mind, emergency clinicians should start the intubation procedure by placing the laryngoscope blade just to the base of the tongue and lift up to view the airway anatomy. Identify structures progressively, first directly identifying the base of the tongue and the epiglottis prior to insertion of the straight blade underneath the epiglottis or the curved blade into the vallecula to visualize the vocal cords. If no laryngeal structures are identified due to inadvertent deep insertion, the blade should be slowly withdrawn under visualization, and the cords or the epiglottis will often fall into view.

Given the superior position of the larynx in children, use of a stylet is often helpful in guiding the ETT into the glottic opening. This is particularly true during videolaryngoscopy, where the delivery of the endotracheal tube to the glottic opening is often performed under *indirect* visualization. Given the relatively small size of the oropharyngeal cavity, the tube should be placed from the 3 o'clock position, often with an assistant applying lateral traction to the child's lip to provide more room for tube insertion.

There is a tendency to insert the ETT too far in the young child in whom the distance from the vocal cords to the tracheal carina may just be a few centimeters.[16] Right mainstem intubation is difficult to appreciate on auscultation, particularly in the infant whose breath sounds are easily transmitted throughout the chest. Using a pediatric resuscitation resource as described earlier, or the formula (tube size × 3 = depth [cm] at the lip) can approximate insertion depth. Under direct visualization, the vocal cord markers on the tube should rest just below the glottic opening, or the cuff observed to pass just beyond the vocal cords.

Post-Intubation Management

Optimally, the ETT should be visualized to pass into the glottic opening. If vocal cords are not seen, passage of the tube below the epiglottis and above the posterior cartilages indicates ETT placement into the glottic aperture, but should be subsequently assessed clinically in conjunction with other confirmatory tests. Visible chest wall rise, auscultation of breaths sounds in both axillae, absence of gurgling noise in the epigastrium (i.e., exclusion of esophageal placement), and improving oxygenation are all used to confirm tube position. However, end-tidal carbon dioxide ($ETCO_2$) detection, either with a colorimetric device or capnography, is the most reliable and accurate measure of correct tube placement. Waveform capnography is preferred for monitoring pediatric ventilation and for determination of correct airway placement.

If waveform capnography is not available, then pediatric colorimetric $ETCO_2$ detectors are available for children weighing less than 15 kg in whom smaller tidal volumes may result in less apparent detection using adult-sized devices. Detection of $ETCO_2$ confirms the ETT is in the tracheobronchial tree; however, it does not discriminate between intubation of the trachea and the right mainstem bronchus. In patients in cardiac arrest, CO_2 delivery to the lungs is markedly reduced and gas exchange is compromised, therefore CO_2 may not be detectable. Here, an esophageal detector device or bulb may be used to confirm tracheal placement in children who weigh more than 20 kg. Point-of-care ultrasound has been introduced as a real-time modality for detecting bilateral lung sliding, diaphragm excursion, and cuff position in the trachea.[16] However, a chest radiograph is still considered standard of care to confirm appropriate position.

Even small movements of the child's head can result in accidental displacement of the tube: flexion of the neck can advance the tube into a mainstem bronchus, whereas neck extension can lead to unintended extubation. After intubation, the ETT should be secured and, as much as is possible, the child's head and neck kept still. Most sedatives used for induction will wear off before rocuronium; therefore post-intubation sedatives should be administered after the airway has been secured. Table 156.3 lists common drugs used for post-intubation sedation in the pediatric population. Decisions regarding continued neuromuscular blockade can be made based on clinical context, including desire for return of clinical examination, ventilation management strategies, need for additional procedures or diagnostics studies, and need for interfacility transfer.

Video Laryngoscopy

Video laryngoscopy is an emerging approach to pediatric airway management. Much as in adults, data support improved laryngeal views with video laryngoscopes, with particular benefit in cases where there is difficulty visualizing the vocal cords, or Cormack-Lehane airways classified as grade 3 (only epiglottis seen) or grade 4 (neither epiglottis nor glottis seen). In addition, video laryngoscopy allows for shared

TABLE 156.4 Video Laryngoscopy Devices for Use in Pediatrics

Device	Description	Monitor	Disposable	Recording	Sizes
C-MAC	Traditional Miller and Macintosh shaped blades Allows for direct or indirect (video projection) laryngoscopy	7″ LCD monitor or 2.4″ pocket monitor	Reusable blades or disposable blades	SD card in 7″ monitor Pocket monitor also allows recording	Miller (size 0, 1, 2) Macintosh (size 0, and 2 to 4) D-Blade (pediatric and adult sizes)
GlideScope	Blades with 60-degree angulation Different models GVL, AVL (advanced video technology) GlideScope Go (handheld)	7″ LCD monitor or 3.5″ portable screen	Reusable blades Video batons with single use blades	DVR or USB depending on model	Newly available Miller 0 and 1 blades GVL Blades (size 0, 1, 2, 2.5, 3, and 4) Macintosh blades (size 3 and 4)
Airtraq	Different models Disposable blade with reusable optics Fully disposable optical laryngoscope, no electronics Channeled device (provides guide for ETT to pass around curvature of airway)	Direct view eyepiece or 2.6″ camera hood with wi-fi capabilities	Disposable single-use devices Reusable optics with disposable blades available in adult sizes only	Phone adapter or wi-fi camera	Size 0 (infant) Size 1 (pediatric) Size 2 (small) Size 3 (regular)
King Vision	Handheld videolaryngoscope, disposable channeled and unchanneled blades	2.4″ LCD display	Reusable display and video adapter, disposable blades	Video output capability, no internal recording	Size 1 (unchanneled) Size 2 and 3 (channelled and unchanneled)

viewing by multiple providers, which permits real-time guidance and supervision during tracheal intubation. Currently, data on the use of video laryngoscopy in pediatric patients are largely limited to the anesthesia literature or performance in simulated scenarios, although emergency medicine studies focused on use in children are emerging. Data consistently show that video laryngoscopy improves visualization, and newer data suggest it may also improve first-pass success.[18,19] Importantly, video laryngoscopy has been shown to have a faster learning curve than direct laryngoscopy. This may be particularly important for airway management in children, given the infrequency with which pediatric airway management is performed in the ED.

Video laryngoscopes for use in pediatrics are becoming increasingly available. Many are smaller adult models, which permit use in older children. Currently, there are a limited number of devices available with a complete range of sizes that allow for use across all pediatric ages, from neonates to adolescents. There are unique advantages, potential drawbacks, and subtleties in technique for using each (Table 156.4). The decision regarding which device to use is ultimately based on availability, operator preference, operator experience, and patient-specific attributes that may favor a given approach.

Airway Rescue Devices for Children

The overall success rate for advanced airway management in children is more than 99%, so the need for rescue device use is fortunately rare. Nonetheless, it is imperative to have a contingency plan for circumstances in which a provider cannot secure the airway. Bag-mask ventilation is a critical, and often underestimated, skill for establishing adequate oxygenation and ventilation in pediatric patients. A recent retrospective study on nontraumatic out-of-hospital pediatric cardiac arrest found improved survival to hospital discharge among children who received BMV by emergency medical services (EMS) compared to children who received either endotracheal intubation or supraglottic device (SGD).[20] Additionally, a study of children with in-hospital cardiac arrest found no difference in survival to hospital discharge among children receiving either ETI or BVM.[21] Alternative strategies to manage the airway when intubation cannot be accomplished using traditional techniques include SGDs or optical approaches to improve glottic visualization.[22,23] SGDs have been demonstrated to be a reliable way to establish oxygenation and gas exchange in the normal and difficult pediatric airway, as well as during resuscitation. First-generation devices have been used in anesthesia for decades. Newer, second-generation devices often include a channel that allows gastric decompression. In addition to the gastric channel, some current SGDs have alternative construction that may be advantageous in pediatrics.[24] For example, the Air-Q does not have aperture bars and uses a shorter wider tube to allow passage of an ETT through the lumen. The I-gel uses a thermoplastic elastomer that molds to the airway as it warms from body temperature. This allows a tighter seal and avoids complications related to cuff hyperinflation.

In most cases, SGDs are easily and rapidly placed, with more than 90% success rate on first attempts; devices sized for neonates and young infants are the most difficult to place. Placement technique is similar to adults with two potential differences: (1) some studies have demonstrated improved placement success and fewer complications when using a rotational approach with traditional laryngeal mask airways (LMAs); and (2) insertion of the SGD with the cuff partially inflated may facilitate placement and help it mold to the shape of the pharynx. SGDs are available in all sizes from neonatal to adolescent ages but data are limited on their use in emergency settings. The Combitube is not recommended for those under 4 feet tall.[25,26]

Pharyngeal sealers, also called *esophageal blockers,* are double-balloon devices in which the tip is placed into the upper esophagus, and ventilation occurs between one balloon occluding the proximal esophagus and another occluding the airway above the glottis. In small children, laryngeal tubes (and laryngeal mask airways) may cause folding of the epiglottis, leading to iatrogenic airway obstruction and

significant air leaks, requiring repositioning or another modality to secure the airway.

A number of pediatric devices beyond video laryngoscopes are available to facilitate visualization and intubation in cases of difficult airways. Flexible fiberoptic scopes can be effective, although extensive experience is required, and young children may not be cooperative with awake approaches. This approach is most commonly used by anesthesia or otorhinolaryngology, often in the operating room. Similarly, fiberoptic stylets are available in pediatric sizes to facilitate visualization with intubation. As with video laryngoscopes, gaining experience with the technique for a given device prior to use in the stressful scenario of a difficult or failed airway is critical.

Pediatric Surgical Airway Techniques

In the rare case of the "can't intubate, can't ventilate" child, a surgical airway represents the final airway option. This can occur if direct/video laryngoscopy has failed and the emergency clinician is unable to maintain oxygenation and ventilation via BMV or a rescue device, such as an SGD. In this case, direct access to the airway through the neck is the only option. Surgical techniques are challenged by limited optimal visualization or palpation of anatomic landmarks in infants and young children; therefore, we recommend needle cricothyrotomy in these children.

Experience in surgical airway techniques is limited in small children, with most of the published literature representing case reports, operating room experience, or animal studies. Needle-based rescue procedures should be considered an "oxygenation" strategy rather than a "ventilation" strategy, because progressive hypercarbia will inevitably ensue, limiting the utility of this technique for long-term use. Animal models suggest that a needle cricothyroidotomy will provide approximately 30 to 45 minutes of adequate oxygenation.

To perform a needle cricothyroidotomy, the provider places a large needle catheter (e.g., 14-gauge) through the anterior neck into the airway, ideally entering through the cricothyroid membrane. However, difficulty identifying landmarks by palpation or even ultrasound in young children with short, adipose-rich necks may make determination of the exact level of airway entry difficult. The needle is then removed, and the catheter can be connected to the adaptor from a 3.0-mm ETT, which is then connected to a standard bag device. If a 3.0-mm ETT is not available, an adaptor from a 7.0-mm ETT can be placed into a 3-mL syringe with the plunger removed; this can then be attached directly to the catheter. The bag is then squeezed to provide oxygen delivery, allowing prolonged time between breaths for the passive exhalation phase. Alternatively, commercially available oxygen tubing set-up (e.g., ENK modulator, Cook Inc.) can be used with oxygen flow set at 1 L/min for every year of age. These techniques are preferred to true "jet" ventilation, which uses a much higher-pressure oxygen source and has a greater potential for iatrogenic injury. Open surgical cricothyrotomy or percutaneous Seldinger-based cricothyrotomy, performed in the same way as in an adult, is reserved for children *in whom anatomic landmarks can be found* and in whom the cricothyroid membrane is larger. The literature does not support a specific age cutoff for needle cricothyrotomy versus surgical cricothyrotomy, but needle cricothyrotomy should be performed when indicated in infants and small children (<6 years of age or older depending on anatomic landmarks).

OUTCOMES

The majority of pediatric intubations performed in the ED are successful. Despite the relative rarity of the procedure, there is significant overlap in the techniques and strategies used in adult airway management. There are a limited number of anatomic and physiologic differences that can be learned and mastered. The cognitive burden associated with the procedure can be overcome by length/size-based systems or readily available electronic applications to allow the clinician to focus on the critical actions necessary to successfully manage the airway.

CHAPTER 156: QUESTIONS AND ANSWERS

1. Which of the following is a correct formula for use in airway management of children?

- **a.** Cuffed ETT size (1 to 10 years old) = 4 + (age in years/2)
- **b.** ETT depth = 3 × ETT size
- **c.** ETT depth = 4 × ETT size
- **d.** Uncuffed ETT size (1 to 10 years old) = (16/age in years) + 4

Answer: B. Correct formulas are as follows:

Uncuffed ETT size = 4 + (age in years/4)

Cuffed ETT size = subtract 0.5 from formula for uncuffed ETT; (4 + (age in years/4)) − 0.5

ETT depth = 3 × uncuffed tube size

2. Which of the following should be used for proper positioning of the pediatric patient during endotracheal intubation?

- **a.** The chin should be tilted and the head lifted.
- **b.** The infant younger than 6 months old should have a towel roll placed under the occiput to align the airway axes.
- **c.** The neck should be placed in slight flexion and the shoulders extended.
- **d.** The patient should be positioned so that a line drawn through the external auditory canal and the anterior shoulder is parallel to the bed.

Answer: D. The relatively large head and occiput of the infant results in slight flexion at the neck when supine, impeding the ability to visualize the glottis. The infant is correctly positioned so that a line drawn through the external auditory canal and the anterior shoulder is horizontal and parallel to the bed. In the infant (<6 months old), this is accomplished by placing a towel roll under the patient's shoulders, elevating the body and overcoming the flexion associated with their large occiput. A head tilt–chin lift may open the airway.

CHAPTER 156: QUESTIONS AND ANSWERS—cont'd

3. Relative to rapid sequence intubation (RSI) in adults, children undergoing RSI:
   - **a.** Are less affected by stomach pressures.
   - **b.** Are more likely to develop bradycardia in response to hypoxia.
   - **c.** Have less missed intubations.
   - **d.** Have less pliable airways.
   - **e.** Maintain their oxygen saturations longer after paralytics are administered.

Answer: B. Children have a higher metabolic rate and thus a higher oxygen demand. In the absence of respiratory support, children will drop their oxygen saturations more quickly than adults due to their relatively greater consumption of oxygen. Hypoxia is the most common reason for bradycardia during intubation in children. The more pliable pediatric thorax combined with children's lower ventilatory reserve make stominflation a significant impediment to effective respiratory support. Pediatric intubations are infrequent and multiple pediatric intubation attempts are more common in children than in adults.

4. Which of the following does *not* characterize the pediatric airway relative to adults?
   - **a.** A straight blade is used to pick up the floppy epiglottis.
   - **b.** Infants may require a shoulder roll to align airway axes.
   - **c.** The airway is more pliable.
   - **d.** The airway is more superior and posterior.
   - **e.** The epiglottis is larger and omega-shaped.

Answer: D. Small infants have a large occiput and a high, anterior airway, which impacts positioning during intubation, often requiring a shoulder roll to align airway axes. The airway is also more pliable and the membranes thinner, necessitating needle cricothyroidotomy for surgical airways in children younger than 10 years old. Blade choice is age dependent, and a straight blade is recommended in young children; this blade lifts the relatively larger epiglottis to visualize the vocal cords.

5. Following the administration of succinylcholine in a 7-year-old boy with respiratory distress, severe masseter spasm is noted. Which of the following medications should be administered to terminate this spasm?
   - **a.** Diazepam
   - **b.** Fentanyl
   - **c.** Repeated dose of succinylcholine
   - **d.** Rocuronium
   - **e.** Thiopental

Answer: D. Masseter muscle spasm is a rare side effect of succinylcholine administration. It primarily occurs in pediatric patients and is typically terminated by the administration of a competitive neuromuscular blocking agent (NMBA), such as rocuronium, vecuronium, or pancuronium. Failure to respond to such therapy should prompt consideration of malignant hyperthermia.

Pediatric Sedation and Analgesia

Huma Shaikh and Corrie E. Chumpitazi

KEY CONCEPTS

- Patients of all ages experience pain, including infants, neonates, and premature babies.
- Oligoanalgesia, the inadequate treatment of pain, has many short-term and long-term consequences: worse patient outcomes, increase in patient's pain threshold, and development of chronic pain.
- Pain management may include a combination of techniques: analgesics, topical anesthetics, local anesthetic injections, oral sucrose in infants, and nonpharmacologic interventions.
- Nonpharmacologic interventions to decrease pain or anxiety include parental presence; physical measures, such as heat or cold therapy and splinting for musculoskeletal injuries; and behavioral or cognitive measures, such as distraction and play therapy.
- Topical anesthetics are recommended to decrease the pain of minor procedures, such as venipuncture or IV cannulation.
- Techniques for decreasing the pain of intradermal injections include topical agent prior to the intradermal injection; slowly injecting warmed, buffered local anesthetic solution from within the wound with the smallest gauge needle possible; and limiting the number of needle punctures.
- When using large amounts of local anesthetics in small children or infants, calculate the drug dose to avoid toxicity; a 1% solution = 1 g/100 mL or 10 mg/mL.
- Procedural sedation and analgesia (PSA) requires pre-sedation evaluation; sufficient monitoring (during and after the procedure) by qualified individuals capable of dealing with any adverse events that may occur; age-appropriate equipment (including airway equipment) and medications (including reversal agents and advance life support drugs); and discharge criteria for when the patient is fully awake, returns to baseline with normal vital signs, and is able to be discharged in the care of a responsible adult.
- Overall, preprocedural fasting is not necessary for most emergency patients, because large studies show no clinically significant differences with airway complications, emesis, or other adverse effects between groups of patients stratified by their preprocedural fasting status.
- Choice of sedative and analgesic for PSA depends on many variables including patient factors and the procedure to be done. Slow titration of medications can achieve the desired level of sedation and analgesia while minimizing risk of adverse events.

SEDATION

Foundations

Sedation is a controlled reduction of environmental awareness. Sedation is a continuum that begins with minimal, moving to moderate, then deep sedation, and may proceed to general anesthesia.

Definitions[1,2]

- *Anxiolysis* is a state of decreased apprehension concerning a particular situation in which the patient's level of awareness does not change.
- *Analgesia* refers to the relief of pain without the intentional alteration of mental status, such as occurs in sedation. An altered mental state may be a secondary effect of the medications administered for this purpose.
- *Minimal sedation* (e.g., anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive functions and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
- *Moderate sedation/analgesia* (formerly called "conscious sedation") refers to a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Reflex withdrawal from the painful stimulus is NOT considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.
- *Dissociative sedation* is a trancelike cataleptic state induced by the dissociative agent ketamine and characterized by profound analgesia and amnesia, while protective airway reflexes, spontaneous respirations, and cardiopulmonary stability are maintained.
- *Deep sedation/analgesia* describes a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
- *General anesthesia* is a drug-induced loss of consciousness during which patients are not arousable, even with painful stimulation. The ability to independently maintain ventilatory function is usually impaired. Patients require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.
- *Procedural sedation and analgesia (PSA)* are techniques of administering a sedative or dissociative agent, usually along with an analgesic, to induce a state that allows the patient to tolerate painful or unpleasant procedures while maintaining adequate spontaneous cardiorespiratory function. It is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously.

The goal of PSA is to alleviate the anxiety, pain, and suffering associated with medical procedures. PSA is an essential part of emergency medicine practice and part of the core curriculum for emergency medicine training programs. Providers should be prepared to appropriately manage the airway and in rare instances intubate if sedation becomes deeper than expected.

Specific Issues

Preparation

The patient's American Society of Anesthesiology (ASA) physical status classification should be calculated prior to procedure (Table 157.1) and airway assessed, for example, using the Mallampati score (see Chapter 1) to identify potential difficulties. Children with special needs, anatomic airway abnormalities, moderate to severe tonsillar hypertrophy, and current or recent upper respiratory illness present increased risk and require additional consideration.[1,3] ASA classes I and II are considered appropriate candidates for minimal, moderate, or deep sedation.[1–3] Staff are encouraged to consult with appropriate subspecialists (e.g., pediatric anesthesiologist) if there is a question of sedation adverse events because of an underlying medical/surgical condition (e.g. Pierre Robin syndrome). Those aged less than 3 months or with weight less than 5 kg are at increased risk for sedation adverse events.

There should be at least one provider, in addition to the provider performing the procedure, who is responsible to monitor appropriate physiologic parameters and assist in any needed supportive or resuscitation measures.[1–3] Pulse oximetry and capnography readings should be continuously monitored; depth of sedation, heart rate, blood pressure, and respiratory rate should be recorded at regular intervals. Although there are scales for assessing the depth of sedation in pediatric patients, continuous monitoring is more important than any specific measurement on a sedation scale. Although there is no evidence of benefit in young healthy individuals, cardiac monitoring has been shown useful in those with a cardiac history and older patients. Thus, we recommend continuous cardiac rhythm monitoring, especially for high-risk patients (e.g., preexisting cardiovascular disease or a history of dysrhythmias) or high-risk procedures (e.g., cardioversion).

Providers administering pediatric procedural sedation should have training and skills in airway management and be ready to rescue the patient from a deeper level than intended for the procedure, since it is common for children to pass easily into a deeper level of sedation. In addition to monitoring equipment and oxygen, age-appropriate suction, bag-valve-mask, and intubating equipment should be available and readied prior to administering medications. The SOAP-ME mnemonic provides an equipment checklist for sedation[3]:

Size-appropriate suction catheters (connected, checked, and with suction turned on)

Oxygen supply (connected to bag and turned on)

Airway: Size-appropriate airway equipment (appropriate size mask and intubation supplies)

Pharmacy: Advanced life support medications and antagonists

Monitors: Size-appropriate oximeter, end-tidal carbon dioxide monitor, and blood pressure cuff

Equipment or drugs for a particular case

Children over age 4 can benefit from simple information about what to expect for their procedure. Explaining the steps, as well as what they might see or feel, being shown the medical supplies (e.g., irrigation solution), and offering realistic options for their procedure help them feel in control. Similarly, parents should be prepared for where to sit and how they can assist with positioning or distraction. A child's ability to control behavior and cooperate for a procedure depends on chronologic age and cognitive/emotional development.

TABLE 157.1 American Society of Anesthesiologists Physical Status Classification

Class	Description	Examples	Sedation Risk
I	Normal and healthy patient	No past medical history	Minimal
II	Mild systemic disease without functional limitations	Mild asthma, controlled diabetes	Low
III	Severe systemic disease with functional limitations	Pneumonia, poorly controlled diabetes mellitus, hypertension or seizure disorder	Intermediate
IV	Severe systemic disease that is a constant threat to life	Advanced cardiac disease, renal failure, sepsis	High
V	Moribund patient who may not survive without procedure	Septic shock, severe trauma	Extremely high
VI	A declared brain-dead patient whose organs are being removed for donor purposes		

Preprocedural Fasting

The ASA has guidelines for preoperative fasting in healthy patients of all ages undergoing elective procedures. In patients undergoing PSA in the emergency department (ED), the evidence indicates that preprocedural fasting does not decrease the risk of emesis or aspiration, as noted in the American College of Emergency Physicians (ACEP) clinical policy.[1,2] Recent studies in pediatric patients do not find any evidence of association between vomiting and shortened fasting time, and no patients were found to have aspiration.[4] Therefore, adherence to the ASA preoperative fasting guidelines for procedures is not necessary in ED patients undergoing PSA.

Supplemental Oxygen and Capnography During Procedural Sedation and Analgesia

Use of supplemental oxygenation has been shown to decrease the incidence of desaturation in pediatric patients from 17% to 10%, although it may delay the recognition of hypoventilation or apnea. Oxygen desaturation and delay in assisted ventilation events can be significantly reduced with the use capnography.[5] Close capnography monitoring can detect hypoventilation early, prior to a drop in pulse oximetry, irrespective of use of supplemental oxygen.[3] ACEP and AAP clinical policy recommend capnography be routinely used to monitor ventilation in children undergoing PSA.[1–3]

Specific Medications

Table 157.2 details specific PSA sedative agents commonly used in infants and children. Patient age, preexisting conditions, and anticipated level of pain or anxiety should guide choice of sedative. Providers should administer drugs by slow intravenous (IV) titration to decrease the risk of adverse events, including hypotension and respiratory depression. For intranasal medications or nitrous oxide use, employing a Child Life specialist or the parents to assist with

TABLE 157.2 Commonly Used Sedatives for Procedural Sedation in Children and Infants

Sedative[a]	Route	Dose[b]	Usual Dose[c]	Maximum Dose	Onset	Duration	Side Effects	Advantages/Comments[a]
Dexmedetomidine	IN	2–4 mcg/kg/dose	3 mcg/kg/dose	200 mcg (100 mcg/nare)	30 min	60–90 min	Decreased HR and BP	Contraindication with heart block, severe renal or hepatic impairment or use of beta blockers
Etomidate	IV	0.1–0.3 mg/kg	0.2 mg/kg PSA	0.4 mg/kg	<1 min	3–10 min	Pain on injection, myoclonic movements, adrenal insufficiency (prolonged use)	Minimal CV/respiratory depression
Ketamine[d]	IV	1–2 mg/kg initial (repeat 0.5–1 mg/kg for longer procedures)	1.5 mg/kg initial PSA		1 min	15 min	Sympathomimetic effects (↑HR, ↑BP) Nausea, vomiting Emergence reaction Laryngospasm (rare)	Warn parents of nystagmus as an expected effect. Has analgesic effect CV/respiratory stability bronchodilator (use in asthmatics) Battlefield use/disasters
Ketamine	IM	4 mg/kg	4 mg/kg 2 mg/kg if <2 years old		5 min	30 min	(Same as above) Higher risk of nausea	(Same as above)
Ketamine	IN	3–9 mg/kg			10 min	60 min	(Same as above)	(Same as above)
Midazolam[e]	IV	0.05–0.1 mg/kg (6 months to 5 years old or adult) 0.025–0.05 mg/kg (≥6 years old) Give slowly 1–2 mg over ≥ 2 min and titrate to effect	If giving with fentanyl, may dose at 0.02 mg/kg	0.6 mg or 6 mg if ≤5 years old and 10 mg if >6 years old	5 min	30 min	Paradoxical agitation, vomiting, coughing, hiccups, dizziness, respiratory depression, apnea so use lower dose if given with opioids or respiratory depressants	Protective in seizure patients ↓ ICP, CBF, ↓ LV filling pressure may benefit cardiac patients Mild CV effects unless hypovolemic Reversed by antagonist flumazenil
Midazolam	IN	0.2–0.5 mg/kg	0.2 mg/kg	10 mg	<10 min		(Same as above)	(Same as above)
Pentobarbital[f]	IV	1–6 mg/kg	1–2 mg/kg initial, repeat 3–5 min to desired effect or max dose	100 mg/dose	1–2 min	15–60 min	CV/respiratory depression, paradoxical agitation, extravasation can cause tissue necrosis Contraindication: Porphyria	↓ IOP, ↓ ICP , used to treat status epilepticus Use in head injury/neurology patients Can use if malignant hyperthermia

Propofol	IV	0.5–1.5 mg/kg (repeat 0.5 mg/kg every 3–5 min for longer procedures)	Variable, may be 1 mg/kg	None	<1 min	5–15 min (mean 8 min)	CV/respiratory depression Use with caution if shock/low BP/impaired cardiac function Caution if allergy to eggs, soybean oil, EDTA[g]	Rapid onset/recovery No dose change if renal or liver disease Can use if malignant hyperthermia
Nitrous oxide	Inhalation	Dose is 30%–70% mixture	Commercially available in 50%:50% mixture	70%	1–2 min	15–20 min	Contraindications: Trapped air (bowel obstruction, pneumothorax, emphysema, air emboli)	Need a scavenger system and proper ventilation, potential for abuse, chronic exposure may have adverse effects

[a]Other agents used for sedation, e.g., DPT (meperidine [Demerol], promethazine [Phenergan], and chlorpromazine [Thorazine]) IM should be avoided because there are better, newer agents for sedation with fewer side effects. Chloral hydrate has been used in the past but is used infrequently at present because there are other better options.

[b]Doses will vary with the individual patient; these are some generally recommended starting doses. Some patients will need greater than the typical maximum dose, whereas others may be sedated with less than the usual dose. It is best to titrate the dose in all patients.

[c]Be especially cautious in at-risk patients. At-risk patients include those patients with significant heart disease, including heart failure or pulmonary hypertension, liver disease, renal failure, and patients at the extremes of age (infants, particularly neonates and the geriatric patient). It may be prudent in these patients, to "start low and go slow."

[d]Ketamine's effect on ICP is discussed in the text. Previously ketamine was thought to be contraindicated if there was an increase in ICP. However, recently, this concept has been challenged. If ketamine is given PO or PR, higher doses are needed with less predictable effect and increased side effects so PO and PR routes are not recommended.

[e]Midazolam may be given by several routes including IV, IM, IN, PO, and PR. The PO and especially PR routes of administration have more variable absorption and effects, so they are not commonly used.

[f]Pentobarbital can be given PO or PR or IM, but onset and duration are longer with more variable effect, so IV is preferred.

[g]Although the manufacturer's labeling lists egg allergy as a contraindication, available studies (mostly retrospective) and an American Academy of Allergy, Asthma, and Immunology statement have suggested that propofol may be used safely in soy- or egg-allergic patients (AAAAI [Lieberman 2015]; AAAAI 2019; Asserhoj 2016; Dziedzic 2016; Murphy 2011). In patients with more severe soy or egg allergy, some experts recommend the use of an alternative anesthetic or a small trial dose of propofol prior to full dose administration (Sicherer 2020).

BP, Blood pressure; *CBF,* cerebral blood flow; *CV,* cardiovascular; *EDTA,* ethylenediaminetetraacetic acid; *HR,* heart rate; *ICP,* intracerebral pressure; *IM,* intramuscular; *IN,* intranasal; *IOP,* intraocular pressure; *IV,* intravenous; *LV,* left ventricular; *PO, per oz.* (by mouth); *PR,* per rectum; *PSA,* procedural sedation and analgesia; *RSI,* rapid sequence intubation.

distraction, music, or other cognitive behavioral modalities may be advantageous.

Propofol. Propofol has several advantages for PSA; it has a rapid onset in 30-60 seconds, is short acting, and has antiemetic properties. Its side effects include hypotension and respiratory depression. However, studies have shown safe administration in the ED for sedation by physicians who are skilled in airway management and resuscitation of patients that may enter deeper sedation or respiratory distress.[6] Although the dosing of propofol varies from 0.5 to 2 mg/kg, an initial dose of 0.5 to 1.0 mg/kg should be administered and titrated to effect with additional doses, usually in increments of 0.5 mg/kg.

Ketamine. Ketamine, a dissociative anesthetic, has sedative, amnestic, and analgesic properties. Ketamine maintains cardiovascular and respiratory stability, has minimal respiratory depression, and maintains protective airway reflexes in patients with spontaneous respirations. Ketamine's sympathomimetic effects include increased blood pressure, heart rate, cardiac output, and bronchodilation, making it the preferred sedative in patients with asthma.

Apnea is rare with ketamine (0.8% incidence), but has been associated with very high doses, rapid administration, and co-administration with narcotics or other respiratory depressants. Ketamine increases salivary secretions, which may increase the incidence of laryngospasm, especially in oral procedures; however laryngospasm can typically be resolved with simple airway maneuvers.[7] Laryngospasm is usually transient and responds to repositioning of the head, supplemental oxygen administration, gentle suctioning if secretions are the irritant, and positive pressure ventilation with a bag-valve mask. Although rarely needed, the use of a paralytic at lower doses than required for intubation (e.g., succinylcholine given at 10% of a paralytic dose) has been shown to break laryngospasm when the above measures fail. Rapid sequence intubation is rarely needed, but a last resort option to treat laryngospasm.

Ketamine may be given intravenously, intramuscularly, per os (by mouth; PO), or intranasal (IN). For IV administration in pediatric patients, initial doses range from 1.0 to 2.0 mg/kg, with further bolus doses of 0.5 to 1 mg/kg titrated to desired effect. Intramuscular (IM) dosing is an option when IV access is unobtainable; dosing ranges from 4 to 5 mg/kg. The disadvantages of IM ketamine include a higher rate of vomiting, longer recovery time, and lack of IV access in the event of complications requiring IV medication administration (e.g., paralytics). IN ketamine can be used in dosing ranges from 3-9 mg/kg/dose with onset of action between 5 and 10 minutes. As with all intranasal medications, the optimal intranasal dose per nare is 0.5 to 1 mL.[8]

Use of Ketamine in Patients With Head Injury. Multiple studies have dispelled the myth that ketamine increases intracranial pressure (ICP). Ketamine may even have beneficial effects on the brain, including protection against seizures, cerebral ischemia, and secondary brain injury related to hypotension.[9]

Ketamine Recovery Agitation: Use of Benzodiazepines. Emergence reaction or recovery agitation refers to agitation (which may include floating sensation, vivid pleasant dreams, nightmares, hallucinations or delirium) that can occur after waking up or emerging from ketamine. Pediatric studies have not demonstrated benefit in routine use of benzodiazepines to prevent recovery agitation, likely due to their own adverse effects; although rare, they can cause paradoxical agitation. A large pediatric study showed no significant difference in the report of agitation in patients receiving ketamine and benzodiazepine versus ketamine alone.[10] As no pediatric studies to date have shown benefit, we do not recommend that midazolam be routinely given as an adjunct to ketamine in children. However, when recovery agitation occurs, children can be treated with midazolam (0.03 mg/kg; up to a maximum of 5 mg for ages 6 months to 5 years old, or a maximum cumulative dose of 10 mg for children greater than 5 years old).

Emergence reactions occur more frequently in patients greater than 16 years of age, females, shorter operative procedures, large doses, and individuals with psychiatric disorders. Providers should consider an alternate agent or ketamine plus midazolam for older teens and children with psychiatric illness; schizophrenia is an absolute contraindication. Children typically emerge from the sedated state in the format that they achieve sedation; all children, but teenagers especially, may benefit from the use of positive visualization, music, massage, or other distraction techniques in preparation for sedation.

Use of Anticholinergics With Ketamine. Ketamine stimulates tracheobronchial and salivary secretions. However, studies have shown that the co-administration of anticholinergic medications is associated with an increase in the odds of adverse events.[9] Providers may consider anticholinergics for children undergoing an airway examination (e.g., fiberoptic laryngoscopy) to improve visibility, or in patients with clinically significant hypersalivation or an impaired ability to mobilize secretions, but it should not routinely be used.

Glycopyrrolate is the preferred anticholinergic over atropine; it is a more potent anti-sialagogue and has fewer tachy-dysrhythmias. Unlike atropine, glycopyrrolate does not cross the blood brain barrier, so has no central nervous system (CNS) side effects. CNS side effects of atropine range from drowsiness to coma and include headache, nervousness, insomnia, excitement, dizziness, disorientation, hallucinations, and ataxia. Headache is the only CNS side effect listed for glycopyrrolate.

Use of Antiemetics with Ketamine. Vomiting with ketamine sedation in children is common.[10] Vomiting usually develops during recovery, when patients are alert and can clear their airways. Slow IV administration over several minutes may mitigate this response. Risk is higher among adolescents and patients receiving high doses or IM administration. Although ondansetron is associated with a small decrease in the incidence of vomiting associated with ketamine sedation in children, ondansetron is also associated with other adverse effects, including QT prolongation and serotonin syndrome. We recommend reserving treatment with ondansetron for patients who develop nausea or vomiting during recovery from ketamine.

Ketofol: Ketamine Plus Propofol. The combination of ketamine with propofol has the potential to provide benefits of both sedatives. The combination allows for lower doses of each medication, which may theoretically minimize adverse effects of either sedative alone. The incidence of hypotension from propofol alone has been shown to be lessened when combined with ketamine.[10,11] However, studies have not shown significant differences in rates of respiratory depression between co-administration versus either sedative alone.[10–12]

Ketamine and propofol (ketofol) can be dosed at 0.5 mg/kg to 0.75 mg/kg for each drug via separate syringes. For short procedures, re-dosing is usually not needed. For longer procedures, if the sedation is wearing off, propofol is usually re-dosed (due to its shorter half-life) at 0.1 to 0.5 mg/kg IV.

Dexmedetomidine. Dexmedetomidine is an effective sedative, anxiolytic and analgesic that does not cause respiratory depression.[13]A loading dose poses the risk of bradycardia and hypotension due to α_2-agonist effects on the sympathetic ganglia.[13] Lack of amnesia can be a concern in certain situations, however, this can be managed with the addition of low dose benzodiazepines. Use of dexmedetomidine in addition to propofol has been shown to decrease cardiovascular, respiratory, and agitation-related adverse effects.[14] Dexmedetomidine can be used intranasally at 2 to 3 mcg/kg/dose (max 100 mcg/nare). An additional 1 mcg/kg/dose may be administered in 30 minutes (max cumulative dose 4 mcg/kg). Contraindications include heart block, severe renal or hepatic impairment, or use of a beta blocker.

Nitrous Oxide

The use of inhaled nitrous oxide in the pediatric emergency setting has been well established for mildly painful or distressing procedures. Although the exact mechanism of action is not known, sedation is likely achieved due to a noncompetitive inhibition of the NMDA-receptor and analgesia via central opioid and opioid-like receptors. Concentrations between 50% and 70% are commonly used, with best effect to side effect ratios seen with inhalation times less than 30 minutes. The combination of inhaled nitrous oxide and IN fentanyl obviates painful and time-consuming IV access insertions and delivers a short recovery time.[15] Another study in a pediatric emergency department found fewer adverse reactions and lower length of stay in patients treated with inhaled nitrous oxide and IN fentanyl, as compared to ketamine and midazolam, with no difference in efficacy between groups.[16]

Post-Sedation Monitoring

Once the procedure is complete and the painful stimuli are removed, patients are at risk of hypoventilation or hypoxia. Monitoring should continue until the patient has met predetermined discharge criteria, which should include normal vital signs and baseline mental and physical status. Once fully awake, patients should be discharged to the care of a responsible adult. Patients should receive predeveloped age-appropriate PSA discharge instructions.

Outcomes

Adequately treating anxiety and pain results in greater procedural success rates; improved patient and caregiver satisfaction; decreased likelihood of the patient developing chronic pain; and improved patient outcomes. Patients at increased risk of adverse events during PSA include the following: the very young or very old; those with comorbidities (e.g., cardiopulmonary diseases) or craniofacial abnormalities (e.g., Down syndrome and Pierre Robin syndrome); the morbidly obese; and those with a higher ASA physical status classification (see Table 157.1).

PAIN MANAGEMENT

Foundations

Pain is defined as an unpleasant visceral or somatic experience or sensation associated with actual, potential, or perceived tissue damage. Pain receptors, termed *nociceptors,* are the free nerve endings of a sensory neuron that convert mechanical, thermal, or chemical stimuli into electrical activity, and initiates an impulse that travels along the neuron and then on to the dorsal horn of the spinal cord (Fig. 157.1). Input from various peripheral nerves and additional sensory stimuli are processed, undergoing integration and modulation in the dorsal horn of the spinal cord, and then transmitted up the spinal cord to the CNS (Fig. 157.2).

There are two types of pain: nociceptive or neuropathic. Nociceptive pain occurs when tissue injury or inflammation stimulates intact pain receptors. Nociceptive pain can be further divided into visceral pain (i.e., of internal organs) and somatic pain (i.e., of the skin, soft tissue, and musculoskeletal structures). Neuropathic pain occurs when there is abnormal functioning or stimulation of damaged sensory nerves. Children with severe developmental impairment may have central neuropathic pain or pain secondary to visceral hyperalgesia.

Neuropathic pain is typically burning, searing, tingling, shooting, or electric in quality. Nociceptive somatic pain is generally described as sharp and well localized. However, pain in deeper structures (e.g., bones, joints, or tendons) can cause achy, diffuse, or radiating pain. Nociceptive visceral pain is typically poorly localized, deep, and aching. Chronic pain is a maladaptive response in which the pain persists after the original injury or illness has resolved.

Specific Issues

Pain Assessment

Patient self-report is the most accurate measure of pain severity. Pain assessments can be used to guide pain management. Pain scales should be age-specific; subjective or self-reporting scales can start being used at 3 years of age, depending on developmental level. Children younger than 3 years old do not have the cognitive or verbal skills needed to communicate levels of pain and, thus, require behavioral or psychological pain scales. Behavioral pain scales rely on the observation of specific child or infant behaviors. Some of the parameters used in behavioral pain scales include facial expressions, consolability, interaction level, limb responses, trunk motor responses, and verbal

responses. Behavioral and physiologic pain scales combine behavioral observations and physiologic parameters (e.g., vital signs) to obtain a score.

The numeric rating scale (NRS) and the visual analogue scale (VAS) are commonly used self-report scales that have been found to have reliability and validity. With the VAS, patients are asked to place a mark on a 10-cm line with descriptors along the line. With the NRS, patients are asked to rate their pain severity on a scale from 0 to 10 or 0 to 100, with 0 being no pain and 10 or 100 the worst pain possible. Horizontal lines are preferred rather than vertical lines because scores are more normally distributed. Patients with poor hand-eye coordination, visual acuity or hand dexterity have difficulty completing the VAS.

As noted, the use of pain scales is based on age. Adolescents and adults can rate their pain using an NRS or VAS. Older children (8 to 11 years old) can also use an NRS or VAS. Younger children (3 to 8 years old) can quantify their pain using a faces pain scale, most commonly, the Faces Pain Scale–Revised (FPS-R)[17]. The Premature Infant Pain Scale (PIPP) is used to assess pain in premature infants. The Crying, Requires oxygen, Increased vital signs, Expressions, and Sleeplessness (CRIES) scale is for infants. The Faces, Legs, Activity, Cry, Consolability (FLACC) pain scale can be used for infants and toddlers. The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) and the Observational Scale of Behavioral Distress (OSBD) may be used for toddlers and young children.

Nonverbal children with neurological impairment, irrespective of age, cannot self-report their pain. The child's caregiver generally knows his or her typical behavior patterns, both at baseline and in response to stimuli or needs. Behaviors that may indicate pain include facial expressions (e.g., grimacing), vocalizations (crying or moaning), inconsolability, increased movement, increased tone or posture (e.g., stiffening or arching), and uncharacteristic or atypical behaviors (e.g., withdrawal, lack of expression, or even laughing). The revised FLACC (r-FLACC) scale is one pain scale designed for use in children with cognitive impairment.

We recommend that all patients have a pain assessment and that the FLACC scale be used in infants to age 3 years of age and those with developmental delay and nonverbal of any age, the FPS-R scale be used in children 3 to 8 years of age, and the NRS used in children 8 years of age or older.

Nonpharmacologic Techniques

Nonpharmacologic interventions should be routinely used with pharmacologic therapy for pain management; this includes physical comfort measures and distraction techniques. Patients should be given basic first measures, including the application of splints or immobilization to stabilize fractures and dislocations; cold packs can help reduce swelling and provide topical analgesia. Hypnosis is accepted by the American Medical Association as a medical therapy and has been used to treat anxiety, as well as acute and chronic pain. Children may be more easily hypnotized compared to adults. Studies indicate that hypnosis is efficacious in pediatric patients for painful medical procedures, headaches, sickle cell disease, chronic pain, and even in cancer treatment.[18] In non-ED settings, acupuncture and acupressure has also been used as a nonpharmacologic method for pain management.

Techniques that distract from pain should be tailored to patients based on their age and developmental stage.[19] Younger children may not yet comprehend verbal reassurance, and thus benefit more from distraction techniques. Distractions include playing games, blowing bubbles or looking at books. Older children can use music, video games, cartoon videos, and books to distract from pain and reduce anxiety. Preliminary research suggests that the high-tech virtual reality that uses multiple sensory inputs may be effective in decreasing pain.

Educated in human growth, development, and psychology, Child Life specialists are invaluable team members of any pediatric ED. Child Life specialists help children effectively cope with illness or injury and the emotional stressors of healthcare and hospitalization through play, preparation, education, and distraction. A study of children undergoing suturing in the ED found that having a Child Life specialist involved lessened the emotional distress for children.[20] Child Life services have resulted in lower self-reported pain in children receiving peripheral IV placement and greater family satisfaction with the ED visit.[21]

Perhaps one of the most important and common nonpharmacologic methods for limiting the anxiety and pain of the child or infant is parental presence during the procedure. Techniques used in infants include nonnutritive sucking, breastfeeding, skin-to-skin contact (kangaroo care), and oral sucrose. Skin-to-skin care is a safe, effective measure to reduce distress in term and preterm neonates based on composite pain scores. Sucrose water (2mL of 25% glucose solution) administered by pacifier or oral syringe has been shown to effectively decrease pain in infants 3 months old and younger undergoing painful procedures. To optimize pain reduction and recovery in infants, a combination of interventions should be used before, during, and after painful procedures.

Pharmacologic Techniques

Topical Anesthetics. Used in conjunction with other methods for decreasing pain, topical anesthetics may decrease the need for systemic analgesics or local anesthesia. Topical anesthetics can be used for venipuncture, IV cannulation, minor surgical procedures, wound care, suturing, and lumbar puncture. Topical anesthetics are painless to apply and do not distort tissue (e.g., for cosmetically important facial lacerations). Needleless, they also avoid the risk of needle sticks.

Different topical anesthetics can be used on intact skin or broken skin (Table 157.3), as well as mucosal surfaces. Vasoconstrictors, such as epinephrine, increase anesthetic efficacy and duration of effect. While traditionally not used at an end-arteriolar blood supply (e.g., fingertip), the risk of irreversible ischemia is very low. Common formulations used for intact skin (e.g., prior to venipuncture) are eutectic mixture of local anesthetics (EMLA), liposome encapsulated lidocaine (LMX), and vapo-coolants. Lidocaine, epinephrine (adrenaline), tetracaine (LET), and cocaine (TAC) can be used for open wounds. Due to the potential for cocaine toxicity, we recommend using other topical anesthetics instead of TAC. EMLA has been associated with methemoglobinemia, seizures, and respiratory depression with excessive skin application. Methemoglobinemia is associated with the prilocaine component of EMLA and is more likely to occur in patients with glucose-6-phosphate dehydrogenase (G6PD) and those on methemoglobinemia-inducing medications.

The use of topical anesthetic agents (e.g., lidocaine and benzocaine) on mucosal surfaces for teething pain or stomatitis has been associated with overdose toxicity, including seizures, respiratory depression, cardiovascular events, and death. These adverse events have led to a recent black box warning for viscous lidocaine, and the U.S. Food and Drug Administration (FDA) recommendation against using over-the-counter (OTC) topical anesthetics for teething pain. We recommend not using topical anesthetics on mucosal surfaces in infants and young children. For teething pain, use a chilled (not frozen) teething ring or have the caregiver gently massage the gums with a finger. Children with stomatitis can be treated with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs).

The topical vapo-coolants or refrigerant anesthetic sprays have similar uses to topical anesthetics (Table 157.4). Two commonly used vapo-coolants are ethyl chloride, which is flammable, and 1,1,1,3,3 pentafluoropropane/1,1,1,2 tetrafluoroethane, which is nonflammable

TABLE 157.3 Topical Anesthetic Agents for Application to Intact Skin or Open Wounds

Topical Agent[a,b,c]	Composition	Sites	Time to Efficacy	Administration	Comments	Contraindications
Eutectic mixture of local anesthetic agents (EMLA)	Lidocaine 2.5% Prilocaine 2.5% 1 : 1 mixture	Intact skin	Onset: 60 min Peak: 120 min Max ≤ 4 h Max 1 h in children ≤ 3 months	Apply 5–10 g in thick layer Cover with semiocclusive dressing	Dose[d]: 0–3 months old or <5 kg: maximum 1 g per 10 cm^3 3–12 months and >5 kg: maximum 2 g per 20 cm^3 1–6 years and >10 kg: maximum 10 g per 100 cm^3 7–12 years and >20 kg: maximum 20 g per 200 cm^3	Infants EGA <37 weeks, <1 year if susceptible to methemoglobinemia or on methemoglobin-inducing agents (sulfonamides, nitrates, primaquine, others) Use with caution if age <3 months old, heart block, or severe hepatic disorder
Liposome encapsulated lidocaine (LMX)	Lidocaine 4% (LMX4) or 5% (LMX5) (previous name: ELA Max)	Intact skin	Onset: 30–60 min	Apply 2.5 grams in thick layer Cover with semiocclusive dressing	Max dose: 4.5 mg/kg/dose, not to exceed 300 mg/dose	Same as for lidocaine
Lidocaine, epinephrine, and tetracaine (LET)	Lidocaine 4% Epinephrine 0.1% Tetracaine 0.5%	Open dermis	20–30 min	Apply 5 mL to cotton ball, place in wound, cover with semiocclusive dressing, apply gentle pressure to infiltrate tissue		Area of compromised blood supply, or end-arteriolar blood supply
Vapo-coolant (PainEase) (other common vapo-coolant is ethyl chloride)	1,1,1,3,3 pentafluoropropane, 1,1,1,2-tetrafluoroethane (nonflammable and ozone friendly so is preferred over ethyl chloride)	Intact dermis Open dermis	Almost instantaneously, 4–10 s	Hold the spray can 3–7 inches from site, spray for 4–10 s or until blanching occurs	Inexpensive Can use on intact or open dermis (such as, laceration) Should perform procedure quickly since effect wears off rapidly (within 1 min) Can be reapplied	Area of compromised blood supply, insensitive skin cold intolerance or hypersensitivity

[a]Tetracaine, adrenaline (epinephrine), and cocaine (TAC) is a topical anesthetic used on open dermis, but because of the potential toxicity due to the cocaine component as well as for legal and regulatory issues, it has been replaced by other topical anesthetics.
[b]Tetracaine topical (Ametop) has been used in adults and reported in the literature in pediatric patients, but according to Pediatric and Neonatal Lexi-drugs for tetracaine topical under dosing, "Children: safety and efficacy has not been established" so it is not included in this list.
[c]Use of topical anesthetic agents on mucosal surfaces in infants and young children, as for teething pain or stomatitis, has been associated with serious adverse events, including seizures, respiratory depression, and death, so they are not included on this list. The American Academy of Pediatrics (AAP) recommends using a chilled (not frozen) teething ring or gently rubbing/massaging with the caregiver's fingers for teething pain. The U.S. Food and Drug Administration (FDA) recommends against using topical over-the-counter (OTC) medicines for teething pain. Such OTC products may contain up to 20% local anesthetic, such as 20% benzocaine, which is 200 mg/mL. This can be compared with the usual concentration of local anesthetics for subdermal injection for suturing, such as 2% lidocaine, which is 20 mg/mL for a tenfold increase to 200 mg/mL for 20% concentration.
[d]The dose of EMLA® varies by age and weight, with the maximum amount of intact skin in cm^3 over which the cream can be applied and the length of time allowed for skin contact specified.
EGA, Estimated gestational age.

and ozone friendly. A meta-analysis study showed that vapo-coolant spray significantly reduced pain during IV cannulation in comparison to placebo spray or no treatment.[22] To be effective, application should include correct distance 3 to 7 inches from the skin site, a steady spray covering the specific area (about as large as a quarter for a venipuncture or IV cannulation), and adequate spray time for 4 to 10 seconds or until the skin begins to turn white, whichever comes first. Vapo-coolants have also been used to alleviate myofascial pain, muscle pain, and musculoskeletal injury pain. Vapo-coolants have immediate onset. Although the anesthetic effect subsides within a minute, it can be reapplied.

The J tip is a needleless jet injector that uses pressurized gas for the delivery of local anesthetic. J tip lidocaine delivery has been found effective in decreasing the pain of peripheral IV catheter insertion. In one study of neonatal patients in the ED requiring lumbar punctures, jet delivered lidocaine was not found to be more effective in reducing pain than topical anesthetic cream, however, advantages included quick onset of action and increased success rate.[23] Devices used for

TABLE 157.4 Common Local Anesthetics

Local Anesthetics[a]	Maximum Dose[b] (mg/kg)	Onset (min)	Duration[c] (Average) (min)
Amides[d]			
Long Duration			
Bupivacaine (Marcaine)	2	10	200
Etidocaine (Duranest)	3	3	200
Moderate Duration			
Lidocaine (Xylocaine)	4–4.5	5	100
Mepivicaine (Carbocaine)	4–4.5	3	100
Prilocaine (Citanest)	5	5	100
Amides With Epinephrine			
Lidocaine with epinephrine	7	5	120
Mepivicaine with epinephrine	7	5	120
Esters[d]			
Short Duration			
Chloroprocaine (Nesacaine)	8	5	45
Procaine (Novocain)	7	18	40
Long Duration			
Tetracaine (Pontocaine)	1.5	15	200

[a]Use of commercially available brand names does not imply endorsement of any medication or product. They are included because individuals may be more familiar with commercial or brand names than the specific drug or category of drugs.
[b]Maximum dose is based on ideal body weight.
[c]Duration is affected by binding (e.g., ↑ protein binding produces ↑ duration) and concentration (↑ concentration ↑ duration). 2% lidocaine has greater duration than 1% lidocaine.
[d]In case of a true immunoglobulin E (IgE) anaphylaxis, which is very rare, to one class of local anesthetics the other class may be used (e.g., if allergy to esters, then one can use amides and vice versa). If there is an allergy to all "caines" (both amides and esters), then one can use benzoyl alcohol or diphenhydramine. Benzoyl alcohol is preferred over diphenhydramine.
Derived from multiple sources including Berde CB, Strichartz GR. Local anesthetics. In: Miller RD, Cohen NH, Eriksson LI, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:1028–1054.

injection of local anesthetics are often associated with minor local skin side effects (such as, erythema or bruising) and may produce an audible "pop" when used, which could frighten a young child. One study in pediatric patients found that a vibrating cold device showed equal effectiveness in reducing pain and distress during IV cannulation as 4% topical lidocaine cream and is an acceptable alternative due to speedy time to onset.[24]

Local Anesthetics

Local anesthetics reversibly block sodium channels, which inhibits the propagation of nerve impulses (Fig. 157.3). Local anesthetics fall into one of two classes: amides and esters. Amides can be remembered as the prefix before the ending "caine" will have the letter "I" (e.g., lidocaine and bupivacaine). Local anesthetics are also classified by duration

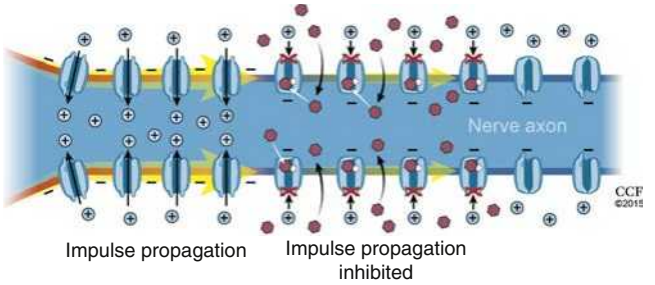

Fig. 157.3 Local Anesthetics Mechanism of Action. Local anesthetics reversibly block sodium channels. (Figure illustration by Department of Medical Art and Photography—Cleveland Clinic and Mr. Dave Schumick with permission.)

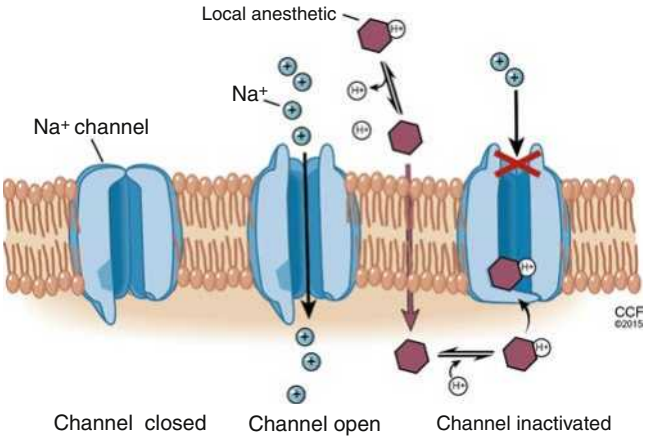

Fig. 157.4 Local Anesthetics Mechanism of Action. Local anesthetics blocks transmission of nerve impulse by binding to the receptor within the sodium channel and inactivating it. *H+*, Hydrogen ion; *Na+*, sodium ion. (Figure illustration by Department of Medical Art and Photography—Cleveland Clinic and Mr. Dave Schumick with permission.)

of action. Local anesthetics that are tightly protein bound to a receptor in the sodium channel (e.g., bupivacaine and tetracaine) have a longer duration of action than less tightly bound anesthetics (e.g., procaine and prilocaine). Greater concentrations of the local anesthetic will also increase the duration of action.

Potency refers to the degree to which the individual local anesthetic blocks transmission in the neural tissue (Fig. 157.4).

When added to a local anesthetic, epinephrine lengthens the duration of the anesthesia, slows systemic absorption, and aids in controlling local bleeding Although the risk is currently being questioned for epinephrine-containing local anesthetics, we recommend generally avoiding in end-arterial fields (e.g., digits) and in patients with vascular pathology (e.g., Buerger's disease or digital vascular injury) who are at high risk for ischemia. Techniques for decreasing injection pain are described in Box 157.1.

The vasoconstrictor reaction is the most common adverse reaction to a local anesthetic. It occurs when an epinephrine-containing local anesthetic is injected into a highly vascular space. The patient suddenly feels a rapid heartbeat and becomes anxious and panicky from rapid absorption of epinephrine. This reaction ends quickly and is not a true allergy.

True immunoglobulin E (IgE)-mediated anaphylaxis to local anesthetics is very rare, especially to the amide class. Reported allergies to amides are more likely to be a reaction to epinephrine or an allergy to one of the preservatives (e.g., methylparaben). There is no cross-reactivity between amides and esters, and they contain

BOX 157.1 Techniques to Decrease the Pain of Local Anesthetics

Use a topical agent prior to the injection
Use smallest gauge needle possible (generally, a 27- to 30-gauge needle)
Use warmed solution: Warmed to 98.6°F–102°F (37°C–39°C)
Inject slowly
Inject into the subcutaneous space, not the dermis
Minimize the number of punctures
Inject from within open wounds, do not inject through the adjacent intact skin
Buffer the local anesthetic: Mix 1% lidocaine with 8.4% sodium bicarbonate solution in a ratio of 9 parts lidocaine to 1 part sodium bicarbonate (Mixing bupivacaine with bicarbonate can cause precipitation of the anesthetic and is not recommended.)

different preservatives. For patients with a known true allergy to lidocaine, a benzyl alcohol solution (made by adding 0.2 mL of 1:1000 epinephrine to a 20 mL vial of normal saline containing 0.9% benzoyl alcohol) can be used. Diphenhydramine is no longer recommended because it is a tissue irritant and can cause local necrosis.

Serious toxicity from local anesthetics is due to their effects on the CNS and to the cardiovascular system (CVS). Early signs of toxicity include numbness or tingling of the lips, metallic taste, muffled hearing, and tinnitus. These symptoms often portend the onset of drowsiness, seizures, status epilepticus, and coma. Direct myocardial depression and pump failure can occur, especially if the patient is on beta blockers or calcium channel blockers; heart block and asystole can also occur. If cardiac arrest is known or presumed to be from local anesthetic toxicity, length of resuscitation should take into consideration time for the negative cardiac effects to wear off. Any of the local anesthetics can have these adverse effects, especially when exceeding recommended doses.

Compared to the amides, the esters have a higher incidence of allergic reactions. Procaine and benzocaine are metabolized to para-aminobenzoic acid (PABA), which has been associated with rare anaphylactic reactions. The metabolites of prilocaine and benzocaine have been associated with methemoglobinemia. Bupivacaine has a higher cardiac toxicity profile than other local anesthetics, but bupivacaine is still widely used and generally safe and effective when used as recommended. In general, the choice of local anesthetic depends more on duration and personal preference than a marked advantage of one specific drug or anesthetic class.

Nerve Blocks. A nerve block is regional anesthesia attained by the injection of a local anesthetic agent near a nerve, nerves, or nerve plexus supplying a particular area. There may be a fairly well circumscribed region of anesthesia (e.g., a wrist or ankle block) or an entire limb, termed *major regional anesthesia.* Nerve blocks are often used to provide anesthesia prior to procedures (e.g., reduction of fractures or dislocations and suturing large lacerations). This approach has the advantage of limiting the amount of lidocaine or other anesthetic needed, decreasing the possibility of reaching toxic levels of the local anesthetic. The use of ultrasound-guided nerve blocks in the ED has been increasing due to the increased safety and efficacy found with sonographic visualization of structures. Although there has been much literature on the use of nerve blocks for adults in the ED, there are relatively few studies dealing with the use of nerve blocks for pediatric patients in the ED.

Complications that can occur with any nerve block include needle breakage (more likely with very small and long needles or if needles are bent to perform the block; e.g., posterior superior alveolar block), needle damage to anatomic structures (e.g., nerves, vessels, viscera, pleura, other structures), neurotoxicity, vascular complications (e.g., hematoma formation, intra-arterial injection), infection, and bleeding. With any nerve block, providers should review the appropriate anatomy (particularly if performed infrequently), be careful not to exceed maximum doses of anesthetics, and calculate the maximum dose based on actual, not ideal, body weight. Mixing lidocaine and bupivacaine will give both a rapid onset and longer duration nerve block.

Nonopioid Systemic Analgesics. Nonopioid systemic analgesics (Table 157.5) include acetaminophen (paracetamol), which has analgesic and antipyretic effects but does not have any anti-inflammatory effects. There is no need for any dosage change for mild renal or hepatic impairment. If therapeutic doses are used and there is no alcohol abuse or preexisting liver disease, then hepatic toxicity is rare. Acetaminophen is an excellent choice for the treatment of mild pain, in combination with opioids for moderate to severe pain, and has several methods of administration, including the IV route. Indications for the IV use of acetaminophen include patients with pain or fever who are unable to take oral medications and those who have impaired gastrointestinal (GI) absorption.

The NSAIDs have analgesic and antiinflammatory properties. NSAIDs inhibit cyclooxygenase (COX)-1 and COX-2, which decreases the synthesis of prostaglandins, thereby elevating the threshold for nociceptor activation. Nonselective NSAIDs inhibit both COX-1 and COX-2. Side effects of COX-1 inhibition include GI bleeding, renal failure, and platelet dysfunction. In pediatric patients, ibuprofen is the NSAID of choice, because it has fewer side effects than other NSAIDs. NSAIDs may be more effective than acetaminophen at reducing pain from inflammation associated with tissue injury.

Aspirin has analgesic, antipyretic, and anti-inflammatory effects. However, aspirin is not recommended in children and infants due to risk of Reye syndrome, a rapid-onset encephalopathy associated with hepatic dysfunction and seizures; for this reason, aspirin should not be used in any individual with chicken pox or flu symptoms.

Opioid Analgesics. Opioids, previously termed *narcotics,* produce analgesia by binding to opioid receptors in the brain, brainstem, spinal cord, and peripheral nervous system. The main adverse effect of opioids is a dose-dependent respiratory depression with blunting of the responses to hypoxia and hypercarbia; this effect is potentiated when co-administered with other sedative medications. Other side effects are primarily GI (e.g., constipation, nausea, vomiting), urinary retention, and pruritus.

There are many routes of administration of opioids. IM is not recommended secondary to injection pain and variable IM absorption. IN administration is useful for quick pain relief in children who have moderate-to-severe pain without established IV access. IN fentanyl has been shown to be effective in treatment of acute pain in children as young as 6 months.[25] IV is used for patients with severe pain and titrated to effect to avoid adverse events.

Morphine and fentanyl are the commonly used opioids used to treat acute and breakthrough pain in pediatric patients. Hydromorphone, though less commonly used, is useful to treat children with chronic pain or opioid tolerance, such as in sickle cell disease. Codeine is a weak opioid that has an increased incidence of side effects compared to other opioids. It is no longer recommended in children because of genetic variability in the metabolism and risk of respiratory depression in fast metabolizers. Meperidine is not recommended due its possible CNS toxicity (e.g., seizures, hallucinations, and psychosis) at therapeutic doses and its risk of serotonin syndrome.

Opioid Prescribing and Use. In 2017, the Department of Health and Human Services declared a public health emergency due to the opioid crisis. Although there is no evidence-based literature documenting

TABLE 157.5 Systemic Analgesics

Systemic Analgesic[d,e]	Route[c,f]	Dose (Pediatric)[a]	Dose (Adult)[b]	Maximum Dose[c]	Formulations and Notes	Comments
Nonopioid[b]						
Acetaminophen (Paracetamol) (Tylenol)	PO	Child/infant 10–15 mg/kg dose every 4–6 h Child 6–11 years old: 325 mg dose every 4–6 h	≥12 years old/ adults 650 mg every 4–6 h 1000 mg every 6 h (maximum 4000 mg daily)	Child single dose 15 mg/kg Total daily dose: Lesser of 75 mg/kg or 4000 mg Not more than 5 doses daily	PO solution or suspension: 160 mg/5 mL, 500 mg/15 mL Tablets/gelcaps: 325 mg, 500 mg Chewable or ODT: 80 mg, 160 mg, 325 mg	Analgesic Antipyretic No anti-inflammatory effect has been associated with liver failure Hepatotoxicity is usually associated with excessive dose Do not exceed maximum daily dose
	PR	10–20 mg/kg dose every 4–6 h	325–650 mg every 4–6 h	Child total daily dose: Lesser of 75 mg/kg/day or 1625 mg/day	80, 120, 325, 650 mg	(Same as above)
Acetaminophen (Ofirmev)	IV	Adolescents >50 kg: 650 mg every 4 hours or 1000 mg every 6 hours	≥50 kg: 650 mg every 6 h or 1000 mg every 6 h	If <50 kg: Single dose 15 mg/kg, total daily dose <75 mg/kg/day ≥50 kg: Single dose 1000 mg daily Total daily dose: 4000 mg	10 mg/mL (100 mL vial)	(Same as above) More expensive, can be used in NPO patients
Ibuprofen (Advil, Motrin)	PO	6 months old to 5 years old: 5–10 mg/kg dose every 6–8 h	≥12 years old/ adults 400–600 mg every 4–6 h or 800 mg every 8 h	<12 years old Single dose: 400 mg Total daily dose: 40 mg/kg up to 1600 mg Adults: Total daily dose 3200 mg	Suspension: 50 mg/1.25mL, 100 mg/5 mL Tablets: 100, 200, 400, 600, 800 mg Chewable tab: 100 mg	Analgesic Antipyretic Anti-inflammatory Side effects: GI bleeding, renal failure, and platelet dysfunction; most side effects occur with the chronic use of nonselective NSAIDs
Ketorolac (Toradol)	IV or IM	0.5 mg/kg dose every 6–8 h	Child >50 kg and adult 15 mg	15 mg/dose Total daily dose: 120 mg	Doses up to 60 mg can be given but are not recommended because doses higher than 15 mg have no greater efficacy but have more incidence side effects	(Same as for ibuprofen) Therapy should not be more than 5 days
Opioids: Oral With or Without Acetaminophen[b]						
Hydrocodone	PO	0.1–0.2 mg/kg dose every 4–6 h Usual dose: 0.15 mg/kg	Child ≥50 kg and adult: 5–15 mg every 4–6 h, usual dose 10 mg	No more than 6 doses/day 60 mg total daily dose	24-h extended-release tablets: 20, 30, 40, 60, 80, 100, 120 mg capsules 12-h extended-release tablets: 10, 15, 20, 30, 40, 50 mg	Weak opioid Preferred over codeine Generally hydrocodone is given in combination with acetaminophen

TABLE 157.5 Systemic Analgesic—cont'd.

Systemic Analgesic[d,e]	Route[c,f]	Dose (Pediatric)[a]	Dose (Adult)[b]	Maximum Dose[c]	Formulations and Notes	Comments
Hydrocodone and acetaminophen[j] (Lorcet, Vicodin)	PO	0.1–0.2 mg/kg dose every 4–6 h (based on hydrocodone component) Usual dose: 0.15 mg/kg	Child ≥50 kg and adult: 10 mg hydrocodone every 4–6 h	No more than 6 doses/day or recommended acetaminophen daily dose, 60 mg hydrocodone total daily dose	Elixir: hydrocodone 10 mg/acetaminophen 300 mg/15 mL Solution: Hydrocodone 7.5 mg/acetaminophen 325 mg/15 mL Tablets: Hydrocodone 2.5 mg/acetaminophen 325 mg Hydrocodone 7.5 mg/ acetaminophen 325 mg Hydrocodone 10 mg/ acetaminophen 325 mg Hydorcodone 5 mg/ acetaminophen 300 mg Hydrocodone 7.5 mg/ acetaminophen 300 mg Hydrocodone 10 mg/ acetaminophen 300 mg	Weak opioid Preferred over codeine Generally hydrocodone is given in combination with acetaminophen
Oxycodone	PO	Age >6 mo: 0.1–0.2 mg/kg dose every 4–6 h Usual dose: 0.15 mg/kg	Child ≥50 kg and adult: Immediate release: 5–10 mg every 4–6 h	Initial: 5 mg/dose oxycodone	Solution: 5 mg/5 mL Concentrate: 100 mg/5 mL Capsule: 5 mg Tablets: 5, 7.5, 10, 15, 20, 30 mg 12-h extended-release tablets: 9, 10, 13.5, 15, 18, 20, 27, 30, 36, 40, 60, 80 mg	Strong opioid Preferred over hydrocodone Generally oxycodone is given in combination with acetaminophen Sustained release form is available but is usually not given for acute pain in the ED setting
Oxycodone and acetaminophen[j] (Endocet, Percocet, Roxicet)	PO	Age >6 mo: 0.1–0.2 mg/kg dose every 4–6 h Usual dose: 0.15 mg/kg (based on oxycodone component)	Child ≥50 kg and adult: Immediate release: 5–10 mg every 4–6 h	Initial: 5 mg/dose oxycodone Total daily dose: Based on acetaminophen component	Solution: Oxycodone 5 mg/ acetaminophen 325 mg/5 mL (Roxicet), oxycodone 10 mg/acetominophen 300 mg/5 mL Tablets: Oxycodone 5 mg/ acetaminophen 325 mg (Roxicet5), oxycodone 2.5 mg/acetaminophen 325 mg, oxycodone 7.5 mg/acetaminophen 325 mg, oxycodone 10 mg/ acetaminophen 325 mg, oxycodone 2.5 mg/ acetaminophen 300 mg, oxycodone 5 mg/ acetaminophen 300 mg, oxycodone 7.5 mg/ acetaminophen 300 mg, oxycodone 10 mg/ acetaminophen 300 mg	Strong opioid Preferred over hydrocodone Generally oxycodone is given in combination with acetaminophen
Opioids: Oral[b]						
Hydromorphone (Dilaudid, Exalgo)	PO	Child <50 kg: 0.03–0.08 mg/kg dose every 3–4 h	Child ≥50 kg and adults; opioid naive: 1–2 mg every 3–4 h	Varies: Depends on whether opioid naive or opioid tolerant	Oral liquid: 1 mg/mL Tablets: 2, 4, 6, 8 mg 12-h Extended release tablets: 8, 12, 16, 32 mg	More potent (×5) than morphine No histamine release and fewer side effects than morphine Sustained release form is available but is usually not given for acute pain in the ED setting

Continued

TABLE 157.5 Systemic Analgesic—cont'd.

Systemic Analgesic[d,e]	Route[c,f]	Dose (Pediatric)[a]	Dose (Adult)[b]	Maximum Dose[c]	Formulations and Notes	Comments
Morphine (Duramorph, Kadian, MS Contin)	PO	Child <50 kg: 0.2–0.5 mg/kg/dose every 3–4 h (immediate release)	Child ≥50 kg and adults: 15–20 mg every 3–4 h		Solution: 10 mg/5 mL, 20 mg/5 mL, 20 mg/mL Tablets: 15 mg, 30 mg 12-h Extended-release tablets: 15, 30, 60, 100, 200 mg 24-h Extended release tablets: 10, 20, 30, 45, 50, 60, 80, 100, 120 mg	Potent opioid Side effect: May cause histamine release (some prefer other opioids for this reason) May be the most commonly use opioid in pediatric patients Sustained release forms available but generally not given for acute pain in the ED
Tramadol (Synapryn, Ultram)	PO	Child ≥ 4 years old: 1–2 mg/kg dose every 4–6 h	Adolescents and adults: 50–100 mg every 4–6 h	Maximum of 100 mg/dose Total daily dose: lesser of 8 mg/kg/day or 400 mg/day	Solution: 5 mg/mL Tablets: 50, 100 mg 24-h extended-release tablets or capsules: 100, 200, 300 mg	Weak opioid; related to codeine; preferred over codeine Less respiratory depression than other opioids Mechanism of action: Central inhibition of norepinephrine and serotonin reuptake, weak affinity for mu receptors
Opioids: Parenteral[b]						
Fentanyl (Abstral, Actiq, Duragesic, Fentora, Lazanda, Onsolis, Subsys)	IV	<50 kg: 1–2 mcg/kg every 1–2 h	Child ≥50 kg and adults: 25–100 mcg/dose every 1–2 h	1–2 μg/kg/dose	Note: Fentanyl is μg or micrograms/kg dose (unlike other opioids which are milligrams or mg/kg per dose), also shorter half-life so given more frequently	More potent (70–100×) than morphine Side effect: Chest wall rigidity with high doses given rapidly More rapid onset and shorter duration than morphine and other opioids
Hydromorphone (Dilaudid, Exalgo)	IV	<50 kg: 0.015 mg/kg every 3–6 h	Child ≥50 kg: 0.2–0.6 mg every 2-4 h	May need higher doses in opioid tolerant patients		More potent (×5) than morphine No histamine release and fewer side effects than morphine
Morphine (Duramorph, Kadian, MS Contin)	IV	<50 kg: 0.05 mg/kg every 2–4 h	Child ≥50 kg and adults: 2–5 mg every 2–4 h	Infants: 2 mg/dose Children 1–6 years: 4 mg/dose Children 7–12 years: 8 mg/dose Adolescents: 10 mg/dose		IM is not recommended because of painful administration, variable absorption, and lag time to peak effect Repeated subcutaneous causes local pain, irritation and induration (see also PO)

[a]Typical doses and maximums are listed. This may not apply to all individuals. Patients differ greatly in their responses to medications, especially opioids. Response may vary due to many factors including age (very young and elderly), previous or chronic exposure to opioids (opioid naive or opioid tolerant), and initial pain severity, so opioids should be titrated to effect.

[b]Use of commercially available brand names does not imply endorsement of any medication or product. They are used because health care providers may be more familiar with brand names than the specific drug name or category or drugs.

[c]There are many routes of administration of opioids, but IM is not recommended, because the injection is painful and has variable absorption and, thus, variable efficacy and unpredictable side effects.

[d]Codeine and meperidine are not included in this table, because they are not preferred and other options are available with fewer side effects.

[e]Oral transmucosal fentanyl is not included in the table, because the fentanyl lollipop was associated with a high incidence of side effects, including nausea, vomiting, and respiratory depression, so it was removed from the market.

[f]Rectal suppositories are available for hydromorphone but are not recommended due to variable absorption.

[g]Other analgesics, such as remifentanil, have been administered for analgesia as part of procedural sedation and analgesia (PSA) but has not yet gained widespread popularity so is not included in the table.

[h]Transdermal patches are available for various medications including lidocaine (Lidoderm), opioids, fentanyl (Duragesic), and buprenorphine (Butrans), but these are generally for chronic pain. They may be encountered in patients with chronic pain, such as cancer patients, but are not generally used for the treatment of acute pain in the ED.

[i]If hydrocodone, oxycodone, or morphine are in the extended release or sustained form, which is for chronic pain, the tablets should be swallowed whole and should not be moistened, dissolved, cut, crushed, broken, or chewed, because this changes the formulation from sustained release to immediate-acting, which can lead to an acute overdose.

[j]Note: Both hydrocodone (Hysingla ER, Zohydro) and oxycodone (Oxecta, OxyContin, Roxicodone) are available in formulations without the acetaminophen component, with the same dosage of hydrocodone or oxycodone, respectively, as for the combinations with acetaminophen. However, they are not frequently prescribed in these formulations without the acetaminophen.

ED, Emergency department; *GI,* gastrointestinal; *IM,* intramuscular; *IV,* intravenous; *NPO, nil per oz.* (nothing by mouth); *NSAID,* nonsteroidal anti-inflammatory drug; *ODT,* orally disintegrating tablets; *PCA,* patient-controlled analgesia; *PO, per oz.* (by mouth); *PR,* per rectal.

a clear superiority of opioid versus nonopioid analgesics, there are multiple adverse effects and consequences for both the individual and the community associated with opioid use, misuse, and abuse. Thus, we recommend that opioids be reserved for more severe pain or pain refractory to other analgesics rather than for routine prescription. If opioids are indicated, they should be given at the lowest effective dose for a limited duration (e.g., 3 days), and the prescriber should consider the patient's risk for opioid use, abuse, or diversion.[26]

Low Dose Ketamine for Treatment of Pain. Low dose ketamine has been successfully used in adults and pediatric patients for the treatment of acute pain.[27] Doses for the treatment of acute pain are lower than those used for sedation and vary. A commonly used dose is 0.15 mg/kg (range 0.1 to 0.2 mg/kg). Higher doses (e.g., 0.3 mg/kg) have been associated with a higher incidence of side effects. Continuous infusions have also been used, in the range of 0.1 to 0.2 mg/kg/h. A randomized control study in children with vaso-occlusive pain crises showed that low dose ketamine had a rapid decrease in pain when compared to morphine.[28] Low dose ketamine was more likely to develop side effects (37.5% vs 3.3% with morphine), with nystagmus and dysphoria being the most common; all side effects were transient and non-life threatening.

Reversal Agents. Naloxone is used for the reversal of opioids effects on the mu receptors (e.g., sedation and respiratory depression). Although the half-life is about 1 hour, the clinically effective duration of action may be much less (e.g., 20 to 60 minutes). Due to longer half-lives of many opioids, re-dosing or an infusion of naloxone is often needed with opioid overdoses. The usual dose for full reversal of opioid intoxication is 0.1 mg/kg/dose with an initial maximum dose of 2 mg. The dose may be repeated every 2 to 3 minutes if there is no response. The IV route is preferred, but intraosseous (IO) can be used if there is no IV line. It may also be given intramuscularly or subcutaneously, but the onset of action may be delayed, especially if there is poor perfusion. Naloxone may be administered intranasally at a dose of 2 mg (1 mg per nare) for adolescents (13 years old and older) and is often given by emergency medical service (EMS) in the field or at home for acute opioid overdoses. Naloxone can also be administered endotracheally at 2 to 3 times the initial IV dose. For reversal of respiratory depression with therapeutic opioid doses, lower doses may be used with an initial dose of 0.001 to 0.005 mg/kg/dose with some recommending 0.001 to 0.015 mg/kg/dose intravenously, intramuscularly, or subcutaneously; the dose is titrated to effect or repeated every 2 to 3 minutes as needed until the desired response is obtained.

Flumazenil antagonizes the action of the benzodiazepines at the gamma-aminobutyric acid (GABA) receptor. It has a half-life of about 1 hour, but the clinically effective duration of action may be much less (20 to 60 minutes). Flumazenil can only be given intravenously. Flumazenil may be given when there is an acute overdose of benzodiazepines which were administered for clinical reasons, and only in a patient who is not benzodiazepine habituated. In individuals who overdose on benzodiazepines, it is likely that they are habituated and on benzodiazepines chronically. In these cases, flumazenil can precipitate benzodiazepine withdrawal with status epilepticus and even death. Thus, except in the acute iatrogenic overdose setting, the use of flumazenil is not recommended. Patients who co-ingest benzodiazepines and tricyclic antidepressants may develop intractable seizures after flumazenil administration. Thus, use of flumazenil should be reserved for patients with an uncomplicated benzodiazepine overdose, no evidence of tricyclic antidepressant use (e.g., no electrocardiogram [ECG] findings and no anticholinergic signs and symptoms), no history of seizure disorder, and no history of benzodiazepine habituation. For benzodiazepine reversal with procedural sedation or anesthesia, the initial dose of flumazenil for infants, children, and adolescents is 0.01 mg/kg (maximum 0.2 mg), which may be repeated after 45 seconds and then every minute up to 4 additional doses. The maximum total cumulative dose is 1 mg or 0.05 mg/kg, whichever is lower. Flumazenil is used infrequently and has a black box warning; we recommend its use only for patients requiring benzodiazepine reversal with procedural sedation or anesthesia (e.g., airway compromise due to oversedation).

Outcomes

There are moral, ethical, legal, and regulatory reasons to adequately treat pain. Oligoanalgesia, the failure to adequately treat pain, continues despite increasing literature demonstrating that pain is too often undertreated. Children and infants, the elderly, individuals with limited cognitive ability, and ethnic and social minorities have a greater risk of oligoanalgesia. The negative consequences of undertreating pain include decreasing the patient's pain threshold and predisposing patients to developing chronic pain syndromes. Inadequate analgesia may lead to harmful physiologic consequences, including an increase in stress hormones and increased sympathetic outflow. This results in an increase in catabolism, myocardial oxygen consumption, production of carbon dioxide, and peripheral vascular resistance, as well as an impaired immune response.

The Joint Commission (TJC) mandates that hospitals adapt a pain management quality improvement program, which includes the measurement, documentation, and therapy for pain. Patient satisfaction and the patient experience are gaining greater importance, and the Centers for Medicare and Medicaid Services (CMS) and the National Committee on Quality Assurance require public reporting of patient satisfaction data for participating health plans. In the future, hospital and physician payment will be based on patient outcomes, as well as patient satisfaction. The positive relationship between adequate treatment of pain and patient satisfaction has been documented for all ages of patients, including children and infants. Eliminating or minimizing the pain of medical procedures can also lead to greater procedural success rates.

CHAPTER 157: QUESTIONS AND ANSWERS

1. When do most adverse events associated with emergency department (ED) procedural sedation occur?

a. During the manipulation or intervention
b. 5 to 20 minutes after the last sedative dose
c. 20 to 30 minutes after the last sedative dose
d. 30 to 60 minutes after the last sedative dose
e. 60 to 90 minutes after the last sedative dose

Answer: b. High-risk times are 5 to 20 minutes after the last medication administration and at the completion of the procedure when there is no longer a painful stimulus, but the patient remains sedated.

2. Which of the following modalities has proven most effective for monitoring patients undergoing procedural sedation?

a. Capnometry or capnography
b. Cardiac rhythm monitoring
c. Continual direct visual observation of qualitative clinical signs
d. Documented respiratory rate
e. Pulse oximetry

Answer: c. The patient's ability to follow commands in response to varied levels of stimulation and direct observation of the ventilatory status have been the most reliably documented methods of assessing the level of consciousness during procedural sedation. Pulse oximetry is a reliable adjunct, but it identifies hypoventilation late, especially when used with supplemental oxygen. Cardiac monitoring has been shown to be helpful in older patients or in those with a history of cardiac disease, but there is no evidence that it is of any benefit in young healthy patients. End-tidal carbon dioxide monitoring has been shown to be useful to detect inadequate ventilation earlier than oximetry, especially when direct observation of the patient is difficult, but no studies have demonstrated an effect on clinical outcome to date. Recently, the American Society of Anesthesiologists (ASA) updated its procedural sedation standards to include capnography during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs. Respiratory rate alone is an insensitive indicator of adequacy of ventilation.

CHAPTER 157: QUESTIONS AND ANSWERS—cont'd

3. Which of the following agents is matched with the correct associated side effect?
   - **a.** Etomidate—longer (>30-minute) duration of sedation
   - **b.** Ketamine—laryngospasm
   - **c.** Methohexital—venoirritation
   - **d.** Pentobarbital—seizures
   - **e.** Propofol—myoclonus

Answer: b. Ketamine has been associated with laryngospasm in children younger than 3 months old and those with a respiratory infection. The following are the other correct associations:

- Etomidate—myoclonus
- Methohexital—seizures
- Pentobarbital—longer (>30-minute) duration
- Propofol—venoirritation

4. Which of the following statements regarding the use of ketamine is false?
   - **a.** Benzodiazepine administration may be useful for emergence phenomenon in children that are not improved by removing stimulation and providing calming interventions.
   - **b.** Despite increased secretions, airway reflexes are generally well maintained.
   - **c.** Hypotension is common.
   - **d.** Profound analgesic and sedative effects occur with minimal respiratory depression.
   - **e.** Repeat doses are well tolerated in longer procedures.

Answer: c. Ketamine increases the release of catecholamines upon administration and supports blood pressure well. It also decreases smooth muscle tone in the bronchial tree and may have a benefit in patients with reactive airways disease. Several studies have failed to show benefit with the concurrent administration of low-to-moderate dosages of benzodiazepines in preventing emergence phenomenon in children. These studies have shown a slightly increased risk of side effects. Their routine use is discouraged and should be reserved for the actual treatment of severe emergency phenomenon that are not improved by removing stimulation and providing calming interventions.

5. Which of the following statements regarding the use of propofol is true?
   - **a.** Propofol has a long duration of action and provides significant analgesia.
   - **b.** Propofol has significant antiemetic properties.
   - **c.** Propofol can be easily reversed with a reversal agent.
   - **d.** Propofol is well tolerated in volume-depleted patients.
   - **e.** The use of "ketofol" (ketamine in combination with propofol) is clinically superior to the use of propofol alone.

Answer: b. Propofol is an ultra–short-acting, sedative-hypnotic, cerebroprotective agent with no analgesic but profound antiemetic properties. Its adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Preload-dependent patients are particularly susceptible to hypotension. Its combined use with ketamine is common. The two agents are felt to have synergistic effects that balance each other's deficits. The combined use has been shown to improve provider satisfaction, sedation quality, and decrease emesis but has not been shown to be clinically superior to either agent used alone regarding respiratory depression, airway complications, or improved recovery times.

6. Which of the following statements is true regarding the need for fasting before procedural sedation?
   - **a.** A 6-hour period of fasting is required after the ingestion of liquids or solids before procedural sedation.
   - **b.** Preprocedural fasting is required in all circumstances.
   - **c.** The recommendation for preprocedural fasting is based on controlled trials involving patients undergoing procedural sedation.
   - **d.** The risk of vomiting and the loss of the airway protective reflexes is an extremely rare occurrence during procedural sedation.
   - **e.** There is an increased risk of aspiration during procedural sedation after a liquid or solid meal.

Answer: d. The American College of Emergency Physicians organized a multidisciplinary Consensus Statement on Unscheduled Sedation that recommends the assessment of the timing and nature of recent oral intake. The urgency of the procedure will dictate the necessity of providing sedation without delay, regardless of fasting status. For patients with established risk factors for aspiration (e.g., serious underlying illness, obstructive sleep apnea, obesity, age less than 12 months, upper endoscopy as the procedure, or bowel obstruction), consider the risks versus benefits of delaying procedural sedation after recent ingestion of a substantial meal. American Society of Anesthesiologists (ASA) currently recommends a period of 2 hours after ingestion of clear liquids, a period of 4 hours after ingestion of breast milk, and a period of 6 hours after ingestion of other liquids or solids before the performance of procedural sedation. This recommendation is based on expert consensus and extrapolated from data on patients receiving general anesthesia and manipulation of the airway during intubation and extubation. There are no published studies showing increased risk of aspiration after a liquid or solid meal, nor benefits of fasting before procedural sedation. There are large studies showing no clinically significant differences with airway complications, emesis, or other adverse effects between groups of patients stratified by their preprocedural fasting status. Adherence to the ASA preoperative fasting guidelines for procedures is not necessary in emergency department (ED) patients undergoing procedural sedation and analgesia (PSA).

Pediatric Resuscitation

Joshua S. Easter

KEY CONCEPTS

- Unlike adults, most cardiac arrests in children arise from respiratory etiologies. Therefore, emphasis is first on oxygenation and ventilation.
- Detection of a child's pulse may be difficult; if a brachial pulse is not definitively present after 10 seconds of palpation, initiate cardiopulmonary resuscitation (CPR).
- Hypotension is a late finding in pediatric shock and requires immediate intervention to prevent cardiac arrest. Progression from tachycardia to bradycardia in a child is often a harbinger of imminent arrest.
- Although few studies support recommendations for exact rate, depths, and ratios of compressions to ventilations in pediatric CPR, emergency clinicians should perform rapid compressions over the lower sternum with minimal interruptions. The hand encircling technique is recommended for infants requiring chest compressions and the two-hand approach in mid sternum for older children. In the emergency department (ED), we recommend 15 compressions to 2 ventilations for children less than 8 years and 30 compressions to 2 ventilations for older children.
- Verbal and quantitative feedback improves compressions and ventilations.
- Advanced airway management (i.e., endotracheal intubation) may be harmful for children in arrest in the ED. If attempted, physicians should strive for minimal interruptions in compressions and to ventilate at 8 to 10 breaths/min. High quality bag-mask ventilation is a reasonable alternative to advanced airway maneuvers.
- If ventricular fibrillation or pulseless ventricular tachycardia arise, defibrillate at 2 J/kg as soon as possible. While preparing the equipment and charging, continue to perform high quality compressions. Administer subsequent defibrillations at escalating energy doses of 4 J/kg and then 10 J/kg.
- Early administration of epinephrine for non-perfusing rhythms may improve survival.
- Empiric administration of medications to children in arrest worsens outcomes. Reserve medications for specific indications, for example, bicarbonate administration for hyperkalemia.
- Knowledge of the child's approximate weight is necessary to administer the appropriate medication doses and to utilize the appropriate equipment. Determine actual weight in kilogram and estimate weight based on parental report or the child's length.
- Prompt vascular access is critical in a resuscitation. Intraosseous access tends to be the easiest and fastest, but care should be taken that the needle is not residing in the subcutaneous tissue. Central venous access is resource intensive and not necessary in the first few hours of a resuscitation.
- Except in specific circumstances, resuscitations greater than 30 minutes are unlikely to yield favorable outcomes for pediatric arrest.
- After return of circulation, maintain normothermia and avoid hypotension.
- Current definitions of sepsis are based on consensus and primarily for research purposes.
- Systemic inflammatory response syndrome (SIRS) criteria are sensitive but not specific for identifying sepsis in children.
- Hypotension should prompt administration of 20 to 60 mL/kg fluids and likely vasopressors.
- Most children with septic shock have cold shock and therefore epinephrine (0.05 mcg/kg/min) is the first line vasopressor.
- Protocols bundling intravenous fluids, antibiotics, and blood culture acquisition in septic children improve outcomes.
- Brief resolved unexplained events (BRUEs) involve alterations in breathing, tone, or behavior that last less than 1 minute before resolving spontaneously. Children appear well on presentation to the ED, and there are no elements of the history that suggest a particular etiology for the event.
- Low-risk BRUEs occur in children that were born greater than 32 weeks, are greater than 60 days of age, have had no prior BRUEs, and CPR was not required during the event. These children require an assessment and brief observation in the ED, little or no diagnostic testing, and may be discharged with close follow-up.

CARDIAC ARREST

Foundations

Background

Pediatric cardiac arrest is rare, but the consequences are dire when considering lost years of life and productivity. The incidence and survival of pediatric cardiac arrest varies with the location of the arrest, the patient's age, and the mechanism (Table 158.1). Most cardiac arrests encountered in the emergency department (ED) occur outside the hospital, from medical causes in infants and traumatic causes in older children. In children, cardiac arrest is most prevalent in infants, occurring primarily in children less than 3 months of age. The incidence of atraumatic cardiac arrest in older children is 30 to 50 times less common than infants and adults. Overall, survival following cardiac arrest in children is low; however, it is improving, and certain groups have higher likelihoods of survival. Infants survive infrequently (6%) but older children survive (14%) comparably to adults (11%).[1] The frequency of survival with good neurologic outcome has been estimated at 6% to 12%.

Pediatric resuscitations are relatively rare, limiting clinicians' proficiency. In a review of resuscitations at a busy pediatric ED, less than half of emergency physicians had completed any critical care procedures

TABLE 158.1 Differences in Cardiac Arrest Pathophysiology, Presentation, and Management by Age

	Infant	Child	Adult
Incidence (per 100,000)	75	5	141
Survival (%)	6	14	11
Etiology	Respiratory	Respiratory > Trauma	Cardiac
Rhythm	Asystole, bradycardia	Asystole	Ventricular fibrillation or tachycardia
Early Focus	Compressions, Ventilations		Defibrillation
Location for pulse check	Brachial	Carotid	Carotid
Compression technique	Hands encircling chest	2 hands	2 hands
Compression depth	1.5 inches	2 inches	2 inches
Defibrillation dose (monophasic)	2J/kg, then 4J/kg, and then 10 J/kg		200 J
Epinephrine dose	0.1 mg/mL		0.1 mg/mL

(e.g., cardioversion, intubation, intraosseous line placement) in the preceding year. No physicians had performed cardiac pacing, needle cricothyroidotomy, diagnostic peritoneal lavage, thoracentesis, arterial line placement, and venous cutdown line placement. In the absence of actual clinical experience, emergency clinicians often rely on didactic resuscitation courses. However, knowledge retention after these courses is poor. As a result, many emergency clinicians remain uncomfortable managing critically ill children.[2–4] This discomfort can lead to insufficient interventions for fear of harming a child, or alternatively, excessive interventions that stress resources, families, and clinicians.

Pathophysiology

Most atraumatic cardiac arrests in children arise from respiratory etiologies, particularly respiratory failure, drowning, and asphyxia. Children commonly progress from respiratory failure to shock, and finally to bradycardia and loss of circulation. Pediatric advanced life support (PALS) guidelines have largely focused on the treatment of these respiratory emergencies. However, population-based studies suggest cardiac causes account for approximately a third of pediatric medical arrests. Another 21% of pediatric arrests follow trauma. These frequencies are in stark contrast to adults, where two-thirds of arrests are attributed to cardiac etiologies. The differences in the etiology of arrests between adults and children have significant implications for management; arrests from respiratory causes require an emphasis on ventilatory support, oxygen delivery, and maintenance of perfusion, whereas arrests from cardiac causes require a more directed emphasis on restoring perfusion and treatment of underlying dysrhythmias (see Table 158.1).

The most common presenting pediatric arrest rhythm is asystole, occurring in two-thirds of children. Pulseless electrical activity and bradycardia are the next most common presenting rhythms. Unlike adults, ventricular fibrillation and tachycardia are rare, occurring in 9% of children in cardiac arrest. These dysrhythmias can arise with prolonged resuscitation and are more common in adolescents and children with congenital heart disease.

With return of circulation after cardiac arrest, reperfusion induces a cascade of physiologic changes that increase morbidity. During the initial minutes after return of circulation, there is not adequate substrate for aerobic metabolism leading to accumulation of free radicals and cellular necrosis. Children may also develop a sepsis like syndrome, with increased cytokines and endotoxin producing capillary leak and coagulopathy. This may lead to hypotension and multiple organ dysfunction. In the hours following return of circulation, nearly half of children may also develop reversible myocardial dysfunction, producing pulmonary edema, hypotension, or arrhythmias.[5]

Clinical Features

The absence of a pulse, respiratory effort, and responsiveness constitute cardiac arrest. While identifying respiratory effort and responsiveness are relatively straightforward, detecting a pulse in a pediatric patient can be difficult. Physicians identified the presence of a pulse when one was not present in one quarter of children undergoing extracorporeal membrane oxygenation (ECMO). Moreover, emergency clinicians require extended time to determine if a pulse is present in a child, with an average of 9 (±6) seconds to detect a brachial pulse and 29 (±14) seconds to determine that a pulse was not present. Current guidelines suggest lay people should initiate cardiopulmonary resuscitation (CPR) in children without performing a pulse check; any child that is unresponsive and apneic should receive CPR. For emergency clinicians, if no pulse is detected in 10 seconds, CPR should be initiated without delay; the adverse effects of delayed CPR outweigh the effects of CPR for an apneic, unresponsive child with a weak pulse.

The ideal location for palpation of a child's pulse is unclear. There are few studies comparing sites, and they are conducted in the operating room with conflicting results. In infants, the carotid pulse can be difficult to detect compared to the brachial or femoral pulse. In adolescents, the carotid is the easiest location to identify a pulse. In children in cardiac arrest, auscultation of the heart or palpation of the apical impulse can be misleading; patients with pulseless electrical activity can have an apical impulse or auscultated heartbeat without central pulses or adequate perfusion.

Recognizing Imminent Arrest

Anticipating impending cardiac arrest allows for early interventions that may prevent progression. Abnormal vital signs, based on age-specific norms, are often the best indicator of imminent arrest in an ill child. These values can be difficult to remember, but physicians can recognize several key features (Box 158.1). While tachycardia and tachypnea are commonly present in children with relatively benign febrile illnesses, hypotension or ill appearance should prompt immediate intervention.

Management

The paucity of pediatric out-of-hospital cardiac arrests limits available evidence on its management. Most pediatric guidelines are consensus-based and much is extrapolated from adult data.[6–8] The American Heart Association (AHA) guidelines for management are illustrated in

BOX 158.1 Worrisome Vital Sign Findings in Children

Blood Pressure

Systolic blood pressure <70 mm Hg + (2 × age in years) is hypotension (less than fifth percentile for age)

Respiratory Rate

Respiratory rate >60 breaths/min is tachypnea

Declining respiratory rate in previously tachypneic patient can represent improvement *or* fatigue and imminent respiratory failure

Fever

Each 1°C (1.8°F) of fever increases heart rate by only 10 beats/min and respiratory rate by 2–5 breaths/min

End-Tidal Carbon Dioxide

Progressive increase or decrease precede desaturation and respiratory failure

Fig. 158.1. Neonatal resuscitation guidelines (see Chapter 159) should be used for newborns and for neonates within the first weeks of life, after which these pediatric guidelines are applicable for children until puberty (i.e., axillary hair in males and breasts in females).

Compressions-Airway-Breathing

During the initial no-flow state of cardiac arrest, the priority is initiation of flow. This priority has prompted a change in the sequence of "airway-breathing-compressions (A-B-C)" to "compressions-airway-breathing (C-A-B)." This avoids delays in the initiation of blood flow and may render bystanders to an arrest more likely to provide CPR. This is particularly helpful in children; bystander CPR improves pediatric survival but is infrequently administered.[9] Although the A-B-C approach is still considered preferred in children, it is feasible to begin with the C-A-B approach and still provide timely ventilations; a simulated pediatric respiratory arrest model found no delays in the initiation of ventilations with the C-A-B approach compared to the A-B-C approach. Moreover, the C-A-B approach led to prompter recognition of cardiac arrest. If untrained bystanders are reluctant to provide ventilations, children with out-of-hospital cardiac arrest should still receive chest compressions without delay. In the ED, with multiple professionals available, compressions should be administered concurrently with ventilations.

Compressions. High quality compressions improve outcomes but are rarely performed. When administered appropriately, compressions generate one-third of a child's normal cardiac output and a coronary artery perfusion pressure of 10 mm Hg. In a prospective, observational study of in-hospital pediatric arrest, one half of children received the recommended rate of chest compressions and one fifth received the recommended depth per AHA guidelines. In an academic pediatric ED study, 87% of compressions exceeded 100 per minute. However, only 40% complied with recommended compression to ventilation ratios, and there were frequent pauses in compressions.[10]

The location of compressions influences cardiac output. Infants' hearts reside inferior to the lower third of their sternums. In these younger children, encircling the chest with both hands and compressing the lower part of the sternum with the thumbs while squeezing the thorax with the remaining fingers yields greater cardiac output than compression with two fingers. In video review of infant CPR, this approach yielded more accurate compression rates compared to a one handed technique.[11] The AHA suggests utilizing the one hand approach to administer compressions to children 1 to 8 years old, but a study of simulated compressions suggested a two-handed technique, identical to that performed on adults, is easier and generates higher pressures. When feasible, a resuscitation board placed under children receiving chest compressions improves compressions; at a minimum, the child should be supine on a firm surface.

The ideal compression depth and rate is unknown, but the AHA recommends pushing "hard and fast." Compressions should be deep enough to achieve optimal cardiac output without being so deep as to cause injuries to other vital organs. Attempts to increase depth excessively can result in leaning, which reduces coronary artery perfusion pressure and cardiac output. Guidelines suggest compressing the chest an estimated one-third of the anteroposterior diameter of the child. However, this estimating method has led to relatively deeper compressions than recommended in adults, and it can be extremely difficult to assess proportional anteroposterior compression depth during CPR. As a result, it is more practical to focus on absolute depths; we recommend 1½ inches in infants and 2 inches in older children.

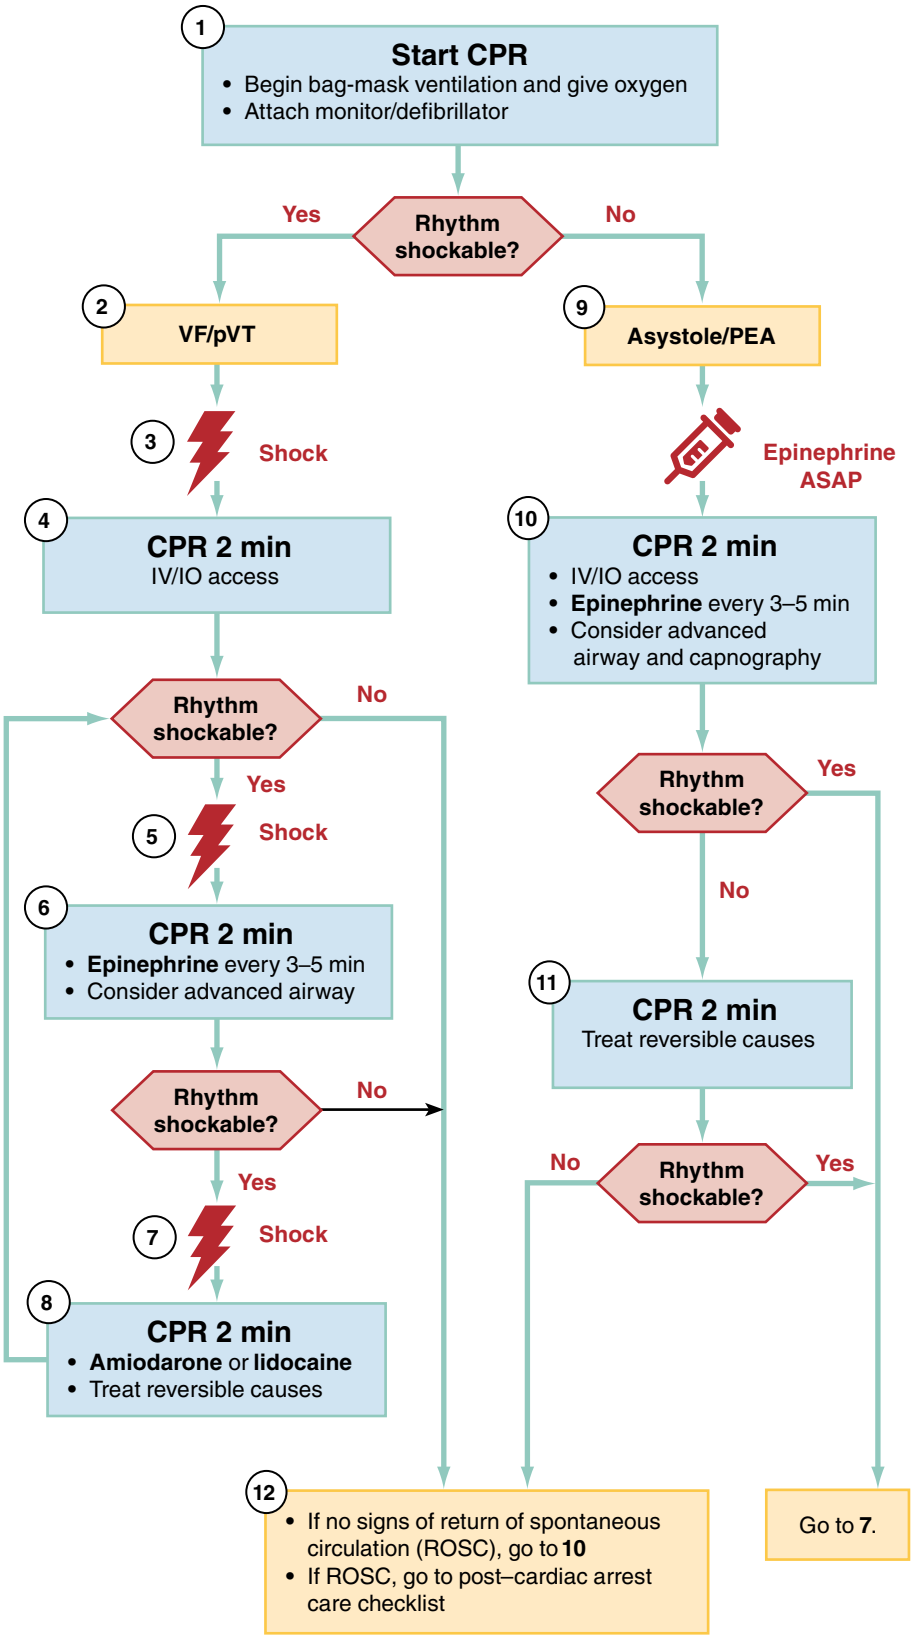
Similarly, the exact rate of compressions to generate ideal cardiac output is unclear. Rates more than 100 compressions per minute improve cardiac output, coronary artery perfusion pressure, and survival compared with rates less than 90 compressions per minute in children. However, attempts to exceed 120 compressions per minute diminish perfusing pressures.[12] High quality compressions diminish after 2 minutes. At this point, emergency clinicians may deny fatigue and be able to maintain the rate of compressions, but depth of compressions decreases substantially. This reduction in quality worsens with time. In adults, pauses in compressions yield substantial drops in coronary artery perfusion pressure, and pauses more than 20 seconds increase the odds of mortality by 50%. A recent study of in-hospital pediatric arrest found that brief pauses (median of 2.4 seconds) did not lead to significant reductions in intra-arterial pressures.[13] Nevertheless, pauses in compressions should be minimized. When pauses are necessary to switch compressors, check rhythms, or provide defibrillation, they should be kept as brief as feasible.

Finally, the appropriate ratio of compression to ventilations is unknown. Animal models indicate the amount of ventilation required during CPR is much lower than with a normal perfusing rhythm, likely due to the lower cardiac output in CPR. The AHA recommends 30:2 compressions to ventilations for single rescuers and 15:2 for two rescuers. However, 15:2 ratios may yield insufficient compressions per minute in older children, and we recommend 30:2 ratios for children greater than 8 years. If an advanced airway is in place, ventilations should be delivered at 8 to 10 breaths per minute and should not interrupt compressions. Overventilation can be dangerous, but is common; in an observational study at a busy pediatric ED, 70% of CPR involved ventilations in excess of recommendations.[10]

Notably, although resuscitation guidelines provide exact rates, depths, and ratios of compressions to ventilations, these recommendations are largely based on consensus. There are no randomized control studies comparing the impact of exact ratios, frequencies, or depths of compressions on survival. Rather than focusing on strict adherence to exact guidelines, we recommend focusing on promptly recognizing the need for compressions and then administering rapid compressions over the lower sternum with minimal interruptions. Practice is critical to maintaining quality, as most individual clinicians have limited real patient experience; in a busy pediatric ED, clinicians averaged 3 minutes of compressions per year.[14,15]

The AHA recommends feedback, as it improves the quality of compressions. Quantitative feedback is most helpful because qualitative assessments can be difficult. During simulated arrests, emergency clinicians significantly overestimated compression depth and rate while underestimating pauses. Accelerometers and force

Pediatric cardiac arrest algorithm – 2020 update



CPR quality

- Push hard (≥⅓ of anteroposterior diameter of chest) and fast (100–120/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Change compressor every 2 minutes, or sooner if fatigued
- If no advanced airway, 15:2 compression-ventilation ratio
- If advanced airway, provide continuous compressions and give a breath every 2–3 seconds

Shock energy for defibrillation

- First shock 2 J/kg
- Second shock 4 J/kg
- Subsequent shocks ≥4 J/kg, maximum 10 J/kg or adult dose

Drug therapy

- **Epinephrine IV/IO dose:** 0.01 mg/kg (0.1 mL/kg of the 0.1 mg/mL concentration, max dose 1 mg). Max dose 1 mg. Repeat every 3–5 minutes. If no IV/IO access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of the 1 mg/mL concentration).
- **Amiodarone IV/IO dose:** 5 mg/kg bolus during cardiac arrest. May repeat up to 3 total doses for refractory VF/pulseless VT
  or
  Lidocaine IV/IO dose: Initial: 1 mg/kg loading dose

Advanced airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement

Reversible causes

- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypoglycemia
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pneumothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

Fig. 158.1 The American Heart Association (AHA) Guidelines Algorithm for Management of Infants and Children in Cardiopulmonary Arrest. *CPR,* Cardiopulmonary resuscitation; *ETT,* endotracheal tube; *IO/IV,* intraosseous/intravenous; *PEA,* pulseless electrical activity; *ROSC,* return of spontaneous circulation; *VF/VT,* ventricular fibrillation/pulseless ventricular tachycardia.

sensors provide real-time data on compression rate and force. These feedback devices improve adherence with compression guidelines amongst children in simulated cardiac arrest.[16] The presence of a coach providing verbal feedback augments feedback devices in simulated arrests.[17–19] End-tidal carbon dioxide ($ETCO_2$) also serves as an adjunct measure of the adequacy of compressions.[20,21] In the low-flow state of CPR, the flow of venous blood to the lungs serves as the rate-limiting step for the elimination of CO_2 as opposed to ventilation. As a result, exhaled CO_2 increases with cardiac output, and the AHA recommends titration to greater than 20 mm Hg, although an observational study of in-hospital pediatric arrest found levels greater than 20 mm Hg were not associated with survival.[22] Despite proven benefits, less than 5% of hospitals employ feedback devices regularly during resuscitation.

Ventilation. Although life-threatening airway emergencies in children are rare, most critical illness in children stems from respiratory etiologies; therefore, focus is largely on effective ventilation and oxygenation. The appropriate method to ventilate children in arrest is unclear, as advanced airway management with endotracheal intubation may not improve outcomes compared to bag-mask ventilation. A randomized trial of intubation versus mask ventilation in the pre-hospital setting found no difference in survival to hospital discharge (OR = 0.82; 95% CI, 0.61 to 1.1) for tracheal intubation versus bag-mask ventilation alone. A large observational study in Japan confirmed these results.[23] In contrast, a retrospective review of an airway registry suggested endotracheal intubation was associated with reduced survival (OR = 0.39; 95% CI, 0.26 to 0.59). While this may stem from complications associated with pre-hospital pediatric intubation, results are similar for in-hospital pediatric arrest. An observational study of 2294 children found intubation was associated with reduced survival (RR = 0.89; 95% CI, 0.81 to 0.99).[24] The lack of benefit of pre-hospital advanced airway management may extend to supraglottic devices, with a retrospective study showing reduced survival (OR = 0.32; 95% CI, 0.12 to 0.84).[25] Advanced airway management may reduce survival by leading to interruptions in compressions; a review of pediatric ED intubation attempts found pauses in over half of attempts with a median duration of 25 seconds.[26]

As a result of this evidence, the 2019 PALS update recommends bag-mask ventilation for pre-hospital arrest.[6] While the AHA found insufficient evidence to create a guideline for the ED, we extrapolate from the pre-hospital and in-hospital evidence and recommend emergency physicians focus on delivering high quality bag-mask ventilation. This requires the appropriate equipment (mask size and airway adjuncts) as well as deliberate practice.[7] If advanced airway management is attempted during resuscitation, care should be taken to avoid prolonged interruptions in compressions. In addition, patients should receive only 8 to 10 breaths/min via the advanced airway without interruptions in compressions. A more in-depth discussion of pediatric airway management can be found in Chapter 156.

Compression-Only Cardiopulmonary Resuscitation

Compression only CPR is utilized in adults, but the benefits in children are less apparent. For arrests secondary to ventricular fibrillation, as are common in adults, patients often have a reservoir of oxygen in their lungs and can maintain adequate arterial partial pressure of oxygen (PaO_2) for 5 minutes with compressions alone. In contrast, animal studies of arrests from respiratory causes show that compression-only CPR leads to rapid depletion of oxygen reservoirs and increased CO_2 and lactate. In a large observational study of children, conventional CPR was associated with improved survival compared to compression-only CPR.[27] For children with cardiac etiologies to their arrest, survival was similar with both approaches. As children commonly suffer respiratory etiologies for their arrest, and there are multiple providers available in the ED, conventional CPR should be the norm.

Bystander CPR improves outcomes, but only half of children receive it. Bystanders may be more willing to perform compression-only CPR, and this should be encouraged compared to no CPR. Compression-only CPR improved survival compared to no CPR (OR = 3.3, 95% CI, 1.9 to 5.7).[9,28]

Defibrillation. Although ventricular fibrillation and pulseless ventricular tachycardia are rarely the presenting rhythm in children, they arise at some point during one quarter of pediatric resuscitations. Children with these rhythms are more likely to survive. Defibrillation applies asynchronous current to the heart to restore a perfusing rhythm. While out-of-hospital arrest studies demonstrated that shorter durations between onset of a shockable rhythm and defibrillation improved survival, a recent observational study of in-hospital pediatric arrest found time to defibrillation was not associated with survival (RR = 0.99; 95% CI, 0.94 to 1.1).[29] This may reflect the abrupt recognition of arrest and initiation of CPR in-hospital, which may mitigate the survival benefit of rapid defibrillation. In the setting of conflicting evidence, in the ED we recommend prompt defibrillation as soon as a shockable rhythm is identified. Delays in defibrillation of over 3 minutes arise in nearly half of simulated shockable arrests. These delays stem from failure to recognize the shockable rhythm and difficulty operating the defibrillator.[30] While awaiting defibrillation, emergency clinicians should focus on administering high quality compressions without interruptions until the defibrillator is placed and charged.

Pediatric specific equipment is available for defibrillation. Both paddles and pads provide adequate energy, assuming gel is placed on the paddles and pads are firmly attached to the chest wall. Optimal pad size has not been well defined in the pediatric population; pads can be used according to the manufacturer's size recommendations and should fit on the child's chest without touching. Anteroposterior and anterolateral positioning of pads provide equivalent energy to the heart. If pediatric pads are not available, apply adult-sized pads anteroposteriorly and minimize contact between the pads.

The optimal energy dose for defibrillation in children is uncertain. The AHA recommends administering 2 to 4 J/kg initially, whereas the European Resuscitation Council recommends 4 J/kg. Dosing based strictly on weight often leads to lower than anticipated energy delivery. Theoretically, a higher dose per kilogram may overcome this variability and ensure adequate energy reaches the heart. However, multiple small studies have not identified any association between energy dose and survival.[31] The primary disadvantage of higher energy doses is damage to the myocardium, but animal studies suggest long-term myocardial necrosis only occurs with doses more than 10 J/kg. The only circumstance where a child would receive such high doses is if adult pads are utilized with an infant. Nevertheless, when presented with an infant in ventricular fibrillation and no other equipment, we recommend employing the adult pads.[32] We also recommend starting defibrillation at 2 J/kg, increasing to 4 J/kg with the second defibrillation, and increasing to 10 J/kg for third and subsequent shocks. There is no difference in survival between monophasic and biphasic defibrillation in children.

Pharmacology

There are no high-quality randomized control studies showing improvement in survival to hospital discharge or neurologic outcome with any medications administered during pediatric cardiac arrest. Observational studies suggest that prompt administration of epinephrine may improve return of circulation and mortality for non-traumatic out-of-hospital cardiac arrest in children; each minute from emergency medical service (EMS) arrival until administration of epinephrine reduced

TABLE 158.2 Medications for Pediatric Cardiac Arrest

Medication	Indications	Dose (mg/kg)	Comments
Epinephrine	Asystole, PEA, bradycardia, VF, pulseless VT	0.01	0.1mg/mL formulation Higher doses of epinephrine may decrease survival May increase harm with bradycardia
Atropine	Bradycardia	0.02	Not for routine use in PEA, asystole 0.02 mg/kg
Amiodarone	VF, VT, SVT	5	Unclear if superior to lidocaine for VF, VT
Lidocaine	VF, VT	1	Avoid in WPW
Procainamide	SVT refractory to adenosine, stable VT	10–15	First line for SVT in WPW May be more effective than amiodarone for SVT Do not give in patients receiving amiodarone, torsades de pointes, or prolonged QT Can cause hypotension
Adenosine	SVT	0.1	First line therapy for stable SVT Avoid in WPW, wide complex tachycardia, long QT Potentially unreliable through IO route
Dextrose	Hypoglycemia	0.5–1 g/kg, maximum 25 g	D10W: 5 mL/kg, D25W: 2 mL/kg, D50W: 1 mL/kg Do not administer empirically
Calcium chloride	Hyperkalemia, hypocalcemia, calcium channel blocker overdose	20	Not for routine use Calcium chloride provides more bioavailable calcium but requires central line
Sodium bicarbonate	Hyperkalemia, TCA overdose	1 mEq/kg	Not for routine use
Magnesium sulfate	Torsades de pointes, hypomagnesemia	Maximum single dose: 2g	Not for routine use

D10W, Dextrose 10% in water; *D25W,* dextrose 25% in water; *D50W,* dextrose 50% in water; *PEA,* pulseless electrical activity; *SVT,* supraventricular tachycardia; *TCA,* tricyclic antidepressant; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia; *WPW,* Wolff-Parkinson-White.

survival 9%.[33–36] Doses of epinephrine greater than 0.01 mg/kg do not improve survival. Pre-filled code cart epinephrine syringes may lead to substantial overdoses in infants.[37] The benefits of epinephrine may not extend to *non*-pulseless events, with a recent observational study showing decreased survival (RR = 0.79; 95% CI, 0.74 to 0.85) with epinephrine administration within the first 10 minutes of resuscitation for children with bradycardia and poor perfusion.[38]

There is mounting evidence to suggest that certain commonly administered medications are associated with decreased survival and poorer neurologic outcome. Bicarbonate continues to be used in two thirds of pediatric in-hospital arrests despite evidence suggesting empiric administration is associated with decreased survival (OR = 0.80; 95% CI, 0.65 to 0.97).[39] Similarly, calcium is administered in nearly half of pediatric in-hospital cardiac arrests, despite an association with decreased survival and poorer neurologic outcome. Atropine is also often administered inappropriately, including in 1 of every 5 out-of-hospital pediatric arrests.[40] These drugs should be reserved for specific indications (Table 158.2).

The ideal drug for ventricular tachycardia and pulseless ventricular tachycardia remains unclear, with recommendations extrapolated from adult data. A prospective study of in-hospital pediatric arrest with shockable rhythms found that there were no differences in return of circulation or mortality (RR = 1.0; 95% CI 0.63 to 1.6) between lidocaine and amiodarone.[41] The implications of this study for out-of-hospital cardiac arrest are uncertain. Without further evidence or consensus, either agent seems appropriate.

Dosing of medications during pediatric cardiac arrest can be difficult; accurate administration requires correct estimation of weight, determination of weight-based dose, and conversion of weight to volume. Time spent on these tasks increases clinicians' cognitive load and errors. Estimations based on length (Broselow-Luten) or upper extremity circumference (Mercy TAPE) are better than estimates based on appearance or age, but may underestimate weight in obese children or overestimate in underweight children.[42] Parents tend to be more accurate than these estimation methods.[43] Regardless, these estimates do not eliminate all dosing errors because clinicians still have to calculate volumes of medications. Utilization of color coded, prefilled syringes corresponding to the weight, or precalculated medication charts or applications based on a standardized formulary may mitigate these dosing errors.[44]

Confirmation of weight estimates reduces errors. Often in the rush of resuscitation, inaccurately estimated weights result in inappropriate equipment and medications. The finger counting method can confirm an estimated weight. The clinician counts age on the left hand, starting with 1 on the thumb and counting by odd numbers to 9 on the small finger (i.e., 1–3–5–7–9 years of age). Weight in kilograms is counted on the right hand, starting with 10 kg and counting by 5 to 30 kg on the small finger (i.e., 10 kg–15 kg–20 kg–25 kg–30 kg). Fingers are matched between hands to estimate weight based on age. To prepare appropriate equipment and medications, emergency clinicians should ask EMS providers for the child's approximate weight.

Vascular Access. The particular site of vascular access is less important than its timely acquisition. Peripheral venous and intraosseous drug administration produce similar onset of drug action and peak levels for the commonly administered resuscitation drugs.[45] Prolonged delays are common in the ED; nearly half of children in the resuscitation area of an ED required greater than 90 minutes to obtain vascular access.[46]

For children in arrest or imminent arrest, an immediate attempt to obtain intraosseous access saves time. Intraosseous access is more successful and faster with minimal complications compared to peripheral or central access in critically ill patients.[47] Directing the needle away

TABLE 158.3 Monitoring After Return of Circulation

Parameter	Assessment	Goal	Action
Oxygen	Arterial blood gas; continuous pulse oximetry	SpO_2 94%–99% PaO_2 80–200 mm Hg	Titrate FiO_2
Carbon dioxide	Continuous capnography	$PaCO_2$ 35–45 mm Hg	Adjust respiratory rate
Perfusion	Arterial line; lactate; urine output	Avoid SBP <70 + 2 × age	20 mL/kg of isotonic fluid; norepinpehrine 0.1–2 mcg/kg/min
Heart rhythm	Continuous cardiac monitor	Avoid arrhythmias	Treat if arise; no prophylaxis
Glucose	Blood glucose	Avoid glucose <60	Dextrose
Temperature	Continuous core temperature	<38	Antipyretics; cooling blanket
Sedation		Avoid shivering	Fentanyl; midazolam
Seizure	EEG	Termination of seizure	Midazolam; phenytoin or levetiracetam

EEG, Electroencephalogram; *SBP,* systolic blood pressure.

from the growth plate during insertion reduces the risk of injury to the growth plate; long-term follow up has shown minimal adverse impact on bone growth from intraosseous placement alone. Monitoring of the insertion site allows detection of compartment syndrome, which can arise from excessive insertion of fluids into a needle misplaced in the subcutaneous tissue. Powered intraosseous insertion devices, such as the EZ-IO (Vidacare), may decrease insertion times and improve the frequency of successful insertion; although, other powered devices that require calibration, such as the Bone Injection Gun (WaisMed) may delay insertion and reduce the frequency of success. Manual placement may avoid insertion through the posterior cortex in children less than 8 kg.[48] In young children, the tibia and femur are preferred, because their marrow cavity is well developed. When administering fluid through an intraosseous line, manual pressure is helpful to overcome the resistance of the marrow cavity. Multiple injections of smaller (10 mL) syringes of fluid (i.e., "flushes") can resuscitate infants and small children through an intraosseous needle. Surveys suggest physicians often unnecessarily delay attempts at intraosseous access while attempting peripheral or central access. Central line access should typically be reserved for children requiring prolonged vasopressors. The femoral vein is the easiest site of cannulation in young children.

Termination of Resuscitation. There are no universal criteria to guide the termination of a pediatric resuscitation. Emergency clinicians are less comfortable terminating efforts in children than adults, often resulting in prolonged, futile resuscitations that increase stress on families and staff. There are anecdotal reports of children surviving with good neurologic outcome after prolonged resuscitations, but these often involve in-hospital arrests or arrests with prompt access to extracorporeal membrane oxygenation (ECMO). Several variables, including length of resuscitation, unwitnessed arrest, initial cardiac rhythm, administration of multiple doses of epinephrine, administration of atropine, and $ETCO_2$ less than 10 mm Hg have been associated with low survival and poor neurologic outcome.[49,50] However, none of these variables possess sufficient discriminative ability to provide absolute cutoffs for termination of resuscitation. Perhaps the most predictive variable is duration of resuscitation; a multicenter retrospective analysis indicated that for every additional minute of pediatric CPR, the frequency of survival decreased by 2.1%. For traumatic arrest, guidelines suggest prehospital termination after 30 minutes of unsuccessful resuscitation.[51] A recent large retrospective study of pediatric arrest following traffic accidents found that when CPR was necessary for greater than 15 minutes, less than 1% of children survived and all had poor neurologic outcome.[52] Such guidelines do not exist for atraumatic arrest. Guidelines designed for adults, such as the Termination of Resuscitation rule, fail to predict survival in children adequately and should not be employed.[53] Outside of family wishes and specific clinical situations where prolonged resuscitation may be beneficial (e.g., hypothermia with drowning or electrocution, in-hospital arrest, or prompt access to ECMO), we recommend considering termination of resuscitation after 30 minutes for atraumatic causes and 15 minutes for traumatic causes. This approach can minimize suffering for the patient, family, and staff.

E-CPR

When readily available, physicians should also consider ECMO early in an arrest course. Although initial studies suggested ECMO provided greater benefits for patients with underlying cardiac disease, a retrospective analysis also identified benefits for children with non-cardiac etiologies of their arrest. Pediatric critical care centers performing high volumes of ECMO and with rapid response teams to initiate timely cannulation have better outcomes. ECMO also should be considered for children with return of circulation but refractory shock, particularly cardiogenic shock.

Post-Arrest Care

For children with return of circulation, several actions may improve survival and neurologic outcome. Focus should shift to treating the underlying etiology of the arrest, minimizing brain injury, and improving end-organ perfusion. This requires monitoring oxygen, carbon dioxide, blood pressure, temperature, glucose, and urine output (Table 158.3).

Blood Pressure

Hypotension develops in over half of children following in-hospital cardiac arrest and predicts increased mortality. A single episode of hypotension (<5th percentile for age) within the first 6 hours after arrest is associated with decreased survival (OR = 0.39; 95% CI, 0.20 to 0.74).[54] More frequent episodes of hypotension further reduce survival. Arterial pressure monitoring facilitates early detection of hypotension; we recommend it for children with hypotension or protracted courses in the ED. While avoidance of hypotension (<5th percentile for age, estimated as systolic blood pressure <70 + age × 2) reduces mortality, the ideal blood pressure target is unknown.

It is also not clear if augmentation of blood pressure with intravenous fluids or vasopressors mitigates the mortality risk. Although vasopressors can help maintain end-organ perfusion in the setting of post-arrest myocardial dysfunction, in observational studies their use has not improved survival. There are no randomized studies of comparing the performance of particular vasopressors for pediatric post-arrest care. In the absence of strong evidence, we administer intravenous fluid

boluses and norepinephrine or push dose epinephrine to maintain systolic blood pressure greater than 5th percentile. Norepinephrine causes fewer arrhythmias than dopamine in adults and is the preferred first-line vasopressor in the post-arrest period. Push dose epinephrine can augment blood pressure while a norepinephrine drip is prepared. Concurrent administration of dobutamine may be necessary to achieve hemodynamic stability in patients with refractory cardiogenic shock.

Ventilation and Oxygenation

Significant alterations in oxygenation and ventilation may also increase mortality. These are quite common; less than one fifth of children have normal oxygen and carbon dioxide levels when measured during the first 6 hours after return of circulation. Confirming the results of a prior smaller study focused on pediatric cardiac arrest, a recent large study of 6250 critically ill children found that severe hyperoxemia ($PaO_2 \geq$ 300 mg Hg) increased mortality (OR = 1.5, 95% CI, 1.1 to 2.1) and recurrent hyperoxemia further increased mortality (OR = 2.5, 95% CI, 1.6 to 3.9).[55] Ventilator settings should be adjusted to maintain oxygen saturations above 94%, while avoiding PaO_2 levels greater than 300 mm Hg. Hypocapnia induces cerebral vasoconstriction, exacerbating ischemia. Meanwhile, hypercapnia leads to vasodilation and cerebral edema. While end tidal CO_2 measurement may allow assessment of trends in carbon dioxide levels, alteration in alveolar dead space in the post arrest period may lead to end tidal CO_2 not accurately representing $PaCO_2$. Therefore, we measure CO_2 directly with a blood gas. Notably, studies of post-arrest oxygenation and ventilation are limited by the timing of oxygen and carbon dioxide measurement, and therefore the true impact of abnormalities on survival is not clear. Nevertheless, in the absence of strong evidence, we recommend adjusting ventilator settings in the post-arrest period to normalize carbon dioxide and oxygen levels.

Targeted Temperature Management

Maintaining normothermia is most important. Theoretically, hypothermia reduces many of the complications seen with reperfusion after cardiac arrest by reducing metabolic demand and free radical production. However, two large randomized control trials of targeted temperature management in children failed to show benefit for children who received induced hypothermia. In a randomized trial of 260 children with out-of-hospital cardiac arrest, targeted temperature management to 33°C (range of 32°C to 34°C) with automated cooling blankets for 120 hours demonstrated no difference from therapeutic normothermia (target temperature of 36.8°C, range of 36°C to 37.5°C) in survival or favorable neurologic outcome (RR = 1.59; 95% CI, 0.89 to 2.85).[56] A subsequent randomized controlled study of 329 children with in-hospital cardiac arrest was terminated early because targeted temperature management to 33°C with the same protocol did not improve survival (RR = 0.92; 95% CI, 0.67 to 1.3).[57] When the in-hospital and out-of-hospital studies were combined to increase the power of the study, targeted temperature management to 33°C continued to show no benefit on survival or favorable neurologic outcome, including in subgroup analyses.[58] These studies were multicenter without standardization regarding other elements of post-arrest care, potentially limiting the conclusions. The 2019 PALS update endorses targeted temperature management or avoidance of hyperthermia as "reasonable" options.[6] In the absence of strong evidence, we recommend monitoring core temperature and focusing on the avoidance of hyperthermia (target temperature of 36°C to 37.5°C) with external cooling and antipyretic medications. If cooling is employed, children should not be allowed to reach temperatures less than 32°C, which increases mortality.[59]

Glucose

In response to the stress of cardiac arrest, alterations in glucose levels are also common. In theory, significant hyperglycemia produces an osmotic diuresis, which impairs perfusion. In critically ill children not suffering from cardiac arrest, hyperglycemia worsens outcomes. However, in pursuit of euglycemia with insulin administration, children often become hypoglycemic. Critically ill children randomized to a lower target glucose (80 to 110 mg/dL) had more frequent episodes of profound hypoglycemia but similar mortality and duration of intensive care unit (ICU) stay compared to higher glucose levels (150 to 180 mg/dL).[56] In the absence of strong evidence in post-arrest care, we recommend targeting modest glucose control (80 to 180 mg/dL) and vigilant avoidance of hypoglycemia.

Arrhythmia and Seizures

Children may develop arrhythmias or seizures following reperfusion. Premature atrial or ventricular contractions are most frequent, particularly with vasopressor administration, and do not require therapy. In contrast, ventricular arrhythmias may arise and require prompt administration of antiarrhythmics (see Table 158.3). Seizures arise in 10% of children, with over two thirds of cases evolving into status epilepticus.[60] As seizures are associated with poor neurologic outcome, consensus guidelines recommend continuous electroencephalogram (EEG) monitoring as soon as possible to detect non-convulsive status, which is common.[61–63] While there are no randomized trials in children seizing after arrest, we recommend benzodiazepines, followed by fosphenytoin or levetiracetam, for seizures.

Family Presence

We endorse the recommendation from the American College of Emergency Physicians (ACEP) and American Academy of Pediatrics (AAP) that physicians offer family the opportunity to be present during their child's resuscitation. The limited evidence to support this recommendation is primarily descriptive or survey-based. Most families want to be present for the resuscitation of their child, and when asked after being present, they report that they would repeat the experience, even if their child died. Families report their presence helps them appreciate the efforts of clinicians, facilitates their understanding of the gravity of the situation, and facilitates the grieving process. In contrast, surveyed physicians frequently are reluctant to have families present, often mistakenly assuming families will impede care. In the only randomized study of family presence during trauma resuscitations in a pediatric ED, 93% of physicians reported increased stress from family presence. However, the adverse effects of family presence seemed limited to stress on the physician. No differences were detected in clinical care, and other studies have confirmed that family presence rarely hinders care. In most situations, the benefits to the family of being present outweigh the increased stress on clinicians.

Structured programs for family presence during resuscitations are helpful. Families should be counseled on anticipated events prior to entering the resuscitation. They should be informed that their presence in the resuscitation is their decision; although, they can be asked to leave if they impede medical care. Designated nurses or social workers with training in grief counseling and free of clinical responsibilities should focus on the family, explaining steps in the resuscitation and answering questions.

SEPTIC SHOCK IN THE PEDIATRIC PATIENT

Foundations

Background

Sepsis is the leading cause of death in children worldwide. Globally, 8% of children in the ICU have severe sepsis with mortality approaching 25%.[64] Young age (<1 month), immunosuppression, chronic debilitating disease, presence of invasive devices, and genitourinary anomalies

increase the risk of sepsis and severe disease.[65,66] Rates of sepsis have increased over time, likely due to increased recognition. Mortality has decreased, likely a result of immunizations and the implementation of consensus recommendations. While these guidelines are not grounded in strong evidence, EDs in the United States implementing these guidelines have reduced mortality and length of stay. Nevertheless, variation and uncertainty persist for multiple elements of ED sepsis management, particularly the optimal approaches to screening, diagnosis, fluid administration, and vasoactive therapy.

Pathophysiology

Sepsis arises when immune dysregulation following an infection promotes pro and anti-inflammatory cascades that may manifest in vasodilation, myocardial depression, activation of the complement system, disseminated intravascular coagulation, and increased production of nitric oxide. Infection tends to arise from common bacterial and viral pathogens in the lungs, blood, urine, or the skin, with the most likely organism depending on the location of the infection and patient risk factors. Immunosuppressed children may develop less common bacterial or fungal infections. Unchecked, infections progress to shock with end-organ hypoperfusion and then multisystem organ failure.

Clinical Features

The diagnosis of sepsis is difficult, with numerous definitions in the literature. Definitions were derived from consensus only and were primarily established for research purposes. For example, the presence of SIRS criteria (abnormal temperature or white blood cell count and tachycardia or tachypnea) plus infection constitutes sepsis per guidelines, but many children with non-life threatening infections display SIRS criteria.[67] Differentiating these patients from patients with early sepsis is crucial, as delays in treatment of sepsis adversely impact outcomes. While definitions of sepsis were revised in adults to improve clinical application during the latest consensus conference (Sepsis-3), pediatric definitions have not been significantly revised in the last fifteen years. We extrapolate from the adult evidence and recommend strong consideration of sepsis in children with concern for infection, SIRS criteria, and any physical examination or laboratory findings of decreased perfusion or organ dysfunction.[68] Systematic screening allows for early detection of sepsis, but clinician assessment is necessary to confirm concern for sepsis and the need for treatment.

Most individual physical examination findings demonstrate poor diagnostic accuracy for sepsis. Hypotension is the most reliable indicator of septic shock and impending organ dysfunction, but it tends to develop late in the disease course, as children are able to maintain their blood pressure through tachycardia and vasoconstriction. In contrast to adults, hypotension is not universally present with pediatric septic shock. Other potential signs of organ dysfunction may be present, including toxic appearance, altered mental status, loss of consciousness, seizures, or respiratory failure. The combination of hypotension and delayed capillary refill together portended the highest mortality in a large study of patients transported to a pediatric ICU. Other findings, such as dry mucus membranes, sunken eyes, decreased urine output, height of fever, or rigors, have poor diagnostic accuracy for sepsis or shock.

Multiple scoring systems exist to identify early sepsis and predict outcomes. Similar to adults, the Quick Sequential Organ Failure Assessment (qSOFA) score may help identify patients with organ dysfunction. qSOFA includes altered mental status, hypotension, and tachypnea. In two large retrospective studies, an age adjusted qSOFA had lower sensitivity but much better specificity compared to SIRS for predicting mortality from pediatric sepsis.[69,70] Other scoring systems, such as the quick Pediatric Logistic Organ Dysfunction-2 Score (qPELOD2) have poorer diagnostic accuracy.[71]

Consensus guidelines define septic shock as hypotension refractory to administration of ≥40 mL/kg of intravenous fluids in one hour. From a practical perspective, we recommend considering any child with hypotension (blood pressure <5th percentile for age) to be in shock. While children may develop cold or warm shock, it is difficult to differentiate these processes without invasive monitoring. Laboratory testing may augment the diagnosis, but treatment should not be delayed if there is high clinical suspicion for sepsis. Venous blood gas can identify a metabolic acidosis and elevated lactate. In an observational study of children with SIRS, lactate greater than 4 mmol/L in the ED was associated with increased 30 day mortality (OR = 3.3; 95% CI, 1.2 to 9.2).[72] Efforts should be made to identify the source of the infection in order to target therapy. Bacteremia and urinary tract infections are common, so blood and urine cultures should be obtained from all patients. Risk-stratification strategies in a research setting include RNA expression profiling and novel serum biomarkers. These techniques hold promise in the future for more objective and systematic assessment to enable clinicians to distinguish children with more benign viral illness from those with early septic shock.

Management

The pillars of emergency treatment of pediatric sepsis are: (1) timely establishment of intravascular access; (2) rapid fluid resuscitation titrated to patient condition; (3) appropriate, broad-spectrum antibiotics; and (4) individualized vasoactive agents directed to reverse shock (Table 158.4).

The 2020 pediatric Surviving Sepsis Campaign guidelines strongly recommend **antibiotic** administration as soon as possible and within 1 hour of recognition of septic shock.[73] Delays in appropriate antimicrobial therapy increase mortality and prolong organ dysfunction in pediatric patients with severe sepsis or septic shock.[74] For children with sepsis-associated organ dysfunction but not shock, guidelines recommend antibiotic administration as soon as possible and within 3 hours of recognition. This allows time to acquire laboratory studies to help differentiate sepsis from other infections. Acquisition of blood cultures should not delay administration of antibiotics. While host factors, suspected source, and local susceptibility patterns should guide antibiotic selection, children with septic shock or organ dysfunction typically require broad spectrum antibiotic therapy in the ED. For otherwise healthy children with community acquired sepsis, a third-generation cephalosporin, such as ceftriaxone, is often appropriate. For chronically ill children or hospital acquired sepsis, an antipseudomonal cephalosporin, such as cefepime; a carbapenem, such as meropenem; or extended spectrum penicillin, such as piperacillin/tazobactam is appropriate. Additional antibiotics may be required in children at risk for drug resistance. Antibiotics can later be tailored to culture results. There is not strong evidence to suggest that children with sepsis require multiple antibiotics targeting the same organism, although multiple antibiotics may be appropriate in certain high-risk scenarios, such as septic shock in immunocompromised children. If available, an infectious disease physician can help guide antibiotic therapy for complex patients.

Septic shock in children is most frequently marked by relative or absolute hypovolemia; outcomes from shock in children are improved when the shock state is reversed as early as possible. Cohort studies have demonstrated improved mortality and hospital length of stay in septic children with hypotension or organ dysfunction treated with 40 to 60 mL/kg of **intravenous (IV) fluid** in the first hour. A highly publicized randomized controlled trial in African children with severe infection, but not hypotension, demonstrated increased mortality in patients receiving 20 to 40 mL/kg in the first hour compared to no fluid. This outcome likely is specific to the setting, as there were limited

resources and a high frequency of malaria and anemia. In another single, small study, rapid administration of fluid bolus in less than 10 minutes increased the risk of needing mechanical ventilation. We follow the 2020 Surviving Sepsis guidelines and administer up to 40 to 60 mL/kg in the first hour.[75,76] Fluid resuscitation should be goal-directed and continue until vital signs and signs of perfusion improve, which may necessitate administration of multiple 10 to 20 mL/kg boluses.

TABLE 158.4 Bundled Management of the First Hour of Septic Shock

	Key Features	Sample Regimen
Antibiotics	Broad spectrum; MRSA coverage if indwelling catheter; Pseudomonas coverage if nosocomial infection	Cefepime 50 mg/kg +/– Vancomycin 20 mg/kg
Fluids	Large bore intravenous access; Bolus isotonic fluid; Monitor fluid responsiveness	20 mL/kg lactated Ringers over 10 min
Vasopressors	Hypotension refractory to fluids	Epinephrine 0.05 mcg/kg/min
Cultures	Blood, urine cultures; Viral testing based on clinical suspicion; Should not delay antibiotics	2nd blood culture if indwelling line
Monitoring	Frequent bedside assessments for signs of fluid overload	Cardiorespiratory monitoring; arterial line for hypotension; not routinely need central venous pressure, mixed venous saturation

MRSA, Methicillin-resistant Staphylococcus aureus.

Concomitant with fluid administration, clinicians should monitor children for signs of fluid overload and reduce or stop fluids for any signs of pulmonary edema (e.g., tachypnea) or new hepatomegaly. Notably, hypoperfusion may persist despite correction of hypotension. Similarly, tachycardia may persist despite restoration of perfusion. In resource limited settings, clinicians should be cautious about reflexively administering excessive amounts of fluid, and guidelines recommend a maximum of 40 mL/kg over the first hour.[73] Most children will not require invasive monitoring in the ED to assess fluid responsiveness.

We recommend prompt acquisition of large bore intravenous access via an intravenous or intraosseous line and fluid bolus administration early in presentation. Fluid can be administered using a "push-pull" inline syringe, rapid infuser, or pressure bag to achieve a goal of administering each 20 mL/kg crystalloid fluid bolus over 10 to 20 minutes, followed by reassessment and potentially additional boluses (Fig. 158.2). There is conflicting evidence from two large retrospective studies about the benefits of balanced fluids, such as lactated Ringers, versus normal saline.[77,78] When data from these studies was combined it showed decreased mortality with balanced fluids. Based on this result and other studies in adults, the 2020 pediatric guidelines recommend administration of balanced fluids.[73] There is *insufficient* evidence to support routine administration of albumin or starches in the resuscitation of children in septic shock in the ED.

If shock does not improve with administration of 60 mL/kg of isotonic fluid, or if signs of fluid overload develop in the setting of ongoing hypoperfusion, children should receive **vasoactive agents**. Epinephrine or norepinephrine may serve as the first-line agent in pediatric septic shock. In two small studies, epinephrine was associated with more rapid resolution of shock and decreased mortality compared to dopamine.[79,80] Therefore, epinephrine (0.05 mcg/kg/min) is our standard first-line agent. If the child's status does not improve with the initial agent, then a second vasopressor should be administered. There is no evidence to guide the choice of the second agent. We initiate vasoactive agents in any pediatric patient with septic shock and hypotension lasting more than 1 hour, regardless of the amount of fluid delivered.

Fig. 158.2 (A) Using a 60-mL syringe with an inline three-way stopcock is an effective way to deliver rapid fluid boluses, particularly in patients less than 25 kg where a bolus is not easily dosed by a standard fluid bag. (B) Rapid infusers and pressure bags rapidly deliver fluid boluses when a full bag is an appropriate dose. (Courtesy Tia Brayman, Children's Hospital Colorado.)

Obtaining central venous access in an ill child is an uncommon procedure in most EDs, and it is a frequent source of delayed care in pediatric septic shock. Instead, we recommend rapid vascular access in critically ill children with large bore peripheral IV catheters or an intraosseous device. Vasoactive infusions can be administered through a peripheral IV catheter to correct shock until a central venous catheter can be placed safely.

Critical illness-related corticosteroid insufficiency is moderately prevalent in pediatric sepsis, and nearly half of septic children receive exogenous **corticosteroids**.[64] However, there is insufficient evidence to support or refute this practice. A small retrospective study found increased mortality with hydrocortisone administration to children with catecholamine resistant shock.[81] Nevertheless, based on larger studies in adults, we administer hydrocortisone (50 to 100 mg/m^2 or 1 to 2 mg/kg, maximum 100 mg/dose) for children in shock refractory to fluids and vasoactive agents. The 2020 pediatric sepsis guidelines state hydrocortisone may be considered under these circumstances.[73]

Although, like adults, children with sepsis may be prone to stress hyperglycemia, they are also prone to hypoglycemia due to their limited glycogen stores. Tight and conventional **glycemic control** has shown equivalence in critically ill children; a large trial is currently underway to determine optimal glucose control strategies. We recommend correction of hypoglycemia and cautious use of insulin with frequent glucose monitoring for blood glucose levels more than 180 mg/day (10.0 mmol/L).

Combining the aforementioned therapies into a **bundle** appears to improve outcomes. A large prospective, multicenter, observational study found that administration of a bundle of antibiotics and fluids coupled with acquisition of blood cultures within one hour reduced mortality (OR = 0.59; 95% CI, 0.38 to 0.93).[82] Notably, administration of each individual element within one hour was not associated with decreased mortality. The 2020 pediatric Surviving Sepsis guidelines recommend a bundled approach for children with signs of organ dysfunction.[73] EDs should establish protocols to ensure acquisition of a blood culture and administration of a fluid bolus and antibiotics within one hour. Despite a mandate at participating hospitals in the aforementioned study to complete the bundle within one hour, less than one in four children met this mandate. Therefore, EDs should have continuing quality improvement measures which facilitate and encourage use of a bundled protocol.

Monitoring Response to Therapy

There are limited options to assess response to therapy beyond the physical examination. Clearance of lactate may reflect reversal of tissue hypoxia. In a small prospective observation study, children whose lactate decreased to less than 2 mmol/L within 3 to 4 hours had less organ dysfunction (RR = 0.46; 95% CI, 0.29 to 0.73).[83] Passive leg raise may predict fluid responsiveness, but there are no large studies in pediatric sepsis. Transthoracic echocardiography may establish a role in refractory septic shock in the future; small studies suggest between 41% and 71% of children have myocardial dysfunction.[84,85] Currently there is insufficient evidence to support routine ED utilization of other modalities for treatment response, including mixed venous oxygen saturation monitoring, central venous pressure, biomarkers, or non-invasive cardiac output monitors.[86]

Brief Resolved Unexplained Events

Background

In 2016, the American Academy of Pediatrics published consensus guidelines creating a new term, BRUE, to describe infants less than 1 year of age presenting with transient alterations in their breathing, appearance, or behavior that cannot be explained based on their history or physical examination.[87] BRUE has supplanted apparent life-threatening event (ALTE), a term that was too broad in scope to be clinically useful. BRUE is more precise and allows for the establishment a low-risk group of infants that do not require further evaluation. The hallmark of a BRUE is that the cause for the event is unclear. As a result, children with potential explanations for their presentation are not classified as having BRUEs, e.g., a child with a transient episode of cyanosis in the setting of congestion is not a BRUE.

TABLE 158.5 Brief Resolved Unexplained Event Compared to Apparent Life-Threatening Event

	BRUE	ALTE
Defining characteristics	Change in breathing, tone, color	
Other elements	Possible alteration in consciousness	Apnea; possible choking, gagging
Perception	Concerning to clinician	Concerning to lay observer
Etiology	Unexplained	Unexplained or GERD, seizure, infection, etc.
Age	<1 year	<1 year
Duration	<1 min	Any
History	Unrevealing	May identify etiology
Vital signs	Normal	May be abnormal
Physical examination	Normal	May identify etiology

ALTE, Apparent life-threatening event; *BRUE,* brief resolved unexplained event.

Clinical Features

With a BRUE, a child may have changes in breathing, tone, or responsiveness. Breathing may be absent, decreased, or irregular, potentially leading to central cyanosis or pallor. This does not include acrocyanosis, perioral cyanosis, rubor, or periodic breathing, which are commonly encountered in healthy infants. Infants may have increased or decreased tone, although this does not include hypertonia with crying or straining, which is normal.

There are multiple differences between BRUEs and ALTEs (Table 158.5), but the primary distinction is that the emergency clinician cannot determine any potential etiology for a BRUE. On presentation to the ED, the infant appears well without any examination abnormalities. Therefore, to determine if an event constitutes a BRUE, clinicians should focus on historical circumstances before, during, and after the event. Certain features may suggest a common or dangerous etiology and indicate the event does not represent a BRUE (Table 158.6).

If no etiology for the event is apparent, BRUEs can be classified further into high or low risk events. Low-risk infants are those born ≥32 weeks and greater than 60 days of age with no prior BRUEs, and CPR (by a health care provider) was not performed during the event. If these features are present, infants are potentially at higher risk of recurrent events or adverse outcomes. Several retrospective studies have confirmed the diagnostic accuracy of these criteria.[88,89]

Management

As the concept of BRUE is relatively new, there is not strong evidence to guide management. However, evidence extrapolated from children with ALTEs suggests that testing low-risk BRUEs is low yield, and we recommend limiting routine testing to an electrocardiogram, which

TABLE 158.6 Presenting Features of Common Conditions Leading to Transient Alterations in Breathing, Responsiveness, or Color in Infants

Condition	Potential Features
GERD	Choking, gagging, vomiting, after feed; Often turn red; Brief apnea
Respiratory infection (RSV, pertussis)	Congestion, cough; Tachypnea; Adventitial lung findings
Seizure	Convulsions; Altered consciousness; Eye deviation
NAT (brain hemorrhage)	Delayed presentation; Inconsistent history; Signs of trauma; Head circumference >95th percentile
Bacterial infection (UTI, bacteremia, meningitis)	Fever; Lethargy; Irritability

GERD, gastroesophageal reflux disease; *NAT,* nonaccidental trauma; *RSV,* respiratory syncytial virus; *UTI,* urinary tract infection.

displayed high sensitivity for arrhythmias and structural heart disease in children with ALTE. While cardiac abnormalities are rare causes of BRUEs, an electrocardiogram is safe, inexpensive, and easy to obtain. For children with signs of central apnea during their event, we consider pertussis testing, as infants may develop apnea before they manifest other respiratory symptoms.

Guidelines explicitly discourage routine acquisition of other tests, including blood, CSF, radiography, EEG, echocardiogram, or testing for gastroesophageal reflux disease (GERD). Moreover, typically viral respiratory testing, urinalysis, or neuroimaging are not necessary for low-risk infants. These guidelines appear to have reduced testing over time.[90,91] There is no definitive evidence about the benefit of ED observation or pulse oximetry measurement, but we observe low-risk infants for 2 to 4 hours in the ED with intermittent pulse oximetry assessments.

There is little evidence for the management of high-risk BRUEs. We agree with a recently proposed tiered approach.[92] To determine occult etiologies for a high-risk BRUEs, we recommend obtaining a respiratory viral panel, hematocrit, glucose, bicarbonate, and lactic acid, as well as a feeding evaluation and screen for non-accidental trauma, to be completed by a social worker. If the evaluation is unrevealing, we recommend the patient be admitted for further evaluation and continued monitoring. Where ED resources are limited or in high demand, some children may require admission to complete this evaluation. This approach is derived from consensus and has not been studied.

Disposition

Low-risk BRUEs are unlikely to benefit from hospitalization and therefore guidelines recommend discharge from the ED with outpatient follow-up within 24 hours. Parents may be reluctant to return home, but a recent meta-analysis may provide reassurance.[93,94] Pooling of data from 3,005 infants found no increased risk of death following a BRUE.[95] There is no evidence to support outpatient cardio-respiratory monitoring.

CHAPTER 158: QUESTIONS AND ANSWERS

1. You are treating a 4-month-old with bronchiolitis. While being observed in the ED, the child becomes bradycardic and then loses pulses. What should be the primary focus of your initial minutes of the resuscitation?
   - **a.** Preparing to insert an endotracheal tube to improve oxygenation and ventilation
   - **b.** Correction of potential acidosis with bicarbonate
   - **c.** Vascular access to administer epinephrine
   - **d.** Uninterrupted compressions with ventilations via bag-mask device

Answer: d. At the beginning of the arrest, the most important elements are restoration of perfusion and ventilations with compressions and ventilations. Early insertion of an endotracheal tube is likely to impede compressions, and initial ventilations should occur with a bag valve mask and oral airway. Vascular access will be needed but is not as time sensitive. Bicarbonate should be given only if there is a clear indication.

2. After return of circulation, which action is most critical to improve a child's prognosis?
   - **a.** Empiric amiodarone to prevent arrhythmias
   - **b.** Avoidance of hypotension
   - **c.** Induced hypothermia to 33°
   - **d.** Strict glucose control less than 110 mg/dL with an insulin drip
   - **e.** Maintenance of oxygen saturation at 100%

Answer: b. A single episode of hypotension increases mortality and therefore efforts should be made to avoid it. Induced hypothermia does not appear to improve outcomes in pediatric arrest. Strict glucose control, hyperoxemia, and empiric amiodarone are not beneficial and may induce harm.

3. A 6-year-old male with Trisomy 21 presents with decreased responsiveness and not eating. His temperature is 39°C, heart rate is 150, blood pressure is 80/55, respiratory rate is 24, oxygen saturation is 98%, and glucose is 90 mg/dL. He receives cefepime and 20 mL/kg of lactated Ringers but his vital sign abnormalities persist. On examination, he is lethargic with a neck that is supple, lungs that are clear to auscultation, cool extremities, and capillary refill of 3 seconds. What is the next best step in the management?
   - **a.** Hydrocortisone 50 mg/m^2
   - **b.** Vancomycin 50 mg/kg
   - **c.** Epinephrine 0.05 mcg/kg/min
   - **d.** Lactated Ringers 20 mL/kg

Answer: D. This child is in septic shock. He received an initial fluid bolus but has ongoing signs of decreased perfusion. In the absence of signs of pulmonary edema, the next step should be to administer another bolus of isotonic fluids. He may benefit from epinephrine and vancomycin but after a second bolus is initiated.

4. A 4-month-old girl presents after changing color and tone at home. She was feeding and started to choke. She turned red-purple in her face and upper body while her arms stiffened. After 30 seconds, she spit up some formula, and the episode resolved. She was born full-term and has no other medical issues. In the ED she is asymptomatic and has a normal physical examination. What is your next step in the management of this patient?
   - **a.** Discharge after 2 hours of observation
   - **b.** Classify the event as a high-risk BRUE and admit to the hospital
   - **c.** Obtain a pH probe to assess for GERD
   - **d.** Obtain an ECG and blood glucose

Answer: a. Choking in the setting of feeding with complete resolution of the symptoms after vomiting suggests reflux. As a potential etiology is apparent based on the history, this event should not be classified as a BRUE. Diagnostic testing is not necessary; pH probes are not specific for GERD and are rarely helpful in the ED.

5. Which of the following medications have shown a mortality benefit for children in arrest without a clear etiology?
   - **a.** Calcium chloride 20 mg/kg
   - **b.** Sodium bicarbonate 1 mEq/kg
   - **c.** Epinephrine 0.01 mg/kg
   - **d.** Normal Saline 20 mL/kg

Answer: c. There are no randomized control trials of medications in pediatric arrest. However, observational studies suggest that epinephrine is beneficial. Other medications are only beneficial for specific indications, such as glucose for hypoglycemia.

Neonatal Resuscitation

Ryan D. Kearney

KEY CONCEPTS

- Resuscitation should be anticipated for all deliveries; 10% of newborns will require some resuscitation, and 1% will require advanced life support interventions after birth.
- Predictable indications for resuscitation include hypoxia, hypothermia, hypoglycemia, hypovolemia, prematurity, maternal infection, and adverse effects of maternal medication.
- Drying, warming, positioning, and stimulating the infant are sufficient resuscitative measures for most deliveries.
- Adequate ventilation will reverse most bradycardia, while oxygenation with more than 21% fraction of inspired oxygen (FiO_2) is not indicated for most neonatal resuscitations.
- The Neonatal Resuscitation Program (NRP) resuscitation algorithm provides a proven guide for management and its implementation has shown to improve short- and long-term outcomes, including neurodevelopment.
- Routine tracheal suctioning of vigorous and nonvigorous infants born through meconium-stained amniotic fluid is no longer recommended.
- Weight-based epinephrine and volume expanders are rarely required.
- Significant hypovolemia is rare in neonates. Hemorrhage is one of the few predictable situations in which volume expansion improves newborn outcome.
- Preterm infants and those born to mothers with suspected infection, including chorioamnionitis, should receive empirical antibiotic therapy. An acceptable regimen includes dual therapy with ampicillin and gentamicin.
- Any neonate with persistent cyanosis or signs of respiratory distress (e.g., grunting, nasal flaring, and tachypnea) should be assisted by continuous positive airway pressure (CPAP) or positive pressure ventilation (PPV). Endotracheal intubation should be performed in several situations, such as when bag-mask ventilation is ineffective or prolonged, chest compressions are performed, an extremely low birth weight infant is born, and tracheal suctioning for meconium in infants results in failure to improve, despite effective PPV.
- Chest compressions are rarely required, because bradycardia generally responds to effective ventilation. However, compressions should be started for a heart rate (HR) less than 60 beats/min despite oxygen and adequate ventilation for 30 seconds.
- The umbilical vein is the preferred route of immediate vascular access, followed by peripheral veins, peripherally inserted central catheter lines, and the femoral vein. Intraosseous (IO) line placement can be problematic in neonates.
- No reliable and widely adopted set of parameters has been identified for newborns who should not receive resuscitative efforts. Unless there is clear family, parent, and health care provider agreement, resuscitation efforts should ensue.
- Infants receiving appropriate resuscitation efforts nonetheless showing no signs of life after 10 minutes may have further efforts withheld, particularly when this decision is in accord with parental preference.
- All newborns requiring intravenous (IV) line placement, medication administration, chest compressions, or endotracheal intubation should be transferred to an appropriate neonatal intensive care unit.

FOUNDATIONS

Approximately 10% of newborns require some assistance at birth, with 1% requiring extensive resuscitative measures.[1] Knowledge of neonatal physiology, appropriate equipment, and procedural skills is essential to successful resuscitation. Preparation for neonatal resuscitation requires an understanding of how it differs from pediatric and adult resuscitation:

1. Newborns have rapidly changing, dynamic cardiopulmonary physiology, with a unique range of normal vital signs.[2,3]
2. Neonatal resuscitation is almost entirely respiratory (not cardiac) management.[2]
3. Neonates require special and dedicated equipment.

TRANSITION FROM FETAL TO EXTRAUTERINE LIFE

The successful transition from fetal to extrauterine life requires three major cardiorespiratory changes: (1) removal of fluid from unexpanded alveoli to allow ventilation; (2) lung expansion and establishment of functional residual capacity (FRC); and (3) redistribution of cardiac output to provide lung perfusion. Failed development of adequate ventilation or perfusion leads to persistent shunting, hypoxia and, ultimately, a deleterious reversion to fetal physiology.[2]

In utero, fetal nutrient and gas exchange is dependent on the placenta, a temporary organ with remarkably low vascular resistance, as well as the maternal circulation. As a result of its low resistance, the placenta receives approximately 30% of total fetal cardiac output between 18 and 41 weeks of gestation. In contrast, fluid-filled fetal alveoli have increased vascular resistance, leading to poor perfusion of the developing lung. The pulmonary arterial bed is so vasoconstricted that the fetal lung receives only 40% of right ventricular output and approximately 10% of total cardiac output; most of the right ventricular output is shunted from the pulmonary artery through the ductus arteriosus to the descending aorta.[4,5] An additional right-to-left shunting occurs at the level of the foramen ovale, with relatively oxygen-rich blood shunted from the right to left atrium. Fig. 159.1 illustrates normal intracardiac fetal circulation. Reversal of these two shunts is essential to the successful transition into extrauterine life and is facilitated by the significant drop in pulmonary vascular resistance that occurs at birth. The first step in this process is alveolar fluid clearance.

Removal of this fluid is partially accomplished by vaginal delivery, which provides some compression of the fluid out of the alveoli into the bronchi, trachea, and pulmonary capillary bed. The remaining fluid is largely evacuated by the first few breaths, with the quality of the first few breaths crucial to establishing adequate ventilation. Alveolar expansion requires the generation of high intrathoracic pressures and the presence of surfactant to maintain alveolar patency. Because the lung is one of the last organs to reach structural and functional maturity,

Fig. 159.1 Meconium Aspirator With Suction and 3.0 Uncuffed Endotracheal Tube (ETT) Attached. (Courtesy Seattle Children's Hospital, Seattle, WA.)

interruptions in this coordinated physiologic process, although rare, should be nonetheless anticipated in all deliveries, particularly those outside of the delivery room.[6]

After the first few breaths, pulmonary vascular resistance decreases as a result of alveolar oxygen exposure. Simultaneously, clamping of the umbilical cord removes the placenta from circulation, predictably increasing systemic vascular resistance. Shunting through the ductus arteriosus reverses as systemic vascular resistance increases; this usually ceases altogether by 15 hours of age as the ductus arteriosus also constricts. This reversal of flow redirects all right ventricular output to the lungs. However, hypoxia or acidosis can cause the pulmonary vascular bed to constrict again, and, when severe or prolonged, recurrent pulmonary vascular constriction can cause the ductus arteriosus to reopen. The reinstitution of fetal circulation, with its attendant shunting, leads to ongoing hypoxia and is termed *persistent fetal circulation*.[2] When indicated, resuscitation facilitates the first few breaths, prevents and reverses ongoing hypoxia and acidosis, and assists the newborn in the transition to extrauterine life.

SPECIFIC ISSUES

Indications for Resuscitation

At least one person, whose exclusive role is to ensure safe transition of the newborn, should be present for all deliveries, including those that occur outside the delivery room. Any infant born outside of a delivery room should be anticipated to need resuscitation.[1–3] Although minimal intervention may be required, a standardized approach should still be followed. Some specific conditions increase the likelihood that additional resuscitative efforts will be required.

Hypoxia

Even in the uncompromised newborn, it can take 10 minutes for blood oxygen saturation to reach normal extrauterine levels.[1] Pulse oximetry may assist in determining hypoxemia, but it may take several minutes for a reliable waveform to be achieved.[7,8] In utero or intrapartum asphyxia (pathologic lack of oxygen to the fetus before or during delivery) can precipitate a sequence of events that results in primary or secondary apnea. With initial hypoxia, rapid gasps are followed by cessation of respirations (primary apnea) and, if prolonged, decreased heart rate (HR). Ostensibly normal respiratory effort does not ensure adequate ventilation. However, bradycardia in the newborn (HR < 100 beats/min) almost always reflects inadequate ventilation and oxygenation. As such, bradycardia is a major indicator of hypoxia.[1,2] Simple stimulation is required at the onset of primary apnea to stimulate ventilation and reverse bradycardia. If asphyxia persists, the newborn takes several final deep, gasping breaths, followed by cessation of respirations (secondary apnea); this is accompanied by worsening bradycardia, refractory to simple stimulation, and eventually hypotension. For newborns with secondary apnea, more vigorous and prolonged resuscitation is needed to restore ventilation and adequate circulation.[2]

Hypothermia

Drying and warming the newborn are vital to initial resuscitation because the newborn's inability to maintain normothermia (>36.5°C [97.7°F]) has potentially dire consequences. Newborns cannot generate heat by shivering, cannot retain heat due to low fat stores, and have excess heat loss due to their large surface-to-volume ratio. Exacerbating these challenges in the immediate postpartum period, newborns have an acutely elevated metabolic rate, are covered with amniotic fluid, and are suddenly exposed to a relatively cool environment. Body temperature rapidly decreases, with hypothermia accelerating metabolic acidosis, oxygen consumption, hypoglycemia, and apnea.[1–3] Prematurity and very low birth weight status exacerbate these consequences and require extra efforts to mitigate.[1]

Hypoglycemia

Poor glycogen stores, coupled with immature hepatic enzymes, place the normal newborn at increased risk for hypoglycemia. Hypoglycemia is particularly common in premature and small-for-gestational-age newborns, as well as those born to diabetic mothers. Hypoglycemia may also be a response to other factors, including respiratory illness, hypothermia, polycythemia, asphyxia, and sepsis. Hypoglycemia can be asymptomatic or may cause an array of symptoms, including apnea, color changes, respiratory distress, lethargy, jitteriness, seizures, acidosis, and poor myocardial contractility.[9,10] A low blood glucose level, particularly when prolonged, recurrent, or associated with hyperinsulinism, has been associated with adverse neurologic outcomes[9]; correction of hypoglycemia, if detected expeditiously, improves outcomes.[11] Neonatal hypoglycemia is generally defined as a blood glucose level less than 40 mg/dL, although this number serves as more of a guideline than a strict cutoff. All newborns exhibiting signs of hypoglycemia, with glucose levels less than 40 mg/dL, should receive intravenous (IV) glucose. *Of note, bedside glucometers tend to underestimate plasma glucose levels by approximately 10 mg/dL.*[10]

Hypovolemia

Clinically significant hypovolemia is rare and usually secondary to blood loss. Risk factors include known maternal hemorrhage during delivery, prematurity, newborns with overt shock, and initiation of cardiopulmonary resuscitation (CPR).[1–3,12] Hemorrhage can lead to respiratory depression and overt shock in the newborn, whether secondary to abruptio placentae, placenta previa, umbilical cord accident, or trauma. In the newborn, hemorrhage is one of the few situations in which fluid resuscitation and volume expansion improves outcomes. At the time of birth, mean arterial pressure should be equivalent to known or estimated gestational age. Examination findings consistent with hypovolemia or hemodynamically significant hemorrhage include pallor, despite oxygenation, weak pulses with a rapid HR, and poor response to resuscitation.[1–3]

Prematurity

Premature infants, especially those born before 34 weeks of gestational age, are uniquely at risk due to their pulmonary immaturity and susceptibility to hypothermia. Those requiring delivery room CPR have increased risk of mortality, intraventricular hemorrhage, periventricular leukomalacia, early sepsis, and retinopathy of prematurity.[13] For these reasons, in utero transfer of high-risk pregnant women to tertiary centers possessing expertise and experience with premature infant resuscitation has been associated with improved neonatal outcomes.[14] Intubation should be performed for the premature newborn in respiratory distress, which is clinically suggested by retractions, desaturation, or tachypnea.[15] In certain cases, surfactant may be delivered via an endotracheal tube (ETT) shortly after birth.

MECONIUM-STAINED AMNIOTIC FLUID

Meconium-stained amniotic fluid (MSAF) indicates potentially significant newborn stress prior to delivery. Aspiration of meconium and its consequences can be avoided, or at least significantly limited, by rapid intervention. Previous recommendations stipulated suctioning meconium from the newborn's airway after delivery of the head but before delivery of the shoulders (intrapartum suctioning). However, there appears to be no benefit from intrapartum suctioning.[16,17] Therefore current recommendations no longer advise routine intrapartum suctioning of newborns with MSAF. To prevent aspiration of meconium, previous recommendations also stipulated tracheal suctioning of all nonvigorous newborns with MSAF immediately on delivery and before any other resuscitative efforts (including drying and stimulation). However, routine endotracheal intubation in nonvigorous and vigorous term, meconium-stained newborns has shown no benefit, including the incidence of meconium aspiration syndrome (MAS), pneumothorax, oxygen need, stridor, seizure, or hypoxic ischemic encephalopathy.[18] Standard measures to support adequate ventilation and oxygenation should be initiated for all infants born through MSAF, with a small subset eventually needing endotracheal intubation, as warranted.[1]

The most recent recommendations from the American Heart Association for the practice of tracheal suctioning after delivery for meconium aspiration is that it should be performed only if indicated for signs of airway obstruction secondary to meconium that do not improve despite standard resuscitative measures, including warming and drying and initiation of effective positive pressure ventilation (PPV). When performing tracheal suctioning, a meconium aspirator (see Fig. 159.1) should be attached to the appropriate-sized ETT and connected to wall suction at 100 mm Hg or less. On intubation by direct laryngoscopy, the ETT is then withdrawn while suction is applied. Serial reintubation with suctioning should be repeated to remove obstructing meconium or until the infant becomes vigorous, which is usually accomplished after two rounds. If bradycardia or apnea persists beyond two passes, ongoing resuscitation should include bag-mask ventilation (BMV) and consideration of endotracheal intubation to secure the airway. In tertiary centers with skilled providers, eventual lung lavage with surfactant for babies born through MSAF is likely to reduce duration of hospital stay, mechanical ventilation, and need for extracorporeal membrane oxygenation.[19]

Maternal Factors

Infection

Maternal infection (chorioamnionitis) is a particularly common trigger for premature delivery; premature infants are themselves more susceptible to infection. Therefore IV antibiotics should be administered after obtaining blood cultures, and a complete blood count should be carried out in all infants born before 37 weeks of gestation.

Medications

Medications provided to the mother during labor or illicit drugs taken before delivery, usually opioids, can promote newborn respiratory depression. Maternal opioid administration or antenatal drug abuse should be considered in any newborn with isolated respiratory depression that persists, despite a seemingly successful initial resuscitation. As in adults, opioid-induced respiratory depression could be reversed with naloxone.[1,20] However, naloxone may precipitate acute withdrawal and seizures in the newborn of an opioid-dependent mother; thus naloxone is not recommended in the initial resuscitation of the newborn.[3,21] Suspected opiate toxicity in the newborn should be treated with support of oxygenation and ventilation rather than pharmacologic reversal. This should include use of a bag-mask device and, if necessary, intubation.

Withholding and Discontinuing Resuscitation

No reliable and widely adopted set of parameters has been identified for newborns who should not receive resuscitative efforts.[22] A recent systematic review attempted to identify international consensus surrounding this medically and ethically complex scenario—worldwide, resuscitation is not typically recommended for neonates with a confirmed gestational age less than 23 weeks.[23] In high-income countries, there is increasing resuscitative efforts and postnatal intervention for babies with confirmed trisomies 18 and 13, highlighting the importance of timely counseling to ascertain parental values and expectations.[24] Parental request has been shown to be the most important factor determining resuscitative efforts for newborns at 22 to 25 weeks of gestation; most neonatologists consider a gestational age more than 25 weeks of gestation as the cutoff for obligatory resuscitation, even with parental refusal.[23] In the setting of uncertain gestational age and unclear or conflicting parental wishes, the recommendation is to initiate resuscitation. Similarly, if prognosis is uncertain at the time of delivery, resuscitation should be attempted until additional data can be obtained and parental wishes have been considered. Outside the delivery room, every attempt should be made to stabilize the neonate until further resuscitation would clearly not improve the likelihood of survival with acceptable morbidity. Neonates with no signs of life (asystole, apnea) after 10 minutes of resuscitation have high mortality or severe lifelong developmental delay, and resuscitation can be terminated.[25] This is a rare and inherently challenging decision to make and should account for availability of local resources and personnel skill, transportation needs and options, and parental preference. However, enhanced resuscitation techniques and postresuscitation therapeutic hypothermia have recently shown promise, even for neonates with a 10-minute APGAR score of zero.[26,27] In one notable cohort of term neonates receiving CPR and subsequent hypothermia, more than 50% were found to have normal developmental trajectory by 18 months of age,[26] highlighting the importance of dialogue with the parent(s) and acknowledgment of their feelings regarding the risks of morbidity. Parents should actively participate in the decision to continue or withdraw resuscitative efforts in cases in which there is prognostic uncertainty. For infants with a low 10-minute APGAR score but showing some signs of life, especially when aligned with parental preference, resuscitation efforts should continue until futility is determined. Although not absolute, we recommend considering terminating resuscitative efforts for infants with no signs of life after 10 minutes of resuscitation.

SPECIAL ANATOMIC ANOMALIES

Diaphragmatic Hernia

In addition to pulmonary hypoplasia, neonates with diaphragmatic hernias have exquisitely reactive pulmonary vascular beds, predisposing them to potentially fatal pulmonary vasospasm in the immediate and late postnatal period.[28] Examination findings concerning for congenital diaphragmatic hernia include barrel chest, ipsilateral absence of breath sounds, tracheal or point of maximum cardiac impulse displacement, and scaphoid abdomen. BMV will distend the stomach, which is usually intrathoracic, further worsening respiratory distress. The neonate should be immediately intubated if a prenatal diagnosis of diaphragmatic hernia is known or if a diaphragmatic hernia is diagnosed on the chest radiograph (Fig. 159.2).

Myelomeningocele and Omphalocele

Infants with myelomeningocele should never be placed supine but instead be placed prone or on the side to avoid pressure on the defect

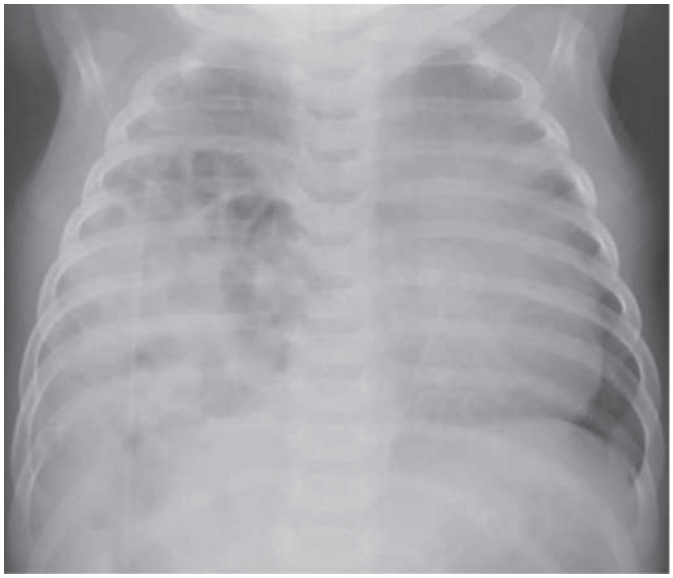

Fig. 159.2 Chest Radiograph Reveals Right-Sided Congenital Diaphragmatic Hernia. (Courtesy Seattle Children's Hospital, Seattle, WA.)

Fig. 159.3 Preoperative myelomeningocele, highlighting the obvious anatomic challenges and sensitivities required in resuscitation of neonates with this condition. (From Elbabaa SK, Luciano MG. Myelomeningocele and associated anomalies. In: Benzel E, editor. *Spine Surgery: Techniques, Complication Avoidance and Management,* 3rd edition. Philadelphia: Saunders; 2012. Figure 117-1.)

(Fig. 159.3). Resuscitation should proceed from this modified position. For unclear reasons, myelomeningocele seems to be associated with an elevated risk for latex allergy, usually necessitating efforts to avoid latex sensitization in these neonates.[29] The spinal defect should be gently wrapped with sterile gauze pads soaked in warm sterile saline and enclosed with plastic wrap.[30] Infants with gastroschisis or omphalocele should be resuscitated as needed, and these defects should also be covered with an occlusive plastic wrapping to decrease water and heat loss.[31] These newborns often require parenteral maintenance fluid infusion, orogastric tube for gastric decompression, and antimicrobial prophylaxis with IV antibiotics.[31]

Choanal Atresia

Because newborns are obligate nose breathers, bilateral choanal atresia causes upper airway obstruction and often severe respiratory distress. Choanal atresia can be rapidly diagnosed by the inability to pass a catheter through either naris into the posterior oropharynx. An oral airway device can bypass the obstruction. Special attention should be paid to a thorough physical examination of these infants because they often have multiple congenital anomaly syndrome.

Pierre Robin Sequence

The hallmark of this abnormality is profound micrognathia, resulting in glossoptosis (retraction or downward displacement of the tongue) and cleft palate. Therefore Pierre Robin sequence confers a high risk for significant upper airway obstruction. A nasal or oral airway should be able to bypass the obstruction; if not, intubation may be necessary. Given the technical challenges of performing endotracheal intubation on a patient with Pierre Robin sequence, fiberoptic intubation is often needed, although prone positioning and a laryngeal mask airway (LMA) or other supraglottic airway device can be attempted to support ventilation.[32] Consultation with anesthesiology or otolaryngology may be required.

Congenital Cardiac Disease

Echocardiographic evidence of congenital heart disease (CHD) is as high as 5% for term newborns.[33] However, critical CHD, defined as requiring surgery, catheter-based intervention, or death in the first 28 days of life, is present in only 1 to 2 per 1000 term births.[33] Stereotypic examination findings seen in critical CHD include a blood pressure gradient between the upper and lower extremities, weak femoral pulses, central cyanosis, pathologic murmur, and hepatomegaly. These signs of cardiogenic shock in a newborn may be fairly indistinguishable from those of severe sepsis and respiratory failure. Resuscitation of a newborn with known or suspected critical CHD should therefore include standard ventilatory management, as well as empiric antimicrobial therapy.[34] Cardiomegaly on a chest radiograph is more likely consistent with cardiogenic shock. Some common laboratory findings include polycythemia and unexplained acidosis. Many newborns with critical CHD have a ductal-dependent lesion and are likely to experience profound physiologic decompensation—defined by severe metabolic acidosis, seizure, cardiac arrest, or renal or hepatic injury—on closure of the ductus arteriosus.[35] Prostaglandin E_1 (PGE_1) should be used in lesions with ductal-dependent systemic or pulmonary blood flow (Box 159.1).[36] In case of an uncertain diagnosis or in preparation for transport to a specialized facility, prostaglandin should be started via continuous IV infusion. A second peripheral IV is recommended to treat the possible adverse effects of prostaglandin: hypotension, tachycardia, and apnea. Continuous alprostadil should begin soon after birth,[36] with gradual dose titration to a maximum of 0.1 μg/kg/min. For a more in-depth discussion on CHD, see Chapter 165.

Newborn Resuscitation Algorithm

Preparation

To maximize the effectiveness of resuscitation, all emergency departments should have an age- and weight-appropriate prestocked drug pack, standardized equipment (Box 159.2), and staff trained on newborn resuscitation.[1,3] There are several pediatric length-based resuscitation tape (e.g., Broselow, PAWPER) that can be used to determine equipment size and drug dosages for newborn resuscitation of infants weighing 3 kg or more.[37,38] A dedicated neonatal resuscitation cart, organized according to the Neonatal Resuscitation Program (NRP) algorithm, increases the speed of equipment retrieval and is preferred by providers to other organizing schemes.[39] When available, additional maternal information (Box 159.3) can help to anticipate resuscitation needs so that appropriate staff, equipment, and disposition plans can be expeditiously managed.

Universal precautions, including gown, gloves, and eye protection, should be followed during neonatal resuscitations. An external heat source should be turned on early and the table warmed prior to the

BOX 159.2 Equipment Checklist for Neonatal Resuscitation

1. Gown, gloves, and eye protection (universal precautions)
2. Timing device
3. Blankets (to warm and dry infant)
4. Plastic wrap (for omphalocele, gastroschisis, possibly premature infant)
5. Radiant warmer
6. Bulb syringe
7. Suction and suction catheters (sizes 5, 8, and 10 Fr)
8. Self-inflating (450 and 750 mL) and flow-inflating (250 and 450 mL) bags
9. Masks (premature, newborn, and infant sizes)
10. Laryngoscope with straight blades (nos. 00, 0, and 1)
11. Endotracheal tubes with stylets (2.5, 3.0, 3.5, and 4 mm), uncuffed
12. Scissors and tape to stabilize endotracheal tube
13. Pediatric CO_2 detector
14. Meconium aspirator
15. Umbilical catheters (3.5 and 5 Fr)
16. Hemostats, sterile drapes and gloves, povidone-iodine solution, scalpel, umbilical tape, suture, and three-way stopcock for umbilical vessel catheterization

BOX 159.3 Maternal History Questions

1. What is the estimated gestational age?
2. Is this a multiple gestation?
3. Is meconium present?
4. Is there a history of vaginal bleeding?
5. Were medications given or drugs taken?
6. Was there documented maternal fever?
7. Did mother have routine prenatal care? If so, were any abnormalities seen on prenatal ultrasonography?

start of resuscitation. Hypothermia is an independent risk factor for neonatal mortality worldwide.[40–42] Similarly, hyperthermia is a risk factor for neonatal encephalopathy and correlates with respiratory depression, cerebral palsy, and mortality. Correct equipment size is essential; in particular, respiratory supplies are most likely to be used and key to most resuscitative efforts. Appropriately sized self-inflating devices (Fig. 159.4) decrease complications from overventilation, prevent injury, and limit the inability to ventilate due to improper mask fit. When available, and in the hands of experienced providers, flow-inflating devices have the added ability to deliver continuous positive airway pressure (CPAP), control ventilation pressure with greater precision, and ensure a proper fit. Table 159.1 lists the recommended ETT sizes by birth weight and gestational age.

Fig. 159.4 Appropriate Self-Inflating Resuscitator With Appropriate Neonatal-Sized Mask Attached. This device has additional functionality with manometer and single-use positive end-expiratory pressure (PEEP) valve attachments. (Courtesy Seattle Children's Hospital, Seattle, WA.)

ETT, Endotracheal tube.
Adapted from American Academy of Pediatrics; American Heart Association. *Neonatal Resuscitation Textbook*. 6th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2016.

As part of their shared NRP curriculum, the American Heart Association and American Academy of Pediatrics, with the International Liaison Committee on Resuscitation, have developed a newborn resuscitation algorithm (Fig. 159.5). This stepwise approach is detailed later.[1–3] However, if a term neonate is crying and appears to have good tone, she or he can be warmed, dried, and returned to the mother for ongoing care and evaluation, without any additional resuscitation efforts.[1]

Dry, Warm, Stimulate, Position, Suction, and Assess Need for Further Intervention

Hypothermia increases metabolic demand and oxygen consumption, which can render seemingly effective resuscitation efforts futile. To prevent hypothermia and its more subtle sequelae, all newborns should be dried immediately on delivery and placed under a radiant heat source. In the case of crying term infants with normal tone, this may be accomplished by simple drying and skin to skin contact with the mother.[1] Wet blankets should be replaced with dry blankets and preferably warm linens, but the baby should be left uncovered to facilitate radiant warming and team access. All resuscitation techniques are designed to be performed with these temperature-controlling efforts in place.[1] The supine neonate should be further positioned to maximize air entry and avoid obstruction of airflow. Due to a relatively large occiput and anterior glottic opening, airway patency is best achieved with the neck in slight extension. A slightly extended position that aligns the posterior pharynx, larynx, and trachea is best accomplished by placing a rolled diaper or small towel under the infant's shoulders. Placement under the neck is not useful. However, a towel that is too large and under the shoulders can also lead to airway occlusion due to hyperextension of the neck.

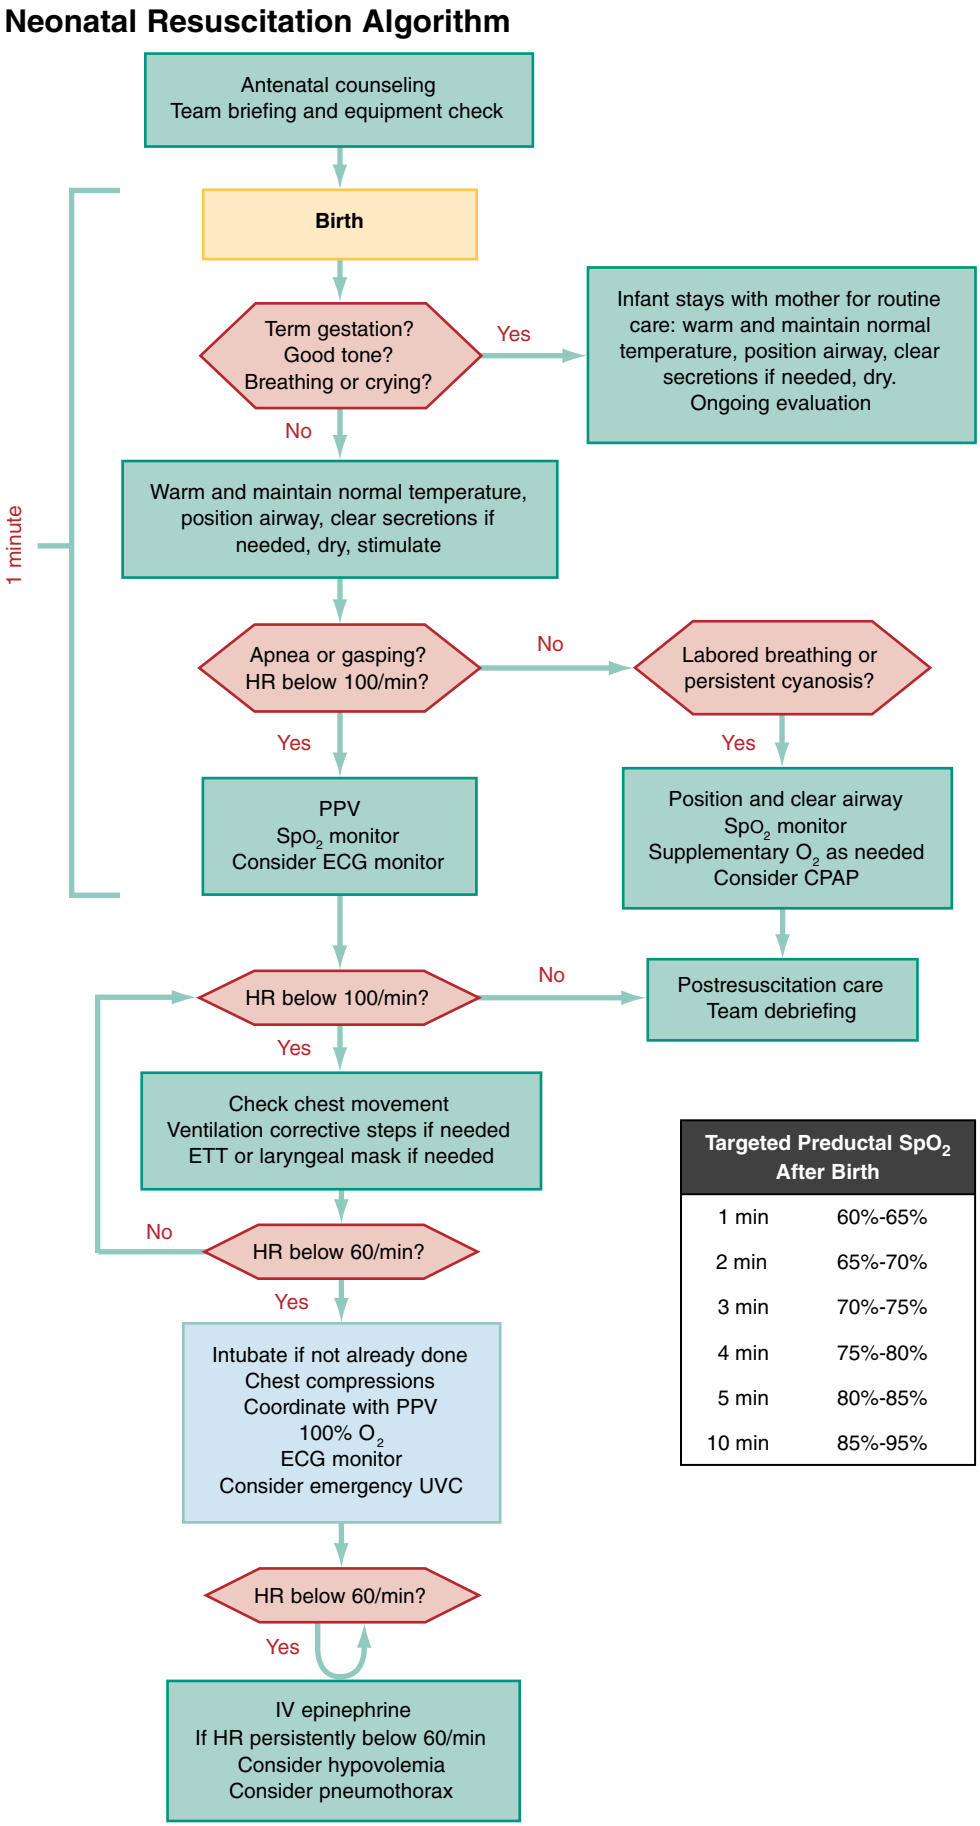

Fig. 159.5 Algorithm for Neonatal Resuscitation. *ECG,* Electrocardiogram; *ETT,* endotracheal tube; *HR,* heart rate; *PPV,* positive pressure ventilation; *UVC,* umbilical vein cannula. (Adapted from Wyckoff MH, Aziz K, Escobedo MB, et al: Part 13: neonatal resuscitation: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation.* 2015;132:S543–S560.)

Only if meconium is present and the newborn has poor tone, poor respiratory effort, or bradycardia (HR < 100 beats/min) after 1 minute of appropriate PPV should the trachea be suctioned with an ETT and meconium aspirator attachment. Poor respiratory effort and obvious obstruction from secretions should otherwise be treated with bulb or mechanical suction (~100 mm Hg wall suction). Upper airway suctioning, including that performed with a bulb syringe, should be reserved only for newborns with these signs because suctioning has been associated with decreased lung compliance, bradycardia, and lowered cerebral blood flow velocity.[1] When suction is indicated, the NRP protocol should be followed, with the mouth suctioned first, followed by the nose. This sequence helps to avoid aspiration of oral secretions if the neonate inspires after nasal suctioning. Overly vigorous or deep suctioning should be avoided because it can cause significant vagal stimulation, and subsequent bradycardia or apnea.[2,43] Because NRP recommendations stipulate suctioning with less than 100 mm Hg, emergency clinicians should be judicious with syringe use because even standard delivery bulb syringes produce a negative pressure that can easily exceed this threshold.[43]

For most term neonates, these measures stimulate breathing sufficiently and may be all that is required to resuscitate a newborn. If adequate respirations are still not present, additional stimulation should be given. This is best done by flicking the soles of the feet and rubbing the back; more forceful efforts could prove harmful. If stimulation and warming efforts prove inadequate, PPV is required, followed by intubation, if necessary.

Time is an important component of NRP guidelines. Within the first 60 seconds of life, the newborn should be assessed with simultaneous warming, drying, and stimulation; if necessary, upper airway clearance should be performed (see Fig. 159.5). If the HR is less than 100 beats/min or if the newborn has primary apnea or respiratory distress, PPV and pulse oximetry should be initiated within the first minute of life. If bradycardia worsens (HR < 60 beats/min), despite adequate ventilation, chest compressions should be initiated. HR calculation can be manual—by palpation of the pulse at the base of the umbilicus or auscultation of cardiac sounds—with pulse oximetry, or most accurately with a standard electrocardiography (ECG) lead.[44] Three-lead ECG is more acute in identifying true bradycardia, as pulse oximetry and palpation of the umbilical pulse have been found to underestimate a newborn's HR.[1] Persistent bradycardia is usually secondary to inadequate ventilation. Thus intubation is recommended in the event that chest compressions are indicated.

Routinely counted at 1, 5, and 10 minutes of life, the APGAR score (Table 159.2) is a composite that reflects HR, respiratory effort, muscle tone, reflex irritability, and color. The score is primarily for assessing the need for (1 minute) and efficacy of (5 minute) ongoing resuscitative measures. In the setting of modern algorithm-based resuscitation, low 5- and 10-minute APGAR scores are associated with increased mortality because they identify infants who are failing medical management.[44] Muscle tone and reflex irritability do not significantly aid in the assessment of the newborn during resuscitation.[44,45]

Instead, HR and respiratory effort are the important indicators and should be continuously monitored. Skin color is a poor indicator of oxyhemoglobin saturation during the first several minutes of life while the transition from fetal to infant circulation ensues.[46–48] In this brief period, pulse oximetry may be a useful tool to assess the oxygenation status of the newborn.[8] However, level of oxygen saturation should take into account normal postductal saturations after birth. An oxygen saturation of 60% would be the targeted normal preductal saturation for 1 minute of life and may not reach 90% or more until 10 minutes of life (see Fig. 159.5). Pulse oximeter should be placed on the baby's right wrist or hand to measure preductal saturations after birth. NRP guidelines recommend pulse oximeter use in only a few select situations—anticipated resuscitation, prolonged PPV use, persistent central cyanosis, and use of supplemental oxygen.[1] We recommend preparing pulse oximetry and ECG monitoring as a standard approach for all ED neonatal resuscitations. Precipitous deliveries are infrequent, yet high-risk presentations and newborns are likely to require accurate HR and pulse oximeter measurements to guide resuscitation.

TABLE 159.2 APGAR Score[a]

	POINTS		
Sign	**0**	**1**	**2**
Heart rate (beats/min)	Absent	Slow (<100)	≥100
Respirations	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active, good flexion
Reflex irritability	No response	Grimace	Cough, sneeze
Color	Blue, pale	Pink body, blue hands and feet	Pink

[a]Calculate at 1, 5, and 10 minutes of life.

Ventilation, Oxygen, Intubation

Any neonate with persistent cyanosis or signs of respiratory distress (e.g., grunting, nasal flaring, tachypnea) should be assisted by CPAP or PPV. For apnea, severe respiratory distress, or HR less than 100 beats/min, BMV (with a manometer, if available) should be initiated. The first breaths often require higher pressures (30 to 40 mm Hg) to remove lung fluid, with the adequacy of ventilation assessed by chest rise. An initial sustained breath of 2 to 5 seconds may further increase FRC and promote clearance of lung fluid, but several clinical trials and meta-analyses have yet to prove the efficacy and safety of this technique.[49–52] Subsequent breaths generally require 20 mm Hg of peak inspiratory pressure.[1,2] To minimize barotrauma and the incidence of pneumothorax, excessive pressures (defined as more than needed to achieve adequate chest rise) should be avoided. An appropriately sized mask with a tight seal (covering the mouth and nose, but not the eyes), proper positioning of the newborn, and use of pressure to attain correct chest wall movement are essential for effective ventilation. Unless otherwise dictated by blood gas levels, recommended ventilation rates are 40 to 60 breaths/min, aimed at achieving a HR greater than 100 beat/min. Current NRP guidelines recommend PPV but do not delineate between CPAP and positive end-expiratory pressure (PEEP). However, preterm neonates (<33 weeks' gestation) receiving single-inflation CPAP (pressure-controlled inflation at 20 cm H_2O for 10 seconds) appear less likely to be intubated at 72 hours of age, receive more than one dose of surfactant, or develop bronchopulmonary dysplasia (BPD). When BMV is required for more than 2 minutes, an orogastric tube should be placed to prevent respiratory compromise from gastric distention.[2]

Resuscitation with 100% oxygen is no longer recommended.[3,53–56] There is reduced mortality in infants resuscitated on room air, with no obvious evidence of harm.[54] Resuscitation-induced hyperoxia results in increased oxidative stress, including direct cardiac and renal injury.[57] Neurologic outcomes appear improved by resuscitation with room air versus 100% oxygen, likely due to a reduction in cerebral free radical generation.[1,3,56,58] Current NRP guidelines recommend initiating resuscitation with room air and then blending to increasing oxygen concentrations, as needed. An updated guideline suggests it is reasonable to initiate resuscitation in preterm newborns (less than 35

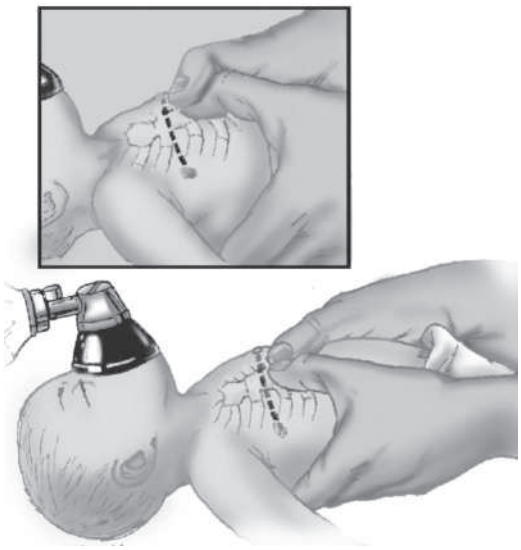

Fig. 159.6 The preferred way to provide chest compressions on a newly born neonate is called two thumbs-encircling hands. This method is best when one rescuer can provide chest compressions and another can ventilate the patient. The two thumbs are placed over the sternum and below an imaginary line between the nipples. If the newborn is very small, the two thumbs can overlap. (From From Gregory GA: In: *The Anesthesiology, The Mother and Newborn.* Edited by Shinder SM, Moya F. Baltimore, Williams and Wilkins, 1974.)

weeks' gestation) with 21% to 30% fraction of inspired oxygen (FiO_2) and titrate to goal saturations.[3] Unless needed to achieve target oxygen saturations, 100% oxygen should be used only for newborns with bradycardia of less than 60 beats/min after 90 seconds (see Fig. 159.5). Attempts to restore adequate ventilation are often more beneficial than increasing the oxygen concentration.

Endotracheal intubation is indicated at several points during neonatal resuscitation—tracheal suctioning for meconium in infants with failure to improve, despite effective PPV; if BMV is ineffective or prolonged; when chest compressions are performed; and for extremely low birth weight infants or infants with anatomic anomalies (e.g., diaphragmatic hernia). Traditional direct laryngoscopy and video laryngoscopy are both reasonable options, with video-assisted techniques consistently having improved views but slightly longer total intubation times.[59–61] Confirmation of proper ETT placement should include detection of expired carbon dioxide using capnography. Although ultrasonography can show appropriate ETT positioning in the term infant, the gold standard remains plain radiography.[62–66]

If acute deterioration occurs shortly after intubation, equipment should be immediately checked. Consider the DOPE and MR SOPA mnemonics when trying to determine the cause of the deterioration (Box 159.4). In the absence of an obvious explanation, it is safest to extubate the newborn and promptly ventilate with a BMV device by an experienced provider. Needle aspiration of the chest may be considered for treatment of a possible pneumothorax, particularly if unequal breath sounds are appreciated upon extubation, ventilatory pressures are inexplicably high, or a neonate's condition fails to improve with effective ventilation.

If ETT intubation is indicated but is technically challenging, the LMA has been shown to be effective for ventilating full-term newborns.[67–69] However, there are limited data on LMA use in preterm infants (<2000 g or <34 weeks' gestation) in the setting of MAS or during CPR.

Chest Compressions

Bradycardia (HR < 100 beats/min) is a reliable indicator of clinically significant hypoxia. Fortunately, most neonates with bradycardia respond promptly to effective ventilation. If a neonate has an HR less than 60 beats/min, despite oxygen and adequate ventilation (good air movement and chest rise) for at least 30 seconds, chest compression should be started.[1,2,70] Compressions should be performed at a rate of 90/min, coordinated with 30 breaths/min for a total of 120 events/min. The preferred neonatal resuscitation compression-to-ventilation ratio is 3:1. If the provider is certain that the cardiac arrest has a primary cardiac cause, a compression-to-ventilation ratio of 15:2 may be considered.[1,3] The preferred method for performing chest compressions, the two thumb-encircling hands technique, is as follows: the fingers of both hands encircle the chest and support the back, with the thumbs of both hands placed side by side or one over the other on the sternum, just below the nipple line (Fig. 159.6).[71,72]

The depth of compression is one-third the anteroposterior diameter of the chest.[2] Spontaneous respirations and HR should be assessed every 30 seconds, attempting to minimize interruptions, when possible, with coordinated chest compressions and ventilation continuing until the HR is at least 60 beats/min.[1,2] A yellow color change on a colorimetric CO_2 monitor or increase in end-tidal CO_2 values during PPV administration often precedes a significant rise in HR and should be used, when available.

Vascular Access

The umbilical vein is the preferred route of immediate vascular access because it can be easily identified and cannulated. Umbilical vein access can have serious complications (e.g., infection, portal vein thrombosis), so the umbilical vein cannula (UVC) should be removed by the accepting neonatologist after the infant has been stabilized and additional venous access has been obtained.[73] Other vascular access routes include peripheral veins, peripherally inserted central catheters, and the femoral vein.[74] Intraosseous (IO) access can be problematic in neonates (especially premature infants) because of bone fragility and the small size of the IO space. However, in simulated resuscitation, placement of an IO line has been shown to be almost 1 minute faster than a UVC, even for skilled providers. Preferred IO access sites in newborns include the distal femur (midline; ≈1 cm above the superior border of the patella, with the leg in extension) and the proximal tibia (≈2 cm below the tuberosity and 1 cm medially on the tibial plateau). If vascular access cannot be achieved, certain drugs including epinephrine, can be given through the ETT, although this is not the optimal route.

TABLE 159.3 Resuscitation Medications

Medication	Concentration	Dose	Route	Comments
Epinephrine	0.1 mg/mL	0.01–0.03 mg/kg (0.1–0.3 mL/kg)	IV (preferred) or ETT	
Dopamine	Varies	Continuous infusion at 5 µg/kg/min; increase to 20 µg/kg/min as needed.	IV	
Glucose	$D_{10}W$	2–4 mL/kg	IV	Avoid higher concentrations
Volume expanders	O-negative packed RBCs	10 mL/kg	IV	Give over 5–10 min for acute bleeding; repeat as needed
	Normal saline	10 mL/kg	IV	Give over 5–10 min; repeat as needed
	Lactated Ringers	10 mL/kg	IV	Give over 5–10 min; repeat as needed
Ampicillin	Varies	100 mg/kg	IV, IM	
Gentamicin	Varies	4 mg/kg	IV, IM	If neonate less than 35 weeks gestational age: 5 mg/kg
Cefotaxime	Varies	50 mg/kg	IV, IM	

$D_{10}W$, 10% dextrose in water; *ETT,* endotracheal tube; *IM,* intramuscular; *IO,* intraosseous; *IV,* intravenous.

Medications

Few neonates require pharmacotherapy during resuscitation. Medications (Table 159.3) are primarily indicated for bradycardia or asystole unresponsive to effective ventilation and chest compressions, as well as hemorrhage (maternal, fetal, or placental) that necessitates fluid resuscitation.[1–3]

Epinephrine. Epinephrine is indicated for asystole and persistent bradycardia (<60 beats/min) despite effective ventilation with 100% oxygen and ongoing coordinated chest compressions. Although it may be given by ETT, IV is the preferred epinephrine administration route. The recommended IV dose is 0.01 to 0.03 mg/kg, or 0.1 to 0.3 mL/kg, of a 0.1 mg/mL solution. Unlike epinephrine use in adult patients, weight-based dosing with no known minimum is required for neonates. Repeat doses may be given every 3 to 5 minutes.[1,2] If administered via an ETT, higher doses (0.05 to 0.1 mg/kg) with a 0.1 mg/mL solution are indicated, but the safety and efficacy of this practice have not been rigorously evaluated.[1,2,74–76] Unlike many adult resuscitations, sodium bicarbonate is not routinely used,[77,78] although it may be beneficial in the neonatal intensive care unit (NICU) setting when ventilation is known to be adequate.[1,79]

Volume Expanders. When indicated, volume expansion is accomplished with packed red blood cells (Rh-negative type O blood), normal saline, or Lactated Ringers solution given in IV boluses of 10 mL/kg over 5 to 10 minutes. During resuscitation of premature infants, rapid administration of volume expanders should be avoided because this practice has been associated with increased incidence of intraventricular hemorrhage.[2] Higher-volume (e.g., 20 mL/kg) fluid boluses are recommended for full-term infants. Boluses may be repeated several times, as indicated by the ongoing response to resuscitative efforts.

Antibiotics. Antibiotics are not indicated in the initial resuscitation phase but may be required once the neonate has been stabilized. When suspected, sepsis should be treated with broad-spectrum antimicrobial therapy directed against the most likely pathogens. The most common bacterial pathogens implicated in early-onset neonatal sepsis are a heterogeneous group that includes group B *Streptococcus* (GBS), *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., and *Listeria*. In the United States, where GBS and *E. coli* represent the most common newborn pathogens, a recommended empirical antibiotic regimen is ampicillin (100 mg/kg IV) plus an aminoglycoside (usually gentamicin, 4 mg/kg).[80] Reasonable alternative regimens include ampicillin with a third-generation cephalosporin, but there is evidence that several members of the latter group predispose a neonate to invasive candidiasis. Because ceftriaxone can increase the risk of kernicterus, cefotaxime (50 mg/kg IV) is preferred.

Glucose. Concomitant hypoglycemia should be considered and promptly treated in a neonate requiring ongoing resuscitation. Hypoglycemia is most easily diagnosed by rapid bedside glucose testing or serum glucose level measurement. Neonates with a glucose level less than 40 mg/dL and with symptoms of hypoglycemia—irritability, tremors, jitteriness, apnea, tachypnea, seizures, cyanosis, lethargy, poor feeding—require treatment with IV glucose. Standard therapy is 2 to 4 mL/kg of 10% dextrose in water ($D_{10}W$)/kg as well as starting a continuous infusion of $D_{10}W$ at 80 to 100 mL/kg/day.[10] Higher concentrations of glucose (e.g., 25% dextrose in water, $D_{25}W$) are hyperosmolar and should be avoided. If the newborn can safely tolerate feeds, oral glucose solution, maternal breast milk, or formula should be given by mouth (PO) on demand. Repeat glucose measurement should be obtained 10 to 20 minutes after glucose administration. Asymptomatic neonates with hypoglycemia should be encouraged to feed more often and are treated with IV glucose only if glucose levels fall precipitously (<25 mg/dL at birth to 4 hours of age or <35 mg/dL at 4 to 24 hours of age).[10]

Dopamine. Dopamine is indicated only when signs of shock (e.g., poor peripheral perfusion, weak pulses) are still present, despite adequate volume replacement. Given as a continuous infusion beginning at 5 µg/kg/min, dopamine may be increased to 20 µg/kg/min as necessary, before additional inotrope support is indicated.

Therapeutic Hypothermia

When moderate to severe hypoxic-ischemic encephalopathy is suspected, selective cerebral hypothermia in asphyxiated infants may protect against brain injury.[1,81–89] Therapeutic hypothermia of 33.5°C to 34.5°C (92.3°F to 94.1°F) in this population can lower mortality and improve the likelihood of normal neurologic outcome at 18 months. Current NRP guidelines recommend therapeutic hypothermia for patients with suspected early neonatal asphyxia. Symptoms of possible evolving brain injury include abnormal levels of consciousness, seizures, hypotonia, and hyporeflexia. Established protocols generally recommend the initiation of cooling within 6 hours of birth, for a total of 72 hours, followed by gradual rewarming over at least 4 hours. Neonates meeting eligibility criteria should be transferred to facilities capable of providing this specialized care. Emergency clinicians and families should be aware that the risks associated with therapeutic hypothermia include thrombocytopenia and hypotension.

DISPOSITION

Early consultation with a neonatologist can assist in the resuscitation and postresuscitation phases of care. Once a neonate is stabilized, the monitoring of oxygenation, ventilation, perfusion, temperature, and glucose level continues. Neonates who require extensive resuscitation (i.e., obtaining venous access, medication requirement, or endotracheal intubation) should be transported to a NICU by personnel skilled in neonatal resuscitation. If feasible and safe, parents should be allowed to see, touch, and hold the newborn before transport.

OUTCOMES

Safety

Advanced life support skills are critical for successful neonatal resuscitation yet are far from routine for most emergency clinicians. For example, in a cohort of almost 5000 births in Norway, only 19 infants required intubation and 10 were given chest compressions.[90] An important step toward improving outcomes is team adherence to NRP guidelines. Highlighting the importance of safety, an essential component of the new NRP curriculum is the inclusion of simulation.[91] Simulation in neonatal resuscitation allows for a multidisciplinary team to practice behavioral and teamwork skills, not only individual technical skills, in a safe environment.[92] Implementation of an integrated Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS) and NRP curriculum improves communication and helps to prevent incorrect medication dosing and inadequate chest compression depth. Furthermore, routine (and unannounced) simulation-based neonatal resuscitation training has been shown to improve provider self-confidence, knowledge, and both technical and nontechnical skills.[93,94]

Effectiveness

In the hands of trained emergency clinicians, neonates requiring advanced resuscitative efforts receive improved PPV, decreased time to vascular access, and shortened time to first IV medication. Deliberate training has been shown to improve ability to perform the key first steps of resuscitation—stimulation, positioning and neck-extension, PPV effectiveness, and HR assessment.[95] Provider level improvements are seen worldwide with the implementation of guideline-based care.[96] Analyses of the NRP program, which has now trained more than 5 million providers in the United States alone, suggests fewer high-risk infants experience a drop in APGAR score from 1 to 5 minutes, with many actually showing an improvement since implementation. However, resuscitation is not without potential pitfalls.

Complications

Relatively common complications post neonatal resuscitation include hypoglycemia, transient tachypnea of the newborn, MAS, pneumothorax, electrolyte disturbances, significant hyperbilirubinemia, and sepsis. These conditions are associated with increased NICU admission rates, as well as morbidity and mortality.[97,98] Additional perinatal risk factors relevant to resuscitation that are associated with length of NICU stay include: placental abruption, assisted delivery, small for dates, gestational age less than 37 weeks, low 5-minute APGAR score, and need for intubation at birth.

The need for chest compressions and CPR is a known prognostic marker for increased rates of morbidity and mortality in neonates.[99] Undergoing CPR at delivery increases the likelihood of pneumothorax, sepsis, severe intraventricular hemorrhage, and death.[100] Unfortunately, these complications have also been associated with poor long-term neurodevelopment outcomes.[100] However, the implementation of neonatal resuscitation protocols appears to improve neurodevelopment outcomes, but data from randomized trials are lacking.[101]

CHAPTER 159: QUESTIONS AND ANSWERS

1. With most neonatal deliveries, which resuscitative measures are usually sufficient?
   a. Administer fluids.
   b. Bag-mask ventilation.
   c. Intubate.
   d. Warm, dry, stimulate, and position.

   Answer: d. Drying, warming, positioning, and stimulating the infant are usually sufficient resuscitative measures in most deliveries.

2. For a term newborn with cyanosis, respiratory distress, and a heart rate more than 100 beats/min, which of the following is not initially indicated?
   a. Apply 100% oxygen.
   b. Position airway.
   c. Suction.
   d. Warm, dry, and stimulate.

   Answer: a. 100% oxygen is not indicated for initial resuscitation in all neonates born at 35 weeks' gestation or later; avoiding unnecessary supplemental oxygen is thought to minimize free radical creation in the brain and decreases the incidence of retinopathy of prematurity. Initial resuscitation with room air is recommended. For select newborns less than 35 weeks' gestation, initial FiO_2 of 21% to 30% may be required to achieve normal oxygen saturations.

3. In a typical neonatal resuscitation, what is the preferred compression-to-ventilation ratio?
   a. 3:1
   b. 5:1
   c. 10:2
   d. 15:2
   e. 30:2

   Answer: a. Unlike pediatric or adult cardiopulmonary resuscitation (CPR), neonatal CPR is performed at a ratio of three compressions to one breath, with a goal of approximately 90 compressions with 30 synchronized breaths (120 "events") per minute. If the cause of the bradycardia is known to be cardiac, a ratio of 15:2 is acceptable.

4. A nonvigorous and crying newborn is delivered with copious meconium-stained fluid. What is the correct recommended resuscitative measure?
   a. Bag-mask ventilate.
   b. Intubate.
   c. Suction at maternal perineum before cutting umbilical cord.
   d. Gentle mouth suctioning if needed, followed by warming, drying, and stimulation.

   Answer: d. For infants born with meconium-stained amniotic fluid, routine intubation and endotracheal tube suctioning are no longer recommended because they have shown no consistent benefit. Vigorous and nonvigorous infants born through even thick meconium should instead have gentle mouth suctioning, if needed, followed by warming, drying, and stimulation.

5. After drying, stimulating, and bag-mask ventilation, what is the next step in resuscitation of a newborn that appears floppy and apneic and with a heart rate of 50 beats/min?
   a. Give a normal saline bolus of 20 mL/kg.
   b. Give epinephrine (0.1 mg/mL) intravenous (IV) at a dose of 0.1 mg/kg.
   c. Intubate.
   d. Start with a chest compression-to-ventilation ratio of 3:1.

   Answer: d. With a heart rate less than 60 beats/min in a neonate, intubation may be considered, but compressions should be started. If the low heart rate persists, IV epinephrine (0.1 mg/mL) may be considered at a dose of 0.01 mg/kg.

Pediatric Trauma

Sonia Singh and James F. Holmes

KEY CONCEPTS

- Trauma is the leading cause of death in children in the United States.
- Avoid hypoxia and hypotension by early administration of oxygen and assisted ventilation, and fluid resuscitation with crystalloid at 20 mL/kg increments. Initiate transfusion of 10 mL/kg of packed red blood cells (pRBCs) if hypotensive or signs of hypovolemic shock after 40 mL/kg of crystalloid is infused.
- Key pediatric anatomic and physiologic differences include:
  - Children are smaller, so bodily force is more widely distributed, making multi-system injuries more likely.
  - The infant's head-to-body ratio is greater, creating a relatively higher center of gravity. This, combined with a less myelinated brain and thinner cranial bones, predisposes infants to more serious head injury.
  - Children have a higher anatomic fulcrum in the cervical spine (C2 to C3 in children <8 years old), resulting in higher cervical spine injuries.
  - Children have greater laxity of the cervical column ligaments, leading to a greater risk of spinal cord injury without radiographic abnormalities (SCIWORA).
  - Children have more horizontally positioned ribs, resulting in a more upward movement during inspiration; this leads to a limited ability to increase tidal volume and risk for respiratory failure with chest or diaphragmatic injury.
  - Children have more elastic ribs, allowing for pulmonary injury without skeletal injury.
  - Children have thinner abdominal walls and a more anterior location of the liver and spleen; this results in a greater chance of injury to those organs.
  - Despite large intravascular volume loss, children are able to substantially increase their systemic vascular resistance to remain normotensive; hypotension is a very late sign.
- Most minor head trauma may be managed with observation and without computed tomography (CT) imaging. When applied, clinical decision rules may reduce imaging and radiation exposure.
- In major trauma patients, indications for intubation include respiratory failure or a Glasgow Coma Scale ≤8.
- The diagnostic test of choice for the evaluation of intra-abdominal injury in a stable patient with high suspicion for injury is abdominal CT.
- Solid organ injuries are generally treated nonoperatively in children.

FOUNDATIONS

Injury is the leading cause of death among children 1 to 18 years of age in the United States, accounting for over 10,000 deaths and 9 million annual emergency department (ED) visits.[1] Motor vehicle collisions (MVCs) account for more than half of all pediatric trauma deaths, whereas nonfatal injuries are primarily due to unintentional falls.[1] Mechanisms of injury vary by patient age, and certain mechanisms result in specific injury patterns (e.g., sports and concussions). Blunt mechanisms account for over 95% of childhood injuries. The trauma history, as well as the initial response, determine injury risk and response required. Criteria for trauma center transport (primary triage) and trauma team activation (secondary triage) are primarily based on expert consensus and an area ripe for further research. Although the examination of the injured patient is standardized, diagnostic testing should be tailored to avoid unnecessary testing while assessing for important injuries.

Anatomy and Physiology

Children have distinct anatomy and unique physiology that impact their evaluation and management (Box 160.1). Force is more widely distributed throughout the child's body, making multi-system injuries more likely in children. The younger a patient is, the higher their surface area to weight ratio, resulting in a greater potential for heat loss. As injured patients are at increased risk of hypothermia, this is especially true in children.

Normal ranges for pediatric vital signs vary greatly and should be readily available in the ED (Chapter 155). A child's physiologic response to injury is different from the adult's, depending on the age and maturation of the child and severity of the injury. Children have a high capacity to maintain blood pressure despite significant hemorrhage; hypotension is a late finding with blood loss exceeding 30% of total blood volume. The younger the child is, the less their ability to increase cardiac contractility. Thus, a young child's cardiac output is primarily determined by heart rate and systematic vascular resistance. Compensated shock should be considered and promptly addressed when a child is tachycardic, especially if capillary refill is delayed. Changes in heart rate, blood pressure and extremity perfusion commonly precede cardiorespiratory failure and should prompt resuscitation.

CLINICAL FEATURES

Initial Assessment and Primary Survey

Most children evaluated in the ED are minimally injured and require limited diagnostic evaluation after the standard history and physical evaluation. In those with *major* trauma, cardiac and pulse oximetry monitoring, supplemental oxygen, frequent vital sign measurements, intravenous (IV) access, and laboratory testing are often needed. Immediately after prehospital notification, preparation should include assigning team member functions, preparing necessary equipment, and donning protective clothing. Color-coded length-based tape measures are often used to provide initial estimates of patient weight, equipment size and medication dosages, but important equipment sizes are in Box 160.2.

The initial trauma assessment is designed to rapidly identify and treat life- or limb-threatening injuries. Treatment of these injuries

BOX 160.1 Important Anatomic Differences in Adults and Children: Implications for Pediatric Trauma Management

- The child's head-to-body ratio is greater, the brain is less myelinated, and cranial bones are thinner, resulting in more serious head injuries.
- The child's internal organs are more susceptible to injury based on more anterior placement of the liver and spleen, and less protective musculature and subcutaneous tissue mass.
- The child's kidney is less well protected and more mobile, making it susceptible to deceleration injury.
- The elasticity of the child's chest wall allows for pulmonary injury without rib fracture.
- Children have a more tenuous spinal cord blood supply and a greater elasticity of the vertebral column, predisposing them to unique spinal cord injuries including SCIWORA.

SCIWORA, Spinal cord injury without obvious radiographic abnormality.

BOX 160.2 Specific Equipment Size Estimates for Pediatric Trauma

Endotracheal Tube (ETT) Size Estimates (Sizing in Millimeters Internal Diameter) and Depth

- Endotracheal (cuffed) tube size (mm) = (Age in years/4) + 3.5
- An ETT 0.5 mm larger and 0.5 mm smaller than the calculated size should also be ready at the bedside
- ETT tube depth = tube size × 3

Chest Tube Size (Diameter) = 4 × the ETT Size

Orogastric, Nasogastric, or Foley Size (Diameter) = 2 × ETT Size

precedes the continuation of the evaluation. The initial assessment and resuscitation occur simultaneously over the initial 5 to 10 minutes of care. Similar to adults, the elements of the primary survey for children are remembered as *A, B, C, D, E,* and *F*.[2] Patient deterioration warrants repeat of the primary survey to identify the cause and institute treatment.

A—Airway and Cervical Spine Stabilization

Children have important anatomic considerations that impact the management of the pediatric airway (Chapter 156). The patient is initially evaluated for possible airway obstruction or inability to maintain their airway. Gurgling or stridor may indicate upper airway obstruction. Maxillofacial trauma, blood, swelling, or vomitus may also obstruct the airway, and efforts are made toward clearing the oropharynx of debris. Initial attempts to open the airway include a jaw-thrust maneuver. If an open airway cannot be established and maintained by noninvasive means, endotracheal intubation (ETI) should be performed. Unless the neck has been cleared of injury, cervical spine immobilization should be maintained with in-line immobilization when airway maneuvers are performed.

Indications for ETI in a pediatric trauma patient include (1) inability to ventilate with bag-mask ventilation (BMV) or the need for prolonged airway control, (2) Glasgow Coma Scale (GCS) score ≤8, (3) respiratory failure from hypoxemia or hypoventilation, and (4) worsening decompensated shock resistant to initial fluid resuscitation. Rapid sequence intubation is the preferred method for ETI in severely injured children, and includes both sedative medications (e.g., ketamine or etomidate) and paralytic medications (e.g., succinylcholine or rocuronium), see Chapter 156. Although unlikely to do harm, premedication with fentanyl or lidocaine to blunt the rise of intracranial pressure (ICP) is not evidence-based, and we do not recommend its use for this purpose.

B—Breathing and Ventilation

Breath sounds and adequacy of chest rise should be assessed. Adequate ventilation is dependent upon airway patency and sufficient air exchange. Pulse oximetry measures the adequacy of oxygenation, but not ventilation. Continuous end-tidal carbon dioxide capnography better informs ventilatory status but should be interpreted in conjunction with the respiratory wave form. For example, a child with a low capnography reading could either be taking slow shallow breaths (e.g., hypoventilation), or may be breathing deeply and rapidly (e.g., hyperventilation). Many factors may compromise ventilatory function in an injured child, including depressed sensorium, airway obstruction, painful respirations, diaphragmatic fatigue, and direct pulmonary injury.

In a young child, chest rise occurs in the lower chest and upper abdomen, and both should move concordantly. Discordant motion or *paradoxical breathing* is a sign of impending respiratory failure. Respiratory rates that are very fast or very slow may indicate impending respiratory failure; tachypnea may also be due to shock or inadequate pain control. If assisted ventilation is necessary, BMV should be initiated with only the volume necessary to cause the chest to rise. In addition to a potential increased risk of vomiting and aspiration, excessive bagging volumes (i.e., hyperventilation) can lead to gastric distension (Fig. 160.1). As the stomach distends, the diaphragm can push into the thoracic cavity, causing increased intrathoracic pressures, decreased venous return, and hypotension. Gastric decompression may be performed with either an orogastric tube or nasogastric tube (if no evidence of facial trauma).

C—Circulation and Hemorrhage Control

Shock occurs when the body is unable to maintain adequate tissue perfusion. Normal systolic blood pressure does not exclude shock. The pediatric vasculature maintains normal blood pressure by constricting peripheral arteries and progressively increasing systemic vascular resistance. Signs of poor perfusion (cool distal extremities, decreased peripheral pulse quality, and delayed capillary refill) are signs of pediatric shock, even when blood pressure is normal (Box 160.3). External hemorrhage should be sought and controlled with direct pressure. IV access should be established and blood collected for laboratory testing (see following).

Vascular access is best obtained by placing two large-bore IV lines, ideally in the upper extremities (lower extremity sites may be used if needed). If obtaining vascular access is unsuccessful or delayed in the critically injured patient, intraosseous (IO) access is a safe, quick, and reliable procedure to access the vascular space and is recommended prior to attempting a central line. The preferred site for IO placement is the proximal medial tibia, just below (and directed slightly away from) the growth plate; other potential locations include the proximal humerus, the flat area of the anterior distal femur, or the distal tibia. Once IO access is obtained, it should be stabilized and secured. More than one IO needle may need to be placed (in separate bones); IV access may be easier after initial fluid resuscitation and vascular volume expansion. IO placement in a fractured extremity is contraindicated. Medications and blood products can be administered through an IO line similar to an IV. Central line placement in young children is difficult, with frequent complications, and should be avoided if possible. If absolutely necessary, ultrasound-guided femoral line placement is our preferred initial option. Much less commonly used vascular access techniques include a venous cut-down, or a central line into the intrajugular, supraclavicular, or subclavian vein. Venous cutdown is a

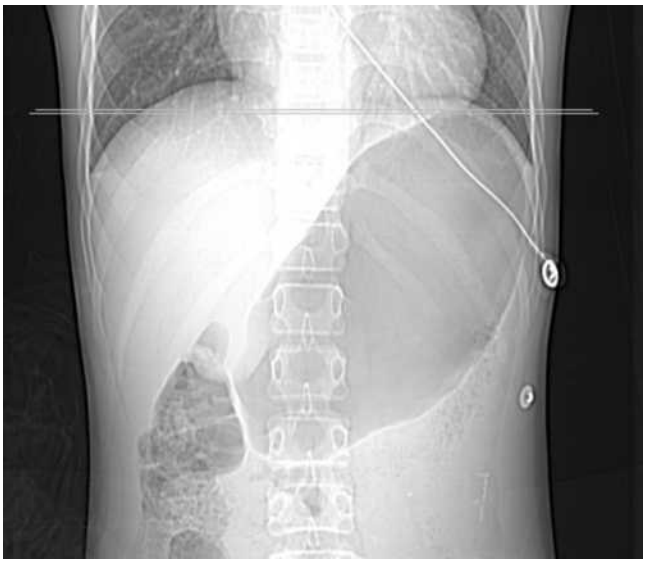

Fig. 160.1 CT (Scout) Demonstrating Gastric Distention in a Child Having Swallowed Large Amounts of Air from Crying. Severe Gastric Distention Can Harm Diaphragmatic Excursion and Impact Ventilation.

BOX 160.3 Circulation Assessment and Treatment in Critical Pediatric Trauma Patients

Assessment

- Tachycardia, delayed capillary refill, decreased peripheral pulses, tachypnea or bradypnea, and altered sensorium may indicate volume loss prior to hypotension.
- Vital signs, monitored every 5 min during the initial assessment.
- Continuous oximeter and cardiac monitor.

Treatment and Interventions for Hypovolemic Shock from Trauma

- Place two large-bore IV lines (above and below diaphragm if indicated).
- Intraosseous line placement if peripheral venous access is difficult.
- Bolus with 20 mL/kg of warm normal saline/lactated Ringers and repeat if necessary.
- Consider intubation and ventilation to decrease work of breathing.
- Transfuse 10 mL/kg pRBC for hemorrhagic shock secondary refractory to crystalloid.

IV, Intravenous; *pRBC,* packed red blood cells.

skill not often performed and is rarely needed to obtain vascular access in the pediatric trauma patient. If performed, the greater saphenous vein at the ankle is the preferred site. In the rare occasion that a neonate presents after trauma, an umbilical vein cannulation can be attempted in infants up to 10 days old if there is enough of an umbilical stump to perform the procedure.

Fluid resuscitation in pediatric trauma patients begins with a 20 mL/kg bolus of warm isotonic crystalloid solution over 10 minutes. A second bolus of 20 mL/kg of warm isotonic crystalloid is given for those who do not initially improve or stabilize. If the patient continues to require fluid resuscitation after two boluses, warmed, packed red blood cells (pRBCs) at 10 mL/kg should be transfused, while identifying and treating any sources of hemorrhage. In cases of massive transfusion (blood products >40 mL/kg in an adolescent or >50 mL/kg in a child/infant), it is important to add plasma and platelets to correct coagulopathy. Adult patients undergoing massive transfusion are

BOX 160.4 Disability: Neurologic Assessment and Treatment

Assessment

- Level of consciousness: Use AVPU scale and age-appropriate GCS
- Pupil size and reactivity
- Movement in all extremities and tone
- Posturing and reflexes

Treatment and Interventions

- Stabilize spinal column with spinal immobilization techniques.
- Rapid Sequence intubation for GCS scores ≤8
- Cranial CT scan all with GCS scores less than 15 and neurosurgical consultation as needed.
- With signs of herniation, elevate head of the bed and 3% hypertonic saline 2–5 mL/kg IV (or mannitol 0.5–1.0 g/kg IV).
- Maintain CPP of at least 40 mm Hg in children.

AVPU, Alert, verbal, painful, unresponsive; *CPP,* cerebral perfusion pressure; *CT,* computed tomography; *ETI,* endotracheal intubation; *GCS,* Glasgow Coma Scale; *IV,* intravenous; Pco_2, partial pressure of carbon dioxide, *RSI,* rapid sequence induction.

resuscitated with plasma, platelets, and pRBCs in a 1:1:1 ratio.[3] Less data exists for this strategy in the pediatric trauma population as data is conflicting,[4,5] although many centers now resuscitate children with a 1:1 plasma: pRBC ratio. In adult patients with significant traumatic hemorrhage, tranexamic acid is now routinely used to stabilize clot and limit blood loss. Although frequently used in non-traumatic pediatric surgery, use of tranexamic acid in injured children is rare.[6] The dosage in injured children (15 mg/kg over 20 minutes, then 2 mg/kg/h for 8 hours or 30 mg/kg over 20 minutes, then 4 mg/kg/h for 8 hours) is currently under study.[7]

D—Disability Assessment

A rapid neurologic and mental status evaluation is performed to assess neurologic status. The assessment of disability in pediatric trauma patients is described in Box 160.4. The alert, verbal, painful, unresponsive (AVPU) system and the GCS (Table 160.1) are utilized to assess neurologic status. The modified pediatrics GCS (used in pre-verbal children) performs similarly to the standard GCS in older children (see Table 160.1). Children's higher metabolic demands result in higher oxygen consumption and glucose utilization; a rapid bedside glucose level should be checked in any child with altered mental status after trauma.

E—Exposure and Environment

Trauma patients should have each body area fully exposed for evaluation; preverbal children are particularly high risk for missed injuries. However, children are often embarrassed or shy about physical exposure. In the stable patient, body areas can be examined in sections, keeping other parts covered from view. Compared to adults, children are also more susceptible to insensible heat and fluid loss due to their greater surface to mass ratios and should be kept normothermic, as hypothermia increases morbidity and mortality. Hypothermia contributes to metabolic acidemia and has direct adverse effects on cardiac inotropy, chronotropy, catecholamine responsiveness, platelet function, and both renal and hepatic drug clearance.

Interventions to maintain normothermia include increasing ambient temperature, administering warmed humidified oxygen, and warming all infused fluids, especially all blood products. Head wraps and convective warmers or radiant heat sources are adjuncts in

[a]Total score key for traumatic brain injury: severe, ≤8; moderate, 9 to 12; mild, 13 to 15.

newborns and infants, as well as older children with mild hypothermia (temperature <36°C). The exposure phase of the survey is often the appropriate time to concurrently begin initial imaging and further diagnostic testing (see following).

F—Family

We recommend the option of family members present during the initial resuscitations, a practice often preferred by families in both traumatic and non-traumatic pediatric resuscitations. A social worker or other qualified staff member dedicated to the family should be available to help explain treatments, answer questions, and provide emotional support.

Secondary Survey

A systematic secondary survey should follow the primary survey and necessary interventions, and should consist of an organized, complete head to toe assessment to detect additional injuries. Significant historical findings are collected at this time and can be remembered by the mnemonic *AMPLE* (Box 160.5). Key points of the ongoing assessment of the patient, after the secondary assessment, are summarized in Box 160.6.[2]

BOX 160.5 Ample History

A—*A*llergies
M—*M*edications
P—*P*ast medical history
L—*L*ast meal
E—*E*vents and *E*nvironment

BOX 160.6 Tasks to Be Completed After the Secondary Survey

- Continuous monitoring of vital signs
- Provision of analgesia, and continuous reassessment of pain
- Antibiotics and tetanus as appropriate
- Ensure urine output of 1 mL/kg/h
- Begin transport process if the patient will obviously need transport

If patient instability prohibits completion of the secondary survey, this should be communicated to the next caregivers. Tertiary surveys are now completed on all trauma patients within 24 hours of admission.

Physical Examination

During the secondary survey, a head-to-toe examination should be carefully performed. Specifics of the head examination include inspection and palpation of the skull (fontanelle) and facial bones, assessing pupillary size and reactivity, and evaluation of extraocular movements. In possible nonaccidental trauma, funduscopic examination may reveal retinal hemorrhages. A fluorescein examination may reveal occult eye injury in the crying child.

Cervical spine immobilization should be maintained until the patient's neck is cleared of injury. Patients in spinal immobilization should be removed from the backboard with spinal motion restriction maintained. When the patient is log-rolled for backboard removal, the thoracic and lumbar spinous processes are individually palpated, evaluating for tenderness or step-offs. To protect them from further injury, obtunded patients and those with signs or symptoms of thoracic or lumbar spine injuries should be carefully moved and positioned until imaging or clinical assessment provides a more definitive assessment.

Chest assessment involves visual inspection for wounds and flail segments, palpation for tenderness or crepitus, and auscultation for breath sounds. The abdominal examination consists of inspection for evidence of abdominal wall trauma and palpation for the presence of tenderness. A "seat belt sign," consists of erythema, abrasions, or ecchymosis extending across the chest or abdomen from the seat belt (see below). Abdominal tenderness is present in approximately 75% of alert children with an intra-abdominal injury; however, the reliability of the abdominal examination decreases drastically in patients with GCS scores less than 14. Digital rectal examination should only be performed to evaluate rectal tone in suspected spinal cord injury, or if the integrity of the rectum is in question. Testing the injured child's stool for occult blood is not useful and we do not recommend this. All pelvic bones should be assessed for stability and tenderness. Although rare in children, urethral injuries may result in perineal, scrotal, penile, or lower abdominal hematomas, or blood at the urethral meatus. If there is a concern for urethral injury, a retrograde urethrogram should be completed prior to insertion of a urinary catheter to avoid further injury.

Extremity examination evaluates for deformities, skin disruptions, neurologic deficits, and abnormal perfusion. Fractures may be stabilized with splinting before definitive management. Careful and

recurrent vascular and neurologic examinations should be performed and documented, especially after interventions such as splinting or reduction.

Trauma patients should be reexamined throughout their time in the ED to ensure their condition is stable, their pain is controlled, and no injuries are missed. When possible, ambulation can expose additional injuries not identified with previous examinations. Up to 70% of injuries with delayed diagnosis in pediatric trauma are orthopedic.[8]

Pain Assessment

Pain assessment and control is an essential part of any trauma patient's management. Analgesic medications, immobilization of injured extremities, and non-pharmacologic techniques should all be considered. Please refer to Chapter 157 for further discussion of pain control in children.

DIAGNOSTIC TESTING

Laboratory Testing

Laboratory testing is used to guide resuscitation, monitor blood loss, and screen for particular injuries, but should be tailored to avoid unnecessary testing. Patients at risk for hemorrhage should have a type and screen in addition to hemoglobin measurements. In acute hemorrhage, hemoglobin requires time to equilibrate and does not initially correlate with severity of blood loss. Serial hemoglobin measurements are not useful to screen for occult injuries; however, serial measurements may identify ongoing blood loss in patients with undifferentiated hypotension. In children with solid organ injuries, serial hemoglobin measurements are routinely performed, but the exact timing and utility is unclear.[9,10] Liver transaminases are useful to screen for hepatic injury, as they immediately elevate following liver injury. Children with GCS scores ≤13, hypotension, open or multiple bony fractures, or major tissue wounds are at risk for coagulopathy and should be screened with coagulation studies (INR and aPTT). Urinalysis is used to assess for blood (see below). Older pediatric trauma patients should be assessed for substance abuse and depression as contributing factors to the traumatic event. Post-pubertal females or those Tanner stage greater than 3 should be tested for pregnancy. Other than glucose testing in patients with altered mental status, serum electrolytes are routinely measured, but of limited initial use.

Radiologic Imaging

In the severely injured patient, we recommend performing an anteroposterior chest radiograph and a focused assessment with sonography for trauma (FAST), particularly if hypotensive. Plain films should be performed following the primary survey (routinely after the patient is rolled to their side, backboard removal and radiograph plates placed under the patient). An initial chest radiograph screens for immediate life-threatening thoracic injuries, but misses more subtle thoracic injuries. The FAST can be performed after the primary survey (or in conjunction if multiple providers), and evaluates for the presence of intraperitoneal and pericardial fluid. In hemodynamically unstable children, the FAST has good test characteristics for detecting intra-abdominal hemorrhage and can guide further management. The extended FAST (eFAST) examination incorporates the addition of lung views to evaluate for pneumothorax or hemothorax, but has yet to be proven useful in children. A plain pelvis radiograph may identify major pelvic disruptions, but should only be performed in patients who are hypotensive or have unstable pelvic bone examinations. In these patients, the pelvic radiograph may guide the use of a pelvic binder to limit further hemorrhage.

Further imaging should be obtained based on findings from the history and physical examination. Computed tomography (CT) has substantially changed the trauma patient evaluation, as it provides rapid injury identification and details to guide treatment. However, CT carries the risk of radiation-induced malignancy, which is greater in children than adults due to their higher organ sensitivity and longer life expectancy. Data suggests the risk of radiation-induced malignancy is 1 per 5000 to 10,000 cranial CT scans and 1 per 300 to 600 abdominal CT scans. Girls are more sensitive to CT radiation than boys. CT use has rapidly increased in injured children and is highly variable, and CT scans are more commonly obtained in children treated at adult or mixed trauma centers than pediatric trauma centers.[11] In an effort to improve and provide evidence-based care, investigators have developed clinical decision instruments that align CT use in injured children with need (see following).

DISPOSITION

The primary role of the emergency physician is to evaluate and stabilize the severely injured patient before admission or transfer to a facility able to provide the necessary care. Moderately to severely injured pediatric patients of all ages have improved outcomes in pediatric trauma centers.[12,13] For patients requiring transport to a pediatric trauma center, the emergency clinician should not delay transfer for extensive radiologic testing. There should be direct communication between the emergency physician and the accepting doctor, and all radiologic imaging, notes and laboratory results should accompany the patient. Technology now allows images to be transported via the cloud for immediate review by a trauma specialist, which has the potential to decrease unnecessary trauma transfers. Parents should be informed of the reason for the transfer and the exact location to which the child is being taken.

SPECIFIC INJURIES

Head Injury

Traumatic brain injury is the leading cause of death and disability in children older than 1 year of age in the United States.[14] Infants and toddlers are more prone to falls from standing height; school-age children are involved in sports injuries and MVCs; and children of all ages are subject to the sequelae of assault or abuse.

Important anatomic variations lead to differences in pediatric and adult head trauma. The cranial vault of a child is larger and heavier in proportion to the total body mass, predisposing young children to high degrees of torque that are generated by forces along the cervical spine axis. Sutures within the pediatric skull are both protective and detrimental to the outcome of head injury; although the cranium may be more pliable relative to traumatic insult, forces transmitted internally can result in parenchymal injury in the absence of skull fractures. The pediatric brain is less myelinated, with higher water content, predisposing it to shearing forces and higher risks for diffuse axonal injury and post-traumatic seizures.

Clinical Features

The height of the fall and the quality of the surface at the point of impact are important risk factors associated with severity of injury. Most children fall from standing height, but impact with an object can increase the localized force despite the short distance. In MVCs, the type of restraint used should be evaluated because unrestrained and improperly restrained children are at increased risk of serious injury. Several methods are available for evaluating mental status of head-injured patients, including the AVPU system and the GCS score.[15] The

GCS score should be modified for preverbal children (see Table 160.1). The "pediatric" GCS performs similarly to the adult GCS in verbal children.[16] In addition to assessing the child's mental status and examining the head for signs of trauma (including hematomas, lacerations and signs of skull fracture), the child and parents should be questioned on risk factors for intracranial hemorrhage, including loss of consciousness, mechanism of injury, behavior since the event, vomiting, and headache.

A brief seizure that occurs immediately after an insult (with a rapid return to a normal level of consciousness) is commonly called an *impact seizure*. Most children with post-traumatic seizures should undergo cranial CT scanning, but if the CT and the child's mental status are both normal, the child may be safely discharged home.[17]

The examination of a moderate to severely head-injured child includes strict attention to the ABCs (airway, breathing, and circulation). As the pediatric brain is highly sensitive to hypoxia and hypoperfusion, maintenance of oxygenation and blood pressure reduces further insult and optimizes the chance of functional recovery. Cerebral perfusion pressure (CPP) is adequate only in the face of a normal mean arterial pressure (MAP). Conceptually, CPP is equal to MAP minus ICP: CPP = MAP – ICP. As MAP is reduced, so is CPP. Therapy should target a CPP greater than 40 mm Hg and ICP less than 20 mm Hg.[18] Localized CPP at the site of injury and surrounding areas may vary greatly and be difficult to detect. Common symptoms and signs of raised ICP in infants and children are listed in Box 160.7. Herniation syndromes in children are similar to those in adults and described in Chapter 33.

Concussion. A *concussion* is a functional brain injury seen after a blow to the head or body, a fall, or another injury that "shakes" the brain within the skull. Radiographic studies should be obtained if there are findings suggestive of intracranial hemorrhage, but imaging solely for concussion is not recommended, as standard structural radiographic studies are normal, and current imaging for concussion is primarily experimental.[19]

Patients who sustain concussive insults may have somatic, cognitive, affective, or sleep symptoms. All children with concussive symptoms should be monitored for progression of symptoms by their primary care physician or a concussion recovery specialist. Treatment recommendations for concussion are a source of current research, as prior recommendations of bed rest are not beneficial.[20] Currently, we recommend a period of 24 to 48 hours of rest followed by increasing physical activity.

Scalp injuries. Bleeding from scalp wounds is often profuse and can lead to hemodynamic compromise in infants and small children if not quickly controlled. Early hemostasis prevents ongoing blood loss and should be addressed during the initial examination of the trauma patient. Scalp injuries in infants and children may also involve the development of three injury complexes. For these injury complexes to be better understood, the layers of the *s*kin, *c*onnective tissue, *a*poneurosis, *l*oose areolar tissue, and *p*eriosteum (SCALP) should be considered (Fig. 160.2). *Caput succedaneum* refers to a hematoma in the connective tissue layer. This is freely mobile and crosses suture lines. A *subgaleal hematoma* refers to a hematoma that is within the loose areolar tissue above the periosteum. Lastly, *cephalohematoma* refers to a collection of blood under the periosteum. Because the periosteum adheres tightly to the various suture lines, cephalohematomas do not cross them.

Skull fractures. In children, skull fractures occur in many different configurations. Simple linear non-depressed fractures rarely require therapy, are associated with good outcomes, and do not routinely require hospitalization in isolation. Factors associated with poor outcomes include the presence of a fracture overlying a vascular channel (especially the middle meningeal artery), a depressed fracture, or a diastatic fracture. Diastatic fractures are defects which extend through suture lines and can lead to leptomeningeal cysts and "growing fractures." Leptomeningeal cysts are more common in children younger than 3 years old and may form after a skull fracture with a dural tear. "Growing fractures" develop when leptomeninges herniate through a dural tear, causing bony erosion around the fracture site.

Signs of basilar skull fractures in children are similar to adults and include the presence of periorbital subcutaneous hematoma (raccoon eyes), posterior auricular ecchymosis (Battle's sign), and CSF rhinorrhea or otorrhea. Both raccoon eyes and Battle signs take hours to days to develop, and therefore an absence of these signs does not rule out basilar skull fracture.

Cerebral contusions. Cerebral contusions are often the result of coup and countercoup forces and manifest as multiple microhemorrhages. Patients often have associated symptoms, which include an altered level of consciousness, severe headache, vomiting, or focal deficits on neurologic assessment.

Epidural hematoma. Epidural hematomas are typically caused by bleeding from the meningeal vessels and are often associated with overlying skull fractures. The classic presentation of an epidural hematoma is the triad of head injury, followed by a lucid interval, and rapid deterioration as the hematoma expands and compresses the brain.

Subdural hematoma. Subdural hematomas are often secondary to the rupture of bridging veins. Subdural hematomas most commonly occur in patients younger than 2 years of age, and less than half have associated skull fractures. Chronic subdural hematomas are associated with nonaccidental injury or "shaken baby syndrome," the result of accelerating and decelerating forces within the cranial vault

BOX 160.7 Symptoms and Signs of Increased Intracranial Pressure in Infants and Children

- Headache
- Stiff neck
- Photophobia
- Altered state of consciousness
- Persistent emesis
- Cranial nerve abnormalities
- Papilledema
- Hypertension, bradycardia, and hypoventilation
- Infants: paradoxical irritability, split sutures, full fontanelle, and "setting sun sign"
- Decorticate or decerebrate posturing

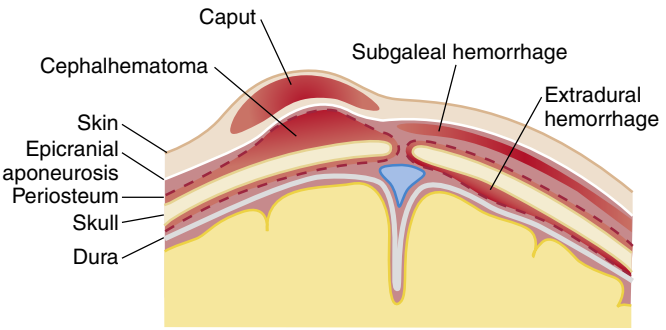

Fig. 160.2 Sites of Extracranial Hemorrhages in the Infant. (From Volpe JJ. *Neurology of the Newborn*. 4th ed. Philadelphia: WB Saunders; 2001.)

from the violent shaking of a child. Subdural hematomas at multiple sites, over areas other than the convexities, in the posterior fossa, or the posterior interhemispheric fissure should raise suspicion for nonaccidental trauma. See Chapter 172 for a more in-depth discussion on nonaccidental trauma.

Diagnostic Testing

Skull radiographs. Clinicians have historically used skull radiographs as a screen for skull fractures in young patients with scalp hematomas. Due to the limited sensitivity of skull radiographs and the increased use of CT scanning in head trauma, skull radiographs are now rarely obtained. Skull radiographs may be considered for part of a skeletal survey in the evaluation of child abuse; to evaluate functioning of a ventricular peritoneal shunt; or to identify suspected foreign bodies underlying scalp lacerations.

Cranial computed tomography. Cranial CT provides substantial information but should be balanced with the risk of radiation. Substantial research has now identified various risk factors for intracranial hemorrhage. The Pediatric Emergency Care Applied Research Network (PECARN) head injury decision instrument was derived in over 42,000 children and validated in a separate population of over 15,000 children.[21] The decision instrument provides evidence based guidelines for children with blunt head trauma (Fig. 160.3). Patients with no risk variables are at very low risk for intracranial injury and should not undergo cranial CT imaging. Furthermore, most patients with only a single risk variable can be observed in the ED and safely discharged after improvement, decreasing CT utilization. However, as the number of PECARN variables increase, risk increases and CT scanning becomes warranted.

Management and Disposition

Alert patients with normal cranial CT scans and normal neurologic examinations may be discharged home. Those with no PECARN risk variables, and those with a single risk factor who clinically improve after a period of observation, can also be discharged home. Reliable caretakers should be given specific return precautions for any focal

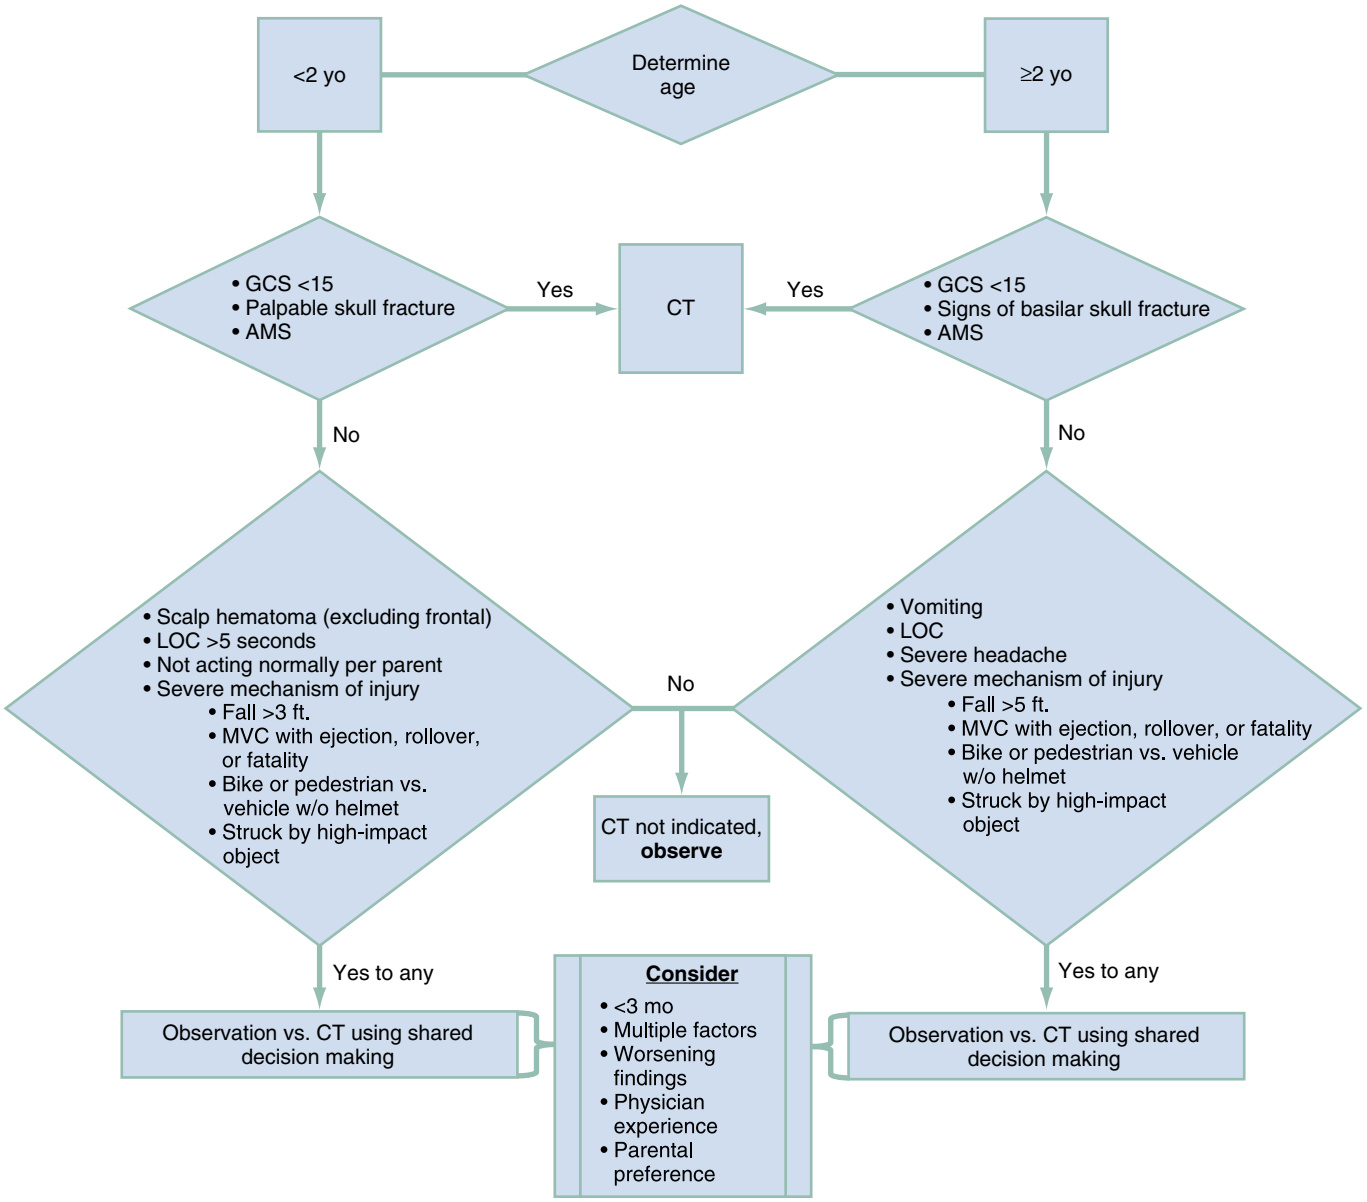

Fig. 160.3 PECARN Head Injury Chart. *AMS,* Altered mental status; *CT,* computed tomography; *GCS,* Glasgow Coma Scale; *LOC,* loss of consciousness; *MVC,* motor vehicle collision.

deficit, lethargy, worsening of symptoms, or alteration of consciousness. Children with intracranial hemorrhage or skull fractures should be evaluated by a neurosurgeon.

Skull fractures. Historically, children with skull fractures are routinely admitted to the hospital. However, alert children with linear, non-depressed skull fracture are unlikely to benefit from hospitalization. In selected cases after neurosurgical consultation, discharge with close outpatient follow-up and return precautions may be acceptable.[22] Skull fractures depressed more than the width of the skull are often repaired surgically. Basilar skull fractures require observation, but no specific therapy unless a persistent CSF leak is identified.

Severe traumatic brain injury. Prehospital BVM is recommended over ETI for support of ventilation and oxygenation. In the ED, ETI is performed in those with rapid deterioration, inability to protect their airway, or GCS scores ≤8. Recommendations for the treatment of children with moderate to severe head injuries are provided and regularly updated by the Brain Trauma Foundation (Box 160.8).[18] Standardization of care with early identification of impending herniation, emergency management of raised ICP, neuroimaging and neurosurgical involvement for appropriate use of ICP monitors improves outcomes.[18] In patients with suspected intracranial hypertension, treatment measures should include elevation of the head of the bed to 30 degrees, appropriate analgesia and sedation, controlled mechanical ventilation with $PaCO_2$ 35 to 40 mm Hg, hemoglobin maintained greater than 7 g/dL, normothermia (35 to 38°C), correcting any coagulopathy, and adequate intravascular volume with normal saline boluses.[18] Management of suspected acute herniation includes administering 3% hypertonic saline between 2 and 5 mL/kg over 15 minutes.[18] Mannitol (0.5–1 g/kg IV) is also used in this setting, but data is insufficient in the pediatric population to support its use. Serial neurologic examinations are the most reliable indicators of clinical deterioration and impending herniation. Repeat cranial CT scanning should be based on clinical assessments and not routinely performed.[18] We recommend a 7-day course of anticonvulsants (phenytoin or levetiracetam) for children with moderate to severe head injury to prevent early post-traumatic seizures. Prophylaxis beyond 7 days is not warranted. If a seizure does occur, rapid treatment with benzodiazepines is indicated.

Vertebral and Spinal Cord Injury

Foundations

Due to anatomic differences in the cervical spine, vertebral and spinal cord injury patterns vary with the age of the patient (Box 160.9) and are most commonly from falls, followed by MVCs. Thoracic and lumbar spine fractures are more common and characterized by compression fractures, whereas burst fractures are rare in children.[23] Cervical spine fractures are rare, especially in children less than 8 years. In this age group, cervical spine injuries are usually C3 or above.[24] As anatomic features of the cervical spine approach adult patterns between ages 8 and 10 years, injuries are more common in the lower cervical spine, and by age 15 years, the injury spectrum is similar to adult patients.

The anatomic differences between children and adults (see Box 160.9) lead to higher cervical cord injuries and an increased incidence of cord injury without bone involvement.[25] Thus, spinal cord injury without obvious radiographic abnormality (SCIWORA) is more common in children.[26] SCIWORA is a misnomer in this era of magnetic resonance imaging (MRI), because most injuries traditionally described as SCIWORA are identified on MRI but not plain radiographs. Treatment and prognosis of cervical spine injury depend on the neurologic presentation and extent of MRI findings. Whenever a cervical spinal injury is identified, careful attention should be paid to the entire spine as multilevel injuries occur frequently.[23]

BOX 160.8 Emergent Management of Severe Traumatic Brain Injury Pertinent to the Emergency Department

- ICP monitoring is suggested for severe TBI with a threshold for treatment of less than 20 mm Hg.
- Excluding increased ICP based on a normal cranial CT in comatose children is not recommended.
- Target CPP is 40–50 mm Hg.
- Bolus 3% hypertonic saline for increased ICP at 2–5 mL/kg IV over 15 min.
- Avoid fentanyl and midazolam boluses during ICP crises.
- Seizure prophylaxis to prevent early post-traumatic seizures with (phenytoin or levetiracetam).
- Avoid prophylactic hyperventilation (PaCO2 <30 mm Hg).
- Prophylactic hypothermia and corticosteroids are not recommended.

CPP, cerebral perfusion pressure; *ED,* emergency department; *ICP,* intracranial pressure; *IV,* intravenously; *$Paco_2$,* arterial carbon dioxide partial pressure; *TBI*, traumatic brain injury.
Kochanek PM, Tasker RC, Carney N, et al. Guidelines for the Management of Pediatric Severe Traumatic Brain Injury, Third Edition: Update of the Brain Trauma Foundation Guidelines, Executive Summary. *Pediatr Crit Care Med*. 2019;20:280-289.

BOX 160.9 Anatomic Differences in the Pediatric Cervical Spine

- Cervical spine fulcrum changes from C2 to C3 in toddlers to C5 to C6 by 8–12 years old.
- Relatively larger head size, resulting in greater flexion and extension injuries.
- Relatively large occiput in children younger than 2 years old leads to flexion of cervical spine if they are laid flat on standard backboard without support under their scapula and pelvis.
- Smaller neck muscle mass with ligamentous injuries more common than fractures.
- Anterior wedge appearance of cervical vertebral bodies is common.
- Increased flexibility of interspinous ligaments.
- Flatter facet joints with a more horizontal orientation.
- Incomplete ossification, making interpretation of bony alignment difficult (synchondrosis).
- Uncinate processes do not calcify until approximately 7 years old.
- Basilar odontoid synchondrosis fuses at 3–7 years old.
- Apical odontoid epiphyses radiographically apparent at 7 years old but may not fuse until approximately 12 years old.
- Posterior arch of C1 fuses at 4 years old.
- Anterior C1 arch may not be visible until 1 year old and fuses at 7–10 years old.
- Neural arches fuse to body by approximately 7 years old.
- Posterior arches fuse by 3–5 years old.
- Epiphyses of spinous process tips may mimic fractures.
- Predental space less than 5 mm in those less than 8 years and less than 3 mm in those ≥8 years.
- Pseudosubluxation of C2 on C3 seen in 40% of children up to 10 years and can be identified by an intact Line of Swischuk (Fig. 160.4).
- Prevertebral space size varies with phase of respiration.

Clinical Features

Although all trauma patients should be examined for vertebral injuries, significant head, neck, or back trauma, high-speed MVCs, or falls from a height onto the head should heighten suspicions. After the initial evaluation and stabilization, the cervical region can be definitively examined. Gentle palpation of the spine for tenderness or bony deformity can be performed to clinically assess the spine in alert children

with otherwise normal neurologic exams. The facial response of a younger child to pain is often more indicative of injury than their verbal response. The neurologic examination in a pediatric patient can be difficult, but several factors should be evaluated in a patient with suspected spinal cord injury. Paralysis, paresthesia, and priapism are highly correlated with spinal cord injuries. Symptoms of paralysis or paresthesia, even if completely resolved at the time of examination, should be considered an indication of spinal cord injury. Spontaneously resolved deficits from an initial stretching of the cord with a rapid deceleration mechanism may return several days later from subsequent cord edema (as commonly described in patients with SCIWORA).[26]

Pediatric presentations of spinal cord injury syndromes are similar to adults and are detailed in Chapter 35. Spinal cord injuries are described as complete or incomplete, depending on the presence or absence of sensory and motor function. Incomplete lesions have preservation of some sensory or motor function below the injury level. Incomplete cord injury has a better prognosis.

Diagnostic Testing

Radiographic recommendations for potential cervical spine injuries are a source of current research and substantial variability. The National Emergency X-Radiography Utilization Study (NEXUS) criteria are often used to clear the cervical spine in adults (see Chapter 35). However, of the 34,069 patients enrolled in NEXUS, only 3065 (9.0%) were less than 18 years of age, and only 30 (0.98%) of these children had cervical spine injuries. Although the NEXUS decision rule identified all patients less than 18 years of age with cervical spine injury, only four children with injuries were younger than 9 years of age, and none were younger than 2 years of age. In a retrospective case-control study, the PECARN reviewed 540 records of children less than 16 years of age with cervical spine injury to identify 8 factors associated with cervical spine injury: altered mental status (including intoxication), focal neurologic findings, any neck pain, torticollis, substantial torso injury, conditions predisposing to cervical spine injury, diving mechanism, and high-risk motor vehicle crash. Children with none of these factors were at very low risk of cervical spine injury.

With limited research to direct pediatric cervical spine clearance, emergency physicians have developed reasonable practice variations in the use of specialist consultation and choice of imaging modalities. We recommend institutions develop multidisciplinary agreements on pediatric cervical spine clearance; establishing protocols has been shown to decrease time to clinical clearance and reduce unnecessary radiation exposure in children. We believe it is reasonable to follow a recent consensus statement and diagnostic algorithms published by the Pediatric Cervical Spine Clearance Working Group, consisting of 15 pediatric orthopedic surgeons, 3 pediatric emergency medicine physicians, 3 pediatric neurosurgeons, 2 pediatric trauma surgeons, and 2 pediatric radiologists.[27] Based on literature and expert opinion, the authors recommend clinical clearance in children with GCS scores 14 to 15, with minor mechanisms of injury (see following), no midline spine tenderness with full range of motion, normal head position, no associated neurological deficits, no painful distracting injuries, hypotension, or intoxication.[27] Patient not meeting all of these criteria should receive cervical spine imaging, starting with plain radiographs that should include a lateral view at minimum. We also agree with this group that a child who is able to maintain focus during an examination can have their cervical spine clinically cleared, despite other significant injuries. However, any child with a visible or known "substantial" injury to the chest, abdomen, or pelvis should have imaging.[27] High risk mechanisms of injury that should prompt imaging include an axial load, clotheslining injury, high-speed MVCs, suspected nonaccidental trauma, or a fall from a height of more than 10 feet. Thus, any alteration of mental status, focal sensory or motor abnormalities, neck pain, the presence of midline neck

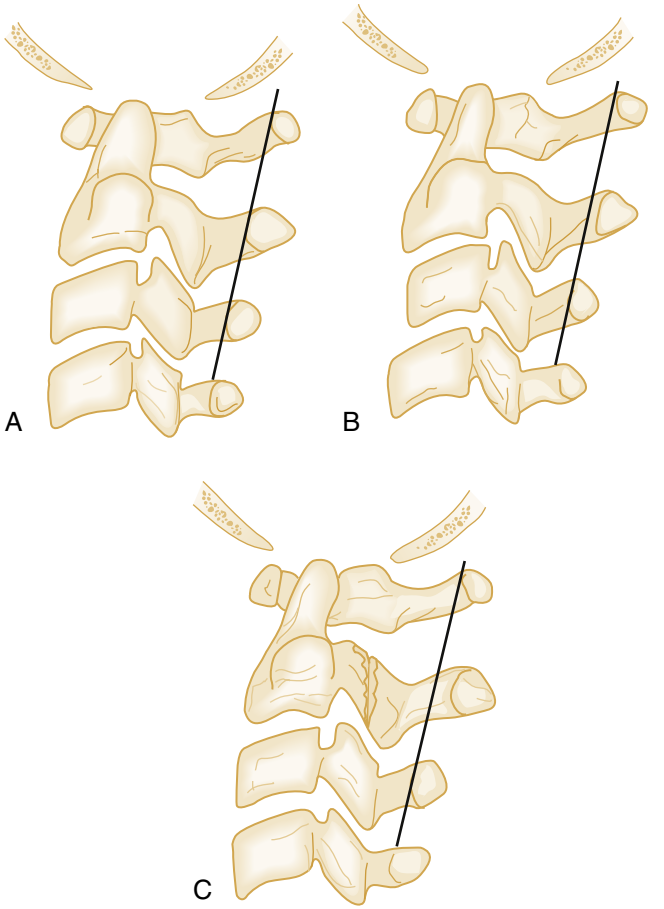

Fig. 160.4 Spinolaminar Line. Use only to access anterior displacement of C2 on C3. A line is drawn from the cortex of the spinous process of C1 to the cortex of the spinous process of C3, and the relationship of the spinous process of C2 is noted. (A) Normal line passing through the cortex of C2. (B) Normal line passing within 1.5 mm of the cortex of C2. (C) Abnormal line passing more than 1.5 mm anterior to the cortex of C2, suggesting underlying fracture of posterior elements of C2. (From American Academy of Pediatrics and American College of Emergency Physicians. *APLS: The Pediatric Emergency Medicine Resource*. 4th ed. Sudbury, MA: Jones and Bartlett Publishers; 2004.)

tenderness or torticollis, limited cervical range of motion or substantial distracting injuries on physical examination, warrant further imaging.[27] To reduce radiation exposure from CT, plain cervical spine radiographs are initially recommended in children with GCS scores 14 to 15 whose cervical spines cannot be clinically cleared.[27] Plain radiographic evaluation consists of lateral and anteroposterior views. In children older than 8 years, an open-mouth odontoid view should be added. The sensitivity of cervical spine plain radiographs is variable, as interpretation in children may be challenging due to the anatomic changes occurring with growth (see Box 160.9).

An essential criterion for radiographic clearance of the cervical spine is complete visualization of all seven cervical vertebrae to the C7 to T1 interface. The pre-dental space should be less than 5 mm in children younger than 6 years old, and the prevertebral soft tissue space should not be greater than one-half the vertebral body width above C4, and not greater than the width of the vertebral body at C6. The four cervical radiographic lines should be evaluated and the atlanto-occipital alignment assessed for dislocation (Fig. 160.4). Pseudo-subluxation of C2 on C3 in children up to age 10 years, occurs in approximately 40% of patients. Subluxation can be differentiated from pseudo-subluxation by the posterior cervical line and the relationship of the spinolaminar line

(line of Swischuk) to the anterior cortical margin of the spinous process at C2 (see Fig. 160.4). This line should maintain its integrity with no more than 1.5 mm of deviation. Although exceptions to this occur, an abnormal line of Swischuk is usually a pathologic finding and should prompt further investigation, typically with specialist consultation.

In children with GCS scores less than 14, we recommend cervical spine CT be obtained at the time of cranial CT imaging.[27] Alternatively, in children less than 3 years of age with GCS scores less than 14, cervical spine CT of C1–C2/C3 can be obtained with plain radiographs of the remaining cervical vertebral. Spine consultation should be obtained in children with injuries found on initial imaging. MRI may be obtained for ongoing concerns or to further delineate spinal cord injury.

Young children are at risk for occipital cervical junction injuries (atlanto-occipital disassociation). Although many of these injuries are immediately fatal, early detection and immobilization are important to prevent further morbidity and mortality. A Power's ratio greater than 1 on imaging indicates atlanto-occipital dislocation (Fig. 160.5). Traumatic atlantoaxial rotatory subluxation should be suspected in an injured child with torticollis. Classically, it is differentiated from muscular, non-traumatic torticollis by history, time course, and the absence of palpable spasm of the sternocleidomastoid muscle on the side contralateral to the direction in which the chin is pointing. When an atlantoaxial rotatory subluxation is suspected, plain radiographs or CT of the cervical spine are indicated. In children with upper cervical spine tenderness, it is prudent to consider a fracture of the synchondrosis between the odontoid and C2. This can be difficult to diagnose on plain radiographs, but it is often recognized as a subtle anterior tilt to the odontoid on C2. A CT scan with sagittal reconstructions can confirm the diagnosis. Children with peripheral neurologic abnormalities should be initially screened with CT or plain radiographs, but undergo MRI if findings persist. If a cervical spine ligamentous or cord injury is suspected with a negative CT scan, we recommend obtaining an MRI. Depending on the scenario and resources, patients with continued neck pain or tenderness despite negative plain radiographs or CT may require spine consultation, MRI, or treatment with a cervical collar and 1 to 2 week outpatient follow-up. The use of cervical spine flexion and extension radiographs to evaluate for ligamentous injury in the acute setting is often limited by the child's pain with neck ranging.

Management

Direct spinal cord injury results in a potentially irreversible injury. Indirect injury results from preventable or reversible injury secondary to ischemia, hypoxemia, and cord edema. Resuscitation of a patient with spinal cord injury should focus on prevention or minimization of the indirect causes of injury to the cervical spine. Spinal injury management begins prehospital, and most injured children arrive with adequate spine immobilization. In transport, the child who requires spinal immobilization should be placed in a stiff cervical collar, a rigid backboard, and external fixation using head blocks, cloth tape, or straps to provide adequate precautions. Appropriate padding should be placed under the shoulder blades of the patient to approximate neutral alignment of the cervical spine and help prevent pressure-related injury. Smaller children can be immobilized in their car seats.

In the ED, spinal immobilization should be maintained throughout the initial trauma evaluation. However, even when thoracic or lumbar fractures exist, patients should be expeditiously removed from the backboard to prevent discomfort and morbidity. Sliding boards (smooth movers) can be used to move patients onto scanner tables and back to their trauma beds.

Breathing should be assessed to determine the presence of hypoventilation, as patients with spinal cord injury may have diminished diaphragmatic activity or intercostal muscle paralysis. Supplemental oxygen should be provided, and ventilatory assistance considered in patients with hypoventilation or altered mental status.

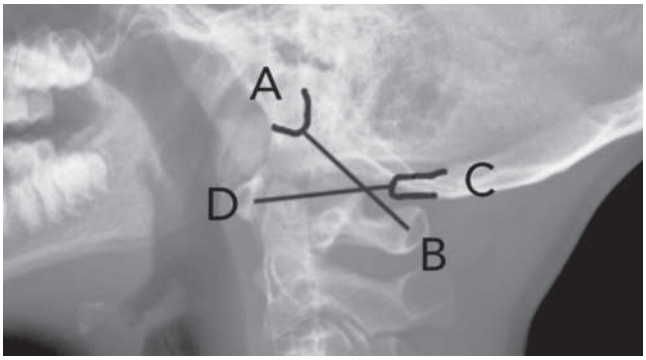

Fig. 160.5 Power's Ratio is Calculated as the Ratio of the Distance From the Basion (Midpoint of the Anterior Margin of the Foramen Magnum) *(A)* to the Anterior Cortex of the Posterior Arch of the Atlas *(B)* Divided by the Distance From the Opisthion (Midline Point of the Posterior Margin of the Foramen Magnum) *(C)* to the Posterior Cortex of the Anterior Arch of the Atlas *(D)*. A Ratio of Ab:cd Greater than 1 Indicates an Atlanto-Occipital Dislocation. The Figure Shows a Normal Power's Ratio.

Spinal shock is the loss of spinal reflexes below the site of injury, and generally resolves in 1 to 24 hours as spinal reflexes return below the site of injury. Neurogenic shock typically occurs with spinal cord injuries above the mid-thoracic level, and should only be considered once hemorrhagic shock has been excluded. Patients with neurogenic shock lose their sympathetic tone, manifested as hypotension and bradycardia. Treatment includes fluid administration, parasympathetic receptor blocking agents (e.g., atropine), and vasopressors with chronotropic, vasoactive, and inotropic characteristics (e.g., norepinephrine). Corticosteroids are no longer recommended in spinal cord injury. Early spine consultation is critical in children with potential spine injury to determine the need for further imaging and treatment, including possible need for transfer with continued spinal immobilization.

Cardiothoracic Injury

Foundations

Thoracic injuries are the second leading cause of death in injured children.[1] Most serious pediatric thoracic injuries are caused by blunt trauma (MVCs or pedestrian accidents). Considering the typical forces associated with blunt trauma, isolated chest injury is relatively infrequent in children. Those with penetrating chest trauma often die from primary vascular injuries which are rare following blunt mechanisms.

Pediatric ribs are less calcified than adults, resulting in more rib flexibility. This results in fewer rib fractures and more energy from the trauma transmitted internally. The presence of actual rib fractures in children suggests high energy and substantially increases the risk of morbidity and mortality. Pediatric rib fractures are generally treated with supportive care, but additional injuries should be sought. Rib fracture in infants should raise suspicion for abuse.[28]

Because of their unique anatomy and respiratory physiology (see Chapter 155), children have an increased risk for early decompensation after chest injury. A child's chest wall circumference does not change substantially during respiration, impairing their ability to increase forced vital capacity. Due to this and their increased metabolic demands, children normally function near maximum tidal volume capacity. As a result, children primarily increase ventilation by increasing their respiratory rate. Thus, anything that impedes a child's ability to increase ventilatory rate can significantly compromise ventilation,

as with diaphragmatic impairment from gastric over-inflation (see Fig. 160.1). Finally, infant diaphragmatic muscle fibers predispose them to muscle fatigue and sudden apnea.

Diagnostic Testing

Plain chest radiography is the initial screening test for thoracic injury and is indicated in children with hypotension, tachypnea, or abnormal thoracic examinations, including any auscultatory abnormalities. This diagnostic test, however, fails to identify 50% of thoracic injuries. Chest CT has greater sensitivity, but exposes the child to substantial radiation, results in increased costs, and has demonstrated limited impact on outcomes.[29] Indications for contrast enhanced chest CT include the need to evaluate for trachea-bronchial or aortic/great vessel injury.[29] Unfortunately, further indications for thoracic CT are not well identified.

Pneumothorax. Traumatic pneumothoraces are less common in children and often associated with a hemothorax. Patients present with symptoms of chest pain, shortness of breath with evidence of chest wall abrasions or ecchymosis. Decreased breath sounds may not be appreciated in children with a pneumothorax because of the extensive transmission of breath sounds in the chest and upper abdomen. Initial anteroposterior supine chest radiography fails to identify half of pneumothoraces. Thoracic ultrasound has higher sensitivity, and chest CT is the gold standard.

Pneumothorax treatment includes the placement of an appropriately sized tube thoracostomy (see Box 160.2) in the mid-axillary line. Chest radiographs should confirm the eyelets of the chest tube are within the chest wall cavity. The chest tube is then attached to an under-water sealed suction device to drain the pneumothorax. A small, simple pneumothorax (<20% volume) in a spontaneously breathing alert, hemodynamically stable child may be observed. Occult pneumothoraces (visualized only on CT or ultrasound and not on plain radiography) are also routinely observed. All pneumothoraces undergoing observation should be treated with high flow oxygen to speed resolution. Children with occult pneumothoraces under positive pressure ventilation may also be observed, but rapid treatment should be available for any decompensation.

Pulmonary air leaks occurring through a one-way valve can cause a tension pneumothorax (Fig. 160.6). Increasing amounts of trapped air within the pleural cavity force the mediastinal structures toward the opposite side, compromising cardiac output. The mediastinal shift forces the trachea to the opposite side, with distention of the neck veins from the decreased venous return to the heart. This results in hypoxia, hypotension, and fluid-refractory shock. Most patients with tension pneumothorax have severe respiratory distress, decreased breath sounds (often bilaterally), and a shift in the point of maximal cardiac impulse. Immediate treatment includes angiocatheter (14 gauge) decompression in the second intercostal space in the midclavicular line or a tube thoracostomy in the fourth intercostal space anterior to the mid-axillary line.

An open pneumothorax occurs when the injured chest wall allows the bi-directional flow of air through the wound. The equalization of pressures between the atmosphere and the chest cavity prevents adequate lung expansion. As a result, ventilation and oxygenation can be severely impaired. In the prehospital setting, a bandage applied over an open pneumothorax wound and taped on three sides, as a temporizing measure, allows air to escape during expiration but not to enter during inspiration.

Management of an open pneumothorax is determined by the size of the chest wall defect and the amount of respiratory compromise. A simple, small, open pneumothorax in a breathing patient may be treated by covering the chest wall defect with an occlusive dressing, such as sterile petroleum gauze, and performing a separate incision for the chest tube. Defects that are too large to seal adequately and patients with ventilatory failure are candidates for intubation with mechanical ventilation in addition to the chest thoracostomy.

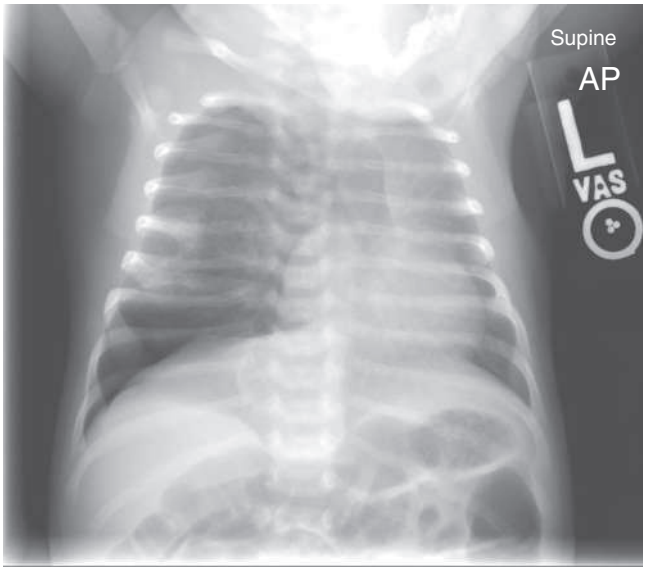

Fig. 160.6 Plain radiograph demonstrating a right sided tension pneumothorax with shift of the mediastinal structures to the left. The mediastinum is more mobile in children resulting in rapid ventilatory and circulatory collapse when under tension.

Hemothorax. Significant bleeding may occur as a result of injury to intercostal vessels, the internal mammary vessels, or lung parenchyma. Clinically, patients have decreased breath sounds and dullness to percussion on the affected side. Approximately 50% of pneumothoraces have concomitant hemothoraces. As hemothoraces collect in the most dependent portion of lung, they are better visualized on upright films as opposed to the standard anteroposterior radiograph. The only sign of hemothorax on a supine radiograph may be a slightly less radiolucent appearance on the affected side of the chest. Although small hemothoraces are observed, significant hemothoraces are treated with tube thoracostomy. In the supine patient with a simple pneumothorax, chest tubes are directed superiorly; in hemopneumothorax, however, they are directed posteromedially. Repeat chest radiographs should be obtained to confirm tube position and document lung expansion.

Massive hemothorax is rare in children and is associated with severe mechanisms of injury (high-velocity MVCs, falls from extreme heights, or gunshot wounds). Indications for open thoracotomy include evacuated blood volumes greater than 15 mL/kg of blood immediately on placement of the chest tube, persistent blood loss (exceeding 2 to 4 mL/kg/h over 3 hours), persistent hemodynamic instability or continued air leak.

Pulmonary contusion. Both penetrating and blunt thoracic trauma may cause pulmonary contusions, the most common thoracic injury in children. The compliance of the rib cage in children makes them susceptible to the development of pulmonary contusion, even in the absence of external signs of chest trauma. Injury to capillary membranes allows blood to collect within the interstitial spaces, resulting in hypoxia and respiratory distress. If bleeding is severe, both oxygenation and ventilation can be impaired. Initial chest radiographs underestimate the degree of injury and chest CT better delineates the insult. Treatment includes close monitoring, as these injuries evolve and patients can progress to respiratory distress over hours. The majority can be treated, however, with observation and supplemental oxygen as needed. Most resolve without sequelae, but those that progress can

require positive pressure ventilation or even extracorporeal membrane oxygenation. Prophylactic steroids and antibiotics are of no known benefit.

Traumatic diaphragmatic hernia. Traumatic diaphragmatic hernias are exceedingly rare. Mechanisms causing these injuries usually involve a sudden increase in intra-abdominal pressure. The degree of symptoms is dependent on the extent of abdominal herniation into the pulmonary space. Most commonly, the herniation occurs on the left side, as the liver hinders the herniation of bowel on the right (Fig. 160.7). Initial management involves placement of a nasogastric tube to decompress the stomach. In cases of severe respiratory distress, intubation with mechanical ventilation is indicated. BMV should be avoided whenever possible, as this can cause distension of the herniated contents in the chest. Surgery is required for definitive repair.

Cardiac and vascular injuries. Although cardiac injuries following trauma are rare, cardiac contusion is the most common injury of the heart but is frequently without symptoms and not diagnosed. Patients often have chest wall tenderness or may report generalized chest pain; tachycardia is the most common finding. No consensus exists on the need and type of evaluation, but most providers screen those at risk with an electrocardiogram. In symptomatic patients (unexplained hypotension) an echocardiogram is indicated and may be diagnostic. Screening with cardiac enzymes is generally not warranted, but normal high sensitivity troponin measurements make the diagnosis unlikely. Patients with significant myocardial contusions should be monitored closely for the development of dysrhythmias and impaired myocardial function; however, in most cases no sequelae occur.

Cardiac tamponade is an immediately life-threatening condition, as extravasated blood fills the pericardial space and impairs cardiac filling during diastole. It presents with tachycardia, distant heart sounds, narrow pulse pressure, jugular venous distention, and pulsus paradoxus. In the scenario of profound hypovolemia, venous distention may be absent. The final common pathway involves the development of cardiopulmonary failure and pulseless electrical activity. The FAST examination (or dedicated echocardiogram) can rapidly identify tamponade (Fig. 160.8), provide an estimate of the pericardial effusion and diastolic dysfunction, and guide therapy. In critical patients with tamponade, emergency pericardiocentesis should be performed to drain the fluid from the pericardial sac. However, this is often inadequate, depending on the volume of blood and the presence of a subpericardial clot. Therefore, a definitive thoracotomy or pericardial window is often required to evacuate the pericardium adequately and repair the primary injury. Penetrating cardiac wounds and tamponade are survivable if recognized early.

Commotio Cordis results from blunt trauma to the anterior chest wall, which causes cessation of normal cardiac function. The patient may have an immediate dysrhythmia or ventricular fibrillation that is refractory to resuscitation efforts. Significant morbidity and mortality are associated with this disorder. Although most patients recover completely, some require extended treatment with antiarrhythmic agents, cardiac pacemaker placement, inotropic agents, or an intra-aortic balloon pump. In patients with prolonged cardiac instability, cardiogenic shock and death may occur despite maximal therapeutic intervention. Aortic and large vessel injuries are fortunately quite rare in young children but begin to increase in adolescents as mediastinal and vascular anatomy more closely resembles adults.

ED thoracotomy is more effective for penetrating trauma; it may be considered for patients with thoracic trauma who deteriorate to cardiopulmonary arrest despite maximal resuscitation. Because their injuries are more likely to be from penetrating mechanisms, adolescents have the best response to intervention.[30] In patients with penetrating chest trauma with cardiopulmonary resuscitation (CPR) for less than 15 minutes, a left anterior thoracotomy may be warranted. Suggested contraindications to ED resuscitative thoracotomy after out-of-hospital CPR include (1) blunt trauma with CPR for longer than 10 minutes with asystole and no signs of life on presentation without ultrasound evidence of cardiac tamponade and (2) penetrating trauma with CPR for greater than 15 minutes and asystole with no signs of life on arrival without ultrasound evidence of cardiac tamponade.

Fig. 160.7 Chest Radiograph with Herniation of the Stomach into the Left Thoracic Cavity. Care should be taken in these patients as the absence of breath sounds on the left may be mistaken for a pneumothorax. Chest tube placement could be complicated if the stomach was punctured during the procedure.

Fig. 160.8 FAST Examination Demonstrating Pericardial Tamponade in a Young Child with unexplained hypotension following a motor vehicle collision. This image resulted in immediate transport to the operating suite for life saving repair of a right atrial perforation in an otherwise uninjured child.

Abdominal and Pelvic Injury

Foundations

After head and thoracic injuries, abdominal injury is the third leading cause of traumatic death in children.[1] Blunt trauma in MVCs is most lethal, causing more than half of abdominal injuries. Certain injury patterns are more common in children due to their unique activities

or anatomy. These range from handlebar-inflicted abdominal injuries (Fig. 160.9) to crush injuries from television toppling. "Lap belt" injuries are most common in children and adolescents, and are characterized by intestinal injuries and "Chance" (horizontal) spinal fractures. Sports-related abdominal injuries often involve an isolated organ, as a result of a direct blow. Finally, abdominal injury is second only to head injury as a cause of death in child abuse cases.

A child's anatomy lends protection from some abdominal injury patterns, while predisposing children to other types of injuries. Children have proportionally larger solid organs, less subcutaneous fat, and less protective abdominal musculature than adults. Children have relatively larger kidneys with fetal lobulations, predisposing to renal injury. Children also have a flexible cartilaginous rib cage that allows for significant excursion of the lower chest wall, permitting compression of the abdominal organs. The combination of these factors provides the basis for the differences in abdominal injury patterns seen between children and adults.

Clinical Features

The rate of abdominal tenderness in alert children with intra-abdominal injuries is similar to that in adults, suggesting that the reliability of the abdominal examination is no different. However, the abdominal examination does become increasingly unreliable in children with significant head injuries (GCS scores <13).

Signs and symptoms of abdominal injury in children include tachypnea (from impaired diaphragmatic excursion and increased metabolic demands), abdominal tenderness, and signs of shock. Patients with abdominal wall injury (e.g., erythema, ecchymosis, abrasions) are much more likely to have intra-abdominal injuries. Abdominal distention is a common nonspecific finding that is often the result of swallowing air (e.g., from crying) after a painful event and not usually from massive hemorrhage (see Fig. 160.1).

Pelvic injuries are uncommon in young children due to their pliable pelvis and relatively larger shielding intraabdominal organs. To exclude injury, pelvic bone stability should be assessed in cases of abdominal trauma, including a genital examination searching for signs of injury. Rectal examination should only be performed in patients with a concern for specific injuries: spinal injury to assess rectal tone; or lower abdominal/pelvic trauma to evaluate rectal integrity.

Diagnostic Testing and Management

In patients with suspected abdominal injuries, management and resuscitation should be carefully planned to balance identification of all clinically important injuries and avoiding unnecessary testing. A careful history and physical examination can risk stratify patients for further evaluation. The PECARN abdominal injury rule risk stratifies children with abdominal trauma for intraabdominal injuries (Fig. 160.10). Children without any PECARN risk variables should not undergo abdominal CT, whereas CT is indicated for most with high risk variables. We recommend that children at intermediate to low risk undergo a period of observation, laboratory screening and FAST examination. Screening laboratory tests considered useful in children include elevated liver enzyme levels (serum aspartate aminotransferase [AST] >200 U/L or serum alanine aminotransferase [ALT] >125 U/L, hematuria, or an initial hematocrit <30%).

Fig. 160.9 Handlebar Injury in a Child Who Fell Off a Bike. Due to the location, the child sustained a liver laceration, but this mechanism often results in pancreatic or duodenal injuries when striking the epigastrium.

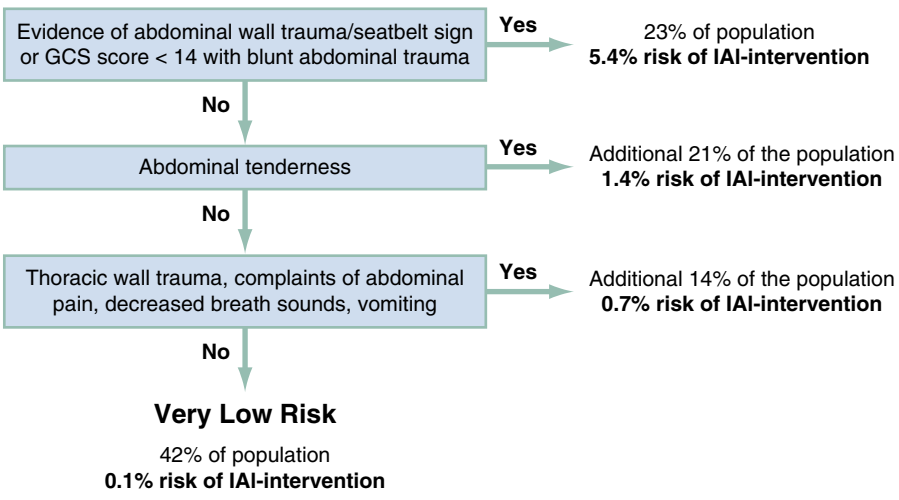

Fig. 160.10 PECARN abdominal injury rule provides evidence-based guidance for abdominal CT use in children. Children at 5.4% risk of injury undergoing intervention are considered at high risk, whereas those at 1.4% or 0.7% are considered at intermediate and low risk, respectively. Children without any risk factors are unlikely to benefit from CT. (Holmes JF, Lillis K, Monroe D, et al. Identifying children at very low risk of clinically important blunt abdominal injuries. *Ann Emerg Med.* 2013;62:107–16.e2)

The FAST examination evaluates the right upper quadrant (Morison's pouch), left upper quadrant and pelvis for intraperitoneal fluid. Although Morison's pouch is the most sensitive location for intraperitoneal fluid in adults, fluid is equally identified in the pelvis and Morison's pouch in children. Unfortunately, FAST has a lower sensitivity for intraperitoneal fluid in children than in adults, leading to uncertainty in its appropriate use.[31] Observational data suggests FAST safely decreases CT in children, however, the single randomized controlled trial in children did not demonstrate any clinical benefit with FAST.[32] Use of the FAST, however, did appropriately decrease the clinical suspicion of intra-abdominal injury, suggesting further study is warranted.[32] The finding of intraperitoneal hemorrhage on FAST does not mandate laparotomy, but if positive, ED abdominal CT is warranted. In hemodynamically unstable children, FAST quickly identifies an abdominal source of hemorrhage and can expedite care.[31]

The diagnostic test of choice to assess for intra-abdominal injury in stable patients at significant risk of intra-abdominal injury is abdominal CT. Abdominal CT scans should be performed with IV contrast; oral contrast is not necessary.[33]

Non-operative management of patients with solid organ injuries was pioneered in children. Now, patients with known sources of bleeding are routinely treated with observation, transfusion, and even arterial embolization instead of surgery.[34,35] Indications for laparotomy include intra-abdominal injuries with hemodynamic instability unresponsive to fluid resuscitation, transfusion greater than 50% of total blood volume, treatment of gastrointestinal injuries, penetrating abdominal trauma, and peritonitis.

Pelvic bone imaging is indicated in children with hemodynamic instability, decreased levels of consciousness, pelvic bone tenderness or instability, hematuria or significant distracting injuries (e.g. femur fracture).[36] If abdominal CT scan is already planned, plain pelvic radiographs are unnecessary, as the sensitivity of plain pelvic radiographs is less than 80%[37] with no additional information to CT. A CT should be considered for children with a strong suspicion for pelvic fracture (severe pain, inability to walk) but normal plain pelvic radiographs.

Splenic injury. The spleen is the most commonly injured abdominal organ. Findings include left upper quadrant abdominal pain that may radiate to the left shoulder. The presence of costal margin tenderness increases the risk of splenic injury, although isolated costal margin tenderness is very low and further evaluation is usually unnecessary.[38] Splenic injuries are best identified and characterized by abdominal CT scans.

Most splenic injuries are managed with simple observation, but surgical consultation should be obtained.[34,35] Almost all patients with splenic injury are admitted, but those with minor (Grade I or II injuries) managed on the ward.[39] Patients with more severe injuries are typically observed in the intensive care unit.[39] Delayed splenic hemorrhage occurs in a small subset of patients, and includes rupture of subcapsular hematomas. To maintain immunocompetency, every effort is made to avoid splenectomy and salvage the spleen.

Hepatic injury. The liver is the second most commonly injured abdominal organ. Abdominal tenderness especially in the right upper quadrant suggests injury. Similar to the left costal margin, tenderness to the right costal margin is associated with hepatic injury, but when present in isolation does not warrant CT imaging.[38] Patients with low-grade injuries are managed on the ward, while high grade injuries are typically admitted to the intensive care unit.[39] Following hepatic injuries, AST levels are usually greater than ALT levels. However, since AST degrades faster than ALT, AST will often be lower than ALT in hepatic injuries greater than 12 hours old.

Renal injury. Due to unique anatomic differences, the pediatric kidney is more susceptible to injury: potential remnant fetal lobules; increased organ mobility with rapid deceleration mechanisms; and lack of protective abdominal musculature. Because of its retroperitoneal location, signs and symptoms of kidney injury are often less obvious and more diffuse than those of other abdominal organ injuries. Flank pain and posterior costal margin tenderness increase risk of injury. Fortunately, patients are readily screened for renal injury by urinalysis. Those without hematuria are unlikely to have significant urinary system injury. Gross hematuria requires abdominal CT scanning as the risk of intra-abdominal injury is approximately 50%. The degree of microscopic hematuria warranting imaging, however, is controversial, as investigators have suggested cutoffs ranging from 5 to 100 RBC/hpf. We recommend ED providers consider hematuria in context with other findings, as isolated asymptomatic microscopic hematuria is unlikely to yield an important injury on CT. For most patients, initial CT scan of the abdomen to assess for genitourinary injury is indicated when there is gross hematuria, microscopic hematuria with additional risk variables (e.g., abdominal pain or evident pelvic trauma), and penetrating injury to the abdomen (with or without hematuria).

Gastrointestinal injury. Approximately 15% of children with intra-abdominal injuries will have gastrointestinal injuries. These injuries range from simple serosal tears or intestinal wall hematomas that often do not require specific intervention, to intestinal perforation and bowel devascularization which require prompt surgical therapy. Fortunately, alert children with severe gastrointestinal injuries have significant abdominal examination findings. Historically, CT had insufficient sensitivity to identify children with gastrointestinal injuries. With improvement in CT technology, abdominal CT now demonstrates abnormalities in approximately 95% of children with gastrointestinal injuries. Abdominal CT findings suggestive of gastrointestinal injuries include intraperitoneal air, bowel wall thickening, bowel wall enhancement, mesenteric infiltration, and vascular contrast extravasation. With improved CT technology, isolated intraperitoneal fluid, once thought to be an ominous sign, is now known to be a common finding in children without diagnosed intra-abdominal injury. Asymptomatic children with normal abdominal examinations and small amounts of isolated intraperitoneal fluid may be observed and ultimately discharged from the ED with appropriate return precautions.

Pancreatic injury. Fortunately, pancreatic injury is rare, occurring in 5% of children with intra-abdominal injuries, but less than 1% of children undergoing abdominal CT scanning. Despite improvements in CT technology, this injury remains difficult to diagnose, as CT has a sensitivity of only 50% for pancreatic injury and fails to correctly grade the injury. Lipase and amylase are poor initial screening labs but increase 24 to 48 hours after pancreatic injury. Most injuries are managed non-operatively, but significant morbidity can occur in those with severe pancreatic trauma.

Penetrating injury. Penetrating wounds to the abdomen usually require rapid evaluation by a surgeon and consideration for operative intervention. Gunshot wounds generally result in more damage and higher mortality than stab wounds. With hemodynamic instability or peritonitis, urgent laparotomy is indicated. Depending on clinical findings, management options for the hemodynamically stable patient include further evaluation with abdominal CT scan; local wound exploration to determine violation of the peritoneum; diagnostic laparoscopy; and observation. In modern practice, diagnostic peritoneal lavage has been supplanted by other diagnostic modalities, including CT and diagnostic laparoscopy.

Straddle injuries. Straddle injuries occur when the child falls, striking their genitals and perineum on a hard object, most commonly bicycles and playground equipment. Injuries are typically localized to the genitalia and perineum, and physical examination is usually

sufficient to identify the extent of injury. Pain and anxiety, however, may limit the ability to adequately examine the area, often requiring sedation. Child abuse should be ruled out, especially if the injury is unlikely from blunt trauma (e.g., rectal or posterior fourchette tears). We recommend observing children with straddle injuries to confirm the ability to void and assess for hematuria. Scrotal ultrasound is recommended for significant scrotal edema or tenderness. Children who should receive referral for definitive care include those with extensive lacerations, vaginal bleeding, large hymenal tears, scrotal laceration through the dartos layer, or evidence of urethral injury.

Pelvic fractures. While pelvic fractures are less common in children than adults, pelvic avulsion fractures are significantly more common in children, especially as related to sports. More severe pelvic fractures are the result of high energy mechanisms, and frequently associated with other injuries. Genitourinary injuries are found in 10% of children with pelvic fractures. Orthopedic consultation is recommended to determine further treatment.

MUSCULOSKELETAL INJURIES

Musculoskeletal injuries are a common ED complaint for children. Pediatric injury patterns differ substantially from those of adults, as children have strong ligaments and growing, less dense bones covered in a thicker periosteum. The Salter-Harris fracture classification characterizes fracture patterns unique in children. In cases where the skin is disrupted at the site of the fracture, the fracture is considered open; the wound should be irrigated and IV antibiotics covering gram-positive skin flora administered. Antibiotics with gram-negative coverage are added in those with more complicated fractures. Fractures with vascular deficits require emergent reduction and splinting, but those with normal neurovascular examinations should be splinted until definitive care. A detailed discussion of these types of injuries is found in Chapter 170.

CHAPTER 160: QUESTIONS AND ANSWERS

1. A 5-year-old male is struck by a car while riding a bicycle with no helmet, presents with heart rate of 92 beats/min, blood pressure 60/30 mm Hg, cervical spine immobilized with a collar, and quadriplegia. The patient has no evidence of hemorrhage on examination or diagnostic testing. You suspect neurogenic shock and attempt to correct the hypotension with fluids but are not successful. Which of the following should be your first choice for a vasopressor?
   a. Dobutamine
   b. Dopamine
   c. Epinephrine
   d. Norepinephrine

Answer: d. Patients with neurogenic shock lose their sympathetic tone, manifested as the triad of hypotension, bradycardia and peripheral vasodilation. Treatment includes fluid administration, parasympathetic receptor blocking agents (e.g., atropine), and vasopressors with chronotropic, vasoactive, and inotropic characteristics (e.g., norepinephrine).

2. A 6-month-old infant is brought to your emergency department (ED) by his mother after he reportedly fell 3 feet from his changing table approximately 45 minutes ago. His mother reports that the child did not lose consciousness but is fussy and has a large scalp hematoma on the right side of head. On exam, the Glasgow Coma Scale (GCS) is 14 (spontaneous eye and motor, irritable cries). The patient has a right sided 4 cm scalp hematoma in the temporal area but otherwise the examination is normal. What is your most important intervention at this point?
   a. Consulting a social worker to help screen for child abuse
   b. Cranial computed tomography (CT) scan
   c. Ice packs for the scalp hematoma
   d. Observation in the ED for 4 hours
   e. Skull radiographs

Answer: b. A 6-month-old infant with a GCS 14 has a 4% risk of clinically important traumatic brain injury (TBI) by the Pediatric Emergency Care Applied Research Network rules. Additionally, the temporal scalp hematoma is associated with a 1.6% risk of clinically important TBI while a severe mechanism of injury carries a 0.5% risk of clinically important TBI. Solely on the GCS 14 score, the infant needs a non-contrast cranial CT to rule out TBI. If the infant had a GCS 15, and was acting normally, based on the severe mechanism alone, shared decision-making with the parents to observe the infant in the ED is a reasonable alternative to an immediate cranial CT scan.

3. Which of the following is the most commonly injured solid organ in pediatric patients with abdominal trauma?
   a. Bladder
   b. Duodenum
   c. Kidney
   d. Liver
   e. Spleen

Answer: e. Injuries to the spleen are the most common injuries in pediatric abdominal trauma. Children involved in motor vehicle collisions (MVCs), sudden deceleration injuries, and contact sports–related injuries may sustain splenic trauma. Clinical exam findings include left upper quadrant abdominal pain that may radiate to the left shoulder. Splenic injuries are best identified and characterized by abdominal computed tomography (CT) scans. Treatment includes fluid resuscitation and blood transfusion as needed. Splenic salvage is important for immunocompetence in children and operative intervention is avoided as long as the patient can be stabilized with fluid resuscitation.

4. A 4-year-old female is brought to your emergency department (ED) from the scene of a motor vehicle collision. Paramedics intubated the child in the field because she was unresponsive at the scene. On arrival, her vital signs are within normal limits. Before transport to the computed tomography (CT) scanner, however, you note that she is becoming mildly bradycardic and hypertensive. Her left pupil becomes dilated and nonreactive. You elevate the head of bed 30 degrees and maintain $ETCO_2$ at 35 mm Hg with controlled ventilation. Which of the following should be your next immediate action?
   a. Mannitol or 3% hypertonic saline IV
   b. Nicardipine infusion
   c. Phenytoin administration
   d. Proceed immediately to the CT scanner

Answer: a. The sudden onset of a dilated, nonreactive pupil, along with bradycardia and hypertension, is indicative of acute brain herniation from raised intracranial pressure. Controlled ventilation to keep $ETCO_2$ greater than 30 mm Hg, a hyperosmolar agent, such as mannitol or hypertonic saline given intravenously, and raising the head of the bed 30 degrees are recommended strategies. Phenytoin can be considered for seizure prophylaxis in this patient, but not before the other measures are instituted. Nicardipine and other antihypertensive agents have no place in the management of a head-injured child. Hypertension is a physiologic response to brain herniation, where increasing the mean arterial pressure (MAP) preserves cerebral perfusion pressure (CPP).

5. A 7-year-old girl is brought into the emergency department (ED) by emergency medical service (EMS) personnel from the scene of a motor vehicle collision (MVC). On your primary survey, she is noted to have a patent airway, decreased breath sounds in the right lung field, and subcutaneous emphysema. She has hypotension and weak distal pulses. What is your next step in stabilizing this patient?
   a. Airway control with endotracheal intubation (ETI)
   b. Bag-mask ventilation (BMV)
   c. Immediate needle thoracostomy in the second midclavicular space on the right
   d. Portable chest radiograph to confirm diagnosis

Answer: c. This patient is presenting with signs of tension pneumothorax. In this case, immediate decompression with a needle thoracostomy, followed by the placement of an appropriately sized chest tube or immediate chest tube placement is required to avoid cardiovascular collapse. A portable chest radiograph should be performed to confirm chest tube placement.

6. Which of the following statements regarding chest injuries in children is correct?
   a. Aortic transection is more likely in a pediatric patient than in an adult patient.
   b. Multiple rib fractures without significant underlying lung injury are common in children.
   c. Penetrating chest trauma is more common than blunt chest trauma in pediatric patients.
   d. Significant pulmonary contusions may be present in the absence of rib fractures in children.

Answer: d. The pediatric rib cage has more compliance than an adult rib cage. Thus children are predisposed to pulmonary injury in the absence of rib fractures. Blunt chest trauma is more common than penetrating chest trauma in pediatric patients and concurrent chest and abdominal injuries are common. Aortic transection is more common in adults.

CHAPTER 160: QUESTIONS AND ANSWERS—cont'd.

7. A 12-year-old male fell while climbing over a 12-foot barbed-wire fence and sustained a deep 10-cm laceration to his medial left thigh. Parents bring him to the ED directly from the scene. There is active oozing from the laceration. What is the first step in the management of this patient?

a. Apply a tourniquet to the leg.
b. Begin with a primary survey and assess the patient's airway and breathing.
c. Obtain intravenous (IV) access and begin blood transfusion immediately.
d. Pack the wound to decrease hemorrhage.

Answer: b. The primary survey should quickly assess the airway, breathing, and circulation (ABCs). Approaching trauma patients in a systemic fashion will ensure that large, obvious injuries do not distract from the detection of other injuries. Oftentimes multiple interventions would be done simultaneously. Jaw thrust to open an airway and then another health care providers quickly applying pressure on the wound for hemorrhage control. The child in the question fell from a fence and may have other fall-related injuries that should be identified during the secondary survey.

8. Which of the following statements regarding imaging of a multitrauma pediatric patient is correct?

a. A negative computed tomography (CT) scan of the cervical spine rules out spinal cord injury, and if normal, immobilization can be discontinued.
b. A negative focused assessment with sonography in trauma (FAST) examination rules out traumatic intra-abdominal injury, making a CT scan unnecessary.
c. In a hemodynamically stable pediatric trauma patient, CT imaging should be completed before transfer to a pediatric trauma facility, even if it delays transfer.
d. In a hemodynamically stable pediatric patient with a high level of concern for intra-abdominal trauma, CT scan is the imaging test of choice.

Answer: d. CT scan is the diagnostic test of choice for evaluation of intra-abdominal trauma in children. Spinal cord injury without radiologic abnormality (SCIWORA) is more common in pediatric patients, and a normal cervical spine CT scan does not rule out ligamentous injuries or spinal cord edema. Although often a useful adjunct, a FAST examination does not rule out intra-abdominal injury. In a hemodynamically stable patient, CT imaging does not need to be completed before transfer to a pediatric trauma center and definitely should not delay transfer.

Pediatric Fever

Nathan W. Mick

KEY CONCEPTS

- Fever is the most common complaint among pediatric patients presenting to the emergency department (ED). Although rates of bacterial illness are lower since the advent of universal vaccination for *Haemophilus influenzae* type b and *Streptococcus pneumoniae*, serious bacterial infection (SBI) should be considered in the under-vaccinated or unvaccinated child.
- Viruses cause the vast majority of childhood febrile illnesses and are generally self-limited and benign.
- SBI is the growth of pathogenic bacteria in a previously sterile site, such as urinary tract infection (UTI), bacteremia, meningitis, osteomyelitis, bacterial gastroenteritis, bacterial pneumonia, cellulitis, or septic arthritis.
- The rate of SBI in infants younger than 3 months old with fever is between 6% and 10%.
- Infants 28 days old and younger are at much higher risk for bacterial illness with fever because of their immature immune systems and incomplete vaccination status.
- Empirical treatment of a febrile neonate is indicated, and appropriate antibiotic regimens include ampicillin plus either gentamicin or cefotaxime, which cover the bacterial organisms likely in this age group.
- Empiric treatment for herpes simplex virus (HSV) in neonates with a maternal history of genital herpes, ill appearance, fever and seizure, cutaneous vesicles on physical examination, transaminitis, or evidence of coagulopathy is recommended.
- The most common cause of SBI in children continues to be UTI. In infants who are not toilet-trained, bladder catheterization is the best method for collecting uncontaminated urine. However, for select patients, bagged urine may be obtained, and if results do not indicate infection, no further studies are needed. Suprapubic aspiration may be considered when a urine sample cannot otherwise be obtained.
- Bacterial meningitis can occur at any age, but most commonly presents in a relatively small proportion of febrile infants younger than 3 months old (3/1000).
- Respiratory syncytial virus (RSV) and influenza are common viral causes of fever and respiratory distress in infants, but the presence of viral infection does not lower the risk of concomitant SBI in children younger than 28 days old.
- In older infants and children, the documented presence of RSV or influenza significantly reduces the incidence of SBI and can be used to modify the evaluation. Because UTI is still common in this population, a urinalysis should be obtained.
- There are numerous risk-stratification strategies (e.g., Boston, Rochester, and Philadelphia criteria) reported in the literature that have similar performance characteristics. All involve a laboratory evaluation designed to identify a subset of febrile infants younger than 3 months old that can safely be managed as outpatients with or without antibiotics.
- Standardization and adoption of a clinical practice guideline for the evaluation of the febrile infant have been shown to reduce variation and cost.
- Due to universal vaccination against pneumococcus, the evaluation of highly febrile children 3 to 36 months old has evolved from one of universal screening for occult bacteremia to one where clinical assessment determines the need for bloodwork.
- Inflammatory markers, such as C-reactive protein (CRP) and procalcitonin, have been shown to predict bacterial illness in febrile children more accurately than the white blood cell (WBC) count but does not solely rule out SBI.
- Traumatic lumbar punctures occur relatively commonly in young infants and can make interpretation of cell counts difficult. The use of various formulas to account for the protein and WBCs in the cerebrospinal fluid (CSF) after a traumatic tap should be used with caution.
- As the risk of meningitis is exceedingly low, we do not recommend lumbar puncture in well-appearing children with a simple febrile seizure.
- Children presenting with fever and petechiae are at risk for infection with meningococcus; blood should include a complete blood count (CBC) and culture and, if available, CRP and procalcitonin (>0.5 ng/mL). Children with an abnormal CRP, WBC count (<5000/mm^3 or >15,000/mm^3), or bandemia should be treated with parenteral antibiotics and admitted. Lower risk, well-appearing children with normal laboratory parameters can be considered for close outpatient follow-up.
- Children with fever who also are receiving cytotoxic chemotherapy for cancer are at high risk for bacteremia and sepsis and should receive prompt broad-spectrum antibiotic therapy after appropriate diagnostic evaluation (at minimum, a CBC and blood culture).
- Patients with fever and a history of sickle cell disease are at risk for bacteremia from encapsulated organisms due to functional asplenia and should be considered high risk, admitted, and treated.

FOUNDATIONS

Background

Fever is the most common chief complaint of pediatric patients presenting to the emergency department (ED). Most cases of fever are viral in origin, benign in course, and resolve spontaneously. Management of children with fever varies by the age of the child, with the following common divisions: 0 to 28 days old, 1 to 2 months old, 2 to 3 months old, 3 to 6 months old, 6 to 36 months old, and 3 years old to adulthood. Understanding that risk is a continuum, these divisions reflect differing immunologic and vaccination milestones, as well as a spectrum of age-specific pathogens.

Anatomy, Physiology, and Pathophysiology

Fever is defined as any elevation in body temperature of 100.4°F (38.0°C) or above. The most reliable method to measure temperature is with a rectal thermometer and is the preferred method of measurement in high-risk groups, such as infants 0 to 3 months old. However, the rectal route should not be used in patients who are potentially immunocompromised (e.g., children receiving cytotoxic chemotherapy) because of the risk of mucosal damage leading to bacteremia. The cutoff for a clinically significant fever (i.e., one that may trigger a laboratory evaluation) varies with the age and immunologic status of the child. A rectal temperature of 100.4°F (38.0°C) is considered a clinically significant fever in an infant younger than 3 months, often warranting laboratory evaluation; however, a toddler with a temperature of 103.1°F (39.5°C) and an upper respiratory infection may not need any evaluation beyond a thorough history and physical examination.

Causes of fever vary with the age of the child (Table 161.1). The majority of pediatric fever is due to infections, and most infections are attributable to a viral source. (See Chapter 120 for a discussion of COVID-19 in children) Upper respiratory infections, viral gastroenteritis, croup, bronchiolitis, stomatitis, roseola, infectious mononucleosis, and varicella are all known causes of fever. Most viral illnesses are benign and self-limited, but infection with measles, herpes simplex virus (HSV), or respiratory syncytial virus (RSV) can lead to significant morbidity and mortality, particularly in the first month of life.

Bacterial disease is also an important cause of fever in children. Serious bacterial infection (SBI) is defined as the presence of pathogenic bacteria in a previously sterile site and includes urinary tract infection (UTI), bacteremia, meningitis, osteomyelitis, bacterial gastroenteritis, bacterial pneumonia, cellulitis, and septic arthritis. The risk of SBI in febrile infants younger than 3 months old with a temperature of at least 100.4°F (38.0°C) is between 6% and 10%; children younger than 28 days old have the highest incidence.[1] Hyperpyrexia (rectal temperature ≥40.0°C) is associated with a higher risk of SBI.[2] Pathogens change during early infancy, with vertical transmission of organisms such as group B streptococcus, *Listeria monocytogenes,* and HSV more common in neonates. By 1 to 2 months of age, organisms such as *Streptococcus pneumoniae, Neisseria meningitidis,* and urinary pathogens *(Escherichia coli* or *Enterococcus)* become more common. In all children younger than 3 months old, the urinary tract is the most common site of infection, followed by bacteremia and meningitis.

Children younger than 3 months old may present with an apparent viral syndrome and still harbor SBI. Levine and colleagues studied 1248 infants younger than 60 days old who had temperatures above 100.4°F (38.0°C). Of these children, 22% were positive for RSV. Overall, children with documented RSV had a lower incidence of concomitant SBI than those without RSV (12.5% vs. 7%), but there was no significant difference in rates of SBI in those younger than 28 days old (14.2% in RSV-negative vs. 10.1% in RSV-positive). Most of the bacterial infections were UTIs. Older children 3 to 36 months old with recognizable viral syndromes (e.g., croup, bronchiolitis, varicella, stomatitis) have a very low incidence of bacteremia; in over 1300 patients with a temperature above 102.2°F (39.0°C) who had a recognizable viral syndrome, the risk of bacteremia was 0.2%.

Occult bacteremia describes the presence of pathogenic bacteria in the bloodstream of a well-appearing febrile child in the absence of a focus of infection; it was first described as a clinical entity in the 1970s. The term typically refers to children 3 to 36 months old who are highly febrile (>102.2°F [39.0°C]) but appear well. Before the adoption of the conjugate vaccines against *Haemophilus influenzae* type b and *S. pneumoniae,* the incidence of bacteremia in this population was approximately 5%. Vaccination has proved remarkably effective, nearly eradicating *H. influenzae* type b as a significant pathogen and greatly reducing the burden of pneumococcal disease (Fig. 161.1).[3,4] Currently, the rate of occult bacteremia is less than 1%, with pathogens such as *N. meningitidis* becoming proportionally more prevalent. Urinary pathogens, occurring in 5% of febrile children younger than 2 years old, continue to be a common source of bacterial illness in infants and children. Risk factors include female sex, absence of another apparent source of infection, fever higher than 102.2°F (39.0°C), white race, and for boys, uncircumcised status.

Bacterial illness in school-age children and adolescents includes focal infections, such as streptococcal pharyngitis, cellulitis, and pneumonia, as well as bacteremia and meningitis. *N. meningitidis* has a bimodal distribution, with the highest incidence in children younger than 12 months old (9.2/100,000 population). A second peak occurs

TABLE 161.1 Etiology of Fever in Children

Age	Bacterial Causes	Viral Causes	Other
0–8 days old	Group B streptococcus	HSV	Bundling (skin temperature only)[a]
	Listeria monocytogenes	Varicella	Environmental
	Escherichia coli	Enteroviruses	
	Chlamydia trachomatis	RSV	
	Neisseria gonorrhoeae	Influenza	
1–3 months old	*Haemophilus influenzae*	Varicella	
	Streptococcus pneumoniae	Enteroviruses	Environmental
	Neisseria meningitidis	RSV	
	E. coli	Influenza	
3–36 months old	*S. pneumoniae*	Varicella	Leukemia
	N. meningitidis	Enteroviruses	Lymphoma
	E. coli	RSV	Neuroblastoma
		Influenza	Wilms' tumor
		Mononucleosis	
		Roseola	
		Adenovirus	
		Norwalk virus	
		Coxsackievirus	
3 years old to adulthood	*S. pneumoniae*	Varicella	Leukemia
	N. meningitidis	Enteroviruses	Lymphoma
	E. coli	RSV	Neuroblastoma
	Group A streptococcus	Influenza	Wilms' tumor
		Mononucleosis	Juvenile rheumatoid arthritis
		Roseola	
		Adenovirus	
		Norwalk virus	

[a]Bundling may raise skin temperature but does not change rectal temperature. Irrespective of how measured, a fever in this high-risk population should not be attributed to bundling alone.
HSV, Herpes simplex virus; *RSV,* respiratory syncytial virus.

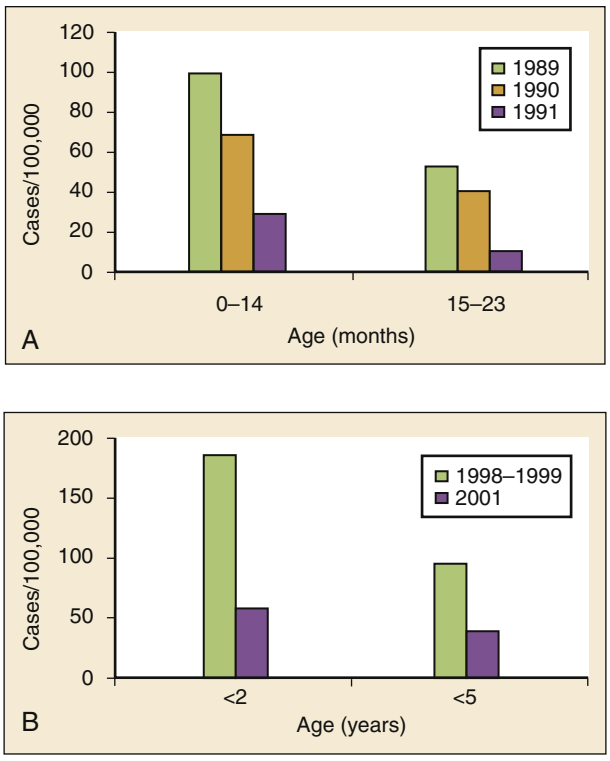

Fig. 161.1 Decline in incidence of occult bacteremia after the introduction of the conjugate vaccine against *Haemophilus influenzae* (A) and *Streptococcus pneumoniae* (B).

during adolescence, when the rate of illness is 1.2/100,000 population, with a significant proportion of cases occurring in college students who reside in a dormitory setting (3.2/100,000 population).

Although it is much less common than in viral or bacterial infection, fever can also be a presenting sign of autoimmune diseases, such as juvenile rheumatoid arthritis or Kawasaki disease. Central nervous system (CNS) lesions such as brain tumors also can infrequently manifest with fever.

The body's ability to fight infection varies with age. Maternal antibodies confer some protection after birth, but the infant's immune system is initially inadequate, particularly T-cell function and the ability to mount an immunoglobulin G response to infection. Their immature immune system and exposure to certain pathogens during the birthing process (e.g., group B streptococcus, *Chlamydia trachomatis, Neisseria gonorrhoeae*) places the newborn at particularly high risk for SBI. Young infants are also at risk for disseminated infection because they are unable to mount the immune response needed to prevent bacterial spread. Thus, a simple cellulitis, mastitis, omphalitis, or, rarely, gonococcal eye disease, can lead to sepsis or seeding of the CNS. Immune function improves during the first 2 to 3 months of life, as does the ability to assess a child clinically. Infants begin the primary series of vaccinations against acquired infections, such as *S. pneumoniae* and *H. influenzae,* at 2 months of age, providing further protection against common bacterial pathogens. As a result, empirical testing and treatment give way to more selective evaluations above 2 to 3 months old.

Clinical Features

History taking should focus on the length of illness, localizing symptoms (e.g., headache and neck pain [meningitis or encephalitis] or ear pain [otitis media]), exposure to ill contacts, travel history, and pertinent past medical history. For infants younger than 28 days old, document birth history, including gestational age and the presence of potentially transmittable maternal infections (HSV or group B streptococcus). Document immunization status, sick contacts, use of antipyretics before evaluation, and prior use of antibiotics. Defervescence after acetaminophen administration has not been shown to reliably exclude bacteremia in children of any age. Prior antibiotic use may mask the classic findings in diseases, such as meningitis. Cough and congestion may suggest pneumonia or viral upper respiratory infection, whereas a harsh, barking, or seal-like cough is often a predominant complaint in viral laryngotracheitis (croup). Parents may report vomiting and diarrhea as a component of gastroenteritis, or the presence of sore throat and lymphadenopathy with viral or streptococcal pharyngitis. Decreased oral intake or decreased urine output is a frequent complaint in gastroenteritis but may also be seen in patients with stomatitis because painful oral aphthous ulcerations prevent fluid intake. A history of lethargy, irritability, or altered mental status can occur with severe dehydration but should raise concern for meningitis or encephalitis. A rash occurs in many viral illnesses (e.g., roseola) but may be seen in life-threatening conditions, such as meningococcemia, Rocky Mountain spotted fever, and toxic shock syndrome (TSS).

The physical examination of the febrile child should begin with a complete set of vital signs, including pulse oximetry. Hypoxia or significant respiratory distress (e.g., tachypnea, grunting respirations, nasal flaring, or retractions) may accompany sepsis or pulmonary infection. Stridor can be seen with croup but also can occur with retropharyngeal abscess, epiglottitis, or bacterial tracheitis. Signs of shock, such as hypotension and poor peripheral perfusion, should be noted. Children typically mount a tachycardic response to fever, and hypotension is often a late and dire finding. Tachycardia is often due to the fever itself, but tachycardia out of proportion to the degree of fever can be seen with early shock, myopericarditis, and dehydration. Estimations of heart rate increase based on fever in infants younger than 12 months old (i.e., heart rate increases linearly by 9.6 beats/min with each 1°C increase in body temperature) should be used with caution and clinical signs of sepsis evaluated before attributing tachycardia to fever alone. Once oxygenation, ventilation, and perfusion have been assessed and deemed adequate, the physical examination should focus on a thorough search for focal infection. In young infants, particularly those younger than 3 months old, and in children who lack immunocompetence, fever may be the only presenting sign of SBI, including meningitis. The physical examination in this age group is insufficiently sensitive to exclude SBI, and emergency clinicians should not be falsely reassured by a normal physical examination in young children. Those who do appear toxic may have decreased tone, poor skin turgor, poor tracking, increased or decreased respiratory effort, a weak cry or suck, or delayed capillary refill times. The neonate who refuses to feed should have a full SBI evaluation, irrespective of temperature. See Chapter 155.

Diagnostic Testing

Numerous laboratory and radiographic studies can be used to evaluate the febrile child. In general, testing should be directed at the identification of the source and complications of infection. Several guidelines exist for the evaluation of febrile children, although there is marked variation in adherence to these guidelines. Office-based practitioners have been found to follow published guidelines only 42% of the time in the evaluation of febrile children. Clinicians with less experience and those based in the hospital tend to order more tests compared with more experienced clinicians and those practicing in an office setting, respectively. The use of institutional clinical decision rules and guidelines can help streamline appropriate testing.[5,6]

White Blood Cell Count

An elevated white blood cell (WBC) count (>15,000/mm^3) can be an indicator of bacteremia but is also present in many viral illnesses. Leukopenia (<5000/mm^3) can also be a sign of SBI or early sepsis. Pneumococcal infection is classically associated with leukocytosis, whereas infection with *N. meningitidis* and *H. influenzae* may be present even with normal WBC counts. In children with fever greater than 102.2°F (39.0°C), Lee and colleagues found that the rate of pneumococcal bacteremia increased from 0.5% with a WBC count between 10,000 and 15,000/mm^3 to 3.5% if the WBC count was 15,000 to 20,000/mm^3 and up to 18% with a WBC count above 30,000/mm^3. More extreme leukocytosis is associated with an increased risk of bacterial infection, particularly lobar pneumonia, and a WBC count of above 25,000/mm^3 should prompt consideration of a chest radiograph unless another definitive source is apparent.[7]

The WBC differential diagnosis has also been used to risk-stratify febrile children in various models; an increase in polymorphonuclear leukocytes increases the risk of bacterial disease. A rise in polymorphonuclear leukocytes is also seen early in some viral infections. An absolute neutrophil count (ANC) above 10,000/mm^3 suggests an increased risk of pneumococcal bacteremia in febrile children (0.8% for children with an ANC below 10,000/mm^3 vs. 8% for children with an ANC above 10,000/mm^3). Routine screening of all febrile children greater than 3 months of age with bloodwork has not been shown to be cost-effective in the post-vaccination era. The vast majority of acute febrile illness is due to self-limited viral infection. If the decision is made on clinical grounds to obtain a WBC and if it is abnormal (<5000/mm^3 or >15,000/mm^3) or the ANC is greater than 10,000/mm^3, then we recommend screening for occult bacteremia with a blood culture, understanding that leukocytosis is neither perfectly sensitive nor specific for bacterial illness. We also recommend treatment with ceftriaxone for incompletely immunized children who have a WBC of more than 15,000/mm^3.

Inflammatory Markers

Both C-reactive protein (CRP) and procalcitonin have been studied as markers of bacterial infection. The utility of the measurement of inflammatory markers is dependent on the cutoff level assigned for clinical significance with lower values having higher sensitivity but lower specificities. Procalcitonin greater than 0.5 ng/mL is highly specific for SBI, though some clinicians use a lower cutoff (>0.2 ng/mL) to increase sensitivity. Both CRP and procalcitonin appear to be more sensitive and specific than the WBC alone, although the lack of widespread availability limits the usefulness of procalcitonin clinically at this time.[8,9]

Blood Culture

Many centers obtain blood for culture during intravenous (IV) catheter placement after sterile preparation of the skin has been performed. Although this eliminates a second venipuncture solely to obtain blood for culture, in children, the rates of contamination with this technique are higher than a sterile straight stick (9.1% vs. 2.8%). The risks of contamination should be weighed against the ability to obtain blood through a separate venipuncture. The yield of a single blood culture in infants and small children is actually good. The routine sending of more than one sample is generally not needed, and bacteremia is often accurately detected even if only 0.5 to 1 mL of blood is obtained. The advent of automated blood culture systems has led to the identification of true pathogens more quickly than by traditional methods, often within 24 hours. Pathogens isolated in the first 24 hours are more likely to be true pathogens than are bacteria isolated after 24 hours.[10]

Urinalysis and Urine Culture

UTIs are common causes of bacterial illness in febrile children, occurring in 5% of infants 2 to 24 months old with fever 100.4°F (38.0°C) or higher. Accurate documentation of UTI is imperative both to diagnose the cause of a fever and to identify those infants who need follow-up radiographic imaging to exclude anatomic abnormalities that will predispose them to further infection. It is currently recommended that febrile infants with documented UTIs undergo renal ultrasonography to evaluate for urinary tract anomalies. For infants with signs of urosepsis or not improving within 24 hours of antibiotic administration, an ultrasound should be performed to evaluate for obstructive uropathy or rare complications, such as renal or perirenal abscesses. Voiding cystourethrography is not indicated after the first febrile UTI in children unless renal ultrasonography reveals evidence of high-grade vesicoureteral reflux or scarring.

The only reliable method to obtain urine in a non-toilet-trained child is bladder catheterization or suprapubic aspiration. Bladder catheterization is the preferred method in *almost all* cases. Bag collection of urine is notoriously unreliable; up to 85% of cultures from bag specimens will be falsely positive (defined as a culture growing a single organism with >10^5 colony-forming units [CFUs]/mL or a mix of two or more organisms), which then places these children at risk for unneeded, potentially painful, and expensive follow-up diagnostic testing and antibiotics. However, for select patients, bagged urine may be obtained, and if results do not indicate infection, no further studies are needed.[11] A clean catch urine specimen is appropriate for toilet-trained children.

UTI is defined as the combination of bacteriuria and pyuria. Bacteriuria in the absence of WBCs on microscopic examination represents asymptomatic bacteriuria. Urine is typically analyzed with a dipstick, followed by microscopic analysis of a centrifuged specimen of urine. An "enhanced" urinalysis, which is an examination with a hemocytometer of an unspun specimen of urine for pyuria (defined as >10 WBCs per high-power field) or the presence of any bacteria per high-power field in Gram stain of unspun urine has a negative predictive value of 99.8%, perhaps making urine culture unneeded if pyuria and bacteriuria are absent by use of the enhanced urinalysis method. However, many centers are not using this enhanced method. Because dipstick and microscopic analysis have lower sensitivities, most experts recommend sending urine for culture in high-risk groups (febrile girls <24 months old, uncircumcised boys <12 months old, and circumcised boys <6 months old).

A positive urine culture is defined as the growth of more than 50,000 CFU/mL of a single uropathogen in urine obtained via catheterization or suprapubic aspirate.

Lumbar Puncture

A sample of cerebrospinal fluid (CSF) should be obtained from any child with signs and symptoms of meningitis. Fluid should be obtained with the smallest spinal needle possible (typically a 22-gauge) and sent for cell counts, manual differential diagnosis, Gram staining, culture, and measurement of CSF protein and glucose concentrations. Meningoencephalitis due to HSV is a potential cause of fever, particularly in neonates; if suspected, CSF should be sent for HSV polymerase chain reaction (PCR) testing. Panel-based nucleic amplification tests that detect a wide array of viral and bacterial pathogens can also be useful but should be coupled with traditional CSF cultures as they do not identify every possible pathogen and do not give information on antibiotic susceptibility.[12,13] The CSF in bacterial meningitis typically contains more than 1000 WBCs/mL, although there is considerable overlap in the CSF profile of bacterial and viral meningitis, making a determination of viral or aseptic meningitis difficult on the basis of

CSF parameters, such as cell count, protein, and glucose; thus, CSF culture of a pathogenic bacterium is the "gold standard." A prediction rule has been developed and validated to differentiate bacterial from aseptic meningitis in children 29 days to 19 years old who have CSF pleocytosis. Children *without* any of the following criteria have a low risk (0.1%) of bacterial meningitis: positive CSF Gram stain, CSF ANC of 1000 cells/mL or more, CSF protein concentration of at least 80 mg/dL, peripheral blood ANC of 10,000 cells/mL or more, and history of seizure before or at the time of presentation. This may obviate the need for empirical antibiotic therapy and hospital admission in some children who are at low risk for bacterial meningitis.[14]

Contraindications to lumbar puncture include cellulitis over the proposed site of puncture, cardiopulmonary instability, bleeding diathesis, or platelet count below 50,000/μL, focal neurologic deficits, and signs of increased intracranial pressure, including papilledema. In these patients, lumbar puncture should be deferred until the child is stable, and blood should be obtained for culture while the child is treated empirically, recognizing that up to 50% of children with meningitis will not have bacteremia.

CSF contaminated by blood (i.e., a traumatic lumbar puncture) can make interpretation of cell counts and differential diagnoses difficult. In these cases, fluid should be obtained for Gram stain and culture and the child hospitalized and treated presumptively for meningitis until culture data are available.

Stool Studies

Stool studies are indicated in patients in whom bacterial gastroenteritis may be a cause of fever. A stool guaiac test for blood, as well as Gram stain for WBCs, should be performed. The presence of more than five WBCs per high-power field in the stool of a febrile child should trigger a culture of stool for *Salmonella, Shigella, Campylobacter,* enterotoxigenic *E. coli,* and *Yersinia* species. Patients with sickle cell disease are at particular risk for focal complications, such as osteomyelitis from *Salmonella* infection (see Chapter 167).

Chest Radiography

Chest radiographs may be useful in the evaluation of the febrile child and are indicated when hypoxemia, respiratory distress, tachypnea, or focal findings on lung examination are present. Children younger than 6 months old may present with tachypnea as the sole finding of bacterial pneumonia. Occult pneumonia can also occur in a small percentage of children, particularly in the highly febrile child (>102.2°F [39.0°C]) without an apparent source of fever and an elevated ANC. Studies done prior to universal vaccination against pneumococcus demonstrated a relatively high rate of pneumonia in highly febrile children who had leukocytosis more than 20,000/mm^3 (26%). Since the advent of universal vaccination, the number of occult pneumonias has declined (15% to 9%) but is not yet low enough to recommend not obtaining radiographs on highly febrile children with leukocytosis or elevated ANC and no other apparent source of infection. Point of care lung ultrasound has been shown to compare favorably to chest radiographs in multiple studies when used for the diagnosis of pneumonia.[15]

Rapid Viral Antigen Testing

Many clinical laboratories have the ability to perform rapid viral antigen testing, either individually or as part of a panel for such common pediatric viral illnesses as influenza A and B, parainfluenza, rhinovirus, and RSV. The presence of a viral "source" for the fever in an ill child may obviate the need for expensive, painful, and lengthy diagnostic evaluations for bacterial processes. Of patients aged 2 months to 21 years old who present with classic signs and symptoms of influenza, more than half have been shown to have positive rapid assays for influenza, leading to fewer antibiotics prescribed. A large multicenter trial of febrile infants 60 days old or younger revealed a decreased risk for SBI (2.5% vs. 11.7%) if the infant was influenza positive.

RSV is also a frequent cause of fever in children. As previously noted, RSV decreases but does not completely eliminate the risk of SBI in children. This is especially true of UTI in infants younger than 28 days old. Routine testing for RSV has not been shown to affect outcomes at the individual patient level.[16] Given the exceedingly low rates of bacteremia and meningitis, it is reasonable to consider a selective, de-escalated evaluation (i.e., urine and urine culture only) of well-appearing infants who have positive viral testing in the ED. Ill-appearing infants or neonates (28 days old and younger) should still undergo a full evaluation for SBI.

Management

Approach to the Febrile Infant and Child

The initial approach to any child with a febrile illness is a rapid assessment for evidence of cardiopulmonary compromise or shock. Significant respiratory distress, hypoxemia unresponsive to supplemental oxygen, or altered mental status may necessitate intubation by rapid sequence induction and mechanical ventilation. Evidence of shock (poor perfusion, hypotension, altered mentation) should be quickly treated with fluid resuscitation. An IV or intraosseous line should be placed, and the initial resuscitative fluid should be 20 mL/kg of isotonic crystalloid. This should be repeated to a total of 60 mL/kg over 60 minutes if signs of hypovolemia persist, followed by vasopressor therapy (dopamine 1 to 20 μg/kg/min or norepinephrine 0.05 to 2 μg/kg/min titrated to blood pressure) to maintain blood pressures.

Every effort should be made to obtain appropriate specimens for culture (blood and urine) before antibiotic administration, even in the critically ill child. Lumbar puncture may be deferred in the critically ill child until stabilization occurs. Empirical antibiotic therapy should be directed at the most likely causative organisms based on age. Sterilization of the CSF starts to occur once antibiotic administration has been initiated—within 15 minutes to 2 hours in patients with meningococcal meningitis and within 4 to 10 hours in patients with pneumococcal meningitis. However, antibiotics should not be delayed awaiting successful lumbar puncture. Antibiotics will not affect PCR or bacterial antigen test results.

Infants 0 to 28 Days Old

Children presenting with a temperature of 100.4°F (38.0°C) or higher who are younger than 28 days old are at particularly high risk for bacterial illness, with rates as high as 12%.[17] Often, fever is the only manifestation of potentially life-threatening disease, with other signs and symptoms that may be exceedingly subtle. This has led to a conservative approach to diagnostic testing, empirical antibiotic therapy, and hospitalization in this age group, even if the child appears well.

Children in this age group often present with nonspecific complaints, such as irritability, lethargy, poor feeding, and grunting. Besides fever, other signs of serious illness include a bulging fontanel, mottled extremities, petechiae, and tachypnea. Bacterial pathogens in this age group include *E. coli*, group B streptococcus, *L. monocytogenes, and less commonly, N. meningitidis, S. pneumoniae*. Viral pathogens, including RSV and HSV, are also important considerations. Neonatal HSV infection carries a high degree of morbidity and mortality and should be considered in any febrile neonate who appears ill, presents with fever and seizure, has cutaneous vesicles on physical examination, has evidence of transaminitis or coagulopathy, or has a maternal history of genital herpes. HSV meningoencephalitis should also be considered in patients with fever and CSF pleocytosis but a negative CSF Gram stain. The highest risk period for HSV disease is between 2 and 12 days old

(Fig. 161.2). Other noninfectious causes of a septic-appearing neonate include inborn errors of metabolism, the acute salt-wasting crisis associated with congenital adrenal hyperplasia, and undiagnosed ductal-dependent congenital heart disease.

Because of the high risk of bacterial pathogens and the difficulty in the clinical assessment of children younger than 28 days old (neonate), febrile neonates require a thorough diagnostic evaluation, including a complete septic evaluation. This consists of a complete blood count (CBC) with differential, blood culture, urinalysis and urine culture, and lumbar puncture. Lumbar puncture is indicated in this age group even in the presence of a UTI because of the risk of concomitant meningitis. All neonates should be admitted to the hospital with empirical antibiotics while awaiting culture results. Appropriate parenteral antibiotic regimens include ampicillin (50 to 100 mg/kg every 6 to 12 hours) plus either gentamicin (4 to 5 mg/kg every 24 to 48 hours) or cefepime (50 mg/kg every 8 to 12 hours). Ceftriaxone should be avoided in infants younger than 28 days old because ceftriaxone causes bilirubin to be displaced from its protein binding sites and has a theoretical risk of inducing acute bilirubin encephalopathy. Empirical acyclovir should be added if risk factors for HSV disease exist or a pleocytosis is found in the CSF (20 mg/kg every 8 hours if adequate renal function).

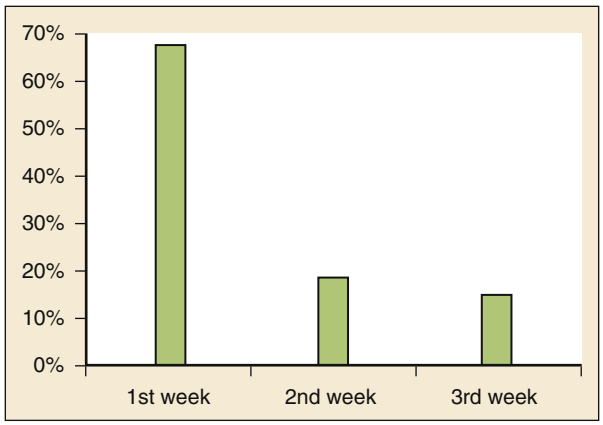

Fig. 161.2 Age at Presentation for Neonatal Herpes Simplex Virus (HSV) Infection.

Infants 29 to 90 Days Old

Although there is a relative consensus as to the evaluation and management of febrile infants younger than 28 days old, there is debate about the appropriate evaluation for slightly older febrile infants. Ill-appearing children of any age should have a complete sepsis evaluation performed and be admitted to the hospital with empirical antibiotic therapy. Appropriate antibiotic therapy for high-risk children includes coverage of neonatal pathogens, such as *L. monocytogenes* and group B streptococci, as well as coverage against *H. influenzae, N. meningitidis,* and *S. pneumoniae*. Ampicillin (50 to 100 mg/kg every 6 to 12 hours based on gestational age and renal function) plus ceftriaxone (50 mg/kg every 12 hours) are two reasonable options. Vancomycin, 10 to 20 mg/kg IV every 6 to 8 hours, should be considered if *S. pneumoniae* resistant to penicillins and cephalosporins is suspected.

Historically, various strategies (herein referred to as the *Rochester, Philadelphia, and Boston criteria*) for the evaluation of well-appearing children have been reported, compared, and retested in the literature. Each strategy has unique features, including the definition of fever (100.4°F [38.0°C] vs. 100.8°F [38.2°C]), the study population (0 to 3 months old, 1 to 2 months old, and 1 to 3 months old), the clinical and laboratory variables studied, and the disposition (hospitalization with or without antibiotics or outpatient treatment with or without antibiotics). Each strategy seeks to identify a set of low-risk criteria that, if met, identify patients that may forgo further testing or empirical antibiotic therapy. The three main strategies are highlighted in Table 161.2. Baraff synthesized the recommendations of the Rochester, Philadelphia, and Boston criteria into an algorithm for the management of the previously healthy febrile infant 29 to 90 days old (Fig. 161.3). To be low risk, the child had to have been previously healthy with an uncomplicated nursery stay, to be nontoxic clinically, and to have no focal source of bacterial infection. Low-risk laboratory criteria in this schema included a normal WBC count (between 5000 and 15,000 WBCs/mm^3), fewer than 1500 bands/mm^3, normal urinalysis (negative Gram stain and

TABLE 161.2 Summary of Major Strategies for the Management of Febrile Infants Younger Than 3 Months Old

	Philadelphia	Rochester	Boston
Age	29–60 days old	<60 days old	28–89 days old

<5 WBCs per high-power field), and negative CSF Gram stain and cell counts (<8 WBCs/mm^3), if obtained. When diarrhea was present, fewer than 5 WBCs per high-power field was the threshold for low risk. Since this publication, numerous variations of these historical criteria have been developed, modified, and tested.[18–21] All seek to identify criteria that categorize febrile young infants into "high risk" and "low risk" groups based on historical features (e.g., prematurity, prior antibiotic exposure, past medical history), physical examination findings (e.g., hyperpyrexia, focal infection) and laboratory parameters (e.g., elevated or depressed WBC, elevated procalcitonin, elevated CRP). Studies evaluating the various permutations of the evaluation of a febrile infant all perform similarly, emphasizing consistent use of a set of criteria is more critical than which set of criteria are used. The use of an evidence-based guideline to standardize the evaluation and disposition of young infants has been shown to reduce costs.

An infant who meets "low risk" criteria can be appropriately managed in several ways. For instance, one management strategy may call for a CBC, blood culture, urinalysis, and urine culture. If the results reveal the patient to be at low risk, the child may be discharged without antibiotics with close outpatient follow-up. If results are abnormal, the patient should receive a lumbar puncture and antibiotics. Another option, based on the Boston criteria, calls for a complete sepsis evaluation, including lumbar puncture, followed by empirical treatment with or without ceftriaxone (50 mg/kg IV or intramuscularly [IM]) and reevaluation within 24 hours. Generally, antibiotics should not be administered unless a complete sepsis evaluation is performed (including a lumbar puncture); children treated with antibiotics will not have reliable culture results if performed much later.

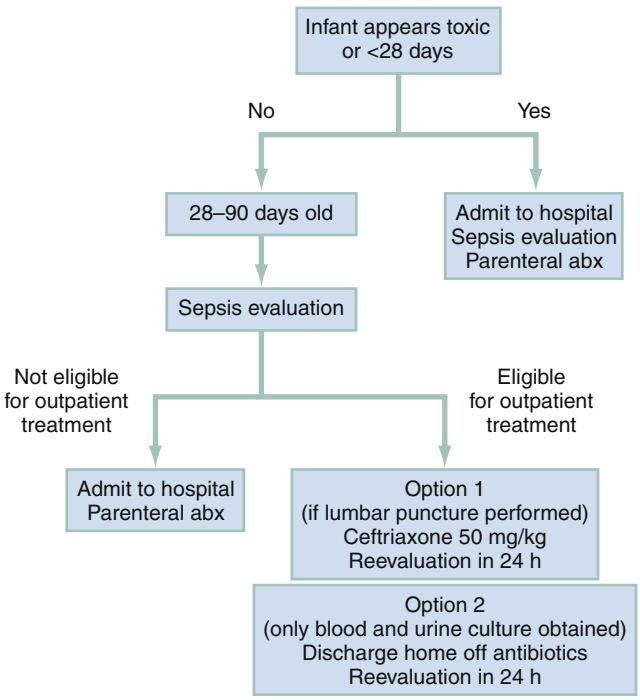

Fig. 161.3 Sample Algorithm for the Management of Febrile Infants Younger than 3 Months Old. To be eligible for outpatient treatment, the following should be met: white blood cell (WBC) count 5000 to 15,000 cells/mm^3, urinalysis is negative, lumbar puncture without pleocytosis or bacteria on Gram stain, able to return for care if necessary, reliable outpatient follow-up, no focal infection present (i.e., cellulitis, omphalitis), and chest radiograph and stool studies negative if obtained. *abx*, Antibiotics.

Infants 3 to 36 Months Old

Most cases of fever in children 3 to 36 months old represent self-limited viral illnesses. Common causes of fever in this age group include viral upper respiratory infections, croup, bronchiolitis, stomatitis (typically caused by HSV or coxsackievirus), gastroenteritis, roseola, and fifth disease (parvovirus B19 infection). Focal infections, such as pyelonephritis, periorbital cellulitis, bacterial pharyngitis (group A streptococcus), septic arthritis, retropharyngeal abscess, meningitis, and bacterial pneumonia, also become more common in this age group. Typically, these focal infections are apparent on the basis of history and physical examination findings, and diagnostic testing and treatment should be directed accordingly.

The history in this age group should focus on the duration of illness, associated symptoms that may focus the evaluation, immunization history (particularly vaccination for *H. influenzae* type B and pneumococcus), and sick contacts. A thorough physical examination is essential to rule out serious focal infection, such as meningitis. Young children may demonstrate inconsolable irritability or lethargy as the sole manifestation of meningitis; furthermore, classic meningeal signs, such as nuchal rigidity, are seen in less than 27% of infants (0 to 6 months old) with bacterial meningitis.

Prior research has focused on the assessment of children in this age group for the presence of occult bacteremia. It was found that a small percentage of highly febrile children (>102.2°F [39.0°C]) 3 to 36 months old were bacteremic. These children were noted to be highly febrile but lacked any localizing signs of infection. No historical or physical examination findings were sufficiently sensitive or specific to identify cases of occult bacteremia, making universal diagnostic testing necessary. A typical evaluation included a CBC and blood culture, and empirical antibiotic therapy was prescribed for children with WBC counts above 15,000/mm^3. Empirical antibiotics were justified on the basis of studies that revealed treatment with antibiotics prevented focal sequelae of bacteremia, such as meningitis, and shortened the duration of fever. Before almost universal immunization against *S. pneumoniae,* the rate of occult bacteremia was approximately 3%, and although pneumococcal bacteremia resolved without therapy up to 75% of the time, a small proportion of children had sepsis or focal infections, such as meningitis. Pneumococcal meningitis has a high degree of morbidity and mortality, including permanent neurologic disability, hearing loss, and death.

Since the advent of PCV7 (conjugate pneumococcal vaccine) and most recently PCV13, the number of invasive pneumococcal infections caused by vaccine-serogroup isolates among eight children's hospitals in the United States has decreased more than 75% among children younger than 24 months old. Because of the decline in invasive pneumococcal disease, young children with fever of unknown source no longer require blood culture; instead, clinical judgment should select high-risk populations that might benefit from testing and treatment. Although the incidence of pneumococcal bacteremia has declined in infants 3 to 36 months old because of the deliberate campaign to vaccinate, infants 3 to 6 months old have not yet completed the primary series of immunizations against *S. pneumoniae* and to a lesser extent against *H. influenzae*. Despite being "incompletely vaccinated" at this age, the rate of bacteremia is exceedingly low, and we do not recommend routine screening in this age group. The 13-valent conjugate pneumococcal vaccine (PCV-13) for routine childhood vaccinations provides expanded coverage. The additional six serotypes included in PCV13 were responsible for more than 60% of the cases of invasive pneumococcal disease in the years preceding the release of the updated vaccine schedule.[22] Despite these vaccine advances, there are approximately 90 serotypes that are capable of infecting humans, and

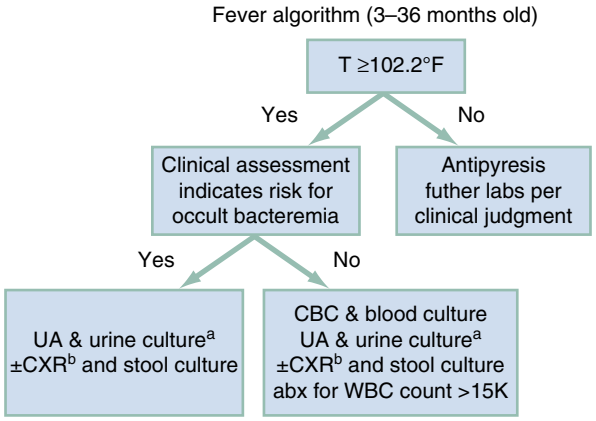

Fig. 161.4 Sample algorithm for the management of febrile infants 3 to 36 months old. [a]Females <24 months old; circumcised males <6 months old, uncircumcised males <12 months old. continued bacterial surveillance is necessary to ensure that other serotypes do not rise in incidence to fill the void left by vaccination.

No clinical prediction algorithm correctly identifies all patients with meningococcal disease. Additional signs and symptoms that may suggest meningococcemia are purpuric rash, bandemia, limb pain, and exposure to a person with the disease. A flow diagram for the evaluation of febrile infants 3 to 36 months old is presented in Fig. 161.4.

Children 3 Years Old to Adulthood

The incidence of occult bacteremia decreases after 3 years of age. Focal infections such as streptococcal pharyngitis, septic arthritis, pneumonia, peritonsillar abscess (most often in adolescents), and cellulitis become more common. Viral pathogens are also common, such as infectious mononucleosis. Infection with atypical pathogens, such as *Mycoplasma pneumoniae,* should also be considered in children presenting with pneumonia. Skin infections secondary to community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) are also becoming more common and should be considered in children who present with pyogenic skin infection and skin abscesses. Community-acquired MRSA occurs in all age groups but has clustered among such children as wrestlers (associated with contaminated wrestling mats) and football players (infected equipment). Appropriate therapy includes incision and drainage of the abscess cavity. Based on recent studies that demonstrate improved primary resolution, decreased recurrences, and decreased spread, we recommend antibiotic therapy in addition to incision and drainage, especially for patients with large abscesses (>5 cm), cellulitis, or fever.[23] Antibiotic selections should be based on local resistance patterns but could include trimethoprim-sulfamethoxazole or clindamycin for younger children and doxycycline for children 8 years old or older.

There is a second peak in incidence of meningococcal disease in adolescent children with an attack rate of 1.2 infections per 100,000 population. As opposed to infants, adolescents with meningococcal infection are more likely to present with meningococcemia (40% vs. 20%) and shock (69% vs. 27%) and to have a fatal outcome (22.5% vs. 4.6%). Meningococcal infections often manifest with one of three clinical syndromes: meningitis, bacteremia, or a combination of the two. College students residing in dormitories are at particular risk for infection, with attack rates of 3.2/100,000 population.

Meningococcal infection is often rapidly progressive, presenting with fever, headache, and a stiff neck. Shock, altered mental status or frank coma, petechiae or purpura, seizures, and myalgias are also common. Some of the first signs of meningococcal infection include leg pain, cold hands and feet, and abnormal skin mottling. Children exposed to a patient with meningococcemia, particularly those with close contact with nasopharyngeal secretions, and who have any of the presenting signs, should receive a full septic evaluation, admission to the hospital, and empirical treatment with antibiotics until results of blood and CSF cultures. Appropriate initial therapy for children suspected of having meningococcal infection is ceftriaxone 100 mg/kg IV.

In January 2005, the U.S. Food and Drug Administration (FDA) approved the quadrivalent meningococcal conjugate vaccine (Menactra) for use in adolescents. This vaccine is a polysaccharide-protein conjugate directed against the four serotypes that cause most cases of invasive meningococcal disease in humans. The Advisory Committee on Immunization Practices recommends vaccination of adolescents at their 11- or 12-year-old well-child checkup, and the American Academy of Pediatrics (AAP) has also advised that all college freshmen living in dormitories be vaccinated. The use of the vaccine is associated with a 67% decrease in invasive disease and a 66% decrease in carriage rates. Younger children with anatomic or functional asplenia, those with complement component deficiencies, and children who travel reside in other countries where the disease is hyperendemic should be vaccinated. Based on age, a number of vaccines for the prevention of meningococcal disease are available (www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html).

SPECIFIC DISORDERS

Febrile Seizures

Febrile seizures are a common cause of convulsions in children younger than 5 years old.[24] They are defined as a seizure accompanied by a fever without the presence of CNS infection. They typically occur in infants and children 6 months to 5 years old. It is thought that the at-risk period is the rapid rise or defervescence of a fever rather than the absolute height of the fever. The subsequent risk of epilepsy after a febrile seizure is a common parental worry, although studies have shown that the risk is only slightly increased. The risk of epilepsy in the general population is thought to be 0.5% to 1%, whereas the risk in a patient who has had a febrile seizure is 1% to 2%. Although they are generally benign in course, febrile seizures can rarely be the presenting complaint of infants and children with CNS infection, such as meningitis. Febrile seizures are classified as either simple or complex. Simple febrile seizures are brief (<15 minutes), single, and nonfocal or generalized tonic-clonic. Complex febrile seizures are prolonged, recurrent (more than one within 24 hours), focal, prolonged, or occur outside the typical age range.

Differentiation of a benign febrile seizure from one that heralds CNS infection can be difficult. The AAP has published consensus guidelines for the evaluation and management of febrile seizures. Laboratory and radiographic evaluation should be directed at finding the source of the fever, not driven by the seizure itself. The AAP suggests that a lumbar puncture be performed in any child with signs of meningeal irritation after the first febrile seizure and be considered in symptomatic children who are incompletely immunized or have received prior antibiotic therapy.

Routine referral for neuroimaging or electroencephalography is not indicated. There is also no role for antiepileptic therapy after a single febrile seizure. Retrospective studies have shown that the incidence of meningitis after the simple or complex febrile seizures is exceedingly low and that infants with meningitis will demonstrate signs of sepsis or meningitis after the seizure, making empirical lumbar puncture based solely on a febrile seizure unnecessary.[25,26] Febrile status epilepticus, in contrast to a simple or even complex febrile seizure, carries a higher risk of meningitis and lumbar puncture should be performed in these cases. See Chapter 169 for a more in-depth discussion on pediatric seizures.

Fever and Petechiae

The presence of a petechial rash in the setting of a febrile illness is concerning for the possibility of meningococcal infection, although the vast

majority are due to a viral cause. The incidence of meningococcal infection has been found to be 7% to 11% in patients hospitalized with fever and petechiae. The rate of bacteremia of any cause was found to be much lower (1.9%) in an ED population. The differential diagnosis of fever and petechiae also includes disseminated intravascular coagulation, Rocky Mountain spotted fever, pneumococcal bacteremia, *Streptococcus pyogenes* infection, various viral infections, idiopathic thrombocytopenic purpura, Henoch-Schönlein purpura, and leukemia. Petechiae can also be caused mechanically by a tourniquet, retching, or violent coughing. Petechiae due to vomiting or coughing are typically confined to the skin above the nipple line, but petechiae caused by SBI can have any distribution.

Because of the risk of serious illness in children with fever and petechiae, blood should be obtained for CBC, CRP, and culture. Patients with associated pharyngitis should undergo testing for group A streptococcus infection. Among patients presenting to a pediatric ED with a temperature higher than 100.4°F (38.0°C) and petechiae, an abnormal WBC count (<5000 WBCs/mm^3 and >15,000 WBCs/mm^3) or abnormal coagulation studies have been shown to be predictive but not diagnostic of invasive bacteremia. We recommend that children with fever and petechiae and an abnormal WBC, high band count, or elevated CRP be admitted and treated for presumptive bacterial infection until blood cultures result. Well-appearing children with normal WBC, CRP, and coagulation studies are unlikely to have invasive bacteremia and can be discharged without antibiotic therapy with close outpatient follow-up.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is one of the most common vasculitides in childhood and should be considered in any infant or child with prolonged fever (greater than 4 days).[27] Accurate diagnosis is important because the main complication of Kawasaki disease is the development of coronary artery aneurysms. Some patients will present with "incomplete Kawasaki disease," which occurs when not all diagnostic criteria are met. Despite the lack of classic findings, these children are still at risk for coronary complications. Laboratory abnormalities found in cases of Kawasaki disease include leukocytosis, thrombocytosis (platelet counts as high as 1,000,000/mm^3), and evidence of systemic inflammation with elevation in the erythrocyte sedimentation rate and CRP level.

Children with suspected Kawasaki disease should be hospitalized and receive therapy with intravenous immune globulin (IVIG; 2 g/kg infused during 10 to 12 hours) and aspirin (initial dose 80 to 100 mg/kg daily divided every 6 hours). Pediatric cardiology consultation for echocardiography is also indicated (see Chapter 165 for a more complete discussion of Kawasaki's Disease and Chapter 120 for a discussion on multi-inflammatory syndrome in children [MIS-C]).

Toxic Shock Syndrome

TSS refers to the toxin-mediated clinical syndrome that occurs from *S. aureus,* although a similar illness is caused by group A streptococcus. The toxin implicated in TSS is an exotoxin termed *TSS toxin 1.* The syndrome is classically associated with tampon use by menstruating women, although cases also occur in males and prepubertal girls from other sources of infection with *S. aureus*.

Clinical manifestations of TSS include fever (>102°F [38.9°C]), hypotension, diffuse erythroderma, and multisystem involvement. Patients may present with vomiting or diarrhea, severe myalgias, oropharyngeal hyperemia, or altered mental status. Laboratory abnormalities are common and include elevated creatine kinase, elevated blood urea nitrogen or creatinine, transaminitis, and thrombocytopenia. The Centers for Disease Control and Prevention (CDC) has developed a set of findings for case definition (Box 161.1).

Treatment of TSS involves fluid resuscitation because these patients typically have immense requirements and antistaphylococcal antibiotic therapy with clindamycin (20 to 40 mg/kg/day in three divided doses) and vancomycin (10 to 20 mg/kg IV every 6 to 8 hours).

BOX 161.1 Centers for Disease Control and Prevention Case Definition for Toxic Shock Syndrome

Fever: Temperature >102°F (38.9°C)
Hypotension: Systolic blood pressure 90 mm Hg for adults or less than fifth percentile by age for children <16 years old; orthostatic drop in diastolic blood pressure by 15 mm Hg
Orthostatic syncope or dizziness
Diffuse erythroderma
Desquamation: 1–2 weeks after onset of illness, particularly involving palms and soles
Multisystem involvement (three or more of the following organ systems):
- Gastrointestinal: Vomiting or diarrhea at onset of illness
- Muscular: Severe myalgia or creatine kinase elevation more than two times the normal upper limit
- Mucous membranes: Vaginal, oropharyngeal, or conjunctival hyperemia
- Renal: Blood urea nitrogen or serum creatinine more than two times the normal upper limit, or pyuria (>5 WBCs/high-power field)
- Hepatic: Bilirubin or transaminases more than two times the normal upper limit
- Hematologic: Platelets <100,000/L
- CNS: Disorientation or alterations in consciousness without focal neurologic signs in the absence of fever and hypotension

Negative results on the following tests, if obtained:
- Blood, throat, or CSF cultures for another pathogen (blood cultures may be positive for *Staphylococcus aureus*)
- Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Criteria for a probable case include a patient with temperature >102°F (38.9°C), hypotension, diffuse erythroderma, desquamation (unless the patient dies before desquamation can occur), and involvement of at least three organ systems. A probable case is a patient who is missing one of the characteristics of the confirmed case definition.

CNS, Central nervous system; *CSF,* cerebrospinal fluid; *WBC,* white blood cell.

Fever in Children With an Underlying Chronic Medical Illness

Oncology Patients

Children with cancer, particularly those undergoing treatment with cytotoxic chemotherapy, are at particular risk for sepsis and bacterial infection. These life-threatening infections are most common during periods of profound neutropenia. Neutropenia is defined as an ANC of less than 500/mL or an ANC of less than 1000/mL that is falling. Children with cancer also frequently have central venous catheters, predisposing them to central line-associated bloodstream infections.

Causative organisms include both gram-positive and gram-negative bacteria. Staphylococci and streptococci as well as *Pseudomonas* are frequent pathogens. Often, patients with focal infection may not present with classic signs because of their leukopenia. Focal infections specific to cancer patients include stomatitis and typhlitis, which is a necrotizing enterocolitis of the terminal ileum and cecum.

Children presenting with fever and possible neutropenia should receive a prompt evaluation with a goal of arrival to antibiotic therapy of fewer than 60 minutes.[28] Blood should be obtained for a CBC and manual differential diagnosis as well as culture. Once appropriate laboratory studies are obtained, empirical antibiotic therapy should be initiated without waiting for

the laboratory results. Appropriate monotherapy antibiotic regimens include cefepime, 50 mg/kg IV every 8 to 12 hours based on gestational age and renal function, or ceftazidime, 50 mg/kg IV every 8 hours. Vancomycin, 10 to 20 mg/kg every 6 to 8 hours, should be added for staphylococcal coverage in children with suspected central line infections or skin and soft tissue infections. Children with fever and neutropenia are rarely treated as outpatients; in very select cases and in consultation with an oncologist, ceftriaxone 50 mg/kg IV may be given every 24 hours with close follow-up.

Patients With the Acquired Immunodeficiency Syndrome

Children with the acquired immunodeficiency syndrome (AIDS) are at risk for bacterial infection due to a whole host of different organisms—some common, some uncommon. Infections specific to AIDS include cryptococcosis and infection with *Mycobacterium tuberculosis, Mycobacterium avium-intracellulare,* and *Pneumocystis jiroveci (carinii)*. Viral infections, such as cytomegalovirus and Epstein–Barr virus infections, are also common.

Laboratory evaluation should be directed by the history and physical examination. Early initiation of broad-spectrum antibiotic therapy is warranted.

Sickle Cell Disease

Febrile children with sickle cell disease are at particular risk for overwhelming infection. In fact, infection is the most common cause of sickle cell-related death, occurring in up to 40% of patients with sickle cell disease who die. Recurrent episodes of splenic infarction lead to functional asplenia early in life. Thus, these patients are at particular risk for infection with encapsulated organisms, including *S. pneumoniae* and *H. influenzae*. Because of this risk of bacterial disease, it is recommended that all children with sickle cell disease be completely immunized. Prophylaxis with penicillin is recommended in children younger than 5 years old, after which it can be safely discontinued in children who have not had a prior severe pneumococcal infection or surgical splenectomy. The dose of penicillin is 125 mg orally twice daily until 3 years old (at about 14 kg) and 250 mg orally twice daily after 3 years old.

High-risk criteria for bacterial infection include toxic appearance, temperature higher than 104°F (40°C), abnormal WBC count (<5000 or >30,000 WBCs/mm^3), and noncompliance with penicillin prophylaxis. Sickle cell patients are at particular risk for *Salmonella* osteomyelitis. All patients presenting with a temperature higher than 100.4°F (38.0°C) and sickle cell disease should have a blood specimen drawn for CBC, reticulocyte count, and culture. A reticulocyte count is important because many infections (e.g., parvovirus B19) can induce a life-threatening aplastic crisis. Infection also predisposes children with sickle cell disease to acute chest syndrome. Common causes of infection include *C. pneumoniae, M. pneumoniae,* RSV, *S. aureus,* and *S. pneumoniae*. Further laboratory and radiographic evaluation should be directed by the presenting history and physical examination findings.

As defined earlier, high-risk patients should be admitted for further evaluation and antibiotic therapy. Low-risk patients may be treated with a single dose of IV or IM antibiotics, typically ceftriaxone 50 mg/kg, and discharged to close outpatient follow-up. All patients should be reevaluated within 24 hours or sooner if the clinical condition deteriorates.

Osteomyelitis typically manifests as fever and bone pain. As patients with sickle cell disease may have frequent bone pain due to vaso-occlusive crisis, the diagnosis can be difficult. All patients should have a blood specimen drawn for CBC with differential diagnosis, erythrocyte sedimentation rate, and culture; a radionuclide bone scan or magnetic resonance imaging (MRI) may help localize the infection. If *Salmonella* infection is suspected, a stool sample should be sent for culture.

Congenital Heart Disease

Children with congenital heart disease are at high risk for cardiovascular complications in the setting of febrile illness. Often, relatively minor viral illness can produce significant changes in cardiac function or make it difficult for children to be compliant with their oral medications. Children with congenital heart disease are also at risk for infective endocarditis. Infective endocarditis is heralded by fever and possibly a changing or worsening cardiac murmur. The modified Duke criteria for the diagnosis of endocarditis are presented in Box 161.2.

BOX 161.2 Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Major Criteria

Blood cultures positive for IE
- Typical microorganism for IE from two separate blood cultures
  - Viridians streptococci
  - *Streptococcus bovis,* including nutritional variant strains
  - HACEK group: *Haemophilus* species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella* species, and *Kingella kingae*
  - *Staphylococcus aureus*
- Community-acquired enterococci, in the absence of a primary focus; *or*
- Persistently positive blood culture, defined as recovery of a microorganism consistent with IE from blood samples drawn more than 12 hours apart; *or*
- All of three or a majority of four or more separate blood cultures, with first and last samples drawn at least 1 hour apart
- Single blood culture positive for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer >1:800

Evidence of endocardial involvement

Echocardiogram positive for IE
- TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE (paravalvular abscess); TTE as the first test in other patients[a]
- Definition of positive echocardiogram
- Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; *or*
- Abscess; *or*
- New partial dehiscence of prosthetic valve

New valvular regurgitation (increase in or change in preexisting murmur not sufficient)

Minor Criteria

Predisposition: Predisposing heart condition or injection drug use

Fever: 100.4°F (38.0°C)

Vascular phenomena: Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions

Immunologic phenomena: Glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

Microbiologic evidence: Positive blood culture but not meeting major criterion (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

IE, Infective endocarditis; *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography.

[a] Echocardiographic minor criteria eliminated.

Endocarditis is typically caused by *S. aureus,* viridans streptococci, *Streptococcus bovis,* enterococci, or infection with organisms from the HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella* species, and *Kingella kingae*). Children with suspected endocarditis should have blood culture specimens drawn and be admitted to the hospital for treatment and echocardiography. The American Heart Association recommends that initial antibiotic therapy be with ceftriaxone, 100 mg/kg IV or IM every 24 hours, or vancomycin, 10 to 20 mg/kg IV Q6-8H. Therapy is typically continued for at least 4 weeks. Ceftriaxone can be combined with gentamicin, 3 to 6 mg/kg IV divided every 8 hours (if renal function is normal), if shorter treatment duration (2 weeks) is desired. See Chapter 165 for a more complete discussion.

Ventriculoperitoneal Shunts

Children presenting with fever in the setting of ventriculoperitoneal shunts are at risk for shunt infection. If shunt infection is suspected, based on the presence of altered mental status or signs of meningismus, neurosurgical consultation should be obtained and a sample of CSF obtained. This is typically accomplished by sterile aspiration of fluid from the shunt reservoir. *S. aureus* and *Staphylococcus epidermidis* are the usual causative organisms. If an altered mental status is present, a computed tomography (CT) scan should be obtained to assess ventricular size. Children with suspected shunt infection are typically managed as inpatients, and antibiotics should begin as soon as possible.

CHAPTER 161: QUESTIONS AND ANSWERS

1. Which of the following are appropriate methods to obtain urine as part of a fever evaluation in a non-toilet-trained child?

a. Catheterized specimen
b. Clean catch, midstream
c. Suprapubic aspiration
d. A and C

Answer: d. The only reliable method to obtain sterile urine in a non-toilet-trained child is bladder catheterization or suprapubic aspiration if a catheter specimen cannot otherwise be obtained. Bag collection has a high rate of false-positive results and is not preferred in a child who is not toilet trained.

2. A 38-day old male infant presents to the emergency department (ED) after parents noted a fever at home today. In the ED, the temperature was noted to be 40.0°C. The child was born at 35 weeks gestation and 1 week ago was diagnosed with otitis media by his primary care physician and has been taking amoxicillin as treatment. Which of the following historical aspects places this child at higher risk for invasive bacterial infection?

a. Fever responsive to acetaminophen
b. Temperature of 40.0°C
c. Prior treatment with antibiotics
d. Prematurity
e. B, C, and D

CHAPTER 161: QUESTIONS AND ANSWERS—cont'd.

Answer: e. Risk for serious bacterial infection (SBI) varies with age. Children less than 3 months are at high risk for SBI, with those less than 28 days of age at highest risk. Hyperpyrexia, prior treatment with antibiotics, and prematurity have also been identified as risk factors for SBI. Response to antipyretics has not been linked to SBI risk.

3. Which of the following statements regarding occult bacteremia in children younger than 36 months old is *true?*
   - **a.** Children with no obvious source of fever and a temperature higher than 102.2°F (39°C) have an incidence of bacteremia of 5%.
   - **b.** Most patients appear toxic.
   - **c.** The most common pathogen is *Neisseria meningitidis.*
   - **d.** There has been a marked decrease in the incidence of occult bacteremia since the advent of universal vaccination against pneumococcus and *Haemophilus influenzae* type B.
   - **e.** With pneumococcal bacteremia, most patients remain febrile until antibiotic therapy is initiated.

Answer: d. Children younger than 36 months old with a fever higher than 102.2°F (39°C) and no obvious source have an incidence of occult bacteremia of less than 1%. Most patients appear nontoxic. The most common pathogen in positive cultures is *Streptococcus pneumoniae,* and the incidence of infection has dropped dramatically since the advent of universal vaccination. With pneumococcal bacteremia, most patients become afebrile in 3 or 4 days with or without antibiotic therapy.

4. A 3-year-old boy presents with a fever of 103°F. His mother reports that the fever started approximately 5 days ago, and he has an associated maculopapular rash. On examination, you find the patient also has bilateral conjunctival injection, a strawberry tongue, and swelling of his hands and feet. Which of the following medications should be included in the treatment of this patient?
   - **a.** Aspirin
   - **b.** Decadron
   - **c.** Penicillin G
   - **d.** Ceftriaxone

Answer: a. This patient has Kawasaki disease. Goals of treatment include amelioration of symptoms and prevention of coronary aneurysms, which are normally accomplished with aspirin and immunoglobulin. There are no indications for antibiotics or steroids.

5. A 2-year-old presents with a high fever and vomiting. On examination, you find an irritable child with a rectal temperature of 102°F rectal and a stiff neck. The patient's past medical history is significant for hydrocephalus with a ventriculoperitoneal shunt placement. You suspect the patient has a ventriculoperitoneal shunt infection. Which of the following is the most likely bacterial pathogen?
   - **a.** *Haemophilus influenzae*
   - **b.** *Neisseria meningitidis*
   - **c.** *Staphylococcus aureus*
   - **d.** *Staphylococcus epidermidis*

Answer**: d.** Patients with ventriculoperitoneal shunts and fever should be evaluated for shunt infection. The most common bacterial pathogen is *S. epidermidis*.

Pediatric Upper Airway Obstruction and Infections

Emily Rose

KEY CONCEPTS

Respiratory arrest precedes most pediatric cardiac arrests. Quick recognition of an airway problem and intervention in potentially life-threatening upper airway obstruction in children are critical.

Retropharyngeal Abscess

- This is a potentially life-threatening emergency in young children with signs of upper airway obstruction or meningismus; a retropharyngeal abscess is often related to oral trauma.
- Retropharyngeal abscess is most frequently caused by *Staphylococcus aureus*, group A streptococci, and anaerobes. Treatment is admission, IV antibiotics, and for more severe cases, surgical drainage.

Epiglottitis

- Epiglottitis may be caused by many bacteria or local injury. In the post–*Haemophilus influenzae* type b vaccine era, the incidence of pediatric epiglottitis has decreased, and epiglottitis is now more likely in older patients.
- Clinical features of epiglottitis are often subtle, such as in the older adolescent, (e.g., sore throat out of proportion to physical findings, anterior neck tenderness), but may also be dramatic, as in infants and young children (i.e., drooling, stridor, toxicity, severe respiratory distress).

Croup

- Viral croup is the most common infection of the upper airway in young children.
- Glucocorticoids (usually given as a single oral dose of dexamethasone) reduce symptoms, hospitalizations, and length of stay in the emergency department (ED).
- Treatment of moderate to severe croup includes vaporized epinephrine in addition to glucocorticoids. Patients can be discharged from the ED after a posttreatment observation period. We recommend discharge after a period of observation, if the child is free of resting stridor and distress and has access to follow-up care.

Bacterial Tracheitis

- Suspect bacterial tracheitis when an upper respiratory infection (URI) progresses to acute toxicity and marked respiratory distress and stridor. Standard treatment for croup may be tried, but usually does not significantly improve the patient's symptoms. Antibiotic therapy should include a cephalosporin plus coverage for *S. aureus*, which is the most common cause of this infection.
- Bronchoscopy is diagnostic and therapeutic and should be emergently performed.

Airway Foreign Body

- Complete obstruction due to an airway foreign body requires emergent life support procedures for removal of the foreign body.
- Plain films may be negative in aspirated foreign bodies. Bronchoscopy should be performed with a clinical suspicion of aspiration.
- Emergency cricothyroidotomy may be required for obstructed patients who cannot be intubated or ventilated as a lifesaving temporizing measure; needle cricothyroidotomy is preferred for infants and young children because of the challenges in identifying landmarks and associated complications of surgical cricothyrotomy.

FOUNDATIONS

Respiratory distress from upper airway obstruction is a rare but potentially a catastrophic emergency in young children. Causes include acute infectious processes, congenital anomalies, or a foreign body in the airway or esophagus. Children are predisposed to respiratory failure due to increased airway resistance (small, compressible airway), low functional residual capacity, high oxygen metabolism, which leads to quicker fatigue, and shorter safe apnea time, with precipitous hypoxia.

Clinical presentations of children with upper airway disease vary with cause, predisposing factors, and age at presentation:

- Acute infections of the upper airway range from relatively mild distress and self-limited signs and symptoms, to the abrupt onset of a rapidly progressive airway obstruction.
- Undiagnosed congenital anomalies of the airway and surrounding structures may be manifested as chronic or progressive stridor, or simply difficulty with feeding.
- An infant with a congenital airway anomaly in whom an acute airway infection develops is at higher risk for decompensation and respiratory failure.
- Upper airway obstruction from a foreign body in the airway or esophagus can cause partial or complete airway obstruction and may require urgent, advanced, airway management skills.

CLINICAL FEATURES

Recent history and observation of the child typically provide clues to the cause of the airway obstruction. Important items to elucidate in the history include the following:

- Onset and duration (acute vs. chronic)
- Associated symptoms (e.g., respiratory distress, fever, toxicity, drooling, cyanosis, neck stiffness, or torticollis)
- Progression with age (number of bouts and severity of "croup" with increasing age)

- Exacerbating factors (supine vs. prone position, upper respiratory infection [URI], crying)
- Feeding abnormality or dysphagia
- Prior airway procedures, such as intubation in the neonatal period
- Choking episode indicating possible foreign body aspiration
- Baseline noises, quality of cry and voice to assist the emergency clinician in pinpointing the location of obstructive lesion

Initial observation can be quickly assessed utilizing the Pediatric Assessment Triangle (see Chapter 155). Observation and physical examination should include vital signs (respiratory rate, heart rate, oxygen saturation) and indicators of increased work of breathing (retractions, flaring, grunting, stridor, wheezing) to gauge the severity of distress. Observe the character and timing of stridor, as well as the symmetry and quality of breath sounds. Respiratory failure is identified by the presence of extreme distress: hypoventilation or hyperventilation; altered mental status; pale, mottled, or cyanotic skin color; or hypotonia. Stridor may not be present in respiratory failure due to the lack of airflow.

Stridor (from the Latin, *stridulus,* indicating creaking, whistling, or grating) is the classic sound associated with upper airway obstruction. Stridor is a harsh vibratory sound of variable pitch caused by partial airway obstruction or collapse and the resultant turbulent airflow through some portion of the airway, from the nose to the trachea. Stridor is described by timing in the respiratory cycle (inspiratory, expiratory, biphasic) and quality (coarse or high-pitched; Table 162.1). Inspiratory stridor is usually associated with obstruction above the glottis, expiratory stridor with intrathoracic obstruction, and biphasic stridor typically with a critical or fixed obstruction at any level. Stridor character differs by cause and anatomic location (Fig. 162.1).

Snoring or stertor is low-pitched inspiratory noise caused by nasal or nasopharyngeal obstruction. Stertor and stridor can coexist. Stridor from the pharynx, such as from a peritonsillar abscess (PTA), tends to have a sonorous, gurgling, and coarse quality. The voice may be altered and have a muffled or "hot potato" quality to it. High-pitched inspiratory stridor occurs in the supraglottic and immediate subglottic trachea, as in croup and laryngomalacia. The voice may sound hoarse or weak, but a normal voice may be heard, even with a laryngeal cause of stridor.

Biphasic stridor is heard with inspiration and expiration and usually suggests a fixed lesion. Examples include laryngeal webs and vocal cord paralysis. Stridor from the lower part of the trachea is usually expiratory, such as in bacterial tracheitis or aspirated foreign bodies (Fig. 162.2).

TABLE 162.1 Causes of Stridor: Anatomic Location, Sound, and Quality

Features (Structures)	Supraglottic (Nose, Pharynx, Epiglottitis)	Glottic (Larynx, Vocal Cords)	Subglottic Trachea (Lower Trachea)
Sound	Sonorous (stertor)	Biphasic stridor	High-pitched stridor
	Gurgling		Inspiratory stridor
	Coarse		Expiratory stridor (if intrathoracic)
	Expiratory stridor		
Congenital	Micrognathia	Laryngomalacia	Subglottic stenosis
	Pierre Robin syndrome	Vocal cord paralysis	Tracheomalacia
	Treacher-Collins syndrome	Laryngeal web	Tracheal stenosis
	Macroglossia	Laryngocele	Vascular ring
	Down syndrome		Hemangioma cyst
	Storage diseases		
	Choanal atresia		
	Lingual thyroid		
	Thyroglossal cyst		
Acquired	Adenopathy	Papillomas	Croup
	Tonsillar hypertrophy	Foreign body	Bacterial tracheitis
	Foreign body		Subglottic stenosis
	Pharyngeal abscess		Foreign body
	Epiglottitis		
Positional stridor	Micrognathia, macroglossia		Laryngomalacia

Diagnostic Testing and Management

Definitive airway management takes precedence in an acute airway emergency. An individualized diagnostic evaluation can be undertaken in a less critical, stable patient with an uncertain diagnosis. Lateral and anteroposterior radiographs of the soft tissues of the neck may be helpful to assess the adenoid and tonsillar size, contour of the epiglottis, thickness of the retropharyngeal soft tissue space, vallecula, aryepiglottic folds, and tracheal air column (Fig. 162.3). The child's head should be positioned in extension and film taken during inspiration. However, plain radiographs are commonly misleading and may be normal, even with significant underlying pathology. Chest views assess the heart size, trachea and bronchi, location of the aortic arch, and presence of other pulmonary pathologic processes.

Additional studies may be indicated in specific settings. Bedside fiberoptic nasopharyngoscopy allows for the visualization and assessment of the supraglottic structures and vocal cords and can assist with intubation when indicated. Esophagography can define lesions compressing the airway and trachea; computed tomography (CT), magnetic resonance imaging (MRI), or bronchoscopy may be needed to evaluate the upper airway.

Specific Disorders

Supraglottic Airway Diseases

The supraglottic portion of the airway includes the nose, pharynx, epiglottis, and surrounding structures. Diseases of the nose and pharynx are commonly associated with noisy congested breathing and respiratory distress. Congenital lesions involving these structures may cause mild symptoms at baseline, but dramatic distress when there is a superimposed infectious process. Congenital lesions include choanal atresia, macroglossia, micrognathia, thyroglossal duct cyst, and lingular thyroid. Acquired causes of supraglottic disease include a nasal foreign body, nasal polyps, hypertrophic tonsils and adenoids, epiglottitis, retropharyngeal abscess (RPA), PTA, pharyngitis, mononucleosis, and upper airway foreign body. The most common conditions are discussed in the following sections.

Congenital Lesions

Choanal atresia. All infants are obligate nose breathers; they breathe nasally when the mouth is closed to allow breathing while feeding. In choanal atresia, the most common congenital anomaly of

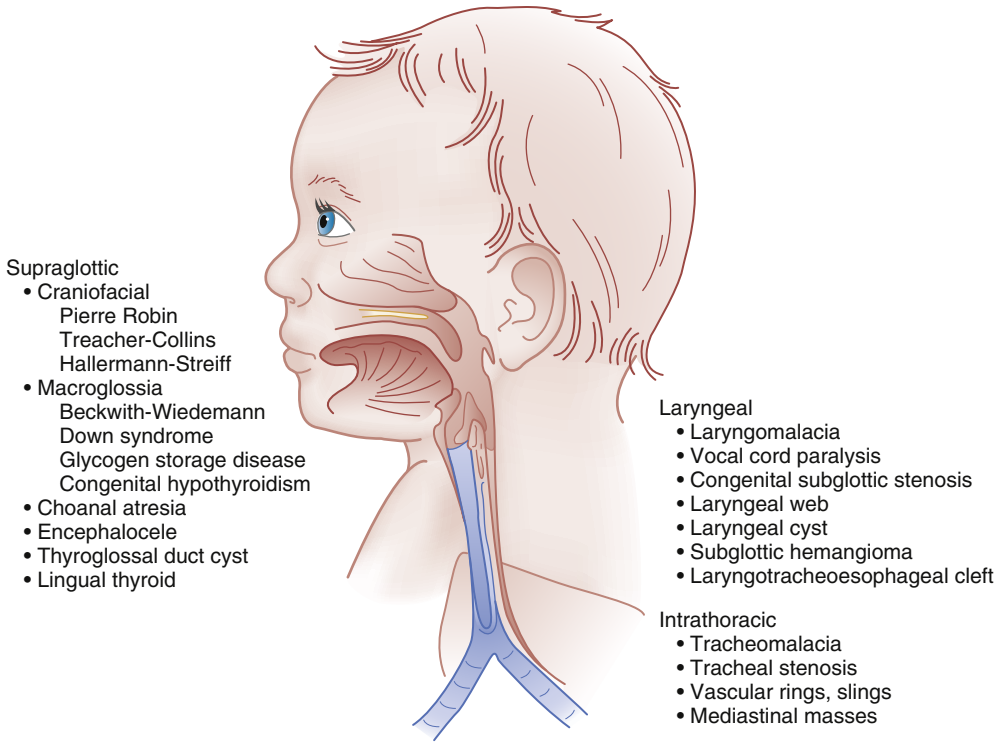

Fig. 162.1 Regions and Associated Diseases of the Pediatric Upper Airway. (From Simon NP, Simon N. Evaluation and management of stridor in the newborn. *Clin Pediatr [Phila].* 1991;30:211.)

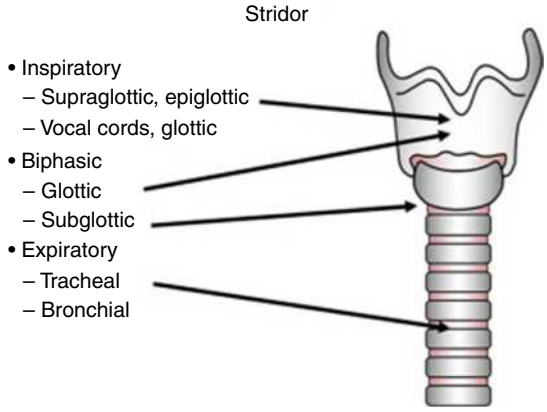

Fig. 162.2 Level of Obstruction Correlates with Phase of Stridor. (From Ida JB, Thompson DM. Pediatric stridor. *Otolaryngol Clin North Am.* 2014;47:795–819.)

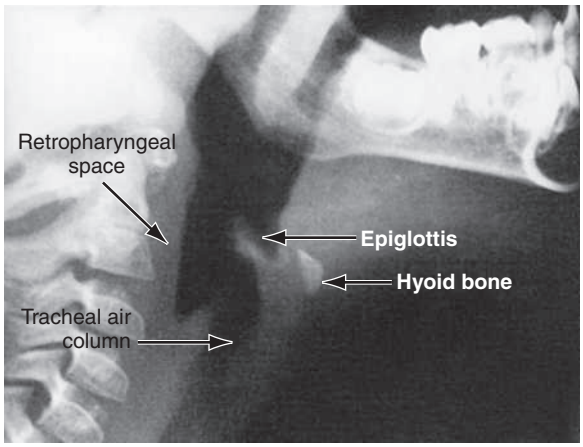

Fig. 162.3 Normal Appearance of Upper Airway Structures on a Lateral Neck Radiographic Study. Note the hyoid bone, epiglottis, retropharyngeal space, and tracheal air column.

the nose, there is persistence of the bucconasal membrane or a bony septum in the posterior naris. The posterior aspect of the infant's soft palate extends downward and contacts the tip of the epiglottis. Bilateral choanal atresia is a life-threatening emergency that is almost always identified early, as neonates become acutely distressed and cyanotic at birth. Immediate airway management is with oral airway and definitive surgical correction of the obstructing membrane. Unilateral choanal atresia is often initially undetected. Infants may present in respiratory distress with a URI when the normal patent naris is obstructed by swelling or secretions. Immediate nasal suction should be performed along with urgent referral for surgical repair.

Macroglossia. Macroglossia, an abnormally large tongue that protrudes posteriorly into the hypopharynx, is associated with conditions such as Down syndrome, glycogen storage disease, and congenital hypothyroidism. The increased secretions with a URI exacerbate underlying obstruction and may induce stridor or labored breathing. Good head positioning with nasal suctioning should be performed to relieve the obstruction.

Micrognathia. With micrognathia, an abnormally small mandible posteriorly displaces the normal-sized tongue (e.g., Pierre Robin and Treacher-Collins syndromes). Obstructive symptoms typically worsen when supine.

Pharyngitis

Infection is the most common cause of sore throat in children. Viruses cause the majority of infections. Certain viruses have characteristic features such as coxsackie A viruses that manifest as herpangina or

hand, foot, and mouth disease. Herpes simplex more commonly causes stomatitis and less commonly may cause pharyngitis. *Streptococcus pyogenes* (Group A streptococcus) is the most common bacterial infectious etiology (see Chapter 19). Diphtheria can cause a thick exudative tonsillar membrane. Acetaminophen (15 mg/kg/dose q4h) or ibuprofen (10 mg/kg/dose q6h) is sufficient supportive treatment for most causes of pharyngitis.

Peritonsillar Abscess

PTA is the most common deep neck infection and usually occurs in older children and teenagers. Drooling and a muffled, hot potato voice is common, but severe respiratory distress is unusual. PTA is associated with trismus (in two out of three patients), bulging or asymmetry of the tonsils, and deviation of the uvula away from the abscess side (in 50% of patients). Throat pain may radiate to the ear. Treatment involves antibiotics and incision and drainage or needle aspiration. Antibiotics alone are insufficient management for an abscess but may resolve a phlegmon or cellulitis.[1] Surgical intervention typically removes the majority of purulence, but additional antibiotics are recommended to clear the remaining infection.

PTAs are typically polymicrobial. Predominant bacterial species are *S. pyogenes* (group A streptococcus), *Staphylococcus aureus* (including Methicillin-resistant *S. aureus* [MRSA]), and respiratory anaerobes. Posterior pharynx ultrasonography can confirm the diagnosis and guide treatment.[2,3] A CT scan may be indicated if extension of infection is suspected. Any drainage effort should take great care to avoid puncture of the carotid artery (the carotid artery lies 25 mm posterolateral to the tonsillar pillar in children >12 years). Approximately 10% to 20% of patients have recurrent PTAs.

Mononucleosis

Infectious mononucleosis, caused by the Epstein-Barr virus (EBV), can lead to mucosal edema and an exudative pharyngitis. Uncommonly, massive tonsillar enlargement can occur and create upper airway distress. EBV IgM antibody is the preferred test for infective mononucleosis (>90% sensitive), particularly in children younger than 4 years who are less likely to generate heterophile antibodies with primary EBV infection. In older children and adults, the heterophile antibody can be detected in 50% of patients within the first week of illness and in 60% to 90% in weeks 2 and 3.

In addition to airway management and general supportive care, there may be additional benefits of steroids in reducing tonsillar edema and pain.[4] Although steroids decrease pharyngitis symptoms, it is important to consider an underlying lymphoid malignancy. Children often present with sore throat prior to malignancy diagnosis. Treatment with glucocorticoids prior to the diagnosis of leukemia may delay leukemia diagnosis, increase the risk of tumor lysis syndrome, complicate risk stratification, and ultimately result in fatal complications. Therefore, great caution should be exercised in using glucocorticoids in children and adolescents and should be avoided in children younger than 14 years or in a child who has any signs of possible lymphoid malignancy such as lymphadenopathy, hepatosplenomegaly, rash, or abnormal complete blood count.

Retropharyngeal Abscess

A RPA is a potentially life-threatening airway emergency resulting from infection of the retropharyngeal soft tissue space. The retropharyngeal space is a potential space between the posterior pharyngeal wall and prevertebral fascia that extends from the base of the skull to the level of T2. It is rich in lymph tissue that drains the nose, pharynx, sinuses, and ears. An abscess may result from direct trauma from a fall with a hard object in the mouth that penetrates the soft tissue, suppuration of lymph nodes, contiguous spread of infection, or hematogenous seeding. RPA is usually a disease of young children because the lymphatic chains are prominent in the young and atrophy before puberty; RPA in older children often occurs after inciting trauma. These infections are commonly polymicrobial, with *Streptococcus* and anaerobes being the most commonly isolated organisms. MRSA is increasing in incidence and is commonly associated with severe infections such as jugular venous thrombosis or mediastinal extension.

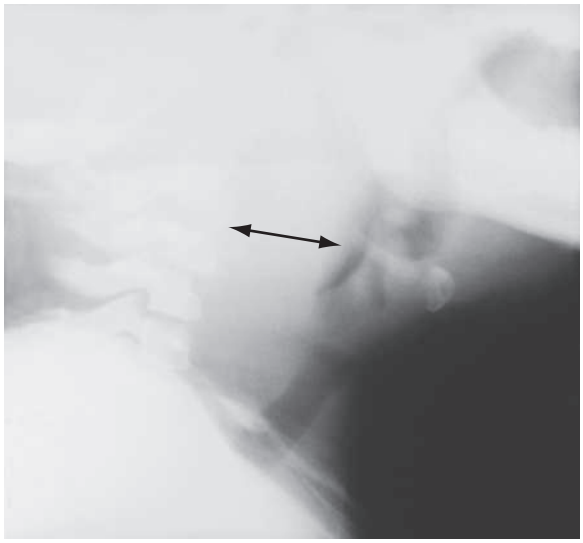

Fig. 162.4 Retropharyngeal Abscess. Note the widened retropharyngeal soft tissue space *(double arrow)*.

Clinical features. Retropharyngeal infections typically progress from cellulitis to organized phlegmon to mature abscess. Presenting symptoms may vary. Common signs and symptoms include fever, sore throat, neck stiffness or nuchal rigidity, torticollis, trismus, neck swelling, drooling, stridor, and muffled voice. Stridor and respiratory distress may occur if a large abscess compresses the trachea; the clinical appearance can resemble that of epiglottitis. Reluctance to extend the neck and an unwillingness to look side to side is often seen with RPA and may help differentiate it from other supraglottic infections. With less obvious signs of airway obstruction, patients can exhibit a mixture of symptoms, including fever, neck stiffness, and generalized toxicity, which may suggest meningitis or sepsis. Other serious complications of a RPA include aspiration pneumonia, mediastinitis, and empyema.

Diagnostic testing. Careful evaluation of airway patency takes precedence in the management of a child with a presumed RPA. Examination of the pharynx may reveal bulging of the posterior pharyngeal wall. A soft tissue lateral view of the neck may be helpful to establish the diagnosis; in the normal patient, the width of the retropharyngeal space should not exceed the diameter of the adjacent vertebral body (Fig. 162.4). The soft tissue width should not be larger than 7 mm at C2, regardless of the patient's age. At C6, this distance should not exceed 14 mm in children younger than 15 years and 22 mm in adults. Most patients will demonstrate retropharyngeal thickening on the lateral neck radiograph. An air-fluid level may be present with perforation or anaerobic infections. Redundant soft tissue of the retropharyngeal space complicates the interpretation of lateral neck films in young infants with an RPA. Artefactual widening of a normal retropharyngeal space is commonly seen when the radiograph is taken with the head and neck in flexion or during exhalation. CT scanning of the neck (thin cuts to T2) may be beneficial in delineating the size and extent of an abscess and determining possible impingement on airway

structures. The ability to tolerate lying supine should first be assessed, and staff and airway equipment should be immediately available.

Management. The size of the abscess, degree of airway obstruction, and overall toxicity of the patient dictate management. The need for intubation or surgical drainage is determined on an individual basis, and these patients generally benefit from the involvement of an otolaryngologist. Intubation can be complicated by distorted anatomy and can lead to abscess rupture. Some retropharyngeal infections respond to intravenous (IV) antibiotics and do not require surgical drainage.[5] Features that suggest abscess and require surgical intervention include imaging findings of scalloping of the abscess wall, rim enhancement, and lesions larger than 2 cm. The decision to admit and provide a trial of antibiotic therapy should be made between the emergency clinician and otolaryngology consultant. Clindamycin and a third-generation cephalosporin are recommended antibiotic therapy. Vancomycin or linezolid should be added with suspected MRSA infection, resistant cases, or with systemic illness.

Ludwig's Angina

Ludwig's angina is a rapidly spreading, woody induration or brawny cellulitis of the sublingual, submandibular, and submaxillary spaces, with the potential for airway obstruction. Most patients have dental sources of infection, which are usually polymicrobial. The spread of infection is direct and not via the lymphatics, so involvement is typically bilateral and without associated lymphadenopathy. Hallmark signs include enlargement and elevation of the tongue above the lower teeth, a tender woody induration in the sublingual space, trismus, and odynophagia. Ludwig's angina can create a functional upper airway obstruction or respiratory distress through significant swelling and direct airway compression. Subsequent abscess formation may occur. CT evaluates the extent of infection but MRI may better delineate soft tissue involvement. Treatment involves broad-spectrum IV antibiotics with anaerobic coverage, airway support, and admission for close monitoring. Otolaryngology and anesthesia consultants may facilitate planning and support if an emergent airway is required.

Epiglottitis

Although still a feared pediatric emergency, acute epiglottitis has declined markedly in incidence since the widespread administration of the *Haemophilus influenzae* type b vaccine in the 1980s.

Foundations. Epiglottitis is an invasive bacterial disease that causes inflammation and edema of the epiglottis, aryepiglottic folds, arytenoids, and surrounding supraglottic tissues. As these structures become inflamed and distended, they protrude downward and over the glottic opening. Supraglottic swelling reduces the upper airway caliber and causes turbulent airflow during inspiration (stridor). The epiglottis may also act as a ball valve, obstructing airflow during inspiration but permitting exhalation. This traditional profile of *H. influenzae* type b (Hib) in young children has changed; the overall incidence has decreased, and now epiglottitis is relatively more common in older children and adults. However, Hib is still the most common infectious cause of epiglottitis in children and can occur in fully immunized children. Additional causes include other *H. influenzae* types (A, F, nontypeable), streptococci, *S. aureus* (including methicillin-resistant strains), and *Neisseria meningitidis*.[6,7] Immunocompromised children may have other infections such as *Pseudomonas aeruginosa* and *Candida* spp. Noninfectious causes are rare and include thermal injury from swallowing hot liquids, steam inhalation, caustic ingestions, allergic reactions, foreign body and irritant injuries, and lymphoproliferative disorders.

Clinical features. Epiglottitis is classically acute in onset. It is marked by high fever, intense sore throat, toxicity, and rapid progression. Children with epiglottitis appear anxious and maintain a sniffing or tripod position, with the jaw jutting forward and the neck extended to maximize airway patency. As symptoms worsen, cough and phonation are usually absent. Drooling is prominent because of an inability to swallow. Toxicity, altered mental status, dyspnea, stridor, retractions, and fever are common initial symptoms; the diagnosis is often delayed and is associated with a significantly increased mortality rate. Croup is a common misdiagnosis made in young children and those without prominent drooling and difficulty swallowing. The older patient is less likely to show dramatic signs of upper airway obstruction compared with the younger child because the diameter of the airway is larger and thus takes a greater degree of swelling to produce symptoms. These patients often complain of a sore throat that is out of proportion to physical findings and may also exhibit tenderness on palpation of the anterior neck. Epiglottitis caused by bacteria other than *H. influenzae* tends to have a slower onset and is less likely to cause airway compromise. Epiglottic abscess may occur, particularly in adolescents. Patients with immunodeficiency may develop necrotizing epiglottitis.

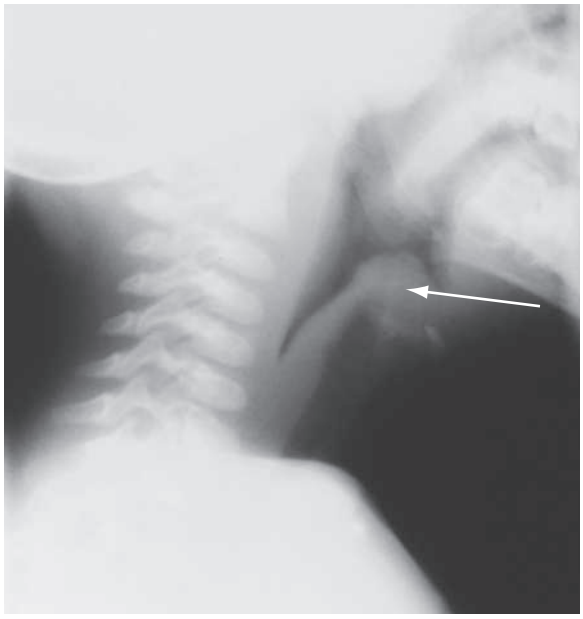

Fig. 162.5 Epiglottitis. Note the thumbprint sign of the epiglottis *(arrow)* and thickened aryepiglottic folds.

Diagnostic testing. When epiglottitis is strongly suspected, a lateral neck radiograph can be helpful to confirm the diagnosis and should be evaluated for an enlarged epiglottis (thumbprint sign; Fig. 162.5), thickened aryepiglottic folds, lack of air in the vallecula, and dilated hypopharynx. However, up to 70% of all patients with epiglottitis have normal radiographic findings. Careful observation of a child in consultation with an otolaryngologist is essential, and clinicians skilled in airway management should accompany the patient at all times; the risk of obstruction is particularly high in younger children with smaller airways.

Management. For the younger child, the importance of securing the airway takes precedence over diagnostic evaluation. A stable patient who is maintaining a patent airway and adequate oxygenation should not be moved or repositioned for examination, laboratory tests, or radiography. Such patients should be carefully transported to a setting where definitive airway management can be achieved in a controlled fashion, generally the operating room. Adolescents with epiglottitis generally have signs and symptoms of adults and do not often require airway stabilization. These patients can be managed as inpatients in a pediatric intensive care unit (PICU) setting with IV antibiotics but do

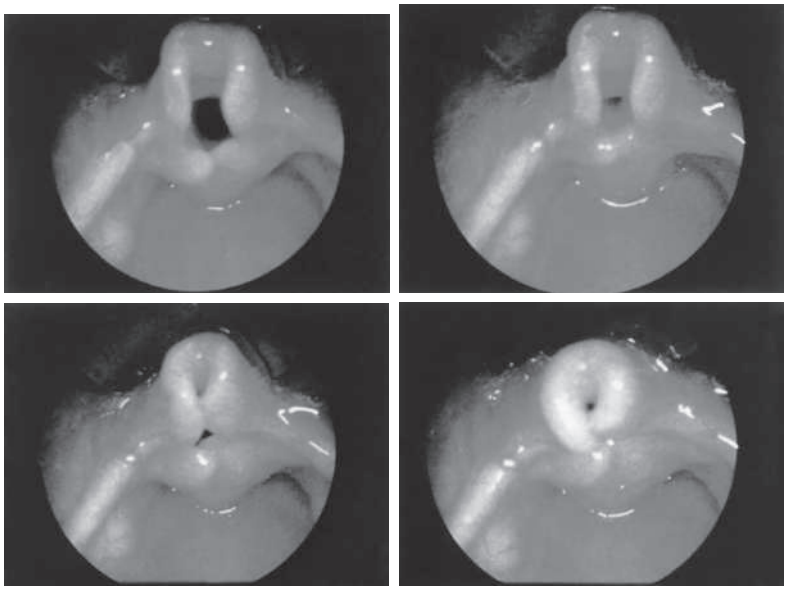

Fig. 162.6 Laryngomalacia. Note the progressive obstruction with inspiration as the epiglottis and surrounding structures collapse into the glottic opening.

not require immediate airway management unless signs and symptoms dictate that this is the case.

Unstable patients with respiratory failure require assisted ventilation. Bag-mask ventilation should be attempted first and, if successful, continued until intubation can be performed. If neither bag-mask ventilation nor intubation is successful, needle cricothyroidotomy or tracheostomy may be indicated. Regardless of the approach to securing the airway, it is prudent for the emergency clinician to consult other experts in airway management rapidly, such as an anesthesiologist (fiberoptic intubation), otolaryngologist, or general surgeon (surgical approaches), so that a plan of approach can be made and morbidity minimized. Patients often remain intubated for 3 to 5 days in order for antibiotic therapy to reduce inflammation and surrounding tissue edema. A second- or third-generation cephalosporin is recommended.

Trauma and Burns

Thermal injury from facial burns and inhaled smoke or steam and trauma to the face and neck can create physical findings similar to those of infectious epiglottitis. Rapidly progressive stridor, drooling, an unwillingness to lie flat, and a swollen inflamed epiglottis may occur. Aspiration of hot liquids is the most common cause of airway burns in infants and young children. Toddlers are particularly prone to inhalation of hot liquids because they can eat and drink independently without initially being attentive to temperature. The initial physical examination of the oropharynx may be relatively normal. The airway should be secured early in suspected laryngeal edema, as progression and obstruction can occur rapidly. Bronchodilators may help with bronchospasm; steroids are not recommended.

Allergic Reactions

Acute allergic reactions may cause rapid supraglottic edema with respiratory distress and stridor. Food is the most common precipitant in infants and children. Children with peanut allergies and those with atopy and asthma have higher mortality rates. The treatment of anaphylaxis is epinephrine. Intramuscular epinephrine (1 mg/mL solution) at 0.01 mg/kg up to 0.5 mg per dose is initial management and may be repeated twice. IV epinephrine (0.1 mg/mL solution) at a 0.001 mg/kg bolus followed by 0.1 to 1 mcg/kg/min up to 10 mcg/min may be necessary for patients in shock with anaphylaxis. IV fluids and oxygen should be administered. Racemic epinephrine may be given to reduce airway edema and other bronchodilators may be given for epinephrine-resistant bronchospasm. H1 and H2 antihistamines and steroids are commonly given for symptomatic relief but do not act rapidly enough to effectively treat anaphylaxis. Intubation may be required and should be considered early for acute airway obstruction unresponsive to epinephrine. On discharge from the hospital, all patients with anaphylaxis should be given a prescription for an epinephrine autoinjector (0.15 mg for children <30 kg; 0.3 mg for older children) and instructed in its use. Follow-up with the primary care physician for allergist referral and a medical alert bracelet is also recommended.

Diseases of the Larynx

The larynx and vocal cords are commonly involved with obstructing airway disease. Many obstructing conditions are congenital lesions, including laryngomalacia, laryngeal web, and vocal cord paralysis. Acquired lesions include laryngeal papillomas.

Congenital lesions. Laryngomalacia is the most common cause of chronic stridor in infants and accounts for 60% to 75% of congenital laryngeal anomalies. It is a result of incomplete development of the supporting cartilage of the larynx. With inspiration, the long floppy epiglottis, arytenoids, and aryepiglottic folds are drawn into the larynx and create a partial obstruction (Fig. 162.6). Baseline inspiratory stridor begins several weeks after birth and worsens with supine positioning, neck flexion, and increased respiratory effort (crying, URI). Laryngomalacia is rarely associated with significant respiratory distress, feeding difficulties, or failure to thrive. Most patients experience complete resolution of symptoms by 2 years of age and are treated conservatively. Fiberoptic bronchoscopy is used to confirm the diagnosis and identify the existence of coexisting or synchronous anomalies (e.g., subglottic stenosis, tracheomalacia). Surgical intervention is warranted in severe cases in which the child suffers from apneic events, respiratory compromise, pulmonary hypertension, or failure to thrive.[8]

Vocal cord paralysis is the second most common cause of chronic stridor in infants. Bilateral vocal cord paralysis results in severe respiratory distress and stridor and typically requires intervention for airway

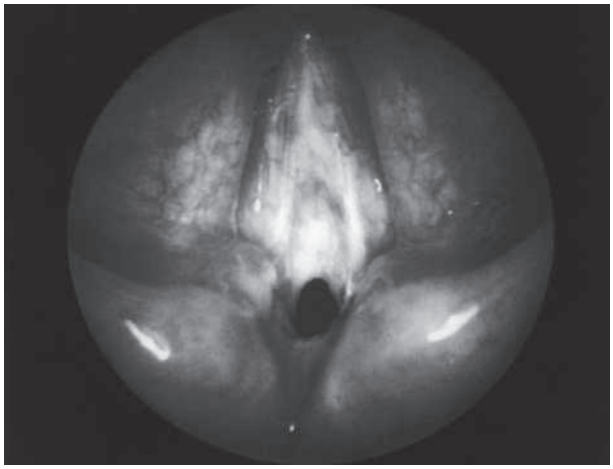

Fig. 162.7 Large Laryngeal Web.

protection; it is often associated with serious central nervous system abnormalities, such as Arnold-Chiari malformations. Unilateral vocal cord paralysis is usually left-sided and related to traction on the left recurrent laryngeal nerve at birth or compression from mediastinal structures. Infants with unilateral vocal cord paralysis have a hoarse weak cry, feeding difficulties, and aspiration. Stridor often worsens with distress and improves with positioning the affected side down. Most children improve with voice and speech therapy and do not require invasive treatment.

A laryngeal web results from failure of complete canalization of the airway. Most webs lie between the cords and appear as a partial anterior fusion (Fig. 162.7). The spectrum of symptoms reflects the size of the web. Small webs may cause a hoarse weak cry and mild stridor. Larger, more complete webs are associated with aphonia and severe respiratory distress.

Congenital laryngotracheal (subglottic) stenosis is a result of a congenital defect in canalization of the subglottic trachea. Deformity of the cricoid ring is usually seen. Infants with severe stenosis have stridor at birth. Milder lesions may be asymptomatic until additional obstruction from infection or inflammation occurs. Subglottic stenosis is also an acquired condition that occurs after prolonged intubation or blunt trauma to the neck.

A subglottic hemangioma is a less common cause of stridor and subglottic airway obstruction in infants. The infant is usually asymptomatic at birth, but stridor (which may be biphasic) and cough develop within the first few weeks to months of life. Symptoms generally peak at 6 months as a result of rapid growth of the infant and hemangioma during the first months of life. Respiratory symptoms worsen with crying and agitation. Cutaneous hemangiomas are seen in approximately 50% of cases (often in a beard distribution; Fig. 162.8). Hemangiomas of the airway may be seen on plain film as an asymmetric lesion along the tracheal air column. Endoscopy is diagnostic (Fig. 162.9).

Acquired lesions

Laryngeal papillomas. Laryngeal papillomas are the most common benign laryngeal neoplasm in children and the second most common cause of hoarseness. They are typically acquired after exposure to human papillomavirus via vertical transmission from an infected mother. Multiple lesions are generally present and usually occur in the vocal cords but may involve any part of the larynx. Hoarseness, abnormal cry, and inspiratory stridor commonly occur by 3 to 4 years of age. Symptoms can progress to severe respiratory distress as the lesions enlarge and obstruct the larynx. Multiple ablation procedures are often required and malignant transformation may rarely occur.

Fig. 162.8 2-month-old infant with a facial hemangioma in the beard distribution. This patient was also found to have a subglottic hemangioma. (From O-Lee TJ, Messner A. Subglottic hemangioma. *Otolaryngol Clin North Am.* 2008;41:903–911, viii–ix.)

Fig. 162.9 Subglottic Hemangioma Seen on Endoscopy. (From Ida JB, Thompson DM. Pediatric stridor. *Otolaryngol Clin North Am* 2014;47:795–819.)

Subglottic tracheal disease. The subglottic trachea is the origin of the high-pitched inspiratory sound commonly associated with upper airway obstruction. The subglottic space is elliptical-shaped and completely surrounded by the cricoid ring. This anatomy predisposes this part of the airway to obstruction. Subglottic narrowing or stenosis can result from a congenital anomaly, inflammation from infection, and trauma associated with prolonged intubation.

Viral Croup

Foundations. Croup (laryngotracheobronchitis) is the most common infectious cause of upper airway distress and obstruction

TABLE 162.2 Simplified Differential Diagnosis of Upper Airway Symptoms

Condition	Distinguishing Features
Anaphylaxis	Abrupt onset, associated trigger, other organ system involvement
Croup	URI symptoms, acute onset of barky cough, stridor, no distinct positional preference
Bacterial tracheitis	Fever, toxicity, prolongation of symptoms, lack of response to croup treatment
Epiglottitis	Drooling a predominant symptom, patient desire to remain sitting. Muffled voice (but hoarseness typically absent), cough absent, anxiety
Retropharyngeal abscess	Fever, toxicity, torticollis, neck pain/stiffness, +/– drooling, +/– muffled voice
Foreign body aspiration	History of choking episode, absence of URI symptoms or hoarseness, +/– drooling
Peritonsillar abscess	Sore throat, trismus, muffled voice, pharyngeal erythema and edema, uvular deviation

URI, Upper respiratory tract infection.

in childhood. It accounts for more than 90% of all cases of stridor in children. It usually occurs between 6 and 36 months of age but can be seen from early infancy through school age. Croup is rare in children greater than 6 years of age. Parainfluenza virus accounts for 50% to 75% of cases; respiratory syncytial virus, influenza A and B viruses, and rhinovirus cause the remainder. Measles can also cause croup and should be considered in unvaccinated children. The clinical picture of croup associated with influenza is more severe than with parainfluenza. Croup is caused by inflammation, exudates, and edema of the loosely adherent mucosal and submucosal tissues of the subglottic space. The inflamed mucosa expands into the airway lumen because the cricoid cartilage forms a complete cartilaginous (nonexpanding) ring in this part of the trachea. In severe disease, the airway may be narrowed to as little as 1 to 2 mm.

Clinical features. Croup is diagnosed clinically. A 1- to 3-day prodrome of mild fever and URI symptoms is followed by a fairly abrupt onset of barky cough, hoarse voice, and high-pitched inspiratory stridor. The barky cough is the predominant presentation in infants and young children, whereas older children tend to present primarily with hoarseness. The cough lasts an average of 3 days and all symptoms typically resolve in 4 to 7 days. A simplified differential diagnosis for croup is shown in Table 162.2. Scoring systems have been developed for the assessment of croup; these include an evaluation of worsening stridor, retractions, cyanosis, heart rate, and respiratory rate. Although a formal croup score is often not assigned in many clinical settings, the determination of mild, moderate, or severe croup should be based on careful evaluation of these five signs as well as on mental status and air movement. See Fig. 162.10 for a clinical treatment algorithm based on croup severity.

Mild croup is characterized by an intermittent barky cough, stridor with agitation but not at rest, mild tachypnea, and tachycardia. A child with mild croup is minimally distressed and well hydrated and has normal mental status. Moderate croup is characterized by audible stridor at rest, worsening stridor with agitation, barky cough, and increased work of breathing (retractions, tachypnea, and tachycardia). A patient with moderate croup may be fussy but is alert, interactive, and comforted by parents. Hypoxia is rare in mild or moderate croup. When hypoxia is seen, it may signify concomitant lower respiratory disease, another disease process, or severe croup. Mild croup occurs in 85% of children; fewer than 1% of children have severe croup. Laboratory tests are nondiagnostic, and radiographic studies of the neck do not change management nor are they sensitive or specific. The classic x-ray finding is a steeple sign—a tapered narrowing of the normal shouldered appearance of the subglottic trachea—which can be seen in those with croup and also in patients without the disease.

Management. Glucocorticoids reduce symptoms, decrease the need for aerosolized epinephrine, and result in fewer readmissions to the ED and shorter ED and hospital stays. Oral dexamethasone (0.15 mg/kg to 0.6 mg/kg, max 10 to 16 mg) is the preferred agent and can improve symptoms within two hours. The IV form of dexamethasone is more concentrated than the oral formulation and can be given orally. Severe cases or patients with oral intolerance may be given the same dose IM/IV. Lower dosing (0.15 mg/kg) has been shown to be as effective as a higher dose (0.6 mg/kg) in most cases. However, there is some evidence that patients with more severe obstruction benefit from the higher dose.[15,16] Inhaled budesonide (2 mg/dose) is also effective but more expensive, so it is not routinely used. Prednisolone may be as effective as dexamethasone in milder cases but should not be used in patients with significant symptoms due to the shorter duration of action.[9]

Aerosolized epinephrine, which reverses edema and relieves acute symptoms through vasoconstriction in the subglottic mucosa, should be given to children with stridor at rest or with significant respiratory distress. It is a temporizing measure with a quick onset of action (<10 minutes) and a duration of up to 2 hours. The L form of epinephrine is the active isomer and has the same degree of safety and efficacy as racemic epinephrine; either form may be used. Nebulized L-epinephrine (1:1000 solution) dosing is 0.5 mL/kg (max, 5 mL) *or* racemic epinephrine (2.25% solution) is 1.125 mg/kg (max, 11.25 mg/dose or 0.5 mL/dose); either should be diluted in 2 to 3 mL of NS and given via nebulizer over 15 minutes. Patients with stridor at rest who receive inhaled epinephrine should be observed in the ED to ensure no recurrence of severe symptoms. The amount of time needed to observe these patients is controversial, but patients are unlikely to deteriorate beyond 3 hours. We recommend that patients be observed in the ED for 2 to 3 hours after epinephrine administration to ensure that stridor and respiratory distress do not recur.

Heliox (i.e., concentrations of helium: oxygen at 80:20, 70:30, or 60:40) may improve resistance to gas flow and thus decrease work of breathing in young children with moderate to severe croup. Heliox has been shown to improve symptoms temporarily (in the first hour), but the benefits are not sustained (after two hours). Heliox (with nebulized epinephrine) may be considered to avoid intubation in young children with moderate to severe increased work of breathing, although studies to date have not been powered to assess its effect on this rare outcome.[10] Cool mist has not been demonstrated to improve outcomes and there is insufficient evidence to support its routine use.

Most children with croup can be safely discharged, provided respiratory distress and resting stridor have resolved.[11] A small percentage of patients with croup require admission. Several factors may impact the decision to admit a child with moderate croup, such as the severity of symptoms at initial evaluation, persistence of respiratory distress, stridor at rest, hypoxia, poor response to treatment, dehydration, history suggesting airway disease or recurrent croup, young age (<6 months), difficulty with feeds, and poor social support (Box 162.1).

Severe croup is rare (<1%) and associated with signs of impending airway obstruction and respiratory failure—fatigue, hypoxia, hypercapnia, abnormal mental status, and extreme respiratory distress. In the rare case in which intubation is required, an endotracheal tube (ETT) at least a half-size smaller than expected for the child's size is often necessary. If the ETT that can be passed is too small to allow adequate ventilation, tracheostomy may be required.

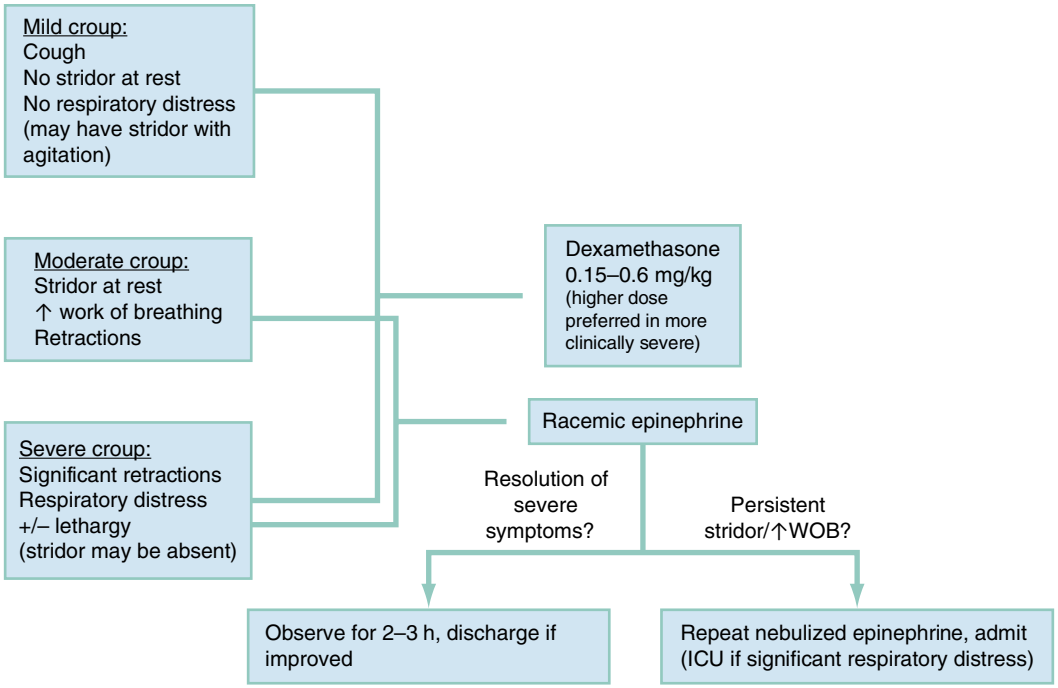

Fig. 162.10 Simplified Croup Treatment Algorithm Based on Presenting Signs, Symptoms, and Severity. (Rose E, ed. *Pediatric Emergencies: A Practical, Clinical Guide*. New York, NY: Oxford University Press; 2021)

BOX 162.1 Croup: Indications for Admission

Severe respiratory distress or failure
Unusual symptoms (hypoxia, hyperpyrexia)
Dehydration
Persistence of stridor at rest after aerosolized epinephrine and steroids
Persistence of tachycardia, tachypnea
Complex past medical history (prematurity, pulmonary, cardiac disease)

Spasmodic or Atypical Croup

Spasmodic or atypical croup is a somewhat indistinct clinical entity with many features that overlap those of viral croup. There is no consensus on the definition, but the term *atypical croup* is often used to describe numerous recurrent episodes or croup in children outside the expected age group. An association with allergy, atopy, airway hyperreactivity, asthma, and gastroesophageal reflux has been described. Airway lesions (most commonly subglottic stenosis) may be present and contribute to the pathophysiology.[12]

Diseases of the Trachea

Obstruction of the trachea distal to the subglottic space can be a result of congenital and acquired lesions.

Congenital lesions

Tracheomalacia. Tracheomalacia results from abnormally soft, undeveloped supporting cartilage of the tracheal rings. Primary or congenital tracheomalacia is seen in otherwise healthy term newborns, as well as in infants with conditions such as Down syndrome and DiGeorge syndrome. Healthy infants with isolated disease have a good prognosis because symptoms improve as the cartilage strengthens with growth. Secondary disease is associated with extrinsic compression of the trachea (e.g., vascular rings, tumor, nodes, and cysts). Tracheomalacia should be suspected in patients with a history of stridor that increases during the first few weeks of life and worsens with agitation, supine positioning, and infection. Plain radiographs are nondiagnostic but dynamic studies, such as fluoroscopy, may be helpful. Patients should follow up with primary care for outpatient monitoring of symptoms.

Tracheal stenosis. Tracheal stenosis is a congenital anomaly that results from complete tracheal rings. Infants have persistent stridor and respiratory distress. Because the tracheal diameter is fixed, symptoms worsen with agitation and age.

Tracheal compression. Tracheal compression may also occur externally from vascular anomalies or mediastinal lesions (Fig. 162.11). A vascular ring is an anomaly of the aortic arch and related vessels in which a ring of vessels encircles the trachea, esophagus, or both. Examples of vascular rings include a double aortic arch, right aortic arch with a persistent left ligamentum arteriosum, anomalous innominate artery and anomalous left common carotid artery, left pulmonary artery, or aberrant right subclavian artery. Stridor, wheezing, dyspnea, and cough are common initial symptoms and are frequently mistaken as a URI. Many patients with vascular rings have additional cardiovascular anomalies and further work up is often indicated. Other associated mediastinal lesions that can compress the trachea include esophageal duplication cysts, bronchogenic cysts, mediastinal cyst, teratomas, lymphomas, and lymphadenopathy.

Vascular rings. Infants with vascular rings typically present with persistent, unexplained respiratory and feeding problems. A chest radiograph revealing an abnormal (right-sided) aortic arch may suggest the diagnosis in the ED; barium esophagography has traditionally been considered to be the single most important diagnostic procedure in patients with complete vascular rings (Fig. 162.12). Additional studies, such as CT, MRI, angiography, or bronchoscopy, may be indicated based on symptoms and associated risk factors for co-morbidities.

Bacterial tracheitis

Foundations. Bacterial tracheitis, also referred to as bacterial laryngotracheobronchitis, pseudomembranous croup, is a serious cause of stridor and airway obstruction in children. The epidemiology of upper airway infections has changed since widespread immunization for *H. influenzae* and the use of steroids for croup. This has increased the relative frequency of bacterial tracheitis as a cause of respiratory

Fig. 162.11 External Vascular Compression of the Trachea Seen on Endoscopy. (From Ida JB, Thompson DM. Pediatric stridor. *Otolaryngol Clin North Am.* 2014;47:795–819.)

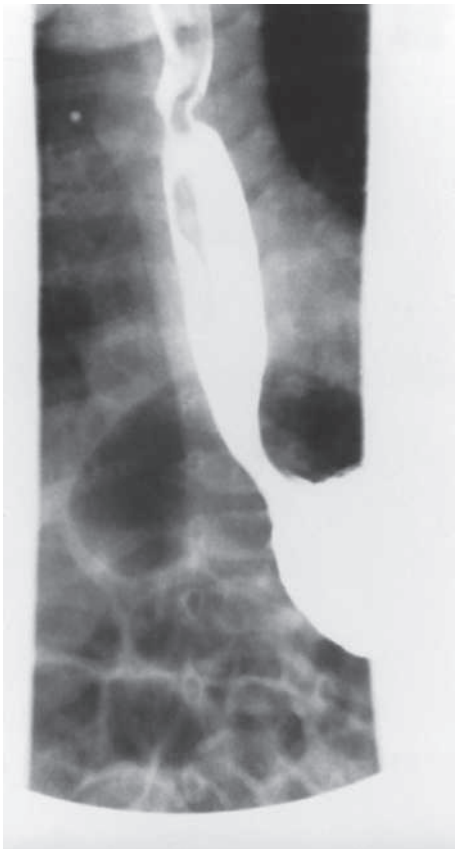

Fig. 162.12 Barium Esophagogram. Note the indentation of the esophagus caused by an encircling vascular ring.

failure from upper airway infection. Bacterial tracheitis is three times more likely to cause respiratory failure than epiglottis and viral croup combined. Bacterial tracheitis usually affects younger children but may occur at any age.

The pathogenesis of bacterial tracheitis is severe inflammation of the tracheal epithelium and the production of thick mucopurulent secretions. The lining of the trachea forms a loosely adherent membrane that may become necrotic and slough, occluding the lumen. Microabscesses may be present in the tracheal mucosa. Perforation and pneumomediastinum have been described. Traditionally, *S. aureus* (including MRSA) has been the organism primarily responsible for bacterial tracheitis, but many causative bacteria have been reported. Fungal tracheitis in immunocompromised individuals portends a grave prognosis.

Clinical features. The classic presentation of bacterial tracheitis is a toxic child with high fevers and rapidly worsening stridor that fails to improve with racemic epinephrine. Symptoms may overlap with those of croup and epiglottitis (Table 162.3). Most patients experience a viral prodrome of fever, barky cough, and stridor. These symptoms typically intensify as the bacterial superinfection grows on damaged tracheal epithelium. The child appears toxic, and signs of airway obstruction and respiratory failure may develop acutely. Less commonly, primary bacterial tracheitis may occur with a fulminant onset and rapid progression to acute respiratory distress. Features that suggest bacterial tracheitis include a viral prodrome followed by acute decompensation, symptoms atypical for croup (e.g., high fever, cyanosis, severe distress), poor response to the usual treatment of croup (e.g., nebulized epinephrine), and inspiratory and expiratory stridor. Changes in bacteriologic profiles have produced less virulent but more prolonged infections, increasing the diagnostic challenge.[13]

Diagnostic testing. The evaluation of a toxic-appearing child with bacterial tracheitis should be conducted expeditiously. Laboratory tests are nondiagnostic. The white blood cell count is often normal or slightly elevated, and blood cultures are rarely positive in bacterial tracheitis. Lateral and anteroposterior views of the neck and chest may be helpful. Findings on plain radiographs include subglottic narrowing, a ragged edge of the usually smooth tracheal air column, and a hazy density within the tracheal lumen, mimicking the appearance of airway foreign bodies. The epiglottis and supraglottic structures appear normal. In addition, the chest radiograph may reveal coexisting pneumonia. Bronchoscopy is both diagnostic and therapeutic and should be performed emergently (Fig. 162.13); this procedure allows visualization of the supraglottic structures and larynx, exclusion of other diseases, suctioning of tracheal secretions and debris, and establishment of an artificial airway.

Management. Severe distress may rarely require immediate intubation and suctioning in the ED, although airway management in the operating room is preferred. Endoscopic tracheal débridement may result in significant clinical improvement and allow the child to be managed without intubation. Serial endoscopy may be needed to manage secretions. Endotracheal intubation is required in children with respiratory distress and hypoxia. Patients should be admitted and receive supplemental oxygen, fluid resuscitation, and broad-spectrum antibiotics.

Broad antibiotic coverage is recommended with an antistaphylococcal agent (e.g., vancomycin, clindamycin) plus a third-generation cephalosporin (e.g., ceftriaxone). Alternatively, an antistaphylococcal agent plus ampicillin-sulbactam may be used. In penicillin-allergic patients, vancomycin or clindamycin plus a quinolone should be administered (ciprofloxacin if *Pseudomonas* is a concern or levofloxacin if *Streptococcus pneumoniae* is suspected). Although 7 to 10 days is usually sufficient, longer courses of antibiotics may be necessary for children with extra-tracheal infection or persistent tracheal inflammation. Complications of bacterial tracheitis include toxic shock syndrome, septic shock, renal failure, postintubation pulmonary edema, acute respiratory distress syndrome, and the need for reintubation. Residual subglottic stenosis has been described.

TABLE 162.3 Comparison of Croup, Epiglottitis, and Bacterial Tracheitis

Parameter	Croup	Epiglottitis	Bacterial Tracheitis
Peak age	6 months–3 years	5–7 years, but can be seen throughout childhood	3–5 years, but seen throughout childhood
Pathologic features	Subglottic inflammation, edema	Inflammation and edema of the epiglottis, aryepiglottic folds	Bacterial superinfection with inflammation of the tracheal mucosa, copious mucopurulent secretions obstructing the trachea
Organisms	Parainfluenza virus, RSV, adenovirus, influenza	*Haemophilus influenzae*, group A beta-hemolytic streptococcus, *Staphylococcus aureus, Streptococcus pneumoniae*	*S. aureus* or mixed flora
Clinical features	Onset follows URI prodrome consisting of croupy cough, hoarse voice, low-grade fever, inspiratory stridor	Rapid progression of high fever, toxicity, drooling, stridor	Several-day prodrome of croup-like illness progressing to toxicity, inspiratory and expiratory stridor, marked distress
Laboratory and radiographic findings	Steeple sign on PA view of the neck or normal	Thumbprint sign on the lateral aspect of the neck, thickened aryepiglottic folds, loss of air in the vallecula	Normal upper airway structures, shaggy tracheal air column
Management	Steroids uncommon, aerosolized epinephrine	Intubation, antibiotics	Intubation common, antibiotics rare, intubation

PA, Posteroanterior; *RSV,* respiratory syncytial virus; *URI,* upper respiratory infection.

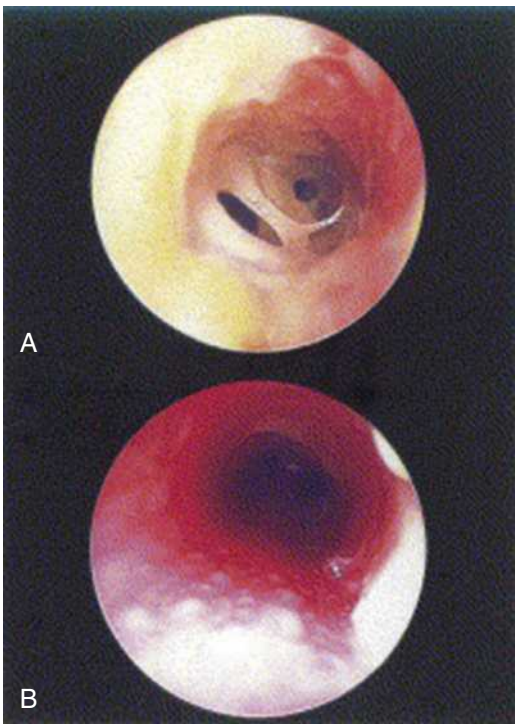

Fig. 162.13 Thick Tracheal Membranes Seen on Rigid Bronchoscopy in Bacterial Tracheitis. (A) Thick adherent membranous secretions. (B), The distal tracheobronchial tree is unremarkable. Foreign Bodies

Airway foreign body

Foundations. Asphyxia from airway obstruction by an airway or esophageal foreign body is a common cause of death in children. Round foods (e.g., peanuts, grapes, raisins, and hot dogs) are especially common. Conformable objects are the most difficult to manage and remove, and balloons, including those made from hospital gloves, are the objects most likely to result in death.

Large objects that lodge in the upper airway and trachea cause dramatic signs of upper airway obstruction (e.g., dyspnea, drooling, stridor, cyanosis) and carry the worst prognosis. Objects that pass through the subglottic space typically will lodge in a bronchus, usually the right mainstem bronchus, or in a more terminal part of the airway. These objects may be "coughed up" again and cause sudden upper airway obstruction.

Clinical features. An upper airway foreign body can cause partial or complete obstruction. Clinical signs of complete obstruction include poor air exchange, inability to speak, ineffective cough, severe distress, and cyanosis. Foreign body aspiration that has settled in the lower airways may have subacute symptoms, such as unilateral wheeze, or may present later (days to years) as recurrent pneumonia. The sensitivity of a witnessed choking episode varies in the literature.

Diagnostic testing. In a child with an aspirated foreign body in the upper airway, there is often no time, nor is it prudent, to perform diagnostic imaging. In a stable patient, a portable lateral neck radiograph and chest radiograph may be obtained as long as the patient is allowed to maintain a position of comfort. Radiographic findings suspicious for foreign body aspiration include radiopaque materials, mediastinal shift, emphysema, and atelectasis. A normal chest radiograph cannot rule out a nonradiopaque foreign body. CT scan and virtual bronchoscopy (a reformatted three-dimensional CT image that generates intraluminal views of the airway and bronchi) may be used to aid diagnosis in equivocal cases. Diagnostic flexible bronchoscopy is indicated with significant clinical suspicion of foreign body aspiration, despite normal imaging.

Management. An acute obstructing upper airway foreign body requires emergent intervention with basic life support maneuvers. Choking infants younger than 1 year should be given five back blows delivered between the shoulder blades, followed by five chest thrusts with the head held below the trunk. Abdominal thrusts should not be performed in infants and may injure abdominal organs. Blind finger sweeps may push the object further into the airway and are no longer recommended.

The Heimlich maneuver is used in conscious children older than 1 year; chest compressions should be delivered to unconscious children. If there is no chest rise with assisted ventilation with a bag-mask device, advanced airway techniques are indicated. Laryngoscopy should be performed to attempt visualization and foreign body removal with pediatric Magill forceps. If the obstructing foreign body cannot be visualized, it may be pushed distally into the right mainstem bronchus with an ETT to ventilate the non-obstructed portion of the lung. Recruiting additional expertise from an otolaryngologist, anesthesiologist, or general surgeon may be needed.

A patient who is adequately oxygenated and is moving air should be initially allowed to maintain a preferred position, continue coughing to clear the obstruction, and breathe spontaneously until operative management can be arranged. Paralysis with rapid sequence induction should be avoided if the patient is maintaining a patent airway; with paralysis, the airway tone may be lost, and a partial obstruction can become complete.

Can't Intubate, Can't Ventilate Scenari. Surgical cricothyrotomy is not generally recommended for infants and young children younger than 8 to 10 years. The anatomy changes with growth (i.e., the larynx is high and cricothyroid membrane small), and it may be difficult to locate pertinent anatomy until a child is of school age.[14] Trachea compressibility also increases complication risk. Needle cricothyrotomy may be performed in children, but significant CO_2 retention limits its effectiveness; it is a temporizing measure used as a bridge to a more definitive, secure airway.

Commercial percutaneous transtracheal ventilation kits are available, but homemade kits can be constructed using tools readily accessible in the ED. A 14- to 18-gauge angiocatheter (the size of the catheter does not affect the rate of turbulent gas flow) is inserted in the cricothyroid membrane and connected to a 3-mL syringe (without the plunger) to a 7.5-mm ETT adaptor (or a 3.0-mm ETT connector directly to the angiocatheter). These homemade kits are rigid and may easily become dislodged. Alternative setups include using IV tubing—attaching IV tubing to the angiocatheter, cutting the tubing, and attaching a 2.5-mm ETT connector—or directly connecting oxygen tubing to the catheter with a Y connector or three-way stopcock. Bag-mask ventilation (recommended in children <5 years) can be performed through the ETT adaptor at 10 to 12 breaths/min to minimize barotrauma by allowing for passive exhalation. Percutaneous transtracheal ventilation (in children ≥5 years) is given at an oxygen flow rate of 1 L/min/year of age with a 1:4 inspiration-to-expiration ratio (I:E). Adults should receive oxygen from the wall source at 15 L/min (50 to 58 psi) and children at a rate of 10 to 12 L/min (25 to 35 psi). Complete airway obstruction does not allow for passive exhalation and necessitates a reduction of bag-mask ventilation rate to five or six breaths/min or an I:E ratio of 1:8 to 10 as a temporizing measure. Complications of needle cricothyrotomy include barotrauma and damage to adjacent structures. See Chapter 156 for further discussion.

CHAPTER 162: QUESTIONS AND ANSWERS

1. Which of the following is the most common cause of upper respiratory obstruction in childhood?

a. Airway foreign body
b. Bacterial tracheitis
c. Croup
d. Epiglottitis

Answer: c. Although all the choices may lead to symptoms of airway obstruction in children, the most common cause of upper airway obstruction is viral croup.

2. A 3-year-old girl presents at 2 AM with complaints of a barky cough, which started abruptly overnight. Vital signs are heart rate, 140 beats/min, respiratory rate, 40 breaths/min, and temperature, 100.1°F (38°C). She has no history of asthma or wheezing. She appears to be in moderate distress and has audible stridor. Indications for admission include which of the following?

a. Low-grade fever
b. Prior history of croup
c. Stridor at rest
d. Severe dehydration

Answer: d. Indications for admission of patients with croup include severe respiratory distress or failure, unusual symptoms (hypoxia and hyperpyrexia), anything but mild dehydration, persistence of stridor at rest after aerosolized epinephrine and steroids, persistence of tachycardia or tachypnea, and complex medical history (e.g., prematurity, pulmonary or cardiac disease).

3. A 5-year-old immunized boy presents with severe stridor at rest, low-grade fever, and nasal congestion. His family reports a barky-sounding cough. After initiating vaporized epinephrine, he appears well and is in no distress. The parents are asking about discharge. Which of the following would be the most appropriate next step in management?

a. Administer dexamethasone, observe the patient for 2 to 3 hours, and discharge if well.
b. Admit the patient for overnight observation.
c. Allow the patient to go home.
d. Allow the patient to go home with a prescription of steroids.

Answer: a. The child has croup and, after being treated with nebulized epinephrine, should be observed for recurrent stridor after 2 hours. If the child is well, is in no respiratory distress, has a good hydration status, and is able to access emergency and follow-up care, he or she can then be safely discharged.

4. What is the ideal head position to assess a pediatric soft tissue radiograph of the neck for upper airway pathology?

a. Extension during inspiration
b. Flexion
c. Flexion during inspiration
d. Neutral

Answer: a. Gentle extension of the head gives the most accurate images, avoiding the artificial soft tissue widening that can be seen in flexion. Inspiration, if possible, allows maximal distention of the pharynx and the best viewing of soft tissue structures defined by an air–soft tissue interface.

5. Which of the following factors is least consistent with the diagnosis of peritonsillar abscess?

a. Muffled, hot potato voice
b. Pain radiating to the ear
c. Patient 3 years of age
d. Patient 13 years old
e. Trismus

CHAPTER 162: QUESTIONS AND ANSWERS—cont'd.

Answer: c. Peritonsillar abscess more commonly occurs in older children and teenagers, whereas retropharyngeal abscess is more common in a younger population. All the other signs or symptoms listed are consistent with peritonsillar abscess, along with deviation of the uvula away from the abscess side.

6. A 3-year-old immunized girl presents after a brief viral illness with progressive dyspnea, ill appearance, and high fever. The child is relatively still, appearing as if she is trying not to cough. Stridor is heard, and she does not respond to croup therapy. You notify the operating room, where the patient undergoes bronchoscopy, with suctioning and airway placement. Culture results are most likely to grow which of the following organisms?

a. *Bacteroides fragilis*
b. *Candida albicans*
c. Parainfluenza
d. *Staphylococcus aureus*
e. *Streptococcus pneumoniae*

Answer: d. The case described is consistent with bacterial tracheitis. Although *Candida,* parainfluenza, and *Streptococcus* have all been reported, *S. aureus* is most common. Broad-spectrum antibiotics are appropriate, with an emphasis on covering *S. aureus*.

Pediatric Lower Airway Obstruction

Richard J. Scarfone and Jeffrey A. Seiden

ASTHMA

KEY CONCEPTS

- No single asthma score has been universally adopted to assess the degree of illness or treatment responses. However, most scores include some combination of respiratory rate, degree of wheezing, inspiratory-to-expiratory ratio, use of accessory muscles, and oxygen saturation.
- Chest x-ray (CXR) is not required for wheezing children, even for those who are febrile, are wheezing for the first time, or require hospitalization. CXR is indicated for those with a history of choking, focal chest findings, extreme distress, subcutaneous emphysema, diagnostic uncertainty relative to respiratory illness, or with clinical findings suggestive of a cardiac etiology.
- Albuterol delivered by metered-dose inhalers with spacers (MDI-S) is as effective as that delivered by nebulizers for children with acute asthma. The mode of delivery is largely chosen on the basis of cost and ability to achieve the goal of three treatments within the first hour of care. Per the 2007 National Heart Lung and Blood Institute guidelines, a high dose (4–12 puffs) of a short-acting beta-agonists (SABAs) metered-dose inhaler (MDI) with a spacer has "equivalent bronchodilation" to nebulized treatment.
- Levalbuterol does not lead to better emergency department (ED) outcomes compared with racemic albuterol. Racemic albuterol, at a substantially lower cost, should remain the drug of choice for children with acute asthma exacerbations.
- Dexamethasone is as effective as prednisone in the ED treatment of acute asthma. Dexamethasone is associated with fewer doses, less vomiting, and greater compliance.
- Continuously nebulized albuterol, corticosteroids, magnesium sulfate, and parenteral SABA are cornerstones of therapy for moderately to severely ill children with asthma.

Foundations

Background and Importance

A recent national survey found that one in 12 children had asthma; however, the prevalence among non-Hispanic black children was 16%.[1] Asthma is associated with significant morbidity, with approximately 17% of children with asthma requiring emergency department (ED) or Urgent Care management and 5% needing to be hospitalized annually[1]

Anatomy, Physiology, and Pathophysiology

Asthma is a lower airway disease marked by bronchoconstriction, mucosal edema, and pulmonary secretions. Upper respiratory infections (URIs) associated with copious rhinorrhea, a common trigger of an asthma exacerbation, may significantly increase airway resistance in young children. Because children have compliant chest walls and horizontally located ribs, their ability to use the thorax to increase tidal volume is limited; thus, ventilation is highly dependent on diaphragmatic movement. Also, as functional residual lung capacity increases with age, minute ventilation is largely rate-dependent in young children and may quickly lead to fatigue. An infant younger than 12 months has an oxygen consumption index that is double that of an adult. Increased airway resistance and a compliant chest wall predispose infants to tachypnea, increased work of breathing, and increased oxygen consumption. As a result, the infant with respiratory distress may rapidly develop hypoxemia, precipitating bradycardia and cardiopulmonary arrest.

Clinical Features

All acutely wheezing children arriving for ED care should be attached to a cardiorespiratory monitor and have oxygen saturation determined by pulse oximetry. For children with hypoxia, supplemental oxygen should be provided while the emergency clinician begins the clinical assessment.

History

To initiate appropriate therapy quickly, based on the degree of illness, a concise history should be obtained upon patient arrival, followed by a physical examination that focuses on the cardiopulmonary system. An abbreviated history should include questions about the child's age, duration and severity of symptoms, recent medication use, and hospitalizations, including the need for intensive care unit (ICU) care or intubation. The parents should be able to relate how the severity of this attack compares with that of previous exacerbations. A history of difficulty sleeping, eating, or speaking suggests a moderate to severe exacerbation. Names, doses, and frequency of asthma medications, as well as preexisting conditions, should be documented.

After starting therapy, a more comprehensive history should include questions about asthma triggers, such as URIs, cigarette smoke, allergies, and exercise. Frequent ED visits or hospitalizations due to asthma may indicate poorly controlled asthma. The impact of asthma on the child's life may be gauged by the monthly frequency of daytime or nighttime symptoms, including cough, as well as missed days of school or restricted activity. A child with persistent asthma marked by frequent symptoms should be receiving daily anti-inflammatory therapy. Family and social histories should focus on asthma, cystic fibrosis, or atopic disease, and on the adequacy of support systems at home.

Physical Examination

The targeted examination includes assessing vital signs, mental status, and cardiopulmonary systems. A child who is anxious, restless, or lethargic may be hypoxic. The oxygen saturation, sometimes referred to as the "fifth vital sign," should be determined soon after ED arrival for any child with respiratory distress, and supplemental oxygen should be provided for values 92% or less. No single asthma score has

TABLE 163.1 Differential Diagnosis of Asthma

Condition	Distinguishing Characteristics
Infectious	
Bronchiolitis	Infant, preceding upper respiratory infection, seasonal, no history of atopy, no family history of asthma
Laryngotracheobronchitis (croup)	Inspiratory stridor, barky cough, fever, response to humidified air or racemic epinephrine
Pneumonia	Focal wheezing, rhonchi, rales, grunting, fever
Tuberculosis	Diffuse adenopathy, weight loss, prolonged fever
Bronchiolitis obliterans	Prolonged cough or chest pain, inhalational exposure to toxin
Anatomic or Congenital	
Gastroesophageal reflux	Frequent emesis, weight loss, aspiration
Cystic fibrosis	Diarrhea, weight loss, chronic cough, salty sweat
Congestive heart failure	Rales, murmur, gallop, hepatosplenomegaly, cardiomegaly, or pulmonary vascular congestion on chest radiograph
Tracheoesophageal fistula	Choking, coughing, cyanosis with feeds
Mediastinal mass	Chest pain, mediastinal density on chest radiograph
Vascular ring	Stridor, cyanosis, apnea, high-pitched brassy cough, dysphagia
Acquired	
Foreign body aspiration	History of choking, toddler, asymmetric pulmonary examination, unilateral hyperinflation on chest radiograph
Anaphylaxis	Abrupt onset, urticarial rash, angioedema, sensation of throat "tightening," history of allergies

been universally adopted to assess the degree of illness or treatment responses. However, most scores include some combination of respiratory rate, degree of wheezing, inspiratory-to-expiratory ratio, use of accessory muscles, and oxygen saturation. These scores can assist in assessing the pretreatment degree of illness and tracking the response to therapy.

Assessing the work of breathing should include a careful inspection of the chest and neck; rarely, an associated pneumomediastinum or pneumothorax will produce subcutaneous air. Severely ill children may have wheezing that is audible without a stethoscope or have no wheezing ("silent chest") due to critically limited aeration. Asymmetric wheezing suggests pneumonia, pneumothorax, or a foreign body. More anxiety-provoking parts of the examination, such as otoscopy, should be delayed until treatment is well underway.

Differential Diagnoses

The differential diagnosis for childhood asthma includes bronchiolitis, laryngotracheobronchitis (croup), pneumonia, cardiac disorders (e.g., myocarditis), and gastroesophageal reflux (Table 163.1).

Bronchiolitis is the disease that is most commonly confused with asthma, and the two are not easily distinguished by examination findings alone. Children with bronchiolitis are typically younger and have symptoms associated with viral illness. Children believed to have bronchiolitis but who have some combination of food allergies, atopic dermatitis, or a strong family history of asthma should receive bronchodilator therapy to determine if their wheezing is reversible. Croup may have a viral or allergic cause and affects children from infancy through early school age. Clinical presentation is marked by an abrupt onset of a harsh barky cough and inspiratory stridor. Symptoms are typically worse at night. Asthma will not be manifested with stridor alone, but a subset of children with croup may present with stridor and wheezing. Children with pneumonia may sometimes present with a component of wheezing, although rales and rhonchi are the usual auscultative findings. Infants and young children with pneumonia may also have a high fever, cough, grunting, nasal flaring, retractions, and an asymmetric lung examination. Children with pulmonary edema secondary to congenital cardiac disease or myocarditis may present with wheezing and rales, often associated with a cardiac murmur and hepatomegaly. A history of weight loss and sweating with feeds may also indicate a cardiac etiology (see Chapter 165).

Diagnostic Testing

Most children with wheezing have asthma or bronchiolitis and do not need imaging or laboratory studies. Performing an arterial blood gas (ABG) analysis is rarely indicated for most children with acute asthma but may be useful among those with severe bronchospasm and signs of respiratory failure despite initial therapy. A high or apparently normal partial pressure of carbon dioxide ($Paco_2$ ≥40 mm Hg) in a child with hypoxia and retractions indicates impaired ventilation and impending respiratory failure. Alternatively, a young child who suddenly appears 'calm' with decreased respiratory effort may be developing hypercarbia and altered mental status from respiratory fatigue; an elevated $Paco_2$ helps differentiate this child from those finally able to rest from improved aeration. Measurement of the peak expiratory flow rate (PEFR) is a means of obtaining an objective assessment of exacerbation severity. However, up to two-thirds of children greater than 5 years are unable to complete PEFR testing during an asthma exacerbation. When feasible, the PEFR should be measured with the child standing and the best of three attempts recorded.

URIs marked by low-grade fever and coughing are common triggers of asthma exacerbations. These signs overlap with those found among children with pneumonia, making it difficult to determine the necessity of obtaining a CXR. No set of predictors has been found that can accurately identify children likely to have radiographic abnormalities. Emergency clinicians frequently obtain a CXR for children in the ED with asthma but rarely are pneumonia or other unsuspected diagnoses discovered, even if the child has never wheezed before.

It should not be routine practice to obtain a CXR for wheezing children, even for those who are febrile, wheezing for the first time, or requiring hospitalization. Performing chest radiography is indicated for those with a history of choking, focal chest findings, extreme distress, subcutaneous emphysema, or diagnostic uncertainty of respiratory versus or suspected cardiac etiology. Reassessment after SABA treatment to evaluate for resolution of focal findings may further decrease the need to obtain a CXR.

Management

Children can be stratified by degree of illness based on the physical examination (Fig. 163.1).

Mild Exacerbation

A mild exacerbation is characterized by alertness, slight tachypnea, expiratory wheezing only, a mildly prolonged expiratory phase, minimal accessory muscle use, and oxygen saturation of greater than 95%. Some children may have 1 or 2 of these features that are more

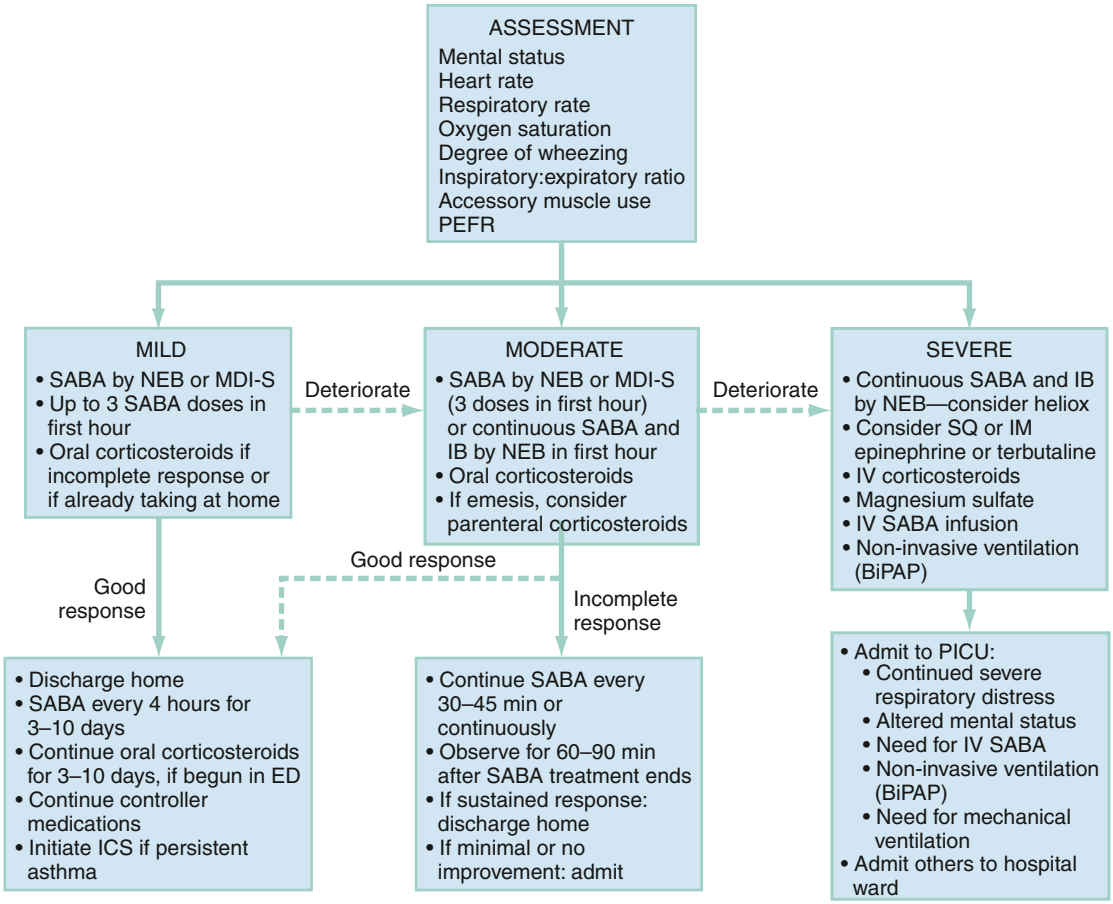

Fig. 163.1 Emergency Department Management of Acute Asthma. *ED,* Emergency department; *IB,* ipratropium bromide; *ICS,* inhaled corticosteroids; *IM,* intramuscular; *MDI-S,* metered-dose inhaler with spacer; *NEB,* nebulizer; *PEFR,* peak expiratory flow rate; *PICU,* pediatric intensive care unit; *SABA,* short-acting β_2-agonist: *SQ,* subcutaneous.

characteristic of a moderate exacerbation, yet still be judged as mildly ill overall. Usually, patients with a mild exacerbation will only require SABA therapy, and the Expert Panel of the National Heart, Lung, and Blood Institute (NHLBI) recommends that it be given every 20 minutes in the first hour of care. Children with mild exacerbations often improve promptly with just one or two SABA treatments and many are managed without corticosteroids (CS). However, CS may be given to mildly ill children who have received home SABA doses prior to presentation or to those who do not respond promptly to SABA therapy (see later, "Moderate Exacerbation").

Racemic albuterol has become the SABA of choice for the treatment of children with acute asthma. Options for the mode of delivery include a small-volume nebulizer (NEB) and metered-dose inhaler (MDI)-S. Most emergency clinicians use NEBs to administer SABA, regardless of illness severity. NEBs provide a passive means of receiving aerosolized medication because precise coordination between respiration and aerosol delivery is not needed; additionally, anticholinergic medication and humidified oxygen may be delivered concurrently. However, medication delivery via NEBs is inefficient, with only about 10% of the drug delivered to the small airways. Also, the administration takes about 10 minutes, increasing respiratory therapy time and costs.

On the other hand, spacers used with an MDI provide a reservoir of medication that is available to be inhaled. Therefore, precise coordination between actuation and inhalation is not needed, and there is no need for breath-holding. After each actuation, children should take five to eight breaths. Drug deposition in the oropharynx and systemic absorption are reduced with the use of a spacer and decreased administration time may result in reduced costs. Face mask–equipped spacers are available for children too young to use the spacer's mouthpiece, although mouthpieces are preferable for older children to decrease nasal filtering of the drug.

Numerous clinical trials and meta-analyses over the past three decades have consistently demonstrated that albuterol delivery by MDI-S is as effective as NEBs among children of all ages and degrees of illness[2]. In some studies, MDI-S use was associated with a greater reduction in wheezing and lower hospitalization rates. The American College of Chest Physicians and American College of Asthma, Allergy, and Immunology have concluded that either NEBs or MDI-S are appropriate for the delivery of SABA in the ED.

Nebulized racemic albuterol should be administered at a dose of 0.15 mg/kg with a maximum dose of 5 mg, while optimal dosing for albuterol administered by MDI-S is not as well defined. Multiple puffs of SABA delivered by MDI-S seem to be well tolerated, even by young children. Children 1 to 4 years of age treated with six puffs of albuterol by MDI-S have been shown to have less tachycardia than those treated with 2.5 mg of albuterol by NEB. Per the 2007 NHLBI guidelines, a high dose (4 to 12 puffs) of a SABA MDI with a spacer has "equivalent bronchodilation" to NEB treatment. We recommend two to eight puffs, depending on weight (Table 163.2).

Another consideration in the use of SABA is the potential role of levalbuterol. Racemic albuterol is an equal mix of the active *R*-albuterol and inactive *S*-albuterol. *R*-Albuterol produces bronchodilation as well

TABLE 163.2 Recommended Doses of Medications for Acute Asthma

Medication	Dosage
Albuterol	0.15 mg/kg/dose (0.03 mL/kg/dose, max, 5 mg)
Continuous albuterol	0.5–1.0 mg/kg/h by nebulization (max, 15 mg/h)
Albuterol by metered-dose inhaler	Dose not well established
• ≤10 kg	2–4 puffs
• 11–19 kg	4–6 puffs
• ≥20 kg	6–8 puffs
Levalbuterol	Half the recommended albuterol doses
Ipratropium bromide	
• ≤20 kg	250 μg/dose
• >20 kg	500 μg/dose
L-Epinephrine (1:1000) or terbutaline (1.0 mg/mL)	0.01 mg/kg (max, 0.5 mg) 0.01 mg/kg (max, 0.25 mg)
IV terbutaline	10 mcg/kg IV over 10 minutes Every 30 minutes, may increase infusion by 0.3 μg/kg/min to max of 5 μg/kg/min
Prednisone	2 mg/kg (max, 60 mg), in ED 1 mg/kg/dose bid (max, 30 mg/dose), home therapy
Dexamethasone	0.3–0.6 mg/kg PO, two or three doses 24 hours apart (max, 8–16 mg/dose)
IV methylprednisolone	1 mg/kg (max, 125 mg)
IV magnesium sulfate	50–75 mg/kg over 20 min (max, 2g)

IM, Intramuscular; *IV,* intravenous; *PO,* by mouth; *SC,* subcutaneous.

as tachycardia and tremors, and *S*-albuterol had been long thought to be inert. However, there is some evidence that *S*-albuterol may increase reactivity to histamine, have proinflammatory effects, and exhibit characteristics of a typical contractile agent. There is also preferential retention of *S*-albuterol in the lungs of healthy volunteers; this may account for diminished effectiveness with frequent dosing. On the other hand, levalbuterol is pure *R*-albuterol without the *S* component. In theory, levalbuterol should be more effective than racemic albuterol at 50% of the dose (same amount of *R*-albuterol) because there are no competing harmful effects from the *S* isomer. However, studies assessing the use of levalbuterol for the treatment of children with acute asthma have not consistently demonstrated this theoretic advantage.

In an early study, the ED use of levalbuterol was associated with a decreased need for hospitalization. Subsequently, other randomized trials comparing the ED use of the two drugs failed to find a levalbuterol benefit and at least one clinical trial failed to demonstrate benefit with continuously nebulized levalbuterol. The cost of levalbuterol is more than 10 times that of racemic albuterol. Until there are more compelling data to demonstrate conclusively that the additional costs of levalbuterol are offset by clinical benefits, racemic albuterol is the drug of choice for children with acute asthma exacerbations.

Children sustaining clinical improvement 60 minutes after the most recent SABA treatment may be discharged; SABA should be weaned over the next 3 to 7 days. If prednisone was administered in the ED, it may be continued as 3 to 5 days of prednisone (1 mg/kg once or twice per day; maximum, 60 mg); however, compliance is not as good as with dexamethasone. Children treated with dexamethasone in the ED should be provided either one or two additional doses to be taken 24 and 48 hours after the ED dose. The recommended dose is 0.3 to 0.6 mg/kg once per day with a maximum of 8 to 16 mg. Children should continue all other asthma controller medications, including inhaled corticosteroids (ICSs).

For those who are not already receiving ICSs, it is unclear if prescribing them at ED discharge leads to improved short-term outcomes, such as fewer ED relapses within 72 hours. Some have found "insufficient evidence that ICS therapy provides additional benefit" when added to systemic corticosteroids at ED discharge. Rather than prescribing ICS to prevent ED relapse, prescribing may be considered to help achieve longer-term symptom relief for patients with persistent disease marked by frequent coughing or wheezing, frequent exacerbations requiring the use of SABA, or recurrent visits to the ED. ICS are safe and well tolerated at recommended doses and may be given concurrently with systemic corticosteroids. In addition to prescribing medications, emergency clinicians should also provide asthma education at discharge. Some EDs provide standardized information to families with a video or DVD while they undergo ED therapy. Descriptions of how to identify and avoid asthma triggers, a written asthma action plan explaining proper steps to take in response to an asthma flare, a review of discharge medications, and instruction on proper MDI-S use should be included. Follow-up asthma care is recommended within 1 to 4 weeks.

Moderate Exacerbation

In general, a moderate exacerbation is characterized by alert tachypneic children who have wheezing throughout expiration, an inspiratory-to-expiratory ratio of 1:2, and significant use of accessory muscles. Typically, the oxygen saturation will be 92% to 95% and the PEFR will be 41% to 70% of personal best. As with children experiencing milder attacks, the cornerstone of therapy is SABA therapy. Other medications include ipratropium bromide and corticosteroids.

Ipratropium bromide, an anticholinergic agent, blocks reflex bronchoconstriction caused by stimulation of airway cholinergic receptors. It is available as an MDI and as an NEB solution for nebulization that may be mixed directly with albuterol. The combination therapy of a SABA with ipratropium bromide has been demonstrated to be more effective than a SABA alone (i.e., lower hospitalization rates and improvements in asthma scores and pulmonary function test results).

The clinical benefits of ipratropium bromide may be delayed for up to 60 minutes. However, it is inexpensive and free of adverse effects because less than 1% is systemically absorbed. Ipratropium bromide should be given to children with moderate to severe exacerbations. Two to three doses may be mixed with three doses of albuterol and delivered continuously by NEB for 1 hour (Table 163.3). This means of administration, although not superior in efficacy to delivery of albuterol and ipratropium bromide by MDI-S, more consistently achieves the goal of three treatments in the first hour of care, as opposed to giving intermittent treatments every 20 minutes. Alternatively, intermittent therapy may be provided for moderately ill children by giving 4 to 8 puffs of ipratropium bromide every 20 minutes in the first hour, along with albuterol via MDI-S.

Moderately ill children who continue with dyspnea or significant work of breathing or poor aeration after the first hour of albuterol and IB therapy need continued albuterol therapy. Children treated with continuously nebulized SABAs have lower rates of hospitalization, greater improvements in PEFR, and similar rates of adverse events compared with those treated intermittently. Additionally, continuous NEB therapy will result in less respiratory therapy, nursing time, and costs, has been shown to be safe, and may benefit the sickest patients the most.

The prompt use of corticosteroids can decrease the need for hospitalization and should be administered early for patients with moderate disease. Although oral prednisone has historically been the corticosteroids of

TABLE 163.3 Short-Acting β_2-Agonists in Acute Asthma.

	Mild	Moderate	Severe
Delivery method	Intermittent NEB or MDI-S	Intermittent by NEB or MDI-S (3 doses in first hour) or continuous by NEB for 1 hour	Consider subcutaneous or intramuscular therapy; continuous by NEB
Comments	Most patients will need one or two treatments; allows MDI-S teaching; no IB needed	Continuous is not superior to MDI-S; easier to adhere to NHLBI guidelines for the first hour of therapy: concurrent IB therapy more easily delivered	Better outcomes in severe asthma

choice in the ED treatment of acute asthma, recent studies demonstrate that oral dexamethasone has equivalent efficacy.[3] Dexamethasone has the advantage of having a substantially longer half-life (36 to 72 hours) than prednisone (18 to 36 hours), permitting a shorter treatment course with less vomiting and greater compliance. At this point, the optimal dose and duration of dexamethasone therapy are being established. Dose ranges from 0.3 to 0.6 mg/kg/dose are commonly used, with maximum doses of 8 to 16 mg[4]. Following the initial ED dose, patients typically receive either one or two additional doses, each spaced apart by 24 hours.

Most children with moderate asthma exacerbation can be managed without the insertion of an IV line. Intramuscular therapy is a reasonable option for children who vomit orally administered corticosteroids. The use of ICS, in addition to systemic corticosteroids, for the ED treatment of acute asthma is an area of ongoing research; at this point, we do not recommend its routine use.

A suggested approach to the management of children with moderately acute asthma is summarized in Fig. 163.1. After 1 hour of therapy, a clinical reassessment should be made; evaluation at this time is more accurate than the assessment at ED arrival in predicting the need for hospitalization. Those who worsen despite the first hour of therapy are likely to need continuously nebulized albuterol and hospitalization. In contrast, children with markedly decreased wheezing and work of breathing with improved aeration may be monitored without SABAs to assess for clinical deterioration. The disposition decision can then be made after the child has been observed for 90 to 120 minutes from their last SABA dose. The disposition decision should take into consideration the frequency of prior hospitalizations and ED visits and issues regarding compliance and support systems. ED discharge medications and education are the same as outlined for those with mild exacerbations.

There is a third group of children who are improved after the first hour of therapy but are not well enough to be discharged home. In a study of children treated with prednisone and 2 hours of SABA therapy who met criteria for admission at the 2-hour point, less than 50% were hospitalized when SABA therapy was continued for an additional 2 hours, and none returned to the ED within 48 hours of discharge. To avoid unnecessary hospitalizations, we recommend observing patients who do not otherwise decline for a total of 3 to 4 hours from ED arrival prior to making the disposition decision.

Severe Exacerbation

A severe exacerbation is characterized by restlessness or lethargy, extreme tachypnea and tachycardia, audible wheezing, inspiratory-to-expiratory ratio exceeding 1:2, significant use of accessory muscles, and oxygen saturation less than 92%. Some older children with a severe exacerbation may have bradypnea due to a prolonged expiratory phase, and auscultated wheezing may be absent with markedly decreased aeration. The PEFR will typically be less than 40% predicted, although most children will be too ill to use a peak flow meter.

Fig. 163.1 outlines the approach to the management of severely ill children. They should be attached to a cardiorespiratory monitor and blood pressure cuff, with continuous monitoring of oxygen saturation by a pulse oximeter. As with moderately ill children, supplemental oxygen and continuously nebulized albuterol and ipratropium bromide should be provided soon after arrival. Nearly all severely ill children will require more prolonged therapy with continuously nebulized albuterol, as outlined above. To achieve an oxygen saturation of 92% or greater, it may be necessary to use a non-rebreathing facemask. Severely ill children may be too sick to tolerate oral medications and may need IV medications. A dose of methylprednisolone or dexamethasone should be given as soon as an IV line is established.

For children with very poor inspiratory flow, nebulized SABAs may not be effectively delivered to the smallest airways; short inspiratory time, low inspiratory pressures, and a prolonged exhalation phase will impair the delivery of inhaled medications. In these cases, subcutaneous or intramuscular terbutaline or epinephrine may be considered. Terbutaline has the advantage of being a more selective agent with fewer side effects, such as tremors, vomiting, or palpitations. This treatment can be of particular benefit for very ill and anxious young children who are uncooperative with the inhalation treatments. There are no data to suggest that one mode of administration is superior to the other, although intramuscular epinephrine therapy is recommended for children with bronchospasm due to anaphylaxis. If it is more readily available, an epinephrine autoinjector is effective for this subset of patients. Subcutaneous or intramuscular therapy may be repeated every 10 to 15 minutes, as needed, in extreme cases. If IV access is already established, instead of the subcutaneous or intramuscular therapy outlined above, the patient may be treated with a bolus of 10 μg/kg of IV terbutaline.

Meta-analyses have determined that the use of magnesium sulfate results in improved outcomes for adults and children. In particular, children with a suboptimal response to initial SABA therapy who are subsequently treated with magnesium have significantly greater improvements in pulmonary function compared with those treated with placebo. In contrast, magnesium has not been found to be efficacious as a component of initial therapy for children with moderate to severe exacerbation when given prior to judging the response to early albuterol therapy.

Magnesium is inexpensive and has minimal adverse effects. Hypotension may be minimized by slowly infusing the dose over 20 minutes. Magnesium (50 to 75 mg/kg over 20 minutes; maximum, 2 g) should be given to moderately ill patients who have a suboptimal response to SABAs, IB, and CS, as well as for all severely ill children.

There are insufficient data to make recommendations for the use of continuously infused IV SABAs. Potential adverse effects from use of continuously infused IV SABAs are substantial and include dysrhythmias, hypertension, and hypokalemia. Continuously infused IV SABAs should not be used except for impending respiratory failure, a situation in which the risk-benefit ratio shifts toward favoring their use.

Heliox is a low-density mixture of helium and oxygen that results in less turbulent flow through narrowed airways. Theoretically, heliox may decrease the work of breathing, resulting in less respiratory muscle fatigue and a lower likelihood of ventilatory failure. Heliox has not been found

beneficial in all asthma exacerbations, but it may be considered for severely ill children who are not responding to more conventional therapy.

Although there is little in the literature to support the use of noninvasive ventilation (NIV), such as bilevel positive airway pressure (BiPAP), in the management of severe asthma in children, clinicians have employed it with good success to avoid the need for mechanical ventilation. Theoretically, the positive pressure of NIV can ease inhalation and decrease the alveolar collapse associated with exhalation. For a child who remains severely ill despite the previously outlined treatment, the risk-benefit ratio favors the use of BiPAP. The need for mechanical ventilation of the severely ill patient should take into account the entire clinical picture, including illness severity, response to therapy, and ABG results. However, the ABG results should not be used solely to make this decision. The child with an initial pH of 7.10 and a $Paco_2$ of 55 mm Hg who shows marked improvement with IV SABA therapy may not require ventilatory assistance, whereas the child with a pH of 7.18 and $Paco_2$ of 50 mm Hg who appears fatigued and is not responding to therapy will likely need mechanical support. Ketamine is a bronchodilator and is the drug of choice for sedation and analgesia of the asthmatic child who requires intubation.

Since mechanical ventilation can result in air trapping and barotrauma, enough expiratory time should be allowed for air exit from the lungs. Permissive hypercapnia describes one strategy to prevent barotrauma; it minimizes tidal volumes and respiratory rates to decrease peak inspiratory pressures.

BRONCHIOLITIS

KEY CONCEPTS

- An infant younger than 12 months has an oxygen consumption index double that of an adult and with bronchospasm, may rapidly develop hypoxemia, bradycardia, and cardiopulmonary arrest.
- Bronchiolitis is a clinical diagnosis based on a history of prodromal upper respiratory infection symptoms in an infant or young child, followed by findings on physical examination of wheezing (often with shifting crackles) and increased work of breathing. The value of diagnostic imaging and laboratory evaluation is limited, and these measures should not be used routinely.
- All febrile infants in the first month of life should undergo testing and evaluation for serious bacterial infection and be empirically treated with antibiotics, regardless of respiratory syncytial virus (RSV) status or presence of clinical bronchiolitis.
- A urinalysis and culture should be performed for febrile infants between 1 and 3 months of age who are known to be RSV-positive or have clinical bronchiolitis. The decision to obtain blood or cerebrospinal fluid cultures and give empirical antibiotics should be made on an individual basis (see Chapter 161).
- The management of infants with bronchiolitis focuses largely on supportive measures, and most patients able to tolerate oral hydration can be managed as outpatients. There are currently no consistently effective pharmacologic therapies for bronchiolitis (including SABA, corticosteroids, or antibiotics).
- Despite reports that more than 50% of infants may be prescribed corticosteroids when diagnosed with bronchiolitis, well-designed controlled trials have demonstrated no benefit for their use in rates of admission, clinical scores, or any other clinical outcomes.
- High-flow nasal cannula (HFNC) and continuous positive airway pressure (CPAP) may have some utility in preventing the need for endotracheal intubation, but the evidence is limited and so the use of these modalities should be reserved only for patients with moderate to severe bronchiolitis.
- Disposition from the ED for bronchiolitis depends on the assessment of multiple risk factors, including young age, prematurity, significant hypoxemia, and severe tachypnea, which may predict a more severe clinical course.

Foundations

Bronchiolitis is an acute infectious disease that results in inflammation of the small airways in children younger than 2 years of age. This process is manifested clinically as wheezing and crackles and increased work of breathing, along with the typical signs and symptoms of a URI. Nearly all children are affected by the viruses that cause bronchiolitis at least once during their first 2 years of life, but it is more common for infants younger than 12 months to manifest clinical signs of bronchiolitis.

Bronchiolitis is a seasonal disease, with most cases occurring between November and April in temperate climates. Bronchiolitis is rarely fatal, and severe cases are associated with a number of risk factors, including low birth weight, prematurity, chronic lung disease, and congenital heart disease. Many viruses are implicated as the underlying cause of bronchiolitis, but respiratory syncytial virus (RSV) is estimated to cause up to 70% of cases in previously healthy children. Other viruses commonly isolated are parainfluenza, human metapneumovirus, influenza, adenovirus, bocavirus, and rhinovirus.

Most respiratory viruses that cause bronchiolitis in children are transmitted from one host to another by fomites spread from hand to nose or by droplets produced by sneezing or coughing of respiratory secretions. Shedding of the virus often begins before the onset of significant clinical symptoms and can continue for 2 to 3 weeks in an immunocompetent infant. The typical incubation period is 2 to 8 days from the time of initial contact.

Anatomy, Physiology, and Pathophysiology

In an infected patient, viral replication often begins in the epithelial cells of the upper airway before spreading to the mucosal surfaces of the lower respiratory tract. The infected epithelial cells are generally destroyed by lysis or apoptosis, which results in the desquamation of these cells and the release of host inflammatory mediators. Affected lungs demonstrate epithelial cell necrosis, monocytic inflammation and edema of the peribronchial tissues, and mucus and fibrin plugging of the distal airways on histologic examination. These findings translate into the clinical findings of wheezing and lower airway obstruction in an infant with bronchiolitis. Younger infants, whose distal airways are of smaller caliber and who lack active immunity to most respiratory viruses, are prone to more severe clinical symptoms. Severe lower airway obstruction leads to air trapping and atelectasis, resulting in mismatched ventilation and perfusion and hypoxemia. In addition, younger infants are at increased risk for fatigue, leading to hypercarbia and respiratory failure.

Clinical Features

Infants with bronchiolitis are typically younger than 12 months and present during the winter months. The first symptoms are generally those of a URI, such as nasal congestion and copious rhinorrhea. This is followed within a few days by a tight cough, often associated with difficulty in feeding. Some parents will report audible wheezing as well. Approximately one-third of patients admitted with bronchiolitis will have a fever. Very young infants may present with a history of apnea, which may precede the onset of typical symptoms of respiratory infection. The emergency clinician should ascertain information about the infant's hydration status, including the amount and frequency of oral intake, urine output, vomiting, and diarrhea.

Comorbidities, such as congenital heart disease, chronic lung disease, and prematurity, can have a significant impact on the clinical course of bronchiolitis. A past history or family history of wheezing or atopy may make the diagnosis of asthma more likely, particularly in the older infant; daycare attendance and household contacts with respiratory symptoms favor a diagnosis of bronchiolitis.

TABLE 163.4 Suggested Bronchiolitis Assessment Tool

	DEGREE OF BRONCHIOLITIS		
Parameter	**Mild**	**Moderate**	**Severe**
Feeding	Normal	Less	Poor
Sao_2 in room air	≥95%	92%–94%	<92%
Respiratory rate (breaths/min)	<60	60%–70%	>70
Retractions	None or minimal	Intercostal	Substernal
Accessory muscle use	None	None	Neck or abdominal
Wheeze	None or minimal	Moderate expiratory	Severe inspiratory-expiratory; audible without a stethoscope
Air exchange	Good, equal breath sounds	Localized, decreased breath sounds	Multiple areas of decreased breath sounds

Common vital sign abnormalities include fever, tachycardia, tachypnea, and hypoxia. The oxygen saturation (Sao_2) of any moderately or severely ill infant should be obtained soon after ED arrival as an adjunct to the physical examination. With the use of pulse oximetry, an ABG analysis is generally unnecessary to assess a patient's oxygenation. Thus, carrying out ABG analysis should be reserved for those with severe disease and impending respiratory failure to measure the extent of hypercarbia and respiratory acidosis.

Nasal flaring and retractions are visible signs of respiratory distress. Lung auscultation often reveals decreased air movement, rales, rhonchi, wheezing, and a prolonged expiratory phase. Irritability or lethargy, particularly in young infants, indicates a more severe disease. Children can be stratified into mild, moderate, and severe categories based on the physical examination findings (Table 163.4). The combination of poor feeding and increased insensible fluid losses often has an impact on an infant's hydration status. A careful assessment of the anterior fontanel, mucous membranes, capillary refill time, and skin turgor can help identify dehydration.

The worst phase of the illness generally occurs in the first few days and children admitted for bronchiolitis have a median length of hospital stay of 2 to 3 days. However, the entire course of illness can last much longer, with a median duration of 12 days. Coughing and noisy breathing, in particular, can last for more than 4 weeks.

Acute bacterial otitis media is the most common associated illness, with a prevalence of up to 60%. The bacterial pathogens are similar to those recovered in other children with acute otitis media and should be treated accordingly. Other concurrent bacterial infections are rare.

Young infants with fever and bronchiolitis present a unique dilemma for the emergency clinician. The rate of serious bacterial infections (SBIs), defined as UTI, bacteremia, bacterial meningitis, or bacterial enteritis, among all febrile infants younger than 8 weeks is as high as 12%. However, in infants with documented RSV infection or clinical bronchiolitis at the time of ED presentation, the incidence of an SBI is substantially lower. Due to their particularly high level of SBI risk, all febrile infants in the first month of life should undergo a complete laboratory evaluation for SBI and be empirically treated with antibiotics, regardless of RSV status or presence of clinical bronchiolitis. For infants between 1 and 3 months of age who are known to be RSV-positive or have clinical bronchiolitis, we recommend catheterized urinalysis and culture for rectal temperatures above 38°C (100.4°F), since nearly all concomitant SBIs in this age group are UTIs. Urine testing should also be considered for febrile infants with bronchiolitis who are older than 3 months of age, particularly for those with high-risk features for a UTI: temperatures over 39°C (102.2°F), fever for greater than 24 hours, females, and nonblack race.[5] Additional testing to obtain culture specimens of cerebrospinal fluid and blood may be done selectively. Assuming a normal urinalysis and no concern for bacteremia or meningitis, these infants will not typically require empiric antibiotic therapy for presumed SBIs; decisions to treat with antibiotics should be made on an individual basis, considering the degree of ill appearance and comorbidities.

Apnea is commonly reported in young infants with bronchiolitis, especially among those who are hospitalized. Of admitted patients, nearly 5% will have apnea during the hospital stay. Risk factors for the development of in-hospital apnea include post-menstrual age ≤43 weeks, low birth weight, and a history of apnea reported by the caregiver.[6] The absence of all these risk factors has a high negative predictive value for the development of in-hospital apnea.

Differential Diagnoses

Asthma is the condition that has the most clinical overlap with bronchiolitis. Physical examination findings alone cannot often distinguish the two. Younger age, presentation during the winter months, antecedent URI symptoms, and absence of a prior or family history of atopic disease and wheezing suggest bronchiolitis as the cause of wheezing in an individual patient. Some infants will have clinical features consistent with both conditions. For example, a 12-month-old may present in July with a URI and wheezing for the first time. For this child, a clinician may choose to initiate SABA therapy in the ED but continue it only if the child has a favorable response. Conditions that should be differentiated from bronchiolitis are summarized in Table 163.1.

Diagnostic Testing

Bronchiolitis should be diagnosed primarily on the basis of history and physical examination findings. In general, expensive viral diagnostic testing is not warranted for the majority of patients, although confirmation of a viral cause of the illness may eliminate the need for further laboratory evaluation in young infants with fever. (See Chapter 161 for a comprehensive overview of recommendations for pediatric fever.)

There is tremendous variability in the use of diagnostic imaging, with some centers reporting that chest radiographs are obtained for more than 70% of infants hospitalized with bronchiolitis. In children with clinical findings typical for bronchiolitis, however, radiographic imaging is rarely helpful. Hyperinflation, atelectasis, and peribronchial cuffing are the radiography findings most commonly associated with bronchiolitis. In ambulatory patients with acute lower respiratory infections, obtaining a chest radiograph does not affect the clinical outcome but has been associated with increased use of unnecessary antibiotics. Furthermore, the chance of identifying an alternative diagnosis from a chest x-ray is less than 1%. Diagnostic imaging may be helpful in patients with severe distress, significant hypoxia, or an atypical presentation. We agree with the clinical practice guideline published by the American Academy of Pediatrics in 2014 that "when clinicians diagnose bronchiolitis on the basis of history and physical examination, radiographic or laboratory studies should not be obtained routinely."[7]

Management

Whereas the diagnosis of bronchiolitis is fairly straightforward, the management of children with the disease often presents emergency clinicians with confusing and controversial dilemmas. The literature

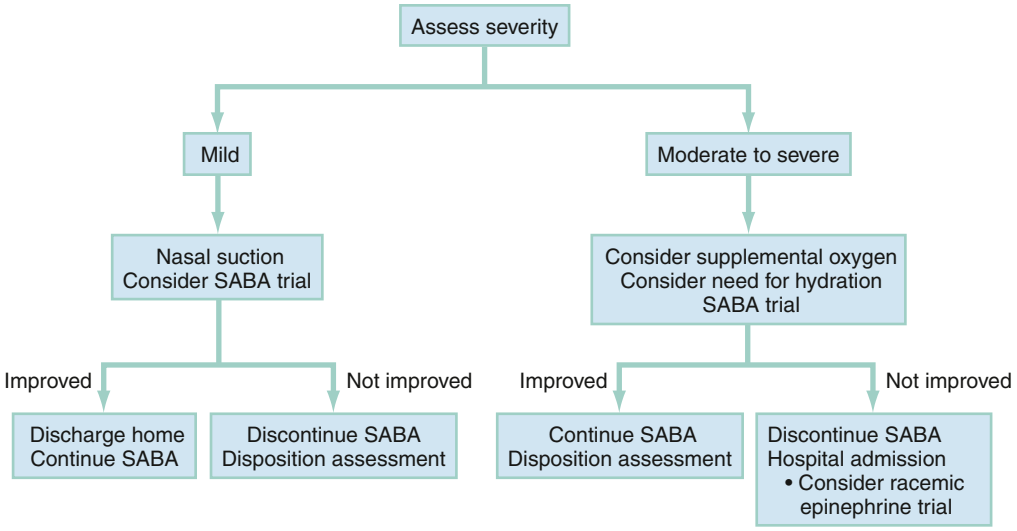

Fig. 163.2 Emergency Department Management of Bronchiolitis. *SABA,* Short-acting β_2-agonist.

is often contradictory, making it difficult to reach a consensus. As a result, there is wide practice variation in the management of bronchiolitis. However, it is clear that a consistent, evidence-based approach to this disease can lead to more efficient and effective care. Supportive care, such as nasal suctioning, providing hydration and supplemental oxygen, is the cornerstone of therapy for affected children A management strategy, stratified by the patient's initial degree of illness, is outlined in Fig. 163.2.

SABAs are the treatment of choice for children with wheezing due to asthma. However, the evidence supporting their use in wheezing caused by bronchiolitis is considerably less favorable. Treatment with SABAs has no significant effect on rates or duration of hospitalization. Conversely, adverse effects such as tachycardia, decreased oxygen saturation, flushing, and hyperactivity occur more frequently in children treated with SABAs. Thus, we do not recommend the routine use of SABAs for bronchiolitis; instead, we recommend a trial of such medications to determine if a patient has a beneficial clinical response *only* if it is unclear whether the patient has asthma or bronchiolitis.

Similar controversy exists with respect to the use of racemic epinephrine in the treatment of bronchiolitis. We recommend that a trial of nebulized epinephrine be considered for a select group of infants with moderate to severe distress who might otherwise require more invasive interventions (e.g., endotracheal intubation) secondary to disease severity. As with SABAs, nebulized epinephrine should be continued only for those patients who demonstrate a clinical benefit. There is currently no sufficient evidence to recommend the use of other bronchodilators, such as anticholinergic agents, for young children with wheezing and suspected bronchiolitis.

Many of the symptoms of bronchiolitis are a result of increased and thickened respiratory secretions. A great deal of literature supports the use of nebulized hypertonic saline in the treatment of cystic fibrosis, in which clearance of thickened secretions is vital. Although there is not yet enough evidence to recommend the routine use of nebulized hypertonic saline in the ED for bronchiolitis, several studies have suggested that it is a safe medication that may reduce the length of stay for some hospitalized children.

Systemic corticosteroids are a well-established and effective treatment of wheezing due to acute asthma. Despite reports that more than 50% of infants may be prescribed corticosteroids when they are diagnosed with bronchiolitis, well-designed controlled trials have demonstrated no benefit for their use in terms of rate of admission, clinical score, or any other outcome. Thus, our recommendation is that emergency clinicians not use corticosteroids for the treatment of bronchiolitis.

Whereas infants with severe bronchiolitis, who require intensive care and mechanical ventilation, frequently have concurrent or secondary bacterial infections, this is an uncommon complication for most children. There is no evidence for the routine use of antibiotics for bronchiolitis, and they should be reserved for patients with identified bacterial infections.

High-flow nasal cannula (HFNC) is a treatment modality that utilizes heated and humidified air flow with FiO_2 ranging from 21% to 100% to deliver variable degrees of positive airway pressure. By increasing the intraluminal diameter of airways, HFNC can stabilize unsupported airways and relieve air trapping and hyperexpansion. In addition, HFNC can improve alveolar gas exchange by increasing the transpulmonary pressure gradient. Finally, the delivery of heated and humidified air decreases the metabolic demand on the patient. While a few small studies suggest that non-invasive positive pressure ventilation (e.g., CPAP) may be helpful in avoiding endotracheal intubation in severe disease, a Cochrane meta-analysis failed to find sufficient evidence for its use in children with bronchiolitis.[8] A randomized trial of HFNC vs. standard oxygen therapy demonstrated that patients treated with HFNC had fewer escalations of care due to treatment failure.[9] However, the definition of treatment failure in this study is controversial and not widely accepted. A meta-analysis of the available literature regarding HFNC in bronchiolitis concluded that there is not sufficient evidence to show significant benefit from HFNC when compared with standard oxygen therapy or nasal CPAP.[10] While awaiting results from larger, well-designed clinical trials, we believe the risk/benefit ratio favors utilizing HFNC and other forms of non-invasive positive pressure ventilation for patients with moderate to severe disease and judging the response by assessing rate and work of breathing.

Prophylaxis

Although emergency clinicians generally do not have a role in the administration of preventive medications, they should be aware that selected infants will be receiving prophylactic management. Palivizumab (Synagis) consists of monoclonal antibodies against RSV. Whereas RSV-specific immune globulin is not effective for treating the acute disease process, palivizumab is effective in reducing hospitalization rates for RSV in certain high-risk populations; it is recommended for most children

younger than 24 months with chronic lung disease, congenital heart disease, or prematurity and is administered as a monthly intramuscular injection during the high-prevalence months. The emergency clinician should be aware that although preventive treatment has been initiated, treated infants with signs of bronchiolitis may still have RSV infections.

Disposition

Because bronchiolitis is a dynamic disease, evaluations at a single point in time may not be sufficient to estimate its severity fully; thus, serial examinations are necessary. A number of demographic and clinical features have been associated with a more severe clinical course. These factors include age younger than 12 weeks, history of prematurity, ill appearance, hypoxemia (Sao_2 <95%), tachypnea (>70 breaths/min), and significant atelectasis on the chest radiograph (when obtained). In addition to younger age and prematurity, a history of hemodynamically significant congenital heart disease, chronic lung disease, and immunocompromised state has been associated with higher morbidity and mortality among inpatients.

Ultimately, the emergency clinician should assess more than just the child's degree of respiratory distress. Patients should be admitted if they are unable to maintain oral hydration due to respiratory symptoms, difficulty with feeds due to increased work of breathing, or copious nasal secretions requiring frequent deep suctioning. The family or caregiver should be able to continue supportive measures at home and have access to medical care. Discharge instructions should include 24-hour follow-up with a primary care provider or emergency clinician for reevaluation. For the small subset of children who are treated with and had a sustained clinical improvement to SABA therapy, this treatment should be continued at home every 4 hours, as needed. Although home oxygen therapy for selected patients with mild to moderate disease has demonstrated success in reducing inpatient hospitalization, primarily in high-altitude conditions, this practice requires careful coordination of care and resources, which may not be feasible in all practice settings. Furthermore, its application to children at sea level is still unclear and thus is not recommended. Parents should be instructed to seek immediate medical care for signs of worsening respiratory distress, including poor feeding, retractions, increased tachypnea, lethargy, and irritability.

CHAPTER 163: QUESTIONS AND ANSWERS

1. A 19-month-old girl with a history of asthma presents with severe respiratory distress marked by wheezing, tachypnea, deep retractions, and an oxygen saturation of 92% in room air. She fails to improve 10 minutes after nebulized short-acting β_2-agonist (SABA) therapy and repeatedly tries to pull off her face mask. Which strategy is likely to produce the most rapid clinical benefits in this setting?

a. Administering IM terbutaline
b. Administering IV methylprednisolone
c. Administering the SABA via metered-dose inhaler (MDI) instead of by nebulization
d. Doubling the dose of SABA in the nebulizer reservoir
e. Taking off her face mask and holding it close to her face to reduce her agitation

Answer: a. This patient's degree of bronchospasm and lack of cooperation makes it difficult to deliver aerosolized medication effectively. In this setting, IM terbutaline is most likely to result in rapid bronchodilation, making subsequent aerosolized therapy more effective.

2. A 6-month-old male infant presents to the ED with his father, who reports that the patient has been wheezing. His vital signs are a temperature of 39.7°C, respiratory rate 62 breaths/min, and oxygen saturation of 90%. On examination, you find diffuse wheezing and copious nasal secretions. While in the ED, the patient does not have a wet diaper; his father reports that he has had decreased oral intake for the past 2 days. Which of the following findings with bronchiolitis is not associated with the need for admission?

a. Age
b. Decreased oral intake
c. Oxygen saturation
d. Respiratory rate
e. Temperature

Answer: a. Patients often in need of admission for bronchiolitis include those with respiratory rates more than 70 breaths/min, O_2 saturation of 95% or less, age younger than 3 months, and poor feeding.

3. Which of the following side effects are seen with the use of intravenous magnesium in the treatment of asthma in children?

a. Change in serum pH
b. Development of a prolonged QT interval on the electrocardiogram
c. Hypercalcemia
d. Hyperkalemia
e. Hypotension

Answer: e. Most patients who receive a magnesium infusion at the recommended dose will experience a clinically insignificant decrease in blood pressure. This may be minimized by infusing the medication over 20 minutes and by concurrently administering normal saline solution.

4. You are about to treat a child with acute asthma with albuterol. Which of the following factors is most important when considering the method of aerosolized drug delivery?

a. About 20% to 30% of nebulized drug reaches the alveoli.
b. Children receiving β-agonists by nebulizer (NEB) have similar outcomes compared with those using a metered-dose inhaler (MDI-S).
c. Children weighing >20 kg should receive a maximum of four puffs of albuterol via MDI-S.
d. MDI-S therapy is more costly than NEB therapy.
e. The use of MDI-S for acute asthma is not supported by national guidelines.

Answer: b. Clinical trials and systematic reviews have repeatedly shown these two forms of therapy to be equivalent. With NEB treatment, less than 10% of nebulized drug reaches the alveoli. A recommended MDI-S dose for older children is eight puffs. Most studies demonstrate that MDI-S therapy is more cost-effective because of a slightly reduced need for hospitalization. National guidelines support the use of MDI-S to deliver albuterol to children with acute asthma.

5. A 7-month-old male infant was diagnosed 2 days ago with bronchiolitis. He continues to have wheezing and increased work of breathing, prompting his parents to bring him into the ED because of a new-onset fever. Which of the following is the most likely secondary bacterial infection in this infant with bronchiolitis?

a. Pneumonia
b. Acute otitis media
c. Meningitis
d. Urinary tract infection

Answer: b. Bacterial acute otitis media (AOM) is the most common condition associated with bronchiolitis, with a prevalence of up to 60%. The bacterial pathogens are similar to those recovered in other children with AOM; thus, it should be treated according to standard recommendations. Other concurrent bacterial infections are rare.

Pediatric Lung Disease

Eric R. Schmitt

KEY CONCEPTS

- Determining the causative agent of pneumonia by clinical presentation and radiographic findings is not reliable; empirical treatment is based on guideline recommendations and likely pathogens.
- Causative agents vary by age; viral agents predominate, especially in younger children, and *Streptococcus pneumonia* is the leading bacterial cause outside of the neonatal period.
- Infants and younger children with pneumonia may have subtle or nonspecific symptoms and signs on presentation, and fever may be the only sign of disease.
- First line therapy for the treatment of bacterial pneumonia in children is amoxicillin for an outpatient and ceftriaxone or ampicillin for an inpatient.
- Pertussis should be considered in a young infant with a staccato cough or episodes of cyanosis.
- In patients with cystic fibrosis, defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, which leads to an increased likelihood for pneumonia, especially that caused by *Pseudomonas aeruginosa.*
- Cystic fibrosis may respond favorably to bronchodilator therapy and mucolytics, such as inhaled *N*-acetylcysteine.
- Patients with bronchopulmonary dysplasia have increased airway resistance, decreased lung compliance, and obstructive lung disease; reactive airway disease and pneumonia are common in these patients.

SPECIFIC DISORDERS

Pneumonia

Foundations

Although upper respiratory tract infections are more common, children frequently develop lower respiratory tract infections, most notably pneumonia and bronchiolitis. Bronchiolitis (see Chapter 163– Pediatric Lower Airway Obstruction) is primarily seen in children younger than 2 years old and manifests as wheezing and congestion due to a viral infection. Pneumonia is an inflammation of the lung tissue that is most often due to an infection but occasionally may follow a noninfectious insult. The diagnosis of pneumonia is made by clinical signs and symptoms and is often aided by an abnormal chest radiograph demonstrating pulmonary infiltrates (Fig. 164.1).[1] The clinical presentation of pneumonia is variable, ranging from a mild illness to life-threatening disease. A specific organism may be suggested by clinical and radiographic findings, but determination of a precise causative agent is not always possible given the limitations of diagnostic testing, nor is it critical in an emergency setting, as initial treatment is empiric. Infection rates for pneumonia in children vary inversely with age, averaging 40/1000 in preschool-age children and decreasing gradually to 7/1000 in 12- to 15-year-olds.[2] Most deaths from pneumonia result from bacterial infections.

The causative organisms vary with the age of the child. Overall, viral agents cause up to 90% of all pneumonias and are more common in younger children.[3] Bacteria predominate in neonates but become less frequent in toddlers and older children. Outside the neonatal period, the incidence of bacterial agents is stable throughout different age groups. *Chlamydia trachomatis* is a unique cause of pneumonia in infants 3 to 19 weeks of age. *Bordetella pertussis* classically occurs in infants younger than 1 year but may occur in older children and adolescents. *Mycoplasma pneumoniae* is one of the most common causes of pneumonia among children older than 5 years but may also be seen in younger children.[3] *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* is also seen more often in children older than 5 years but may cause infection in younger children.

Among bacteria, group B streptococci and gram-negative bacilli predominate in neonates. Although rare, *Ureaplasma urealyticum* and *Listeria monocytogenes* may cause illness in infants younger than 2 months. *Streptococcus pneumoniae* is the leading bacterial cause of pneumonia in all age groups beyond the newborn period, whereas *Staphylococcus aureus* and *Haemophilus influenzae* are less common causative agents. A vaccine against *H. influenzae* type b first became available in 1985, and incidence of disease has decreased markedly with widespread immunization of infants and young children. In 2010, the 13-valent pneumococcal vaccine (Prevnar 13, Wyeth Pharmaceuticals, NY) replaced the heptavalent pneumococcal conjugate vaccine Prevnar (Wyeth). Prevnar 13 is recommended for the primary series at 2, 4, and 6 months of age, with a fourth booster dose given at 12 to 15 months of age. Vaccination is highly efficacious, with 85% protection against serotype-specific cases of pneumococcal pneumonia, decrease in carriage rates of the included serotypes in daycare settings, and even some protection against viral pneumonia (possibly due to frequent concomitant infection of viral pneumonia with pneumococcal infection).[2,4,5]

Less common bacterial agents include group A streptococci, *Neisseria meningitidis,* and anaerobic bacteria (usually in the setting of aspiration pneumonia). Unusual causes of pneumonia include *Pseudomonas aeruginosa, Legionella pneumophila, Pneumocystis jiroveci,* and rickettsial infections. The incidence of *Mycobacterium tuberculosis* has been increasing in the United States, particularly in urban and low-income areas and among non-White racial or ethnic groups. Infants and adolescents are at highest risk in the United States.[6] Respiratory syncytial virus (RSV) and parainfluenza are the most frequent viral agents in infants younger than 1 year.[3] Viruses that may be responsible for neonatal pneumonia include rubella, cytomegalovirus (CMV), and herpes simplex virus. Other viral agents include influenza, adenovirus, rhinovirus, enterovirus, measles, varicella, and Epstein-Barr virus. In addition, immunocompromised hosts are susceptible to mixed and opportunistic infections, including bacterial, viral (CMV, varicella), protozoan (*P. jiroveci*), and fungal disease (*Coccidioidomycosis*, etc.).

Fig. 164.1 Radiograph showing a right upper lobe consolidation with air bronchograms in a 13-year-old. (Courtesy Dr. Eric R. Schmitt.)

The lung is protected from infection by a variety of local and systemic immune mechanisms. Passively acquired maternal antibodies are important in protection against *S. pneumoniae* and *H. influenzae* infections during the first few months of life. Children with altered protective mechanisms are at increased risk for development of pneumonia; this includes children with congenital anatomic abnormalities (e.g., cleft palate, tracheoesophageal fistulas, pulmonary sequestration, congenital cystic adenomatoid malformation), immune deficiencies (e.g., congenital, acquired, medication induced), neurologic alterations that predispose to aspiration (e.g. coma, seizures, cerebral palsy, general anesthesia), and alterations in quality of secreted mucus (cystic fibrosis [CF]).

Bacterial pneumonia and mycoplasma infections are usually transmitted person to person by droplet aspiration. Asymptomatic upper airway colonization often occurs in children and may spread infection to other children. Much less commonly, bacterial pneumonia may result from hematogenous spread from a distant focus or during primary bacteremia. Viral agents that cause pneumonia proliferate in the upper respiratory tract and spread contiguously to involve the lower respiratory tract. Viruses such as varicella, CMV, herpes simplex, Epstein-Barr, measles, and rubella also may infect the lungs through hematogenous spread.

Clinical Features

Clinical symptoms and signs of pneumonia in pediatric patients vary with patient age, specific pathogen, and disease severity.[2] Infants younger than 3 months of age generally have respiratory symptoms, such as tachypnea, cough, retractions, and grunting, but may show only nonlocalizing symptoms, such as isolated fever or hypothermia, vomiting, poor feeding, irritability, and lethargy. Toddlers with *S. pneumoniae* infection may have nonspecific symptoms, such as high fever and lethargy, without significant respiratory symptoms. In general, signs and symptoms in children become more specific with increasing age, although pneumonia may have only subtle manifestations in any child.[1] Systemic symptoms include fever and chills, headache, rigors, and malaise. Symptoms of lower respiratory tract disease may include cough and wheezing. Pleural irritation often causes chest pain, but the child may also complain of pain in the abdomen or neck. Vomiting (often posttussive) and poor oral intake are common.

TABLE 164.1 Tachypnea as Defined by the World Health Organization for the Clinical Diagnosis of Pneumonia

Patient Age	Respiratory Rate
Younger than 1 year	Greater than 50 breaths/min
1–5 years old	Greater than 40 breaths/min
Older than 5 years	Greater than 30 breaths/min

Key historical factors include birth and immunization history (particularly pneumococcal and *H. influenzae* type b vaccination), sickle cell status, history of previous pneumonia or frequent infections, and presence of underlying chronic disease. Children with known respiratory (e.g., bronchopulmonary dysplasia [BPD], CF) or cardiac disease tend to have more severe courses of illness; children with a primary or acquired immunodeficiency are also prone to more severe and fulminant disease from common, uncommon, and opportunistic pathogens.

The physical examination should begin with the general appearance and breathing pattern. A full set of vital signs, including oxygen saturation, should be obtained on arrival. Fever is often present but may be low grade or absent. Important findings include hydration status, perfusion, and level of alertness and interaction. Abnormal cardiovascular parameters may indicate dehydration or, rarely, shock. Tachypnea, although not universal, is the most sensitive indicator of pneumonia and may be the only manifestation in younger children. The World Health Organization (WHO) has published guidelines for the clinical diagnosis of pneumonia in developing countries and cites tachypnea and retractions as indicators of lower respiratory disease (Table 164.1).

Other manifestations of lower airway disease include cough, wheezing, or signs of increased work of breathing: nasal flaring, retractions, grunting, and accessory muscle use. The characteristics of the cough may aid in the diagnosis; a staccato cough in an infant may indicate pneumonia caused by *C. trachomatis* or *B. pertussis*. The patient's lungs should be auscultated, and findings may include rales, wheezing, or diminished breath sounds. Although these may be present in younger children, the findings are much less consistent and may be masked by poor inspiratory effort or noisy upper airway sounds. Pleural irritation can cause abdominal tenderness or meningismus, and pulmonary hyperinflation may cause downward displacement of the liver and spleen. Extrapulmonary exam findings may include rhinorrhea, pharyngitis, or exanthem with viral infections. Conjunctivitis can be seen with chlamydial pneumonia, whereas pharyngitis and exanthems are associated with *M. pneumoniae.*

Several complications of pneumonia may result from local and systemic effects of the infection, with the most common systemic complication being dehydration. Pleural effusion or empyema is usually associated with bacterial pathogens (notably *S. pneumoniae, H. influenzae,* and *S. aureus*) but are occasionally seen with mycoplasma, viral, and tuberculosis pneumonia. Similarly, lung abscess, pneumatocele, and pneumothorax are local complications primarily seen with bacterial disease, particularly with *S. aureus*. Extensive pulmonary involvement, regardless of the causative agent, may lead to hypoxia, progressive respiratory deterioration, and multiple organ failure (Fig. 164.2). Apnea in isolation without other symptoms can occur in infants younger than 3 months and is usually associated with viral (especially RSV), chlamydial, and pertussis infections. Additional infectious foci may develop from concomitant bacteremia (e.g., meningitis, epiglottitis, pericarditis, septic arthritis, soft tissue infections). Viral or bacterial

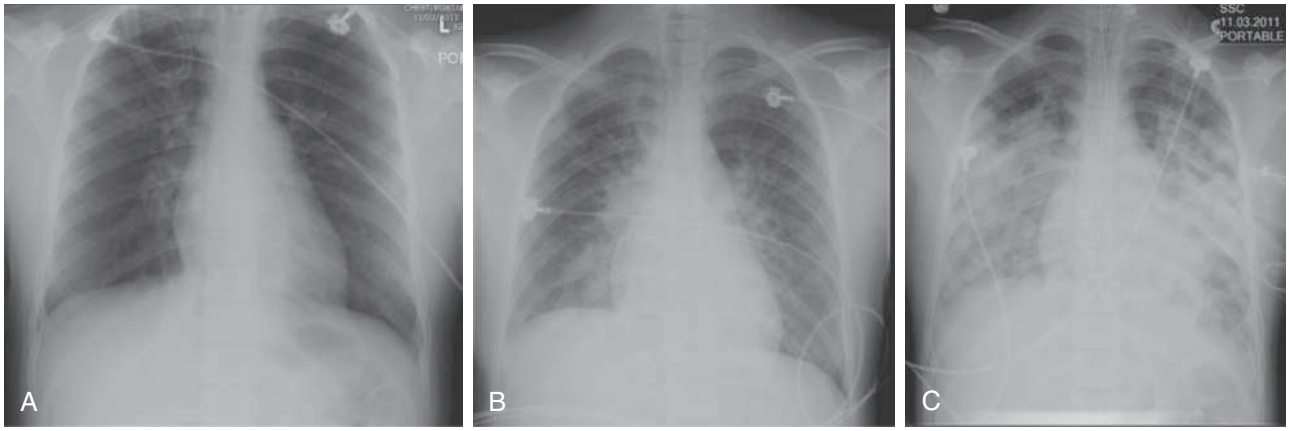

Fig. 164.2 An 11-year-old presented in respiratory distress; radiographs at presentation (A), 4 hours later following resuscitation (B) showing the development of diffuse bilateral infiltrates, and after intubation (C) as the patient rapidly progressed to respiratory failure. (Courtesy Dr. Eric R. Schmitt.)

pneumonia is rarely associated with meningitis, encephalitis, arthritis, rhabdomyolysis, and hemolytic uremic syndrome.

Differential Diagnoses

Unfortunately, no single finding can reliably differentiate pneumonia from other causes of respiratory distress in children.[7] The major conditions to be differentiated in children with pneumonia include bacterial pneumonias, viral disease, other unusual infectious causes (mycobacterial, protozoal, fungal), and noninfectious pathologic conditions (Box 164.1). Common infectious causes classically present with certain historical, clinical, and laboratory findings (Table 164.2). However, the broad spectrum of illness for each condition makes a definitive diagnosis difficult for any individual patient, and no specific feature can reliably differentiate bacterial from nonbacterial pneumonia. Providers should consider a bacterial cause in a child with a temperature higher than 39°C (102.2°F), clinical toxicity, lobar infiltrate, or pleural effusions (Fig. 164.3). Host factors, epidemiology, clinical presentation, and judicious use of diagnostic tests can establish a likely diagnosis and appropriate empiric management.

Bacterial Pneumonia

S. pneumoniae is one of the most frequently seen bacterial causes of pneumonia in children. Children with immunodeficiency, chronic renal disease, and functional or anatomic asplenia and Native Americans are at increased risk for *S. pneumoniae* infections. *S. aureus* pneumonia, although less common, tends to cause a more severe pneumonia and should be considered in any patient who is unusually ill appearing or presenting with respiratory failure or shock.[8] Children with foreign body aspiration, immunosuppression, or concomitant skin infections are at increased risk for *S. aureus* pneumonia. Progression of the disease is rapid, and empyema (90%), pneumatocele (50%), and pneumothorax (25%) are common complications (Fig. 164.4).

Before widespread immunization, *H. influenzae* type b was the second most common bacterial cause of pneumonia. However, its incidence has decreased by 90% since the advent of effective immunization. *H. influenzae* was previously considered a disease of younger children, but most cases now occur in older children.[9] Although clinically indistinguishable from *S. pneumoniae* pneumonia, *H. influenzae* pneumonia historically had a higher incidence of associated pleural effusions (25% to 75%) and bacteremia (75% to 95%).

Although still uncommon, the incidence of group A streptococcal pneumonia has increased since the 1980s. Group A streptococcal pneumonia may occur sporadically and may be a complication of varicella infection. It is typically a severe illness with abrupt onset, rapid progression to toxicity, and high fatality rate (30% to 60% fatality rate reported in a study of all ages).

In bacterial pneumonia beyond the neonatal period, fever is almost universal (often >39°C [102.2°F]). Patients usually have a cough and tachypnea disproportionate to fever and may also appear relatively toxic (e.g., pallor, poor tone, lethargy, delayed capillary refill). Focal lung findings (rales, wheezes, and decreased or bronchial breath sounds) are easier to appreciate in older children, whereas the physical examination in a younger child may be completely unrevealing.

BOX 164.1 Noninfectious Diagnoses for Patients Presenting With Lung Disease

Radiologic technique
- Inadequate inspiration
- Breast shadow
- Thymus
- Underpenetration

Primary pulmonary
- Asthma
- Bronchiectasis
- Atelectasis
- Bronchopulmonary dysplasia
- Cystic fibrosis
- Pulmonary sequestration
- Congenital cystic adenomatoid malformation
- α_1-Antitrypsin deficiency

Aspiration
- Foreign body
- Chemical
- Recurrent, caused by anatomic or physiologic disorders

Primary cardiac
- Congenital heart disease
- Congestive heart failure

Pulmonary infarction
- Sickle cell vaso-occlusive crisis
- Pulmonary embolism

Collagen vascular disorders

Acute respiratory distress syndrome

Pleural effusion

Neoplasm

TABLE 164.2 Pneumonia Syndromes

	INFECTIOUS CAUSE			
Typical Feature	**Bacterial**	**Viral**	**Chlamydial**	**Mycoplasmal**
Historical				
Age	Any	Any	4–16 weeks	5–18 years
Fever	High (>39°C [102.2°F])	Low grade	Usually none	Low
Onset	Abrupt, often after upper respiratory infection	Gradual	Gradual	Gradual
Cough	Productive	Nonproductive	Staccato	Hacking
Associated symptoms	Chest pain; focal infarct	Myalgias, rash, sore throat, coryza	Conjunctivitis	Headache, sore throat, rash
Physical	Toxic appearance			
Lungs	Confined rales	Diffuse rales, wheeze, stridor	Diffuse rales, rare wheeze	Unilateral rales
Chest radiograph				
Infiltrate	Lobar or segmental	Interstitial	Diffuse, interstitial	Lobar or diffuse
Pleural effusion	Occasional	Rare	None	Rare
Other	Pneumatocele; abscess	Hyperinflation, atelectasis	Hyperinflation	
Laboratory test results	Increased WBC granulocytosis	Normal or increased WBC count, lymphocytosis	Normal WBC count, eosinophilia	Normal WBC count
Pathogens (common)	*Streptococcus pneumoniae* *Haemophilus influenzae* *Staphylococcus aureus* <2 months—group B streptococcus; gram-negative enterics; *Listeria monocytogenes*	RSV, parainfluenza, influenza, adenovirus, enterovirus	*Chlamydia trachomatis*	*Mycoplasma pneumoniae*

RSV, Respiratory syncytial virus; *WBC,* white blood cell.

Viral Pneumonia

Viral pneumonia is more common in the winter season and generally has a gradual onset, often with associated cough, congestion, and low-grade fever. Tachypnea may be the only physical finding; however, retractions, rales, and wheezing are common. Grunting, cyanosis, lethargy, dehydration, and apnea are seen in more severely affected children.

Radiographic findings typically include hyperinflation and peribronchial thickening, with a diffuse increase in interstitial findings (Fig. 164.5). Patchy areas of consolidation may be present, representing lobular atelectasis or alveolar pneumonia (Fig. 164.6). Although lobar consolidation and small pleural effusions may occur in viral pneumonia, these findings are more consistent with a bacterial cause.

Children do not require chest radiography or viral testing to make the diagnosis of viral pneumonia, particularly in a child who presents during the winter months with fever, cough, congestion, and wheezing. Most viral pneumonias resolve without therapy; however, because of the possibility of secondary bacterial infection and the difficulty in differentiating between bacterial and viral pneumonia, antibiotics should be considered for a more severely ill child.[10] Complications seen with viral pneumonia include dehydration, local progression of the disease, bronchiolitis obliterans, and apnea (usually in the first 3 months of life).

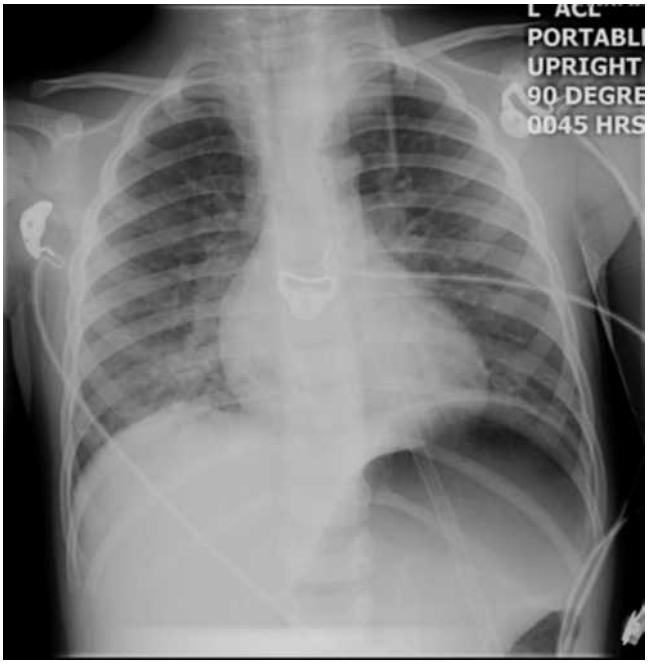

Fig. 164.5 Radiograph of a 3-year-old with viral pneumonia showing hyperinflation, peribronchial thickening, and diffuse interstitial infiltrates. (Courtesy Dr. Eric R. Schmitt.)

Mycoplasma Pneumonia

Mycoplasma pneumonia accounts for 10% to 20% of all pediatric pneumonias. It occurs more commonly in 5- to 18-year-olds, but can be seen in younger children (although rare in infants younger than 1 year).[3] Onset is classically gradual and insidious, but some patients may have an abrupt onset of symptoms. Prodromal symptoms include fever, headache, and malaise, followed several days later by a nonproductive, hacking cough. Associated symptoms of infection may include hoarseness, sore throat, and chest pain; coryza is unusual.

Children with mycoplasma pneumonia generally appear nontoxic and may have rales or, less often, wheezing. Patient may have associated pharyngitis, cervical lymphadenopathy, conjunctivitis, or otitis media.

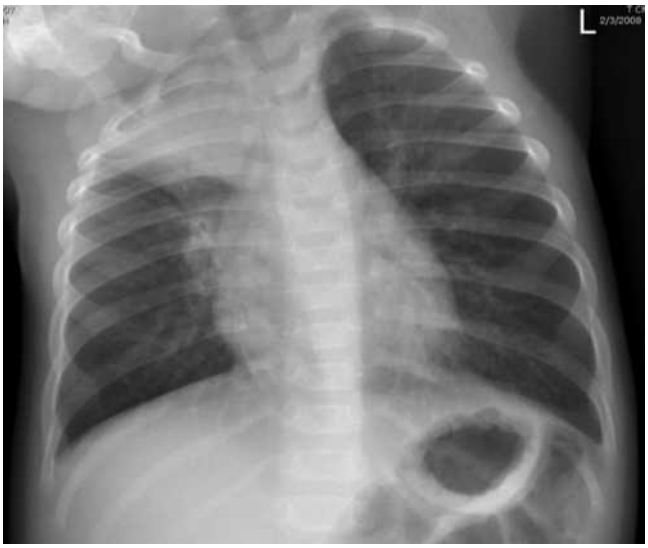

Fig. 164.6 Radiograph showing right upper lobe atelectasis and bilateral interstitial infiltrates in a 9-month-old. (Courtesy Dr. Eric R. Schmitt.)

A rash is present in 10% of patients but can take various forms: urticaria, erythema multiforme, maculopapules, or vesicles. *Mycoplasma* infection is typically benign and self-limited but can play a significant role in the exacerbation of asthma and may cause chronic pulmonary structural abnormalities (e.g., pneumatocele, pleural effusion, pneumothorax, or bronchiectasis). Physical findings are generally less impressive than the radiographic picture. Radiographic findings typically show lower lobar consolidation, but scattered segmental infiltrates and interstitial disease can also be seen (Fig. 164.7). Pleural effusions are uncommon. The white blood cell (WBC) count is usually normal.

Because specific testing and treatment is not applicable to the emergency department (ED) setting, infection is diagnosed clinically and treated empirically. Cold agglutination is rarely used nowadays and is not accurate, particularly in patients younger than 12 years old. Diagnosis may be confirmed with acute and convalescent antibody titers; however, patients may take 4 to 6 weeks to seroconvert, and some patients may fail to mount an immune response altogether. Multiplex polymerase chain reaction (PCR) panels can demonstrate the vital etiology and also bacterial causes including *M. pneumoniae*. Complications of mycoplasma pneumonia are varied, but unusual, and include hemolytic anemia, hemolytic uremic syndrome, myopericarditis, neurologic disease (e.g., meningoencephalitis, Guillain-Barré syndrome, transverse myelitis, and cranial neuropathy), rhabdomyolysis, arthritis, and Stevens-Johnson syndrome.[11,12]

Chlamydia Pneumonia

C. trachomatis is a common sexually transmitted organism that causes cervical infection in 2% to 30% of pregnant women. It is transmitted from the genital tract of infected mothers to their newborn infants, resulting in conjunctivitis in 22% to 44% and pneumonia in 5% to 20%.[13] An infant with pneumonia caused by *C. trachomatis* presents at 3 to 19 weeks of age after colonization at birth. The illness usually begins with nasal congestion followed by cough. In 50% of cases, conjunctivitis precedes the onset of respiratory symptoms. The infant is often afebrile and alert but tachypneic, with a repetitive staccato cough that may interfere with feeding or sleeping. It can resemble the paroxysms of pertussis and occasionally precipitates episodes of alarming respiratory distress. Mild retractions and diffuse inspiratory rales may be noted on chest examination; expiratory wheezing is usually absent or minimal. Middle ear abnormalities are present in 50% of cases.

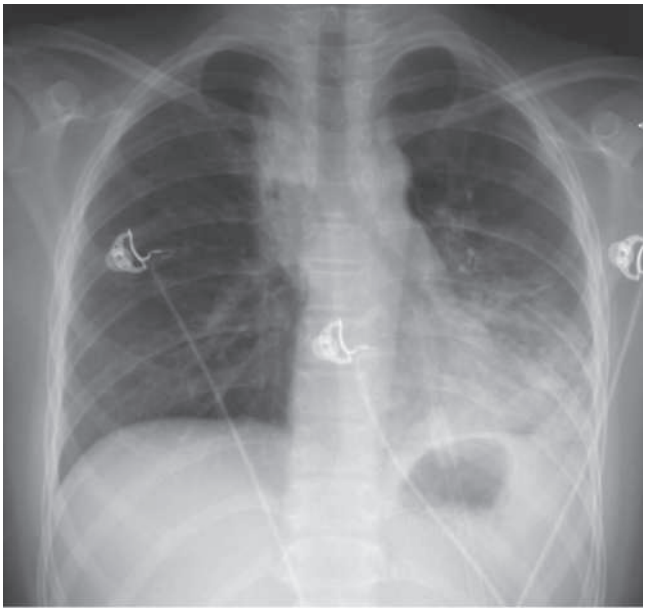

Fig. 164.7 Radiograph of a 12-year-old showing a left lower lobe infiltrate consistent with mycoplasma pneumonia. (Courtesy Dr. Eric R. Schmitt.)

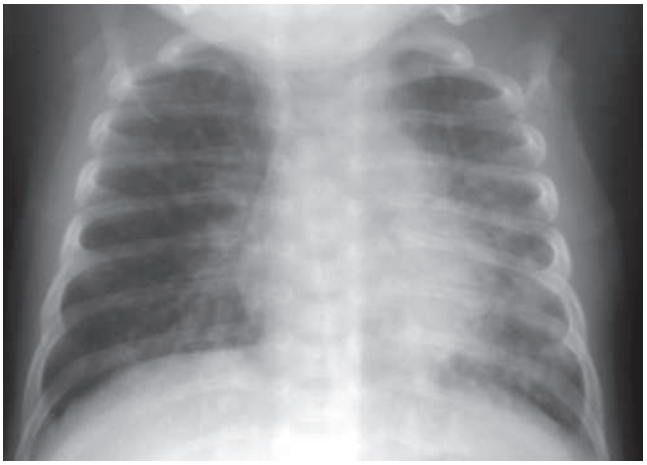

Fig. 164.8 Radiograph showing chlamydial pneumonia in an infant. Note the symmetric interstitial infiltrates. (Courtesy Dr. Michael Diament.)

Chest radiograph usually shows hyperinflation with bilateral and symmetric, diffuse, interstitial infiltrates (Fig. 164.8). Nucleic acid amplification tests have replaced other detection methods (e.g., culture, direct fluorescent antibody tests) because of their higher sensitivity and specificity. Chlamydial pneumonia is often a mild illness but may rarely be complicated by apnea and hypoxemia. Treatment with erythromycin may shorten the course; however, the disease tends to be protracted, and cough and tachypnea can persist for weeks despite antibiotic treatment.

C. pneumoniae is a species of *Chlamydia* that is antigenically, genetically, and morphologically distinct from other *Chlamydia* species. *C. pneumoniae* infection is transmitted from person to person, may play a role in respiratory tract infections in infants and young children, and may cause mild illness or asymptomatic infection in children and adults. Like *Mycoplasma, C. pneumoniae* may play a greater role in pediatric pneumonia than was previously thought. It has been reported to cause sore throat, fever, headache, pertussis-like cough, pneumonia, and influenza-like illness.[14] Outbreaks have been reported in schools, daycare centers, military camps, adolescents, and families. Infection with *C. pneumoniae* can trigger acute episodes of wheezing in children with asthma. Infection can be confirmed with PCR testing.

Aspiration Pneumonia

Aspiration pneumonia may be due to mechanical, chemical, or bacterial causes. Bacterial aspiration occurs in children with anatomic abnormalities and central nervous system disturbances that impair normal swallowing or protective airway reflexes.[15] Pulmonary damage results from chemical (e.g., stomach acid) and bacterial (e.g., gastrointestinal and upper respiratory organisms) insults. Within several hours of the aspiration, the child may have the onset of cough, tachypnea, and fever. Physical examination commonly reveals rales and wheezing, with cyanosis as the disease progresses. Radiographic findings include both localized (right middle lobe or lower lobe) and diffuse/bilateral infiltrates.

Pneumonia in the Immunocompromised Patient

Children with chronic disease and congenital, acquired, and iatrogenic immunodeficiencies are susceptible to the aforementioned respiratory pathogens and to a multitude of opportunistic organisms, including *P. jiroveci,* CMV, and fungi. Presenting symptoms may be similar to those in normal hosts; however, the course tends to be more rapid, severe, and fulminant. While awaiting organism identification and the results of culture, patients should be hospitalized for monitoring, supportive therapy, and treatment with intravenous antibiotics active against a broad spectrum of organisms. Invasive sampling for diagnosis of potentially treatable organisms may need to be considered if the patient fails to improve after initial therapy.

Diagnostic Testing

Radiography. A chest radiograph is unnecessary in children without comorbid conditions who have no fever, tachypnea, or focal findings on auscultation, because they are unlikely to have pneumonia. Chest radiography can also be deferred in a well-appearing child who has pneumonia based on clinical presentation (fever, tachypnea, abnormal lung auscultation). We recommend that any child who appears ill or in whom the diagnosis is unclear receives radiographic evaluation, with chest radiography. A clear chest radiograph (without infiltrate) is sufficient to exclude pneumonia in the majority of children.[16,17] However, an infiltrate may not be initially apparent in a dehydrated child with suspected pneumonia, only becoming visible on subsequent imaging after rehydration (see Fig 162.2).

Although great variability exists, bacterial pathogens classically produce alveolar infiltrates in a lobar distribution (Fig. 164.9) but may produce diffuse interstitial infiltrates. Viral and chlamydial infections tend to appear as diffuse interstitial infiltrates, commonly with hyperinflation and atelectasis (see Fig. 164.5). Chest radiographs can identify multilobar disease, pleural effusions, pneumatoceles, and pneumothorax (see Fig. 164.4). Hilar adenopathy may indicate tuberculosis or malignant neoplasm.

Lateral decubitus radiographs in patients with pleural effusions can help assess effusion size and loculation. Computed tomography (CT) may be useful to provide greater detail of effusions and lung abnormalities in critically ill children with complicated pneumonia, or when alternative pathology is suspected based on the plain radiograph (Fig. 164.10). Routine CT of the chest to establish the diagnosis is not recommended.

Ultrasound. Recent studies have examined the utility of lung ultrasound for the diagnosis of pneumonia in children.[18] Most studies use highly skilled sonographers with specific training in pediatric

thoracic ultrasound, and this level of expertise is not widely available.[19] When performed by a skilled sonographer, ultrasound has sensitivity similar to chest radiography, although it may not be as specific.[20] Ultrasound predicts the presence of consolidation on chest radiography; the best correlation occurs when the consolidation measures greater than 1 cm on ultrasound.[21,22] When available, a positive ultrasound study may safely allow for the reduction of chest radiography.[23]

Laboratory Studies. Children with pneumonia are at risk for hypoxemia and should undergo pulse oximetry to determine oxygen saturation; arterial or venous blood gas analysis should be reserved for patients in significant distress or respiratory failure to monitor respiratory status or response to therapy. A complete blood count (CBC) is not useful in differentiating between viral and bacterial pneumonia and should not be obtained unless the results will change management. We do not recommend blood cultures in otherwise well-appearing children with uncomplicated pneumonia, because they are unlikely to be helpful.[24] Blood cultures may be considered in ill-appearing hospitalized patients.[8,25] Sputum cultures are technically difficult in younger children and should not be routinely obtained.[18]

Patients with pleural effusions that are enlarging or compromising respiratory function should undergo thoracentesis for diagnostic and therapeutic purposes. Although parapneumonic effusions are most suggestive of bacterial infection, they also occur with mycoplasmal and occasionally with viral infections. The fluid should be sent for Gram staining and culture (anaerobic and aerobic bacterial), cell count and differential, total protein level, pH, and glucose concentration. Interpretation of pleural fluid in children follows adult guidelines (see Chapters 62 and 63). Cultures for rare pathogens may be considered if the initial assessment is not diagnostic or specific risk factors are identified. Bronchoscopy with bronchoalveolar lavage may be useful in a child who is severely ill or refractory to treatment.

Rapid antigen testing for RSV is not indicated unless the result would change management (e.g., risk stratification in a young infant with fever, or to cohort for inpatient treatment).[26] A real-time influenza PCR assay may be helpful for atypical cases when the use of antivirals is being considered.[18] However, influenza may be diagnosed clinically during times of high prevalence (i.e., a higher likelihood of a false negative influenza assay). Children at higher risk (e.g., children <2 years or those with significant comorbid disease) should be empirically treated with antivirals without confirmatory testing. Although most pediatric patients with tuberculosis do not have pulmonary symptoms, testing for tuberculosis should be considered for patients with lobar pneumonia, pulmonary effusions, or hilar adenopathy, especially in immunocompromised children or children who have recently immigrated from less developed countries.

Fig. 164.9 Radiograph showing pneumococcal pneumonia, with infiltrate in the right upper lobe. (Courtesy Dr. Marianne Gausche-Hill.)

Management

Treatment of pneumonia in a pediatric patient consists of appropriate antimicrobial use and supportive therapy (Table 164.3). Because of the difficulty in identifying a specific pathogen, antibiotic choice is generally empirical. The three most important factors in directing management are the patient's age, likely pathogen, and degree of illness.

Infants Younger Than 2 Months. An infant younger than 2 months with pneumonia should usually be admitted to the hospital and monitored with continuous pulse oximetry for signs of needed respiratory support; apnea and respiratory failure may be precipitous. This age group is immunologically immature, and signs of sepsis may be subtle. We recommend blood, urine, and cerebrospinal fluid cultures before the initiation of antibiotics when possible (see Chapter 161). In infants younger than 1 month, ampicillin, plus ceftazidime, or gentamicin (recommended in premature infants) are appropriate choices; ampicillin and ceftriaxone should be used for infants 1 to 2 months of age. If *C. trachomatis* or *B. pertussis* is suspected, the infant should also be treated with azithromycin or erythromycin (given the association of erythromycin with infantile hypertrophic pyloric stenosis, we recommend azithromycin when available).

Infants 2 to 3 Months of Age. Blood and urine cultures should be obtained for infants 2 to 3 months of age. The decision to perform a

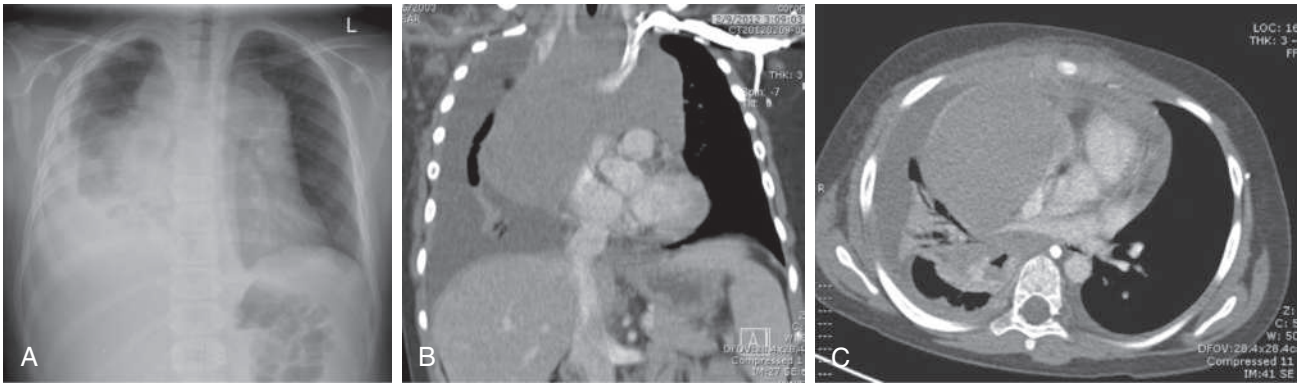

Fig. 164.10 Radiograph (A) of an 8-year-old that was initially interpreted as a right-sided pneumonia with effusion; coronal (B) and axial (C) computed tomography images demonstrate a large mediastinal mass later determined to be a T-cell lymphoma. (Courtesy Dr. Eric R. Schmitt)

TABLE 164.3 Empiric Antibiotic Treatment of Bacterial Pneumonia

Age Group	Most Frequent Pathogens	Outpatient Treatment	Inpatient Treatment
Neonate (<4 weeks)	Group B streptococcus, *Escherichia coli*, other gram-negative bacilli		Ampicillin (150–200 mg/kg/day every 6 hours) + ceftazidime (100 mg/kg/day every 12 hours) *or* Gentamicin (2.5 mg/kg daily) Avoid ceftriaxone.[a]
4 weeks–3 months	*Streptococcus pneumoniae, Haemophilus influenzae, Chlamydia trachomatis* (if afebrile)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5) *or* Erythromycin (50 mg/kg/day every 6 hours)	Ampicillin (150–200 mg/kg/day every 6 hours) + ceftriaxone (50 mg/kg daily)
	Bordetella pertussis (if afebrile and prolonged cough)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)
3 months–4 years	*S. pneumoniae, H. influenzae,* group A streptococcus	Amoxicillin (75–90 mg/kg/day every 12 hours) *or* Amoxicillin–clavulanic acid (90 mg/kg/day of the amoxicillin component every 8 hours) *or* Cefuroxime (20-30 mg/kg/day every 12 hours)	Ceftriaxone (50 mg/kg daily) *or* Ampicillin (150–200 mg/kg/day every 6 hours) In critically ill patients add: clindamycin (40 mg/kg/day every 6 hours) *or* vancomycin (10–20 mg/kg IV every 6–8 hours) for coverage of MRSA[b]
	Mycoplasma pneumoniae	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5) *or* Clarithromycin (15 mg/kg/day every 12 hours)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5) *or* Erythromycin (20 mg/kg/day every 6 hours)
	B. pertussis (if afebrile and prolonged cough)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)
≥5 years	*M. pneumoniae, Chlamydophila pneumoniae*	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5) *or* Clarithromycin (15 mg/kg/day every 12 hours)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5) *or* Erythromycin (20 mg/kg/day every 6 hours)
	S. pneumoniae, H. influenzae	Amoxicillin (75–90 mg/kg/day every 12 hours) *or* Amoxicillin–clavulanic acid (90 mg/kg/day of the amoxicillin component every 8 hours) *or* Cefuroxime (20–30 mg/kg/day every 12 hours)	Ceftriaxone (50 mg/kg daily) *or* Ampicillin (150–200 mg/kg/day every 6 hours) In critically ill patients add: clindamycin (40 mg/kg/day every 6 hours) *or* vancomycin (10–20 mg/kg IV every 6–8 hours) for coverage of MRSA[b]
	B. pertussis (if afebrile and prolonged cough)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)	Azithromycin (10 mg/kg on day 1, 5 mg/kg daily on days 2–5)

[a]Ceftriaxone is not preferred in neonates due to risk of hyperbilirubinemia, particularly in premature infants.
[b]*MRSA,* Methicillin-resistant *Staphylococcus aureus*.

lumbar puncture depends on clinical suspicion of central nervous system infection. Ampicillin and ceftriaxone should be given for an infant 2 to 3 months old. If *C. trachomatis* or *B. pertussis* is suspected, the infant also should be treated with azithromycin or erythromycin. Supportive therapy in this age group consists of fever control and hydration. As with infants under 2 months of age, we recommend admission for infants 2-3 months of age, as they are only partially protected against *S. pneumoniae* and *H. influenzae* with one dose of vaccinations.

Infants and Children Older Than 3 Months. In an older child, pneumonia should be categorized into likely bacterial, viral, or mycoplasmal. The emergency clinician should base the presumptive causative diagnosis on clinical and radiographic findings (if obtained). A toxic child with high fever and lobar consolidation is likely to have a bacterial process, whereas a child with a disease of gradual onset, low-grade fever, and interstitial infiltrate with air trapping is more likely to have a viral process.

A well-appearing infant or preschool-age child with isolated pneumonia may be treated with outpatient oral antibiotics. In an infant beyond the neonatal period or a preschool-age child, high-dose amoxicillin is the first line agent and will treat susceptible *S. pneumonia*.[27] Amoxicillin–clavulanic acid is a second line agent and includes some gram-negative and methicillin-sensitive *S. aureus* coverage. Oral cephalosporins are relatively poorly absorbed and highly protein-bound, resulting in inferior pharmacokinetics as compared with amoxicillin; we recommend their use be reserved for penicillin-allergic patients. Azithromycin should not be used to treat *S. pneumoniae,* because there is significant resistance, but it is appropriate therapy for presumed atypical pneumonias in this age group. Azithromycin is the antibiotic of choice in a school-age child or adolescent, in whom *M. pneumoniae* and *C. pneumoniae* are more common. Uncomplicated bacterial pneumonia often has a rapid response to antibiotics; a stagnant or

worsening clinical picture should prompt further investigation (e.g., postobstructive pneumonia from an unrecognized foreign body).

Children with neurologic or anatomic abnormalities who aspirate oral or gastric contents are susceptible to pneumonia, predominantly from anaerobes. Penicillin (100,000 to 250,000 units/kg/day every 4 to 6 hours) and clindamycin are appropriate first line antibiotic choices. In seriously ill patients or patients not responding, agents such as metronidazole (40 mg/kg/day every 6 hours) and cefoxitin (80 to 160 mg/kg/day every 4 to 6 hours) may be administered. Nosocomial infections should be treated with antibiotics also active against aerobes and gram-negative bacilli. Children with significant aspiration should be admitted to the hospital, and supportive therapy should include hydration, supplemental oxygen, and oropharyngeal suctioning.

Disposition. Well-appearing children who can maintain hydration and are not in respiratory distress should be considered for outpatient management. Oral antibiotic therapy is appropriate if there is concern for bacterial etiology. Children treated as outpatients should be reevaluated within 24 to 48 hours.[2] Inpatient hospitalization for parenteral antibiotic therapy should be considered for patients who are dehydrated or clinically worsening; a repeat chest radiograph may reveal progression of disease or development of a pleural effusion.

Indications for hospitalization at the time of diagnosis include a toxic appearance, vomiting or dehydration, respiratory compromise (e.g., distress, hypoxia, or inadequate ventilation), multilobar disease, pleural effusions, impaired immune function, and unreliable social environments. Strong consideration should be given to hospitalization of children younger than 6 months, because they are more prone to complications of bacterial pneumonia than older children. Supportive therapy for the inpatient should include maintenance of hydration, fever control, supplemental oxygen, ventilatory assistance, and pleural fluid drainage, as indicated. Parenteral antibiotic therapy should be administered until clinical improvement.

Long-term management of a child with pneumonia should include a clinical reevaluation 2 to 3 weeks after diagnosis. If the child had a prompt response to therapy and is well at the follow-up evaluation, a repeat radiograph is unnecessary at this time. If the child had a complicated course (e.g., pleural effusion) or residual symptoms or if the illness is not the child's first episode of pneumonia, a chest radiograph can ensure resolution.

Pertussis

Pertussis, or whooping cough, is a respiratory tract infection, classically seen in infants younger than 6 months. The incidence of pertussis increased in the 1980s and 1990s, especially in adolescents and adults, likely due to waning immunity.[28] More recently, inconsistent immunization has led to epidemics in vulnerable populations.[29]

Pertussis disease is characterized by three clinical stages—catarrhal stage, paroxysmal stage, and convalescent stage. Pertussis begins with mild upper respiratory tract symptoms and cough; this *catarrhal stage* usually lasts 1 to 2 weeks. The disease progresses to severe paroxysms of a staccato cough *(paroxysmal stage),* followed by posttussive emesis, and may be accompanied by periods of cyanosis and apnea in infants younger than 6 months. The classic whoop is rare, occurring in only 6% of patients and generally seen in children older than 2 to 3 years. Fever is often absent, and the examination findings are remarkably normal between paroxysms. The paroxysmal stage lasts 2 to 4 weeks and is followed by a *convalescent stage*, during which symptoms gradually wane. The duration of the illness in more complicated cases may be 6 to 10 weeks. Immunization is only 80% effective in providing immunity after three doses, making pertussis possible in immunized infants.[30]

The WBC count (if obtained) is usually elevated, often with a marked lymphocytosis. The chest radiograph may show a shaggy, right-sided heart border or have clear lung fields. *B. pertussis* is a fastidious organism, making culture difficult. The organism is most easily recovered in the catarrhal or early paroxysmal stages. Cultures may be negative during the first week or after the fourth week of illness in immunized patients or in patients treated with antibiotics. The PCR assay has been increasingly used for the detection of *B. pertussis,* because of its high sensitivity and more rapid turnaround time than culture.

Pertussis is a particularly severe disease in the first year of life and is often complicated by apneic episodes; less common complications include seizures, secondary bacterial pneumonia, encephalopathy, and death.[31] Pertussis has been increasing in incidence among immunized children and young adults who have waning immunity. The illness in these older patients does not follow the classic stages as described earlier; patients have a mild but prolonged course (often lasting 3 weeks or more), with a dry cough as the predominant symptom.

Because of the risk of apnea, we recommend that all children younger than 3 to 6 months with presumed pertussis be observed in the hospital for monitoring and supportive care, and treated with azithromycin or erythromycin. Antimicrobials have no effect on disease progression after the beginning of the paroxysmal stage but limit the spread of organisms. Vaccination of all health care workers and the general adult population with tetanus, diphtheria, and pertussis (Tdap) is recommended and has been shown to decrease rates of pertussis in infants.

Cystic Fibrosis

CF is an autosomal recessive disease caused by a mutation in the CF transmembrane conductance regulator *(CTFR)* gene. In Whites, approximately 1 in 25 is a carrier, and the disease has an incidence of 1 in 2500 births. The disease also is present (in decreasing incidence) in Hispanics, Native Americans, African Americans, and Asians. Progressive lung disease and infection account for most of the morbidity and nearly all the mortality in those with CF.[32] Defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, decreased antimicrobial effect of the airway surface, increased bacterial adherence, and innate secretion of inflammatory cytokines. All these factors result in a unique sensitivity to bacterial infection of the airway.

Chest radiographic findings of CF include emphysema, peribronchial thickening, bronchiectasis, and focal infiltration, which may be linear or nodular (Fig. 164.11). Identification of the pathogens involved is crucial to the effective treatment of pulmonary infections in CF patients (usually through sputum culture), although early childhood pneumonias in patients with CF are predominantly caused by *S. aureus* and *H. influenzae*. With the emergence of methicillin-resistant *S. aureus* (MRSA), careful attention should be paid to antibiotic coverage. Patients receiving antistaphylococcal prophylaxis may be at increased risk for pseudomonal infections. By 18 years of age, 80% of patients are permanently colonized with *P. aeruginosa*. Acute infective exacerbations generally are managed by oral and intravenous antimicrobial drugs, typically a penicillin (e.g., ticarcillin or piperacillin) or ceftazidime, combined with an aminoglycoside for synergistic effects. If a patient's previous sputum culture results are available, antibiotic coverage for the last known bacterial pathogen should be used. Resistant strains may benefit from imipenem or meropenem, and patients should often be hospitalized for the course of therapy.[33] *Burkholderia cepacia* is a significant pathogen in CF patients and has been associated with an accelerated decline in clinical status and increased mortality. Antimicrobial coverage is similar to that for *Pseudomonas*, although resistance is common and the existence of differing colonization and resistance patterns of patients with CF necessitates respiratory isolation from other susceptible individuals.

Clearance of the thick mucoid secretions is important for treatment. Patients may respond favorably to bronchodilator therapy and to mucolytics, such as inhaled *N*-acetylcysteine, in the acute setting. Chest physiotherapy provided by a high-frequency oscillator device is often used. A flutter valve or positive expiratory pressure mask may be of assistance for improved mucoid clearance. Short-term control of

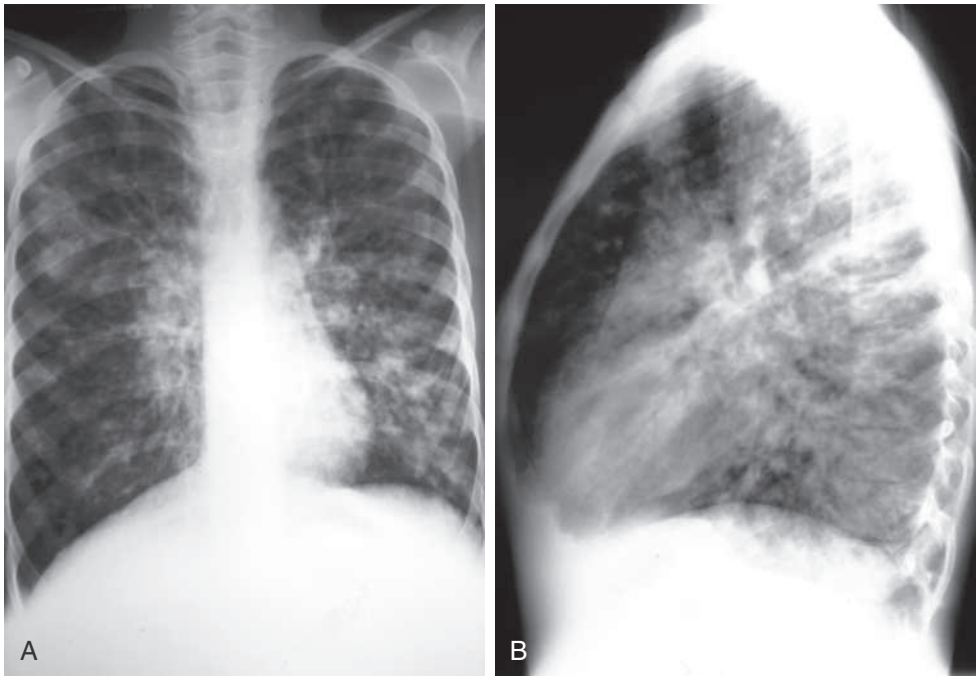

Fig. 164.11 Posteroanterior (A) and lateral (B) radiographs of a teenager with cystic fibrosis. Note emphysema and nodular infiltrates. (Courtesy Dr. Michael Diament.)

inflammation may be obtained by inhaled corticosteroids. Given the complicated nature of these patients and the need for individualized treatment plans, we recommend early consultation with a pediatric pulmonologist.

Bronchopulmonary Dysplasia

BPD is defined as the need for supplemental oxygen 28 days postnatally.[34] BPD is a common cause of diffuse lung disease in infants. Approximately 40% of children with a birth weight less than 1000 g will develop BPD. The severity of disease is related to several factors, including degree of prematurity, use of peripartum steroids, damage incurred by ventilation in the neonatal period, and nutritional status.[35] Infants with BPD have greatly increased rates of hospitalization because of respiratory illness in the first year of life, approaching 65% in infants born weighing less than 1000 g.

Immunizations are used to help prevent pneumonia in patients with BPD. All infants 6 to 23 months old should receive the influenza vaccine during the appropriate season. The 13-valent pneumococcal vaccine and *H. influenzae* type b vaccine are especially important for the prevention of bacterial pneumonia. Monthly prophylaxis against RSV with the monoclonal immunoglobulin palivizumab should be administered to carefully selected patients because it reduces the incidence of RSV disease and risk of subsequent hospitalization.

Patients with BPD have increased airway resistance, decreased lung compliance, and obstructive lung disease. Pneumonia in patients with BPD may be complicated by a reactive airway component. If complicated by pneumonia, radiographs show marked hyperinflation and infiltrates (Fig. 164.12). Inhaled bronchodilators may be efficacious, although these medications may worsen air exchange in patients with concomitant airway malacia. Hypoxia and hypercarbia are common, despite an increased respiratory effort. Patients with severe BPD may be receiving long-term diuretic therapy to improve lung mechanics; care should be taken not to confuse pneumonia with cor pulmonale, which can occur in younger infants with chronic supplemental oxygen requirements.

CHAPTER 164: QUESTIONS AND ANSWERS

1. A 5-month-old boy presents with a cough. His parents report that for the past several weeks he has had mild respiratory tract symptoms and cough; however, during the past day, he has developed a severe paroxysm of staccato cough followed by posttussive emesis. What is the most appropriate antibiotic choice for this patient?

a. Amoxicillin
b. Ampicillin
c. Azithromycin
d. Trimethoprim-sulfamethoxazole

Answer: C. This patient likely has pneumonia caused by *Bordetella pertussis*. All children younger than 6 months with presumed pertussis should be observed in the hospital for monitoring and supportive care. First line treatment is with azithromycin, and erythromycin is a possible alternative. Amoxicillin and ceftriaxone are used to treat other types of pneumonia.

2. Which of the following findings is an indication for admission to the hospital in children with a diagnosis of pneumonia?

a. Abnormal chest radiograph showing pulmonary infiltrates
b. Decreased breath sounds in a lower lung field
c. Dehydration and vomiting
d. Diffuse rales and mild tachypnea

Answer: C. Many children with pneumonia can be managed as an outpatient with appropriate therapy. Clinical dehydration or inability to orally maintain hydration should prompt admission for ongoing treatment and monitoring. Abnormal lung auscultation or findings on

CHAPTER 164: QUESTIONS AND ANSWERS—cont'd

a chest radiograph by themselves would not be contraindications to outpatient treatment.

3. Which of the following statements best describes the epidemiology of pneumonia in children?
   - **a.** B*ordetella pertussis* is the most common cause in infants.
   - **b.** *Haemophilus influenzae* type b is still an important pathogen.
   - **c.** *Listeria monocytogenes* may cause illness in children younger than the age of 5 years.
   - **d.** Viral agents are the most common cause of pneumonia in children overall.

Answer: D. Viral agents are the most common cause of pneumonia in children. Bacteria predominate in neonates but are less common causative agents in toddlers and older children. Although *L. monocytogenes* may cause pneumonia in infants, it is rare after 3 months of age. *H. influenzae* type B has decreased by 90% since the onset of immunization of infants and young children.

4. What is the most common viral agent causing pneumonia in infants younger than 1 year?
   - **a.** Adenovirus
   - **b.** Enterovirus
   - **c.** Epstein-Barr virus
   - **d.** Respiratory syncytial virus (RSV)

Answer: D. RSV and parainfluenza are the most common viral agents in infants younger than 1 year. Viruses that may be responsible for the other agents may also cause viral pneumonia but are not as common as RSV.

5. A 2-year-old presents with fever, cough, and rales. Chest radiograph reveals right middle lobe pneumonia. Which of the following antibiotics would be recommended for outpatient treatment for this toddler who is not penicillin allergic?
   - **a.** Amoxicillin
   - **b.** Azithromycin
   - **c.** Ceftriaxone
   - **d.** Cephalexin

Answer: A. High-dose amoxicillin is the treatment of choice for children with pneumonia younger than 5 years. Once the child reaches school age, azithromycin is suggested as empirical therapy because of the increased risk of *Mycoplasma pneumoniae* infection.

Pediatric Cardiac Disorders

Timothy Horeczko

KEY CONCEPTS

- Consider a congenital heart defect in an infant with central cyanosis who does not respond to 100% supplemental oxygen (hyperoxia challenge).
- Neonates with ductal-dependent cardiac lesions typically present within the first 2 to 3 weeks of life with either acute cyanosis or shock. Prostaglandin E_1 (alprostadil, 0.05 to 0.1 μg/kg/min) can maintain a patent ductus arteriosus to supply mixed blood and temporize the patient.
- Treatment of a hypoxic "tet spell" first includes the placement of an infant in the knee-to-chest position (or an older child in a squatting position) to increase systemic vascular resistance (SVR) and the provision of supplemental oxygen. Sedative agents can be used to decrease hyperpnea. Various medications can be used as adjunctive treatment to increase the SVR and thereby decrease the degree of right-to-left shunting across the ventricular septal defect (VSD).
- Prompt recognition of the clinical findings and symptoms of Kawasaki disease along with the rapid initiation of high-dose aspirin and intravenous immune globulin (IVIG) infusion may prevent the formation of coronary aneurysms.
- Acute bacterial endocarditis should always be considered in a child with a known congenital heart defect or an acquired cardiac defect who presents with fever of unknown origin, acute neurologic deficits, new-onset microscopic hematuria, myalgias, splenomegaly, petechiae, or other signs of systemic embolization.
- Oxygen, positive-pressure ventilation (noninvasive or invasive), diuretics, and possibly inotropes are the main emergency department (ED) treatment of infants and children who present with congestive heart failure (CHF). Nitroglycerin can cause profound hypotension in children and is not a first-line therapy.
- If vagal maneuvers fail to convert stable paroxysmal supraventricular tachycardia in children, rapid adenosine administration (0.1 mg/kg for the first dose, followed by 0.2 mg/kg on repeated doses) is the treatment of choice. Verapamil should be avoided in children because of its profound hypotensive effects.
- Young athletes with a positive family history of sudden unexplained death or exertion-induced symptoms (such as, chest pain, dyspnea, palpitations, and syncope) should be evaluated by a cardiologist before their resumption of vigorous activity.

FOUNDATIONS

Children with cardiac disorders present to the emergency department (ED) in one of two scenarios. In the first scenario, the child presents with an exacerbation or complication of an already known underlying cardiac disorder. Early consultation with the child's cardiologist along with comparisons of the child's previous and most recent diagnostic studies are very useful in the evaluation and management phases.

The second scenario represents more of a challenge to the emergency clinician: the child with an undiagnosed congenital or acquired cardiac disorder who presents with concerning signs and symptoms (Box 165.1).

Fetal and Neonatal Circulation

During fetal development, blood oxygenated by the placenta flows to the fetus through the umbilical vein, bypasses the fetal liver through the ductus venosus, and returns to the fetal heart through the inferior vena cava. From the inferior vena cava, blood enters the right atrium and is preferentially shunted to the left atrium through the patent foramen ovale (Fig. 165.1). Fetal pulmonary vascular resistance (PVR) is higher than fetal systemic vascular resistance (SVR); this forces deoxygenated blood to mostly bypass the fetal lungs (see Fig. 165.1). From the left atrium, blood flows to the left ventricle and the aorta. The oxygenated blood ejected through the ascending aorta is preferentially directed to the fetal coronary and cerebral circulations.

The proportion of returning deoxygenated blood from the superior vena cava that empties into the right atrium and then right ventricle is pumped into the pulmonary artery. This poorly oxygenated blood enters the aorta through the patent ductus arteriosus and mixes with the well-oxygenated blood in the descending aorta. The mixed blood in the descending aorta then returns to the placenta for oxygenation through the two umbilical arteries.

Once the infant is delivered and the umbilical cord is cut, expansion and aeration of the lungs cause a decrease in PVR, which enhances pulmonary blood flow. Increased global oxygenation causes a physiologic closure of the umbilical arteries, umbilical vein, ductus venosus, and ductus arteriosus. Increasing pulmonary blood flow to the infant's left atrium promotes closure of the foramen ovale. Complete anatomic closure of the foramen ovale does not occur until about 3 months of age. Although the ductus arteriosus functionally closes at about 10 to 15 hours of life, complete anatomic closure does not occur until 2 to 3 weeks of life.

In the absence of any congenital cardiac defects, these transitional circulatory changes pose no physiologic problems to the infant. However, closure of the ductus arteriosus can be life-threatening in neonates with cardiac defects that depend on the patency of the ductus arteriosus for survival.

Pathophysiology of Cardiovascular Compensatory Responses

The young myocardium is inefficient and unable to increase contractility in response to demand.[1] When more cardiac output is needed, infants and children respond with an increase in heart rate; therefore, bradycardia is an ominous sign that connotes a severely compromised cardiac output. Children develop the adult capacity to increase contractility by 8 to 10 years of age.

BOX 165.1 Common Presenting Signs and Symptoms of Cardiac Disorders in Infants and Children

General
Fussiness
Lethargy
Poor feeding (with or without associated diaphoresis)
Poor growth

Respiratory
Respiratory distress
Wheezing
Apnea

Cardiovascular
Tachycardia
Shock
Paleness
Mottling
Cyanosis
Palpitations
Chest pain
Syncope
Various dysrhythmias

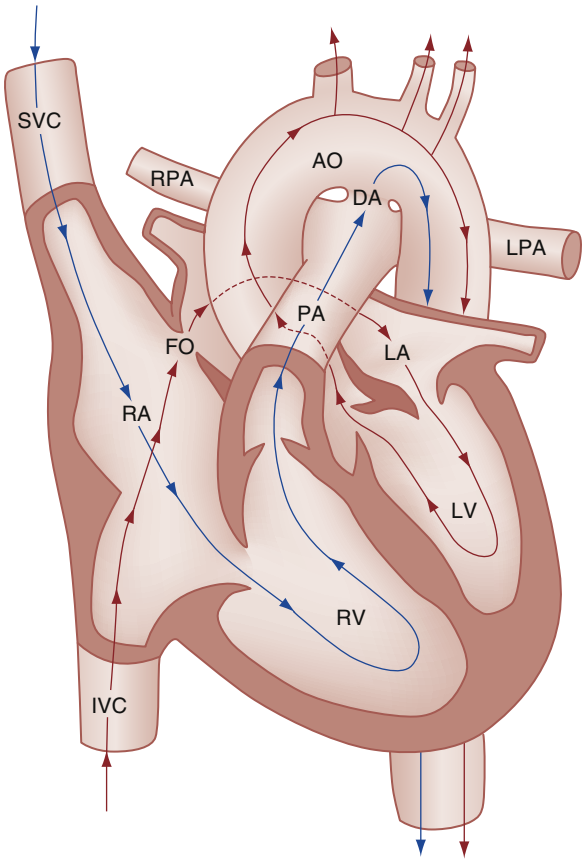

Fig. 165.1 Normal intracardiac fetal circulation: Physiologic shunting through the patent foramen ovale *(FO)* and the patent ductus arteriosus *(DA)*. Oxygenated blood from the placenta *(red arrows)* reaches the right atrium *(RA)* through the inferior vena cava *(IVC)*. This well-oxygenated blood is preferentially shunted from the RA across to the left atrium *(LA)* through the FO and is then ejected out the left ventricle *(LV)* to the ascending aorta *(AO)*. Deoxygenated blood *(blue arrows)* returning from the superior vena cava *(SVC)* preferentially travels from the RA into the right ventricle *(RV)* and then out through the main pulmonary artery *(PA)*. Because of the high pulmonary vascular resistance (PVR) in the fetal lungs, this deoxygenated blood bypasses lungs and enters the descending aorta through the DA. Thus the areas of the fetal body that are perfused by arteries proximal to the DA receive well-oxygenated blood, whereas those areas of the body that are perfused by arteries distal to the DA receive blood with a mixed oxygenation. *LPA,* Left pulmonary artery; *RPA,* right pulmonary artery.

BOX 165.2 Causes of Decreased Stroke Volume in Infants and Children

Hypovolemia (most commonly secondary to dehydration)
Congestive heart failure (CHF; acquired or secondary to underlying congenital cardiac defects)
Myocarditis
Hypertrophic cardiomyopathy with decreased diastolic filling
Dilated cardiomyopathy with decreased systolic ejection
Pericarditis or pericardial effusion with cardiac tamponade
Tachydysrhythmias with decreased diastolic filling times

A decrease in stroke volume can be caused by a weak "pump," decreased volume in the circulation, or both. As stroke volume decreases, a compensatory increase in the heart rate is needed to preserve normal cardiac output. The most common cause of decreased stroke volume in children is hypovolemia from dehydration. Other causes of decreased stroke volume in children are listed in Box 165.2.

CLINICAL FEATURES

Tachycardia is the first compensatory cardiovascular response to decreases in stroke volume. If tachycardia alone is not enough to maintain a normal cardiac output, the next compensatory physiologic mechanism to preserve perfusion is an increase in the SVR. This change in SVR is exhibited as an increase in the diastolic blood pressure, which in turn creates a narrowed pulse pressure. The clinical examination findings of the extremities of a child with an increased SVR include pallor, mottling, cool skin, delayed capillary refill time (>2 seconds), and weak or thready distal pulses.

Pathophysiology of Cyanosis

Cyanosis is a clinical sign caused by the preponderance of deoxygenated blood in the capillary beds, most readily observed in the mucous membranes, conjunctiva, nail beds, and skin. For cyanosis to be evident clinically, there must be at least 4 to 5 g/dL of deoxyhemoglobin admixed in the blood; this usually correlates with an oxygen saturation of approximately 80% to 85%. However, children with anemia—even if hypoxic—may not show overt signs of cyanosis (i.e., the critical mass of deoxygenated hemoglobin is not met to manifest cyanosis clinically). Central cyanosis results from a decrease in pulmonary ventilation and oxygenation, a decrease in pulmonary perfusion, the shunting of deoxygenated blood directly into the systemic circulation, or the presence of abnormal hemoglobin. Cyanosis in the neonate may be due to a variety of cardiac, pulmonary, hematologic, or toxic causes. Cardiac causes of cyanosis include congenital lesions with right-to-left shunts and cardiac lesions with decreased or increased pulmonary blood flow. Common pulmonary causes of cyanosis include bronchiolitis, pneumonia, and pulmonary edema. Methemoglobinemia is a hematologic cause of cyanosis.

Clinical Features of Cyanosis

Central cyanosis involves the lips, tongue, and mucous membranes; peripheral cyanosis (acrocyanosis) involves the hands and feet. Acrocyanosis is a common mostly benign finding in neonates caused by cold stress and peripheral vasoconstriction. Infants with cyanosis due to a congenital heart defect may not exhibit as much respiratory distress compared with the infant with cyanosis due to a pulmonary cause. Thus, a cardiac cause of central cyanosis should be suspected in a child who appears "comfortably blue." Another important clinical clue to the cause of central cyanosis is that cyanosis of cardiac origin usually worsens with crying, whereas cyanosis due to a pulmonary cause may

improve. Cyanotic congenital heart defects with right-to-left shunting will demonstrate a minimal improvement with supplemental oxygen, whereas cyanosis of a purely pulmonary origin typically exhibits a significant improvement with supplemental oxygen (Table 165.1).

History

Infants with an underlying congenital heart disorder may be detected with a thorough history targeting key question (Box 165.3). Additional history including diaphoresis during feeds and poor weight gain may signal early congestive heart failure (CHF). The cause of the infant's hypoxia—cardiac or pulmonary—may be ascertained by the age at onset and the events surrounding a change in color. For example, an infant who sweats during feeding may exhibit a splanchnic steal from anomalous coronary arteries, causing transient ischemia, pain, color change, and diaphoresis that resolve after eating. A child with an undiagnosed congenital heart defect resulting in CHF and pulmonary edema may take longer to feed, frequently pausing to catch his or her breath, with subsequent poor weight gain and gradually increasing work of breathing. Respiratory tract infections are common during childhood and may cause an acute deterioration in a child with an underlying cardiac disorder. In turn, children with congenital heart disease (CHD) with large left-to-right shunts and increased pulmonary blood flow tend to have a higher incidence of lower respiratory tract infections. Acute respiratory distress in these patients may be from a combination of pulmonary and cardiac factors (e.g., CHF).

TABLE 165.1 Clinical Clues to Help Distinguish Between Cardiac and Pulmonary Causes of Central Cyanosis[a]

	Cardiac Etiology	Pulmonary Etiology
Respiratory status	May be "comfortably blue"	Respiratory distress
Response to crying	Worsening cyanosis	Improved cyanosis
Response to oxygen	Minimal or no improvement	Improvement with oxygen

[a]Cyanosis due to severe pulmonary disease (e.g., severe pneumonia, tension pneumothorax, acute chest syndrome of sickle cell disease) may not show significant improvement with supplemental oxygen, but these children will also typically exhibit severe respiratory distress along with clinical cyanosis.

BOX 165.3 Key Elements to Elicit in the History of a Child With a Known Cardiac Disorder

Cardiac Diagnosis

Congenital or acquired disorder?

Any episodes of previous decompensation? (If so, are the current signs and symptoms similar to or different from those previous episodes?)

Oxygen Issues

Currently receiving home oxygen supplementation (continuous or only during feedings and sleep)?

Baseline oxygen saturation (room air or while receiving home oxygen)?

Any recent need for increasing the amount of supplemental oxygen?

Medications

Names and dosages of all current medications (cardiac and noncardiac medications)?

Were any of these cardiac medications stopped recently (by the cardiologist or parental noncompliance)?

Any recent increases in the cardiac medications (reasons for the increase, previous dosage versus the current dosage, and the date this dosage was increased)?

Any new cardiac medications added recently and the reason for these additions?

Recent digoxin level if the patient is receiving daily digoxin therapy?

Results of Most Recent Studies (Chest Radiograph, Electrocardiogram, Echocardiogram, and Cardiac Catheterization)

When were the last studies performed, and what were the results?

Why were those studies performed (routine follow-up studies or obtained because of decompensation from baseline, or a planned evaluation for an upcoming surgical procedure)?

Surgical Procedures

Previous procedures and complications?

Any future planned procedures?

Chest Pain

Common causes of pediatric chest pain are musculoskeletal chest wall pain, asthma exacerbation, pneumonia, pleurisy, gastritis, and gastroesophageal reflux. Precordial catch syndrome (also known as *Texidor's twinge*) presents as a sharp, focal pain, usually located in the left periapical area of the chest wall. It occurs suddenly, is often worsened by inspiration, and is not associated with dyspnea. The child may report that the pain "took my breath away" or that "I was afraid to move"; the pain typically resolves within a few minutes and is not associated with dysrhythmias or other sequelae.

Chest pain or syncope on exertion should be investigated for an underlying cardiac condition, especially if there is a positive family history of sudden unexplained death in young adulthood. Myocardial injury may also be secondary to drug abuse (e.g., cocaine, methamphetamines, synthetic or over-the-counter drugs of abuse). Pulmonary embolism is a possible cause of chest pain, especially in pregnant adolescent girls, patients taking oral contraceptive agents, or those with blood dyscrasias. The rare, though life-threatening, condition of aortic dissection should be considered as a cause of chest pain in a patient with physical examination findings suggestive of a collagen vascular disorder, such as Marfan syndrome.

Physical Examination

General Appearance and Pulses

Clinicians can use the Pediatric Assessment Triangle (PAT) to evaluate the child's overall appearance: alertness and interaction with the environment (mental status); presence of retractions, nasal flaring, or posturing (breathing); and skin color including perfusion (circulation) (see Chapter 155). All four extremities should be palpated for the presence and quality of pulses. In infants, feel for the brachial and femoral pulses. Bounding pulses are typically present in infants with a patent ductus arteriosus. Coarctation of the aorta should be suspected in any child with strong or unequal pulses in the upper extremities and weak pulses in the lower extremities. A child presenting with CHF and shock will have weak and thready pulses in all extremities.

Vital Signs and Blood Pressures

A mild resting tachypnea or tachycardia may be the only clinical clue to an underlying cardiovascular disorder. A simplified table of normal pediatric vital signs may be used at the bedside (Table 165.2).

To measure blood pressure accurately, use a cuff that covers two-thirds of the upper arm or thigh. A cuff that is too narrow will overestimate the patient's true blood pressure; conversely, a cuff that is too large will underestimate the true blood pressure. Measure blood pressures in both arms in children with a suspected cardiac disorder. Coarctation of the aorta

TABLE 165.2 Pediatric Vital Signs and Pertinent Formulas for Estimation of Blood Pressure

SIMPLIFIED PEDIATRIC VITAL SIGNS

Age Group	Average Normal Heart Rate (beats/min)	Respiratory Rate (breaths/min)
Newborn to 1 year	140	40
1–4 years	120	30
4–12 years	100	20
>12 years	80	15

FORMULAS TO CALCULATE THE ESTIMATED NORMAL BLOOD PRESSURES IN CHILDREN 1 YEAR OLD AND OLDER

Estimated average systolic blood pressure (SBP): [age in years × 2] + 90 mm Hg
Estimated average diastolic blood pressure: ⅔ × [estimated SBP]

MINIMUM ACCEPTABLE SYSTOLIC BLOOD PRESSURE FOR AGE (LOWER FIFTH PERCENTILE)

Newborn to 1 month	60 mm Hg
1 month to 1 year	70 mm Hg
1–10 years	[Age in years × 2] + 70 mm Hg
>10 years	90 mm Hg

(proximal to the origin of the left subclavian artery) may present with a left arm blood pressure significantly lower than the right arm. Measure blood pressures in the thighs in any child with a suspected aortic coarctation or with documented hypertensive blood pressures in the upper extremities. The presence of femoral pulses does not rule out the possibility of a coarctation of the aorta. Because of the lack of well-designed blood pressure cuffs for the legs, blood pressures in the thighs can be 10 to 20 mm Hg higher than the blood pressures in the upper extremities. Therefore, blood pressures in the lower extremities that are lower than blood pressures in the upper extremities suggest coarctation of the aorta. Pulse oximetry readings lower in the legs than in the upper extremities suggests either a coarctation of the aorta or a right-to-left-shunt across a patent ductus arteriosus.

Cardiac Auscultation

Listen for the intensity and degree of splitting of the S_2 heart sound (closure of the pulmonic and aortic valves). In normal children, both aortic closure and pulmonic closure of S_2 should be heard along the left upper sternal border. A widely split and fixed S_2 suggests a physiologic problem from either a constant volume overload to the right side of the heart (e.g., atrial septal defect [ASD]) or a pressure overload to the right side of the heart (e.g., pulmonic stenosis). An ASD classically presents as a widely split and fixed S_2. The intensity of the S_2 component may be louder than normal in the child with pulmonary hypertension.

The third heart sound (S_3) is best heard along the lower left sternal border or the apex and may be a normal finding in children and young adults. An S_3 is produced by a rapid filling of the ventricles and is heard during early diastole, just after the S_2 sound. A loud S_3, however, is pathologic and due to dilated ventricles from volume overload (e.g., CHF and large ventricular septal defects [VSDs]). The fourth heart sound (S_4) occurs late in diastole, just before the S_1 sound. The finding of an S_4 is due to a decrease in compliance of a stiff, hypertrophic ventricle, best heard at the apex with the patient in the left lateral decubitus position (Box 165.4).

Cardiac murmurs are produced by turbulent blood flow through the heart and may not be associated with an underlying cardiac defect. The location, intensity, quality, timing, and radiation of the murmur determine whether the murmur is suggestive of an underlying cardiac pathologic condition. Although systolic murmurs can be present without any underlying anatomic abnormalities, diastolic murmurs are always considered pathologic in nature. Murmurs may be difficult to appreciate in the noisy ED setting, especially in tachycardic children. However, the location of the murmur may be a valuable clinical tool in determining the underlying anatomic origin of the murmur (Box 165.5).

Murmurs without any underlying anatomic abnormalities or hemodynamic significance are termed *innocent* or *functional murmurs*. All innocent murmurs are associated with normal ECGs and normal chest radiographs. Two of the most common innocent murmurs encountered in the pediatric population are the neonatal pulmonic flow murmur (peripheral pulmonic stenosis murmur) and Still's murmur. The pulmonic flow murmur of the neonate is due to the relatively thin walls and angulation of the right and left pulmonary arteries at birth. This systolic murmur is best heard at the left upper sternal border with radiation throughout the entire chest, axilla, and back. It usually disappears

BOX 165.4 A Pathologic Etiology of a Heart Murmur Should Be Suspected With Any of the Following Criteria

- Diastolic murmurs
- Systolic murmurs that are louder than a grade 3/6, continuous, or associated with a thrill
- Murmurs that are associated with abnormal heart sounds (clicks, rubs, or gallop rhythms)
- Presence of cyanosis or respiratory distress
- Bounding pulses or weak pulses
- Abnormalities on the electrocardiogram (ECG)
- An abnormal cardiac silhouette, abnormal pulmonary vascularity, or cardiomegaly on the chest radiograph

BOX 165.5 Auscultation Locations of Common Systolic Murmurs in Children

Left Upper Sternal Border (Pulmonic Area)
- Pulmonic valvular stenosis
- Atrial septal defects (ASDs; due to an increased pulmonic flow)
- Innocent pulmonic ejection murmur
- Neonate pulmonic flow murmur
- Patent ductus arteriosus (a continuous, "machinery" sounding murmur)

Left Lower Sternal Border
- Innocent vibratory Still murmur
- Ventricular septal defects (VSDs)
- Endocardial cushion defects
- Tetralogy of Fallot
- Hypertrophic cardiomyopathy

Apex
- Innocent vibratory Still murmur
- Mitral regurgitation
- Aortic stenosis
- Hypertrophic cardiomyopathy

Right Upper Sternal Border (Aortic Area)
- Aortic stenosis
- Coarctation of the aorta

by 3 to 6 months of age. Persistence of a systolic murmur in the pulmonic area beyond this period raises the possibility of pathologic pulmonary arterial stenosis.

Still's murmur is a common innocent murmur found in children between 2 and 6 years of age. Best heard along the left midsternal border, this murmur has a vibratory, musical, or twanging quality from turbulent flow. The distinct quality of Still's murmur distinguishes it from the harsher quality of a VSD murmur. The intensity of Still's murmur increases in the supine position, or with fever, excitement, exercise, or anemia; like most murmurs, it is best heard with the bell of the stethoscope.

DIAGNOSTIC TESTING

Hyperoxia Test

The hyperoxia test may help differentiate between cardiac and pulmonary causes of central cyanosis. This test consists of assessment of the rise in arterial oxygenation with the administration of 100% oxygen. An arterial blood gas is measured after several minutes on high-flow oxygen (100% oxygen). When the child is breathing high-flow oxygen, an arterial oxygen partial pressure (Pao_2) of more than 250 mm Hg virtually excludes hypoxia due to CHD—a "passed" hyperoxia test. An arterial oxygen reading of less than 100 mm Hg (in a child without obvious pulmonary disease) is consistent with a right-to-left shunt and is highly predictive of CHD—a "failed" hyperoxia test. Values of 100 to 250 mm Hg may indicate lesions with intracardiac mixing. Pulse oximetry is not an appropriate substitute for an arterial blood gas analysis; it is not sensitive enough to determine "pass" or "fail" of the test, because a child breathing high-flow oxygen and registering 100% on pulse oximetry may actually have a Pao_2 anywhere between 80 and 680 mm Hg. Prolonged administration of 100% oxygen may cause some theoretic problems, such as, closure of the ductus arteriosus in infants with critical left-sided heart obstructions or pulmonary vasodilation (which could potentially worsen pulmonary vascular congestion). However, oxygen should not be initially withheld in critically ill infants based on this concern alone; rather, clinicians should closely monitor the response to oxygen in infants with suspected CHD.

Laboratory Analysis

Patients with CHF exacerbation may exhibit respiratory acidosis (low pH and high $Paco_2$), in addition to a low Pao_2, due to respiratory fatigue; this may initially be clinically subtle. In contrast, children with compensated cyanotic congenital heart defects may have a normal pH despite a (chronically) low Pao_2. Chronic mild hypoxemia causes a chronic mild acid load on the respiratory, renal, and blood buffer systems; acute illness, such as a respiratory infection, can rapidly cause a decompensation in this fragile balance, resulting in a worsening acidosis. Patients with congenital heart defects who are not experiencing respiratory compromise are unlikely to exhibit elevation in $Paco_2$.

Children with cyanotic CHD often partially compensate with an acquired polycythemia. Hemoglobin and hematocrit levels can also help determine if a child with CHF has pallor due to CHD or high-output failure from anemia. Serum electrolyte values may be helpful in the evaluation of children with acute dysrhythmias, suspected metabolic acidosis, or chronic diuretic therapy. We recommend that patients with a known congenital heart defect or an acquired cardiac disorder (e.g., Kawasaki disease, acute rheumatic heart disease, myocarditis, pericarditis, and cardiomyopathy) who present with dysrhythmias, syncope, chest pain, or unexplained shortness of breath be assessed with cardiac biomarkers and an ECG.

Chest Radiography

Three important features of the chest radiograph (Fig. 165.2) are the cardiac size (cardiothoracic ratio), the cardiac shape (silhouette), and the degree of pulmonary vascular markings. The easiest method to gauge heart size in children is to determine the cardiothoracic ratio: compare the largest transverse diameter of the cardiac shadow on the posteroanterior view of the chest radiograph with the widest internal diameter (measured from the inside rib margin at the widest point above the costophrenic angles) of the chest. The films should be obtained during maximal inspiration whenever feasible. Of note, the cardiothoracic ratio is not very accurate in preverbal children, in whom a good inspiratory view is rarely obtained.

The normal cardiothoracic ratio in children is 50% to 55%. A cardiac silhouette that is larger than normal may be due to a shunt lesion,

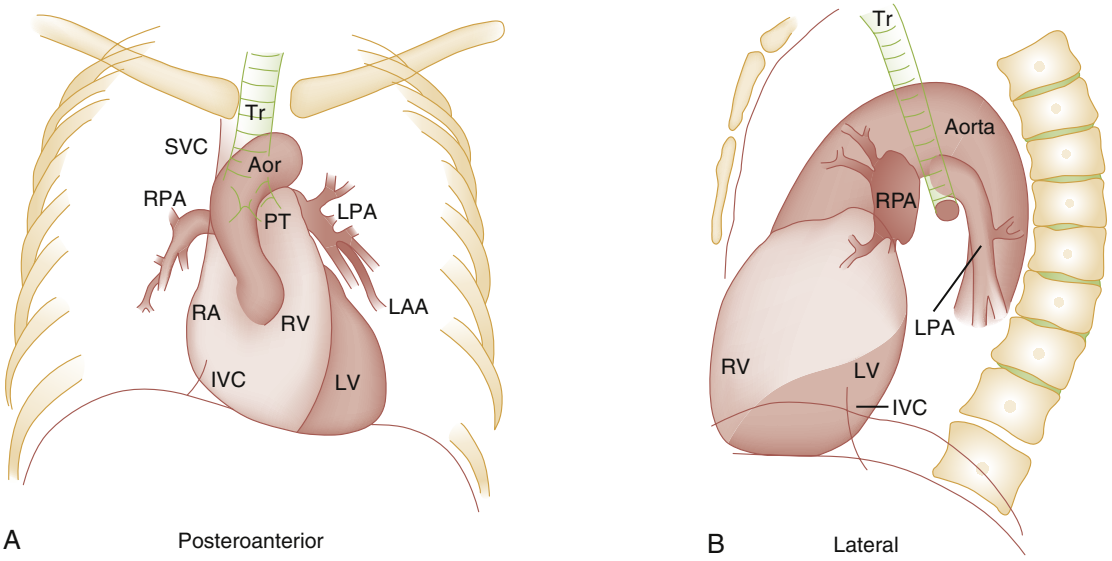

Fig. 165.2 Diagrammatic representations of the anatomy of the chest radiograph. (A) Normal heart in a young man, posteroanterior projection. (B) Right lateral projection of a normal heart in a young man. *Aor,* Aorta; *IVC,* inferior vena cava; *LAA,* left atrial appendage; *LPA,* left pulmonary artery; *LV,* left ventricle; *PT,* pulmonary trunk; *RA,* right atrium; *RPA,* right pulmonary artery; *RV,* right ventricle; *SVC,* superior vena cava; *Tr,* trachea.

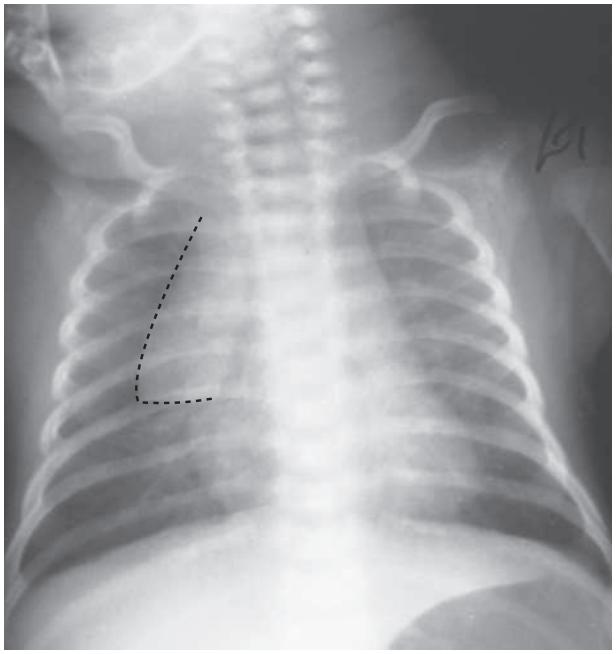

Fig. 165.3 Thymic shadow demonstrating the "sail sign" along the right cardiac border *(dotted line)*.

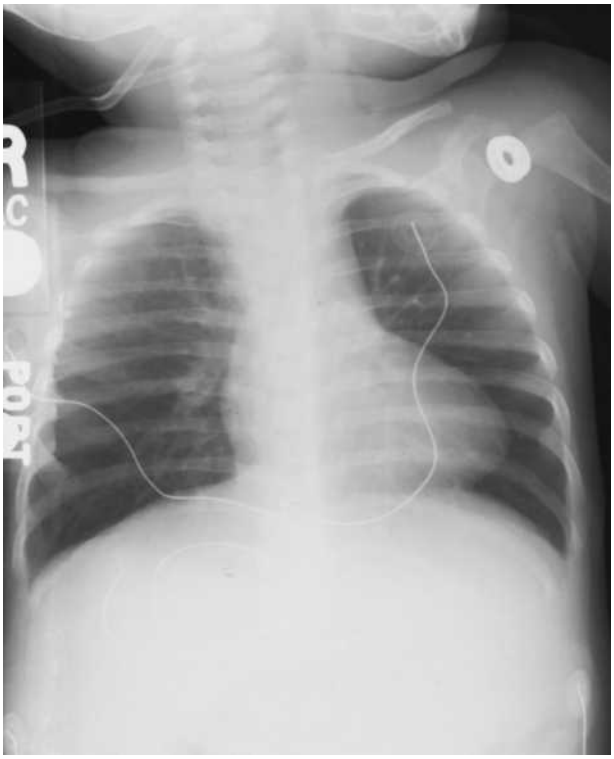

Fig. 165.4 The classic boot-shaped heart of tetralogy of Fallot.

cardiomegaly, or pericardial effusion. An enlarged heart shadow on a chest radiograph more reliably reflects a volume overload rather than pressure overload. The cardiac size can be falsely increased in infants by the presence of the thymus, seen in the mediastinum on the chest radiograph from birth until about 5 years of age. The thymic borders are typically wavy in appearance and sometimes can be seen as the classic "sail sign" along the superior right border of the heart (Fig. 165.3). The thymic shadow may not be visible radiographically in infants during times of physiologic stress, but should reappear when the infant recovers.

The three classic cardiac silhouettes seen in patients with congenital heart defects are the "boot-shaped heart" of tetralogy of Fallot (Fig. 165.4), the "egg-on-a-string" silhouette of transposition of the great arteries, and the "snowman-shaped" or "figure-of-eight" heart of total anomalous pulmonary venous return.

The degree of pulmonary vascular markings is a key factor in the differential diagnosis of congenital heart defects. Increased pulmonary vascularity is present when the pulmonary arteries appear enlarged and are visible in the lateral third of the lung fields or the lung apices. Another marker of increased pulmonary vascularity is seen on the posteroanterior view of the chest radiograph: the diameter of the right pulmonary artery in the right hilum is wider than the internal diameter of the trachea. The differential diagnosis of a cyanotic infant with decreased vascular markings includes Tetralogy of Fallot, pulmonary atresia, and tricuspid atresia. The cyanotic infant with increased vascular markings may have transposition of the great arteries, total anomalous pulmonary venous return, or truncus arteriosus. Increased vascular markings in an acyanotic infant are suggestive of an endocardial cushion defect, VSD, ASD, or patent ductus arteriosus.

In a normal left-sided aortic arch, the aorta descends to the left of the midline and slightly displaces the tracheal air shadow toward the right of midline above the level of the carina. With a right-sided aortic arch, the tracheal air shadow may be midline or deviated toward the left. A right-sided aortic arch is found in up to 25% of the children with tetralogy of Fallot. Rib notching secondary to increased collateral blood flow along the intercostal vessels can sometimes be appreciated between the fourth and eighth ribs in older children with undiagnosed

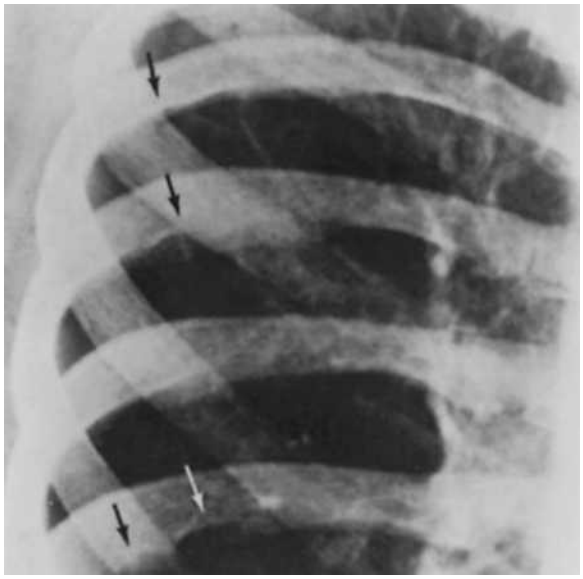

Fig. 165.5 Rib notching *(arrows)* in an 11-year-old girl with coarctation of the aorta. (From: Park MK. *Park's Pediatric Cardiology for Practitioners*, ed 6. Philadelphia: Elsevier/Saunders; 2014: 67-74. Figure 4-9 from: Caffey J. *Pediatric X-ray Diagnosis*, ed 7. Chicago: Mosby; 1978.)

coarctation of the aorta (Fig. 165.5) but is rarely visualized in children with coarctation of the aorta who are younger than 5 years old.

Electrocardiography

Electrocardiographic findings in infants and children change with the child's age (Table 165.3). At birth, muscle mass of the right ventricle is greater than that of the left ventricle; this is demonstrated by right axis deviation on the neonatal ECG. By the end of the first month of life, the left ventricle assumes dominance. By 6 months old, the left ventricular

to right ventricular mass ratio is 2 : 1, which then reaches the adult ratio of 2.5 : 1 by adolescence. The durations of the PR interval, QRS complex, and QT intervals increase with age.

Left axis deviation is present when the QRS axis is less than the lower limit of normal for the child's age; it occurs with left ventricular hypertrophy and left bundle branch block. Right axis deviation is present when the QRS axis is greater than the upper limit of normal for the child's age; this is seen with right ventricular hypertrophy and right bundle branch block. A "superior" QRS axis (0 to −180 degrees with an S wave in aV_F greater than the R wave) may be suggestive of an endocardial cushion defect or tricuspid atresia.

Some common indications for ECG in a pediatric patient include chest pain, dyspnea, syncope, palpitations, suspected dysrhythmias, or an underlying cardiac disorder. A rare but potentially fatal congenital cardiac abnormality detected by ECG, anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA), will show ischemic changes. Infants may have a history of poor feeding, irritability, and failure to thrive. Older children and adolescents may have acute-on-chronic ischemic symptoms. Anyone of any age with ALCAPA may suddenly present with cardiogenic shock secondary to myocardial ischemia. Evidence of volume overload seen on ECG includes: right atrial enlargement (also seen with ASD, atrioventricular [AV] canal defects, tricuspid atresia, Ebstein anomaly, and severe pulmonary stenosis); and right ventricular hypertrophy (also seen with pulmonary stenosis, Tetralogy of Fallot, transposition of the great arteries, VSD with pulmonary stenosis or pulmonary hypertension, coarctation of aorta [CoA] in the newborn, pulmonary valve atresia, and hypoplastic left heart syndrome).

TABLE 165.3 Normal Electrocardiographic Values (PR, QTc, and QRS Axes) in Infants and Children

	PR INTERVAL	QRS DURATION
Age	Average (Upper Limit)	Average (Upper Limit)
0–1 month	0.10 (0.12)	0.05 (0.07)
1 month to 1 year	0.10 (0.14)	0.05 (0.07)
1–3 years	0.11 (0.15)	0.06 (0.07)
3–8 years	0.13 (0.17)	0.07 (0.08)
8–12 years	0.15 (0.18)	0.07 (0.09)
12–16 years	0.15 (0.19)	0.07 (0.10)
Adult	0.16 (0.21)	0.08 (0.10)

The corrected QT (QTc) interval should not exceed:
0.45 second in infants <6 months old
0.44 second in children and adolescents

NORMAL QRS AXES IN INFANTS AND CHILDREN

Age	Mean Degrees (range)
1 week to 1 month	+110 (+30 to +180)
1–3 months	+70 (+10 to +125)
3 months to 3 years	+60 (+10 to +110)
>3 years	+60 (+20 to +120)
Adults	+50 (–30 to +105)

NORMAL T WAVE AXIS IN INFANTS AND CHILDREN

Age	Leads V_1 and V_2	Lead Av_f	Leads I, V_5, and V_6
Birth to 1 day	+/–	+	+/–
1–4 days	+––	+	+
4 days to adolescent	–	–	+
Adolescent to adult	+	+	+

+, Upright T wave; –, inverted T wave.

Biochemical Markers

As in adults, cardiac troponin T (cTnT) and cardiac troponin I (cTnI) are highly sensitive and specific in children for myocardial damage. Reference values are slightly higher for neonates younger than 3 months of age; normal and indeterminate values will depend on the bioassay used. The indications for troponin testing in children include suspected cardiac ischemia (of any etiology), myocarditis, and myocardial dysfunction in sepsis syndrome. Several studies have supported the use of plasma B-type natriuretic peptide (BNP) levels in the assessment and management of CHF in adults. Elevated BNP levels have demonstrated a similar correlation in children with CHF. BNP levels also correlate with the clinical symptoms of heart failure and ejection fraction.

SPECIFIC DISORDERS

Congenital Heart Disease

Foundations

Although a large percentage of CHD is now detected with prenatal ultrasound, pulse oximetry before discharge from the nursery is currently a standard screening for CHD, and its false-negative rate is very low.[2]

Clinical Features

Age, severity of symptoms, and time of presentation of a child with CHD vary by the specific defect, complexity, severity, and timing of the normal physiologic changes that occur as the fetal circulation transitions to that of a neonate (Table 165.4). The more severe or complex

TABLE 165.4 Symptomatic Presentation of Congenital Heart Defects and Time of Presentation

Defect	Time of Presentation
CONGENITAL HEART DEFECTS THAT PRESENT WITH CYANOSIS	
Transposition of the great arteries	Birth to 2 weeks
Total anomalous pulmonary venous return	Birth to 2 weeks
Tricuspid atresia	Birth to 2 weeks
Ebstein anomaly of the tricuspid valve	Birth to 2 weeks
Truncus arteriosus	Birth to 2 weeks
Pulmonary atresia	Birth to 2 weeks
Hypoplastic right heart syndrome	Birth to 2 weeks
Hypoplastic left heart syndrome	Birth to 2 weeks
Tetralogy of Fallot	Birth to 12 weeks
CONGENITAL HEART DEFECTS THAT PRESENT WITH SHOCK	
Coarctation of the aorta	From first week on
Aortic stenosis	From first week on
CONGENITAL HEART DEFECTS THAT PRESENT WITH CONGESTIVE HEART FAILURE	
Ventricular septal defects (VSDs)	From 4 weeks on
Patent ductus arteriosus	From 4 weeks on

CHD lesions may not be clinically apparent immediately after birth. As the ductus arteriosus begins to close in the first several weeks of life, cardiac defects with obstructive lesions of the pulmonary or systemic circulations will be unmasked, and these infants will present with acute cyanosis, shock, or both. In general, the more severe the anatomic defect is (i.e., lack of pulmonary blood flow or lack of systemic blood flow), the earlier in life these conditions will be manifested with cyanosis and shock.

Differential Diagnosis

Many children with CHD do not fit neatly into a single pattern; some have mixed defects. The exact anatomic diagnosis of a CHD is dependent on echocardiography, cardiac catheterization, or advanced imaging; establishment of the exact anatomic diagnosis is seldom possible in the ED setting.

Diagnostic Testing

The emergency clinician should rely on several key elements of the clinical evaluation in addition to findings on the chest radiograph and ECG to narrow the diagnostic possibilities. Pattern recognition may be helpful (Box 165.6). For example, the presence of cyanosis, a grade 3/6 systolic ejection murmur best heard at the mid left sternal border, a boot-shaped heart, and a decreased pulmonary blood flow on the chest radiograph with evidence of right ventricular hypertrophy on the ECG suggest Tetralogy of Fallot.

Management

The majority of children who present to the ED in shock have volume depletion or sepsis. These patients should receive rapid repeated fluid boluses of 20 mL/kg. Children with poor perfusion and suspected CHD, however, should receive smaller aliquots of 10 mL/kg to avoid precipitation or exacerbation of CHF. This is especially important in the neonate with undifferentiated shock. In these cases, give the initial 10 mL/kg bolus and assess for effect. If the child is improved or no worse, give more fluids. Be judicious in suspected CHD and ready to provide inotropic support or positive pressure ventilation, either by noninvasive or endotracheal means.

CHD that is manifested within the first 2 to 3 weeks of life with a sudden onset of cyanosis or cardiovascular collapse is typically due to ductal-dependent cardiac lesions (Box 165.7). Closure of the ductus arteriosus in these patients interrupts blood flow either to the lungs, producing cyanosis (e.g., tricuspid atresia) *or* to the systemic circulation, producing shock (e.g., hypoplastic left heart syndrome). To maintain an open ductus arteriosus and promote mixture of oxygenated and deoxygenated blood, prostaglandin E_1 (alprostadil) is typically started at 0.05 to 0.1 μg/kg/min. A known adverse reaction to a PGE_1 infusion is apnea (30%). Assiduous monitoring of the child's respiratory drive is essential with PGE_1 administration. Although some small studies endorse the omission of endotracheal intubation of neonates on a PGE_1 infusion, endotracheal intubation should be considered for these infants, especially before inter-facility transport.

Children with cardiac conditions are at risk of post-intubation cardiovascular collapse due to positive pressure ventilation, increased intrathoracic pressures, and decreased venous return (e.g., cyanotic heart disease is often preload dependent). To support cardiac output and SVR (which mitigates a right-to-left shunt), ketamine is the preferred induction agent along with a non-depolarizing metabolically neutral neuromuscular blocker, such as rocuronium. Not only will intubation provide a secure airway, but controlled ventilation will also help decrease the infant's work of breathing, shunting much needed cardiac output and metabolic demands from the overtaxed respiratory apparatus. Other adverse reactions to a PGE_1 infusion include fever, seizures, bradycardia, hypotension, flushing, and decreased platelet aggregation.

BOX 165.6 Clinical Clues to Aid in the Diagnosis of Congenital Heart Disease

Presence or Absence of Central or Peripheral Cyanosis?

Central cyanosis with minimal respiratory distress ("comfortably blue") is suggestive of CHD more than of a purely pulmonary etiology.

Abnormalities in Cardiac Auscultation?

Murmurs: Systolic versus diastolic, location, and radiation

Quality of S_1, S_2, and the presence of any clicks or gallops

Change in the Degree of Central Cyanosis With Crying?

Worsening of cyanosis with crying suggests a cardiac rather than a purely pulmonary etiology.

Response of Pa_{O_2} to the Hyperoxia Challenge (Administering 100% Oxygen)?

Purely pulmonary causes of cyanosis: Pa_{O_2} should rise to levels above 250 mm Hg

Cyanotic CHD associated with an increased pulmonary blood flow: Pa_{O_2} may occasionally reach as high as 150 mm Hg

Cyanotic CHD associated with a decreased pulmonary blood flow: Pa_{O_2} will not rise above 100 mm Hg

Chest Radiograph Abnormalities?

Cardiac size and shape (one of the three classic cardiac silhouettes)?

- Boot-shaped heart: Tetralogy of Fallot
- Egg-on-a-string silhouette: Transposition of the great vessels
- Snowman-shaped or figure-of-eight heart: Total anomalous pulmonary venous return

Degree of Pulmonary Blood Flow?

Increased (acyanotic): ASD, Eisenmenger syndrome, VSD, patent ductus arteriosus, endocardial cushion defects

Increased (cyanotic): Transposition of the great arteries, total anomalous pulmonary venous return, hypoplastic left heart syndrome, truncus arteriosus

Decreased or normal (acyanotic): Pulmonic stenosis, aortic stenosis, coarctation of the aorta

Decreased (cyanotic): Tetralogy of Fallot, severe pulmonic stenosis, Ebstein anomaly, tricuspid atresia, pulmonary atresia, hypoplastic right heart syndrome

Electrocardiographic Abnormalities?

Evidence of chamber enlargement: right ventricular hypertrophy, left ventricular hypertrophy, biventricular hypertrophy, right atrial hypertrophy, or left atrial hypertrophy

An abnormal superior QRS axis is suggestive of endocardial cushion defect or tricuspid atresia.

ASD, Atrial septal defect, *CHD,* congenital heart disease; *Pa_{O_2},* arterial oxygen partial pressure; *VSD,* ventricular septal defect.

Acyanotic Congenital Heart Defect

Foundations

Acyanotic CHD can be further subdivided (Fig. 165.6) into obstructive lesions (e.g., pulmonic stenosis, aortic stenosis, coarctation of the aorta) and lesions characterized by left-to-right shunting with an associated increase in pulmonary blood flow (e.g., VSDs, ASDs, patent ductus arteriosus, endocardial cushion defects). These acyanotic lesions

BOX 165.7 Ductal-Dependent Cardiac Lesions in the Neonate

Congenital Heart Diseases That Require a Patent Ductus Arteriosus to Preserve Blood Flow From the Aorta to the Pulmonary Circulation

Tetralogy of Fallot

usually present within the first 6 months of life with symptoms of CHF; however, ASDs can remain asymptomatic until adulthood.

Specific Disorders

Ventricular Septal Defect. VSD is the most common congenital cardiac defect and accounts for 20% to 25% of all cases of CHD. Spontaneous closure occurs in 30% to 40% of all VSDs overall and in 50% to 70% of smaller VSDs.

Clinical Features. Symptoms from a VSD are dependent on its size, and the degree of pulmonary vascular resistance present. Most VSDs are clinically asymptomatic (minimal or no left-to-right shunting) immediately after birth because of normal, relatively higher pulmonary vascular resistance. By 6 to 8 weeks of age, pulmonary vascular resistance naturally decreases. If a VSD is present, then left-to-right shunting can occur, and its typical systolic murmur may be appreciated.

Small VSDs may remain completely asymptomatic throughout childhood. In contrast, by 2 to 3 months of age some infants with large VSDs may experience an abnormally high pulmonary blood flow, and signs and symptoms of CHF (e.g., poor feeding and poor growth). Older children with VSDs may present with decreased exercise tolerance or recurrent pulmonary infections. If moderate to large VSDs are not corrected surgically, by 6 to 12 months of age irreversible changes occur in the pulmonary vasculature; high pulmonary vascular resistance is established, possibly resulting in pulmonary hypertension. Subsequently, high pulmonary vascular resistance increases right atrial and right ventricular pressures. If a large VSD is also present, the direction of the shunt is reversed, now right-to-left. The previous left-to-right shunt would have been tolerated relatively well. Once the reversal is established—a right-to-left shunt—poorly oxygenated blood flows into the systemic circulation with resulting degrees of cyanosis, called Eisenmenger syndrome.

Diagnostic Testing. The chest radiograph in children with small VSDs may be entirely normal. Cardiomegaly with increased pulmonary vascular markings is usually present with untreated moderate-to-large VSDs. The ECG of moderate-sized VSDs typically reveals left ventricular hypertrophy, but biventricular hypertrophy may be present in VSDs with large left-to-right shunting.

Management. All VSDs, regardless of the size of the defect, are at risk for bacterial endocarditis because of the high velocity of turbulent blood flow through them, and thus, should be repaired.

Traditional closure of VSDs required open heart surgery. Today, however, a transcatheter closure technique that avoids the inherent risks and complications of open heart surgery and cardiopulmonary bypass has supplanted traditional methods.

Atrial Septal Defect. ASDs account for 5% to 10% of all cases of CHD. The majority of infants and children with ASDs remain clinically asymptomatic until adulthood. Spontaneous closure has been reported in up to 40% of the cases within the first 5 years of life.

Clinical Features. Large ASDs or those associated with comorbid conditions, such as bronchopulmonary dysplasia, can be manifested with symptoms of CHF and pulmonary overcirculation (e.g., dyspnea with feedings, poor weight gain, and frequent lower respiratory tract infections). The majority of ASDs are discovered when a suspicious murmur is detected on a routine physical examination: a widely split and fixed S_2 is a characteristic finding of ASDs.

Diagnostic Testing. The chest radiographs of children with ASDs will reveal varying degrees of cardiomegaly, right atrial and right ventricular enlargement, and a prominent main pulmonary artery segment and increased pulmonary vascular markings. The ECG will show right axis deviation and right ventricular hypertrophy. All patients with unrepaired ASDs will have symptoms if pulmonary hypertension develops. Patients with large ASDs that are not detected and repaired are at risk for development of Eisenmenger syndrome. Unlike VSDs, uncomplicated ASDs are not associated with high risk of bacterial endocarditis because of the lower turbulence and velocity of blood flow through the atrial defect.

Management. Traditionally, ASDs required open heart surgery to place a patch over the septal defect. Newer therapies include septal occlusion devices placed by the transcatheter approach.[3] Antiplatelet therapy during the 6-month period after placement of the device is typically given and is safe and effective in preventing thrombus formation on the surface of the septal occluder.

Eisenmenger Syndrome

Clinical Features. Eisenmenger syndrome can occur in any large left-to-right shunt defect. Left uncorrected, irreversible changes in the pulmonary arterioles lead to pulmonary vascular obstruction and pulmonary hypertension. As the degree of pulmonary hypertension increases, PVR may then begin to exceed SVR. This causes right-sided pressures to exceed those on the left, causing right-to-left shunting. The reversal in the direction of shunt flow produces cyanosis. Other clinical features of patients who have Eisenmenger syndrome include chest pain, dyspnea on exertion, and hemoptysis.[4]

Coarctation of the Aorta

Foundations. Nearly 50% of patients with coarctation of the aorta also have an associated bicuspid aortic valve. The area of coarctation can occur proximal to the insertion of the ductus arteriosus (preductal type) or distal to the insertion of the ductus arteriosus (most common, postductal type).

Clinical Features. The severity of symptoms and age at time of presentation are dependent on the location of the coarctation, the degree of narrowing, and the presence of any other associated cardiac defects. Infants with the rarer, preductal type of coarctation of the aorta may also exhibit differential cyanosis if the ductus arteriosus remains open. With differential cyanosis, the upper half of the body is perfused with well-oxygenated blood supplied by the left ventricle and the ascending aorta. However, the lower half of the body will appear cyanotic, being largely perfused by right-to-left shunting of deoxygenated blood from the patent ductus arteriosus into the descending aorta. Infants with the preductal type of coarctation of the aorta will present with signs of circulatory failure and shock when the ductus arteriosus begins to close. The clinician should search for a "brachial-femoral delay" by palpating both pulses simultaneously.

Most of the asymptomatic cases of the more common postductal coarctation of the aorta are diagnosed as a result of a cardiology referral for a systolic murmur or a hypertension evaluation, but infants with severe postductal coarctation of the aorta can also present during the first few weeks of life with signs of circulatory failure and shock. If a child is discovered to have hypertension on a routine physical examination, obtain blood pressure measurements in the lower extremities to assess the possibility of coarctation of the aorta. Coarctation of the aorta should be suspected if the systolic blood pressure in the right arm is 15 to 20 mm Hg higher than that in the legs. If the systolic pressure in the right arm is higher than that in the left arm, the area of coarctation is probably preductal and located proximal to the origin of the left subclavian artery. In general, diastolic blood pressures are similar in the upper and lower extremities, although lower extremity pressures often have higher measured values due to use of smaller blood pressure cuffs meant for arms.

Diagnostic Testing. The chest radiograph will most often reveal a normal cardiac silhouette and normal pulmonary vascular markings, but notching along the lower borders of the posterior fourth to eighth ribs due to the pressure of the dilated collateral vessels may be exhibited in children older than 5 years of age. The ECG typically reveals a left axis and left ventricular hypertrophy. Suspected cases of coarctation of the aorta should be imaged with transthoracic echocardiography or cardiac magnetic resonance imaging to confirm and define the coarctation. In stable patients, this can be done on an outpatient basis.

Management. Definitive surgical repair of coarctation of the aorta involves angiography or stenting of the narrow aortic lumen; resection of the narrowed section of the aorta with an end-to-end anastomosis may be necessary. Complications of undiagnosed cases are related to resultant hypertension, and can include heart failure, hypertensive encephalopathy, and intracranial hemorrhages.

Cyanotic Congenital Heart Diseases

Foundations. Cyanotic CHDs are a result of either decreased pulmonary blood flow to the lungs or right-to-left shunting of desaturated blood directly into the systemic circulation (Fig. 165.7). The classic cyanotic CHDs can be remembered by the five Ts: truncus arteriosus, transposition of the great arteries, tricuspid atresia, Tetralogy of Fallot, and total anomalous pulmonary venous return. Other forms of cyanotic CHD include Ebstein anomaly, pulmonary atresia, severe pulmonary stenosis, hypoplastic left heart syndrome, and hypoplastic right heart syndrome. Many of these cyanotic heart lesions are routinely detected either on prenatal ultrasound or in the nursery; only Tetralogy of Fallot is covered in this section.

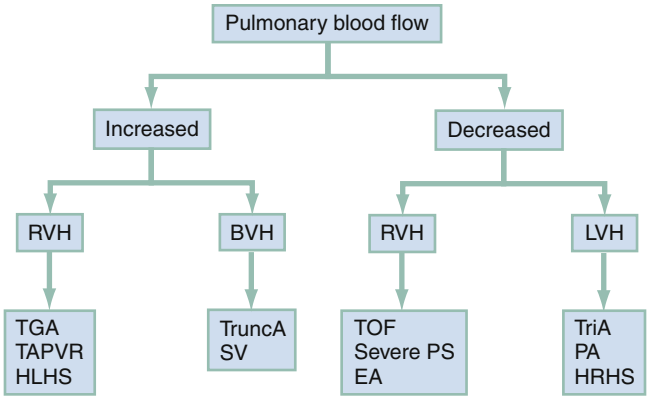

Fig. 165.7 Clinical clues to diagnosis of cyanotic congenital heart defects. *BVH,* Biventricular hypertrophy; *EA,* Ebstein anomaly; *HLHS,* hypoplastic left heart syndrome; *HRHS,* hypoplastic right heart syndrome; *LVH,* left ventricular hypertrophy; *PA,* pulmonary atresia; *PS,* pulmonary stenosis; *RVH,* right ventricular hypertrophy; *SV,* single ventricle; *TAPVR,* total anomalous pulmonary venous return; *TGA,* transposition of the great arteries; *TOF,* Tetralogy of Fallot; *TriA,* tricuspid atresia; *TruncA,* truncus arteriosus.

Tetralogy of Fallot

Foundations. Tetralogy of Fallot is the most common cause of cyanotic CHD beyond infancy. It arises from a single embryologic defect in which the subpulmonic conus fails to expand, resulting in four abnormalities (Fig. 165.8): (1) right ventricular outflow tract obstruction; (2) large, unrestrictive, misaligned VSD; (3) overriding aorta that receives blood flow from both ventricles; and (4) right ventricular hypertrophy secondary to the high pressure load placed on the right ventricle by the right ventricular outflow tract obstruction. These anatomic defects collectively result in decreased pulmonary blood flow and varying degrees of right-to-left shunting of deoxygenated blood across the VSD. Tetralogy of Fallot is often associated with other cardiac defects, such as right-sided aortic arch, ASD, and anomalous origin of the left coronary artery.

Clinical Features. The degree of cyanosis and the age at presentation are directly dependent on the degree of right ventricular outflow tract obstruction. Infants with Tetralogy of Fallot typically have worsening of their cyanosis during crying and feeding. Older children with tetralogy of Fallot may have cyanotic exacerbations during periods of physical exertion. Infants with milder forms of right ventricular outflow tract obstruction may be acyanotic, and sometimes referred to as having a "pink" Tetralogy of Fallot. Infants with severe right ventricular outflow tract obstruction exhibit profound cyanosis within the first few days of life; they may even require PGE_1 infusion to preserve pulmonary blood flow by left-to-right shunting from the aorta into the main pulmonary artery through the patent ductus arteriosus.

The physical examination can reveal varying degrees of cyanosis, and a systolic ejection murmur along the left sternal border. Chronic hypoxemia results in a compensatory polycythemia and varying degrees of clubbing of the fingers and toes.

Diagnostic Testing. The chest radiograph of a patient with cyanotic Tetralogy of Fallot (see Fig. 165.4) shows decreased pulmonary vascular markings and a boot-shaped heart (secondary to a concave main pulmonary artery segment along the superior aspect of the left border of the heart). The heart size in Tetralogy of Fallot is normal; a right-sided aortic arch may be seen in 25% of the cases. The ECG of cyanotic Tetralogy of Fallot reveals right ventricular hypertrophy and a right axis deviation. Children with pink Tetralogy of Fallot may not

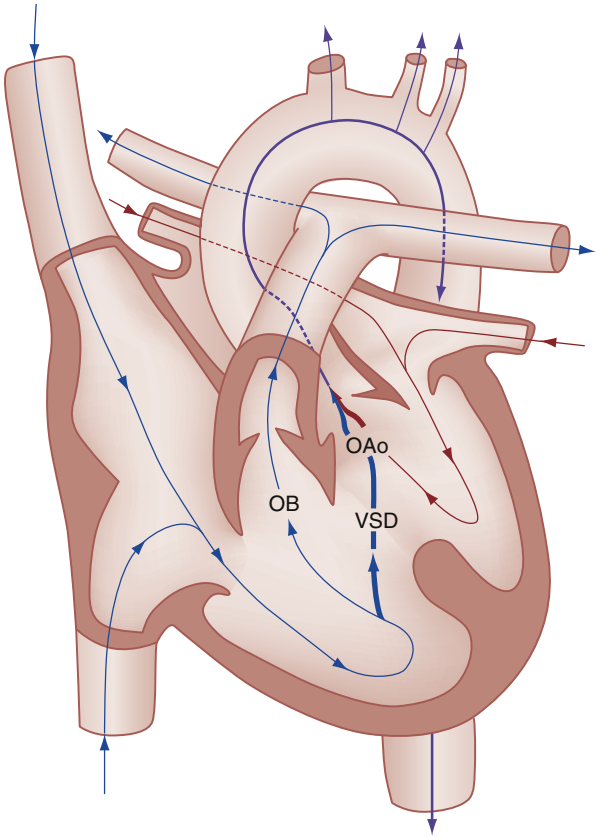

Fig. 165.8 Diagrammatic representation of the right-to-left shunting that occurs in Tetralogy of Fallot. Some of the deoxygenated blood *(thick blue arrow)* in the right ventricle is shunted across the ventricular septal defect *(VSD)* into the left ventricle. This deoxygenated blood mixes with the well-oxygenated blood from the lungs *(red arrow)*. The blood that is ejected out through the overriding aorta *(OAo)*, therefore, contains blood of mixed oxygenation *(purple arrows)*. The amount of deoxygenated blood that is shunted through the VSD *(thick blue arrow)* is dependent on a combination of factors, including the severity of right ventricular outflow tract obstruction *(OB)*, the size of the VSD, and the degree of systemic vascular resistance (SVR). When the SVR falls (as occurs during a tet spell), more deoxygenated blood from the right ventricle will be shunted across the VSD into the systemic circulation, which results in hypoxia, metabolic acidosis, and worsening cyanosis.

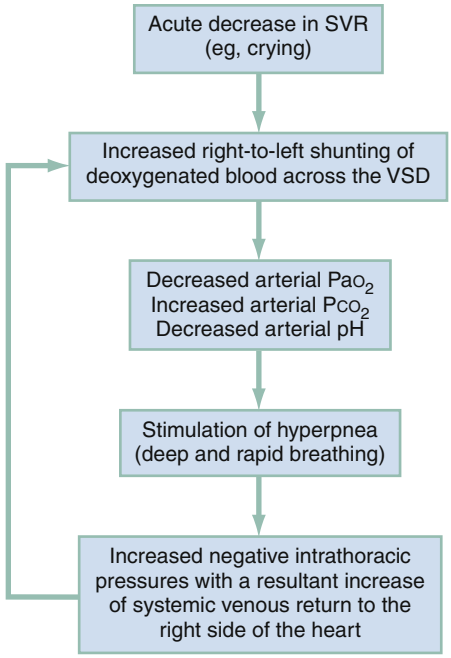

Fig. 165.9 Pathophysiologic mechanisms of a hypoxic (tet) spell. *PaO_2,* Arterial oxygen partial pressure; *PCO_2,* partial pressure of carbon dioxide in the arterial blood; *SVR,* systemic vascular resistance; *VSD,* ventricular septal defect.

BOX 165.8 Management of Tetralogy of Fallot Hypoxic Spells

- Place the child in the knee-to-chest position to increase the systemic vascular resistance (SVR), which decreases the right-to-left shunt across the ventricular septal defect (VSD).
- Provide supplemental oxygen (limited value by itself).
- Morphine: 0.1 to 0.2 mg/kg IV or IM
- Fentanyl: 1 μg/kg/dose IV or IM as an alternative to morphine
- Fentanyl: 1.5–2 mcg/kg/dose intranasally (anatomic limit of 1 mL solution per naris)
- Midazolam: 0.2 to 0.3 mg/kg/dose intranasally (anatomic limit of 1 mL solution per naris)
- Sodium bicarbonate: 1 mEq/kg IV if suspected or documented acidosis
- Consider ketamine: 1 to 2 mg/kg IV or 3 to 5 mg/kg IM
- Consider propranolol: 0.1 to 0.2 mg/kg IV
- Consider phenylephrine: 0.01 to 0.02 mg/kg IV

IM, Intramuscular; *IV,* intravenous.

initially exhibit any degree of right ventricular hypertrophy, but these acyanotic variations of Tetralogy of Fallot gradually develop into the cyanotic form by 1 to 3 years old.

A potentially life-threatening complication of Tetralogy of Fallot is the so-called *tet spell,* also known as a hypercyanotic or hypoxic spell. These episodes occur most commonly in infants, with a peak incidence between 2 and 4 months old.

Any event that suddenly lowers the SVR (such as crying or defecation), hypovolemia, or tachycardia will promote a large right-to-left shunt across the VSD, beginning the vicious circle of a hypoxic spell. The large right-to-left shunt through the VSD bypasses the lungs, which then causes a decrease in the Pao_2, an increase in the Pco_2, and a fall in the arterial pH. These metabolic changes then stimulate the respiratory centers in the brain to produce hyperpnea (deep and rapid respirations), which increases the negative intrathoracic pressure during inspiration, causing an increase in the systemic venous blood return to the right side of the heart. This increased volume of blood in the right ventricle is then shunted through the VSD by the combination of the existing right ventricular tract outflow obstruction and the acute decrease in the SVR. This in turn further decreases the arterial oxygen saturation, perpetuating the hypoxic spell (Fig. 165.9).

These hypoxic spells are characterized clinically by periods of hyperpnea, prolonged crying, and worsening cyanosis. Limpness, seizures, cerebrovascular accidents, and even death have been reported with more severe tet spells. During a tet spell, the intensity of the murmur decreases because of less blood flow through the right ventricular tract obstruction and more blood being shunted from the right ventricle to the left ventricle through the VSD.

Management. The overall treatment goals for tet spells are to increase the SVR, to abolish the hyperpnea, and to correct the metabolic acidosis (Box 165.8). Give supplemental oxygen and increase the child's SVR by placing him or her in a knee-to-chest position; older children may be placed in the squatting position, if tolerated. Both maneuvers are believed to increase SVR and to decrease the

pathologic right-to-left shunting of blood. Analgesics should be given to calm the child, decrease the catecholamine surge, and decrease the respiratory rate. Morphine (0.1 to 0.2 mg/kg) intramuscularly has been a traditional option but has the possible untoward effect of systemic vasodilation (further decreasing the SVR) by endogenous histamine release. Fentanyl and midazolam are newer options without the potential risk of endogenous histamine release. Both may be given via the intranasal route and may be less distressful than intramuscular morphine. Ketamine (1 to 2 mg/kg IV or 3 to 5 mg/kg IM) is a good choice for its analgesic and sedative effects; it is an excellent choice to improve SVR. In the event of clinically suspected or documented (pH <7.4) metabolic acidosis, sodium bicarbonate (1 mEq/kg IV) may be given to break the cycle of hypoxemia, acidosis, and worsening hypotension and perfusion. Most infants respond to these measures and exhibit an improvement in their oxygenation and a decrease in their degree of cyanosis.

An infant whose condition does not improve with these measures may require a vasopressor (such as phenylephrine) to increase the SVR and thereby decrease the degree of right-to-left shunting across the VSD. An intravenous fluid bolus may also be considered to increase the volume of blood flow through the pulmonary artery. If the aforementioned pharmacologic interventions are not successful, consider propranolol 0.1 to 0.2 mg/kg IV (0.01 to 0.2 mg/kg IV) administered slowly and repeated if needed every 10 to 15 minutes (possibly reduces infundibular spasm at the right ventricular outflow tract) or phenylephrine (5 to 20 mcg/kg IV) administered slowly and repeated if needed every 10 to 15 minutes (alpha-antagonist to increase SVR).

Palliative surgical procedures to increase the amount of blood flow temporarily to the pulmonary arteries are performed in infants with severe cyanotic Tetralogy of Fallot. The most commonly performed procedure is the modified Blalock-Taussig shunt, in which an anastomosis is created between the subclavian artery and the ipsilateral pulmonary artery. Definitive surgical repair consists of closing the VSD and opening the right ventricular outflow tract obstruction by resection of the infundibular tissue. The mortality rate is 5% to 10% within the first 2 years after definitive surgical repair in uncomplicated Tetralogy of Fallot cases. Complications that can occur after definitive surgical repair include complete heart block, ventricular dysrhythmias, and right bundle branch block (secondary to the right ventriculotomy).

Postoperative Complications of Congenital Heart Defects

A variety of postoperative complications can be seen in patients who present to the ED weeks to months after cardiac surgery: thrombosis of a shunt conduit with decreased flow; increased shunt conduit flow with resultant CHF; atrial and ventricular dysrhythmias; heart block; myocardial ischemia; and endocarditis. The size of the cardiac silhouette and the degree of pulmonary blood flow on the chest radiograph may provide valuable clues as to whether there is an increased or decreased blood flow through a surgical conduit that was created to provide an improvement in blood flow to the pulmonary system. Comparison of the child's other postoperative chest radiographs can help determine whether there has been a change in the heart size and pulmonary vascularity.

The post-pericardiotomy syndrome is an inflammatory pericarditis that can occur 1 to 6 weeks after any surgical procedure that involved a pericardiotomy. An immunologic inflammatory response is characterized by fever, chest pain, and pericardial effusion. A pericardial friction rub may be heard, depending on the amount of fluid that accumulates in the pericardial sac. The chest radiograph may reveal an enlarged cardiac silhouette, and the echocardiogram will confirm the diagnosis. Pericardiocentesis is rarely required but may be necessary if the amount of pericardial effusion is significant enough to cause pericardial tamponade. The majority of cases of post-pericardiotomy syndrome will resolve within 2 to 3 weeks with bed rest and nonsteroidal anti-inflammatory medication.

BOX 165.9 Conditions Associated With an Increased Risk of Severe or Fatal Respiratory Syncytial Virus Infections

- Cyanotic or complex congenital heart defects
- Pulmonary hypertension
- Prematurity (especially those infants with bronchopulmonary dysplasia or chronic lung disease)
- Immunodeficiency states

Respiratory Syncytial Virus Infections in Infants and Children With Congenital Heart Defects

Respiratory syncytial virus (RSV) is the most common cause of lower respiratory tract infections in infants and children worldwide, with the majority of children infected at least once by 2 years of age. Reinfection occurs commonly throughout life. Children with CHD who have RSV infections tend to have a higher rate of intensive care unit (ICU) admissions and require mechanical ventilation more frequently than those children who do not have CHD. RSV infection in a child with CHD carries a 40% mortality rate (Box 165.9).

Congestive Heart Failure

Foundations

CHF occurs when cardiac output is unable to meet the hemodynamic and metabolic demands of the body. Although there is a wide array of causes of CHF, the primary cause in infants and children is CHD. Other causes of CHF include the anomalous left coronary artery in infants, myocarditis, endocarditis, rheumatic heart disease, pericardial effusions, anemia, cardiomyopathies, systemic hypertension, hypothyroidism, hyperthyroidism, electrolyte imbalances, endocrine disorders, cardiac toxins, and dysrhythmias that compromise cardiac output.

CHF can result from a derangement in any of the four primary determinants of normal cardiac function: (1) excessive preload (e.g., large left-to-right shunts and severe chronic anemia); (2) decreased cardiac contractility (e.g., myocarditis); (3) excessive afterload (e.g., left-sided obstructive lesions); and (4) rhythm abnormalities that compromise cardiac output or stroke volume (e.g., paroxysmal supraventricular tachycardia and severe forms of heart block). The treatment of CHF depends on which of these four primary determinants of normal cardiac function are compromised. For example, inotropic agents and diuretics may be required in a child with volume overload and decreased cardiac contractility, whereas vasodilatory agents may be required in a child with CHF due to an increased afterload.

Clinical Features

Clinical manifestations of CHF depend on the exact pathophysiologic cause of the CHF; common presenting signs and symptoms include tachycardia, gallops (especially an S_3), tachypnea with rales, hepatomegaly, peripheral edema, and decreased peripheral perfusion of the extremities. Wheezing and a chronic cough may also be the presenting symptoms of CHF.

Diagnostic Testing

The chest radiograph typically reveals an enlargement of the cardiac silhouette and varying degrees of pulmonary congestion. An echocardiogram will be able to assess the ejection fraction, as well as to identify

underlying anatomic defects. BNP may be helpful in differentiating cardiac from pulmonary causes of dyspnea in children.[5]

Management

Acute stabilization of any child who presents with CHF includes administration of supplemental oxygen and agents to augment cardiac contractility and to improve cardiac output. Children with respiratory distress due to pulmonary congestion may benefit from elevation of the head and upper torso—if available, place the infant in a car seat. Continuous positive airway pressure (CPAP) or biphasic positive airway pressure (BiPAP) ventilation via mask or nasal cannula (nasal CPAP) may be useful initially to decrease work of breathing and avert the need for endotracheal intubation. Children who present in severe respiratory distress secondary to pulmonary edema may require intubation to support oxygenation and ventilation. Plasma BNP levels have been used also to monitor the response to treatment regimens in patients with CHF.

Diuretics and inotropic agents may be considered. Furosemide (0.5 to 1 mg/kg) is the most common loop diuretic used to increase renal perfusion and to improve urine output. In contrast to adults, nitroglycerin is not first-line therapy for CHF in children. Children are much more sensitive to the drug's potent vasodilatory effects than adults, and they can experience profound and rapid hypotension with administration of nitroglycerin.

In the past, dopamine was administered for undifferentiated shock in children; however, other agents with less arrhythmogenic side effects are available. Increasingly, guidelines advocate for an approach based on etiology and pathophysiology. Norepinephrine is a good choice as a first-line vasopressor for pediatric decompensated cardiogenic shock due to its effectiveness in supporting SVR. Dobutamine may be added for its selective cardiac inotropic effects. Epinephrine is also potent inotrope and chronotrope that increases the SVR.

Amrinone and milrinone, most commonly used in the ICU setting, may be added to an inotrope to promote forward blood flow via peripheral vasodilatory effects. These agents have been used to improve cardiac index in septic shock and to prevent low cardiac output states for children with CHD. Side effects of these medications include profound hypotension, dysrhythmias, hypersensitivity reactions, fever, hepatotoxicity, and thrombocytopenia.

Pediatric Dysrhythmias

Foundations

The most common cause of cardiopulmonary arrest in infants and children is the untreated progression of respiratory failure or shock, rather than a primary cardiac dysrhythmia. Accordingly, the most common arrest rhythm is asystole or bradycardia rather than ventricular fibrillation or ventricular tachycardia.

The most common dysrhythmia in children is supraventricular tachycardia, which occurs most commonly in infants and young children. Although supraventricular tachycardia can spontaneously occur in infants without any underlying structural cardiac defects, ventricular tachycardias, in contrast, are typically due to an underlying myocardial abnormality.

Clinical Features

Rhythm disturbances in infants can be manifested with symptoms, such as fussiness, lethargy, poor feeding, pallor, respiratory distress, or cardiogenic shock. Older children present with chest pain, palpitations, difficulty in breathing, or syncope. The type and degree of severity of the presenting signs and symptoms should be taken into account in the evaluation and management of the specific dysrhythmia in each case (Box 165.10).

BOX 165.10 Conditions Associated With a High Risk for Development of Dysrhythmias

- Congenital heart defects (uncorrected defects and postoperative complications)
- Congenital complete heart blocks (e.g., maternal systemic lupus erythematosus)
- Myocarditis
- Rheumatic heart disease
- Kawasaki disease with involvement of the coronary arteries
- Cardiomyopathy
- Prolonged QT syndrome
- Aberrant atrioventricular conduction pathways (e.g., Wolff-Parkinson-White syndrome)
- Electrolyte abnormalities (e.g., potassium, calcium, and magnesium disturbances)
- Commotio cordis
- Profound hypothermia
- Hypoxia

Management

Children who exhibit electrocardiographic evidence of conduction abnormalities (e.g., Mobitz type II second-degree heart block, complete heart block, prolonged QT intervals, or aberrant conduction, such as the Wolff-Parkinson-White syndrome) may require emergent management, depending on symptoms and hemodynamic status.

Although some medications can be used to treat only atrial tachycardia (e.g., adenosine for supraventricular tachycardia) or ventricular tachycardia (e.g., lidocaine for ventricular tachycardia), amiodarone and procainamide can be used for an array of both atrial and ventricular dysrhythmias, including supraventricular and ventricular tachycardia.

Bradydysrhythmias

Sinus Bradycardia. Bradycardia is defined as a heart rate that is slower than the lower limit of normal for a child's age. Clinically significant bradycardia in children is a heart rate slower than 60 beats/minute and associated with poor systemic perfusion. An athletic adolescent may have a resting baseline heart rate lower than 60 beats/minute, requiring no treatment if asymptomatic with good perfusion.

Bradycardia is poorly tolerated in infants and children because they are not physiologically capable of increasing their stroke volume to maintain an adequate cardiac output in the face of significant bradycardia. **The most common cause of symptomatic bradycardia in infants and children is hypoxia.** First, ensure adequate oxygenation and ventilation. Epinephrine is the first-line medication for treatment of symptomatic bradycardia in children that is not responsive to appropriate oxygenation and ventilation. If additional doses of intravenous or intraosseous epinephrine are required to treat symptomatic bradycardia, the dose should remain at standard dosing (0.01 mg/kg). Atropine is indicated for vagally induced bradycardia or treatment of primary atrioventricular block. Atropine will have no effect on the denervated heart (e.g., after cardiac transplantation). If vascular access is not available, both epinephrine and atropine can be administered through the tracheal tube, although the intravenous route is preferred.

Other causes of bradycardia include hypothermia, increased intracranial pressure, heart blocks (congenital and acquired), denervated heart status after cardiac surgery, hypothyroidism, sick sinus syndrome, and various medications and toxins (e.g., digoxin, beta-blockers, calcium channel blockers, and cholinergic agents). Children with presyncopal or syncopal symptoms or poor perfusion with Mobitz type II second-degree atrioventricular block, complete third-degree heart block, or sick sinus syndrome should be paced.

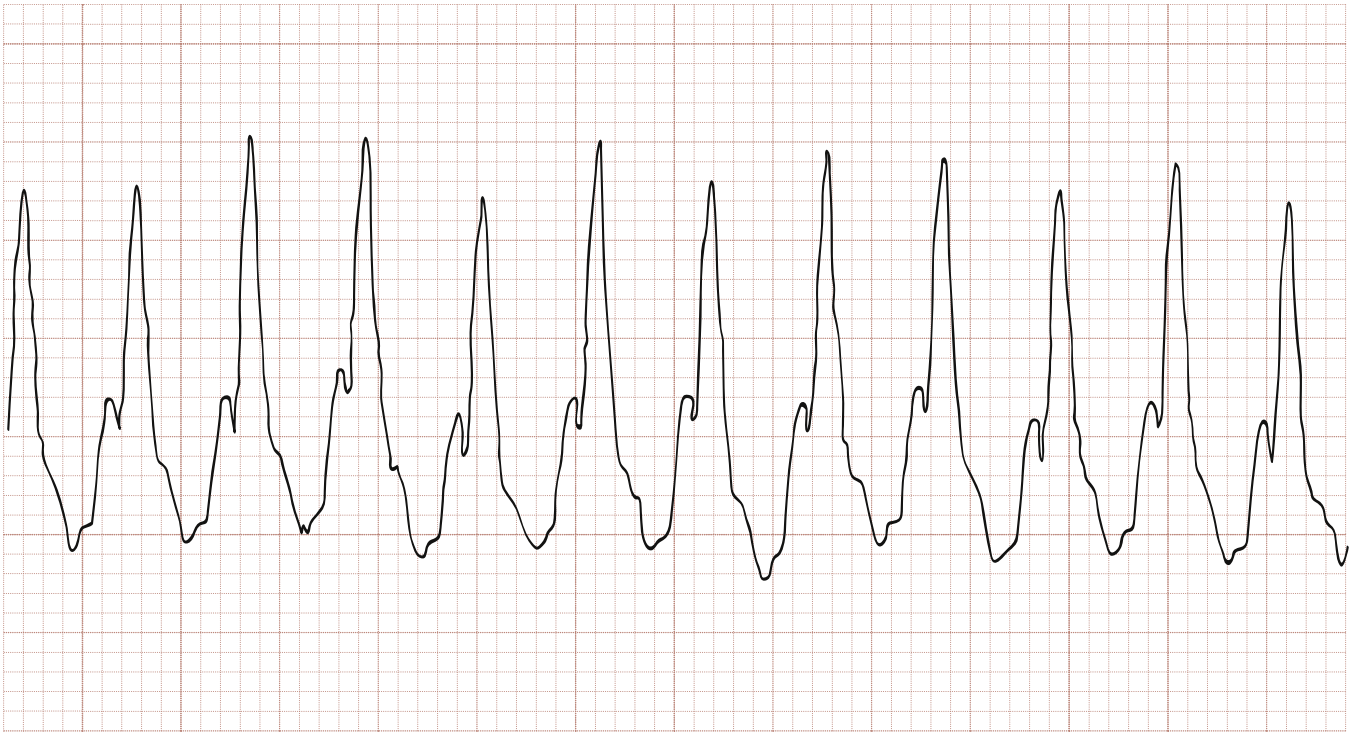

Fig. 165.10 An example of an electrocardiogram (ECG) showing a wide-complex supraventricular tachycardia at a rate of approximately 270 beats/minute in an infant with Ebstein anomaly of the tricuspid valve. This infant was in supraventricular tachycardia for approximately 2 days and presented with an acute exacerbation of her congestive heart failure (CHF), as evidenced by the cardiomegaly on the chest radiograph (see Fig. 165.11). Note that the cardiothoracic ratio in this infant is approximately 70%.

Tachydysrhythmias

Supraventricular Tachycardia. Supraventricular tachycardia is the most common symptomatic dysrhythmia in infants and children. No cardiac abnormalities are found in approximately half of cases; the Wolff-Parkinson-White syndrome is present in only 10% to 20%. The type of supraventricular tachycardia that occurs most commonly in infants and children involves a reentrant mechanism that uses an accessory pathway and the atrioventricular node (i.e., atrioventricular reentrant tachycardia [AVRT]). The *orthodromic* reentry phenomenon involves the normal antegrade conduction from the atria to the ventricles down the atrioventricular node, with retrograde conduction back from the ventricles to the atria by the accessory pathway. Orthodromic conduction will produce a narrow–QRS complex supraventricular tachycardia. The less common reentry mechanism is the *antidromic* form in which conduction from the atria to the ventricles first goes antegrade down the accessory pathway then retrograde back to the atria by the atrioventricular node. Antidromic conduction will produce a wide–QRS complex supraventricular tachycardia. Supraventricular tachycardia in a child with a preexisting bundle branch block can also result in a wide-complex supraventricular tachycardia. The ECG in Figure 165.10 reveals a case of a wide-complex supraventricular tachycardia in a child with Ebstein anomaly of the tricuspid valve who also presented with CHF (Fig. 165.11).

Clinical Features and Diagnostic Testing. Supraventricular tachycardia is most likely with heart rates above 180 in young children and 220 in infants, without beat-to-beat variability (Fig. 165.12 and Table 165.5). Although healthy infants can generally tolerate supraventricular tachycardia with heart rates approaching 300 beats/minute, supraventricular tachycardia may begin to produce signs of CHF and shock if left untreated. Older children with supraventricular tachycardia commonly present with palpitations, difficulty in breathing, and chest discomfort.

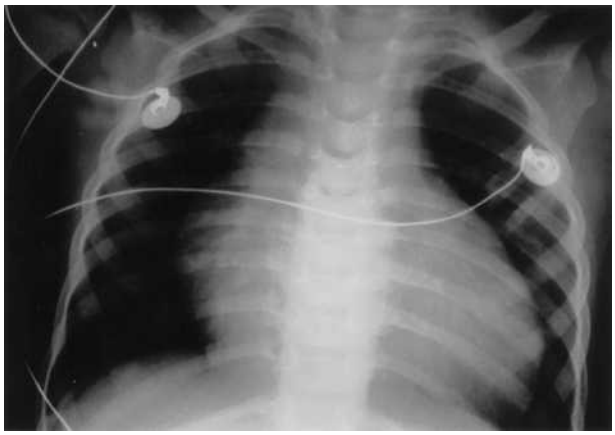

Fig. 165.11 Chest radiograph of same infant as in Figure 165.10.

Management. The emergency clinician should quickly initiate synchronized cardioversion (0.5 to 1 J/kg) for children in supraventricular tachycardia (SVT) with signs of poor perfusion, such as altered mental status, delayed capillary refill, pallor, cyanosis, or hypotension (i.e., decompensated shock). If the child does not convert with this initial cardioversion attempt, the energy dose can be doubled up to 2 J/kg on subsequent attempts. If the child is hemodynamically stable, vagal maneuvers, then adenosine, may be attempted initially before cardioversion; a continuous rhythm strip should be run to document the response to each conversion attempt. Vagal maneuvers (e.g., blowing into a syringe) can be attempted before adenosine administration in the child with hemodynamically stable supraventricular tachycardia. Application of ice to the face has been demonstrated to be a fairly effective method of converting supraventricular tachycardia in infants and children.

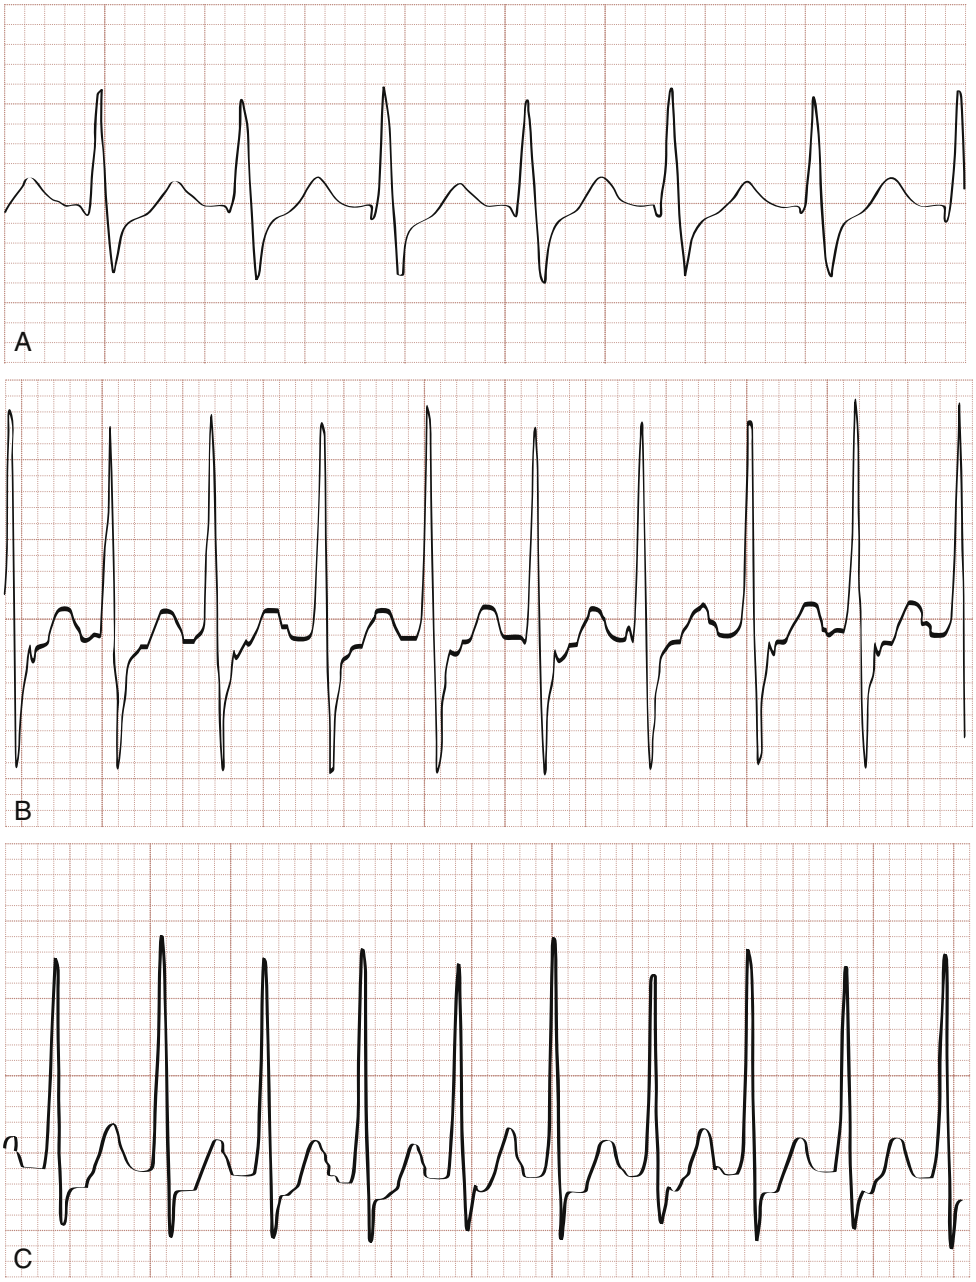

Fig. 165.12 Three electrocardiographic examples of classic narrow-complex supraventricular tachycardia in children. The heart rate is approximately 240 beats/minute in the first two examples (A and B) and approximately 270 beats/minute in the third example (C).

TABLE 165.5 Clinical and Electrocardiographic Features to Differentiate Sinus Tachycardia From Supraventricular Tachycardia in Children

	Sinus Tachycardia	Supraventricular Tachycardia
Precipitating events	Dehydration, fever, pain	No precipitating event
P waves on electrocardiogram (ECG)	Present	Absent
Heart rate varies with activity	Yes	No
Beat-to-beat variability	Yes	Constant R-R intervals
Heart rate in infants (beats/minute)	Usually <220	Usually >220
Heart rate in children (beats/minute)	Usually <180	Usually >180

One method to perform this maneuver is to fill a plastic bag or surgical glove with a slurry of crushed ice and water, which is then placed over the infant's forehead, eyes, and bridge of the nose for 10 to 15 seconds. Placement of the ice bag should not occlude the nose or mouth. External ocular pressure should be avoided. Carotid massage is less effective and is not recommended as a vagal maneuver in infants or children.

The initial dose of adenosine in children is 0.1 mg/kg with a maximum initial dose of 6 mg. If this initial dose of adenosine fails to convert the supraventricular tachycardia, the dose is then doubled to 0.2 mg/kg with a maximum of 12 mg/dose. This 0.2 mg/kg dose of adenosine may be repeated once. Elective cardioversion with procedural sedation may be required in children who fail to convert with adenosine. Adenosine-induced wide-complex tachycardia (secondary to an occult accessory conduction pathway) is an uncommon complication (Fig. 165.13). Amiodarone may be given at a loading dose of 5 mg/kg

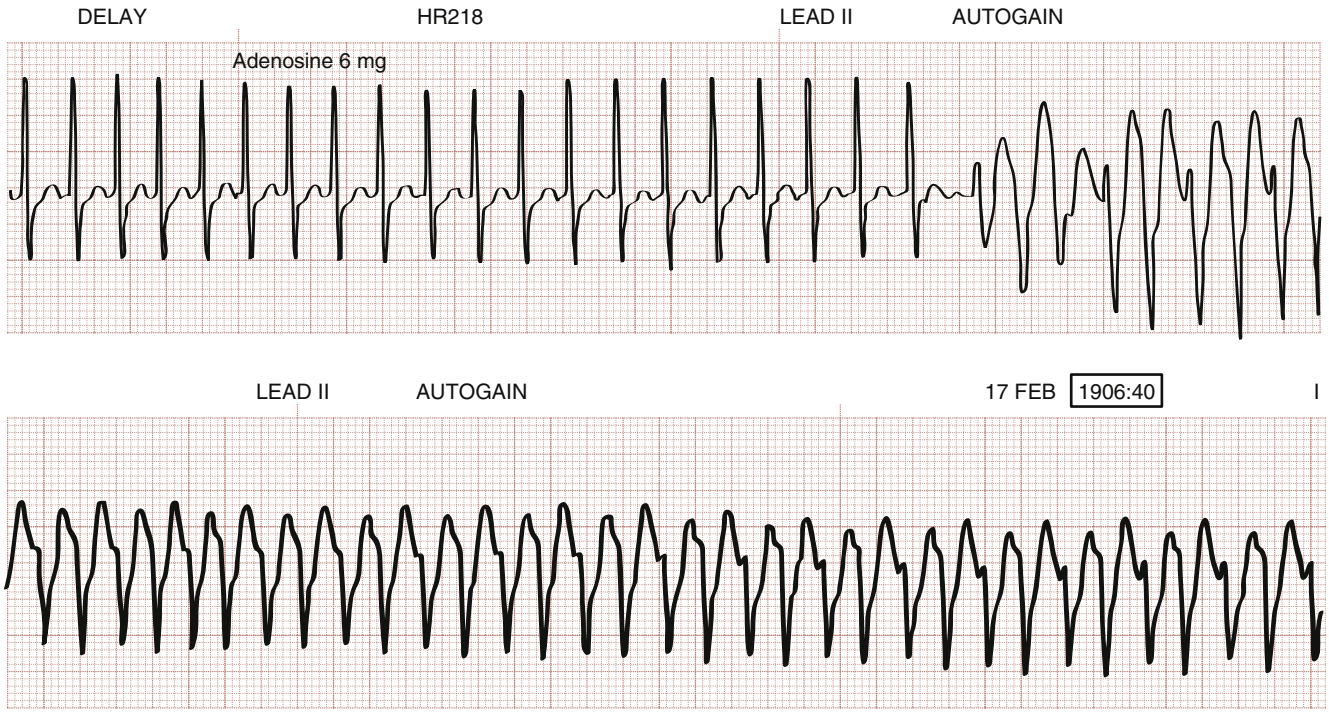

Fig. 165.13 An example of adenosine-induced wide-complex tachycardia. A dose of 6 mg of adenosine was administered to this previously healthy 15-year-old girl who presented with a 6-hour history of palpitations. She had no previous cardiac problems except for intermittent palpitations in the past that always resolved spontaneously without any medical interventions. Once adenosine blocked the conduction through the atrioventricular node, a wide-complex tachycardia appeared on the electrocardiogram (ECG), which was probably due to antegrade conduction through an accessory pathway. During the 30 seconds of this wide-complex tachycardia, the patient remained alert with excellent perfusion parameters. This wide-complex tachycardia then spontaneously converted to normal sinus rhythm. Although the patient's postconversion ECG did not reveal an accessory pathway, Holter monitoring 1 month later detected the classic electrocardiographic findings of Wolff-Parkinson-White syndrome.

over 20 to 60 minutes, then continued at 5 mcg/kg/min. Verapamil should be avoided altogether in infants and children, and not given to those younger than 2 years old because of the risk of profound hypotension and cardiovascular collapse in this age group. Once the patient has converted to sinus rhythm, a 12-lead ECG should be obtained to assess for the possibility of Wolff-Parkinson-White syndrome or any other underlying conduction abnormalities that may have predisposed the child to development of the supraventricular tachycardia.

Atrial Flutter and Atrial Fibrillation. Both atrial flutter and atrial fibrillation are rare in children and are usually associated with underlying heart conditions (e.g., CHD, status post–open heart surgical procedures that involved the atria, myocarditis, and digoxin toxicity). Hemodynamic stability depends on the ventricular response. As in adults, children with hemodynamically unstable atrial flutter or atrial fibrillation should be electrocardioverted. The initial treatment priority in patients with hemodynamically stable atrial flutter and atrial fibrillation is first to slow the rate of the ventricular response with medications such as diltiazem, beta-blockers, or digoxin. IV calcium channel blockers and IV beta-blockers often cause complete heart block and should not be given concurrently.

If the patient who presents with atrial flutter or atrial fibrillation is known to have an underlying Wolff-Parkinson-White syndrome, the four medications that should be avoided are the A-B-C-D medications (adenosine, amiodarone, beta-blockers, calcium channel blockers, and digoxin); all of these medications preferentially block conduction down the atrioventricular node, leaving the accessory pathway open to conduct the atrial tachycardia to the ventricles at a potentially lethal rate. Safer alternatives are amiodarone, procainamide, or cardioversion. Procainamide is preferred to amiodarone as there have been reports of VF following amiodarone administration in WPW. Consultation with the cardiologist and initiation of anticoagulation should also be considered.

Ventricular Tachycardia. The majority of children with ventricular tachycardia have an underlying condition, such as post–cardiac surgery status, myocarditis, prolonged QT syndrome, drug or toxin exposures (e.g., cyclic antidepressants), or electrolyte abnormalities. The treatment of ventricular tachycardia will depend on hemodynamic status of the patient. Torsades de pointes is a unique type of polymorphic ventricular tachycardia characterized by QRS complexes that change in polarity and amplitude. Prolonged QT syndrome, underlying congenital cardiac defects, hypomagnesemia, and various medications (e.g., cyclic antidepressants) have been identified as known causes of torsades de pointes. The treatment of choice is intravenous magnesium at an initial dose of 25 to 50 mg/kg, up to the adult dose of 2 g over 2 minutes. Class IA (i.e., procainamide) and class III (i.e., amiodarone) antidysrhythmic agents are contraindicated in the treatment of torsades de pointes because these agents are capable of prolonging the QT interval, which can precipitate the degeneration of the torsades de pointes into a lethal rhythm.

Special Resuscitation Situations in Children

Children with single-ventricle physiology (e.g., hypoplastic left heart syndrome and double-outlet right ventricle physiology) after a palliative shunting procedure should be given standard resuscitation care. Heparin may be used in the pre-arrest or arrest of infants with a systemic–to–pulmonary artery shunt or right ventricle–to–pulmonary

artery shunt to halt thrombus propagation in this low circulatory flow state. A target oxyhemoglobin saturation (Spo_2) of approximately 80% is preferred in these children. End-tidal carbon dioxide readings after resuscitation may lag behind, because varying pulmonary blood flow changes do not necessarily reflect cardiac output. The goal is to provide adequate preload with judicious fluids to balance systemic and pulmonary blood flow. If available, extracorporeal membrane oxygenation should be considered.

Children with a history of pulmonary hypertension should also receive standard resuscitation management. Preload should be optimized with isotonic saline boluses. Inhaled nitric oxide in the ICU may be given to reduce PVR. Early contact with the child's cardiologist and cardiothoracic surgeon is instrumental in the post-resuscitative care of children with CHD.

Bacterial Endocarditis

Foundations

Although bacterial endocarditis most commonly occurs in children with an underlying CHD or an acquired cardiac lesion (e.g., acute rheumatic valvular heart disease), it can also occur in patients with no underlying anatomic defects of the valves or endocardium.

Cardiac lesions that carry this higher risk include VSD, aortic valvular stenosis, tetralogy of Fallot, single-ventricle states, bicuspid aortic valves, prosthetic valves, and postoperative systemic-to-pulmonary shunts. Isolated secundum ASD carry a much lower risk for bacterial endocarditis because the shunt flow through the ASD is typically of a much lower velocity (Box 165.11).

Clinical Features

The early clinical manifestations of bacterial endocarditis are nonspecific. The child may simply present with only fever and tachycardia (see Box 165.11). A new heart murmur is present in less than 50% of the bacterial endocarditis cases. Common presenting signs are fever (99%), petechiae (21%), changing murmur (21%), dental caries (14%), and hepatosplenomegaly (14%). Less common signs are CHF (9%), splinter hemorrhages (5%), Roth spots (5%), and Osler nodes (4%).

Diagnostic Studies

Diagnostic studies for a child with suspected bacterial endocarditis include a complete blood cell count, C-reactive protein (CRP) assessment, measurement of erythrocyte sedimentation rate (ESR), three blood cultures, chest radiography, and electrocardiography. *Streptococcus viridans* and *Staphylococcus aureus* are the two most common offending organisms recovered from the blood cultures of children with bacterial endocarditis. Studies have shown that in children with CHD, 60% of the cases caused by staphylococcal species are methicillin resistant and associated with increased risk of mortality. Formal echocardiography is typically done as an inpatient.

BOX 165.11 Clinical Conditions in Which Bacterial Endocarditis Should Be Suspected in a Child With an Underlying Anatomic Cardiac Defect

- Fever of unknown etiology
- A change in the quality of the preexisting heart murmur or the presence of a new heart murmur
- Development of a neurologic deficit (secondary to central nervous system emboli)
- New-onset microscopic hematuria
- Splenomegaly
- Petechiae
- Splinter hemorrhages involving the conjunctiva, nail beds, palms, or soles
- Myalgias

Management

In some patients, antibiotic prophylaxis to prevent endocarditis is recommended. Box 165.12 lists the cardiac conditions for which endocarditis prophylaxis is recommended and Box 165.13 lists the procedures for which these patients should receive antibiotic prophylaxis. In children with suspected acute bacterial endocarditis, antibiotics should be started immediately after blood culture samples have been obtained. Although the choice of intravenous antibiotics depends on the suspected source of seeding and the child's immune status, a commonly recommended regimen includes an aminoglycoside plus a penicillinase-resistant penicillin, such as oxacillin. If methicillin-resistant *Staphylococcus* is suspected, vancomycin should also be included in the initial empirical antibiotic regimen. Surgical intervention may be required to remove septic vegetations, or valve replacement is sometimes necessary. Further reading on endocarditis may be found in Chapter 69.

Pericarditis

Foundations

Pericarditis is an inflammatory process within the pericardial sac that may not be associated with a pericardial effusion. In the majority of cases, pericarditis in children is self-limited and follows a benign clinical course. A sudden increase or a large amount of fluid within this

BOX 165.12 Cardiac Conditions for Which Endocarditis Prophylaxis Is Recommended

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD)[a]
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device during the first 6 months after the procedure[b]
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device (which inhibit endothelialization)
- Cardiac transplantation recipients who have cardiac valvulopathy

[a] Except for those conditions above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
[b] Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.
From: American Heart Association. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation*. 2007;116:1736.

BOX 165.13 Procedures for Which Endocarditis Prophylaxis Is Recommended

- All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa[a]
- Consider prophylaxis for incisional procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients

[a] The following procedures do not need prophylaxis: routine anesthetic injections through noninfected tissue, dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.

pericardial sac can cause a tamponade-induced decrease in stroke volume, resulting in diminished cardiac output and hypotension.

The most common causes of pericarditis include bacterial and viral infections; other causes are ARF, systemic lupus erythematosus, uremia, post-pericardiotomy syndrome, leukemia, lymphoma, and tuberculosis. Approximately 30% of pericarditis cases are due to bacteria, such as pneumococcus, *S. aureus,* meningococcus, and *Haemophilus influenzae*. Viral causes are most common, but a specific viral pathogen is recovered in only 20% to 30% of cases. Viral causes include coxsackieviruses, echoviruses, adenovirus, Epstein-Barr virus, and influenza viruses.

Clinical Features

The presenting signs and symptoms of pericarditis depend on the cause of the pericarditis, as well as on the amount of fluid that has accumulated within the pericardial sac. Chest pain that varies with position is a common complaint with pericarditis; pain is exacerbated with inspiration and the supine position but relieved when the patient sits up or leans forward. Tachycardia is also a common finding in patients with pericarditis and may be the only clue to the diagnosis. Other findings include fatigue, tachypnea, neck vein distention, pulsus paradoxus, hepatomegaly, lower extremity edema, and thready distal pulses if heart failure is present. Cardiac auscultatory findings can include a harsh-sounding friction rub or diminished or muffled heart tones if there is a significant amount of fluid within the pericardial sac. A pericardial friction rub, if present, is best heard when the patient sits up or leans forward. The friction rub of pericarditis can be distinguished from a pleural friction rub by having the patient hold his or her breath during auscultation. The friction rub of pericarditis will remain present during breath-holding, while the pleural friction rub will no longer be heard.

The chest radiograph in a child with pericarditis may not reveal an enlarged cardiac silhouette. If there is a large collection of fluid within the pericardial sac, the heart shadow on the chest radiograph will resemble a "water bottle" silhouette. Approximately 50% of pericarditis cases have some associated pleural effusion.

The classic electrocardiographic findings of viral pericarditis include diffuse ST segment elevation and diffuse T wave inversions. The classic electrocardiographic changes associated with pericarditis evolve through four phases (Fig. 165.14). During the initial phase,

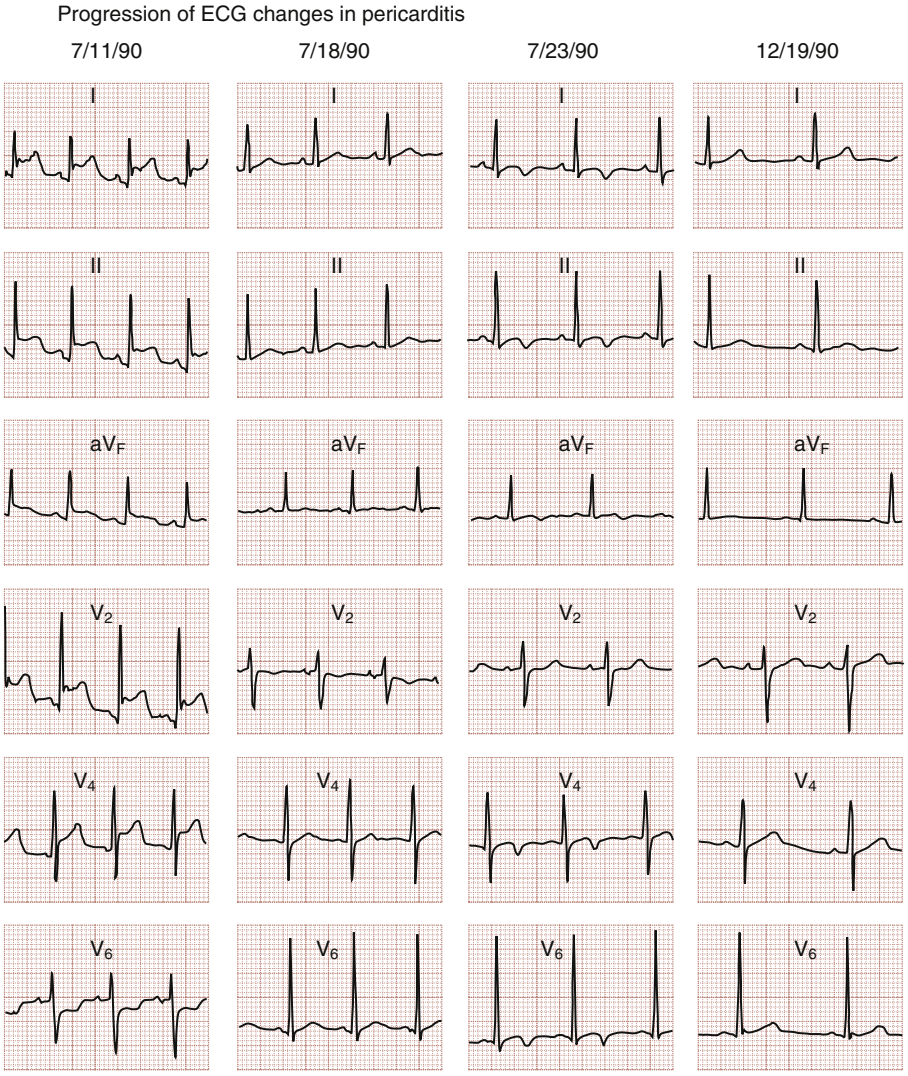

Fig. 165.14 The classic electrocardiographic progression of a patient with pericarditis. First phase: Diffuse ST segment elevation. Second phase: ST segments back to isoelectric but decreased T wave amplitude. Third phase: T wave inversion. Fourth phase: Complete resolution. Notice that the first three phases of the electrocardiographic abnormalities of pericarditis in this patient are evident during the first 2 weeks of his illness. A follow-up electrocardiogram (ECG) obtained 5 months later reveals a complete resolution of all the previous electrocardiographic abnormalities.

there is diffuse ST segment elevation secondary to subepicardial inflammation; PR segment depression may also be seen. During the second phase, the previously elevated ST segments begin to return to isoelectric baseline, and the T wave amplitudes begin to decrease with flattening of the T waves. During the third phase, although the ST segments are now back to isoelectric baseline, the T waves are inverted. The fourth and final phase demonstrates complete resolution of the ST segment and T wave abnormalities. Diminished electrocardiographic voltages in all leads can also occur if there is a significant amount of fluid accumulated within the pericardial sac.

Diagnostic Studies

Ultrasound will confirm both the presence and the amount of accumulated fluid within the pericardial sac. Although echocardiography cannot accurately quantify the exact amount of fluid that has accumulated within the pericardial space, the presence of an anterior and posterior fluid collection is suggestive of a large collection.

Management

The management of a child with pericarditis depends on both the suspected cause, severity of symptoms, and amount of fluid that has accumulated within the pericardial space. Patients with fever, respiratory distress, or signs of CHF should be admitted and an echocardiogram emergently performed. An emergency pericardiocentesis is required in those patients with signs of acute cardiac tamponade. Fluid that is aspirated from the pericardial space should be sent for routine cell counts, Grams stain, and cultures. Antiinflammatory agents and appropriate antibiotics should be initiated on the basis of the suspected cause. Steroids are reserved for refractory cases that are not responsive to these agents and should be considered only after an infectious etiology is ruled out. See also Chapter 68 for more on pericarditis.

Myocarditis

Foundations

In the United States, the most common cause of myocarditis is viral; adenovirus and enteroviruses account for the majority of cases.[7] Other viral causes include echoviruses, influenza, coxsackie, adenovirus, varicella-zoster, Epstein-Barr, cytomegalovirus, and hepatitis B virus. Bacterial causes include *Corynebacterium diphtheriae, Streptococcus pyogenes, S. aureus, Mycoplasma pneumoniae, Borrelia burgdorferi,* and meningococcus. Noninfectious causes include Kawasaki disease, acute rheumatic fever (ARF), collagen vascular disorders (e.g., systemic lupus erythematosus), toxins (e.g., cocaine and doxorubicin), endocrine disorders (e.g., hyperthyroidism), and drug-induced hypersensitivity (e.g., penicillins, sulfonamides, phenytoin, carbamazepine).

Clinical Features

Viral myocarditis usually has a gradual onset with preceding upper respiratory tract infection. Clinicians should consider myocarditis in infants and children with symptoms out of proportion to the typical course of a benign cause, such as a viral syndrome. Early in its course, the only sign of myocarditis may be tachycardia. Tachycardia that is disproportionate to the degree of fever should alert the emergency clinician to the possibility of myocarditis. Other presenting signs and symptoms include fever, myalgias, fatigue, tachypnea, wheezing, abdominal pain, and chest pain. More severe cases of myocarditis can even have signs and symptoms of acute CHF and various dysrhythmias. The physical examination may reveal a new murmur, a gallop rhythm, or a pericardial friction rub with muffled heart tones (if the myocarditis is also accompanied by pericarditis and subsequent pericardial effusion). In general, these are sick children with vague symptoms.

Diagnostic Testing

The evaluation and management of the child with myocarditis depend on the suspected cause and presenting signs and symptoms. Blood cultures and viral titers should be considered in infectious and postinfectious cases. Appropriate antibiotics should be initiated immediately in cases with suspected bacterial origin. The chest radiograph may be normal in very mild cases, but cardiomegaly will be evident in more advanced cases. The electrocardiographic findings are usually nonspecific and can include low-voltage, nonspecific ST segment abnormalities, T wave inversions, atrioventricular block, and various other dysrhythmias. Creatine kinase-MB, cTnT, cTnI, CRP, and ESR may be elevated.

Bedside echocardiography can evaluate for effusion, tamponade, and global function. The goal of treatment is to maintain adequate cardiac output and to control any associated dysrhythmias.

Management

Children who present in CHF with poor perfusion (e.g., lethargy, delayed capillary refill, poor urine output, or hypotension) will likely require inotropic support, positive-pressure ventilation, or diuretics. The role of intravenous immunoglobulin (IVIG) in pediatric myocarditis is unclear.[8] The use of beta-blockers is contraindicated, and the routine use of immunosuppressive agents remains controversial.[9,10] Although the majority of children with acute viral myocarditis make a full recovery, a few patients will progress to dilated cardiomyopathy, which is characterized by dilated ventricles and impaired systolic contractility. See Chapter 68 for more on myocarditis.

Kawasaki Disease

Foundations

Kawasaki disease, originally described as mucocutaneous lymph node, has emerged as a significant cause of acquired cardiac disease in children in the United States. This febrile, exanthematous, multisystem vasculitis is seen most commonly in children younger than 5 years old. Up to 20% of untreated children have some degree of coronary artery abnormalities.[11] Although the exact cause of this vasculitis of small- and medium-sized vessels remains unknown, early clinical recognition and initiation of high-dose aspirin and IVIG improve the morbidity and mortality rates of Kawasaki disease in children.

Clinical Features

In addition to fever, the physical examination of a child with Kawasaki disease may reveal the typical findings as listed in Box 165.14 and illustrated in Figure 165.15. The classic features of Kawasaki disease may be manifested simultaneously or in series of days; a careful history and physical examination may elucidate the need for further testing. In addition, very young children may not have a classic presentation and require further investigation. All children with suspected Kawasaki disease, with either classic or incomplete features, should undergo echocardiography for detection of the presence and degree of coronary aneurysm.[11]

Incomplete Kawasaki Disease. The classic presentation of Kawasaki disease is a clinical diagnosis of four or more of the five criteria in a child who is febrile 5 days or more. However, these strict criteria may miss a substantial number of children who present with incomplete Kawasaki disease. Any child may have an incomplete presentation, but this is mostly seen in infants younger than 6 months old.

Current criteria recommend that in a child who is febrile 5 days or more, the presence of two or three criteria should prompt further testing. We recommend that a CRP of 3 mg/dL or more or an ESR of 40 mm/hr or more prompt further laboratory investigations; children with elevated inflammatory markers should be empirically treated

BOX 165.14 Diagnostic Criteria for Kawasaki Disease

- Fever for 5 days or more
- At least four of the five following physical examination findings:
  1. Bilateral, nonexudative bulbar conjunctival injection (bilateral scleral injection with perilimbic sparing)
  2. Oropharyngeal mucous membrane changes (pharyngeal erythema, red and cracked lips, and a strawberry tongue)
  3. Cervical lymphadenopathy (with at least one node >1.5 cm in diameter)
  4. Peripheral extremity changes (diffuse erythema and swelling of the hands and feet during the acute phase or periungual desquamation during the convalescent phase of the illness); this diffuse palmar erythema seen in Kawasaki disease is in contrast to the discrete macular lesions of various viral illnesses (e.g., measles) that can sometimes be seen on the palms and soles
  5. A polymorphous generalized rash (nonvesicular and nonbullous); there is no specific rash that is pathognomonic for Kawasaki disease
- In a child with four or more criteria, the diagnosis may be made on day 4 of the fever.

(Box 165.15). During their hospital stay, children should receive an echocardiogram to assess for coronary aneurysms.

Children with a CRP of less than 3 mg/dL and an ESR of less than 40 mm/hr may be observed daily and reassessed without treatment; serial ESR and CRP should be obtained daily on an outpatient basis. Infants 6 months of age or younger are more likely to present with incomplete Kawasaki disease and are more susceptible to giant coronary artery aneurysm formation. For this reason, irrespective of general well appearance or lack of clinical findings, infants 6 months of age or younger with fever lasting for 7 days or more should undergo supplemental laboratory testing and undergo echocardiogram when inflammatory markers are abnormal.

Kawasaki disease is postulated to be caused by an infectious agent that enters the respiratory tract and initiates an oligoclonal immunoglobulin A response, which activates lymphocytes, cytokines, and proteinases that weaken vessel walls and predispose the entire circulation to aneurysms. Approximately 25% of patients have mild diffuse myocardial inflammation. This occurs during the acute febrile period and is characterized by tachycardia, a gallop, and nonspecific ST-T wave changes. Up to 5% of the children also exhibit some degree of CHF during this acute phase of their illness; this carditis usually resolves when the fever resolves. Pericardial effusions also occur in up to 20% to 40% of cases. Mild mitral and aortic regurgitation is seen in 1% to 2% of untreated cases on echocardiographic examinations. This phase of the disease is mild and self-resolving.

Differential Diagnoses

Measles can mimic Kawasaki disease (i.e., a febrile illness with red eyes, a rash, and erythema of the oropharynx). The measles rash classically begins on the head and face and progresses caudally. The rash of Kawasaki disease typically begins on the trunk and then spreads to the face and extremities; it may be polymorphous, but not bullous or vesicular.

The palmar lesions of measles are discrete macular lesions (see Fig. 165.15F), whereas the palmar finding in children with Kawasaki disease is diffuse erythema, which may later desquamate (see Fig. 165.15C).

There are many imitators of Kawasaki disease. For example, Kawasaki disease can present with nausea, vomiting, and abdominal pain in a febrile child, which may be mistaken for a surgical abdomen. A febrile irritable child with Kawasaki disease may have a cerebrospinal fluid pleocytosis and be misdiagnosed with viral meningitis.

Streptococcal disease, including pharyngitis and scarlet fever, can be confused with Kawasaki disease, but conjunctivitis and swelling of the hands and feet are unusual for streptococcal disease. Other infectious or autoimmune causes that mimic Kawasaki disease include Rocky Mountain spotted fever, leptospirosis, Stevens-Johnson syndrome, and juvenile rheumatoid arthritis.

Management

The main goal of treatment during the acute febrile phase of Kawasaki disease is to provide supportive care and to decrease the inflammation of the myocardium and coronary arteries. IVIG and high-dose aspirin have an additive effect and, when initiated within 10 days from the onset of the illness, can substantially decrease the progression to coronary artery dilation and aneurysm formation compared with aspirin therapy alone.[12] The combination results in a more rapid resolution of fever and the other indicators of acute inflammation.[12] However, despite prompt treatment with IVIG and high-dose aspirin, 2% to 4% of children still have coronary artery abnormalities.[11]

The current IVIG regimen involves an infusion of 2 g/kg over 10 to 12 hours. Side effects include hypotension, nausea, vomiting, headache, and seizures. Close cardiac monitoring during the IVIG infusion is recommended. The 5% to 10% of children who receive IVIG and experience a persistent or recurrent fever after the initial dose of IVIG may be given a second infusion at the same dose. Approximately two-thirds of children who fail to respond to the initial dose of IVIG will improve with the second infusion.

Aspirin is initiated at 80 to 100 mg/kg/day orally divided into an every-6-hour dosing regimen until the child is afebrile for 48 to 72 hours. Prompt diagnosis and treatment leads to rapid symptomatic improvement in 90% of cases and prevents coronary aneurysm formation in 95%.

The follow-up of children with Kawasaki disease depends on the degree and presence of carditis and coronary artery abnormalities detected on the initial echocardiogram. Other imaging modalities used to follow aneurysmal parameters include electron-beam computed tomography, coronary magnetic resonance angiography, and computed tomography. Those children with more severe cardiac abnormalities should have close follow-up by a cardiologist experienced in Kawasaki disease.

Acute Rheumatic Fever

Foundations

ARF, one of the most common causes of acquired heart disease in children, is the result of a delayed immune reaction to a group A streptococcal infection. In the United States, ARF most commonly occurs in children 5 to 15 years old, with an attack rate of 0.3% in children with an untreated streptococcal infection. Although this disease affects multiple organ systems, carditis is the most serious complication.

Clinical Features

The diagnosis of ARF is based on the Jones criteria (Box 165.16). In addition, there must also be evidence of an antecedent streptococcal infection, which can be documented by a positive throat culture, a positive rapid streptococcal antigen test finding, or an elevated antistreptolysin O (ASO) titer. The ASO titer begins to rise 1 to 3 weeks after streptococcal infection, peaks at 3 to 5 weeks, and reliably falls to baseline after 6 months. The diagnosis of ARF is made in a patient with a documented antecedent streptococcal infection who exhibits either two major criteria or one major plus two minor criteria.[13]

The most common presenting major criterion is migratory polyarthritis, which commonly involves the larger joints of the extremities, as well as the

Fig. 165.15 Classic physical examination findings of Kawasaki disease. Note the bilateral nonexudative scleral injections (A) with perilimbic sparing (the thin margin of white sclera around the cornea), red and cracked lips with a strawberry tongue (B), diffuse palmar erythema (C), red soles (D), and polymorphous exanthem (E). The diffuse palmar erythema of Kawasaki disease (C) is distinct from the palmar findings seen in other viral illnesses, such as the discrete macular lesions on the palms in this child with measles (F).

BOX 165.15 Supplemental Laboratory Criteria for Kawasaki Disease

Albumin ≤3 g/dL
Anemia for age
Platelet count of ≥450,000/mm^3
White blood cell (WBC) count ≥15,000 mm^3
Elevation of alanine aminotransferase
Sterile pyuria of ≥10 WBCs per high-power field

smaller tarsal joints in the foot and the smaller carpal joints in the hand. The carditis of ARF most commonly involves valvulitis of the mitral and aortic valves, which clinically is manifested as occult mitral or aortic insufficiency. The murmur of mitral insufficiency is characterized as a holosystolic murmur best heard over the apex with radiation to the axilla. The murmur of aortic insufficiency is characterized as a diastolic murmur that is best heard over the base of the heart. Innocent murmurs that are normally exacerbated with fever can be mistaken for the murmurs of mitral or aortic insufficiency.

Other cardiac manifestations of ARF include CHF, pericarditis, and various degrees of heart block. The two dermatologic major

BOX 165.16 Jones Criteria for the Diagnosis of Acute Rheumatic Fever

The diagnosis of acute rheumatic fever (ARF) is based on the documentation of an antecedent streptococcal infection and (1) two major criteria or (2) one major criterion plus two minor criteria.

Major Criteria

Carditis
Migratory polyarthritis
Erythema marginatum
Subcutaneous nodules
Chorea

Minor Criteria

Clinical findings:
- Fever
- Arthralgia

Laboratory findings:
- Elevated C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)
- Prolonged PR interval

Supporting evidence of an antecedent group A streptococcal infection with either of the following:
- A positive throat culture or rapid streptococcal antigen test result
- An elevated antistreptolysin O (ASO) titer

criteria (erythema marginatum and subcutaneous nodules) and chorea occur less commonly than the migratory polyarthritis and carditis. Chorea may occur as the only manifestation of ARF. If arthritis is used as a major component, arthralgia cannot be used as a minor component to make the diagnosis. Likewise, if carditis is used as a major component, a prolonged PR interval cannot be used as a minor component.[13]

Differential Diagnoses

The differential diagnosis of ARF includes myocarditis, bacterial endocarditis, Lyme disease, systemic lupus erythematosus, juvenile rheumatoid arthritis, serum sickness, and septic arthritis.

Diagnostic Testing

In addition to the ECG, CRP or ESR levels, and documentation of an antecedent streptococcal infection, the diagnostic evaluation of ARF should also include a chest radiograph, as well as an echocardiogram to evaluate the degree of cardiac involvement.

Management

The acute management of ARF should focus on stabilization and treatment of any of the symptomatic cardiac manifestations of the illness, such as CHF or tamponade due to a pericardial effusion. Treatment should also include appropriate antibiotic therapy to eradicate the streptococcal infection, bed rest, and antiinflammatory agents for arthritis. Steroids should be used in the treatment of carditis only under direction of a cardiologist. Monthly injections of benzathine penicillin G provide prophylaxis against recurrent attacks; alternative regimens include oral penicillin administered twice daily and, for penicillin-allergic patients, twice daily oral erythromycin. Prophylaxis is required until 18 years of age but can be continued for life, depending on the degree of cardiac involvement and risk of recurrence.[13]

BOX 165.17 Cardiovascular Causes of Sudden Death in Young Athletes

Hypertrophic cardiomyopathy
Various congenital coronary artery anomalies
Prolonged QT interval syndrome
Various preexcitation syndromes (e.g., Wolff-Parkinson-White syndrome)
Commotio cordis
Aortic rupture secondary to Marfan syndrome
Idiopathic dilated cardiomyopathy
Myocarditis
Coronary artery disease secondary to Kawasaki disease
Aortic stenosis
Mitral valve prolapse

Cardiac Causes of Sudden Death in Young Athletes

The most common cardiovascular cause of sudden death in the athlete is hypertrophic cardiomyopathy, accounting for up to 36% of the cardiovascular-related cases (Box 165.17). Brugada syndrome is uncommonly diagnosed in childhood.[13]

Specific Disorders

Congenital Coronary Artery Anomalies. Although there are a variety of congenital coronary artery anomalies, the most common potentially lethal lesion is the anomalous left coronary artery, in which the left main and right coronary arteries both arise from the right sinus of Valsalva. Individuals with this particular anomaly have a 46% incidence of sudden death, with more than 85% of the known cases of sudden death occurring during exercise. Congenital coronary artery hypoplasia is another uncommon cause of exercise-induced sudden death. Any athlete with exertional syncope or chest pain should be evaluated by a cardiologist for the possibility of a congenital coronary artery anomaly. If an anomaly is detected and surgically corrected, the athlete may resume full activity and participation in competitive sports.

Marfan Syndrome. Clinical manifestations of the disease include tall and slender habitus, striae atrophicae, disproportionately long extremities compared with the trunk, scoliosis, pectus excavatum or carinatum, and lens dislocation. Approximately 50% of patients with Marfan syndrome have cardiac manifestations, such as mitral valve prolapse or aortic dilation. The most serious cardiac complication of Marfan syndrome is the progressive dilation of the aorta with the potential risk of aortic rupture, which most commonly involves the descending portion of the aorta. Therefore, patients with Marfan syndrome should be prohibited from participation in contact sports. Those individuals who are known to have aortic dilation should also be prohibited from participation in any competitive sports regardless of the degree of contact involved. All patients with Marfan syndrome with or without cardiac involvement on their initial evaluation should be observed by a cardiologist with serial imaging studies of the aorta by echocardiography, magnetic resonance imaging, or computed tomography.

Hypertrophic Cardiomyopathy. Obstructive hypertrophic cardiomyopathy involves a thickened muscular intraventricular septum that bulges into the left ventricle and impedes forward flow, causing chest pain, shortness of breath, pre-syncope, or syncope. The nonobstructive form, which occurs when the thickened septum does not block forward flow, occurs in only 0.2% of the general population, yet it is the single most common cardiac cause of sudden death in the young athlete. Sudden death in previously asymptomatic individuals with

hypertrophic cardiomyopathy occurs during moderate or severe physical exertion. The proposed pathophysiologic mechanism of sudden death during exertion in these individuals is thought to be a transient decrease of blood flow out through the aorta or dysrhythmia originating from the hypertrophied ventricular myocardium.

Clinical Features. Some individuals with hypertrophic cardiomyopathy have experienced previous "warning" episodes of chest pain, dyspnea, syncope, or palpitations during vigorous activities. A family history of sudden unexplained death in young adults should also alert the clinician to the possibility of hypertrophic cardiomyopathy. The majority of young athletes who die of this condition have the nonobstructive form of hypertrophic cardiomyopathy. The classic loud systolic ejection murmur that is present with the obstructive form may not be heard during the routine pre-sports physical examination.

If a systolic murmur along the lower left sternal border is heard on the routine screening physical examination of a young athlete, a Valsalva maneuver may help differentiate the murmur of aortic stenosis from the systolic murmur associated with the obstructive form of hypertrophic cardiomyopathy. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. The transient reduction in the size of the left ventricle will increase the degree of obstruction and thus an increase in the intensity of the systolic murmur heard with the obstructive form of hypertrophic cardiomyopathy. In contrast to this, the systolic murmur of aortic stenosis will decrease in intensity during a Valsalva maneuver because of the transient reduction of blood flow through the stenotic aortic valve.

Current recommendations for pre-sports screening include a detailed family and personal history of known or suspected heart disease, physical examination, and 12-lead ECG. If any suspicion remains, further evaluation (e.g., echocardiography, Holter monitoring, other imaging studies) and referral to a cardiologist are indicated.

Diagnostic Testing. The electrocardiographic findings in hypertrophic cardiomyopathy show left ventricular hypertrophy and left atrial enlargement. Other findings include prominent Q waves in the inferolateral leads and diffuse T wave inversions. The most accurate study for the diagnosis of hypertrophic cardiomyopathy is the echocardiogram, which will demonstrate various degrees of left ventricular hypertrophy and involving the ventricular septum in up to 90% of the cases. Patients with echocardiographic evidence of hypertrophic cardiomyopathy should receive serial echocardiographic examinations to monitor progression.

Management. No pharmacologic therapy has been proven to prevent sudden death. Beta-blockers exert negative inotropic effects, attenuate adrenergic-induced tachycardia, improve myocardial oxygen supply-and-demand, and improve diastolic filling. The use of digoxin is contraindicated in patients with hypertrophic cardiomyopathy because its positive inotropic effect may worsen the left ventricular outflow obstruction. Sudden death in patients with hypertrophic cardiomyopathy is thought to be due to exertion-induced ventricular fibrillation or pulseless ventricular tachycardia. Therefore, all individuals diagnosed with hypertrophic cardiomyopathy, as well as those with an equivocal diagnosis of hypertrophic cardiomyopathy, should not participate in vigorous activities and competitive sports.

A transaortic septal myomectomy may be considered for patients with severe symptoms unresponsive to medical therapy. For suboptimal surgical candidates, implantation of a dual-chamber pacemaker may improve symptoms by decreasing the left ventricular outflow tract gradient.

Long QT Syndrome. Both the Jervell–Lange-Nielsen (congenital deafness) and the Romano-Ward syndromes are inherited disorders characterized by a prolonged QT interval and associated with sudden death. The corrected QT (QTc) interval in normal individuals should not exceed 0.44 second in children or 0.42 second in adolescents. Individuals with QTc intervals longer than 0.55 second have a higher risk of sudden death. Prolongation of the QT interval predisposes the individual to ventricular tachycardia, torsades de pointes, and ventricular fibrillation, which is often initiated by a premature ventricular contraction occurring during the prolonged repolarization phase. In addition to the inherited syndromes of prolonged QT intervals, other causes of prolonged QT intervals include hypocalcemia, hypokalemia, hypomagnesemia, myocarditis, and medications (e.g., procainamide, erythromycin, cyclic antidepressants, phenothiazines, quinidine, and organophosphates).

Clinical Features. Symptoms in the young athlete that are suggestive of QT prolongation include exercise-induced palpitations, chest pain, syncope, dizziness, and atypical seizures. The young athlete who has any of these symptoms should be evaluated by a cardiologist, especially if the family history is positive for sudden unexplained death, cardiac problems, syncope, or deafness. Any young athlete who has been diagnosed with a prolonged QT syndrome should be prohibited from participation in competitive sports and vigorous activities. The growing popularity and presence of AEDs in public places and at sporting events can potentially save the lives of those athletes who suddenly collapse because of an underlying prolonged QT syndrome–induced nonperfusing ventricular dysrhythmia.

Management. Treatment of a prolonged QT interval depends on the cause. Underlying metabolic disorders should be corrected, and medications that induce prolongation of the QT interval should be discontinued. Magnesium sulfate is the drug of choice in the treatment of torsades de pointes. Lidocaine is the safest medication for patients with prolonged QT interval–induced ventricular tachycardia or fibrillation. Anti-dysrhythmic agents that can prolong the QT interval, such as procainamide and amiodarone, should be avoided. Beta-blockers have been used to prevent sudden ventricular dysrhythmias in those patients with the familial forms of QT prolongation. Adjunctive treatment in these selected patients also includes the insertion of pacemakers or internal defibrillators.

Commotio Cordis. Commotio cordis occurs after a high-impact trauma to the chest, as in a high-speed motor vehicle collision or a baseball to the sternum. The impact occurs during the vulnerable repolarization period of the cardiac cycle, mechanically inducing ventricular fibrillation. This phenomenon most commonly occurs in children between 5 and 15 years old with no known predisposing cardiac conditions. Although commotio cordis most commonly occurs in baseball, it has also been reported to occur in ice hockey, lacrosse, softball, and fist fights. The majority of patients who sustain commotio cordis do not survive unless rapidly treated with defibrillation. If an AED is not immediately available and the patient is completely unresponsive with no pulse after sustaining a direct blow to the chest, a chest thump during CPR should be attempted.

The author would like to thank Alson Inaba, M.D. for his work on previous editions of this chapter.

CHAPTER 165: QUESTIONS AND ANSWERS

1. Which of the following increases the systemic vascular resistance (SVR), thus producing a left-to-right shunt through the ventricular septal defect (VSD) associated with Tetralogy of Fallot?

a. Acute hypovolemia
b. Crying
c. Defecation
d. Squatting

Answer: D. Squatting or knee-to-chest positions increase the SVR, thus improving tet spells by producing the left-to-right shunt. Acute hypovolemia, crying, defecation, and tachycardia are all events that suddenly lower the SVR and produce large right-to-left shunts across the VSD, beginning the vicious cycle of a hypoxic (tet) spell.

2. A 14-year-old girl presents to the emergency department (ED) with altered level of consciousness and trouble breathing. Her vital signs are blood pressure (BP), 72/39 mm Hg; heart rate, 240 beats/min; temperature, 99.6° F; respiratory rate, 60 breaths per minute; and oxygen saturation, 80%. An electrocardiogram (ECG) is performed, which shows supraventricular tachycardia. The patient weights 50 kg. Which of the following is the most appropriate initial treatment?

a. Adenosine 5 mg IV
b. Cardioversion with 50 J
c. Cardioversion with 200 J
d. Diltiazem 12.5 mg IV

Answer: B. This patient should be considered unstable supraventricular tachycardia (SVT), with trouble breathing, low O_2 saturation, and hypotension. In stable patients, vagal maneuvers may be appropriate to try first, followed by adenosine. Diltiazem may be used for rate control in patients with atrial flutter or atrial fibrillation. Cardioversion is the treatment of choice in patients with hemodynamic instability and SVT. The dose is 0.5 to 1 J/kg.

3. What is the most common cause of bradycardia in infants?

a. Complete heart block
b. Hypothermia
c. Hypothyroidism
d. Hypoxia

Answer: D. Although all of these may cause bradycardia in infants and children, the most common cause is hypoxia.

4. A 16-year-old boy presents with complaints of syncope during a basketball game. His mother reports a family history of sudden death in young adults, and you are concerned that the patient may have hypertrophic cardiomyopathy. Which of the following increases the murmur associated with this condition?

a. Hand grip
b. Methoxamine
c. Squatting
d. Valsalva

Answer: D. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. This transient reduction will increase the degree of obstruction and thus cause an increase in the intensity of the murmur. Hand grip, methoxamine, and squatting will increase return of blood to the heart and therefore decrease the murmur associated with hypertrophic cardiomyopathy.

5. A 5-month-old girl presents with fever for a week, rash, and fussiness; reportedly yesterday her rash was faint throughout her body and has since resolved. On examination, she is febrile with otherwise reassuring vital signs; she is fussy and has conjunctival injection in both eyes. Her parents think she got sick from their other children. Which of the following statements regarding this patient's most likely disease is *true?*

a. If present, other systemic signs (such as, nausea, vomiting, and diarrhea) suggest an alternative diagnosis (such as, acute gastroenteritis).
b. Laboratory investigation in the emergency department (ED) will assist in her risk stratification.
d. Older children are at the highest risk for aneurysm formation.

Answer: B. Kawasaki disease is a systemic vasculitis, and gastrointestinal findings (nausea, vomiting, abdominal pain, diarrhea) and neurologic findings (irritability, positive pleocytosis on lumbar puncture if done) may mislead the clinician. Although she only has one criterion currently, signs of Kawasaki disease may occur in series or simultaneously over the course of the disease. With two or more signs in a child who is febrile for more than 5 days, markers of systemic inflammation (such as, C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]) are indicated to determine the need for further laboratory testing (complete blood count, liver function tests [LFTs], albumin, urinalysis), imaging (echocardiography), or next day follow-up (with repeat laboratory tests). This child is at high risk because infants are more prone to vascular complications (such as, giant aneurysm formation); tragically they are also more likely to present with incomplete Kawasaki disease and may be overlooked. Accordingly, consensus guidelines recommend that all infants younger than 6 months old with fever of 1 week or greater (regardless of other findings) should undergo laboratory testing for markers of inflammation and, if positive, should have an echocardiogram performed emergently.

166

Pediatric Gastrointestinal Disorders

Patrick J. Maloney

KEY CONCEPTS

- Physiologic jaundice of the newborn and breast milk jaundice are the most common causes of jaundice in the neonatal period.
- Direct hyperbilirubinemia in infants is always pathologic and requires a detailed evaluation.
- Hypertrophic pyloric stenosis is associated with gradually progressive nonbilious emesis that becomes projectile.
- Hypochloremic-hypokalemic metabolic alkalosis is the classic electrolyte derangement associated with hypertrophic pyloric stenosis.
- Bilious vomiting in the neonate is an ominous sign and should initiate a diagnostic evaluation for possible malrotation with volvulus or other intestinal obstructive pathology.
- Infants with bilious emesis should receive an emergent surgical consultation, particularly if ill-appearing.
- Necrotizing enterocolitis (NEC) occurs more commonly in premature infants, but 10% of affected infants are full term. Pneumatosis intestinalis in neonates—intramural air seen on x-ray—is pathognomonic for NEC.
- Gastroesophageal reflux (GERD) is very common in infants and is usually benign and self-limited. Occasionally, GERD may cause more severe symptoms, including irritability, respiratory distress, and failure to thrive. GERD usually responds to conservative measures (e.g., positioning, thickening of formula, smaller and more frequent feedings); pharmacologic interventions are seldom needed.
- The classic clinical triad of intussusception includes colicky, intermittent abdominal pain, a palpable sausage-shaped abdominal mass, and bloody "currant jelly" stools; however, this triad occurs in less than one-third of patients.
- Children with intussusception may present atypically, with an altered level of consciousness (e.g., lethargy) rather than abdominal pain.
- Hirschsprung disease is a pathologic cause of constipation in the neonate and usually manifests as delayed passage of meconium. Occasionally, children may present later in life with symptoms of chronic constipation. Toxic megacolon is the most serious complication.
- Meckel diverticulum classically manifests in children younger than 5 years with massive, painless, "brick red" colored rectal bleeding.
- More than 90% of GI foreign bodies pass without complications.
- Lithium button batteries lodged in the esophagus may cause serious burns, erosions, and perforations within as little as two hours. Of all foreign bodies, button batteries require the most expeditious removal, usually by endoscopy.
- Appendicitis is the most common surgical disease in children. Diagnosis depends on a combination of clinical factors, including history, physical examination, laboratory values, and imaging studies.
- Effective imaging strategies for children with suspected appendicitis include initial ultrasound examination followed by CT scanning of the abdomen for those with equivocal findings.
- Causes of pancreatitis in children include viruses, trauma, drugs, and toxins.
- Biliary disease in children is more commonly caused by cholestasis rather than biliary obstruction.
- Pigment gallstones are more common than cholesterol stones in children. Biliary tract disease is usually diagnosed with right upper quadrant ultrasound imaging; management strategies are similar to those for adults.

FOUNDATIONS

Gastrointestinal (GI) symptoms are common among pediatric patients presenting to the emergency department (ED). Because young children lack the knowledge, social skills, and vocabulary to describe and localize their symptoms, the signs and symptoms commonly attributed to the GI tract, such as abdominal pain, nausea, anorexia, and vomiting, are often nonspecific and ill-defined. As a result, their evaluation and management may be challenging.

Pediatric gastrointestinal disorders may be divided into different groups on the basis of their unique pathophysiologic mechanisms (Table 166.1). Several disorders occur as normal variants of early neonatal and infant development (e.g., neonatal jaundice, gastroesophageal reflux, hypertrophic pyloric stenosis). Others result from congenital malformations (e.g., malrotation, Meckel diverticulum) or genetic abnormalities (e.g., Hirschsprung disease). Idiopathic or poorly explained disorders include necrotizing enterocolitis (NEC), intussusception, Henoch-Schönlein purpura (HSP), and inflammatory bowel disease (IBD). The child's age can also help identify common causes of abdominal pain. Infants, for example, may have disorders such as NEC, hypertrophic pyloric stenosis, or intussusception, whereas older children are more likely to present with appendicitis, pancreatitis, or biliary tract disease.

SPECIFIC DISORDERS

Neonatal Jaundice

Foundations

Bilirubin is formed by the breakdown of heme-containing proteins, primarily hemoglobin. Unconjugated bilirubin binds to albumin and

is carried to the liver, where it is conjugated by glucuronyl transferase and excreted into bile. While jaundice in adults is usually a conjugated hyperbilirubinemia, resulting from primary hepatobiliary disease, neonatal jaundice is usually the result of extrahepatic causes and results in an unconjugated hyperbilirubinemia (Table 166.2). There are typically three physiologic factors that contribute to neonatal jaundice: (1) increased bilirubin production, (2) decreased clearance and excretion, and (3) increased enterohepatic resorption. Conjugated hyperbilirubinemia in neonates, on the other hand, is less common and always pathologic.

Nearly every newborn develops an unconjugated serum bilirubin level greater than 1 mg/dL— the normal upper limit in adults—during the first week of life. Jaundice, the yellow discoloration of the skin and sclera, becomes clinically noticeable when the total bilirubin level rises above about 5 mg/dL. Risk factors for the development of severe

hyperbilirubinemia in the neonate include prematurity, isoimmune-mediated hemolysis (ABO incompatibility), sepsis, cephalohematomas, dehydration, and inherited abnormalities, such as hereditary spherocytosis and glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Unconjugated bilirubin crosses the blood-brain barrier, where it causes cell death. At levels greater than approximately 20 to 25 mg/dL, there is an increased risk of bilirubin-induced neurologic dysfunction (BIND). Kernicterus refers to the chronic, irreversible, long-term neurologic sequelae of BIND.

Jaundice during the newborn period is usually the result of an immature metabolism of bilirubin. This benign self-limited jaundice is termed *physiologic jaundice of the newborn*, occurring in approximately 50% of normal newborns. Although it varies based on ethnicity, total bilirubin levels typically peak between two and five days of life, and the yellow discoloration of the skin usually resolves by the first two weeks of life.

Breast milk jaundice is the second most common cause of neonatal jaundice. The exact pathophysiology is uncertain, but it may be hormonally mediated or related to increased enterohepatic resorption of bilirubin. Breast milk jaundice is typically characterized by a mild unconjugated hyperbilirubinemia that peaks a bit later than physiologic jaundice and may persist for several weeks to months. Other causes of jaundice vary significantly (see Table 166.2)

Clinical Features

Healthy infants are born with normal bilirubin levels that gradually increase to a peak level of 6 mg/dL on approximately the third day of life and then decline to normal levels within 2 weeks. Infants with hyperbilirubinemia usually begin life with similarly low bilirubin levels but exhibit a faster rise in bilirubin levels over the first few days of life. Physiologic jaundice is rarely present on the first day of life, meaning that a total bilirubin level greater than 5 mg/dL within the first 24 hours of life is almost always pathologic. Children with breast milk jaundice typically demonstrate the same gradual increase seen with physiologic jaundice, but levels continue to increase and peak at around 10 to 21 days of life. Elevated levels may persist for 3 to 10 weeks before gradually declining.

Toxic levels of bilirubin (dependent on age, but in general >20 mg/dL) may be associated with neurotoxicity and encephalopathy, termed *bilirubin-induced neurologic dysfunction* (BIND), and the development of kernicterus. Symptoms of BIND include poor feeding and lethargy, sometimes progressing to muscle rigidity, opisthotonos, seizures, and death. Other potential clinical manifestations are cerebral palsy, sensorineural hearing loss, and gaze abnormalities (usually upward gaze limitations).

Acute bilirubin encephalopathy (ABE) refers to the early and potentially reversible signs and symptoms of the hyperbilirubinemia, including somnolence, poor feeding, hypertonia or hypotonia, and a high-pitched cry. If untreated, symptoms can progress to lethargy, hypertonia, backward arching of the neck and trunk (retrocollis and opisthotonos, respectively), fever, irritability, and apnea. Ultimately, this can lead to seizures and death. Survivors may have chronic, permanent coordination problems, cerebral palsy, hearing loss, and learning disabilities. If treated, some or all of these symptoms may be reversible. Ultimately, the management of neonatal jaundice aims to prevent the development of BIND and kernicterus.

Differential Diagnoses

Once the diagnosis of neonatal jaundice is established based on physical exam and laboratory confirmation of an elevated unconjugated bilirubin level, focus should be directed to identifying and managing the physiologic factors contributing to the derangement. The birth history may reveal prematurity or a history of birth trauma–related cephalohematomas. Review of the maternal and infant perinatal records may identify maternal-child blood type (ABO) incompatibility or other risk factors for isoimmune-mediated hemolysis. A detailed history of feeding patterns, urine output, and stool appearance may identify poor nutritional intake, poor weight gain, and dehydration. The presence of hyper- or hypothermia may suggest the presence of infection/sepsis. The family history may identify siblings or other relatives with a history of jaundice or genetic or metabolic disorders. Table 166.2 presents additional differential considerations for jaundiced infants.

BOX 166.1 Indications for Evaluation of Jaundiced Infants

- Jaundice appearing within 24 hr of birth
- Elevated direct (conjugated) bilirubin level
- Rapidly rising total serum bilirubin unexplained by history or physical examination
- Total serum bilirubin approaching exchange level or not responding to phototherapy
- Jaundice persisting beyond 3 weeks of age
- Sick-appearing infant

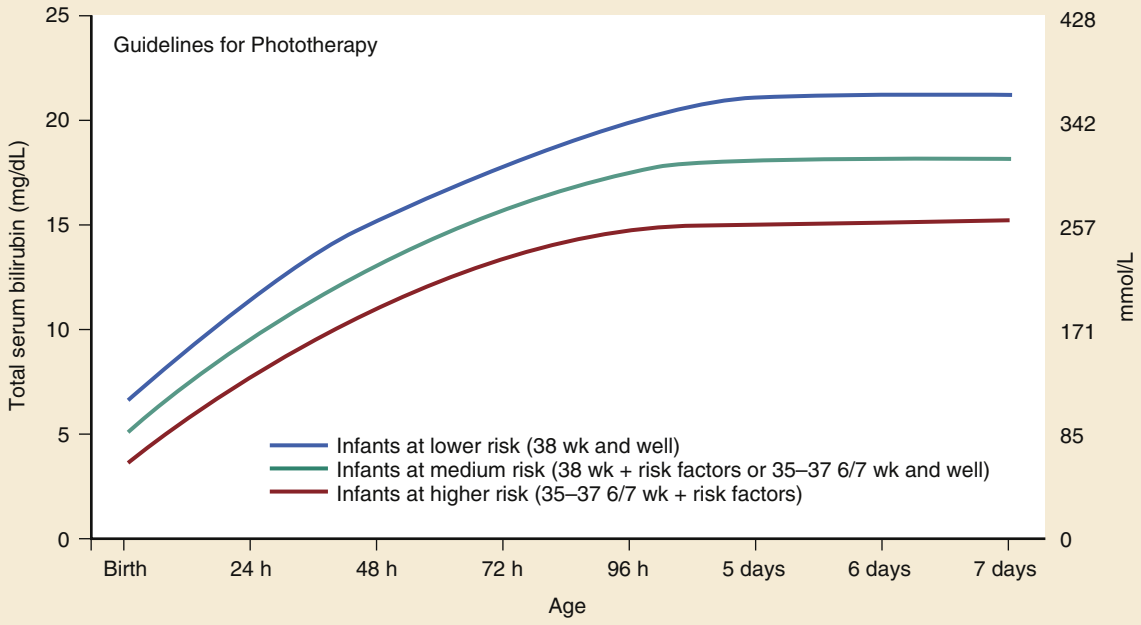
Diagnostic Testing

Physiologic and breast milk jaundice are the most common causes of neonatal jaundice; pathologic causes and indications for evaluation of hyperbilirubinemia are listed in Box 166.1. Transcutaneous bilirubin meters can be used to quickly measure bilirubin levels through the skin in otherwise well-appearing neonates who are beyond 24 hours, but within 7 days, of life. Infants who have previously undergone phototherapy, those with known risk factors for hemolysis, and those with high transcutaneous levels (based on the meter manufacturer's recommended product range) should also have serum levels sent.[1] Initial serum testing can also determine fractionated levels of total versus direct (conjugated) bilirubin.

We recommend that further laboratory evaluation include a complete blood count (CBC) with a peripheral smear and Coombs test to determine immune-mediated major blood group incompatibility, if not previously known. Diagnostic testing in ill-appearing infants includes finger stick blood glucose measurement, electrolyte panel, urine assay for reducing substances, serum ammonia levels, ketones, lactate and evaluation for infection. Conjugated hyperbilirubinemia is always pathologic, resulting from biliary atresia, other biliary obstructive pathology, severe infections, toxins, or inborn errors of metabolism.

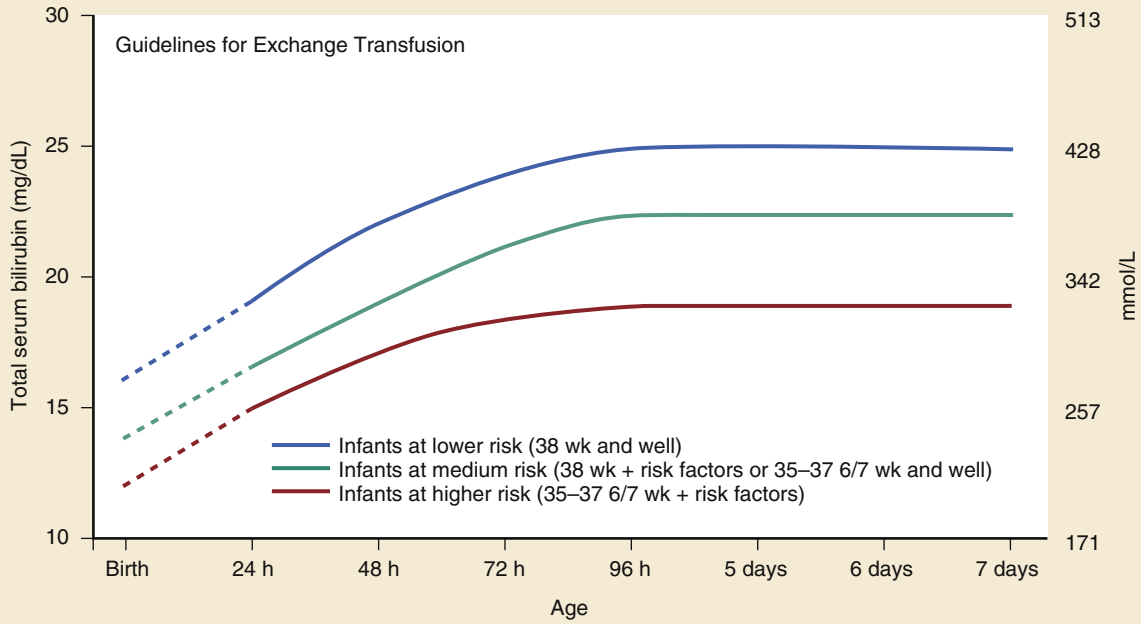
Management

The treatment of infants with unconjugated hyperbilirubinemia centers on the prevention of kernicterus. Because oral intake stimulates enterohepatic circulation and decreases bilirubin levels, feeding (including breast-feeding) should be encouraged. Phototherapy is the initial intervention used to reduce the total bilirubin level in affected infants. Guidelines for the use of phototherapy, based on age, risk factors for developing BIND, and bilirubin level, have been established and recommended by the American Academy of Pediatrics (AAP) (Fig. 166.1). BiliTool (www.bilitool.org) is an additional online resource that utilizes the same AAP guidelines to help clinicians assess the risk of developing hyperbilirubinemia in late preterm and full term infants.



- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk, can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

A



- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is 5 mg/dL (85 mmol/L) above these lines.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk), can individualize TSB levels for exchange based on actual gestational age.

B

Fig. 166.1 (A) Guidelines for phototherapy in hospitalized infants at 35 weeks or more of gestation. Note that these guidelines are based on limited evidence. The guidelines refer to intensive phototherapy, which should be used when the total serum bilirubin (TSB) exceeds the line indicated for each category. Infants are designated higher risk because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. (B) Guidelines for exchange transfusion in infants at 35 weeks or more of gestation. Note that these suggested levels represent a consensus but are based on limited evidence. Exchange transfusion is recommended if the TSB continues to rise or remains above these levels, despite intensive phototherapy. *B/A*, Bilirubin/albumin; *G6PD*, glucose-6-phosphate dehydrogenase. (From: American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297-316.)

Infants with severely elevated bilirubin levels are at greatest risk for developing BIND. Exchange transfusions are the most effective and rapid way to remove bilirubin. Indications for exchange transfusion include bilirubin level above age-specific threshold recommended by the AAP guidelines (see Fig. 166.1), failure of phototherapy (i.e., the bilirubin level continues to rise despite intensive phototherapy), and jaundiced infants with signs and symptoms of BIND. The procedure is time-consuming and should be performed in a pediatric or neonatal intensive care unit (NICU), where the infant's hemodynamic status may be closely monitored. A double-volume transfusion (180 to 190 mL/kg packed red blood cells) replaces approximately 85% of an infant's blood volume and reduces the total bilirubin level by at least 50%. It is performed by serially removing small aliquots of the infant's blood, typically no more than 5 to 10 mL/kg and replacing it with a similar volume of packed red blood cells until the total transfusion volume is achieved.

Disposition

Infants with bilirubin levels greater than established age- and risk factor-specific levels should receive phototherapy (Fig 166.1A). Infants who appear ill, are below their expected weight for day of life, cannot maintain oral intake, or require exchange transfusion (Fig 166.1B) should undergo hospital admission for phototherapy, IV hydration, and on-going evaluation. Home phototherapy is an option for infants who are otherwise well-appearing, have reliable caregivers with access to emergency care, and can receive follow-up within 24 hours.[2] All infants with direct hyperbilirubinemia should be admitted to the hospital for evaluation of the cause, treatment of sepsis or other treatable cause, and consultation with subspecialist (e.g., pediatric gastroenterology) as indicated.

Hypertrophic Pyloric Stenosis

Foundations

Hypertrophic pyloric stenosis is the most common cause of infantile GI obstruction beyond the first month of life. This condition occurs in 1 of every 250 live births, although rates and trends vary significantly by region. Boys are affected at four times the rate of girls. Approximately one-third of cases occur in first-born children. Prematurity and infant exposure to macrolide antibiotics are additional risk factors.[3] Hypertrophic pyloric stenosis tends to have familial patterns, but the exact pattern of inheritance is unclear.

Affected infants are born with a normal sized pylorus that enlarges as time progresses. The exact cause is unknown, although hypertrophy seems to be stimulated by feeding. As the pylorus enlarges, a progressive gastric outlet obstruction develops, and vomiting ensues. Vomiting causes loss of fluid and gastric acid (hydrogen and chloride ions). As dehydration and electrolyte derangements worsen, the kidney attempts to retain hydrogen ions in exchange for potassium, resulting in the classic hypochloremic-hypokalemic metabolic alkalosis.

Clinical Features

Infants classically present at 2 to 6 weeks of chronologic age, with gradually progressive vomiting that becomes projectile but remains nonbilious. Early in the disease process, infants remain vigorous, with a ravenous appetite. They rapidly finish an entire feeding, only to regurgitate the entire volume in a projectile fashion. In the later stages of the disease, infants may exhibit poor weight gain, clinical dehydration, and malnutrition, along with visible waves of abdominal peristalsis in response to intense contractions against the obstruction.

Diagnostic Testing

Infants may have a palpable pylorus in the right epigastrium on abdominal examination, commonly referred to as an "olive." Because access to ultrasound is now readily available in the developed world, pyloric stenosis is generally diagnosed earlier compared to decades ago, and the "olive" is now palpated in only a minority of infants who present later in the disease course. Laboratory derangements reflect a state of dehydration and electrolyte loss through vomiting—a hypochloremic metabolic alkalosis (serum bicarbonate [HCO_3] levels ≥29 mmol/dL and chloride levels ≤98 mmol/dL), although these abnormalities may be absent early in the disease course.

Hypertrophic pyloric stenosis may be confirmed by ultrasonography or fluoroscopic upper GI series (UGI). Ultrasonography is often the first diagnostic modality of choice because it is simple, readily available, and without serious complications such as aspiration. Upper GI series may be preferred when there is bilious vomiting and concern for more distal bowel obstruction. With both modalities, reported accuracy is greater than 95%. On ultrasound, the pylorus appears thickened (pyloric muscle thickness > 4 mm; pyloric diameter > 14 mm) and elongated (>19 mm), which is diagnostic (Fig. 166.2). On UGI series, a characteristic string sign, reflecting passage of contrast material through the narrowed pyloric sphincter, may also be evident. In advanced stages with complete obstruction at the pylorus, plain films may reveal a distended, air-filled stomach.

Differential Diagnoses. Vomiting in infants is common, and the differential diagnosis is broad. Usually, infants present early in the disease progression and are well-appearing, and the common consideration is differentiating hypertrophic pyloric stenosis from gastroesophageal reflux. Reflux classically begins shortly after birth and remains relatively constant. Infants with pyloric stenosis typically have progressively worsening emesis beginning around 2 or 3 weeks of life. In advanced stages, it occurs with every feed and is often described as projectile.

Infants who present with sudden onset of severe vomiting and bilious emesis, or who are ill-appearing, should be evaluated for other surgical emergencies, including malrotation with midgut volvulus, duodenal atresia, and necrotizing enterocolitis. With reflux and pyloric stenosis, emesis is rarely bilious.

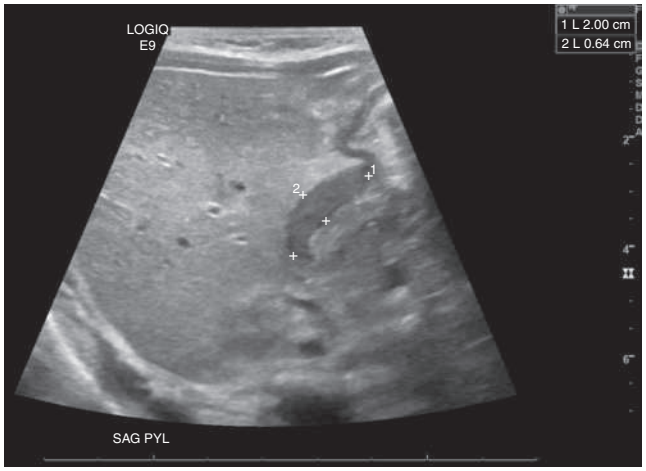


Fig. 166.2 Ultrasound of the abdomen revealing an elongated (20 mm) and thickened (6 mm) pylorus muscle consistent with hypertrophic pyloric stenosis. Normal pylorus muscle measurements are: pyloric muscle thickness < 4 mm; pyloric diameter <14 mm; pylorus length <19 mm. (Courtesy Dr. Patrick J. Maloney)

Many causes of vomiting do not have a true GI origin, including sepsis, metabolic disturbances (e.g., diabetic ketoacidosis), increased intracranial pressure, urinary tract infections, inborn errors of metabolism, adverse medication reactions or side effects, and drug intoxications. Differential considerations for vomiting in children vary by age (Table 166.3).

Management

Treatment consists of fluid and electrolyte replacement and surgical consultation. Hypertrophic pyloric stenosis is not a true surgical emergency but may be a fluid and electrolyte emergency. Fluid resuscitation should begin with repeated boluses of 20 mL/kg of normal saline as necessary to treat dehydration and hypovolemic shock.[4] Potassium supplementation (KCl, 0.5 to 1 mEq/kg IV over 1 to 2 hours) is often necessary. Definitive management is surgery. The corrective procedure, called a pyloromyotomy, may be performed open, referred to as the Ramstedt pyloromyotomy, or laparoscopically. Associated mortality is rare.

Disposition

Most children are best managed with hospital admission for rehydration and correction of electrolyte abnormalities in conjunction with urgent imaging and surgical consultation.

Malrotation with Midgut Volvulus

Foundations

Malrotation of the intestines occurs in 1 in 500 live births and has a male predominance of at least 2 : 1. Among infants with malrotation, symptomatic volvulus of the midgut occurs in the first month of life in approximately one-third, in the first year of life in approximately one-half, and before the age of 5 years in 75% of children. Rarely, patients born with intestinal malrotation develop midgut volvulus later in life as adults. Some remain asymptomatic. When midgut volvulus does occur, the mortality rate may be as high as 10% with surgical intervention.

During embryologic development, the GI tract rotates around the superior mesenteric artery. As it completes the rotation, the duodenum forms a C-loop and is fixed to the retroperitoneum in the left upper quadrant at the ligament of Treitz. The cecum becomes similarly fixed in the right lower quadrant. Thus, the duodenum and cecum normally come to lie widely separated and are firmly fixed in position by peritoneal attachments called Ladd bands. They are only loosely connected by a broad-based mesentery. In cases of malrotation, the duodenum and cecum do not rotate completely, remain closely positioned, and are suspended in the midgut region by the mesenteric vascular stalk. This unusually close proximity results in a short stalk of mesentery that easily twists on itself, resulting in obstruction of the distal duodenum and bowel ischemia and necrosis secondary to compression of the superior mesenteric artery.

Clinical Features

The hallmark presentation of acute midgut volvulus associated with intestinal malrotation is sudden-onset bilious emesis and abdominal distention in an infant. Affected infants usually appear quite ill and may present in shock. Any yellow or green pigmented staining of the vomitus suggests the presence of bile. When bile is initially produced, it is bright yellow and turns green only with time and oxidative exposure. Therefore, differential coloring of bile-stained emesis, yellow versus green, is not predictive of a surgical condition.

Diagnostic Testing

Plain radiographs may demonstrate nonspecific signs of a small bowel obstruction, including dilated loops of proximal small bowel with air-fluid levels and a paucity of bowel gas distally (Fig. 166.3). The diagnostic procedure of choice to identify midgut volvulus is a limited upper GI contrast series, revealing an abnormal position of the duodenal C-loop, which fails to normally cross the midline from right to left (Fig. 166.4), and a characteristic corkscrew appearance of the more distal small bowel (Fig. 166.5).

Ultrasonography, usually performed to evaluate for hypertrophic pyloric stenosis, may reveal an abnormal orientation of the superior mesenteric artery and vein (the vein is abnormally positioned anteriorly or to the left of the artery (Fig. 166.6) or a whirlpool sign caused by the vessels twisting around the mesenteric stalk, causing an echogenic twisting pattern.[5] CT is usually not recommended because it carries the risk of additional radiation without benefit of improved diagnostic ability over upper GI series.

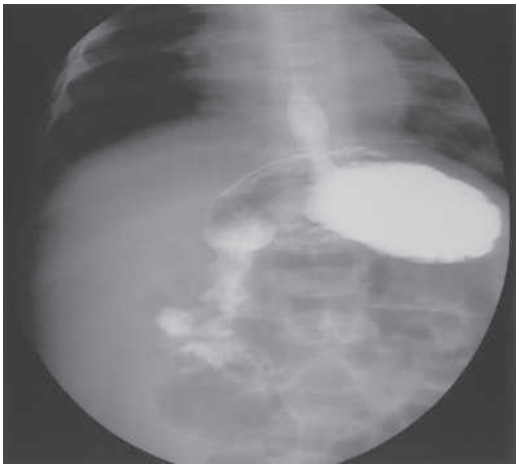

Fig. 166.3 Upright abdominal radiograph obtained in an infant with bilious vomiting illustrates dilated loops of small bowel and a paucity of bowel gas distally, consistent with proximal obstruction secondary to malrotation with midgut volvulus. (Courtesy Dr. Mark A. Hostetler.)

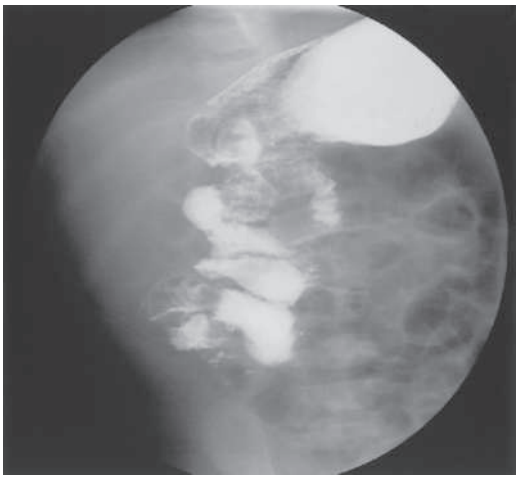

Fig. 166.4 Upper gastrointestinal film, obtained in the same infant as in Fig. 166.3, reveals abnormal positioning of the duodenal C-loop to the right of the spinal column, consistent with malrotation. (Courtesy Dr. Mark A. Hostetler.)

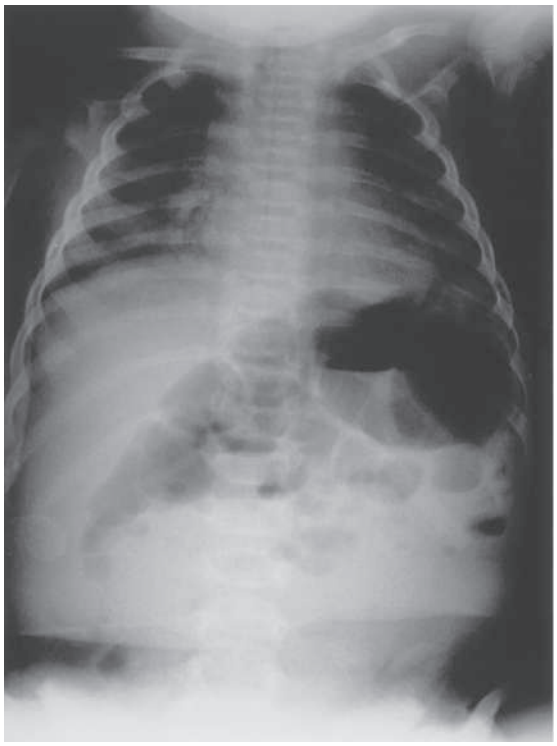

Fig. 166.5 Spot film from the upper gastrointestinal series obtained in the infant in Fig. 166.3. This radiograph shows the characteristic corkscrew appearance seen on small bowel follow-through in patients with malrotation. (Courtesy Dr. Mark A. Hostetler)

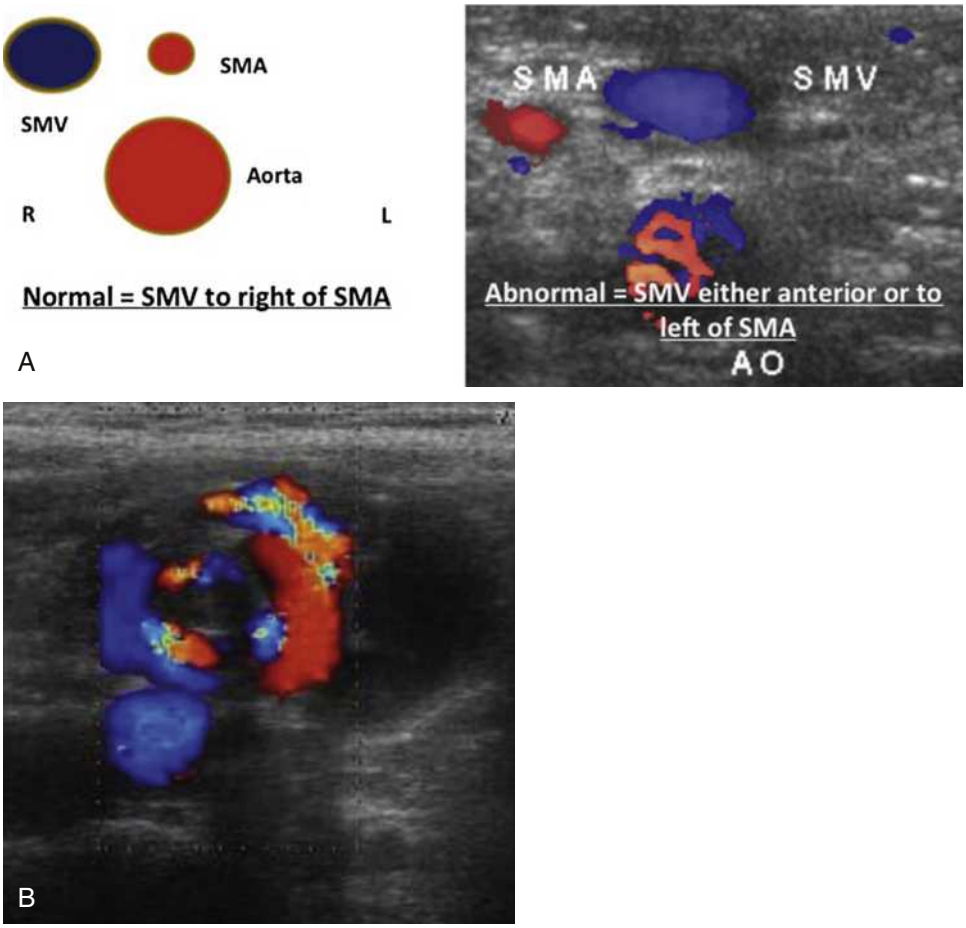

Fig. 166.6 Ultrasonographic findings in malrotation with midgut volvulus. (A) Abnormal orientation of mesenteric vessels associated with malrotation with midgut volvulus. Normally, the superior mesenteric vein (SMV) is positioned to the right of the superior mesenteric artery (SMA). In malrotation, the vein is abnormally positioned anteriorly or to the left of the artery. (B) Whirlpool sign caused by the vessels twisting around the mesenteric stalk, resulting in an echogenic twisting pattern. *AO,* Aorta. (Courtesy Dr. Patrick J. Maloney.)

Differential Diagnoses

Vomiting in childhood, especially infants, is common and occurs across a wide spectrum of illnesses (see Table 166.3). Causes vary by age, progression of symptoms, and vomitus appearance. In children less than one year old, sudden onset of bilious vomiting is an ominous sign and should prompt emergent evaluation for acute bowel obstruction, including malrotation with midgut volvulus. Gastroesophageal reflux disease (GERD) and hypertrophic pyloric stenosis typically cause nonbilious emesis in relatively well-appearing infants. NEC may also present with obstructive signs and symptoms, including bilious emesis and abdominal distention. However, unlike malrotation with volvulus, NEC is characterized radiographically by diffusely dilated loops of small bowel and the presence of air within the bowel walls, termed *pneumatosis intestinalis*.

Management

Emergent pediatric surgical consultation should be obtained for any neonate or infant with bilious vomiting, even before diagnostic studies have been completed. In acute midgut volvulus, operative intervention should be rapid to save the bowel from necrosis.

Intravenous (IV) access should be obtained, and laboratory studies should include blood glucose level, a CBC with differential, electrolyte values, and renal and liver function tests. If there are clinical signs of shock, repeated fluid boluses of 20 mL/kg of normal saline or lactated Ringers solution should be given until adequate circulation has been established.

BOX 166.2 Empirical Antibiotic Regimens for Enteric Bacterial Pathogens

Regimen

- Piperacillin-tazobactam + gentamicin
- Piperacillin-tazobactam + gentamicin + vancomycin
- Ampicillin + gentamicin + metronidazole
- Ampicillin + ceftriaxone + metronidazole
- Meropenem

Dosing

- Piperacillin-tazobactam: 200–300 mg/kg/day of piperacillin component q6–8 hours
- Gentamicin: 3–7.5 mg/kg/day in divided doses based on age/renal function
- Ampicillin: 200 mg/kg/day q6h
- Vancomycin: 10–20 mg/kg IV q6–8h
- Metronidazole: 30–40 mg/kg/day q8h
- Ceftriaxone: 50 mg/kg/day once daily
- Meropenem: 60 mg/kg/day q8h

Ill-appearing infants should receive empirical broad-spectrum antibiotic coverage for enteric bacterial pathogens (Box 166.2). A nasogastric or orogastric tube should be placed to decompress the proximal bowel and

stomach. A limited upper GI series should also be emergently obtained but should not delay resuscitation and surgical consultation.

Disposition

Patients with a confirmed or equivocal diagnosis should be admitted with emergent surgical consultation.

Necrotizing Enterocolitis

Foundations

Necrotizing enterocolitis (NEC) is the most common gastrointestinal emergency in neonates. However, because most affected infants are premature and acquire the condition in the NICU, NEC usually is not usually encountered in the ED setting. NEC does occur in a small subset of late preterm and full-term infants, although most of them have other underlying illnesses and rarely are discharged from the NICU prior to the onset of disease. Complications in children who survive NEC, which are often encountered in the ED, include strictures, fistulas, and short gut syndrome.

The exact pathophysiologic mechanism of NEC is unclear but is likely multifactorial. The primary pathophysiologic event is inflammation or injury to the intestinal wall. Prematurity is the most common and universally accepted risk factor, as 90% of all affected infants are born prematurely.

Clinical Features

Infants with NEC usually first develop feeding intolerance and bilious or nonbilious emesis. In the more advanced stages of the disease, infants may appear extremely ill with hematemesis, hematochezia, fever, and shock. Abdominal radiographs may show intestinal dilation, pneumatosis intestinalis, or intestinal perforation.

Differential Diagnoses

Feeding intolerance and vomiting are common and nonspecific findings in neonates. However, unlike most infants with GERD, pyloric stenosis, and other relatively benign or self-limited causes of vomiting, infants with NEC are usually quite ill-appearing. GERD classically begins shortly after birth and remains relatively constant in character. Pyloric stenosis–related vomiting does not begin until 2 to 3 weeks of age and then gradually increases in severity and forcefulness, but these infants rarely appear acutely toxic. Bilious vomiting, while common in NEC, requires careful consideration to rule out other obstructive pathology, including malrotation with midgut volvulus, especially in children born at or near full term. The appearance of the plain radiographs may help differentiate NEC and volvulus. Volvulus is associated with dilated, air-fluid loops of small bowel proximally and a paucity of bowel gas distally, whereas the hallmark of NEC is diffusely dilated loops of small bowel and pneumatosis intestinalis.

Diagnostic Testing

Plain abdominal radiographs are the imaging study of choice in NEC. Radiographs may show nonspecific signs reflecting the presence of small bowel obstruction (dilated, air-fluid filled loops of bowel), bowel ischemia (intramural bowel wall gas, called pneumatosis intestinalis, or air within the portal system and biliary tract), or bowel perforation (pneumoperitoneum). Pneumatosis intestinalis (Fig. 166.7) is pathognomonic for NEC and is present in 75% of patients. No individual laboratory test is diagnostic or specific for NEC, but may reflect dehydration, electrolyte derangements, and sepsis.

Management

Patients suspicious of having NEC should receive nothing by mouth (NPO), with placement of an orogastric or nasogastric tube for decompression of the stomach and small bowel. Because these patients are frequently hemodynamically unstable and may have periods of apnea or significant respiratory distress, intubation may be needed. IV or intraosseous access should be established; laboratory studies should include a CBC with differential, electrolyte panel, glucose, renal and liver function tests, and type and screen. Blood and urine cultures should be obtained. Fluid resuscitation with 20 mL/kg boluses of normal saline or lactated Ringers solution should be repeated until adequate circulatory volume has been reestablished. Vasoactive agents such as epinephrine, or norepinephrine are indicated for patients in refractory shock. Broad-spectrum antibiotic coverage is indicated (see Box 166.2). Emergent pediatric surgery consultation should be obtained in all cases because perforation and bowel necrosis may not be immediately evident on plain radiographs. Mortality is very high (30% to 50%) despite appropriate management.

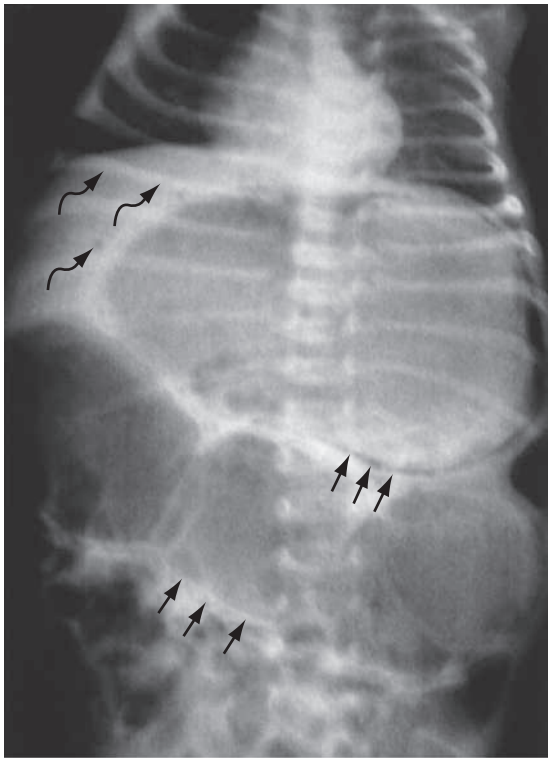

Fig. 166.7 Plain radiograph obtained in an infant with necrotizing enterocolitis. *Straight arrows* indicate air within the wall of the small bowel and gastric mucosa (pneumatosis intestinalis and gastralis). *Curved arrows* indicate air in the biliary tree (portal venous gas). (Courtesy Dr. Mark A. Hostetler.)

Disposition

Children thought to have NEC require admission to an ICU and should have emergent pediatric surgical consultation.

Gastroesophageal Reflux

Foundations

Gastroesophageal reflux (GERD) refers to the symptomatic regurgitation of stomach contents into the esophagus, with or without vomiting. Reflux occurs as a result of an incompetent lower esophageal sphincter. Reflux is a normal physiologic event in infants, and essentially all infants experience intermittent reflux during at least the first six months of life. When reflux causes troublesome symptoms or complications, it is referred to as GERD. Chronic reflux of gastric contents

into the esophagus may result in esophagitis, chronic cough, aspiration, and failure to thrive if severe.

Clinical Features

Reflux and GERD generally begin shortly after birth and resolve with time, usually by the age of one year. Clinical manifestations occur along a wide spectrum of disease, ranging from asymptomatic to occasional episodes of spitting up to severe persistent vomiting and failure to thrive. Sandifer syndrome, although rare, refers to the stereotypical opisthotonic movements highly suggestive of severe GERD. Chronic GERD may cause chronic cough, recurrent stridor, and persistent wheezing. GERD may even be implicated in infants who experience "brief resolved unexplained events" that include symptoms of respiratory distress or apnea, transient color change (i.e., pallor, cyanosis), and possibly a change in muscle tone (flaccidity or rigidity), although evidence of this direct causation is lacking.[6]

Differential Diagnoses

Children with GERD exhibit nonbilious emesis that begins shortly after birth and is relatively constant over time. Unlike pyloric stenosis, vomiting is usually neither progressive nor projectile. Most children with GERD of milder severity continue to gain weight. Unlike midgut volvulus and other causes of small bowel obstruction, the emesis associated with GERD should never have a yellowish-green or darker pigmented appearance. In addition, the presence of hematemesis or hematochezia or significant abdominal tenderness or distension should prompt considerations other conditions than GERD.

Diagnostic Testing

In the ED, the diagnosis of GERD is typically made on the basis of the history and physical examination. Well-appearing infants with nonbilious vomiting, a normal physical exam, and an adequate weight gain trajectory may cautiously be diagnosed with GERD presumptively. However, ill-appearing infants in whom the diagnosis is uncertain may benefit from additional diagnostic studies; these tests, such as esophageal pH probes, barium swallow studies, and direct visualization by endoscopy, are not routinely available in the ED and should be conducted in consultation with a pediatric gastroenterologist.

Management

Most infants respond to conservative lifestyle modifications, such as smaller feedings, frequent burping, formula thickened with cereal, and a semiupright position after feeding. Parents should avoid using a car seat to maintain a semiupright position during and after feeding because these devices have actually been shown to exacerbate reflux rather than alleviate it.

Pharmacologic regimens are not recommended for infants with uncomplicated reflux (so-called "happy spitters"). Although lacking supportive evidence, acid suppression can be used, but should be reserved for those with more severe symptoms, such as esophagitis, weight loss, or significant irritability, in whom more conservative lifestyle modifications have failed.[7] Severe and refractory cases occasionally require pediatric surgical consultation for Nissen fundoplication.

Disposition

Most children may be discharged home safely with conservative measures. Children with more severe symptoms or poor weight gain should be referred to a pediatrician or pediatric gastroenterologist for testing and additional pharmacologic management. Those with severe dehydration, weight loss, or failure to thrive should be admitted.

Intussusception

Foundations

Intussusception refers to the invagination of part of the intestine into itself. It is the most common cause of intestinal obstruction in children younger than 2 years, occurring most frequently in infants 5 to 12 months of age. Most cases of intussusception in children are idiopathic and occur in otherwise healthy children.

The exact cause of intussusception is unclear, but the most prevalent theory relates to a lead point that causes telescoping of one segment of the intestine into another. Bowel wall edema develops, resulting in mechanical obstruction, vascular compromise, and, ultimately, bowel wall ischemia and necrosis.

Intussusception may occur at any point along the GI tract, but ileocolic intussusceptions are most common in children. In younger children, lead points are usually the result of enlarged Peyer patches secondary to a recent viral infection. In children older than 5 years, pathologic lead points, including HSP vasculitis, Meckel diverticulum, lymphoma, polyps, postsurgical scars, celiac disease, and cystic fibrosis, are more common. Ileoileal intussusception occurs more frequently in children with HSP.

Clinical Features

The classic triad of clinical findings in intussusception consists of abdominal pain, a palpable sausage-shaped abdominal mass, and bloody stools, described as "currant jelly" in appearance. All three features are present in a minority of patients, however. Abdominal pain is the most common symptom. Affected children experience cyclic episodes of severe abdominal pain as waves of peristalsis cause bowel dilation adjacent to and proximal to the involved bowel. These episodes typically last 10 to 15 minutes and occur in intervals of 15 to 30 minutes. During the painful episode, children may be irritable and inconsolable, often drawing the legs up to the abdomen and screaming in pain. Vomiting is usually present. Blood, gross or occult, may or may not be present in the stool.[8] Diarrhea containing mucus and blood constitutes the classic "currant jelly stool," a relatively infrequent and late finding. Occasionally, children present with atypical symptoms, including altered level of consciousness and profound lethargy, rather than the more typical abdominal pain syndrome.

Differential Diagnoses

Differential considerations for abdominal pain in children by age are listed in Table 166.1. A slow progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. A sudden onset of severe pain is usually associated with acute bowel obstruction, such as intussusception or volvulus, or acute vascular compromise, as seen with torsion of a testicle or ovary. Infants and children with intussusception classically have severe intermittent colicky pain.

Diagnostic Testing

Initial screening radiographs of the abdomen may be obtained, but findings are usually nonspecific. Images should be examined for signs of small bowel obstruction, including dilated small bowel loops followed by a paucity of gas in a decompressed colon. Perforation may demonstrate free air within the peritoneum. More specific, although less commonly seen, signs on radiograph include evidence of a soft tissue mass or mass effect in the right abdomen, a "target sign" (representing air in the intussusceptum as it telescopes into adjacent bowel), and a "meniscus sign" (representing air compressed like a meniscus from invaginating bowel, Fig. 166.8). Plain radiographs may be obtained to rule out perforation which would preclude nonoperative reduction but cannot be used to exclude intussusception. The common clinical scenario is that radiographs reveal indeterminate or nonspecific findings, which do not exclude the diagnosis.

Fig. 166.8 Plain radiograph obtained in a child with crampy abdominal pain and vomiting, later confirmed to have intussusception. Findings include a poorly defined soft tissue density in the right upper quadrant, obscuration of the liver edge, and focally dilated loops of small bowel, consistent with an acute obstructive process (intussusception). (Courtesy Dr. Mark A. Hostetler.)

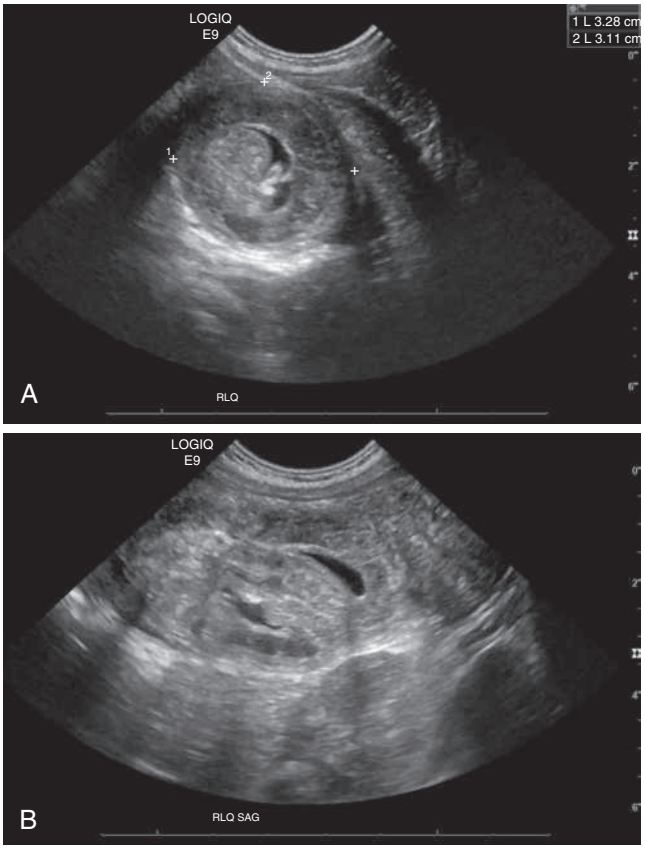

Fig. 166.9 Abdominal ultrasound examination in a child with colicky abdominal pain and vomiting, later confirmed to have intussusception. (A) On the transverse view, findings include a complex mass with a multilayered or rolled appearance (i.e., "target sign"). (B) In the long view, the ileum can be seen protruding up into the cecum, forming the intussuscipiens-intussusceptum complex. (Courtesy Dr. Patrick J. Maloney.)

When performed by skilled hands, ultrasound is highly sensitive and specific and the initial imaging modality of choice. The classic finding is a "target sign" (also referred to as a "bull's eye" or "doughnut sign"), which refers to visualization of the telescoping intestinal wall in the transverse or cross-sectional view. When visualized in the longitudinal plane, it is referred to as the "pseudo–kidney sign" (Fig. 166.9). Alternatively, contrast enemas have the advantage of being diagnostic and therapeutic. Occasionally, in children with the triad of paroxysms of pain, vomiting, and blood in the stool, contrast enemas may be safely done as first-line therapy (Fig. 166.10). Air-contrast enemas are equally efficacious and may be favored over contrast enemas due to speed of performing and efficacy.[9] Either type of enema requires readily available consultation by a pediatric surgeon in the event that reduction is unsuccessful or iatrogenic perforation occurs.

Management

IV fluids should be given in repeated boluses of 20 mL/kg of normal saline until adequate intravascular volume has been achieved. Children should be maintained on NPO status. Prompt surgical consultation is recommended. Diagnostic and therapeutic interventions depend on the location and resources available. Patients may undergo an initial ultrasound examination or, if history and plain film findings are highly suggestive of intussusception, may go directly to therapeutic enema.

The overall success rate for an air-contrast or barium enema approaches 90%. Surgical intervention is indicated in cases of prolonged intussusception with signs of perforation or shock or if enema reduction is unsuccessful. A severe, acutely life-threatening complication of air-contrast enema reduction is intestinal perforation with tension pneumoperitoneum.

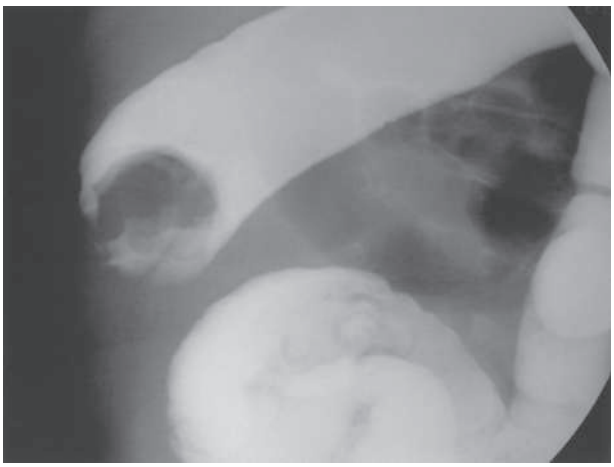

Fig. 166.10 Contrast enema image obtained in a child with intussusception shows a sharp cutoff where the contrast material meets the intussusceptum and acute obstruction. (Courtesy Dr. Mark A. Hostetler.)

Intussusception recurs within the first 48 hours after successful reduction in a very small minority of patients. Therefore, a short observation period (6 hours) is safe, and children who are able to tolerate oral fluids may be discharged home.[10]

Disposition

Children with suspected intussusception should receive definitive imaging with ultrasonography or enema. Confirmed intussusception requires reduction with enema or surgery.

Hirschsprung Disease

Foundations

Hirschsprung disease accounts for approximately 20% of cases of partial intestinal obstruction in early infancy. It occurs at a rate of 1 in 5000 live births and is four to five times more common in boys. Cases are usually sporadic in occurrence but may be associated with Down syndrome or other congenital anomalies.

Hirschsprung disease refers to congenital aganglionosis of the colon—that is, an absence of ganglion cells in the myenteric plexus of the distal colon. The anus is invariably involved, with aganglionic bowel usually extending proximally 4 to 25 cm. The absence of colonic ganglion cells interferes with that segment's ability to relax, creating a functional obstruction. Stool accumulates proximal to the level of obstruction and produces dilation of the colon, referred to as megacolon.

Clinical Features

Neonates with Hirschsprung disease often present in the newborn nursery with failure to pass meconium; however, a spectrum of disease is recognized, and presentation may be later in life. Affected infants brought to the ED usually have a history of chronic constipation. Digital rectal exam may cause an explosive passage of stool, sometimes referred to as the "squirt sign." Vomiting, irritability, poor weight gain, failure to thrive, and abdominal distention may be present. Children who appear ill with fever should be evaluated for other serious pathology, including enterocolitis, inflammatory bowel disease, and toxic megacolon.

Differential Diagnoses

Constipation is one of the most common causes of abdominal pain and vomiting in children. During the first few months of life, normal infants may have stool frequencies that range from one per feeding to one every few days, with breast-fed infants having more frequent stools than formula-fed infants. Truly pathologic causes of constipation are uncommon. In addition to Hirschsprung's disease, alternative etiologies for constipation include cystic fibrosis, infantile botulism, and hypothyroidism.

Diagnostic Testing

Plain films of the abdomen are usually nonspecific and may reveal evidence of fecal impaction with proximal obstruction, air-fluid levels, and a dilated colon. Barium enema studies revealing a narrowed aganglionic segment of distal colon with proximal dilation is highly suggestive of Hirschsprung disease. The diagnosis is confirmed by biopsy or manometry.

Management

Initial management should focus on ensuring adequate fluid and electrolyte status. Abdominal films should be obtained. With evidence of acute obstruction, such as marked bowel dilation, decompression with a rectal tube may acutely relieve symptoms. Definitive therapy of Hirschsprung disease is surgical, with resection of the aganglionic segments.

Disposition

Unless a child appears ill, most constipated children may be managed safely on an outpatient basis often with pediatric gastroenterology consultation.

Meckel Diverticulum

Foundations

Meckel diverticula are remnants of the omphalomesenteric duct and contain bowel wall, with 60% containing heterotopic tissue, usually gastric mucosa. Bleeding occurs when acid secretion from the ectopic gastric mucosa causes ulceration and erosion of the surrounding small bowel mucosa. Meckel diverticulum is the most common congenital malformation of the small intestine.

Meckel diverticula traditionally follow the "Rule of 2's": the diverticulum is approximately 2 cm wide, 2 cm long, and located within 2 feet of the ileocecal valve; moreover, the condition occurs in 2% of the population, and only 2% of affected patients ever become symptomatic; of symptomatic patients, 50% manifest symptoms by the age of 2 years, and most present by the age of 20 years.

Clinical Features

The classic presentation of a Meckel diverticulum is massive, painless rectal bleeding. Some children may have complaints of abdominal cramping. The abdominal examination is usually benign. The blood is often described as brick red but may range from melena to bright red. Complications may include intussusception, obstruction, perforation, and peritonitis.

Differential Diagnoses

Massive GI bleeding is uncommon in childhood. Children commonly eat or drink substances containing red dyes that lead to changes in the stool's color that may be mistaken for hematochezia. In addition, bismuth subsalicylate (e.g., Pepto-Bismol), iron, and spinach may cause black stools falsely appearing melanotic. A Hemoccult test of stool or Gastroccult test of emesis can confirm the presence or absence of blood, although false positives and negatives do occur.

Similar to adults, the location of bleeding may be theorized on the basis of the appearance of the blood. Hematemesis suggests bleeding proximal to the ligament of Treitz. Melena results from bleeding beyond the ligament of Treitz but proximal to the ileocecal valve. Hematochezia implies bleeding from the colon. Occasionally, in young children, GI transit time may be rapid enough for an upper GI source to cause hematochezia.

In neonates, the cause of GI bleeding is usually never identified. In young breast-fed neonates, an Apt test may be performed to differentiate fetal from swallowed maternal blood. Nursing mothers should be asked about cracked bleeding nipples. Milk protein allergy is another common cause of GI bleeding in infancy. Affected children are typically younger than 6 months, with a history of sudden-onset, mucoid, blood-streaked stools. Table 166.4 lists the differential considerations for GI bleeding in children by age.

Diagnostic Testing

A technetium-99m (^{99m}Tc) scan, also called a Meckel scan, is the diagnostic modality of choice and has an accuracy of 90% when ectopic gastric mucosa is present, since technetium has an affinity for gastric mucosa. A computed tomography (CT) scan of the abdomen may be performed to look for signs of inflammation or obstruction. Definitive diagnosis is confirmed by laparoscopy or laparotomy.

Management

Management of GI bleeding begins by assessing the child's circulatory status administering volume resuscitation as indicated. In cases of minimal or mild bleeding in otherwise healthy and well-appearing children, laboratory studies are unlikely to be useful. The child may be referred to urgently see a pediatric gastroenterologist as an outpatient. When there is concern for more serious disease, screening laboratory

studies should include a CBC, coagulation studies (e.g., prothrombin time, partial thromboplastin time), and type and screen. A pediatric surgeon should be consulted.

Disposition

Children with massive GI bleeding suspicious for Meckel diverticulum should undergo a Meckel scan, usually after admission to a pediatric intensive care setting. Children with minor bleeding may be discharged home after consultation with a surgeon and with close follow-up. Children with ongoing active bleeding should be hospitalized.

Henoch-Schönlein Purpura

Foundations

HSP, also known as anaphylactoid purpura, is a hypersensitivity vasculitis with immune complex deposition with immunoglobulin A. Although most well-known for its characteristic petechial to purpuric rash, HSP is a systemic vasculitis affecting any vessels.

HSP is commonly associated with abdominal pain, palpable purpuric rash, arthralgias, and renal disease. Its incidence is highest among children 4 to 11 years of age. It more commonly occurs during the spring season following viral upper respiratory infections.

Clinical Features

Patients are usually diagnosed clinically on the basis of the classic palpable purpuric rash located on the buttocks and lower extremities (Fig. 166.11). Up to 70% of patients have GI complaints, including abdominal pain, nausea and vomiting, diarrhea, intestinal bleeding, and ileoileal intussusception. Laboratory findings are significant for a lack of thrombocytopenia. Microscopic hematuria occurs in half of patients. The syndrome is often relapsing and remitting for several weeks and may be associated with arthralgias. Neurologic involvement is uncommon.

Fig. 166.11 Henoch-Schönlein purpura in a 7-year-old child. Note the typical red-purple rash on the lower extremities. (Courtesy Dr. Marianne Gausche-Hill.)

Differential Diagnoses

Patients with HSP do not have thrombocytopenia. This differentiates HSP from most other clinical diseases associated with petechiae or purpura, including meningococcemia. In addition to a thrombocytopenia,

patients with meningococcemia are typically febrile and ill-appearing. The classic triad of palpable purpura, abdominal pain, and hematuria in an otherwise well-appearing and afebrile child with a normal platelet count is most likely to be HSP.

Diagnostic Testing

Patients are usually diagnosed clinically on the basis of the classic rash. All children diagnosed with HSP should have a urinalysis for evaluation of renal involvement, which manifests as white cells, red cells, casts, and protein in the urine. Those with apparent renal involvement should have serum electrolyte and creatinine levels measured. Patients with an uncertain diagnosis should have a CBC with differential, coagulation studies, blood culture, and sedimentation rate. Children diagnosed with HSP who have worrisome abdominal pain should be evaluated for intussusception.

Management

Most children with HSP require only supportive management. Mild and moderate pain is usually well controlled with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen. Glucocorticoids reduce the pain associated with HSP but have not been shown to affect the other disease complications, including nephropathy. Prednisone, at a dose of 1 mg/kg/day (maximum, 60 mg), is reserved for patients with severe symptoms, including severe abdominal pain, GI bleeding, hematuria, or severe arthralgias.

Disposition

Most patients can be managed symptomatically with close outpatient observation and follow-up. Indications for hospital admission include uncertain diagnosis to exclude the possibility of meningococcemia, severe abdominal pain, and intractable vomiting. Those with compromised renal function should have a nephrology consultation and be considered for admission, particularly if presenting with hypertension.

Inflammatory Bowel Disease

Foundations

Inflammatory bowel disease (IBD) comprises two disorders: ulcerative colitis and Crohn disease. Ulcerative colitis is an inflammatory disease primarily involving the mucosa and submucosa of the rectum and distal colon. Crohn disease is a transmural inflammatory disease that may involve any portion of the intestinal tract. Chronic inflammation may result in the formation of an abscess, fistula, or stricture. Crohn disease is commonly associated with extraintestinal manifestations, especially in children.

Most patients with IBD do not experience symptoms until adolescence or adulthood. However, a small subset do develop symptoms before the age of 20 years. IBD is rare in children younger than 1 year of age.

Clinical Features

Although patients experiencing complications of IBD frequently present to the ED, the diagnosis is rarely made in this setting. Usually, children with known disease present in the midst of an acute flare, commonly associated with increased frequency of diarrheal stools, bloody diarrhea, abdominal pain, and occasionally fevers. Patients with toxic megacolon or intestinal perforations demonstrate significant abdominal tenderness with peritonitis and are usually febrile, volume-depleted, and ill-appearing.

Diagnostic Testing

Acute IBD flares are usually diagnosed clinically based on the history of present illness and physical exam. There are no laboratory or radiologic tests that are specific for acute IBD flares, and basic laboratory studies, including CBC with differential and electrolyte panel, usually reflect dehydration, inflammation, and possible anemia. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels may be beneficial in the diagnosis and management because most patients have elevated levels at the time of diagnosis as well as with acute flares. Plain radiographs are helpful when evaluating for intestinal perforation and toxic megacolon.

Differential Diagnoses

There are a large number of differential considerations for abdominal pain, vomiting, and GI bleeding (see Tables 166.1, 166.3, and 166.4). Gastroenteritis is the most common consideration in this clinical scenario. Children experiencing their first episode of IBD and children outside the usual age at presentation are much more likely to be misdiagnosed with acute gastroenteritis.

Management

Management in the ED begins with attention to volume status and resuscitation with repeated boluses of 20 mL/kg of normal saline or lactated Ringers solution until the volume status is adequate. Acute exacerbations should be treated in conjunction with a gastroenterologist. Corticosteroids (e.g., prednisone, 1 mg/kg/day; maximum dose, 60 mg/day) are usually recommended for mild to moderate exacerbations. Other agents commonly used include sulfasalazine and azathioprine, among other immunosuppressive agents. Patients with suspected toxic megacolon require IV broad-spectrum antibiotic therapy (see Box 166.2) and surgical consultation.

Disposition

Children not diagnosed with IBD but who have recurrent GI symptoms or a family history of IBD should be referred to a pediatric gastroenterologist for further evaluation. With acute flares, indications for admission include dehydration, toxic or ill appearance, and inability to tolerate oral fluids. Children with evidence of toxic megacolon should have a surgical consultation.

Gastrointestinal Foreign Bodies

Foundations

GI foreign bodies usually are seen in children younger than 5 years of age and in those with developmental delays. Coins, small toys, magnets, batteries, and jewelry are the most common esophageal foreign bodies in children, compared to food boluses in adults. Most ingestions in children are accidental.

The vast majority of swallowed foreign bodies pass through the entire GI tract without complications. However, foreign bodies commonly become lodged in one of three areas of normal physiologic narrowing within the esophagus: (1) the upper esophageal sphincter (cricopharyngeus muscle)/thoracic inlet (C6-T1); (2) the aortic arch/tracheal bifurcation (T4-6); and (3) the lower esophageal sphincter/diaphragmatic hiatus (T10-11). Of objects that successfully pass into the stomach, 80% to 90% also pass through the entire GI tract without complications.

Clinical Features

Many accidental ingestions are unwitnessed. Children may gag as they attempt to swallow the object. Objects aspirated into the respiratory tract generally produce persistent coughing, wheezing, increased work of breathing, and respiratory distress. Children who swallow objects which then become lodged within the esophagus may remain asymptomatic or develop a wide spectrum of symptoms, including food refusal, persistent gagging, drooling, or continuous dry heaves. Some esophageal foreign bodies may cause local airway compression, resulting in stridor, wheezing, and respiratory distress. Complications such as esophageal or

intestinal perforation are more likely to occur when foreign bodies have been impacted for an extended period of time; symptoms include progressive dysphagia, pain, respiratory distress, and fever.

Swallowed lithium button batteries warrant special mention. Button batteries lodged in the esophagus cause severe mucosal erosions, burns, and mediastinitis in as little as 2 hours, most likely as a result of the electrical current discharged from these batteries. Gastrointestinal or pediatric surgical consultation for emergent foreign body removal is warranted. Button batteries in the stomach usually pass without complications and do not require removal unless they fail to pass the pylorus within 48 hours of ingestion. The National Capital Poison Center operates a 24/7 website (www.poison.org/battery) and hotline (800-498-8666) for battery ingestion cases.

On occasion, objects successfully pass into the stomach, but are too large to pass through the pylorus. As a general rule, objects longer than 5 cm and wider than 2 cm are less likely to pass the pylorus spontaneously. Persistent vomiting may herald obstruction. If not removed, foreign bodies may, over time, result in erosion, perforation, infection, stricture, or fistula formation.

Diagnostic Testing

Plain radiography is the most common method of diagnosing and locating foreign bodies. Classically, coins and button batteries in the esophagus project en face (round) in the frontal (coronal/AP or PA) view (Fig. 166.12). When coins or button batteries are lodged in the upper airway, they will project on end in the frontal view. Occasionally, it may be difficult to differentiate the appearance of a coin from a button battery radiographically. A button battery will typically have a distinctive double-rim contour on radiographs (Fig. 166.13).

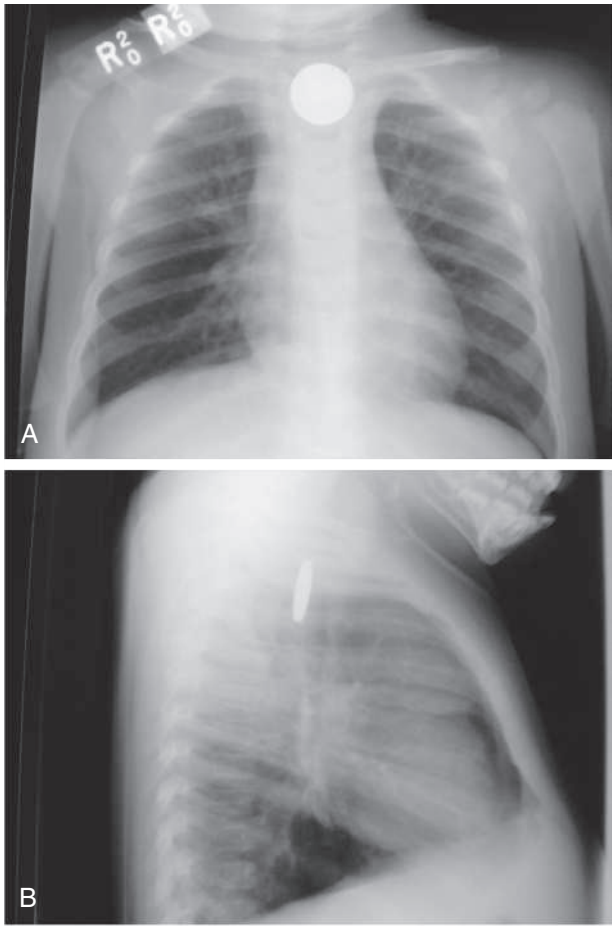

Fig. 166.12 Plain radiographs obtained in a child with an esophageal coin foreign body. Posteroanterior (A) and lateral (B) views show the expected orientation for a coin lodged in the esophagus. (Courtesy Dr. Mark A. Hostetler.)

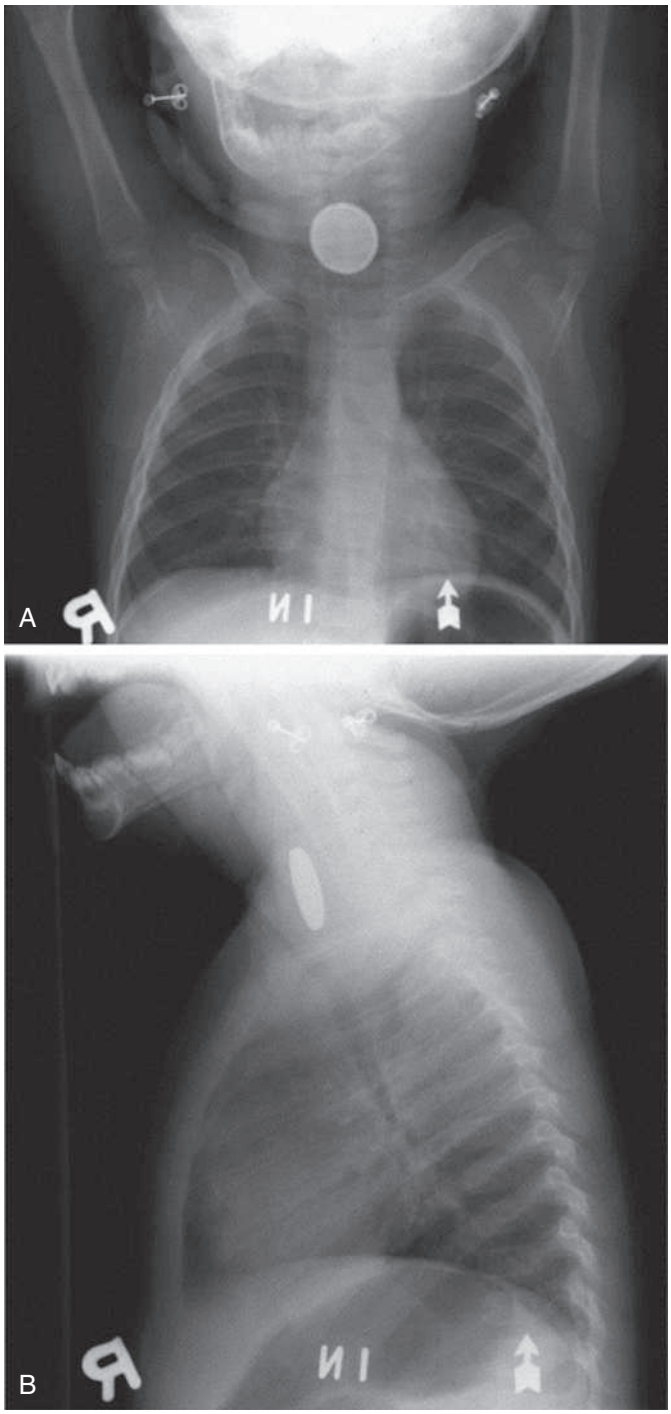

Fig. 166.13 Esophageal button battery. It may be difficult to differentiate the appearance of a coin from a button battery radiographically. However, a button battery will typically have a distinctive double-rim contour on radiographs, as seen in this posteroanterior radiograph. (From: Lin VYW, Daniel SJ, Papsin BC. Button batteries in the ear, nose and upper aerodigestive tract. *Int J Pediatr Otorhinolaryngol*. 2004;68:473-479.)

Differential Diagnoses

Not all foreign bodies are radiopaque and visible with standard radiography. Patients who remain symptomatic require further contrast-enhanced imaging or direct visualization.

Management

Most GI foreign bodies will spontaneously pass without complications. In general, small objects that successfully pass into the stomach do not require further treatment or routine serial imaging. Button batteries and multiple magnetic objects represent two exceptions. Patients with button batteries located in the stomach should have serial films to ensure successful passage beyond the pylorus. Ingestion of multiple magnets or a single magnet plus a second metallic object may result in the objects attaching to each other across bowel wall, resulting in bowel necrosis and perforation. Therefore, multiple magnets or a single magnet plus another metallic object located within the stomach are typically removed urgently by endoscopy because they are more likely to require more complicated surgical removal if allowed to pass beyond the pylorus. However, if they have already passed into the small bowel in a well-appearing, asymptomatic patient without any signs of bowel obstruction or peritonitis observation and serial radiographs are recommended. Surgical consultation for removal should be obtained if there are signs of bowel necrosis, obstruction, perforation, or peritonitis.

Asking parents to check the child's stool for a passed foreign body is rarely productive. The timing of intervention for foreign body removal is based largely on the type of object, location, duration, and symptoms. With the exception of button batteries, which should be removed emergently within 2 hours, esophageal foreign bodies may be removed urgently within 24 hours. Blunt objects, such as coins, in the esophagus of asymptomatic children may be observed for 12 to 24 hours because many of them will pass spontaneously into the stomach. Indications for more emergent removal are listed in Box 166.3.

The preferred method to remove esophageal foreign bodies varies by institution; flexible endoscopy is most common and has a high success rate. Other options include fluoroscopic Foley catheter removal, bougie advancement into the stomach, and removal by rigid bronchoscopy under general anesthesia in the operating room.

Disposition

Esophageal foreign bodies require removal, as described previously. Once foreign bodies have passed into the stomach, most pass without complications, and no specific follow-up is usually necessary. Abdominal pain, food aversion, and intractable vomiting may suggest a retained gastric foreign body warranting repeat radiography. Button batteries in the stomach and multiple magnets constitute exceptions. Button batteries in the stomach necessitate follow-up films in 24 hours to document passage beyond the pylorus, even in asymptomatic children. When multiple magnets are suspected of being within the stomach, urgent endoscopy and removal is warranted. When they have passed the pylorus but there is no evidence that they have attached to each other across bowel wall causing tissue necrosis and/or perforation, close observation and serial radiographs is recommended. If there are clinical concerns for bowel necrosis, obstruction, or perforation, surgical consultation is emergently necessary.

BOX 166.3 Indications for Emergency Removal of Gastrointestinal Foreign Bodies

- Signs of respiratory distress
- Evidence of esophageal obstruction (inability to swallow secretions)
- Lithium button batteries in the esophagus
- Sharp or long (>5 cm) objects in the esophagus or stomach
- Multiple magnets or single magnet plus another metallic object within esophagus or stomach
- Signs or symptoms of intestinal inflammation, obstruction or perforation
- Esophageal foreign bodies impacted for >24 hr or for an unknown amount of time

Appendicitis

Foundations

Appendicitis is the most common surgical condition involving the abdomen and the most common nontraumatic surgical emergency in children. It develops in approximately 1 of every 15 people during their lifetime. The peak age of incidence is between 9 and 12 years, and it is uncommon in children younger than 5 years of age.

The appendix is a blind pouch that may become obstructed, resulting in edema, vasocongestion, inflammation, ischemia, infarction, necrosis, and perforation. In adults, a thicker appendiceal wall resists perforation, and a well-developed omentum aids in walling off the infection to prevent its diffuse spread. Children have neither, so rupture tends to occur earlier, and diffuse peritonitis develops more readily.

Morbidity and mortality related to acute appendicitis increase significantly if the appendix ruptures prior to operative management. Therefore, the goal of management is diagnosis and operative management prior to appendiceal perforation. Perforation seems to be directly related to the duration of symptoms. In children, the rate of appendiceal perforation varies inversely with age. Perforation is highest among children younger than 5 years, among whom more than 50% are ruptured at the time of surgery. This likely reflects, at least in part, the fact that preschool children have a limited ability to describe their symptoms and often present for evaluation later in the disease course.

Clinical Features

Patients classically present with a constellation of symptoms that includes abdominal pain, nausea, vomiting, and anorexia. Symptoms are gradually progressive over the first 24 hours. Abdominal pain is usually first described as vague, crampy, and periumbilical. Pain becomes more severe, constant, and localized to the right lower quadrant as the disease progresses. Fever usually develops later or not at all. A subset of patients may have a multiphasic course to their illness, with symptom resolution followed several days later by the development of fever, chills, and abdominal pain. This likely represents spontaneous appendiceal rupture and formation of an abscess.

The physical examination may reveal several typical findings. In patients with inflammation surrounding the appendix, peritoneal findings that localize to the right lower quadrant are classic. Pain occurs with movement; patients may be unwilling to jump up and down, and tapping their heels may cause abdominal pain. Bowel sounds are usually decreased or absent. Rebound tenderness may be elicited in the right lower quadrant. The Rovsing, psoas, and obturator signs are difficult to assess in young children and should not be relied on due to their poor sensitivities and specificities. The absence of the classic signs and symptoms of appendicitis unfortunately does not exclude the diagnosis, especially in younger children.

Diagnostic Testing

Appendicitis may be diagnosed clinically on the basis of the history and physical findings alone in children with a classic constellation of findings. Patients with an equivocal presentation should undergo a diagnostic evaluation. There are no sufficiently sensitive or specific laboratory tests that alone can confirm or exclude the diagnosis of acute appendicitis. Screening studies may include a CBC with differential,

CRP, urinalysis, electrolyte levels, and renal and liver function testing. Pregnancy testing, vaginal wet mount, and gonorrheal and chlamydial testing should be considered in postpubertal females. Most children with acute appendicitis have an elevated white blood cell count (>10,000 × 10^6/L), absolute neutrophil count, or an elevated CRP level (>0.6 mg/dL). Because none of these tests are sufficiently sensitive or specific, they should not be exclusively used to diagnose or exclude appendicitis. Acute appendicitis occasionally causes a mild sterile pyuria (<5 to 10 white blood cells/high-power field in the absence of bacteria) related to local inflammation of the right ureter.

Several clinical scoring systems have been developed to assist in the evaluation of appendicitis. The most widely studied prospectively include the Alvarado score, Pediatric Appendicitis Score, and Refined Low-Risk Appendicitis Rule. Each system relies on a combination of clinical factors and laboratory values to risk-stratify children into low-, moderate-, and high-risk categories for appendicitis. Unfortunately, none of these have been shown to be sensitive and specific enough to be recommended alone for widespread clinical use.

Diagnostic imaging options include plain films of the abdomen, ultrasonography, and CT. Plain films have limited value in appendicitis and are not recommended in the routine evaluation. Occasionally, an appendiceal fecalith will be evident (Fig. 166.14). Although the presence of an appendicolith in a child with acute abdominal pain is essentially pathognomonic for acute appendicitis, it is present in less than 10% of cases.

Ultrasonography is routinely recommended as the first-line imaging modality in suspected appendicitis. It has the advantages of lacking ionizing radiation and the ability to evaluate ovarian anatomy. Ultrasonographic findings consistent with appendicitis include an enlarged, noncompressible appendix (wall thickness > 2 mm; total appendix diameter > 6 mm) that is painful during scanning (Fig. 166.15A, B). Appendiceal ultrasound has a sensitivity and specificity of more than 90% when the appendix is successfully visualized. Unfortunately, the ability to visualize the appendix adequately with ultrasound is limited in obese children and highly user-dependent.

In the child in whom the appendix is not visualized or findings are equivocal with ultrasonography, clinical observation with serial examinations or CT imaging may be undertaken. CT in general has high sensitivity and specificity for unruptured and ruptured appendicitis, and the use of IV contrast improves sensitivity slightly. Limited appendiceal CT protocols decrease the ionizing radiation exposure without sacrificing sensitivity or specificity. The increased use of CT has been shown to reduce the negative laparotomy rate without increasing the risk of perforation.

Fig. 166.14 Fecalith in a child with appendicitis. (Courtesy Dr. Marianne Gausche-Hill.)

Differential Diagnoses

Differential considerations for abdominal pain by age are listed in Table 166.4. Mesenteric adenitis is the most common imitation of appendicitis. Similar to appendicitis, it often is associated with significant diffuse tenderness that may localize in the right lower quadrant. Children with mesenteric adenitis lack true peritoneal signs, however.

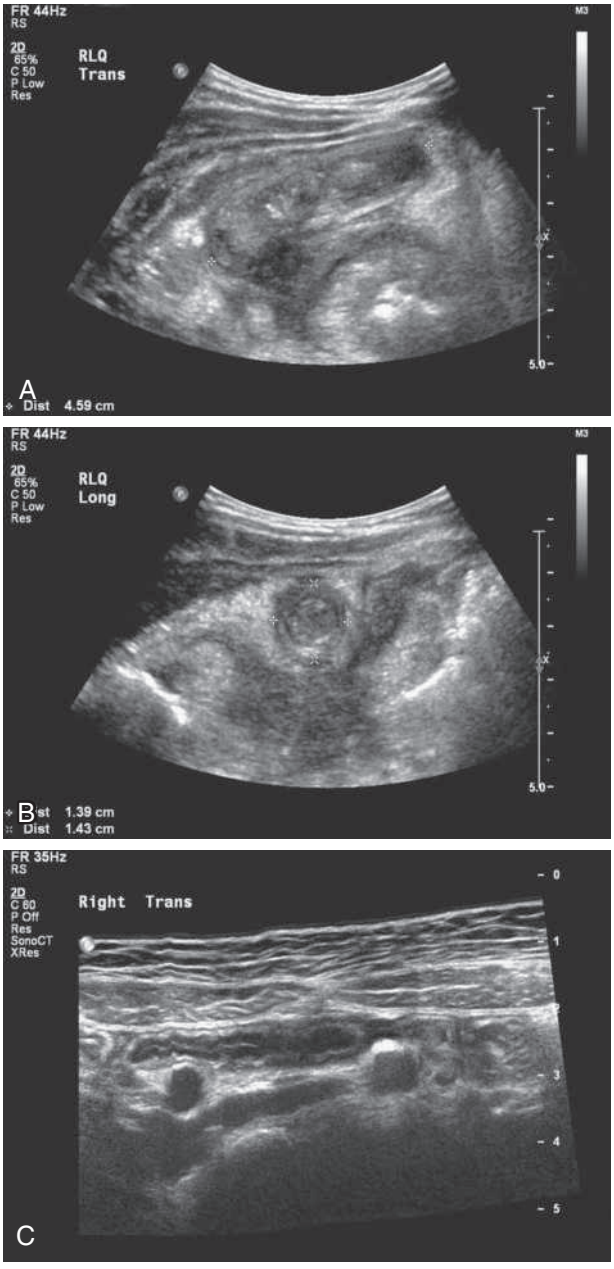

Fig. 166.15 Ultrasound images obtained in children with appendicitis. Findings include an enlarged, noncompressible, tubelike structure in the longitudinal view with an appendicolith (A), an enlarged noncompressible structure seen in cross section (B) and, in another patient, an enlarged, poorly compressible structure with a moderate amount of free fluid consistent with acute perforation (C). (Courtesy Dr. Mark A. Hostetler.)

Mesenteric adenitis usually follows a viral illness and results from nonspecific inflammation of the mesenteric lymph nodes.

Girls of reproductive age merit consideration of gynecologic pathology, including ectopic pregnancy, ovarian torsion, ovarian cyst, pelvic inflammatory disease, and tubo-ovarian abscess. Testicular torsion may manifest with nausea, vomiting, and abdominal pain, but the testicular examination is usually grossly abnormal in these boys. Boys with abdominal pain on the side of an undescended testis should be evaluated for torsion of an intra-abdominal testicle. Group A streptococcal pharyngitis may also present with abdominal pain and mimic appendicitis.

Management

Definitive management of acute appendicitis is open or laparoscopic appendectomy. The exact timing of surgery is controversial but should optimally be performed within 12 to 24 hours of diagnosis. Most patients benefit from IV fluids and parenteral administration of opioid pain medications and antiemetics. Opioids are safe and effective and do not alter the diagnostic accuracy of the physical examination. Patients with a nonperforated appendicitis should receive a single dose of parenteral antibiotics (Box 166.4) 30 to 60 minutes prior to surgery to decrease the risk of wound infection and intra-abdominal abscess formation. Patients with suspected perforation, signs or symptoms of sepsis, or unusual delay in surgical management should receive empirical broad-spectrum IV antibiotics (see Box 166.2) in the ED and continued postoperatively.

While appendectomy remains the standard of care in most cases of acute appendicitis, nonoperative management with parenteral antibiotics and observation alone is an emerging option in a subset of older children with uncomplicated disease. Nonoperative management typically results in fewer days of disability and overall decrease health care costs.[11]

Disposition

Children with appendicitis should be hospitalized for appendectomy. Patients with nonspecific signs and symptoms in whom imaging studies are nondiagnostic should be observed for a period of 12 to 24 hours with serial examinations or, with adequate family and social support, discharged home with careful instructions to return for reexamination.

Pancreatitis

Foundations

Pancreatitis is uncommon in childhood, especially in children younger than 10 years. In adults, pancreatitis is most commonly associated with alcohol abuse and biliary tract disease. In children, pancreatitis is usually caused by trauma, infection, structural anomalies, systemic disease, and drugs or toxins. Idiopathic causes account for 30% of cases. Biliary disease should be considered in adolescents and teenagers.

The common pathophysiologic pathway of acute pancreatitis is inflammation, edema, and autodigestion of pancreatic tissue by pancreatic enzymes. In severe cases, the inflammatory cascade may progress to necrotizing or hemorrhagic pancreatitis. Other complications include the formation of abscesses, pseudocysts, and fistulas.

Clinical Features

Abdominal pain is the hallmark of pancreatitis in adults and children. Patients typically present with complaints of severe, constant epigastric pain that worsens gradually and radiates to the back. Nausea, vomiting, diarrhea, fevers, irritability, and lethargy are also described. Patients have significant abdominal tenderness in the epigastric area.

Diagnostic Testing

Screening laboratory studies reveal an elevation in the serum lipase level. The degree of elevation and serial changes are not always directly related to disease severity. Evidence of liver inflammation (i.e., elevated aspartate transaminase and alanine transaminase levels) and elevated bilirubin and alkaline phosphatase levels may be seen in patients with associated hepatobiliary disease. Plain films of the abdomen commonly show an ileus pattern, often with a sentinel loop of dilated small bowel in the left upper quadrant. An ultrasound study or CT may be helpful to evaluate anatomy for congenital malformations, biliary tract disease, pseudocyst, or abscess formation. In patients with respiratory distress, a chest radiograph may identify a secondary pleural effusion.

Differential Diagnoses

Slow progressive onset of pain is more likely to be associated with appendicitis, constipation, and pancreatitis. Sudden onset of severe pain is usually associated with acute intestinal obstruction, such as intussusception or midgut volvulus, or vascular occlusion, as seen with testicular or ovarian torsion. Differential considerations for abdominal pain in children by age are listed in Table 166.4.

Management

Patients should receive volume replacement and electrolyte correction and be maintained on an NPO status. IV fluids are given in repeated boluses of 20 mL/kg of normal saline until adequate vascular volume has been established. Patients should receive adequate symptomatic relief with parenteral narcotics and antiemetics. Steroids and antibiotics are not indicated.

Disposition

Children with acute pancreatitis should undergo hospitalization. Children with known or recurrent disease, who are able to self-hydrate and have adequate analgesia, may be managed as outpatients in select cases.

Biliary Tract Disease

Foundations

Biliary tract disease is uncommon in childhood and has causes that differ from those in older individuals. Cholestasis in the neonatal period is usually associated with biliary atresia, biliary cysts, infections, and other metabolic and genetic disorders. Gallstones in children are usually associated with hemolytic disease (e.g., sickle cell disease), cystic fibrosis, total parenteral nutrition, sepsis, and dehydration. Acute acalculous cholecystitis has been associated with Rocky Mountain spotted fever and a variety of bacterial infections, including those due to *Salmonella* and *Shigella* organisms. Hydrops of the gallbladder

BOX 166.4 Empirical Antibiotic Regimens for Acute Appendicitis

Regimen

- Cefoxitin
- Ceftriaxone + metronidazole
- Cefotetan
- Gentamicin + clindamycin or metronidazole (penicillin-allergic patients)
- Piperacillin-tazobactam

Dosing

- Cefoxitin: 40 mg/kg IV; maximum dose, 2000 mg
- Ceftriaxone: 50 mg/kg IV; maximum dose, 2000 mg
- Metronidazole: 10 mg/kg IV; maximum dose, 500 mg
- Cefotetan: 40 mg/kg IV; maximum dose, 2000 mg
- Gentamicin: 2–7.5 mg/kg/day
- Clindamycin: 10 mg/kg IV; maximum dose, 900 mg
- Piperacillin-tazobactam: 80–100 mg/kg of the piperacillin component, max 4.5 g

(i.e., fluid distention of the gallbladder from chronic cystic duct inflammation or obstruction without inflammation or infection) is associated with viral upper respiratory or GI infections, Kawasaki disease, streptococcal pharyngitis, mesenteric adenitis, nephrotic syndrome, and leptospirosis.

Pigment gallstones stones are more common in childhood; cholesterol stones are uncommon prior to adolescence. Pigment stones result from the excess breakdown of red blood cells and are usually seen in those with hemolytic anemia, such as sickle cell disease and spherocytosis. Adolescents may form cholesterol gallstones in association with oral contraceptives, pregnancy, or obesity.

Clinical Features

Similar to adult patients, pediatric patients usually present with postprandial right upper quadrant pain associated with fever, nausea, and vomiting. Jaundice occurs in one-third of patients.

Diagnostic Testing

Biliary tract disease is usually associated with elevations in alkaline phosphatase, liver transaminases, and bilirubin levels; however, absence of elevations does not exclude the diagnosis. An elevated white blood cell count is nonspecific. Although only 15% of gallstones in adults are calcified and visible on plain radiographs, 50% of stones in children are radiopaque. Ultrasonography is the imaging modality of choice. It not only can determine the presence of gallstones, dilation of the gallbladder and common bile duct, gallbladder wall thickness, and pericholecystic fluid, but can also reproduce pain on compression of the gallbladder (sonographic Murphy sign). When ultrasound findings are equivocal or normal and clinical suspicion is high, cholescintigraphy biliary tract imaging (HIDA [hepatobiliary iminodiacetic acid] scan) can further assess the functional status of the gallbladder. Magnetic resonance cholangiopancreatography (MRCP) can assess the intrahepatic and extrahepatic ducts.

Differential Diagnoses

Pediatric biliary tract disease is uncommon in children and requires consideration of an underlying or coexistent disease. Differential considerations are listed in Table 166.4.

Management

Asymptomatic patients with incidental findings of gallstones require no further therapy in the ED and may be referred to a surgeon for outpatient care. Febrile patients and those with intractable pain or nausea and vomiting require hospital admission, fluid resuscitation, IV antibiotics, and surgical consultation. Laparoscopic cholecystectomy is considered safe and effective in children.

Disposition

Indications for hospital admission for biliary disease include pain control, need for IV hydration, fever, and need for operative management.

CHAPTER 166: QUESTIONS AND ANSWERS

1. What is the most common cause of jaundice in the newborn?
- **a.** Breast milk jaundice
- **b.** Crigler-Najjar syndrome
- **c.** Gilbert syndrome
- **d.** Physiologic jaundice of the newborn

Answer: D. Although each of these may be a cause of hyperbilirubinemia in the newborn, the most common cause of jaundice is physiologic jaundice of the newborn.

2. A 4-week-old white infant presents with projectile vomiting. The mother denies that the patient has a history of fevers, irritability, or signs suggestive of abdominal pain. On physical examination, you palpate an olive in the patient's right epigastrium. Which of the following laboratory abnormalities would you expect to find?
- **a.** Hyperchloremia and hypokalemia
- **b.** Hyperglycemia and hypokalemia
- **c.** Hypernatremia and hyperkalemia
- **d.** Hypochloremia and hypokalemia

Answer: D. This patient likely has pyloric stenosis. As vomiting continues, the infant loses hydrogen and chloride ions through emesis of gastric juices. As this metabolic derangement worsens, the kidney attempts to retain hydrogen ions by substituting potassium, resulting in a hypochloremic-hypokalemic metabolic alkalosis.

3. An 11-month-old infant presents with vomiting. The patient's mother reports that he has been crying out in pain intermittently throughout the day, at which times he brings his knees to his abdomen. In between these episodes, the patient acts normally and plays. He has not had a fever, but the mother complains that his stool earlier looked like currant jelly. On examination, you find a playful afebrile patient, with a soft nontender abdomen. Which of the following may be used as an initial screening examination?
- **a.** Air-contrast enema
- **b.** Barium enema
- **c.** Computed tomography scan of the abdomen-pelvis
- **d.** Ultrasound

Answer: D. The initial screening examination for intussusception is abdominal ultrasonography. Although each of the other imaging modalities may be useful to exclude other diagnoses or identify intussusception, ultrasonography has high sensitivity and specificity and is the screening modality of choice.

Pediatric Infectious Diarrheal Disease and Dehydration

Patricia Padlipsky and William White

KEY CONCEPTS

Identification of Pathogen

- Stool studies are not indicated in most uncomplicated cases of acute gastroenteritis (AGE). Exceptions are those cases in which specific treatment, specific prophylaxis, or health precautions are required, or in which the patient has systemic involvement, underlying medical complications, or dysenteric features.
- Antibiotics are not required for most cases of uncomplicated acute bacterial enteritis. Antibiotics are recommended routinely for *C. difficile, Giardia intestinalis,* and *E. histolytica.* Antibiotics can be considered for *Campylobacter*, *Cryptosporidium,* traveler's diarrhea, and *Shigella* (because antibiotics have been shown to decrease diarrhea and eradicate organisms in the stool).
- Patients with Shiga toxin–producing *E. coli* (STEC) should not empirically receive antibiotics, because they may increase the risk of hemolytic-uremic syndrome (HUS).
- Testing for fecal leukocytes is a useful initial test because it may support a diagnosis of invasive disease. This test should be considered in children with diarrhea who are febrile or have mucus or blood in the stool. If the test result is positive, stool culture is indicated to further guide management.

Oral Rehydration

- Most patients with mild to moderate dehydration can be treated with oral rehydration therapy (ORT). Resumption of feeding with age-appropriate diets should begin as soon as vomiting subsides. Routine fasting with infectious diarrhea is not recommended.

Dehydration Assessment

- The degree of volume depletion is estimated from the history and physical examination findings. The desired volume of oral rehydration solution is calculated as 30 to 50 mL/kg for mild dehydration and 60 to 80 mL/kg for moderate dehydration; 25% of the volume of oral rehydration solution is to be replaced every hour (100% over 4 hours). Continue to replace ongoing losses with 10 mL/kg for each diarrheal stool and 2 mL/kg for each vomiting episode. Patients who fail an oral rehydration trial of 4 to 8 hours in the emergency department (ED) should be admitted for intravenous hydration.

Severe Dehydration

- In severe dehydration, 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) given intravenously or intraosseously should reverse signs of shock within 5 to 15 minutes. Repeated boluses of 20 mL/kg are indicated until clinical improvement occurs, but volume requirements greater than 60 mL/kg without signs of improvement suggest other conditions, such as septic shock, hemorrhage, capillary leak with third-space fluid sequestration, and adrenal insufficiency. Rapid correction of sodium derangements in dehydration can lead to central nervous system complications.

DIARRHEA

Foundations

Background and Importance

Acute infectious diarrhea is a common illness seen around the world. Acute diarrhea is generally self-limiting in industrialized nations but can have significant morbidity and mortality for the elderly, very young, and immunocompromised patients. In underdeveloped countries, diarrheal diseases are a significant cause of death. According to the Global Burden of Disease Study 2016, diarrhea was found to be the eighth leading cause of death among all ages, responsible for more than 1.6 million deaths worldwide. Approximately half a million of the deaths from diarrhea worldwide occurred among children younger than 5 years of age, making it the third leading cause of death in children less than 5 years of age globally.[1,2] The rotavirus vaccine in the United States and internationally has markedly reduced pediatric diarrhea-associated emergency department (ED) visits, hospitalizations, and deaths.

Acute diarrhea is defined as the abrupt onset of abnormally high fluid content in the stool, with increased volume or frequency. As supported by the World Health Organization (WHO), "acute" diarrhea has a sudden onset and lasts no longer than 14 days; "chronic" or "persistent" diarrhea lasts longer than 14 days. This classification is important for epidemiologic studies and to identify the most likely offending organism. Protracted diarrhea has different causes, poses unique problems in management, and has a prognosis different from that of acute diarrhea. Acute infectious diarrhea can occur with or without vomiting. When it occurs with vomiting, it is often referred to as *acute gastroenteritis (AGE).*

Anatomy, Physiology, and Pathophysiology

Up to 9 L of exogenous fluid and endogenous secretions enter the adult proximal bowel each day, and proportionally even more in children. Ninety percent of fluid is absorbed in the small bowel and the remainder in the large bowel. Water follows osmotic gradients created by active and passive transport of electrolytes, sugars, and amino acids into the bloodstream by the following mechanisms:

- Sodium chloride absorption in the small bowel, with an exchange of cations (Na^+/H^+) and anions (Cl^-/HCO_3^-).
- Electrogenic sodium absorption in the colon, but also in the small intestine, wherein Na^+ enters the cell through an electrochemical gradient; this mechanism is often damaged in acute diarrhea.
- Sodium co-transport mechanism in the small bowel. Na^+ absorption is coupled with the absorption of glucose, amino acids, and peptides. This mechanism often remains intact during acute diarrhea illness, making oral rehydration possible.

Pathophysiology

Infectious agents cause diarrhea by adherence, mucosal invasion, enterotoxin production, and cytotoxin production. Under normal circumstances, the absorptive processes for water and electrolytes predominate over secretion, resulting in net water absorption. Diarrhea occurs when this balance is disrupted, either as a result of increased secretion from the gastrointestinal tract, decreased absorption of fluids, or from inflammation.

Secretory diarrhea is the result of increased intestinal secretion of water into the gut lumen or an inhibition of absorption. For example, *Vibrio cholera* produces an enterotoxin, resulting in increased chloride and bicarbonate secretion. Secretory diarrhea is characterized by the absence of expected reduction in stool volume with fasting, a stool pH above 6, and the absence of reducing substances in the stool. Other bacteria that produce enterotoxins include *Salmonella, Shigella, Escherichia coli,* and *Clostridioides difficile*.

Osmotic diarrhea is caused by the presence of poorly absorbed solutes from altered bacterial gut flora, damage to the mucosal absorptive surface, or ingestion of substances. These substances create an osmotic gradient across the bowel lumen, resulting in intraluminal movement of water and electrolytes. Typical acute viral gastroenteritis produces injury to the small bowel epithelium with consequent disruption of microvilli, decreasing the absorptive area, and preventing normal fluid, electrolyte, and nutrient absorption. The illness is compounded if the colon is unable to compensate for the large fluid volume. Osmotic diarrhea is often characterized by diarrhea that decreases or stops with fasting, a stool pH below 6, and the presence of reducing substances in the stool.

Inflammatory processes can cause destruction of villous cells or dysfunction of cellular transporters, leading to loss of fluids and electrolytes, as well as mucus, proteins, and blood in the intestinal lumen. *Dysentery,* diarrhea associated with blood and mucus in the stool, implies a compromised bowel wall. Acute inflammation, caused by enteroinvasive organisms such as *Salmonella, Shigella,* and *Campylobacter,* leads to infiltration of the gastrointestinal tract by neutrophils, which release a host of enzymes and factors causing both increased secretion and decreased absorption by the intestinal tract. Although blood loss may be clinically appreciable, it is usually less significant than fluid and electrolyte losses. Infectious diarrhea can present with significant signs of dehydration and electrolyte abnormalities.

Pediatric patients have several physiologic factors that predispose them to more severe complications from vomiting and diarrhea. As a result of their relatively larger extracellular fluid compartments, children can lose proportionately more fluids through the gastrointestinal tract. Furthermore, the turnover of fluids and solute in infants and young children can be three times that of adults. This rapid turnover of fluids is the result of higher metabolic rates, increased body surface area to mass index, and higher body water content. Children also have limited stores of metabolic substrates such as fat and glycogen, limited ability or desire to access fluids when ill, and a more limited ability to conserve water through their kidneys compared to adults. These factors make children more susceptible to large fluctuations in fluid, electrolytes, and nutrients, resulting in hypoglycemia, electrolyte abnormalities, dehydration, and shock.

Some groups are at higher risk for developing serious complications of infectious diarrhea (e.g., invasive disease, bacteremia, and sepsis). These include premature infants, very-low-birth-weight infants (up to a year), young infants (younger than 3 months old), immunosuppressed or malnourished children, and those with chronic underlying conditions. Recent hospitalization, treatment with broad-spectrum antibiotics, and travel to developing countries are additional risk factors.

Clinical Features

Infectious diarrhea can present with diarrhea alone or accompanied by vomiting (i.e., acute gastroenteritis [AGE]). Signs and symptoms usually begin 12 to 72 hours after contracting the infectious agent. If due to a viral agent, the condition usually resolves within 1 week. See Box 167.1 for a list of common signs and symptoms. The history and physical examination should help differentiate acute infectious diarrhea from other causes of vomiting and diarrhea and help estimate the degree of dehydration. History and physical examination can sometimes aid in determining the type of pathogen responsible, although this will rarely affect management. Box 167.2 summarizes important information to gather from the history.

Vital signs should be assessed relative to age norms. The evaluation of the child should begin with looking at the child from across the room in a position of comfort, noting the patient's overall appearance, responsiveness, activity, and work of breathing (see Chapter 160). A head-to-toe physical examination of the patient should focus on signs of dehydration that may indicate another cause for the diarrhea (e.g., otitis media, pyelonephritis, appendicitis, diabetic ketoacidosis), or signs that indicate the disease may have become extraintestinal or systemic—bone pain (osteomyelitis), altered mental status (meningitis), petechiae (hemolytic-uremic syndrome [HUS]).

Acute infectious diarrhea in developed countries is often self-limited. The clinical presentation, course of illness, and treatment depends on the etiology of the diarrhea and the host. In the United States, viruses are responsible for most cases of acute infectious diarrhea, with bacteria causing only 7% to 10% of cases in children. Parasites are uncommon in the immunocompetent patient, unless they have traveled to endemic areas. Table 167.1 lists the most common viruses, bacteria, and protozoa that can cause acute infectious diarrhea in children in the United States.[3-6]

Specific Etiologies

Viruses. In the United States and Europe, the majority of cases of diarrhea are caused by viral pathogens, with incidence peaking in the winter. The most common of these are rotavirus and norovirus. See Table 167.2 for presentation and associated characteristics.

BOX 167.1 Common Signs and Symptoms in Patients With Acute Infectious Diarrhea

Diarrhea—frequent, loose, watery, mucousy, bloody, or foul smelling
Nausea
Decreased appetite
Weight loss
Vomiting
Headache
Abdominal pain or cramps
Fever
Malaise
Signs of dehydration (see Dehydration section)

BOX 167.2 Patient History

- Behavior: Weight loss, amount and frequency of feeding, level of thirst, level of alertness, level of activity, lethargy, irritability, quality of crying, presence or absence of tears with crying, frequency of wet diapers in infants or urination in children
- Orthostatic symptoms
- Diarrhea: Duration, frequency, and amount of stools; consistency and content of stool; watery, blood, mucus
- Vomiting: Duration, amount and quality of the vomitus, time since last vomited
- Abdominal pain: Location, quality, radiation, severity per parent and child
- Signs of infection: Fever, chills, myalgia, rash, rhinorrhea, sore throat, cough
- Symptoms in relationship to eating and drinking
- Similar symptoms in other household members or school
- Similar episodes in the past
- Food history
- Water exposure and recent camping
- Travel to endemic or epidemic areas
- Household pets
- Past medical history; chronic medical problems, recent hospitalizations; vaccine status
- Current/recent antibiotic

TABLE 167.1 Common Causes of Childhood Infectious Diarrhea in Developed Countries

Viruses (70% to 80%)	Bacteria (10% to 20%)	Protozoa (<10%)
Rotavirus	*Salmonella* species	*Cryptosporidium*
Norovirus and Sapovirus	*Shigella* species	*Giardia intestinalis*
Astrovirus	*Campylobacter jejuni*	*Entamoeba histolytica*
Adenovirus	*Yersinia enterocolitica*	
	Escherichia coli; ETEC,	
	Clostridium perfringens	
	Clostridium difficile	
	Staphylococcus aureus	
	Vibrio cholera	
	Vibrio parahaemolyticus	

ETEC, Enterotoxigenic *E. coli.*

Rotavirus (RV) continues to be the leading cause of diarrhea and significant morbidity worldwide among children younger than 5 years old. Neurologic symptoms, most commonly seizures, occur in 2% to 3% of children with rotavirus infection.[7] The chronically ill or malnourished child often fails to repair damaged intestinal epithelium post rotavirus infection, leading to a vicious cycle of malnutrition and progressive epithelial injury.

With the introduction of the rotavirus vaccine, there has been a significant decrease in the incidence of RV in the United States.[8-10] According to the CDC, norovirus is now the most common cause of diarrheal illness in children. Two live rotavirus oral vaccines, RotaTeq (RV5) (Merck & Co., Inc.) licensed in 2006 and Rotarix (RV1) (GlaxoSmithKline Biologicals) licensed in 2008, are now approved and are given widely for prevention of rotavirus gastroenteritis. Since the introduction of the RV vaccine in the U.S., a biennial pattern has emerged, with small, short seasons in late winter/early spring,[11] and annual hospitalizations have declined among U.S. children younger than 5 years of age by 80% to 90%.[11,12] It is estimated that since the introduction of the RV vaccine, an estimated 177,000 hospitalizations, 242,000 ED visits, and 1.1 million outpatient visits for diarrhea have been averted among children younger than 5 years of age.[13] The decrease in hospitalization and ED visits is also decreasing in many other countries as the use of the RV vaccine spreads globally.[14,15]

The current rotavirus vaccines were not associated with intussusception in large pre-licensure trials. There continues to be controversy over whether an increase in intussusception does occur. Some post-licensure studies done in the United States, Canada, Korea, Africa, Brazil, and Taiwan agree with the prelicensure trials showing no increase in intussusception with the RV vaccines.[16-21] However, recent postlicensure surveillance data in the United States[22-24] and internationally[25-27] indicate there is an increased risk of intussusception from the currently licensed RV vaccines. These studies found that most of the increased risk occurs within the first week after the first dose but may occur up to 21 days after the first dose. Although there may be a slight increased risk of intussusception following the oral vaccines, the Centers for Disease Control and Prevention (CDC) and the World Health Organization still recommend the rotavirus vaccine as the benefits of the RV vaccine in preventing severe RV disease far outweigh the risk of intussusception. Parents should be made aware of the risk, the early signs and symptoms of intussusception, and the need for prompt care if they develop.[13]

Human Caliciviruses (Norovirus and Sapovirus). According to the CDC Burden of Norovirus Illness in the United States,[28] each year, norovirus causes approximately 20 million cases of acute gastroenteritis, leading to 1.7 to 1.9 million outpatient visits and 400,000 ED visits, primarily in young children. It also contributes to about 56,000 to 71,000 hospitalizations and 570 to 800 deaths, mostly among young children and the elderly. Norovirus is now the leading cause of acute gastroenteritis among U.S. children less than 5 years of age.[29] Norovirus AGE is associated with more frequent and prolonged vomiting, but less fever, than AGE caused by rotavirus. Seizures are the most common central nervous system (CNS) complication, whereas encephalopathy is possible but rare.[30] Clinical manifestations for sapovirus are similar to those of norovirus.[31]

Astrovirus has a worldwide distribution and has been found in up to 17% of sporadic cases of nonbacterial AGE in children. It accounts for only 2.5% to 9% of severe childhood AGE requiring hospitalization. In healthy children, it is an illness of short duration, although asymptomatic shedding continues up to several weeks after symptom resolution. In the immunocompromised patient, astrovirus infections have been associated with extraintestinal disease, encephalitis, and meningitis.[32,33]

Adenovirus is well known for causing infections of the respiratory tract along with pharyngitis, otitis media, and pharyngoconjunctival fever. Enteric adenovirus serotypes (31, 40 and 41) cause gastroenteritis, accounting for 2% to 4% of cases of acute infectious diarrhea in children. In healthy people, infection with one adenovirus type may confer type-specific immunity or at least lessen symptoms associated with reinfections. Asymptomatic shedding of the virus for months is common.[34]

The mainstay for treatment of viral enteritis is supportive care with rehydration and electrolyte correction.

Bacteria. The common bacterial organisms causing acute diarrhea in U.S. children along with their presentations and associated characteristics are listed in Table 167.3, and their treatment is listed in Table 167.4.

Nontyphoidal *Salmonella* (NTS) is the most common cause of laboratory confirmed cases of enteric disease. The CDC estimates that approximately 1.35 million illnesses and 420 deaths occur annually in the United States due to NTS. In a recent study, the most commonly reported human isolates were *Salmonella* Enteritidis, Typhimurium, Newport, Heidelberg, and Javiana; these 5 serotypes accounted for 62% of U.S. *Salmonella* infections.[35] The incidence of NTS is highest in children less than 4 years of age. Infection can result in an asymptomatic carrier state, AGE, bacteremia, invasive disease, or a disseminated abscess syndrome.

TABLE 167.2 Viruses Causing Diarrheal Illness: Characteristics and Associated Symptoms

	Age	Season	Lasts	Incubation Period	How Spread	Length of Excretion	Abdominal Pain	N/V	Fever	Diarrhea Characteristics	Diagnostics
Rotavirus	<5 years old	Winter and spring	4 to 8 days	Less than 48 hours (1 to 3 days)	Mainly Fecal-oral (can stay on surfaces for weeks to months) or respiratory secretions	Up to 21 days	±	++	± ⅓ have high fever	Watery; large volume	ELISA and latex agglutination most commonly used; PCR most sensitive
Norovirus	<5 years old	Anytime; colder months	2 to 3 days (up to 5 days)	12 to 48 hours	Fecal-oral; contaminated food and water	5 to 7 days after onset of symptoms; up to 3 weeks	++	++ (some may not vomit)	±	Abrupt onset; watery	RT-PCR testing available; CIDT
Astrovirus	<4 years old	Late winter; early spring	2 to 5 days	1 to 4 days	Fecal-oral	Few days after symptoms resolve	±	+	++	Watery; large volume	CIDT now available
Adenovirus	<4 years old	All year	5 to 12 days	3 to 10 days	Fecal-oral	Most contagious first few days; asym excretion for months	±	+	Low grade	Watery	Commercial test available

Key: ++, common; +, occurs; ±, variable.
N/V, Nausea/vomiting*; ELISA,* enzyme-linked immunosorbent assay; *PCR,* polymerase chain reaction; *RT-PCR,* reverse transcription polymerase chain reaction; *CIDT,* culture-independent diagnostic test.
Data from: World Gastroenterology Organization. *World Gastroenterology Organization global guidelines: acute diarrhea in adults and children: a global perspective*. TABLE 167.3 Bacteria Causing Diarrheal Illness: Characteristics and Associated Symptoms

	Who Affected	Incubation (range)	Duration of Illness	How Spread	Length of Excretion	Abdominal Pain	N/V	Fever	Diarrhea Characteristics	Other Characteristics	Diagnostic Tests
Salmonella species	<4 years old	12 to 36 hours (6 to 72 hours)	2 to 7 days	Foods from animals; contaminated water; infected reptiles, amphibians, rodents, and mammals	Up to 12 weeks in children <5 years old	++	+	++	Mild to severe; can have blood or mucus	Bacteremia can occur, focal infections in 10%	Stool culture; CIDT starting to be used
Salmonella typhi	Travelers	7 to 14 days (3 to 60 days)	Requires antibiotics	Contaminated food or water	Chronic carriers	++	+	++	Not main problem; mild diarrhea	Gradual onset; HA, malaise, anorexia; HSM, rose spots, dactylitis, ams	Blood, bone marrow, or bile culture
Shigella species	≤5 years old	1–3 (1 to 7 days)	48 to 72 hours	Fecal-oral, contaminated food/ water, objects	1 to 4 weeks, antibiotics may shorten excretion	++	++	++	Mild to severe: watery to mucoid with or without blood	Can have systemic symptoms; neurological symptoms; tenesmus Fecal PMNs often positive	Stool culture; improved with fresh stool, CIDT have high sensitivity; high false-positive rate
Campylobacter	<4 years old	2 to 5 days	5 to 7 days; 15% can relapse or have prolong or severe disease	Ingestion of contaminated foods; fecal-oral in the very young; greatest in acute phase	2 to 3 weeks without treatment 2 to 3 days with treatment	++ Can mimic appendicitis or intussusception	+	++ Infants may not have fever	Watery to mucoid/bloody	Malaise; can have febrile symptoms before GI symptoms Infants may have bloody diarrhea and no fever Can mimic acute inflammatory bowel disease	*C. jejuni* and *C. coli* from stool culture; CIDT, don't differentiate species
Yersinia enterocolitica	<5 years most common	4 to 6 days (1 to 14 days)	Variable; usually few days but diarrhea up to 2 weeks	Contaminated food or water; contact with animals, person to person is rare	Average 2–3 weeks (up to 2–3 mos if untreated)	+	±	++	Often with blood and mucus	Pseudoappendicitis syndrome Fecal PMNs often positive Bacteremia; <1 year old, excessive iron storage, immunosuppressed	Stool culture; need to specify
Clostridium difficile	>24 months	Not really known. Colitis usually starts 5 to 10 days after starting antibiotics (up to 10 weeks)	Variable	Fecal-oral or environment	Unknown	+	–	+ Low grade	Mild: watery diarrhea to pseudomembranous colitis; mucus in stool		EIA detection of toxins NAAT good sensitivity and specificity
Clostridium perfringens	Any age	8 to 12 hours (6 to 24 hours)	24 hours	Catered foods	As long as illness persists	++ Crampy, epigastric	–	–	Sudden onset; watery diarrhea	Common in healthy people's stool Treatment not necessary; short course	High spore count in stool Commercially available kits

TABLE 167.3 Bacteria Causing Diarrheal Illness: Characteristics and Associated Symptoms—cont'd.

	Who Affected	Incubation (range)	Duration of Illness	How Spread	Length of Excretion	Abdominal Pain	N/V	Fever	Diarrhea Characteristics	Other Characteristics	Diagnostic Tests
Staphylococcus aureus	Any age	2 to 4 hours (30 minutes to 8 hours)	1 to 2 days	Contaminated food that remains at room temperature for hours	Short time	+	++	± Low grade	Watery	Violent onset of nausea/vomiting; can have mild hypothermia	Culture stool or vomitus EIA or PCR detect enterotoxin
Vibrio cholera	Traveled to endemic area	1 to 3 days (hours to 5 days)	3 to 7 days	Contaminated food and water (shellfish; raw vegetables)	Short time	±	±	±	Large amounts watery diarrhea; stool colorless with flecks of mucus; rice water appearing	Dehydration, hypokalemia, metabolic acidosis and shock within 4 to 12 hours; coma, seizures, hypoglycemia	Stool culture; need to request
Vibrio parahaemolyticus	All ages	23 hours (5 to 92 hours)	2 to 5 days	Seawater; undercooked seafood	Not excreted	++	±	± Low grade	Acute onset Watery stools	Liver disease, low gastric acidity, immunosuppressed increased risk	Lab needs to be notified when test; can test stool, blood, or wounds
E. coli (STEC)	All ages	3 to 4 days (1 to 8 days)	Usually 7 days	Contaminated food or water with human or animal feces; person to person occurs		++	+	– Sometimes low grade	Bloody or nonbloody	Stool becomes bloody after 3 to 4 days; can cause HUS Shiga toxin produced	Stool culture; must request test for *E. coli* O157 EIA for Shiga toxin if available
E. coli (EPEC)	<2 years old; RLAs and travelers	10 hours to 6 days	Usually few days but variable	Contaminated food or water with human or animal feces		–	–		Watery, usually mild	Can become chronic and cause growth retardation No toxin produced	Not widely available
E. coli (ETEC)	Infants in RLAs and travelers of all ages	10 hours to 6 days	1 to 5 days	Contaminated food or water with human or animal feces; person to person occurs		+	–	±	Watery	Uncommon in the U.S. Enterotoxin produced	Not widely available
E. coli (EIEC)	All ages	10 hours to 6 days	Variable	Contaminated food or water with human or animal feces		±	–	+	Usually watery without blood or mucus; dysentery can occur	Related to *Shigella* can cause similar dysenteric illness	Not widely available
E. coli (EAEC)	All ages	10 hours to 6 days	Variable	Contaminated food or water with human or animal feces		±	–	±	Watery, occasionally bloody	Enterotoxin and cytotoxin Associated with prolonged diarrhea; becoming more common in U.S.	Not widely available

Key: ++, common; +, occurs; ±, variable; –, not common.

CIDT, Culture-independent diagnostic test; *EAEC,* enteroaggregative *Escherichia coli; EIA,* enzyme immunoassay; *EIEC,* enteroinvasive *E. coli; EPEC,* enteropathogenic *E. coli; ETEC,* enterotoxigenic *E. coli; HA,* headache; *HUS,* hemolytic-uremic syndrome; *GI,* gastrointestinal; *NAAT,* nucleic acid amplification test; *N/V,* nausea/vomiting; *PCR,* polymerase chain reaction; *PMN,* polymorphonucleocyte; *RLA,* resource limited area; *STEC,* Shiga toxin–producing *E. coli*

TABLE 167.4 Treatment Recommendations for Common Bacteria Causing Acute Infectious Diarrhea in Children

	Routine Treatment	Treatment Indicated—High-Risk Groups	Antibiotic	Comments
Salmonella non-typhi	No; treatment prolongs excretion; does not shorten disease	Infants <3 months old, prolonged illness, chronic GI disease, neoplasms, hemoglobinopathies, HIV, immunosuppression, localized invasive disease (osteomyelitis, abscess, meningitis) or bacteremia	Susceptibility is known Oral: Amoxicillin 25–50 mg/kg divided every 8 hours IV: Ampicillin 200 mg/kg divided every 6 hours (max 8 g/d) Oral: TMP-SMX 10 mg/kg divided every 12 hours (max 160 mg/dose) Susceptibility not known or areas of high resistance or invasive disease or bacteremia IV or IM: Ceftriaxone 50–75 mg/kg q24h (max 2 g) or Oral or IV: Azithromycin 10–20 mg/kg (max 500 mg/dose) or Oral: Adult—[a]Ciprofloxacin 500 mg/dose every 12 hours, Children—[a]Ciprofloxacin 20–40 mg/kg divided every 12 hours (max 1 g/day)	Blood cx before initiating antibiotics. Bacteremia: Treat for 10 to 14 days Localized invasive disease: Treat for 4 weeks (6 weeks if meningitis) and begin with IV medications Aminoglycosides not recommended for invasive disease Drug of choice, route of administration, and duration of therapy based on susceptibility of organisms, site of infection, host and clinical response
Salmonella typhi	Yes	All patients with enteric fever Delirium, stupor, coma, or shock	Start with IV medications; change to oral when susceptibility is known Ceftriaxone 50– 75 mg/kg q24h (max 2 g) or [a]Ciprofloxacin 20–40 mg/kg divided every 12 hours(max 1g/day)	Multidrug resistance is common 10- to 14-day treatment Check susceptibilities Azithromycin for uncomplicated disease Consider: Dexamethasone IV 3 mg/kg, followed by 1 mg/kg every 6 hours for 48 hours; relapse is common
Shigella species	No; usually self-limited but treatment decreases diarrhea and eradicates organism from stool	Severe disease, bacteremia, dysentery, immunosuppression Less ill and able to tolerate PO (See Oral dosing)	IV: Ceftriaxone 50 mg/kg (max 2 g) for 5 days (≥ 17 years old) or [a]Ciprofloxacin 20–30 mg/kg/day divided bid or Azithromycin 20 mg/kg/day (max 500 mg) Oral: Azithromycin 12 mg/kg for first day, then 6 mg/kg for days 2 to 5 or [a]Ciprofloxacin 20 mg/kg divided every 12 hours for 5 days	Oral route preferred when possible and disease is not serious TMP-SMX and ampicillin only if isolated strain is susceptible because of high resistance Amoxicillin less effective because of rapid absorption from GI tract; avoid fluoroquinolones if MIC >0.12 even if says susceptible.
Campylobacter jejuni	Variable	Variable recommendations. Most children will resolve on own.	Oral: Azithromycin 10 mg/kg for 3 days (max 500 mg/dose) or Erythromycin 40 mg/kg/day divided every 6 hours (max 2g/day) for 5 days	Shorten duration of illness and excretion of organisms and prevent relapse if given early Resistance to fluoroquinolones is frequent
Yersinia enterocolitica	No; although can be considered as it decreases shedding of the organism;	Neonates, septicemia or extraintestinal sites of infection; immunocompromised host	Oral: TMX-SMX 10 mg/kg divided every 12 hours or Oral or IV fluoroquinolone[a], 10 mg/kg/day of TMP component: Ciprofloxacin 20 mg/kg divided every 12 hours or IV: Ceftriaxone 50 mg/kg qd	Usually resistant to penicillin and first generation cephalosporins Antibiotics do decrease the duration of fecal excretion but do not decrease length of diarrhea Extraintestinal disease treat for 4 weeks. Usually susceptible to tetracycline and doxycycline
C. difficile	Yes	Symptomatic patients Severe disease, underlying intestinal tract disease, and those who don't respond to oral metronidazole use vancomycin	Stop antimicrobial therapy Oral or IV: Metronidazole 30–40 mg/kg/day for at least 10 days (maximum dose 500 mg/dose) if failure to respond in 5 days then: Oral: Vancomycin 40 mg/kg /day divided every 6 hours for at least 10 days (maximum 125mg/dose	25% relapse after treatment, usually responds to second course; IV vancomycin is not effective Do not give antimotility agents; if no abdominal distention and severe disease use Vanco PO and metronidazole IV. If ileus or toxic colitis add vancomycin (1–3 years old: 250 mg/50 mL q6h; 4–9 years old: 375 mg/75 mL q6h; ≥10 years old: 500 mg/100 mL q6h) NS enema until improved

Continued

TABLE 167.4 Treatment Recommendations for Common Bacteria Causing Acute Infectious Diarrhea in Children—cont'd.

	Routine Treatment	Treatment Indicated—High-Risk Groups	Antibiotic	Comments
Vibrio cholera	No	Patients with moderate to severe disease	Oral: Doxycycline[a] 4.4 mg/kg/day divided bid or Azithromycin 20 mg/kg single dose or Tetracycline[a] 50 mg/kg/day divided every 6 hours (maximum 3 g/day) for 3 days	Susceptibility testing recommended Treatment decreases duration of diarrhea and eradicates bacteria from stool; Cipro not recommended in children high treatment failures
V parahaemolytica	No	Severe diarrhea, septicemia Consider in patients <8 years old	Third-generation cephalosporin and doxycycline[a] TMX-SMX and aminoglycoside	
E. coli	No for STEC infection or concern for STEC	Severe watery diarrhea in a traveler to RLA	Azithromycin 10 mg/kg qd ×3 days, ciprofloxacin 30 mg/kg/day divided BID ×3 days[a]	Treating patients with STEC may increase risk for HUS

[a]Fluorquinolone: ciprofloxin recommended for greater or equal to 17 years unless benefits outweigh the risks. Tetracyclines/doxycyclines are not recommended in children younger than 8 years because of teeth staining, but the benefit of using the drug may outweigh the risk of teeth staining. Each case is considered separately. Ciprofloxacin recommended for greater or equal to 17 years unless benefits outweigh the risks.
GI, Gastrointestinal; *HIV,* human immunodeficiency virus; *HUS,* hemolytic-uremic syndrome; *IM,* intramuscular; *IV,* intravenous; *PO, per os* (by mouth); *RLA,* resource limited area; *STEC,* Shiga toxin–producing *E. coli, TMP-SMX,* trimethoprim-sulfamethoxazole.
Data from: Kimberlin DW, Brady MIT, Jackson MA, Long SS, editors. *Red Book: 2018-2021 Report of the Committee on Infectious Disease*, ed 31. Itasca, IL: American Academy of Pediatrics; 2018; and Hughes HK, Kahl LK, editors. *The Harriet Lane Handbook: A Manual for Pediatric House Officers*, ed 21. Philadelphia: Saunders; 2018.

Salmonellae invade the mucosa of the distal small intestine and the colon; they produce a cholera-like enterotoxin and a cytotoxin, which can cause significant diarrhea and fluid and electrolyte abnormalities similar to patients with documented cholera. Fever in NTS patients usually lasts about 48 hours, and patients with prolonged fever may have intermittent bacteremia. Patients with *Salmonella* bacteremia are at increased risk for developing extraintestinal infections, seen in up to 10% of patients with *Salmonella* bacteremia. Infants, the elderly, patients with hemoglobinopathies, and the immunosuppressed are at highest risk for invasive disease. Extraintestinal sites of infection can result in endocarditis, vascular infections, cholecystitis, hepatic and splenic abscesses, urinary tract infections, pneumonia, meningitis, septic arthritis, and osteomyelitis.[36]

Although uncommon, *Salmonella* serotype *typhi* is only found in humans and can cause a bacteremic illness often referred to as *enteric* or *typhoid fever.* Although uncommon in the United States, *S. typhi* is endemic in many resource-limited countries. Typhoid fever may be acquired during international travel and appear as a nonspecific febrile illness in young children in whom sustained or intermittent bacteremia may occur. Constipation can be the presenting symptom and is often seen early in the course of the disease, but diarrhea can also occur. If *S. typhi* is suspected, blood, bone marrow or bile should be cultured, because stool cultures are often negative.[35]

Treatment of noninvasive NTS infection is usually supportive. Antimicrobial treatment is only recommended for infants younger than 3 months and people with chronic gastrointestinal disease, malignant neoplasms, hemoglobinopathies, HIV infections, or other immunosuppressive illnesses or therapies. If treatment is started for presumed disease, stool and blood cultures should be obtained prior to initiating antibiotics. On the other hand, for children with *S. typhi* infection, antibiotics *are* recommended. Relapse of enteric fever occurs in up to 17% of patients and requires retreatment. Treatment failures have occurred in people treated with cephalosporins, aminoglycosides, and furazolidone, despite in vitro testing indicating susceptibility.[36]

Among *Shigella* isolates reported in industrialized nations, most are *Shigella sonnei* (84%). *Shigella flexneri, Shigella boydii,* and *Shigella dysenteriae* account for the remainder.[37] *S. sonnei* is the most common cause of dysentery in the United States. Extraintestinal symptoms and signs are relatively common in children with *Shigella* infection, including hallucinations, confusion, and seizures. Reactive arthritis (Reiter syndrome) can occur weeks after the infection. Rare complications of *Shigella* infection include bacteremia, HUS, toxic megacolon, pseudomembranous colitis, and encephalopathy (Ekiri syndrome). The risk of septicemia increases in neonates, malnourished children, and with *S. dysenteriae.* There is some evidence that antibiotic treatment is effective in shortening duration of diarrhea and hastening eradication of organisms from feces.[37] Drug-resistant *Shigella* has been rapidly increasing; resistance to first-line drugs, ampicillin and trimethoprim-sulfamethoxazole, has become so high that emergency clinicians must rely on alternative drugs like ciprofloxacin and azithromycin. However, over the last 5 years, resistance to these medications has also increased drastically. According to the CDC, both ciprofloxacin and azithromycin resistance has increased from approximately 2% to over 20%. Of particular concern are frequently reported outbreaks of multidrug-resistant *Shigella* among men who have sex with men.[38,39]

Campylobacter species cause a significant proportion of diarrheal disease worldwide, with 1.5 million annual U.S. cases and children younger than 5 years most commonly infected. Of the five types, *C. jejuni* and *C. coli* are the most common.[40,41] In neonates and young infants, bloody diarrhea without fever can be the only manifestation of infection. Febrile seizures can occur in young children before any gastrointestinal symptoms are present. The clinical presentation may be similar to acute appendicitis or intussusception. Severe or prolonged disease can mimic inflammatory bowel disease. Bacteremia is uncommon but can occur in children, including neonates. Immunocompromised hosts can have prolonged, relapsing, or extraintestinal infections. Immunoreactive complications include Guillain-Barré syndrome, reactive arthritis, myocarditis, pericarditis, and erythema

nodosum.[41] Antibiotic treatment is recommended for those with severe invasive disease, those at increased risk for severe disease, and for those with prolonged excretion of the bacteria. According to the CDC and the World Health Organization, most healthy children will recover without antibiotic treatment. Azithromycin and erythromycin do shorten the duration of the illness and excretion of the organisms if susceptible. Resistance to antibiotics is increasing. Over 10% of isolates are resistant to azithromycin and erythromycin and over 35% are resistant to ciprofloxacin in the United States. Therefore, if using culture-independent diagnostic tests (CIDT) tests to diagnosis *Campylobacter*, cultures are recommended to confirm diagnosis and for susceptibility information.[38]

Yersinia enterocolitica is a relatively uncommon cause of simple self-limited diarrhea and vomiting in the United States. According to the CDC, there has been a recent increase in the incidence, most likely from CIDT results. *Y. enterocolitica* most often affects children younger than 5 years of age. As many as 6% of older children and adults may present with an appendicitis-like illness, with right lower quadrant tenderness, usually as a result of reactive mesenteric adenitis. Antibiotics are indicated for the immunocompromised patient with enterocolitis and in cases of septicemia or extraintestinal infections. Isolates are often resistant to first-generation cephalosporins and most penicillins. Bacteremia is the major complication of *Y. enterocolitica,* occurring mostly in children less than 1 year of age and in older children with predisposing conditions, including excessive iron storage (e.g., deferoxamine use, sickle cell disease, and beta-thalassemia) and immunosuppressive states. Extraintestinal manifestations of *Y. enterocolitica* are rare. Postinfectious sequelae include erythema nodosum, reactive arthritis, and proliferative glomerulonephritis, most often associated with older children and adults with HLA-B27.[42]

Humans acquire *C. difficile* from their environment or via the oral-fecal route, which can lead to infection. The disruption of the body's normal flora, often as a result of antimicrobial treatment, leads to overgrowth of *C. difficile*, toxin production, and disease development. Exposure to antibiotics is the most important risk factor for *C. difficile*.[43] Penicillins, cephalosporins, clindamycin, and fluoroquinolones are associated more commonly with *C. difficile* infection, whereas sulfonamides, tetracyclines, vancomycin, metronidazole, and aminoglycosides are less commonly linked in children. Pediatric patients who are exposed to multiple antibiotics from different classes in the previous 30 days have been shown in recent studies to be associated with severe and recurrent *C. difficile* infection.[44] Other risk factors include acid-suppressing medications, such as proton pump inhibitors, and use of gastrointestinal feeding tubes.[45]

C. difficile infections cause a spectrum of illnesses ranging from asymptomatic to watery diarrhea to pseudomembranous colitis.[46] Clinical illness is rare before 12 to 24 months of age. Asymptomatic infants can be colonized with *C. difficile*; carriage rates vary by age and range from 37% in neonates to less than 3% by age 2 years.[46,47] *C. difficile* should be considered in children 1 to 3 years old, but only after other causes of diarrhea (particularly viral) are excluded.[47] Endoscopic findings of pseudomembrane and friable rectal mucosa are sufficient to diagnose *C. difficile* at any age. This is helpful when trying to determine if a child younger than 3 years old is colonized or has disease. The endoscopic findings are diagnostic of disease. Complications include toxic megacolon and intestinal perforation. Severe or fatal disease is more common in neutropenic patients with leukemia, infants with Hirschsprung disease, and patients with inflammatory bowel disease.[46,47,48]

See Tables 167.3 and 167.4 for presentation and associated characteristics and treatment recommendations for *Clostridium perfringens, Staphylococcus aureus, V. cholera*, and *Vibrio parahaemolyticus*.[48-51]

Each year, the WHO Global Burden of Foodborne Diseases reports over 300 million illnesses and nearly 200,000 deaths caused by *E. coli* diarrheagenic infections. *E. coli*, part of the normal flora in the lower gastrointestinal tract, includes five species types recognized to cause acute diarrheal disease. The enterohemorrhagic *E. coli* (EHEC) strain is also known as Shiga toxin–producing *E. coli* (STEC). While there are 50 other serotypes that can cause illness, *E. coli* O157:H7 is the prototype and most virulent of the EHEC and is the one more commonly reported in industrialized countries. Outbreaks have been linked to ground beef, petting zoos, contaminated apple cider, raw fruits and vegetables, and ingestion of water in recreational areas. The infectious dose is low, and person-to-person transmission does occur.[51] In 2016, 52 state and regional public health laboratories reported 5441 cases of culture-confirmed STEC infections. Compared with 2015, the incidence of both STEC O157 and non-O157 infections in 2016 was higher (9% and 15% increase respectively).[52]

HUS, a triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency, is a serious complication of EHEC infection and occurs in up to 15% of children with *E. coli* O157:H7.[51] The overall incidence of HUS caused by a diarrheal pathogen (usually STEC) is estimated to be 2.1 cases per 100,000 persons per year, with a peak incidence in children younger than 5 years old (6.1 cases per 100,000 per year). HUS typically develops as diarrhea is resolving, usually at 7 days but may be up to 3 weeks after the onset of the illness.[51] Patients often present with pallor, weakness, irritability, and oliguria or anuria. Patients with HUS can develop neurologic complications, such as seizures, coma, and cerebral vessel thrombosis. Approximately 50% of patients who have HUS will require dialysis, and 3% to 5% die. Indicators that may predict poor outcome for patients with HUS include white blood cell counts greater than 20,000, oliguria or anuria, normal or high hematocrits (≥10.8 g/dl), low sodium less than 128 mEq/L, or presence of a respiratory tract infection within 3 weeks of the diagnosis.[52-54]

A serious risk posed by hemorrhagic colitis is the rapid loss of fluids, which can cause electrolyte abnormalities and result in poor perfusion and end-organ damage. Patients should receive adequate amounts of intravenous (IV) fluids (or by mouth if able to take in enough) to restore intravascular volume (monitor urine output, capillary refill time, blood pressure, pulse, and mental status), and electrolyte abnormalities should be corrected. Fluids should be continued and ongoing losses replaced, with possible admission for ongoing treatment and monitoring of electrolytes, complete blood cell count, blood urea nitrogen (BUN), and creatinine. Evidence from a recent study suggests that patients with HUS who received early volume expansion (increase of body weight by 12.5%) had lower rates of central nervous system involvement, less need for dialysis or intensive care support, and fewer days of hospitalization. These patients also had significantly better long-term outcomes in renal and extrarenal sequale.[55]

Controversy continues to exist about the indications for antibiotic treatment of STEC infections due to a possible association with an increased risk of HUS. To date, there are no controlled trials to support or disprove this association with HUS and the most recently published observation studies found that at least some classes of antimicrobial agents were associated with HUS. Experts continue to advise not prescribing antibiotics for children with *E. coli* 0157 enteritis or a clinical picture strongly suggestive of STEC infection, because no benefit has been found from the use of antibiotics. See Tables 167.3 and 167.4 for presentation and associated characteristics and treatment recommendations for other *E. coli* infections.

Protozoa. Protozoa can also cause diarrhea in children but are responsible for less than 1% of all cases of acute infectious diarrhea in the United States (Tables 167.5 and 167.6). The most common protozoa causing diarrhea are *Cryptosporidium, Giardia intestinalis,* and *Entamoeba histolytica*.

Cryptosporidium hominis is the most common of the *Cryptosporidium* species to infect humans. The parasite is protected by an outer shell that allows it to survive outside the body for long periods of time and makes it very tolerant to chlorine disinfection. While this parasite

TABLE 167.5 Protozoa: Presentation and Associated Characteristics

	Who Affected	Incubation	How Spread	Length of Excretion	Abdominal Pain	Nausea/ Vomiting	Fever	Diarrhea Characteristics	Other Characteristics	Diagnostic Tests
Cryptosporidium hominis	All ages	3 to 14 days	Contaminated water; fecal-oral	Immunocompetent: up to 2 weeks Immunosuppressed: Months	±	+	±	Frequent, nonbloody, diarrhea	Fatigue, anorexia and weight loss	DFA for detection of oocysts in stool
Giardia intestinalis	1 to 9 years old	1 to 3 weeks	Fecal-oral, contaminated water or food	Weeks to months	++	+	–	Acute watery diarrhea; foul smelling, flatulence	Can be protracted, abdominal distention, anorexia; FTT, anemia	EIA and DFA tests available; EIA with high sensitivity and specificity
Entamoeba histolytica	Immigrants or visitors to endemic areas	2 to 4 weeks (few days to months)	Fecal-oral; contaminated food or water; sexual transmission	Can excrete for years if untreated	+	±	<½	Colitis to dysentery	Gradual onset of symptoms over 1 to 3 weeks; tenesmus; weigh loss is common	Trophozoites or cysts in stool; serial specimens often necessary; EIA commercially available

Key: ++, common; +, occurs; ±, variable; –, not common.
DFA, Direct fluorescent antibody; *EIA,* enzyme immunoassay; *FTT,* failure to thrive.

TABLE 167.6 Treatment Recommendations for Common Protozoa Causing Infectious Diarrhea in Children

	Treatment Routinely Recommended	When Treatment Indicated—High-Risk Groups	Antibiotic Indicated	Comments
Cryptosporidium	Not for immunocompetent	If treat: Children >1 year old HIV-positive, organ transplant	Nitazoxanide for children 1 to 3 years old: 100 mg/dose every 12 hours for 3 days 4 to 11 years old: 200 mg q12h x3 days >12yo: 500mg Q12H x3 days	
Giardia intestinalis	Yes	Most require treatment Children >1 year old Children ≥3 years old	Oral: Metronidazole 15–30 mg/kg/day divided every 8 hours for 5 to 10 days (maximum 250 mg /dose) Nitazoxanide: oral use same doses as for Cryptosporidium Tinidazole 50 mg/kg single dose (maximum 2 g/dose)	FDA has not approved of metronidazole for *Giardia* but is least expensive, poor palatability; not as effective as other 2. Symptom recurrence attributed to reinfection, lactose intolerance, immunosuppression, insufficient treatment or drug resistance Second course with same drug should be effective
Entamoeba histolytica	Yes	Asymptomatic excreters Mild to severe intestinal or extraintestinal disease	Oral: Drug of choice: Iodoquinol 30 to 40 mg/kg/day divided every 8 hours for 7 days (maximum 2 g) or Paromomycin 25 to 35 mg/kg/day divided every 8 hours for 7 days Drug of choice: Metronidazole 35 to 50 mg/kg/day divided every 8 hours for 7 to 10 days (max dose 750 mg/dose) or Tinidazole (>3 years old) 50 mg/kg/day for 3 days or 5 days for severe disease followed by Iodoquinol 30 to 40 mg/kg/day divided every 8 hours for 20 days (maximum 2 g) or Paromomycin (if no intestinal obstruction)(same dose as above)	Metronidazole is not effective against cysts. Do not give antimotility agents or corticosteroids Iodoquinol and paromomycin should be taken with meals

Data from: Kimberlin DW, Brady MIT, Jackson MA, Long SS, editors. *Red Book: 2018-2021 Report of the Committee on Infectious Disease*, ed 31. Itasca, IL: American Academy of Pediatrics; 2018; and Hughes HK, Kahl LK, editors. *The Harriet Lane Handbook: A Manual for Pediatric House Officers*, ed 21. Philadelphia: Saunders; 2018.

can be spread in several different ways, water (drinking water and recreational) is the most common way to spread the parasite. In the United States, *Cryptosporidium* is a leading cause of waterborne disease among humans. In the immunocompromised patient, chronic, severe diarrhea can develop and result in malnutrition, dehydration, and death. Cryptosporidiosis should be considered in any patient with solid organ transplant or HIV with diarrhea. Cryptosporidiosis can lead to an increase in tacrolimus levels in transplant patients, leading to acute renal injury. Because shedding can be intermittent, at least three stool specimens collected on separate days should be examined before considering test results to be negative. Treatment is usually supportive. However, the U.S. Food and Drug Administration (FDA) has approved a 3-day course of nitazoxanide oral suspension for the treatment of immunocompetent children older than 1 year of age.[56]

Infection with *Giardia intestinalis* is limited to the small intestine and biliary tract. It is the most common intestinal parasitic infection of humans in the United States and globally. Asymptomatic infection is common. Humans are the main reservoir, although it has been found in the stool of dogs, cats, cattle, rodents, and other animals. These animals can contaminate water with stool containing cysts that are infectious for humans. Epidemics from person-to-person transmission occur in childcare centers and in institutions for people with developmental delay. Treatment includes correction of dehydration and electrolyte abnormalities and antibiotics. If therapy fails, a course can be repeated with the same drug. Relapse is common in the immunocompromised host, who often requires prolonged treatment. Patients with hypogammaglobinemia or lymphoproliferative disease are at higher risk of giardiasis and more difficult to treat. Patients with acquired immunodeficiency syndrome (AIDS) often respond to standard therapy. Treatment of asymptomatic carriers is not recommended except in households of patients with hypogammaglobinemia or cystic fibrosis.[57]

E. histolytica can be found worldwide but is more prevalent in the lower socioeconomic population and in developing countries, where the prevalence of amebic infection may be as high as 50% in some communities. In the United States, amebiasis is most common in people who have traveled to or immigrants from tropical places with poor sanitation, people who live in institutions with poor sanitary conditions, and men who have sex with men.[58] Symptoms can become chronic and may mimic inflammatory bowel disease. Complications include fulminant colitis, toxic megacolon, and ulceration of the colon and perianal area, rarely with perforation. Complications are more common in patients treated inappropriately with corticosteroids or antimotility drugs. Ultrasonography, computed tomography, and magnetic resonance imaging can identify liver abscesses and other extraintestinal sites of infection. Because complete eradication of intestinal infection is difficult, follow-up stool examination is recommended after completion of therapy. Asymptomatic household members with stools positive for *E. histolytica* should also be treated.[59]

See Tables 167.2, 167.3 and 167.5 for common signs and symptoms of the different viruses, bacteria, and protozoa.

Complications

The complications of acute diarrheal illness are reflected primarily in abnormalities of fluid, electrolytes, acid-base status, and systemic complications (bacteremia, osteomyelitis, polyarthritis, and HUS). Hypoglycemia and metabolic acidosis are common in younger children, yet manifested with nonspecific signs and symptoms, such as tachypnea and decreased activity. With severe illness or illness superimposed on underlying chronic conditions, children may present with weakness, lethargy, respiratory distress, shock, anuria, cardiac dysrhythmia, seizure, or coma. Children with early signs of shock (e.g., persistent tachycardia, hyperpnea, irritability, and lethargy) should have their intravascular volume restored before decompensation occurs.

Diagnostic Strategies

Acute diarrhea in children is usually a self-limited mild disease; it can, however, cause significant fluid and electrolyte abnormalities with serious consequences. Indications for medical evaluation of children with diarrhea have been proposed (Box 167.3). The principal goals of the ED evaluation are to identify and to correct fluid, electrolyte, acid-base, and nutrient deficits that may result from vomiting, diarrhea, or decreased oral intake, and to determine which children would benefit from admission.

Children who present with mild to moderate disease can often rehydrate orally and require no diagnostic testing. In children with moderate to severe dehydration from acute diarrhea (with or without vomiting) who require IV fluids, we recommend assessing serum electrolyte, bicarbonate, urea/creatinine, and glucose levels. Laboratory tests to estimate hydration status have been found helpful only when markedly abnormal, with no single test definitive for dehydration. Children who are critically ill or hemodynamically unstable should have intravenous/intraosseous hydration started immediately along with a finger-stick blood glucose and serum electrolytes.

Testing for fecal leukocytes may be useful to support a diagnosis of invasive disease and should be considered in children with diarrhea who are febrile or have mucus or blood in their stool. Many children with acute diarrhea caused by *Salmonella* or *Shigella* organisms will have fecal leukocytes in the stool. Fecal leukocytes are also found in patients with *Campylobacter*, *Y. enterocolitica,* invasive *E. coli,* and *V. parahaemolyticus*. Although a negative test does not rule out invasive disease, a positive test (more than five fecal leukocytes per high-power field) increases the likelihood of an invasive pathogen and should be followed with a stool culture.

BOX 167.3 Indications for Medical Evaluation of Children With Acute Diarrhea

- Young age (e.g., <6 months old or weight <8 kg)
- History of premature birth, chronic medical conditions, or concurrent illness
- Fever to ≥38°C for infants <3 months or ≥39°C for children 3 to 36 months old
- Visible blood or mucus in stool
- High output, including frequent and substantial volumes of diarrhea
- Persistent vomiting
- Caregiver's report of signs consistent with dehydration (e.g., sunken eyes or decreased tears, dry mucous membranes, or decreased urine output)
- Change in mental status (e.g., irritability, apathy, or lethargy)
- Suboptimal response to oral rehydration therapy (ORT) already administered or inability of the caregiver to administer ORT

Modified from: King CK, et al. Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52:1.

Stool culture is not indicated in most cases of uncomplicated AGE. Stool cultures should be obtained when needed to guide specific therapy, hospitalization, or infection control measures. We recommend stool cultures in patients with systemic involvement, underlying chronic medical conditions, dysenteric features, or a prolonged course (longer than 2 weeks). Many hospital laboratories do not include testing for *E. coli* O157:H7 or *Y. enterocolitica* in their routine stool culture, thus the emergency clinician should order these tests separately. According to the CDC, all stools submitted for testing for *Salmonella, Shigella,* and *Campylobacter* (routine stool culture) should be cultured for *E. coli* O157:H7. These stools should also be simultaneously assayed for non-O157 STEC with tests that detect the Shiga toxins or the genes encoding these toxins. In immunosuppressed patients, patients with chronic disease, infants younger than 3 months, or children with possible bacteremia or localized invasive disease, a complete blood count, stool studies, blood and urine cultures, chest x-ray, and lumbar puncture should be considered. For patients with more than 2 weeks of watery diarrhea, consider sending stool for enzyme-linked immunoassay for rotavirus; consider ova and parasites in those with a history of travel to an endemic area.

There is an increase use of culture-independent diagnostic tests for diagnosing intestinal infections: bacterial, viral, and protozoan. CIDTs work by detecting the presence of a specific antigen or genetic sequence of an organism. CIDTs do not require isolation or identification of living organisms. Consequently, these tests can be conducted more rapidly and yield results within a few hours. However, they do not produce bacterial isolates that are needed to distinguish between strains and subtypes of bacteria, information needed to detect and prevent outbreaks, track antibiotic resistance, monitor disease trends, and assess prevention measures. The CDC is encouraging clinical laboratories to do cultures when CIDTs are positive and considering ways to make follow-up cultures easier and cheaper for clinical laboratories. The CDC is encouraging companies to design their CIDTs in a way that keeps the bacteria alive so they can be cultured if the test is positive. The CDC is also adapting their surveillance systems, such as the Foodborne Disease Active Surveillance Network or FoodNet, to include infections diagnosed only by CIDTs.[60]

Differential Diagnoses

Most children with diarrhea or vomiting have a relatively benign cause of their illness, but more serious diagnoses should be considered and ruled out. A few disorders causing diarrhea may be life-threatening in children: intussusception, HUS, pseudomembranous colitis, appendicitis, toxic megacolon, and in very young infants, the congenital secretory diarrheas. See Tables 167.7 and 167.8 for other conditions that may cause vomiting and diarrhea.

Management

The American Academy of Pediatrics (AAP), The European Society of Pediatric Gastroenterology and Nutrition, and the WHO all recommend oral rehydration solution as the treatment of choice for children with mild to moderate dehydration (see the Dehydration section). In addition to fluid resuscitation, the priorities in ED management of children with diarrhea are to consider and rule out potential causes of diarrhea, assess for and treat underlying fluid and electrolyte deficits and potential complications, determine which patients require prolonged treatment or hospitalization, and arrive at a microbiologic diagnosis when indicated. Tables 167.4 and 167.6 list the common infectious agents of diarrhea and their recommended treatment.

Antibiotics are not needed in viral gastroenteritis or in most cases of uncomplicated bacterial gastroenteritis in healthy patients. Antibiotics are routinely recommended for *C. difficile, Giardia intestinalis,* and *E. histolytica* and can be considered in *Shigella, Campylobacter,* and

TABLE 167.7 Common Causes of Vomiting in Children

Etiologic Category	Clinical Syndromes
Central nervous system (CNS)	Infections, space-occupying lesion
Gastrointestinal	Obstruction, peritonitis, hepatitis, liver failure, appendicitis, pyloric stenosis, midgut volvulus, intussusception, inborn errors of metabolism
Drug	Ingestion, overdose, drug effect
Endocrine	Addisonian crisis, diabetic ketoacidosis, congenital adrenal hyperplasia
Renal	Urinary tract infection, pyelonephritis, renal failure, renal tubular acidosis
Cardiac	Congestive heart failure of any cause
Infection	Pneumonia, acute otitis media, sinusitis, sepsis
Other	Psychogenic, respiratory insufficiency

TABLE 167.8 Common Causes of Diarrhea in Children

Etiologic Category	Clinical Syndromes
Gastrointestinal	Malabsorption (e.g., milk intolerance, excessive fruit juice), inflammatory bowel disease, irritable bowel syndrome, short gut syndrome
Drug	Ingestion, overdose, drug effect
Endocrine	Thyrotoxicosis, addisonian crisis, diabetic enteropathy, congenital adrenal hyperplasia
Renal	Urinary tract infection, pyelonephritis
Infection	Pneumonia, acute otitis media, sinusitis, sepsis
Other emergencies	Intussusception, appendicitis, hemolytic uremic syndrome (HUS), pseudomembranous colitis, toxic megacolon, and in very young infants, the congenital secretory diarrheas
Other	Parental anxiety, chronic nonspecific diarrhea

Cryptosporidium. Premature babies (younger than 1 year old), neonates, young infants, and patients with immunosuppression, chronic diseases, and articular or valve prostheses are at increased risk for developing complications from pathogens causing acute diarrhea (e.g., bacteremia, sepsis, invasive disease, extraintestinal disease). Antibiotics should be considered in these populations based on severity of presentation and in consultation with appropriate specialists (e.g., pediatric infectious disease specialist, pediatric oncologist, or pediatric cardiologist). Children with bloody diarrhea are at higher risk for complications, including sepsis and other systemic diseases, and should be considered for admission. In the majority of cases, empirical antimicrobial agents should not be administered while awaiting culture results. Antimicrobial therapy may not be indicated, even when culture results are positive, and antibiotics may increase the risk for developing HUS if the offending agent is STEC.[61] For severe watery diarrhea in a traveler to a developing country, azithromycin or a fluoroquinolone may be considered.[51]

Antidiarrheal compounds that impair gastrointestinal motility, such as loperamide (Imodium), diphenoxylate, and atropine (Lomotil), can prolong and exacerbate disease and have no role in the treatment of acute infectious diarrhea in young children. These agents may also cause lethargy, paralytic ileus, toxic megacolon, CNS depression, coma, and even death.[61]

Probiotics have been studied extensively over the past several years for the treatment of acute infectious diarrhea. Studies done in the past showed that probiotics, especially *Lactobacillus rhamnosus* (LGG), decrease the duration of diarrhea by approximately one day. Recent studies evaluating specific probiotics (i.e., *Lactobacillus reuteri*,[62] *Lactobacillus casei* variety rhamnosus,[63] and *Bifidobacterium lactis*64) found a modest decrease in duration, frequency of diarrhea, and length of hospital stay in patients with acute infectious diarrhea. The European Society of Gastroenterology, Hepatology, and Nutrition recommend that only LGG and *S. boulardii* be considered in the treatment of AGE in children as an adjunct to oral rehydrating solution.[65] Recommendations for children in the Asia–Pacific region have also strongly supported the use of LGG and *S. boulardii* as adjunct treatments to oral rehydration therapy for gastroenteritis.[66] However, the PECARN Probiotic Study Group recently published a large prospective, randomized, double-blind trial involving over 900 children 3 months to 4 years of age with acute gastroenteritis. They found that the children receiving LGG did not benefit with respect to the duration or frequency of vomiting or diarrhea, the rate of household transmission, or the duration of day-care or work absenteeism.[67] No studies have found any significant side effects in probiotics used in otherwise healthy children. However, it is recommended that caution be used for premature infants, immunocompromised and critically ill patients, and those with central venous catheters, cardiac valvular disease, and short–gut syndrome.[66] Further research is needed to establish efficacy, safety, and dosing of probiotics for children with acute infectious diarrhea.

Zinc deficiency is common in developing countries and occurs in most parts of Latin America, Africa, the Middle East, and south Asia. During the past 10 to 15 years, studies have shown that zinc supplementation given to children living in developing countries has decreased the duration and severity of diarrhea illness. A recent Cochrane review of 33 published studies including over 10,000 children found zinc supplementation may be effective in reducing the duration of diarrhea in children older than 6 months in areas where zinc deficiency and moderate malnutrition are prevalent.[68] The WHO recommends zinc supplementation (10 to 20 mg/day for 10 to 14 days) for all children younger than 5 years old with AGE, although few data exist to support this recommendation for children in developed countries.

Disposition

Most cases of childhood diarrhea can be managed on an outpatient basis by continuing breastfeeding, routine formula, or diet specific for age. Supplemental maintenance electrolyte solutions may be given or recommended to purchase over the counter. Before discharge from the ED, careful and specific instruction about the signs and symptoms of expected improvement or complications should be given to the parents or caregiver. Instructions should address proper hygiene and handwashing techniques to prevent others from contracting the illness. Follow-up by the patient's primary care physician should be timely and address concerns of worsening of the condition and potential complications. Hospitalization should be considered in children at high risk for complications: infants, especially those younger than 3 months old; very-low-birth-weight infants; children with chronic medical problems; children with electrolyte abnormalities who require IV repletion; children with severe dehydration; and children with dysentery. Hospitalization may also be warranted in cases of protracted vomiting, diarrhea with losses in excess of fluid administration, worsening clinical status despite therapy, presence of an underlying condition that would complicate therapy, or suspected systemic involvement. Very-low-birth-weight infants, because of low physiologic reserve and immature immune system, are at the highest risk for complications of AGE in the first year of life.

TABLE 167.9 Isonatremic, Hyponatremic, and Hypernatremic Volume Depletion

Volume Depletion Type	Sodium and Water Balance	Pathologic Causes	Fluid Shifts	Osmotic CNS Complications
Isonatremic (Na 130–150 mEq/L)	Balanced loss of sodium and free water	GI fluid loss with or without replacement	None	None
Hyponatremic (Na <130 mEq/L)	Greater sodium loss	GI fluid loss with excess free water replacement, cerebral salt wasting, syndrome of inappropriate antidiuretic hormone (SIADH)	Shift to intracellular space; Depleted intravascular volume (appears more ill than history suggests)	Cerebral edema, seizures
Hypernatremic (Na >150 mEq/L)	Greater free water loss, associated with severe dehydration	GI losses with hypertonic fluid replacement or poor breastfeeding, excess insensible losses, diabetes insipidus	Shift to extracellular space; preserved intravascular volume (appears less ill than history suggests)	Cerebral dehydration (risk for bridging vein injury and thrombus)

CNS Complications From Rapid Correction	Skin Turgor on Exam	Management
None	Normal or tenting	Mild-moderate: oral rehydration therapy; severe: Rapid infusion of 20 ml/kg isotonic saline to restore perfusion, then oral rehydration therapy or maintenance IV fluid to resolve fluid loss
Osmotic demyelination syndrome (central pontine myelinolysis)	Tenting	Rapid infusion of 20 mL/kg isotonic saline to restore perfusion, then correction of sodium over 24–48 hours, avoid correction >10 mEq/L/day
Cerebral edema	Doughy	Rapid infusion of 20 mL/kg isotonic saline to restore perfusion, then correction of sodium over 24–48 hours, avoid correction >10 mEq/L/day

DEHYDRATION

Foundations

Anatomy and Physiology

The average adult male and female bodies are comprised of approximately 60% and 50% water, respectively. Total body water is divided between the extracellular (one-third) and intracellular compartments (two-thirds). The extracellular compartment is further divided into interstitial fluid (three-quarters) and plasma (one-quarter). Interstitial fluid serves as a reservoir to replenish intravascular plasma volume in hypovolemia. Water makes up over 70% of an infant's total body weight; the majority of this "extra" fluid resides in the extracellular compartment. Because infants excrete far more water than adults per body weight (100 mL/kg versus 40 mL/kg daily), they require far more water per body weight to maintain homeostasis. As a result, infants and children are more vulnerable to rapid volume depletion from decreased water intake or increased output.

Pathophysiology

Volume depletion management and complications depends on serum sodium concentration (Table 167.9). The most common clinical presentation is isonatremic volume depletion with hypernatremic volume depletion being less common than isonatremic or hyponatremic volume depletion.

Metabolic acidosis often accompanies pediatric dehydration due to AGE through several mechanisms: bicarbonate loss in the stool, starvation causing ketone production, decreased tissue perfusion leading to anaerobic metabolism and lactic acid production, and decreased hydrogen ion excretion from poor renal perfusion. For the majority of patients, the acidosis is easily reversed by oral or parenteral volume replacement.

Clinical Features

The severity of dehydration is usually measured as the acute weight loss (presumably fluid loss) as a percentage of pre-illness total body weight.

TABLE 167.10 Clinical Assessment of Degree of Dehydration

	Mild (3% To 5%) (30 to 50 mL/kg)	Moderate (5% To 10%) (60 to 100 mL/kg)	Severe (>10%) (90 to 150 mL/kg)
Signs and Symptoms			
Dry mucous membrane	±	+	+
Reduced skin turgor (pinch retraction)	–	±	+
Depressed anterior fontanel	–	+	+
Mental status	Alert	Irritable	Lethargic
Sunken eyeballs	–	+	+
Hyperpnea	–	±	+
Hypotension (orthostatic)	–	±	+
Increased pulse	–	+	+
Capillary refill	<2 seconds	>2 seconds	>2 seconds

+, Present; –, absent; ±, variable.

Dehydration of 3% to 5% or more is considered significant and can often be identified by history and physical examination (Table 167.10). Because pre-illness weights are neither generally available nor reliably reported, the clinician should rely on historical information and physical examination findings to assess the severity of dehydration. Parental reports of decreased oral intake, urine output, and tear production are of significant value, with good sensitivity in detecting dehydration. In a child who is dehydrated, initial physical examination may reveal an

Fig. 167.1 Skin tenting. (Image courtesy of Dr. Stanley Inkelis.)

activity level lower than expected for age. The child may also appear weak or lethargic. If the fontanel is still open, it may be sunken. The eyes may appear sunken and the mucous membranes dry. However, if the child has recently had something to drink, the mucous membranes may falsely appear moist. Tachycardia and hyperpnea may be present. The skin over the trunk should be examined for tenting (Fig. 167.1; suggesting hyponatremia) or a doughy texture (suggesting hypernatremia). The three most useful signs to determine dehydration of more than 5% are prolonged capillary refill time, abnormal skin turgor, and abnormal respiratory pattern. However, clinical signs and symptoms of dehydration are variable and often subtle and determining the severity of dehydration is an ongoing challenge for emergency clinicians. Because individual signs are often inadequate for accurately diagnosing dehydration and estimating severity, most recent research has focused on noninvasive methods of dehydration assessment, including clinical scoring systems, bedside ultrasound, and laboratory testing.[69]

Clinical scoring systems have been developed by combining historical features and examination findings in an effort to better predict the presence and severity of pediatric dehydration. The Clinical Dehydration Score (CDS) and the Gorelick scale (Table 167.11) are the most widely used and well-studied. In 2015, a meta-analysis found both the CDS and Gorelick scale improve diagnostic accuracy over unstructured clinician assessment. However, with only approximately 80% accuracy, neither can definitively rule in or out dehydration in infants and children.[69] Falszewska and colleagues analyzed a cohort of 118 patients hospitalized for dehydration with the CDS, Gorelick, and WHO scales in 2017 and found only the CDS to be useful only in ruling in (LR 3.9) moderate dehydration (>6 %).[70] This suggests that additional clinical tools are needed to aid in the diagnosis of dehydration.

Diagnostic Strategies

The role of point-of-care ultrasound (POCUS) in the assessment of volume depletion in children is uncertain. Inferior vena cava (IVC) collapsibility has not been shown to correlate with dehydration in pediatric patients. IVC to aorta diameter ratio was analyzed in a population of 771 children with diarrhea and dehydration in a resource-limited environment in Bangladesh by Modi and colleagues; they found it has an unacceptably low sensitivity (67%) and specificity (49%) for evaluation for severe dehydration.[71] Current research suggests that the POCUS measurement of the ratio of the areas of the aorta to the IVC correlate with clinical dehydration scores and that this ratio changes in response to rapid IV fluid administration.[72,73] Further research is required before this application can be recommended for routine evaluation of dehydration in pediatric patients.

Laboratory tests are of little diagnostic value in the mildly dehydrated child, but they may be helpful in the severely dehydrated or ill-appearing child to assess etiology, severity, and complications of dehydration. A serum electrolyte panel, BUN, serum creatinine, and blood glucose level are most likely to be clinically useful. Sodium concentration is important in identifying isonatremic, hyponatremic, and hypernatremic states for appropriate choice of therapy, but resuscitation and treatment should not be delayed for laboratory results. A low serum bicarbonate level may indicate bicarbonate loss in the stool or may reflect poor tissue perfusion. Children with dysentery, characterized by fever, bloody stools, and abdominal cramping, should have BUN and serum creatinine concentrations measured and stool culture specimens sent and examined for *E. coli* O157:H7 to identify potential cases of HUS. Serum glucose level is important because hypoglycemia is not uncommon in young children with AGE, and this test may help identify children with previously undiagnosed fatty acid oxidation disorders or other inborn errors of metabolism (e.g., galactosemia). Urine specific gravity and ketones are neither sensitive nor specific and should not be used in the assessment of pediatric dehydration.

TABLE 167.11 Clinical Dehydration Scale

	0	1	2
	0: No Dehydration (<3%)	**1–4: Some Dehydration (≥3% to 6%)**	**5–8: Moderate Dehydration (≥6%)**
General appearance	Normal	Thirsty, restless, or lethargic but irritable when touched	Drowsy, limp, old, sweaty, or comatose
Eyes	Normal	Slightly sunken	Very sunken
Mucous membranes	Moist	"Sticky"	Dry
Tears	Present	Decreased	Absent
	GORELICK SCALE		
	No or Minimal Dehydration	**Moderate to Severe Dehydration**	
General appearance	Alert	Restless, lethargic, unconscious	
Capillary refill	Normal	Prolonged or minimal	
Tears	Present	Absent	
Mucous membranes	Moist	Dry, very dry	
Eyes	Normal	Sunken, deeply sunken	
Breathing	Normal	Deep, rapid	
Quality of pulses	Normal	Thready, weak or impalpable	
Skin elasticity	Instant recoil	Slow recoil, recoil >2 seconds	
Heart rate	Normal	Tachycardia	
Urine output	Normal	Reduced	

Four-point scale (italics): Two signs or more ≥5%; three signs or more ≥10%.
Ten-point scale (including all): Three signs or more ≥5%; seven signs or more ≥10%.

TABLE 167.12 Differential Diagnosis of Volume Depletion

Fluid Loss Category	Potential Etiologic Disorders or Conditions
Renal	Diuretics, renal tubular acidosis, renal failure, urinary tract obstruction, diabetes insipidus, diabetes mellitus, hypothyroidism, adrenal insufficiency, renal trauma, salt-wasting nephritis
Extrarenal	Third spacing (pancreatitis, peritonitis, sepsis), skin loss (burns, cystic fibrosis), lung loss, congestive heart failure, liver failure, hemorrhage

BOX 167.4 Principles of Appropriate Treatment of Children With Diarrhea and Dehydration

Oral rehydration solutions should be used for rehydration.
Oral rehydration should be performed as rapidly as possible.
Unrestricted diet is recommended as soon as dehydration is corrected.
For breast-fed infants, nursing should be continued.
For formula-fed infants, diluted formula is not recommended. Special formula is not necessary.
Additional oral rehydration solution should be administered for ongoing diarrheal losses.

Modified from: King CK, et al. Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep.* 2003;52:1.

Differential Diagnoses

Most commonly, dehydration in children results from diarrhea and vomiting caused by infectious gastroenteritis. Table 167.12 lists some other causes of dehydration that should be considered when the gastrointestinal tract is not primarily involved.

Management

Oral Rehydration Therapy

Oral rehydration therapy (ORT) is a safe and effective treatment of infants and children with mild to moderate dehydration. ORT may be instituted even if the patient continues to vomit or has diarrhea. However, children with severe dehydration, shock, lethargy, acute abdomen, suspected intestinal obstruction, sodium derangement, or significant underlying illness should receive IV fluids. Some of these principles are illustrated in Box 167.4.

The ORT period in the ED may span 4 to 8 hours and provides an opportunity to educate the family in skills of evaluating and treating childhood diarrhea. A number of oral rehydration solutions have been shown to be effective. The main ingredients are water, glucose, sodium chloride, citrate, and bicarbonate in various concentrations. In most situations, rehydration can be accomplished without the risk of causing hyponatremia or hypernatremia. Polymer-based carbohydrate solutions (derived from wheat or rice) continue to be investigated as an alternative to glucose-based solutions. A Cochrane review in 2016 showed that patients treated with polymer-based solutions compared with high osmolarity solutions (>310 mOsm/L) had cessation of diarrhea sooner.[74] Their comparison of polymer-based solutions to low osmolarity solutions (<270 mOsm/L, which describes most current oral rehydration solutions) trended towards faster resolution of diarrhea, but the study was not powered sufficiently to demonstrate the effect. These data suggest that polymer-based and low osmolarity glucose solutions are both effective at treating mild to moderate dehydration.

In infants and children with minimal dehydration, treatment should be directed at maintaining hydration and nutrition with an age-appropriate diet. Freedman and colleagues showed that children age 6 months old to 60 months old with mild dehydration (CDS of 4 or less and with capillary refill < 2 seconds) from AGE given dilute apple juice in the ED and discharged with instructions for patient preference of hydration had significantly less treatment failure and less frequent need for IV fluids compared to children given oral rehydration solution in the ED and discharged with oral rehydration solution information.[75] This suggests that age-appropriate diet and fluids of patient preference is an effective alternative to oral rehydration solutions in patients with mild dehydration from AGE. Fluid intake should be increased, or oral rehydration can be administered to cover maintenance and to replace losses. Losses can be replaced at 10 mL/kg for each stool and 2 mL/kg for each emesis. Diet should not be restricted.

Children with mild to moderate dehydration should have their estimated fluid deficit replaced, often started in the ED and continued at home. The volume of ORT is calculated in the following manner:

1. Estimate the degree of volume depletion as mild or moderate with information from the history, clinical signs, and physical examination findings (see Tables 167.10 and 167.11).
2. Calculate the desired volume of oral rehydration solution as 30 to 50 mL/kg for mild (3% to 5%) and 60 to 80 mL/kg for moderate (6% to 9%) volume depletion.
3. Administer 25% of the volume of oral rehydration solution to be replaced each hour for the first 4 hours.
4. Replace ongoing losses at 10 mL/kg for each stool and 2 mL/kg for each emesis.
5. Monitor progress hourly and reevaluate frequently.

This technique requires that the ED have the facilities and personnel to observe and to monitor the patient for an extended time to determine the success or failure of ORT. The parent or other caregiver should be taught to administer ORT. Nursing personnel should instruct the parent in observation skills, methods of administration of the fluid, and types of fluid that are considered appropriate for children with vomiting and diarrhea. During the monitoring period, a child who is unable to tolerate intake of the prescribed volume of fluid at the expected rate should receive IV fluids. It is important to determine whether the failure is the result of the child's inability to ingest the fluid, excessive fluid loss through vomiting or diarrhea, or poor technique or motivation on the parent's part. It usually is possible to maintain the fluid administration rate in children who continue to vomit by administering small volumes frequently. This may require, for instance, use of a spoon or syringe to slowly drip the fluid by hand. Some success has been obtained with the use of nasogastric tubes; this method is often useful for prolonged fluid replacement in an inpatient setting, though its invasiveness limits its use.

The patient is reassessed at the end of the first few hours of ORT. If the clinical examination indicates adequate volume repletion, the child may be discharged home with further specific instructions for parents about maintenance fluid requirements with oral rehydration solution. If the child still exhibits mild or moderate volume depletion on clinical examination but no deterioration in status has occurred, another 2- to 4-hour trial may be warranted. If the child is unable to ingest the appropriate volume to keep up with ongoing losses, or if volume repletion is not adequate at the end of 8 hours, IV therapy and admission are recommended.

Ondansetron has become a useful adjunct in the treatment of AGE in the ED. Ondansetron, a selective 5-hydroxytryptamine type 3

receptor antagonist, acts at chemoreceptors in the peripheral and CNS to alleviate nausea. Ondansetron has been shown in a meta-analysis of numerous well-designed studies in children to reduce episodes of vomiting in the ED, improve oral intake in the ED, reduce the need for IV fluid rehydration, and reduce admissions.[76] Prescribing oral ondansetron for home use with good return precautions is safe in AGE, but multiple studies have shown it does not significantly change frequency of ED return visits.[77,78] Further research on patient-centered outcomes in this area is needed to evaluate the effectiveness of ondansetron prescriptions in outpatient management of dehydration.

Intravenous Therapy

Some dehydrated children brought to the ED may not qualify for ORT, and others may fail to improve with ORT. These patients include those with shock, severe dehydration, increasing deficit or clinical deterioration during ORT, intractable vomiting, hypoglycemia, or electrolyte derangements.

Patients are evaluated in accordance with their immediate (emergency phase), short-term (repletion phase), and long-term (early refeeding phase) needs.[79] During the *emergency* phase, the aim of fluid resuscitation is to restore circulatory volume. Fluid needs to be administered rapidly to prevent tissue hypoperfusion, end-organ damage, and death. During the *repletion* phase, fluid and electrolyte derangements are reversed, and ongoing losses are replaced. This phase lasts 24 hours. In the *early refeeding* phase, long-term needs are addressed in the next few days, during which the body recovers fluid, electrolyte, and nutritional homeostasis. Immediate and short-term therapies are initiated in the ED, with subsequent phases carried out in the inpatient setting or at home through the primary care physician. In clinical practice, this algorithm represents a continuum of care and not three separate phases.

Emergency Resuscitation Phase. Rapid reexpansion of the intravascular space is the goal of immediate resuscitation and can be achieved with an isotonic crystalloid solution. Administration of 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) intravenously at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. Avoid low sodium solutions such as lactated Ringers solution (Na 130 mEq/L) in isonatremic and hyponatremic volume depletion.[80] In critical situations, intraosseous routes should be used if venous access is not immediately available. Patients should be reevaluated periodically, and those with excessive deficits should receive repeated boluses of 20 mL/kg until clinical improvement occurs. Signs of recovery include normalization of blood pressure measurements, improvement of mental status, improvement of tachycardia and capillary refill time, and production of urine. Intravenous volume replacement greater than 60 mL/kg, without signs of improvement, warrants investigation for other conditions, such as cardiogenic shock, septic shock, hemorrhage, capillary leak with third-space fluid sequestration, adrenal insufficiency, and toxic shock.

A rapid determination of serum glucose is important. Children require glucose as an energy substrate and often have marginal stores available in illnesses. If the serum glucose concentration is low (<50 mg/dL), dextrose 0.25 to 0.5 g/kg should be rapidly administered intravenously or intraosseously. Glucose can be administered per the "rule of 50," whereby the percent dextrose multiplied by the number of mL per kilogram equals 50. For neonates, a 10% dextrose solution should be given at approximately 5 mL/kg. Children 1 month old to approximately 8 years old or 25 kg should be given 2 mL/kg of 25% dextrose. In children older than 2 years old, 1 mL/kg of 50% dextrose can be used. The higher tonicity 50% and 25% dextrose solutions have a risk of causing tissue necrosis if they extravasate during peripheral IV infusion. Ten percent dextrose is a safe and effective treatment for hypoglycemia in all ages, and it has a lower tonicity if there is concern for extravasation in a peripheral IV. Glucose levels should be monitored (every 30 to 60 minutes until stable) to ensure improvement and to identify ongoing needs. Repeated episodes of hypoglycemia should raise concern for sepsis, adrenal insufficiency, fatty acid oxidation defects, or other inborn errors of metabolism.

Dehydration due to AGE in children often leads to metabolic acidosis and ketosis, in part due to reduced carbohydrate intake leading to free fatty acid breakdown. It has been hypothesized that the addition of dextrose to initial IV rehydration fluids in moderately to severely dehydrated children will stimulate insulin release, reduce free fatty acid breakdown and ketone production, and reduce ketone-induced nausea and vomiting. A meta-analysis of two studies that had 333 pooled, randomized patients to IV solutions with and without glucose, found no difference in hospitalization rates or ED return visits.[81] Further research focusing on patient-oriented outcomes is needed to determine whether dextrose should be included in the optimal rehydration regimen for moderately to severely dehydrated children requiring IV hydration.

Repletion Phase. Appropriate fluid therapy for the patient should be determined after initial resuscitation. Some patients may tolerate ORT; others may require ongoing parenteral hydration with 5% dextrose in half-normal normal at a weight-appropriate maintenance volume (Table 167.13), compensating for ongoing losses (10 mL/kg and 2 mL/kg for each diarrhea and vomiting episode, respectively). Potassium may be added to maintenance fluids once urine output is established and serum potassium levels are within a normal range. Overly rapid correction of serum sodium levels can lead to osmotic demyelination syndrome (central pontine myelinolysis) in hyponatremia and cerebral edema in hypernatremia.[80] Neurologic status and serum sodium concentration should be closely monitored and the amount of sodium content of repletion fluid adjusted to maintain a slow correction. Ongoing sodium losses should also be replaced. In addition to oral, IV, intraosseous, and nasogastric routes of fluid delivery, hyaluronidase-facilitated subcutaneous hydration (hypodermoclysis) offers yet another alternative for treatment of dehydration. A small-gauge catheter is inserted in subcutaneous tissue in an area without local neurovascular structures (e.g., between scapulae, anterior chest, deltoid, anterior/lateral thigh) and 20 ml/kg isotonic crystalloid can be infused. Hyaluronidase (150 units subcutaneously, independent of age or weight) breaks down hyaluronic acid, a chief component of the extracellular matrix that holds body tissues together and expedites the subcutaneous infusion. Subcutaneous hydration can be performed without hyaluronidase at a significantly reduced rate, limiting its utility in the ED. Certain medications, such as ondansetron and other antiemetics, can be administered by this route.[82] Subcutaneous hydration should be considered in mildly to moderately dehydrated children who are unable to tolerate oral fluids and who have difficult IV access; patients with severe dehydration should be evaluated for intraosseous or IV access.

TABLE 167.13 Holliday-Segar Method for Maintenance IV Fluids

	MAINTENANCE RATE	
Body Weight	**mL/kg/day**	**mL/kg/hr**
First 10 kg	100	4
Second 10 kg	50	2
Each additional kg	20	1

Modified from: Nalley CM. Fluids and electrolytes. In: Hughes HK, Kahl LK, editors. *The Harriet Lane Handbook: A Manual for Pediatric House Officers,* ed 21. Philadelphia: Saunders; 2018: 290-315.

Hospital-Acquired Hyponatremia. IV rehydration can lead to hyponatremia in children. This rare complication can lead to significant neurologic morbidity, including seizures, coma, and brain herniation or even death; children receiving IV fluids should have their neurologic status closely monitored. AAP clinical practice guidelines recommend use of isotonic saline for maintenance IV fluids, except in patients with voluminous watery diarrhea; in these patients, providers should consider hypotonic maintenance fluids to treat persistent free water loss with higher than normal maintenance rates.[83]

Disposition

Children with severe dehydration, intractable vomiting, inability to maintain oral hydration, severe metabolic acidosis or sodium derangement, or whose caregivers are unable to provide adequate care at home should be hospitalized. Observation status is often suitable for severely dehydrated children showing signs of improvement during their ED course.

CHAPTER 167: QUESTIONS AND ANSWERS

1. For which of the following patients should the emergency clinician not obtain diagnostic testing of the stool?
   - **a.** 1-month-old with fever to 38°C with bloody diarrhea
   - **b.** 8-month-old with sickle cell disease with fever and diarrhea
   - **c.** 12-month-old, well-appearing child with 2 days of watery diarrhea
   - **d.** 2-year-old with nephrotic syndrome on prednisone with diarrhea and fever for 3 days
   - **e.** Community outbreak of diarrhea

   Answer: C. Most children with uncomplicated gastroenteritis or acute diarrhea do not need laboratory studies. Stool cultures are useful and important to obtain in febrile infants and children with blood in their stools, in community outbreaks, and in the immunosuppressed.

2. A 4-year-old child presents with moderate dehydration from gastroenteritis. He is still actively vomiting. Which of the following statements regarding this patient's rehydration is correct?
   - **a.** A nasogastric tube should be placed for rehydration.
   - **b.** Oral rehydration should not be started.
   - **c.** Oral rehydration success can be determined in 2 or 3 hours.
   - **d.** Oral rehydration target volume is 80 mL/kg.
   - **e.** Target oral rehydration volume should be administered over 2 hours.

   Answer: D. Oral rehydration can be effective even in the face of vomiting in cases of mild or moderate dehydration. Target oral volumes are 60 and 80 mL/kg, respectively. Nasogastric tubes may occasionally be useful but should not be used unless oral rehydration therapy (ORT) fails. The target oral volume should be given in doses of 25% of total replacement per hour over 4 hours.

3. A 9-year-old child with a history of sickle cell disease presents for evaluation of fevers, diarrhea, and vomiting. The parents say the patient has not had a sickle cell crisis in almost a year. On examination, the vital signs are stable and the child is nontoxic-appearing with mild dehydration. His abdominal examination is benign. In addition to rehydration, which of the following would be the most appropriate management and disposition for this child?
   - **a.** Obtain blood cultures and admit for observation.
   - **b.** Obtain cultures (stool and blood), begin antibiotics, continue hydration, and admit for observation.
   - **c.** Obtain electrolytes; and if he has a normal bicarbonate level, then discharge home.
   - **d.** Perform a stat Rotazyme assay; and if negative and patient tolerates oral intake, then discharge home.
   - **e.** Provide oral rehydration therapy (ORT); and if successful, then discharge home.

   Answer: B. Patients with sickle cell disease are more susceptible to *Salmonella* infections and are at increased risk for complications. It has been shown that giving antibiotics to patients with nontyphoidal *Salmonella* has been ineffective in shortening the duration of symptoms and prolonging the carrier state. Therefore, antibiotics are generally not recommended for asymptomatic cases or for uncomplicated cases. However, antibiotic treatment is indicated in infants younger than 3 months old or those with complications, such as failure to improve within 5 to 7 days; bacteremia; focal infection in the central nervous system (CNS), bone, joint, kidney, or pericardium; or those with immunosuppressive conditions, hemoglobinopathies, malignant neoplasms, human immunodeficiency virus (HIV), or chronic gastrointestinal disease. The recommended antibiotics are for unknown susceptibility or in areas of high resistance to use ceftriaxone or cefotaxime until susceptibility is known. Ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX) may also be effective, but they should be used only in high-risk individuals once susceptibility is known.

4. A 5-month-old infant presents with persistent vomiting and diarrhea for 3 days. The parents came to the emergency department because their child suddenly seemed to be passing out. Parents have noted significant weight loss and poor breastfeeding. Exam shows an unconscious infant with doughy skin and dry mucous membranes. IV access is obtained, the airway is secured, and a normal saline infusion is started. What central nervous system complication of dehydration is most likely in this patient?
   - **a.** Cerebral edema
   - **b.** Central pontine myelinolysis
   - **c.** Hypoxic ischemic encephalopathy
   - **d.** Primary epilepsy
   - **e.** Subdural hematoma

   Answer E: The clinical picture suggests hypernatremic dehydration (infant with poor breastfeeding, doughy skin, significant weight loss). Hypernatremia leads to dehydration and shrinking of the brain, which increases the risk of injury to bridging veins, subdural hematoma, and CNS thrombi. Cerebral edema is a complication of hyponatremic dehydration (more often in older children with skin tenting on examination). Central pontine myelinolysis is a complication of rapid sodium correction in hyponatremic dehydration. HIE and epilepsy are not complications of dehydration alone.

5. A 4-year-old girl presents with acute gastroenteritis. On history and examination the child has lost 12% of her weight from her last primary care appointment 3 weeks ago. She appears lethargic and has mottled skin with a capillary refill of 5 seconds. Multiple attempts at IV access are unsuccessful. What is the next best approach for rehydration?
   - **a.** Hypodermoclysis (subcutaneous rehydration)
   - **b.** Obtain intraosseous access
   - **c.** Oral ondansetron
   - **d.** Nasogastric tube insertion
   - **e.** Transfer to a pediatric tertiary hospital

   Answer B: Patients with severe dehydration (>10 % body weight loss) or evidence of decreased perfusion (poor capillary refill, lethargy) should have emergent infusion of isotonic crystalloid at a rapid rate to restore perfusion. In this patient, the fastest method to achieve this is with intraosseous access. In a conscious patient, the line can be primed with lidocaine for 1 to 2 minutes before the infusion to help with the pain of the infusion. Hypodermoclysis, nasogastric tube rehydration, and oral rehydration are all appropriate management options for mild-moderate dehydration. Transferring the patient before IV rehydration would delay her care and increase her mortality risk.

Pediatric Genitourinary and Renal Tract Disorders

Brittany Boswell and Anita A. Thomas

FOUNDATIONS

Genitourinary (GU) and renal tract emergencies in children are common. These issues span age and gender and have varying clinical presentations. Underlying pathology is due to both congenital and acquired disease. Careful history of present illness and family history can help guide a focused differential diagnosis. A complete physical is especially important in children who present with abdominal pain; in particular, a GU examination must be performed for any male that presents with abdominal pain because children may not be as forthright with GU complaints. The history and complete physical are key in guiding workup and management of renal and GU emergencies. This chapter outlines the most prevalent GU and renal disorders presenting to emergency clinicians.

SPECIFIC DISORDERS

Priapism

KEY CONCEPTS

- Ischemic priapism is a urologic emergency due to compartment syndrome of the penis and is managed with local analgesia with or without sedation, cavernosal aspiration, irrigation, and possibly injection with phenylephrine.

Foundations

Priapism is a pathologic painful penile erection, unrelated to sexual stimulation, lasting more than 4 hours. There are three types of priapism: low flow (ischemic), high flow (nonischemic), and stuttering (recurrent). Ischemic priapism is due to venous occlusion, leading to compartment syndrome of the penis, and is a *urologic emergency*. Nonischemic, or high flow priapism, is due to unregulated cavernosal blood flow, often due to trauma or arteriocavernous fistula, and is usually painless. In this subtype, oxygenation is preserved and can be managed conservatively. Lastly, stuttering priapism is due to recurrent episodes of ischemic priapism, lasting less than 4 hours. It is often self-limited, and primarily occurs in patients with sickle cell disease.

Clinical Features

Priapism is rare in pediatrics, although it may be underreported. It can occur at any age, even rarely, in the neonatal population.[1] Sickle cell disease accounts for 65% of all episodes of priapism occurring in children. Up to 89% of men with sickle cell disease have reported at least one episode of priapism before the age of twenty.[2] Patients present with painful rigidity of the corpus cavernosa and a soft glans (Fig. 168.1). Depending on the duration of the episode, one may see sequelae of ischemia such as erythema, other color change, or gangrenous appearance.

Differential Diagnoses

Priapism is a clinical diagnosis. The differential diagnosis of the underlying etiology is outlined in Table 168.1.[3] Laboratory testing can help determine an underlying etiology but is often not helpful in acute management. Complete blood count (CBC), reticulocyte count, and hemoglobin electrophoresis are useful in identifying undiagnosed sickle cell anemia. A cavernosal blood gas and color duplex ultrasonography can help differentiate the subtype of priapism.

Management

Determination of subtype and underlying etiology guide management of priapism. Ischemic priapism requires time-sensitive intervention. Conservative measures may be trialed in patients presenting before 4 hours: physical exercise, urination, and cold packs (except in sickle cell patients in which this may worsen priapism). In patients presenting after 4 hours, or in whom conservative measures have failed, additional treatment includes hydration, pain control, and local anesthesia. This should be followed with intracavernous irrigation of saline and injection of sympathomimetics to achieve detumescence. Various case reports have shown detumescence using procedural sedation alone with either ketamine or nitrous oxide.[4,5] A dorsal penile block with or without a ring block should be performed prior to intracavernous injection, using no more than 4 mg/kg of lidocaine without epinephrine (Fig. 168.2). After local anesthesia, corporal aspiration can be performed by using a 23- to 21-gauge butterfly needle in prepubescent males and a 19-gauge needle in adolescents; the needle should be inserted laterally, into the corpus cavernosum at 3 or 9 o'clock, avoiding the neurovascular bundle superiorly and the urethra inferiorly. Blood should be aspirated in 5 mL aliquots until it appears bright red followed by flush with 0.9% normal saline. A cavernosal blood gas can be sent using this sample. If detumescence is not achieved, the next step is intracavernosal injection of an alpha-adrenergic sympathomimetic agent, phenylephrine (100 mcg every 5 minutes, up to 1 hour.[6] If these measures fail, the patient should be considered for emergent urologic intervention with surgical shunt placement.

Contrary to ischemic priapism, management of stuttering and nonischemic priapism is not urgent, as many cases resolve spontaneously. Ultrasound may identify a fistula that may require arterial embolization or surgical ligation.[7]

Disposition

With successful detumescence, patients may be discharged home with close follow-up. Those who require ongoing injections of phenylephrine will likely need admission, especially if they have cardiac history. Patients who fail injection and require surgery should receive emergent urologic consultation and admission.

TABLE 168.1 Differential Diagnosis of the Underlying Etiology of Priapism

Ischemic	Nonischemic	Medication Induced	Neonatal
Hemoglobinopathy (SCD, thalassemia)	Trauma	PDE 5 inhibitor	Polycythemia
Leukemia	Hematologic (SCD, leukemia)	Hormone (testosterone)	Infection
Infection	Fabry disease	Antipsychotic	Forceps assisted delivery
Neurogenic	Iatrogenic (surgery)	Antidepressant	Respiratory distress syndrome
Toxin (scorpion, spider)		Antihypertensives	UAC manipulation
Henoch-Schönlein purpura		Alcohol, cocaine, marijuana	

Phimosis

KEY CONCEPTS

- Phimosis is usually physiologic, but is pathologic when associated with urinary retention, urinary tract infections, or balanoposthitis.

Foundations

Phimosis is a clinical diagnosis and defined as the inability to fully retract the prepuce beyond the glans penis. Parents or patients may describe a "balloon appearance" of the foreskin with urination. The majority of phimosis cases are physiologic. The ability to retract the prepuce increases with age, with 50% resolving by age one and 89% by age three.[8] Phimosis is pathologic when it leads to balanoposthitis, urinary tract infections (UTI), or urinary retention.

Diagnostic Testing

Asymptomatic patients do not require further workup, but those with pain on urination should have a urinalysis (UA) and culture to evaluate for urinary tract infection.

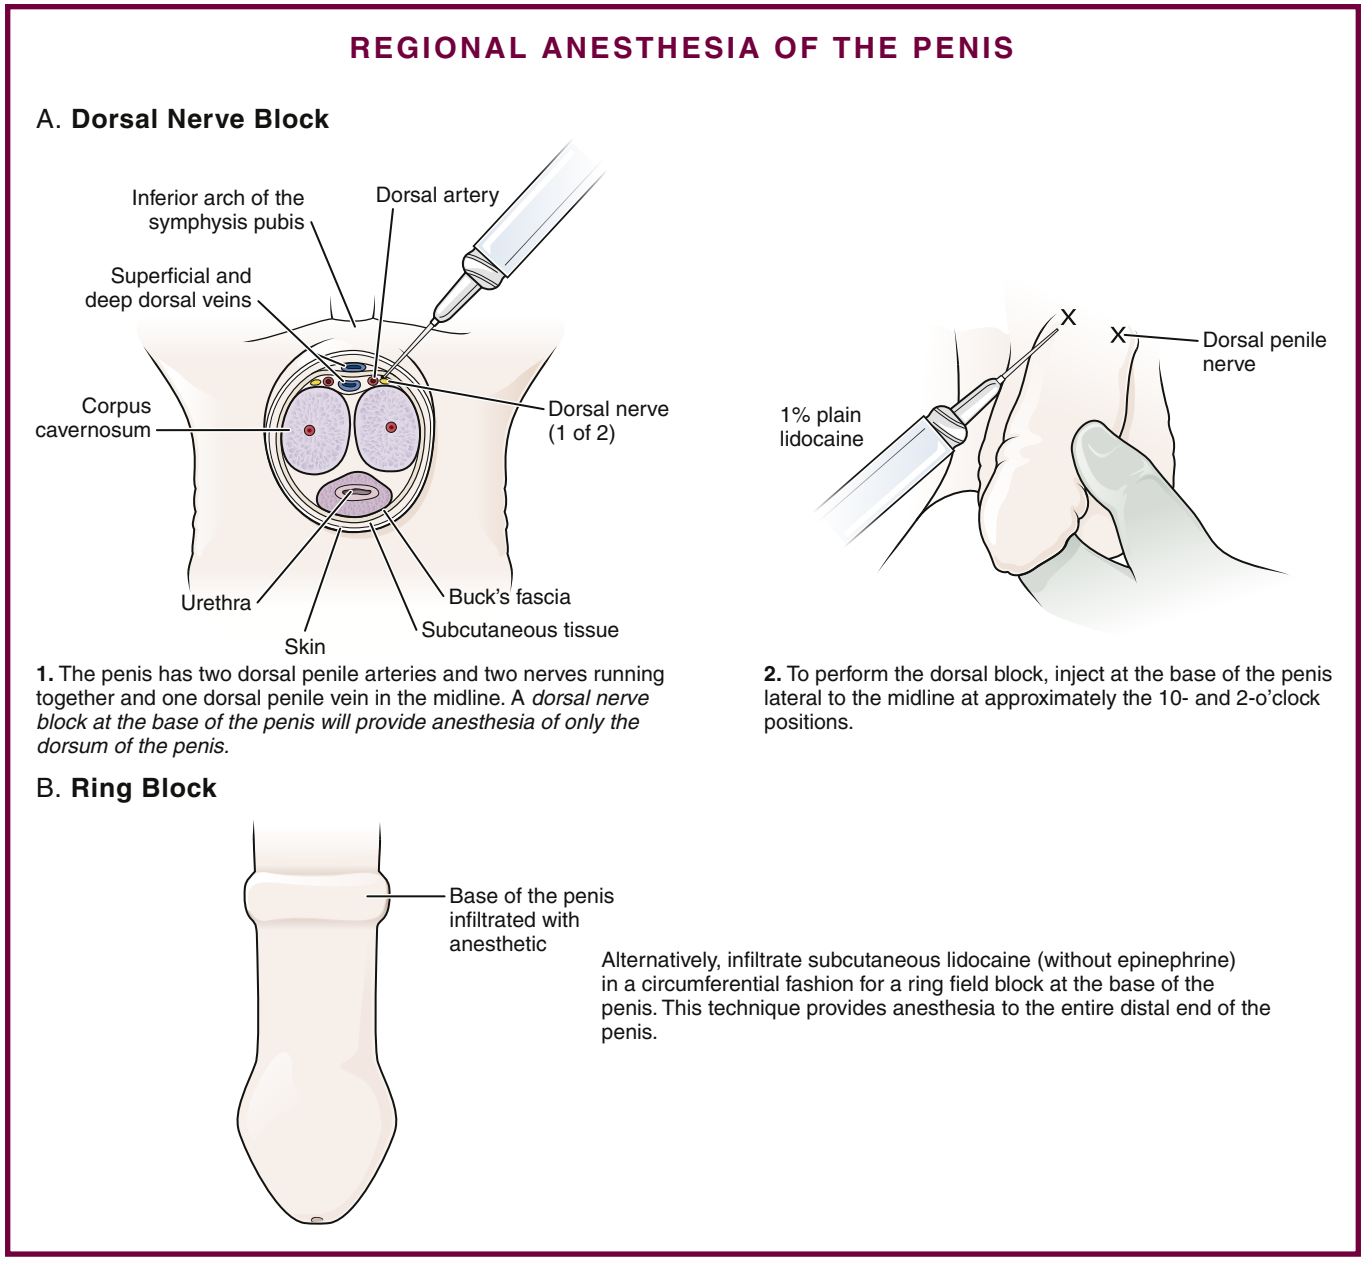

Fig. 168.2 Penile analgesia. (From: Davis JE, Silverman MA. Urologic procedures. In: Roberts JR, Custalow CB, editors. *Roberts and Hedges' Clinical Procedures in Emergency Medicine.* Philadelphia: Elsevier Saunders; 2014: 1113-1154.)

Management

Management of phimosis is conservative in most cases, but ongoing issues may require circumcision for definitive treatment. There is no general consensus among urologists on the care of phimosis.[9] Parents should be instructed on general hygiene measures of the uncircumcised penis and may practice gentle retraction beginning at 2 years of age. If there are minor recurrent issues with hygiene, infection, or urination, a course of 1% topical hydrocortisone or 0.1% topical triamcinolone applied BID for up to 12 weeks have similar rates of phimosis resolution.[8]

Disposition

Those with chronic UTIs, balanoposthitis, or issues with urination should be referred to urology for circumcision consideration. Patients who are able to urinate and have a reassuring physical examination can be managed as outpatients with primary care or urologic follow-up.

Paraphimosis

KEY CONCEPTS

- Paraphimosis is a urologic emergency wherein the foreskin of the penis is trapped at the corona, resulting in venous congestion and vascular compromise.

Foundations

Paraphimosis is a urologic emergency, wherein the foreskin of the penis is trapped behind the glans at the corona, resulting in engorgement,

Fig. 168.3 Paraphimosis in a 4-year-old uncircumcised boy. (Courtesy Dr. Marianne Gausche-Hill.)

venous congestion, and vascular compromise. If left untreated, venous congestion and arterial compromise can lead to distal ischemia and even necrosis of the penis.

Clinical Features

History may reveal a recent penile examination, Foley catheter placement, parental attempts at hygiene, trauma, or recent sexual intercourse. This occurs more commonly in the uncircumcised male, but circumcised individuals who have excessive foreskin can develop paraphimosis. On examination, patients present with painful swelling of the penis with foreskin visibly retracted behind the glans. Any discoloration may indicate ischemia and compromised blood supply (Fig. 168.3).

Diagnostic Testing

The diagnosis is clinical, based on history and physical examination, and there is no role for blood work or imaging. The penis should be inspected for hair tourniquet, which can mimic symptoms of paraphimosis.

Management

Management is directed at replacing the foreskin back over the glans penis. In uncomplicated cases, the foreskin can be manually reduced. Ice packs are useful in decreasing edema but could worsen already compromised penile arterial flow. With manual reduction, gentle pressure is applied for 5 to 10 minutes, either by hand or with compression bandages. After applying pressure to reduce the edema, the provider should use two thumbs to gently press the glans, while pulling the foreskin into place (Fig. 168.4). Osmotic methods with sugar or 20% mannitol-soaked gauze can reduce edema prior to manual reduction.

If manual reduction is not successful, analgesia with dorsal penile block and procedural sedation may be required to facilitate the procedure. If unsuccessful, a dorsal slit may be required, using two clamps at the foreskin at 12 o'clock followed by an incision to release the constriction.[10] Ultimately, surgical circumcision by a urologist may be required.

Disposition

Patients with uncomplicated cases that are manually reduced can be discharged home with outpatient follow-up. The foreskin should be inspected for any abrasions, which should be treated with topical bacitracin if found. Patients should not retract the foreskin for a week to avoid recurrence. Patients should be evaluated for need for definitive treatment with circumcision by urology. Patients with ischemia or necrosis should be admitted for pain control, antibiotics, and further care by urology.

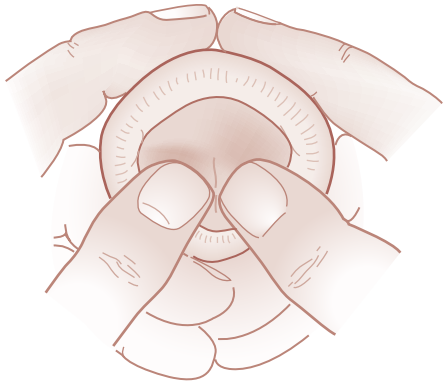

Fig. 168.4 Paraphimosis reduction. (Courtesy P.P. Kelalis.)

Balanoposthitis

KEY CONCEPTS

- Inflammation of both the glans (balanitis) and foreskin (posthitis) is usually due to poor hygiene.

Foundations

Balanoposthitis is the inflammation of both the glans (balanitis) and foreskin (posthitis) of the penis, and is most common in young uncircumcised males. In pediatrics, the majority of cases are due to poor hygiene, with accumulated sebaceous material leading to bacterial or fungal overgrowth; however, there are also other infectious (fungal, bacterial, HPV, STIs) and noninfectious (contact dermatitis, chemical irritant, trauma) etiologies to consider.[11]

Patients present with localized pain, erythema, and sometimes dysuria due to local irritation. Penile discharge, rash, or lymphadenopathy raises suspicion for a sexually transmitted infection, such as *Neisseria gonorrhea* or *Chlamydia*, whereas oral ulcerations or arthralgias may point to a rheumatologic etiology, such as psoriasis or lichen sclerosis. The foreskin should be assessed for concomitant phimosis or paraphimosis.

Clinical Features and Diagnostic Testing

The diagnosis of balanoposthitis is clinical, based on history and physical examination. Additional evaluation for patients with dysuria, discharge, extragenital findings, or recurrent balanitis may include UA, STI testing, or glucose (to assess for diabetes in recurrent candidal balanitis).

Management

Management of balanoposthitis is mainly supportive and directed at adequate hygiene measures. Parents and teenagers should be educated on hygiene and care of the uncircumcised penis. Teenagers should also be provided with education on safe sex practices. Treatment should include coverage for both bacterial and fungal overgrowth, with topical bacitracin and topical nystatin (or clotrimazole), respectively. Inflammation can be managed with 0.5% hydrocortisone cream twice daily. In the event of overlying mild cellulitis, patients should be prescribed cephalexin, 25 to 50 mg/kg/day in divided doses for seven days.

Disposition

We recommend that children who are unable to urinate, have signs of systemic illness (e.g., fever), or evidence of more than a mild cellulitis be admitted for IV antibiotics and receive consultation from a urologist.

Complications of Circumcisions

KEY CONCEPTS

- Complications of circumcisions are rare, and most commonly involve minor bleeding.

Foundations

At times a controversial topic, circumcision rates are approximately 38% worldwide.[12] The most recent American Academy of Pediatrics Task Force Recommendations in 2012 concluded that there are lifelong benefits to circumcision that outweigh the risks of the procedure itself.[13] The rate of adverse events from circumcision is low at 1% to 4%.[12]

Management

The major postoperative circumcision complication is bleeding, which may reveal an underlying coagulopathy. Coagulants such as topical thrombin and local pressure should be applied to the circumcised area;[14] patients with a bleeding diathesis may warrant a hemoglobin check and coagulopathy studies, as well as fresh frozen plasma (FFP) or factor replacement. Urgent urologic consultation may be required.

Other immediate postoperative complaints include pain, concern for infection, or extremely rarely, a more severe injury to the penis. Pain usually self-resolves and should not require intervention; if a child is older than 6 months, nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen may be trialed. As the circumcision dressing can contribute to urinary retention, patients are predisposed to a urinary tract infection. Those with symptoms should have a UA sent. Systemic infection is uncommon, but in the neonatal period may require a full septic workup with blood work, urine, and cerebrospinal fluid (CSF) studies. Delayed presentation may indicate postoperative adhesions or meatal stenosis. Adhesions or meatal stenosis require outpatient urology follow-up and potential repeat circumcision at a later date.

Penile Entrapment and Tourniquet Injuries

KEY CONCEPTS

- Foreskin injuries occur in pediatrics, and the goal is removal of the offending object to prevent further tissue damage.

Foundations

Penile injuries due to entrapment or hair tourniquet may present from childhood to adolescence and can result in neurovascular damage. Metallic rings used to improve sexual activity are placed by the patient, whereas zippers or hair are the result of accidental entrapment. These objects create damage by reducing vascular supply to the penis and can become a urologic emergency.[15]

Clinical Features and Diagnostic Testing

The patient will present with pain and swelling of penis. In the event of a hair tourniquet, the hair itself may be difficult to visualize. This does not require any lab testing or imaging, unless there is concern for underlying urethral injury, in which case a retrograde urethrogram may be required along with urology consult.

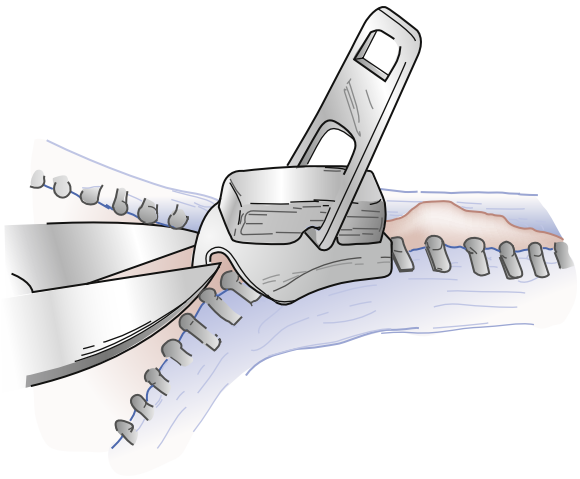

Fig. 168.5 Release of zipper entrapment by cutting of the median bar. (From: Snyder HM III, et al. Genitourinary trauma. In: Fleisher GR, Ludwig S, editors. *Textbook of Pediatric Emergency Medicine*, ed 4. Philadelphia: Lippincott Williams & Wilkins; 2000.)

Management

Management depends on the offending agent. Nonmetallic objects can be cut off with ring cutters or a saw, while using cooling agents to avoid burns to the skin.[15] Hair can be removed using a hair removal cream or by direct visualization and cutting the hair. Depending on the amount of edema, one may need to apply ice or compression before attempting removal. Pain control using a penile block will facilitate manipulation and removal of an object.

In the event of zipper entrapment, the zipper should be removed to free the foreskin from entrapment. There are 5 common methods to remove a zipper from the genitals: cutting the median bar with bone or wire cutters (Fig. 168.5); using a screwdriver to separate the teeth; application of mineral oil as lubricant; lateral compression of the fastener with pliers; and removal of the teeth with trauma sheers.[16] The cloth of the zipper should be cut close to the zipper teeth, which should release the underlying skin. Upon release, the underlying tissue may be damaged. If these techniques are unsuccessful, urology should be consulted for surgical intervention with circumcision as the last option.

Disposition

Most of these cases do not require surgical intervention and can be discharged home after the removal of the offending agent.

Epididymitis and Orchitis

KEY CONCEPTS

- Epididymitis is acute pain and swelling of the epididymis, lasting less than 6 weeks.
- Treatment of epididymitis is based on age and probability of underlying infection.
- Orchitis is pain and swelling of the testicle and is usually viral.

Foundations

Acute epididymitis is pain and swelling of the epididymis lasting less than 6 weeks, whereas orchitis is pain and swelling of the entire testicle. The etiology of the inflammation in epididymitis is due to infectious and noninfectious causes. Infectious causes vary by age of presentation. The most common cause in prepubescent males is viral infections. Adolescents may get epididymitis from *N. gonorrhoeae* or *C.*

trachomatis; other bacterial causes in this age group may be related to structural anomalies of the urinary tract.[17] Noninfectious causes may be due to a vasculitis (e.g., in Henoch-Schönlein purpura, see later), chemical irritation, or trauma. Orchitis is usually the result of bacterial or viral infection and is classically associated with mumps.

Clinical Features

Patients present with scrotal pain and swelling, with tenderness on physical examination. Patients may complain of nausea, vomiting, or referred abdominal pain. Urethral discharge may indicate a sexually transmitted infection (STI). Cremasteric reflexes should be intact, and one may see relief of pain with scrotal elevation (Prehn sign), although these elements *do not* rule out testicular torsion. Those with mumps may also present with viral symptoms, as well as lymphadenopathy and parotid gland swelling. Differential diagnosis should include epididymitis, orchitis, testicular torsion and torsion of the appendix testis, inguinal hernia, hydrocele, and varicocele.

Diagnostic Testing

Though the diagnoses of epididymitis and orchitis are clinical, UA and culture should be obtained to evaluate for pyuria. STI testing should be considered for all adolescents and those who are sexually active. Ultrasound (US) should be obtained in cases where testicular torsion is considered possible. US may show increased vascular flow to the epididymis. Patients with bacterial orchitis may rarely get a scrotal abscess, which would also be detected on ultrasound.

Management

Management of epididymitis and orchitis includes supportive care with analgesia, ice packs, and scrotal elevation. If there is concern for gonococcal STI, patients should be empirically treated with 500 mg IM ceftriaxone for patients <150 kg. If there is concern for chlamydial STI, treatment is with either doxycycline 100 mg PO BID for 7 days or azithromycin 1 g PO once.[18] Those with UA evidence of UTI should be treated for a complicated UTI according to local sensitivity patterns for *E. coli*. Scrotal abscess should receive antibiotics and consultation with urology.

Disposition

Most patients with uncomplicated epididymitis or orchitis can be discharged home with outpatient follow-up.

Testicular Torsion

KEY CONCEPTS

- Testicular torsion is a urologic emergency treated by detorsing the testis.
- Patients with classic symptoms and signs of testicular torsion should have an emergent urologic consultation for operative management.

Foundations

Testicular torsion is a urologic emergency associated with acute onset of scrotal pain. Testicular torsion should always be considered in acute scrotal pain, as delayed diagnosis can lead to loss of viability of testicular tissue and potentially loss of spermatogenesis. Testicular torsion can occur at any age, but in particular, has peaks in the neonatal and adolescent periods. Testicular salvage rates depend on time to presentation, as well as time to surgical intervention, with increased orchiectomy rates when blood flow is not restored within 6 hours of symptom onset.[19]

Testicular torsion can occur within the tunica vaginalis (i.e., intravaginally), constricting arterial blood flow, or within the scrotum (i.e., extravaginally). If there is inadequate fixation of the testicle, in which the tunica vaginalis completely covers the testis superior to the spermatic cord, this "bell clapper" deformity predisposes to torsion (Fig. 168.6). Other risk factors include cryptorchidism, trauma, familial history, or prior episodes.

Clinical Features

Patients with testicular torsion usually present with acute onset unilateral scrotal pain and edema, often associated with nausea and vomiting. Pain may radiate to the abdomen, and children may be embarrassed to note genital complaints; thus, even without a testicular complaint, a complete GU examination should be performed. Patients may have a high-riding, transverse, swollen testicle, with possible discoloration, and lack of cremasteric reflex on the affected side, though a normal cremasteric reflex *does not* rule out torsion.

Differential Diagnoses

Differential diagnosis includes torsion of the testicular appendage, which presents similarly, but usually occurs in prepubescent males with a more indolent course and less intense pain at the superior pole of the testis. Other considerations include orchitis, epididymitis, trauma, hydrocele, varicocele, inguinal hernias, or testicular tumors.

Diagnostic Testing

Testicular torsion is a clinical diagnosis, but scrotal ultrasound with Doppler can confirm the diagnosis when the testis is torsed. A UA may show hematuria or leukocytosis, which would be more indicative of epididymitis or orchitis. Doppler ultrasound may show decreased perfusion to the testicle or twisting of the spermatic cord.

Management

Urology should be consulted emergently for definitive surgical management. Once testicular torsion is confirmed, management requires surgical detorsion on the affected side, with either orchiopexy or orchiectomy if the testicle is not viable. Time to the operating room is directly related to testicular salvage, with less than 6 hours as most optimal.[19]

In the event of surgical delay, a bedside manual detorsion under analgesia can be attempted after discussion with urology. Because most torsion occurs medially, the testicle is rotated in an "open book" fashion, laterally until detorsion has occurred.[20] However, a small percentage of cases do torse laterally, so this maneuver could worsen symptoms in those cases. If manual detorsion fails, surgical management is warranted. For suspected testicular torsion that has detorsed and has normal findings or high flow (i.e., from reperfusion) on ultrasound, we recommend urology be consulted and surgery be considered to prevent recurrence.

Varicocele and Hydrocele

KEY CONCEPTS

- Consider reactive hydroceles in the setting of epididymitis, orchitis, testicular torsion, or testicular tumors.
- Consider abdominal mass or renal vein thrombosis in the event of right-sided varicocele.

Foundations

Painless scrotal swelling in children may occur secondary to a hydrocele or varicocele. A hydrocele occurs when peritoneal fluid accumulates within the tunica vaginalis; hydroceles are either communicating or noncommunicating with the peritoneal cavity. Hydroceles commonly

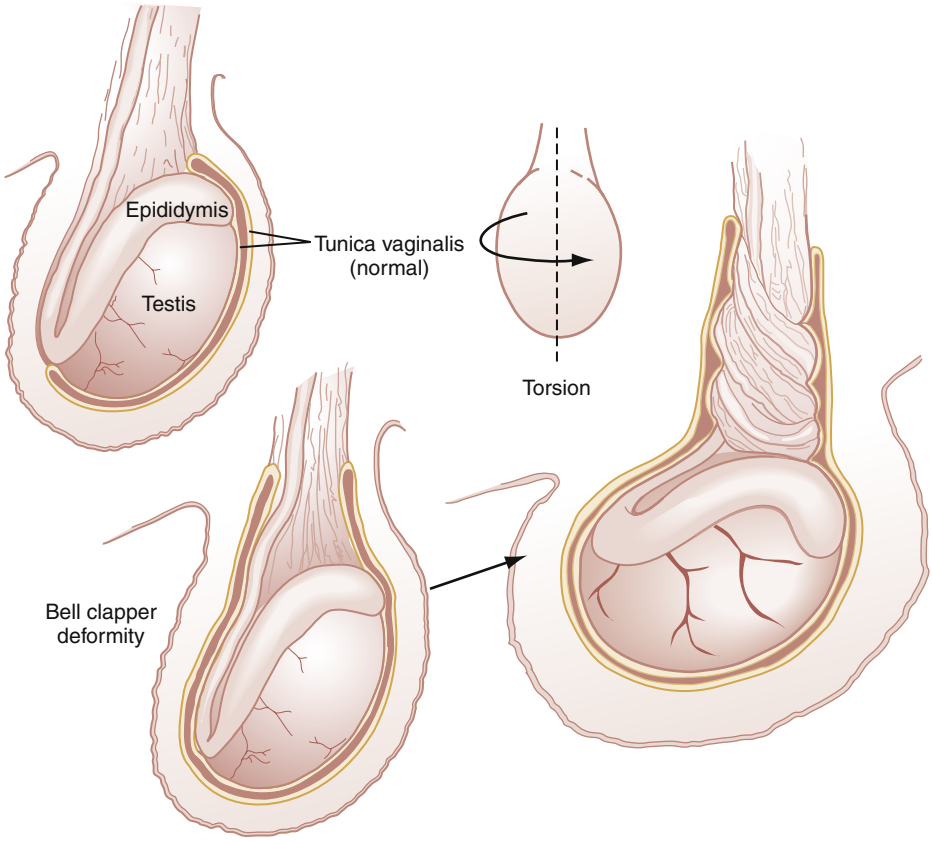

Fig. 168.6 Anatomy of testicular torsion. (From: Snyder HM III, et al. Pain—scrotal. In: Fleisher GR, Ludwig S, editors. *Textbook of Pediatric Emergency Medicine,* ed 4. Philadelphia: Lippincott Williams & Wilkins; 2000.)

occur in newborns and will spontaneously resorb by age one.[21] However, in older children, hydroceles may occur secondary to epididymitis, orchitis, torsion, or tumor. A varicocele is a collection of dilated veins in the pampiniform plexus, which surrounds the spermatic cord, and occurs in about 15% of adolescent males.[22] Primary varicoceles occur spontaneously, while secondary varicoceles occur due to some obstruction of venous outflow of the plexus. Most varicoceles are left-sided due to the 90-degree angle of drainage that occurs from the left spermatic vein to the left renal drain. A right-sided varicocele raises concern for intra-abdominal mass.

Clinical Features

If a hydrocele is communicating, painless scrotal swelling may increase when the patient performs a Valsalva maneuver. Transillumination will reveal clear fluid surrounding the testicle. Although varicoceles will also cause painless scrotal swelling, examination will reveal a "bag of worms" consistency on palpation, and a varicocele does not transilluminate. The differential for painless scrotal swelling includes hydrocele, varicocele, spermatocele, cyst, inguinal hernia, or testicular tumor. If there is pain, the differential includes reactive hydrocele secondary to epididymitis, orchitis, torsion, or a tumor.

Diagnostic Testing

If there is concern for testicular tumor, a CBC, lactate dehydrogenase (LDH), and uric acid would be reasonable. An ultrasound of the testes will be helpful to evaluate for torsion or mass. For right-sided varicoceles or those of sudden onset, we recommend patients undergo imaging with ultrasound with Doppler, CT, or MRI to evaluate for inferior vena cava thrombus, renal vein thrombosis, or abdominal mass.

Management and Disposition

Hydroceles in newborns can be managed expectantly as most will resorb on their own.[21] Outside the newborn period, there is moderate evidence that surgical correction of varicocele leads to improved sperm concentration and testicular volume.[23] Patients may be referred to urology for conservative management versus surgical repair with ligation or embolization; in the absence of an abdominal or testicular mass, these cases may be managed as outpatients.

Acute Idiopathic Scrotal Edema

KEY CONCEPTS

- Acute idiopathic scrotal edema (AISE) is rare and is a diagnosis of exclusion.

Foundations

Acute idiopathic scrotal edema (AISE) is a rare diagnosis characterized by acute scrotal erythema, swelling, and tenderness. It is a benign, self-limiting condition with an unclear etiology and is a diagnosis of exclusion. AISE generally affects prepubertal boys, though can affect males into adulthood.[24]

Clinical Features and Diagnostic Testing

Physical examination shows swelling, induration, and erythema of a unilateral testicle, which may or may not be tender. Diagnosis is via ultrasound and demonstrates edematous thickening and increased vascularity of the scrotal wall, but normal-appearing testes.

Management

Once more insidious causes have been ruled out, AISE generally resolves within a few days with NSAIDs and scrotal support.

Inguinal Hernia

KEY CONCEPTS

- Inguinal hernias can occur in males (intestines) and females (ovary more often than intestines).
- Manual reduction of inguinal hernia should be attempted, but definitive management is surgical repair.

Foundations

An inguinal hernia is a common cause of scrotal swelling in males and labial swelling in females, with indirect hernias accounting for just under 5% of full-term infants.[25] Risk increases with prematurity, low birth weight, and male gender. In males, an indirect hernia results from failed closure of the processus vaginalis, and usually contains intestines. In females, a hernia results from the failed closure of the canal of Nuck, and more often contains ovary rather than bowel. The greatest risk is with incarceration (inability to reduce the herniated contents), as well as strangulation (vascular compromise), of the herniated contents.

Clinical Features

Patients present with intermittent bulge of the inguinal region into the scrotum or labia, or a persistent bulge consistent with incarceration. Patients with a reducible bulge usually have no complaints of pain, whereas those with incarceration may have a significant amount of pain. The patient may also experience vomiting and diffuse abdominal pain from intestinal obstruction.

Differential Diagnoses

Differential diagnosis should include hydrocele, varicocele, testicular/ovarian torsion, or malignancy. The diagnosis is often clinical, but ultrasound with Doppler can assist in identifying herniated contents as well as ovarian flow in females.

Management and Disposition

Ultimately, surgery is needed for definitive repair. As long as the patient is clinically stable, manual reduction should be attempted with appropriate analgesia, by applying traction to the proximal inguinal canal with one hand and gentle pressure to the distal canal towards the abdomen with the other hand for up to 5 minutes. Incarcerated hernias with strangulation, as well as canal of Nuck hernias containing ovary, have high risk for bowel ischemia or ovarian torsion without prompt surgical intervention.[25] In the event of painless, reducible hernias without incarceration or strangulation, patients can be referred for surgery and outpatient evaluation.

Testicular Carcinoma/Tumors

KEY CONCEPTS

- Testicular tumors are the most common solid organ tumor in adolescents.
- Patients who have a hydrocele that does not transilluminate should have an ultrasound to investigate for an underlying mass.

Foundations

Although a small percentage of overall pediatric malignancies, testicular tumors are the most common solid organ tumor in adolescents, comprising 14% of all adolescent cancer.[26] Patients with cryptorchidism, prior testicular cancer on the contralateral side, or family history of cancer are all at increased risk. Most testicular cancers are teratomas, carcinomas, yolk sac tumors, Leydig cell tumors, or Sertoli cell tumors; however, lymphoma and leukemia can also metastasize to the testicle.

Clinical Features

Patients present with painless unilateral testicular swelling or mass. Some may describe an aching or pulling sensation, or abdominal pain. There may be a reactive hydrocele present, but the testis does not transilluminate with an underlying mass. Examination may demonstrate lymphadenopathy, hepatosplenomegaly, or gynecomastia.

Diagnostic Testing and Management

Diagnostic evaluation should include a CBC with differential, chemistry panel, LDH, uric acid, human chorionic gonadotropin (HCG), UA, and ultrasound. Labs are obtained to evaluate for cell line suppression, tumor lysis syndrome, or end-organ damage. Chest x-ray should be performed to rule out mediastinal mass with testicular metastasis. Tumor markers such as HCG, alpha fetal protein (AFP), luteinizing hormone (LH), and follicular stimulating hormone (FSH) can be sent and are helpful to the oncologist for further delineation of the underlying subtype. An ultrasound is necessary to identify solid tumor versus a cystic structure.

Once the workup is complete, pediatric oncology should be consulted for further management, including CT chest, abdomen, and pelvis for staging purposes, orchiectomy for histologic evaluation, and possibly retroperitoneal lymph node dissection or chemotherapy.[27] A testicular biopsy should not be performed due to concern for possible tumor seeding. Initial management may be inpatient, with long term outpatient follow-up.

Urinary Tract Infections

KEY CONCEPTS

- *E. coli* is the most common uropathogen isolated from urine cultures in patients with urinary tract infections (UTI).
- First time febrile UTI from 2 months to 2 years should have a renal bladder ultrasound.

Foundations

Urinary tract infection (UTI) is a common diagnosis in pediatrics and risk increases with age younger than 12 months, uncircumcised status, and anatomic obstruction or vesicoureteral reflux. The most common bacterial cause of UTI is *E. coli*, accounting for 80% of cases.[28]

Clinical Features

Patients present with dysuria, urgency, frequency, abdominal pain, fever, incontinence, or vomiting. In younger children, fever may be the only presenting symptom (see Chapter 161). Physical examination may reveal suprapubic tenderness; an upper tract infection may cause costovertebral angle or flank tenderness. GU examination should be performed to look for retained foreign bodies or signs of obstruction from phimosis or labial adhesions.

Differential Diagnoses

Differential diagnosis includes other sources of fever or abdominal pain, although those would not eliminate a concurrent UTI. Asymptomatic bacteriuria is a possibility in the event of colonization or gastroenteritis. In patients with pyuria but negative culture, consider balanitis, vulvovaginitis, or sexually transmitted disease. Also consider Kawasaki disease in the event of sterile pyuria.

Diagnostic Testing and Management

A urinalysis and urine culture should be obtained. A catheterized specimen is preferable in those who are not toilet trained to preserve

a sterile sample. Blood work is not usually needed for otherwise well-appearing immunized children over 3 months of age. A UTI is diagnosed when there is pyuria or bacteriuria on UA, and at least 50,000 cfu/mL of a uropathogen cultured by catheterization.[29] Febrile infants with a UTI should receive renal bladder ultrasound, which may be performed as an outpatient, to assess for hydronephrosis or renal scarring. Once back to their usual state of health, infants with an abnormal ultrasound should undergo a voiding cysto-urethrogram to assess for reflux or obstruction.[29] See Chapter 161 for a comprehensive discussion on treatment of pediatric UTI.

Hematuria

KEY CONCEPTS

- Hematuria refers to >5 RBCs per high power field on UA.
- Gross hematuria is usually due to bladder or urethral bleeding, whereas microscopic hematuria is due to glomerular or tubular bleeding.

Foundations

Hematuria refers to red blood cells (RBCs) in the urine and can be either macroscopic or microscopic. While macroscopic hematuria is visible to the patient, microscopic hematuria refers to greater than 5 RBCs per high-power field. The prevalence of microscopic hematuria detected on two or more urinalysis samples in school age children is estimated at 1% to 2%, but in cases of isolated hematuria, 57% do not have underlying pathology.[30]

Irrespective of grossly visible or microscopic hematuria, patients should be assessed for trauma, queried for flank or abdominal pain, and inspected for bleeding from other sites. Patients with infection as the cause of hematuria may report fevers, dysuria, urgency, frequency, abdominal pain, or recent illness. Medical history should include documenting any sickle cell disease, bleeding disorders, medications, or family history of kidney disease. Physical examination should document other areas of bleeding/bruising (skin or mucosal), signs of renal impairment (hypertension, periorbital or lower extremity edema, pulmonary crackles), abdominal pain or masses, and GU examination to assess for external causes of bleeding (i.e., meatal, vaginal, or rectal sources). Causes of hematuria are categorized as extrarenal or intrarenal etiologies (Table 168.2).[30,31] Macroscopic hematuria is typically due to bladder/urethral damage, whereas microscopic hematuria is more commonly from glomerular or tubular damage.

Patients with hematuria have a UA with greater than 5 RBCs per high-power field. Proteinuria and RBC casts suggest glomerular damage. Patients with concern for hematuria, and dipstick positive for blood, but no RBCs on UA may have myoglobinuria from rhabdomyolysis. In patients with discolored urine but normal UA, consider certain foods (e.g., beets, rhubarb, berries) and medications (e.g., rifampin, nitrofurantoin, metronidazole).[31] Findings of leukocyte esterase, nitrite, or white blood cells (WBC) indicate urinary tract infection. WBC casts may be found in patients with pyelonephritis. In the context of recent throat or skin infection, a throat culture, anti-streptolysin O (ASO) titer, and complement levels may help diagnosis poststreptococcal glomerulonephritis. If there is greater than 3+ protein on UA, nephrotic syndrome should be considered and a basic metabolic panel (BMP) sent for electrolytes, creatinine, and albumin. If BMP reveals hypercalcemia, urine calcium levels should also be obtained, because hypercalciuria is a common cause of hematuria. If there is concern for lupus, erythrocyte sedimentation rate (ESR) and antinuclear antibodies (ANA) can be obtained. If the patient complains of flank or abdominal pain with hematuria, ultrasound or CT scan can help diagnose nephrolithiasis, renal vein thrombosis, nutcracker syndrome, or mass.

TABLE 168.2 Causes of Hematuria in Children

Extrarenal	Trauma
	Meatal stenosis or posterior urethral valves
	Menstrual or rectal bleeding
	Foreign body
	Cystitis, urethritis, epididymitis
Intrarenal	Pyelonephritis
	Nephrolithiasis or urolithiasis
	Poststreptococcal glomerulonephritis
	Acute interstitial nephritis
	Acute tubular necrosis
	Basement membrane glomerular disease
	Renal vein or artery thrombosis
	Recurrent familial hematuria
	Polycystic kidney disease
Systemic	Alport syndrome
	Henoch-Schönlein purpura
	Lupus
	Hemolytic uremic syndrome
	Mononucleosis
	Sickle cell disease/hemoglobinopathy
	Endocarditis
	Bleeding diathesis
	Medications (amitriptyline, chlorpromazine, radiocontrast dye)

If the patient has a history of trauma, we recommend a CT scan of the abdomen and pelvis be performed to evaluate for sources of injury and bleeding (see Chapter 160).

The management of hematuria depends on the etiology and may warrant subspecialty referral to nephrology, urology, or oncology. Well-appearing children with normal blood work, imaging, and no identifiable cause should be discharged to follow-up with their PCP for serial UAs to assess for persistent hematuria and need for further outpatient workup.

Nephrolithiasis

KEY CONCEPTS

- Clinical presentation in pediatrics may be more nonspecific than adults.
- Ultrasound is first-line imaging in diagnosis.
- Stones <6 mm will likely pass spontaneously.

Foundations

Nephrolithiasis, or kidney stones, is increasing in incidence across all ages. Calcium oxalate stones are the most common, followed by calcium phosphate, and less likely struvite, uric acid, and cysteine. Increased risk is associated with family history, low fluid intake, increased dietary sodium, urinary tract infections, metabolic abnormalities (hypercalciuria, hypocitraturia, renal tubular acidosis), anatomic abnormalities (ureteropelvic junction obstruction, posterior urethral valves), systemic disease (inflammatory bowel disease, nephrocalcinosis), genetic disease (cystinuria, cystic fibrosis), and medications (topiramate, acetazolamide, vitamin C).[32]

Clinical Features

Adolescents often present with colicky flank pain and hematuria, while younger children present with nonspecific abdominal pain or isolated hematuria which may lead to a delayed diagnosis. Patients may also

complain of nausea, vomiting, or malaise. Children with concomitant UTI may complain of dysuria, urgency, and frequency. Some younger patients may be asymptomatic with stones detected incidentally. History should include any prior history of stones, UTIs (*Proteus* species are associated with struvite stones), congenital malformations, family history of nephrolithiasis, specific dietary constraints (ketogenic diet), and current medications.

Differential Diagnoses

In patients with intermittent abdominal pain, constipation, gastroenteritis, appendicitis, intussusception, testicular torsion, ovarian torsion, and cholelithiasis should be considered in the differential. In children with hematuria, consider urinary tract infection, trauma, and other causes of hematuria listed in Table 168.2.

Diagnostic Testing

Workup for suspected nephrolithiasis includes a UA with microscopy to evaluate for hematuria, crystals, and evidence of infection, as well as a BMP to evaluate for electrolyte abnormalities and acute kidney injury. Although hematuria is a common presenting symptom, up to 20% of patients with nephrolithiasis will not have hematuria on their UA. CBC with differential may be obtained if there is concern for infection or significant blood loss. Stones may be visualized using plain films, ultrasound, or non-contrast helical CT scans. Plain films will only detect radio-opaque stones; ultrasound will detect both radio-opaque and radiolucent stones but may miss smaller stones. CT scans will detect both types of stones, as well as small stones and ureteral stones. Renal bladder ultrasound is first-line imaging in children to avoid radiation, but with negative ultrasound and high suspicion, a non-contrast CT is diagnostic.

Management

Management of stones in pediatric patients focuses on pain control, as well as expectant management of stone passage versus surgical removal. In children with normal renal function, NSAIDS are preferred for pain relief, followed by opioids. Uncomplicated cases with adequate pain control, normal renal function, and stones of less than 6 mm can be discharged home, as they will likely pass the stone spontaneously.[33] For distal ureteral stones of less than 10 mm, the addition of medical expulsive therapy with tamsulosin (alpha antagonist) may increase successful expulsion.[33] Once passed, stones can be collected by families and sent for stone composition analysis. A 24-hour urine collection is recommended after the stone has passed, to evaluate for underlying metabolic abnormalities that may predispose to recurrence. Stone causing hydroureter or hydronephrosis and infected urine is a urologic emergency, requiring intravenous antibiotics and decompression, usually with ureteral stent or percutaneous nephrostomy tube.[33] Additional interventions may include extracorporeal shock wave lithotripsy, percutaneous nephrostolithotomy, or ureteroscopy. Admission criteria for children with nephrolithiasis are any of the following: significant obstruction (unlikely to pass spontaneously), UTI with obstruction, persistent pain despite adequate therapy, persistent vomiting or inability to self-hydrate, struvite stones, failed conservative management, and patients with a solitary kidney.[34]

Renal Tumors

KEY CONCEPTS

- Wilms tumor is the most common renal tumor in children.
- Patients often present with hematuria or an abdominal mass detected by caregivers.

Foundations

Renal tumors make up 7% of all pediatric cancers, of which Wilms tumor is the most common, followed by congenital mesoblastic nephroma (in children <12 months) and renal cell carcinoma (in children >5 years).[35,36] Certain syndromes such as Beckwith-Wiedemann, Denys-Drash, and WAGR, carry increased risk of developing Wilms tumor.

Clinical Features

Children with renal tumors often present with a palpable abdominal mass, but can also present with abdominal pain/distension, hematuria, or emesis. Vital signs may be normal or may reveal hypertension. In addition to renal tumors, the differential diagnosis includes other causes of abdominal mass such as hepatosplenomegaly, hydronephrosis, polycystic kidneys, cysts, abscesses, a full bladder, and constipation.

Diagnostic Testing

A suspected renal mass warrants laboratory workup, including CBC with differential and smear, complete metabolic panel (CMP), uric acid and LDH to assess for tumor lysis, urinalysis, and urine catecholamines (to help differentiate Wilms tumor from neuroblastoma). Renal ultrasound is preferred for diagnosis, followed by additional imaging with a CT, MRI, or PET scan for staging and surgical planning.

Management and Disposition

Once a renal tumor has been identified, pediatric hematology-oncology should be consulted for ongoing management. Children who are well-appearing with normal renal function may be discharged for outpatient follow-up after discussion with oncology, but often children will be admitted for expedited diagnostic workup and treatment planning.

Proteinuria

KEY CONCEPTS

- Trace or mild proteinuria may be seen in hypovolemia, fever, stress, or exercise.
- Patients with moderate or severe proteinuria require workup with blood work, imaging, and nephrology consultation.

Foundations

Proteinuria is associated with renal pathology; however, trace or mild proteinuria is benign and generally asymptomatic. It is often seen with hypovolemia, fever or hypothermia, stress, seizures, or exercise. However, more insidious causes, such as nephrotic syndrome, can present with high levels of proteinuria (>1000 mg/m^2 per day, Table 168.3) and edema secondary to hypoalbuminemia less than 3 g/dL.[37] Glomerular filtration issues lead to the abnormal passage of albumin, a macromolecule, which is detected on urine dipstick. Tubular and overflow proteinuria are caused by extrusion of low-molecular-weight molecules, which are not typically detected on urine dipstick. Tubular proteinuria is associated with proximal tubular dysfunction, whereas overflow proteinuria, which is uncommon in children, occurs when tubular resorptive capacity is overwhelmed.

Clinical Features

The cause of proteinuria determines presentation. Edema commonly presents around the eyes (i.e., periorbital), in the lower extremities, and in the GU area. Eliciting a history of preceding illness (e.g., a recent streptococcal infection), weight changes, changes in urine output, and family history of kidney issues/autoimmune disease may assist in diagnosing the etiology of the proteinuria. If the patient has systemic

TABLE 168.3 Urine Dipstick Proteinuria

Mild Proteinuria				Moderate Proteinuria	High Proteinuria
Negative	Trace	1+	2+	3+	4+
<15 mg/dL	15–30 mg/dL	30–100 mg/dL	100–300 mg/dL	300–1000 mg/dL	>1000 mg/dL

TABLE 168.4 Causes of Proteinuria

• Hypothermia	• Fanconi syndrome
• Seizures	
• Stress	
• Exercise	
• Postural/Orthostatic	
• Proteinuria only when upright	

symptoms, such as joint pain or rash, this may point to an autoimmune process as the culprit.

In children, proteinuria is either glomerular or tubular; common causes are listed in Table 168.4.[37] False-positive proteinuria on urine dipstick is often related to alkaline or dilute urine, mucous, blood, vaginal or seminal secretions, or the presence of inflammatory cells (i.e., a urinary tract infection).[38]

Diagnostic Testing and Management

If a patient has mild proteinuria (≤2+ or ≤100 mg/dL), no further emergent testing is necessary. Patients with moderate proteinuria (≥3+ or ≥300 mg/dL), should have their blood pressure monitored, and a laboratory workup, including serum protein, serum albumin, electrolytes, BUN, creatinine, complement levels (C3 and C4), urine culture, antistreptolysin O (ASO), and urine protein-to-creatinine ratio (Pr/Cr). Random urine Pr/Cr correlates with a 24-hour urine collection and is easier to obtain, particularly in a pediatric patient. First morning void urine Pr/Cr is most accurate. Urine Pr/Cr greater than 3.0 is associated with nephrotic syndrome. We recommend pediatric nephrology consultation and follow-up for any child with moderate proteinuria or an elevated urine Pr/Cr value (Table 168.5).[37] Imaging such as a renal ultrasound may demonstrate anatomic abnormalities such as polycystic kidney disease, but can be completed on an outpatient basis.

Disposition

All children with proteinuria require follow-up with their primary care doctor for a reevaluation, including blood pressure monitoring and repeat UA. A pediatric nephrologist should determine the need for renal biopsy in children with moderate proteinuria.

We recommend hospital admission and pediatric nephrology consultation for children with significant proteinuria (3+), along with edema/ascites, hypertension greater than the 99th percentile, or renal dysfunction with elevation of greater than 50% of BUN or creatinine. Some children with new-onset mild nephrotic syndrome may be managed outpatient, particularly if well-appearing; however, we recommend this decision be made in consultation with a pediatric nephrologist.

TABLE 168.5 Normal Urine Protein-to-Creatinine Ratio

Age	Urine Pr/Cr
>2 years old	<0.2
6 months–2 years old	<0.5

Poststreptococcal Glomerulonephritis (PSGN)

KEY CONCEPTS

- Patients with PSGN have a history of a preceding pharyngeal or skin infection in the past 2 to 6 weeks, respectively.
- Treatment of PSGN is supportive, with fluid restriction and diuretics for more significant disease.

Foundations

Poststreptococcal glomerulonephritis (PSGN) is the most common cause of pediatric glomerulonephritis globally and is caused by recent infection with group A beta-hemolytic streptococcus (GAS).[39] The exact mechanism is unclear, but it is believed to be caused by deposition of glomerular immune complexes, which leads to a decreased glomerular filtration rate from complement activation, and subsequent proteinuria.

Clinical Features

Generally, patients will present with a history of pharyngitis and fever about 2 weeks prior, or skin infection with fever up to 6 weeks prior.[39] PSGN symptoms can range from asymptomatic gross hematuria to acute nephritic syndrome with acute kidney injury including proteinuria, edema, hypertension, lethargy, cardiac arrhythmias, and renal failure. It occurs more frequently in males, patients ages 4 years to 12 years old, and is uncommon in children less than two years old.[39]

Diagnostic Testing

In children with PSGN, a urinalysis should be obtained and demonstrates hematuria (±RBC casts) and proteinuria, and sometimes pyuria. Generally, most children with PSGN do not have nephrotic range proteinuria. Lab values typically show an elevated BUN, low sodium, high potassium, elevated ASO, elevated IgG levels, and decreased C3 and decreased CH50 during the first 2 weeks of illness.[39] Complement levels generally return to normal within 4 to 8 weeks after initial presentation.[40]

If hematuria and nephritic symptoms persist beyond 2 weeks, clinical clues can point to diagnoses other than PSGN. Antecedent upper respiratory or gastrointestinal infection is often present in patients with IgA nephropathy or membranoproliferative glomerulonephritis

BOX 168.1 Indications for Hospitalization/ Dialysis in Pediatric PSGN

Refractory or significant hypertension
- >99th percentile for age and height

End-organ damage from fluid overload
- Congestive heart failure
- Pulmonary edema

Hyperkalemia >6.5 mEq/L
Severe uremia >89 mg/dL

(MPGN). In IgA nephropathy, hematuria typically presents sooner (i.e., less than 5 days) after the preceding illness. Patients with MPGN have persistent hematuria and lab abnormalities of low complement and elevation in creatinine. Lupus nephritis and Henoch-Schönlein purpura (HSP) can present similarly, but can be differentiated by complement levels, with both C3 and C4 depressed in lupus nephritis, and normal complement levels in HSP. PSGN has a decreased C3 and generally has a normal C4 level, though a depressed C4 level can portend a poorer prognosis.[40] Hemolytic uremic syndrome (HUS) can also result in symptoms similar to PSGN, but has characteristic bloody diarrhea and is often associated with *E. coli* O157.

Management

PSGN is primarily managed supportively via fluid and salt restriction, often in consultation with a pediatric nephrologist. It is generally self-limited, with most creatinine levels returning to baseline about 3 to 4 weeks after initial manifestation. PSGN does not necessarily warrant antibiotic treatment, as the streptococcal infection has typically cleared by the time of presentation, although a streptococcal infection should be treated if still present. If hypertension or fluid overload develops, patients should be treated with calcium channel blockers or diuretics.

Diagnosis can be delayed if there is no history of antecedent infection or the patient does not have gross hematuria. In PSGN, the nephritis typically resolves within 1 to 2 weeks. Patients with persistent disease beyond 2 weeks should receive a pediatric nephrology consultation to determine additional diagnostic testing.

Most children with mild PSGN can be managed on an outpatient basis. Indications for pediatric nephrology referral and dialysis are outlined in Box 168.1.[41]

Nephrotic Syndrome

KEY CONCEPTS

- Nephrotic syndrome is defined by proteinuria, decreased albumin, hypertriglyceridemia, and edema.
- Patients have an increased risk for thrombosis and bacterial infections, especially *Streptococcus* and *E.coli.*

Foundations

Nephrotic syndrome occurs when impaired glomerular filtration leads to proteinuria (3+ or 4+ or >300 to 1000 mg/dL protein on urine dipstick) and hypoalbuminemia (<30 g/L or <3g/dL). As a result of this increased permeability, patients can present with significant edema. It can affect any age, although is most common in school-aged children and teenagers. The incidence in children is 2 to 7 per 100,000 children and it affects males more frequently (2 : 1).[42] Primary nephrotic syndrome is idiopathic and occurs without an inciting systemic illness while secondary nephrotic syndrome occurs due to systemic causes, such as infections, immune disorders, cancer, or medications. The

BOX 168.2 Types of Nephrotic Syndrome (most common to least common)

Minimal change disease (MCD)
Focal segmental glomerulonephritis (FSGS)
Membranoproliferative glomerulonephritis (MPGN)
Other glomerulonephropathies
- Membranous glomerulopathy
- Focal and global glomerulosclerosis
- Mesangial proliferation
- Proliferative glomerulonephritis

BOX 168.3 Nephrotic Range Labs

Proteinuria ≥40 mg/m^2/hour or >50 mg/kg/day or >1000 mg/m^2/day
- 3+ or 4+ protein on urine dipstick

Hypoalbuminemia <30 g/L or <3 g/dL
Total serum protein 4.5–5.5 g/dL
Spot urine protein: creatinine >2

various types of nephrotic syndrome are listed in Box 168.2.[43] Most children have primary nephrotic syndrome, generally minimal change disease or focal segmental glomerulonephritis.

Clinical Features

Nephrotic syndrome is characterized by edema, although the presentation can vary from mild periorbital edema to anasarca. Some children can present without edema, but still have nephrotic range proteinuria. Nephrotic syndrome can be triggered by a recent upper respiratory illness or can present without incitement.[42] Some children can present with weight gain not recognized to be edema, and insidiously present with pulmonary edema or severe ascites. Children with nephrotic syndrome may have hypertension, hematuria, or oliguria, with resultant acute kidney injury, although acute renal failure is rare.

Children with nephrotic syndrome are at high risk for thrombosis with thromboemboli. Venous thrombosis can occur in the renal vein, sagittal sinus, or pulmonary artery.[42] Patients with nephrotic syndrome are also at higher risk for developing bacterial infections secondary to loss of immunoglobulins, and because they are often on corticosteroid treatment. Infections are the leading cause of morbidity and mortality in nephrotic syndrome, from spontaneous bacterial peritonitis, sepsis, and pneumonia resulting from *E. coli* and encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and Group B *Streptococcus*.

Diagnostic Testing

In suspected nephrotic syndrome, a urinalysis, protein : creatinine ratio, and serum labs including electrolyte, albumin, BUN, creatinine, CBC, and cholesterol should be checked. Nephrotic range labs are listed Box 168.3.[42] Labs generally reveal normal BUN and creatinine levels, but will have hypoalbuminemia, hyponatremia, hyperlipidemia, and can have hemoconcentration with elevated hemoglobin and hematocrit. Patients generally have normal complement levels, but if abnormal, other diagnoses should be considered.

Imaging such as chest x-rays and abdominal x-rays can demonstrate fluid overload with pulmonary edema and ascites. Abdominal ultrasound for nephrotic syndrome is otherwise nonspecific, but may demonstrate ascites or structural changes of the kidneys from chronic illness. Renal biopsy can characterize a specific nephrotic syndrome

diagnosis, and is recommended for patients with hematuria, elevated BUN, persistent hypertension or renal dysfunction refractory to steroid treatment.

Differential Diagnoses

Primary renal disease such as glomerulonephritis and renal failure can also result in edema similar to nephrotic syndrome. These can be differentiated by gross hematuria, RBC casts in urine, elevated creatinine, or hypertension. Other causes of edema to consider include heart failure, drug-induced, liver failure/cirrhosis, cystic fibrosis, and other protein losing enteropathies such as malnutrition.

Management

Primary nephrotic syndrome can be treated with steroids (e.g., prednisone 2 mg/kg/day orally divided TID), with the duration determined by a pediatric nephrologist.[44] Some forms of nephrotic syndrome may be refractory to steroids, in which case subsequent steroid courses and renal biopsy may be warranted. Children with nephrotic syndrome require fluid and salt restriction. In ill-appearing patients with severe ascites or respiratory distress, furosemide 0.5 to 1 mg/kg and titrated based on response can be used as a diuretic. However, in spite of edema, children with nephrotic syndrome who appear hypovolemic or septic should receive fluid resuscitation with crystalloid. If patients develop chest pain, shortness of breath, abdominal pain, or extremity swelling/pain, thromboembolic complications should be considered. Children with significant ascites and pain should undergo paracentesis to assess for spontaneous bacterial peritonitis. Due to immunoglobulin loss and T-cell dysfunction, children with nephrotic syndrome are considered immunocompromised and if they present with a fever, can not only relapse but should also be hospitalized with blood cultures, respiratory viral studies if available, and initiation of antibiotic therapy effective against *S. pneumoniae* and *E. coli*.[44]

Disposition

As with many new-onset pediatric chronic illnesses, pediatric patients with new-onset nephrotic syndrome are generally hospitalized under the care of a pediatric nephrologist to expedite workup, treatment, and education. In mild cases, patients can be discharged home in consultation with a pediatric nephrologist. Patients who are ill-appearing with concern for thrombus, sepsis, shock, respiratory distress, worsening renal function, steroid-refractory disease, or infection should be hospitalized.

Acute Kidney Injury

KEY CONCEPTS

- Evaluation of fluid status in AKI is important in management strategies.
- Management is directed at correcting fluid and electrolyte derangements.

Foundations

Acute kidney injury (AKI) occurs when injury of renal tissue leads to alteration in fluid status, electrolyte imbalance, and poor elimination of waste, which can lead to chronic kidney disease and failure.[45] AKI is often multifactorial, but may be due to an underlying disease process, dehydration, medications, or toxins. AKI is often classified as prerenal, renal or postrenal (Table 168.6). Prerenal AKI is usually due to poor renal perfusion, renal AKI is due to intrinsic kidney parenchymal damage, and postrenal AKI is due to anatomic abnormality that prevents adequate drainage of the collecting system.

Clinical Features and Differential Diagnoses

Clinical presentation and differential diagnosis depend on the underlying etiology of AKI. Patients may have vital sign and physical examination findings consistent with dehydration (e.g., sunken fontanelle, dry skin, delayed capillary refill, dry mucous membranes). History may reveal poor oral intake, vomiting, diarrhea, or little to no urine output. History of sore throat or bloody diarrhea may point to poststreptococcal glomerulonephritis or hemolytic uremic syndrome (HUS), respectively. Medication history is important because many medications may be nephrotoxic. Patients may be edematous from fluid shifts and may have hematuria from renal injury.

TABLE 168.6 Causes of AKI

Prerenal	Decreased renal perfusion: dehydration, hemorrhage, diuretics, burn, heart failure, sepsis, anaphylaxis
Renal	NSAIDs, ACE inhibitors, acute tubular necrosis, HUS, vasculitis (lupus, HSP), interstitial nephritis, malignancy, glomerulonephritis
Postrenal	Nephrolithiasis or urolithiasis, thrombosis, neurogenic bladder, medication-induced urinary retention, anatomic obstruction

Diagnostic Testing

Patients with suspected AKI should have a BMP drawn to assess for alterations in electrolytes, BUN, and creatinine. UA with microscopy may show hematuria or proteinuria depending on underlying etiology, and may have elevated specific gravity or ketones if the patient is dehydrated. RBC casts, WBC casts, or hyaline casts may also help identify glomerulonephritis, pyelonephritis, or acute tubular necrosis, respectively. Electrolyte abnormalities may be apparent such as hyponatremia, hyperkalemia, hyperphosphatemia and hypocalcemia. Elevated BUN and creatinine are hallmarks of AKI. If there are concerns for infection or HUS, CBC may identify leukocytosis, thrombocytopenia, or microangiopathic changes. Renal bladder ultrasound may be necessary to evaluate renal parenchyma, obstruction, and vessel thrombosis.

Management

Management of AKI is supportive and directed at correcting the underlying cause, as well as fluid and electrolyte abnormalities. Patients with prerenal or renal AKI may be fluid challenged with a 20 mL/kg normal saline (NS) bolus to assess for urine output response. Patients with nephrotoxic medication exposure would also benefit from fluid therapy, along with cessation of the exposure.[46] In patients with fluid overload or heart failure, fluids would worsen the clinical picture and pediatric nephrology should be consulted for diuretic management because furosemide is also nephrotoxic and could lead to hypotension in certain situations.[47] Severe electrolyte disturbances can lead to hyponatremic seizures or hyperkalemic cardiac arrhythmias. Hyponatremic seizures should be treated with 3% hypertonic saline at 3 to 5 mL/kg.

An electrocardiogram (EKG) also should be obtained in children with AKI. Hyperkalemia with QRS widening should be treated with calcium gluconate 30 to 60 mg/kg to stabilize the myocardium; additional hyperkalemia treatment includes dextrose (0.5 g/kg) and insulin (0.1 units/kg), albuterol, sodium bicarbonate (1 mEq/kg), kayexalate (1 g/kg) and Lasix (0.5–1 mg/kg). Dialysis may be necessary in cases of severe acidosis, electrolyte disturbances, toxic ingestions, fluid overload, or uremia.

Disposition

Pediatric patients with AKI warrant admission for fluid and electrolyte management; consultation with pediatric nephrology should be obtained for possible dialysis.

Hypertension

KEY CONCEPTS

- In children, blood pressure percentile is interpreted using sex, age, and height.
- Blood pressure measurements are defined as normal, elevated, stage 1 hypertension, or stage 2 hypertension

Foundations

The prevalence of clinical hypertension in pediatrics is about 3.5%, and pediatric blood pressures (BP) are interpreted using sex, age, and height.[48] The definition of hypertension in children and adolescents differs from that of adults, and the most updated clinical guidelines for hypertension are outlined in Table 168.7.[48] If left untreated, children with hypertension are at increased risk of adult hypertension, cardiovascular disease, and metabolic syndrome.

Clinical Features

On presentation, children may be symptomatic or completely asymptomatic. If the initial BP is elevated, two separate BP measurements should be taken, and the three measurements averaged. If the patient still falls into one of the categories of hypertension, a thorough history should be completed including maternal complications at birth, gestational age, any umbilical vein catheter manipulation (risk of renal vein thrombosis), dietary salt intake, and family history. A physical examination, including 4-extremity blood pressure, is recommended to look for secondary signs of hypertension, such as coarctation of the aorta.

Differential Diagnoses

Children with confirmed hypertension greater than the ninety-fifth percentile should have follow-up with their primary care provider for ambulatory blood pressure monitoring. Patients with strong family history, elevated BMI, and poor dietary habits may have primary or essential hypertension. If this is not clear by history and physical examination, secondary causes of hypertension can be considered. Renovascular disease is the most common secondary cause of hypertension in children. Cardiac causes such as coarctation of the aorta also lead to hypertension in children and can go undiagnosed depending on the degree of narrowing. Other causes of secondary hypertension include sleep apnea, hormonal excess (e.g., catecholamines release of pheochromocytoma), genetic disease (neurofibromatosis 1), anatomic causes (renal artery stenosis), and medications/supplements (OCPs, stimulants, steroids).[48]

Diagnostic Testing

Laboratory evaluation for secondary causes of hypertension should include a BMP, lipid panel, and UA; other optional tests include renin, aldosterone, and urine catecholamines. Patients with a history of snoring and pauses in sleep can be referred for an outpatient sleep study. A urine toxicology screen can be helpful in patients suspected of drug abuse causing hypertension, but should not preclude urgent or emergency treatment. An ECG and echocardiography can assess for left ventricular hypertrophy or other structural causes of hypertension. Renal Doppler ultrasound is used to assess for renovascular disease, as well as renal artery stenosis or renal vein thrombosis.

Management and Disposition

Long-term goals in the treatment of hypertension in children include achieving a BP lower than the ninetieth percentile or less than 130/80 in adolescents to reduce end-organ damage and decrease the risk for cardiovascular disease in adulthood.[48] Lifestyle modifications that address diet, sleep, stress reduction, and physical activity are the initial management of choice for patients with elevated BP and asymptomatic stage I hypertension. If ongoing elevation persists despite lifestyle modifications, symptomatic stage I hypertension, or stage 2 hypertension, patients should undergo a diagnostic evaluation and pharmacologic treatment (with an ACE inhibitor, ARB, calcium channel blocker, or thiazide diuretic) with pediatric nephrology guidance and close follow-up.[48] Patients with stage 2 hypertension and end-organ damage such as encephalopathy, AKI, and heart failure are considered to have hypertensive emergency and should receive immediate reduction of BP by 25%. If the patient has stage 2 hypertension and remains symptomatic, or if the BP is greater than 30 mm Hg above the ninety-fifth percentile (>180/120 in adolescents), inpatient management is recommended.[48]

TABLE 168.7 Definitions of Hypertension

	Children Age 1–13 years	Children Age >13 years
Normal BP	<90th percentile	<120/80 mm Hg
Elevated BP	>90th percentile but <95th percentile	120/80 to 129/80
Stage I Hypertension	> 95th percentile to <95th percentile +12 mm Hg or 130/80 to 139/80 (whichever is lower)	130/80 to 139/80
Stage 2 Hypertension	>95th percentile + 12 mm Hg or >140/90 (whichever is lower)	>140/90

Henoch-Schönlein Purpura

KEY CONCEPTS

- HSP is a vasculitis that causes abdominal pain, GI bleeding, renal involvement, scrotal swelling, and arthralgias, and leads to an increased risk of intussusception
- Consider inpatient admission for patients with HSP who cannot bear weight, cannot tolerate oral pain medications, or have GI bleeding or renal involvement.

Foundations

Henoch-Schönlein purpura (HSP) is the most common vasculitis in children and has an annual incidence of 10 to 20 per 100,000 children, peaking at age 4 to 6 years.[49] HSP is a small vessel IgA vasculitis which has the proclivity to affect any organ, but in particular causes issues with the gastrointestinal (GI) tract, skin, and kidneys. Its etiology is uncertain, but there may be an association with preceding upper respiratory tract illnesses since it is most commonly seen in the fall, winter, and spring and rarely in the summer months.

Clinical Features

Clinical manifestations are variable, and many sets of diagnostic criteria exist, but in general, the diagnosis is based on the tetrad of abdominal pain, nonthrombocytic palpable purpura, arthralgia, and renal involvement. Patients may present on a spectrum of mild to severe symptoms. The rash occurs in dependent areas of the buttocks and posterior legs and is typically palpable and purpuric. Gastrointestinal (GI) symptoms range from mild nausea and abdominal pain to severe GI bleeding and risk of intussusception. (See Chapter 166 for GI evaluation in patients with HSP.) Renal disease ranges from mild hematuria to more severe nephritis. Less common clinical

manifestations also include scrotal edema, seizures, and interstitial lung disease.

Differential Diagnoses

Differential diagnosis may be broad depending on the patient presentation as some symptoms such as abdominal pain may be nonspecific. Given the purpuric nature of the rash, other causes of thrombocytopenia should be considered: sepsis, idiopathic thrombocytopenic purpura (ITP) or thrombotic thrombocytopenic purpura (TTP). Infection in the setting of rash and arthralgias can point to a strep infection, Lyme disease, or septic joint, as well as other rheumatic diseases. In patients with hematuria, a broad differential is necessary, as discussed in prior sections.

Diagnostic Testing

In patients with classic features of HSP, the diagnosis can be made clinically, as there is no diagnostic lab test. A UA is recommended to evaluate for renal involvement with hematuria. Patients with elevated blood pressure and hematuria should have a BMP to assess BUN and creatinine levels. CBC will be nonspecific and coagulopathy panels are generally normal. In patients with abdominal pain and/or GI bleeding, an ultrasound is recommended to assess for intussusception because these patients are at increased risk.

Management

Management of HSP is supportive and directed at symptomatic treatment. Pain can be treated with acetaminophen and NSAIDs (in the absence of severe renal involvement and ongoing GI bleeding). In general, patients who cannot bear weight due to arthralgias, pain not controlled with oral medications, ongoing GI bleeding, or renal involvement and signs of fluid overload should be admitted for pain control and fluid management. Use of glucocorticoids is controversial, as some evidence suggests improvement in GI sequelae but little benefit in preventing renal complications.[50]

Disposition

HSP nephritis may cause fluid overload, electrolyte derangements, and elevated blood pressure, requiring treatment with albumin, diuretics, and nephrology consultation. Milder cases of HSP may be managed outpatient with weekly PCP follow-up for BP and UA monitoring. Most cases resolve uneventfully, but some will have renal complications and recurrence.

Hemolytic Uremic Syndrome

KEY CONCEPTS

- Hemolytic uremic syndrome consists of a triad of acute kidney injury, thrombocytopenia, and microangiopathic hemolytic anemia, and is most frequently associated with *E. coli* 0157 Shiga toxin–producing bloody diarrhea.
- Care is mostly supportive with red blood cell transfusion, fluid and electrolyte management, and possibly renal replacement therapy.

Foundations

Hemolytic uremic syndrome (HUS) consists of acute kidney injury, thrombocytopenia, and microangiopathic hemolytic anemia, occurring secondary to an inciting etiology. Classification of HUS can be divided into either diarrhea positive, or typical HUS, versus diarrhea negative, or atypical HUS; 90% of cases are due to typical HUS secondary to Shiga toxin–producing *E. Coli* 0157, *Shigella*, or *Streptococcus* pneumoniae. The other 10% of cases are due to atypical HUS secondary to hereditary complement-mediated disease, pregnancy, malignancy, or medications.[51]

Clinical Features

Children often present with prodromal fever, abdominal pain, vomiting and diarrhea. After the first few days, the diarrhea progresses to bloody diarrhea and urine output may drop. Though rare, patients with HUS secondary to pneumococcal disease will present with fever, cough, and respiratory distress consistent with pneumonia. Patients with atypical HUS present with low urine output, signs of thrombocytopenia and anemia, and may also have neurologic complaints. Physical examination may reveal a petechial rash, pallor, and a tender abdomen.

Differential Diagnoses

Differential diagnosis includes other causes of thrombocytopenia and AKI, such as disseminated intravascular coagulation (DIC), TTP, or other vasculitides.

Diagnostic Testing

Laboratory studies recommended include a CBC with differential and smear to assess for microangiopathic anemia and thrombocytopenia, BMP to evaluate BUN and creatinine, as well as stool PCR to evaluate for *E.coli* O157 Shiga toxin. Coagulation studies can assess for DIC, and patients with fever and neurologic changes can have ADAMTS autoantibodies measured to diagnose TTP. Patients who are ill-appearing can have blood and urine cultures drawn, and those with altered mental status with severe thrombocytopenia may need a CT head scan to assess for intracranial hemorrhage.

Management

Management of HUS is largely supportive, with red blood cell transfusion for anemia, fluid and electrolyte management, and close monitoring for progression of AKI to renal failure, as dialysis may be required. Antibiotics should be avoided in *E. coli* O157 Shiga toxin–induced HUS, because it leads to lysis of more bacteria and can precipitate renal failure and need for dialysis. However, HUS cases due to pneumococcal disease should be treated with ceftriaxone and vancomycin.[52] Drugs that slow down GI transit, such as loperamide and opioids, should be avoided. Severe cases may have significant neurologic involvement due to intracranial hemorrhage, seizures, or altered mental status from uremia. Platelet transfusion may be required in clinically significant bleeding, but otherwise should be avoided due to ongoing consumption. Seizures can be treated with benzodiazepines. Atypical HUS has a higher risk of progression to end-stage renal disease, and may require dialysis, biologics such as eculizumab, plasmapheresis, and eventually require renal transplantation.[53]

Disposition

Overall, most patients will warrant inpatient admission for supportive care. Patients who fully recover should have yearly follow-up for close monitoring of hypertension and renal function.

CHAPTER 168: QUESTIONS AND ANSWERS

1. A 12-year-old male presents due to right-sided scrotal pain for the last 2 days. On examination you note a swollen right testicle with normal cremasteric reflex that has a "bag of worms" consistency on examination. What is your next step in this patient's workup?
- **a.** Further imaging of the abdomen
- **b.** Further imaging of the testicles
- **c.** Mumps titers
- **d.** Urine to assess for *Neisseria gonorrhea* and *Chlamydia trachomatis*

Answer: A. Further imaging of the abdomen. The patient described has a right-sided varicocele. Most patients have a left-sided varicocele due to the angle of drainage of the left spermatic vein to the left renal vein; however, a right-sided and abrupt onset varicocele warrants abdominal imaging to investigate for an intra-abdominal mass. Imaging of the testicle would be appropriate to investigate for testicular torsion, but abdominal imaging is still necessary to rule out mass in this presentation. Mumps may present with orchitis, but not usually with varicocele. STIs do not usually present as varicoceles and in absence of other symptoms testing is not necessary at this time.

2. A family brings their 10-day-old girl into the ED for a newly developed bulge in the right inguinal area which appeared about an hour ago and is not reducible. Patient has otherwise been feeding well and afebrile prior to this. On examination, the infant is fussy but consolable and has a palpable lump in the right inguinal region which is not reducible and has no overlying erythema. What is your next step in care?
- **a.** Full septic workup with CBC, UA, blood culture, and CSF studies
- **b.** Pain control and outpatient follow up
- **c.** Surgery consult
- **d.** Ultrasound with Doppler

Answer: D. Ultrasound with Doppler. Inguinal hernia in females may contain ovary in the hernia sack due to failure of closure of the canal of Nuck, whereas hernias in males are more likely to have intestines. All females with inguinal hernia should have an ultrasound with Doppler to assess contents and assess for ovarian viability because torsion could occur. These cases do require surgical consultation after ultrasound as ovarian hernia will require more urgent surgical management. Sending the patient home with incarceration would not be appropriate in this case. Full septic workup is not indicated in an afebrile otherwise well child without signs of infection.

3. You are caring for a 3-year-old boy who was brought in by his mother for a possible abdominal mass palpated during his bath tonight. As part of your workup you obtain a renal bladder ultrasound that demonstrated a right-sided renal mass. What is the most likely etiology of his renal mass?
- **a.** Congenital mesoblastic nephroma
- **b.** Neuroblastoma
- **c.** Renal cell carcinoma
- **d.** Wilms tumor

Answer: D. Wilms tumor. The most common renal cancer in children is Wilms tumor. The second most common cancer in patients <12 months is congenital mesoblastic nephroma and <5 years is renal cell carcinoma.

4. Patients with nephrotic syndrome are at risk for which complication?
- **a.** Henoch-Schönlein purpura
- **b.** Supraventricular tachycardia
- **c.** Thrombosis
- **d.** Vascular malformations

Answer: C. Thrombosis. Due to increased permeability of the basement membrane, patients lose antithrombin 3 molecules which predisposes them to thrombosis. Patients are also at risk for infections, fluid overload, and electrolyte abnormalities. In general, patients do not have increased risk of Henoch-Schönlein purpura, supraventricular tachycardia, or vascular malformations.

5. A 5-year-old male presents with 5 days of diarrhea followed by 1 day of bloody diarrhea, fever, and abdominal pain. Labs reveal acute kidney injury, thrombocytopenia, and schistocytes on smear. Further workup most likely reveals which pathogen?
- **a.** *Campylobacter*
- **b.** *E. coli* 0157
- **c.** *Salmonella*
- **d.** *Shigella*

Answer: B. *E. Coli* 0157. Most cases of HUS occur secondary to Shiga toxin–producing *E. coli* 0157 and less frequently due to *Shigella* or *Salmonella*. Though *Campylobacter* can result in bloody diarrhea, it does not usually cause hemolytic uremic syndrome as described with acute kidney injury, thrombocytopenia, and microangiopathic hemolytic anemia.

Pediatric Neurologic Disorders

Marc Auerbach and Niyati Mehta

KEY CONCEPTS

- Altered mental status in children has a varied spectrum of clinical presentations, and may include any of the following: altered level of consciousness, excessive sleepiness, irritability, lethargy, and abnormal behavior.
- A careful and detailed history is instrumental in determining whether an event was a seizure.
- Status epilepticus constitutes a neurologic emergency that carries high morbidity and mortality rates. Initial treatment is typically with IV benzodiazepines, followed by fosphenytoin or levetiracetam. If the seizure continues to be refractory after a second-line agent, the patient may require airway management.
- A simple febrile seizure is generalized, lasts less than 15 minutes, and occurs in a neurologically and developmentally normal child between 6 months and 60 months of age.
- Breath-holding spells occur in children 6 months to 6 years of age, and are triggered by pain or emotional upset. After a trigger, the child becomes pale or cyanotic and may lose consciousness, sometimes with a brief period of clonic movements or opisthotonos that may mimic a seizure.
- Warning signs of secondary headaches include sudden onset, occurrence with straining or exertion, association with neurologic symptoms, change in headache pattern, nocturnal awakening, worsening in a recumbent position, and bilateral occipital headaches.
- If there are red flags on the history or physical exam, radiologic evaluation by computed tomography (CT), magnetic resonance imaging (MRI), or both may be necessary to rule out secondary causes of headache, such as intracranial hemorrhage, subarachnoid hemorrhage, brain tumor, or brain abscess.
- A toxicology screen is the test with the highest diagnostic yield for acute-onset ataxia in children.
- In children, 40% of ataxia cases are caused by acute cerebellar ataxia.
- Approximately 45% to 60% of all childhood brain tumors arise in the brainstem or cerebellum and can manifest with slowly progressive ataxia.
- When assessing an infant or child with motor weakness, it is important to distinguish presentations consistent with upper motor neuron pathology from lower motor neuron processes.
- Strokes represent a pediatric neurologic emergency and may be hemorrhagic or ischemic in nature. Imaging with CT or MRI can help confirm the diagnosis of stroke. Children with stroke may present with less specific signs such as headache, seizure, or alteration level of consciousness.
- Children presenting with suspected or confirmed strokes should be emergently transferred to a pediatric stroke center for timely consideration of therapies.
- Spinal cord compression is a medical emergency and requires prompt diagnosis and treatment. It may arise from trauma, infection and inflammation, or malignancy.
- The diagnosis of Guillain-Barré syndrome (GBS) is largely clinical, although lumbar puncture (LP) may be helpful in confirming the diagnosis. Patients with GBS are at risk for respiratory compromise and should be admitted to the hospital for observation and supportive care.
- The diagnosis of infant botulism is largely clinical. If there is high clinical suspicion, treatment should be initiated promptly, without awaiting laboratory confirmation. Given the risk of respiratory compromise, infants with botulism should be admitted to the hospital for observation and supportive care.
- Diagnosis of myasthenia gravis is often not confirmed in the ED. The disorder can often be treated on an outpatient basis, but patients with truncal involvement and concern for respiratory compromise should be admitted to the hospital for observation and supportive care.

SEIZURES

Foundations

Seizures are a common pediatric neurologic disorder presenting to the emergency department (ED); up to 10% of children suffer at least one seizure in the first 16 years of life, most of which are febrile seizures. A seizure is defined as a paroxysmal event characterized by temporary involuntary changes in the patient caused by excessive synchronous electrical neuronal discharges of a group of cortical neurons. The clinical manifestations of the seizures depend on the location of the neurons involved, and may include alterations in motor activity, behavior, level of consciousness, or autonomic function. Infants and children younger than 5 years are thought to be more susceptible to seizures due to an immature nervous system, in which excitatory neuronal activity predominates and inhibitory systems are undeveloped. A paucity of synaptic connections and alterations in the synthesis of neurotransmitters may also play a role. Epilepsy is commonly defined as the occurrence of two or more unprovoked seizures. Provoked seizures are caused by an identifiable trigger and stem from a broad array of disturbances, including fever, metabolic derangements, and trauma (Table 169.1). Reflex seizures may be precipitated by a specific, identifiable stimulus, such as flashing lights on television or video games. Unprovoked seizures have no clear immediate precedent.

Clinical Features

The initial approach to the diagnosis and treatment of a pediatric patient with ongoing seizures involves resuscitation measures to ensure a patent and protected airway, adequate oxygenation and ventilation, stable circulation, and seizure control. The initial history should include duration of the seizures, preceding signs and *s*ymptoms, *a*llergies, current *m*edications, risk of ingestion, *p*ast medical history, *l*ast meal, and *e*vents preceding the seizure (SAMPLE). For patients who are no longer seizing on presentation, witnesses should be asked to provide a description of the event: type of body movements, accompanying

TABLE 169.1 Common Pediatric Presentations and Associated Differential Diagnoses

Pediatric Presentation	Underlying Diagnoses to Consider
Seizure	Infection (meningitis, sepsis, encephalitis) Metabolic derangement Ingestion Trauma Intracranial mass Antiepileptic dose or medication effect (in patient with known seizure disorder)
Altered mental status	Vascular event (stroke, arteriovenous malformation, intracranial bleed) Infection (meningitis, sepsis, encephalitis) Trauma Ingestion (toxin, medication) Seizures (clinical or subclinical) Structural/anatomic (intracranial mass/tumor, hydrocephalus) Metabolic derangements (e.g., diabetic ketoacidosis, hypoglycemia, urea cycle defect) Intussusception
Headache	Nonpathologic: due to stress, inadequate sleep, dehydration, fever, viral infection Migraine Trauma, concussion Intracranial pathology: mass, bleeding, hydrocephalus Infection (e.g., meningitis, sepsis, encephalitis)
Ataxia/disorders of balance	Postviral, postinfectious syndrome Intracranial mass Ingestion Metabolic disorders
Motor dysfunction, weakness	Vascular event (stroke) Spinal cord dysfunction (e.g., secondary to trauma, infection, autoimmune disorder) Infection-related (e.g., Guillain-Barré syndrome, Lyme disease, botulism) Idiopathic (Bell palsy)

trauma, associated symptoms (e.g., urinary incontinence), duration, and postictal signs (e.g., period of sleepiness, lethargy or confusion). Patients with known seizure disorders should be asked about recent medication changes (i.e., new medications, missed doses, or dose adjustments) or any factors that may impact metabolism of medications (e.g., growth, diet change, illness, activity change).

The initial physical examination should focus on signs of systemic disease that can cause seizure, including evidence of meningitis or trauma and a review of the vital signs for hypertension or clinical toxidromes. After the seizure has resolved, a thorough examination should be completed, including a complete neurologic examination and funduscopic examination to assess for papilledema and retinal hemorrhages. Skin lesions may indicate a neurocutaneous disorder such as tuberous sclerosis or neurofibromatosis (Fig. 169.1 and 169.2) and café-au-lait spots or hypopigmented nevi. There is a high incidence of subclinical electrographic seizures in infants. Neonatal or infantile seizures may be subtle; apnea, sustained eye deviation, chewing, or

Fig. 169.1 Café-au-lait spots as seen with neurofibromatosis. (From: Boyd KP, Korf BR, Theos A. Neurofibromatosis type I. *J Am Acad Dermatol*. 2009;61:1-16.)

Fig. 169.2 Ash leaf spots as seen in tuberosclerosis. (From: Jindal R, Jain A, Gupta A, Shirazi N. Ash-leaf spots or naevus depigmentosus: a diagnostic challenge. *BMJ Case Rep*. 2013:2013.)

limb bicycling movements may be the only apparent signs. Focal clonic movements are often associated with an underlying structural lesion in the brain.

If the presenting signs and symptoms are consistent with seizure activity, the seizure can then be classified by type based on the following three elements[1]: (1) location of onset (focal versus generalized); (2) level of consciousness/awareness (aware, impaired awareness, altered level of consciousness); and (3) motor versus nonmotor (i.e., staring, nonconvulsive status epilepticus, versus convulsive) (Table 169.2).

Generalized Seizures

Generalized seizures may be convulsive or nonconvulsive. A convulsive seizure may start focally and generalize secondarily. Convulsive status epilepticus is a true neurologic emergency defined as 5 minutes or more of continuous seizure activity (clinical or electroencephalographic) or recurrent seizure activity without return to baseline between seizures.[2] Refractory status epilepticus is defined as status epilepticus that does not respond to first- and second-line antiepileptics. Super-refractory status epilepticus is defined as status epilepticus that persists 24 hours or more. Super-refractory status epilepticus is associated with a risk of mortality (3%) and long-term morbidity, including recurrent seizures and cognitive-behavioral impairment.[3] The diagnosis of convulsive status

epilepticus is usually obvious; however, the duration of the seizures is often underestimated because the intensity of the jerking tends to diminish with time. Status epilepticus occurs more frequently in children than in adults, particularly in those younger than 1 year. Medication changes, toxic ingestion, idiopathic epilepsy, metabolic derangements, and congenital abnormalities are common etiologies of pediatric seizures.

Nonconvulsive status epilepticus is marked by an altered mental status. Patients may demonstrate confusion, unresponsiveness, abnormal motor movements, twitches, lip smacking, automatisms, and sympathomimetic changes such as tachycardia, hypertension, and dilated pupils. An electroencephalogram (EEG) can confirm the diagnosis and should be obtained if nonconvulsive status is suspected. The most common type of generalized nonconvulsive seizure is absence seizures. Absence seizures are marked by a brief arrest of consciousness and movement, typically lasting 5 to 30 seconds; no postictal drowsiness occurs. It may be difficult to differentiate a brief complex partial seizure, in which a child may stare and not respond, from an absence seizure. Psychogenic nonepileptic seizures (PNES), caused by psychological factors, are events that look like generalized seizures but are not epileptic in nature. PNES are more common in patients with epilepsy, and patients with PNES are often later diagnosed with an epileptic seizure disorder.

Focal Onset

There are two types of partial (i.e., focal) seizures—complex and simple. In simple partial seizures, the patient experiences no change in mentation. In complex partial seizures, the patient experiences a change in level of awareness, and may exhibit bizarre behaviors, including staring, lip smacking, wandering, or picking at clothing. An important subcategory of focal seizures is composed of benign focal epilepsies of childhood, which are idiopathic in nature (i.e., they do not result from abnormalities in brain structure or injury to the brain). Benign focal epilepsies spontaneously resolve over time; benign childhood epilepsy with centrotemporal spikes (i.e., benign rolandic epilepsy) is most common and represents 10% to 20% of all childhood epilepsies.

The etiology of seizures can be divided into three categories—acute symptomatic, remote symptomatic, and idiopathic. Acute symptomatic seizures are provoked by an acute event such as fever. Remote symptomatic seizures are due to a preexisting or remote central nervous system (CNS) lesion such as cerebral palsy, neurocutaneous disorders, neurodegenerative disease, or a congenital brain malformation. Idiopathic seizures have no identifiable cause (Table 169.3).

Fever is the most common cause of acute symptomatic seizures. A febrile seizure is defined as a seizure occurring in the presence of fever without CNS infection or other cause and occurs in up to 5% of children. A simple febrile seizure is generalized, lasts less than 15 minutes, and occurs in a neurologically and developmentally normal child between 6 months and 60 months of age. Complex febrile seizures are diagnosed when multiple seizures occur during the same illness, the seizures are longer than 15 minutes, or the seizures have a focal component. Febrile seizures typically occur early in the course of illness; higher temperature or reduction of fever with antipyretics does not reduce the risk of seizure. Meningitis should be considered

TABLE 169.2 Classification of Seizures

Onset	Focal Onset	Generalized Onset	Unknown Onset
Awareness	Aware Impaired awareness	Impaired awareness	Unsure of awareness
Other Features	Motor Nonmotor	Motor Nonmotor (Absence)	Nonmotor (Absence)
	May progress from focal to bilateral tonic-clonic (generalized)		*Unclassified seizures do not fit in any other category*

(Adapted from: Fisher RS, Cross JH, French JA, et al. Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia.* 2017;58:522-530; and Trinka E, Cock H, Hesdorffer D, et al. A definition and classification of status epilepticus—Report of the ILAE Task Force on Classification of Status Epilepticus. *Epilepsia.* 2015;56:1515-1523.)

TABLE 169.3 Causes of Seizures

CAUSE	EXAMPLES
Fever (febrile seizure)	
• Infectious process	Meningitis, encephalitis, brain abscess, other infectious process (viral or bacterial infections including viral URI, pneumonia, otitis media, AGE, UTI)
• Traumatic lesions	Cerebral contusion, hemorrhage (subdural, epidural, subarachnoid, intraparenchymal), impact seizure
Toxic conditions	Drug intoxication, drug withdrawal
Metabolic disturbances	Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, hypophosphatemia, hepatic or renal disorder, inborn errors of metabolism (e.g., aminoacidurias, organic acidurias, mitochondrial disease)
Neoplastic disease	Brain tumors
• Vascular disorders	Arteriovenous malformation, subarachnoid hemorrhage, intraparenchymal hemorrhage, cerebral venous thrombosis, ischemic infarct, hypertensive encephalopathy
• Neurocutaneous disorders	Neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome
Neurodegenerative disorders—miscellaneous	Hypoxia, ventriculoperitoneal shunt malfunction, cerebral palsy, cerebral dysgenesis, primary epilepsy

in any patient with seizures and fever. However, a child whose mental status is normal before and after the seizure is very unlikely to have meningitis.[4] We recommend considering a lumbar puncture in infants younger than 6 months presenting with febrile seizures, especially those with complex features or who have other risk factors for bacterial meningitis (e.g., underimmunized, comorbid disease, immunocompromised).

Electrolyte derangements including hypoglycemia, hyponatremia, and hypernatremia are other common causes of acute symptomatic seizures in children. Hypoglycemia resulting in seizure may be the first presentation of an infant with an underlying metabolic disease. Dehydration is the most common cause of *hyper*natremia, whereas *hypo*natremia may be secondary to overdilution of infant formula—a feeding history should be obtained in infants with abnormal serum sodium levels. Hypocalcemia and hypomagnesemia may lead to muscle spasms, paresthesias, hyperactive reflexes, weakness, tetany, or seizures. Hypocalcemic seizures are a common cause of neonatal seizures.

Posttraumatic seizures occur in as many as 15% of children after head injury. Impact seizures, occurring within 1 hour of a head trauma, are often not associated with significant injury or with the development of epilepsy and therefore trigger diagnostic imaging with CT. It may be difficult to distinguish impact seizures from those associated with intracranial injury; existing clinical decision rules and electronic decision support systems should determine need for intracranial imaging.[5] Early posttraumatic seizures, occurring within the first week of injury, may arise from cerebral edema or intracranial hemorrhage or contusion.

Brain tumors and intracranial masses can present with seizures, depending on their location. However, infratentorial tumors, the most common location in the pediatric population, do not typically cause seizures. A seizure may be the presenting sign of stroke or vascular anomaly (discussed in more detail later in this chapter). Numerous drugs are known to cause seizures in children, especially in overdose. Cyclic antidepressants, cocaine and other stimulants, antihistamines, and isoniazid are the most common agents of drug-induced seizures. Seizures may occur during drug withdrawal from benzodiazepines or ethanol, usually within 48 hours of cessation.

Differential Diagnoses

Paroxysmal alterations in level of consciousness or motor activity may be confused with seizure activity in children (Table 169.4). Syncope can be mistaken for a seizure, as it is characterized by a sudden loss of consciousness and motor tone caused by a transient, global cerebral hypoperfusion. The patient may complain of lightheadedness and blurry vision or appear pale and sweaty prior to the event. Brief jerking movements with trembling or stiffening are common with syncopal events, but should not be prolonged, and postictal confusion or lethargy does not occur. Vasovagal syncope is common in otherwise healthy children and does not warrant further evaluation unless recurrent. Syncope or seizure-like events occurring during activities or associated with palpitations may be a presentation of potentially fatal cardiogenic syncope, such as prolonged QTc syndrome; patients should have an ECG obtained in their evaluation. Breath-holding spells occur in up to 5% of children and are triggered by pain or emotional upset. The first episode usually occurs between the ages of 6 and 18 months, with episodes recurring up to 6 years of age. After a trigger, the child becomes pale or cyanotic and may lose consciousness, sometimes with a brief period of clonic movements or opisthotonos. The average attack lasts approximately 40 seconds. A history of recurrent episodes associated with crying may be helpful in distinguishing these from seizures or brief resolved unexplained events. Migraines may mimic seizures or stroke, particularly when they are accompanied by an aura, motor dysfunction, clouding of consciousness, or vomiting.

TABLE 169.4 Disorders That Mimic Seizures

Age Group	Features
Neonates	Jitteriness
	Benign neonatal sleep myoclonus
	Nonepileptic apnea
	Opisthotonos
	Normal movement
Nonneonates	Breath-holding spells
	Rigors or chills
	Gastroesophageal reflux (Sandifer syndrome)
	Migraine
	Benign paroxysmal vertigo of childhood
	Syncope
	Neurovascular event
	Sleep disorders
	Sleep myoclonus
	Narcolepsy
	Nightmares, night terrors, somnambulism
	Movement disorders
	Tics or stereotypies
	Infantile shuddering attacks
	Paroxysmal choreoathetosis or dystonia
	Behavioral or psychiatric disturbances
	Psychogenic seizures
	Panic attack

Disorders of sleep are distinguished by excessive daytime sleepiness or by disordered nighttime sleep. Patients with narcolepsy have daytime sleep attacks, sleep paralysis, hypnagogic hallucinations (i.e., vivid hallucinations while falling asleep), and cataplexy (i.e., sudden loss of motor tone). Cataplexy may be mistaken for atonic or absence seizures. Nocturnal enuresis may be a symptom of unwitnessed nighttime seizure associated with incontinence. In night terrors (pavor nocturnus), the child suddenly wakens, crying inconsolably, and is relatively unresponsive. The child returns to sleep and does not typically recall the event. Sleep walking (somnambulism) and sleep talking (somniloquy) are common among school-age children.

Movement disorders may mimic seizures. Tics are rapid, repetitive, brief involuntary movements that occur intermittently and in flurries. Those most commonly seen are eye blinking and head shaking. Patients do not lose consciousness. Sydenham chorea is an autoimmune-mediated systemic inflammatory response that occurs in association with a group A streptococcal pharyngitis infection. It typically manifests with irregular, nonrhythmic, involuntary jerking of the extremities and face, and may present during the acute phase of the streptococcal infection or as a latent manifestation months after the initial illness. Shudder attacks, with movements like the chill experienced when cold water runs down the back, are uncommon but easily mistaken for seizures. Paroxysmal choreoathetosis is an abnormal motor movement that may be spontaneous or triggered by the child's movement.

Behavioral or psychiatric disturbances can produce behaviors that may appear epileptic. Panic attacks may be mistaken for complex partial seizures, with a sudden sensation of intense fear accompanied by shortness of breath, dizziness, palpitations, sweating, choking, chest discomfort, and fear of dying. Psychogenic seizures or pseudoseizures are involuntary events that mimic seizures. Many children with

psychogenic seizures also have epileptic seizures. Prolonged electroencephalographic with video monitoring may be necessary to differentiate an epileptic seizure from a psychogenic seizure.

Infants with gastrointestinal reflux may have Sandifer syndrome and appear to have seizure-like movements with episodes of abnormal posturing, arching of the back, and torticollis.

Management

The initial management of any actively seizing child involves ensuring patency of the airway, adequate oxygenation and ventilation, and support of circulation. Oxygen should be applied via cannula or face mask, and intravenous (IV) or intraosseous (IO) access quickly obtained. Monitoring end-tidal carbon dioxide may be helpful to assess ventilatory status. Patients with ongoing convulsions are at risk for hypoventilation and apnea, and preparations should be made to assist ventilation. The goal is to rapidly stop the seizure with antiepileptic medication while assessing for the underlying cause.

Hypoglycemia causing seizures in infants and children is treated with an IV bolus of 10% dextrose, 5 mL/kg, with repeat boluses as needed to normalize the serum glucose level. Severe symptomatic hyponatremia presenting with seizures is treated with the administration of 3% saline (3 mL/kg IV infused over 30 minutes) to raise the serum sodium chloride level by 3 to 7 mEq/L. Hypernatremia should be corrected slowly over 48 hours. Hypocalcemia is treated with 10% calcium gluconate, 100 mg/kg IV over 5 to 10 minutes; the patient should be on a cardiac monitor during the infusion. Toxic ingestions are treated based on the specific toxin involved. Seizures caused by isoniazid (INH) poisoning are particularly resistant to standard seizure treatment, yet respond to pyridoxine. The dose of pyridoxine is 1 g IV for every gram of INH ingested. When the quantity of INH ingested is unknown, 5 g IV may be administered to an adult and 70 mg/kg (maximum, 5 g) to a child at rate of 1 g/minute until seizure stops or maximum dose.

Status Epilepticus

Status epilepticus is a true medical emergency. The patient should be positioned to maximize ventilation and prevent aspiration; attempts should be made to immobilize the cervical spine if trauma is suspected. Oxygen should be administered by nasal cannula or face mask with a bag valve mask for positive pressure if ventilation is inadequate. A large suction catheter should be available to suction oropharyngeal secretions. In younger patients, the tongue may obstruct the airway; a nasopharyngeal airway should be used to improve ventilation unless there is significant facial trauma. Oral pharyngeal airways may lead to vomiting when the seizure resolves and are often not utilized in treatment of seizures. If there is evidence of increased ICP, the head of the bed should be elevated. In a prolonged seizure, treatment with multiple medications or increased metabolic demand may lead to respiratory failure, necessitating intubation. We suggest that noninvasive measures are used to support ventilation in the initial phases of treatment before moving to intubation. If the decision is made to intubate, a sedative agent with antiepileptic activity should be selected (e.g., propofol, ketamine). In addition, a short-acting neuromuscular blocker (e.g., succinylcholine) is preferred to allow for monitoring of continued seizure activity as long as other contraindications to its use are not present.

Heart rate, blood pressure, respiratory rate, and pulse oximetry should be monitored and hyperthermia treated with antipyretics and cooling blankets. An IV line or, if an IV cannot be established, an IO line should be placed and blood samples sent for electrolyte values, glucose concentration (including rapid blood glucose test), calcium and magnesium levels, renal function tests, liver function tests, antiepileptic levels (when indicated), and CBC. Urine should be sent for toxicology. Metabolic abnormalities should be corrected.

Anticonvulsant treatment should begin as quickly as possible (Fig. 169.3).[6] Delays in the initiation of benzodiazepines of greater than 10 minutes is associated with higher frequency of death, longer seizure duration, and more complications.[7] Benzodiazepines, particularly lorazepam and diazepam, are the initial drugs of choice in the treatment of status epilepticus; they diffuse quickly into the CNS, rapidly terminating seizure activity 70% of the time. Hypotension, respiratory depression, and impaired consciousness may occur after administration. Intranasal, buccal, or intramuscular routes may be used if IV or IO access cannot be obtained within the first 1 to 2 minutes of resuscitation and are preferable to rectal administration. Recommended doses for these non-IV preparations are shown in Fig. 169.3.

A second dose of benzodiazepine should be administered only after 5 minutes of continued seizure activity following the first dose. If the seizure persists an additional 5 minutes after giving the second benzodiazepine dose, consider administering a third benzodiazepine dose and load with a second-line agent. The choices of second-line agents include levetiracetam, fosphenytoin, or valproic acid (Fig. 169.3).[6] There is limited evidence that one of these agents is preferred to the others. Recent controlled trials comparing phenytoin or phosphenytion to levetiracetam did not note a difference in the cessation of seizures.[8,9] One trial in Pakistan noted fewer adverse events and an improved efficacy for levetiracetam compared to phenytoin.[10] Valproic acid is contraindicated in the presence of liver disease, thrombocytopenia, or possible metabolic disease. There is limited evidence consisting of case reports that ketamine may be effective in treating refractory status epilepticus compared to conventional anesthetics and other agents.[11]

Fosphenytoin is a water-soluble phosphate ester of phenytoin that is rapidly converted in plasma to phenytoin. Unlike phenytoin, fosphenytoin can be administered intramuscularly and with common IV solutions and is substantially less cardio-toxic and less sclerosing to the vasculature. In addition, it can be given three times more rapidly than phenytoin. Fosphenytoin achieves plasma concentrations similar to those achieved for phenytoin. If seizures continue after loading with a second-line agent, another second-line agent can be administered. We recommend a propofol or a midazolam infusion as third-line agent to induce a coma. Other options include phenobarbital, pentobarbital, thiopental, or inhalant anesthetics. All have significant associated side effects and cause apnea, depressed consciousness, and hypotension; these side effects are more pronounced in the presence of benzodiazepines. Patients receiving these agents should receive continuous cardiorespiratory monitoring; staff and equipment should be readily available to support ventilation and advanced airway management.

Pediatric refractory status epilepticus is a high stakes and low frequency event and we recommend consultation with a neurologist when possible. Nonconvulsive status epilepticus is more difficult to recognize and often requires electroencephalography for diagnosis. Once the seizure has been effectively terminated, neuroimaging and lumbar puncture (LP) are often indicated to elucidate the cause of the seizure further.

Febrile Seizures

Children with simple febrile seizures do not require blood and urine testing other than as needed for the evaluation of fever source. An LP is not necessary in children older than 6 months with no signs of meningitis and no severe ill appearance before or after the seizure. If a child is less than 6 months or not fully immunized, an LP should be considered. Electroencephalography, neuroimaging, admission, or specialty consultation is not required after a first simple febrile seizure. Children who fully recover after a simple febrile seizure can almost always be sent home. Guidance for families should include high likelihood of recurrence (>33%), the small increased risk for the development of

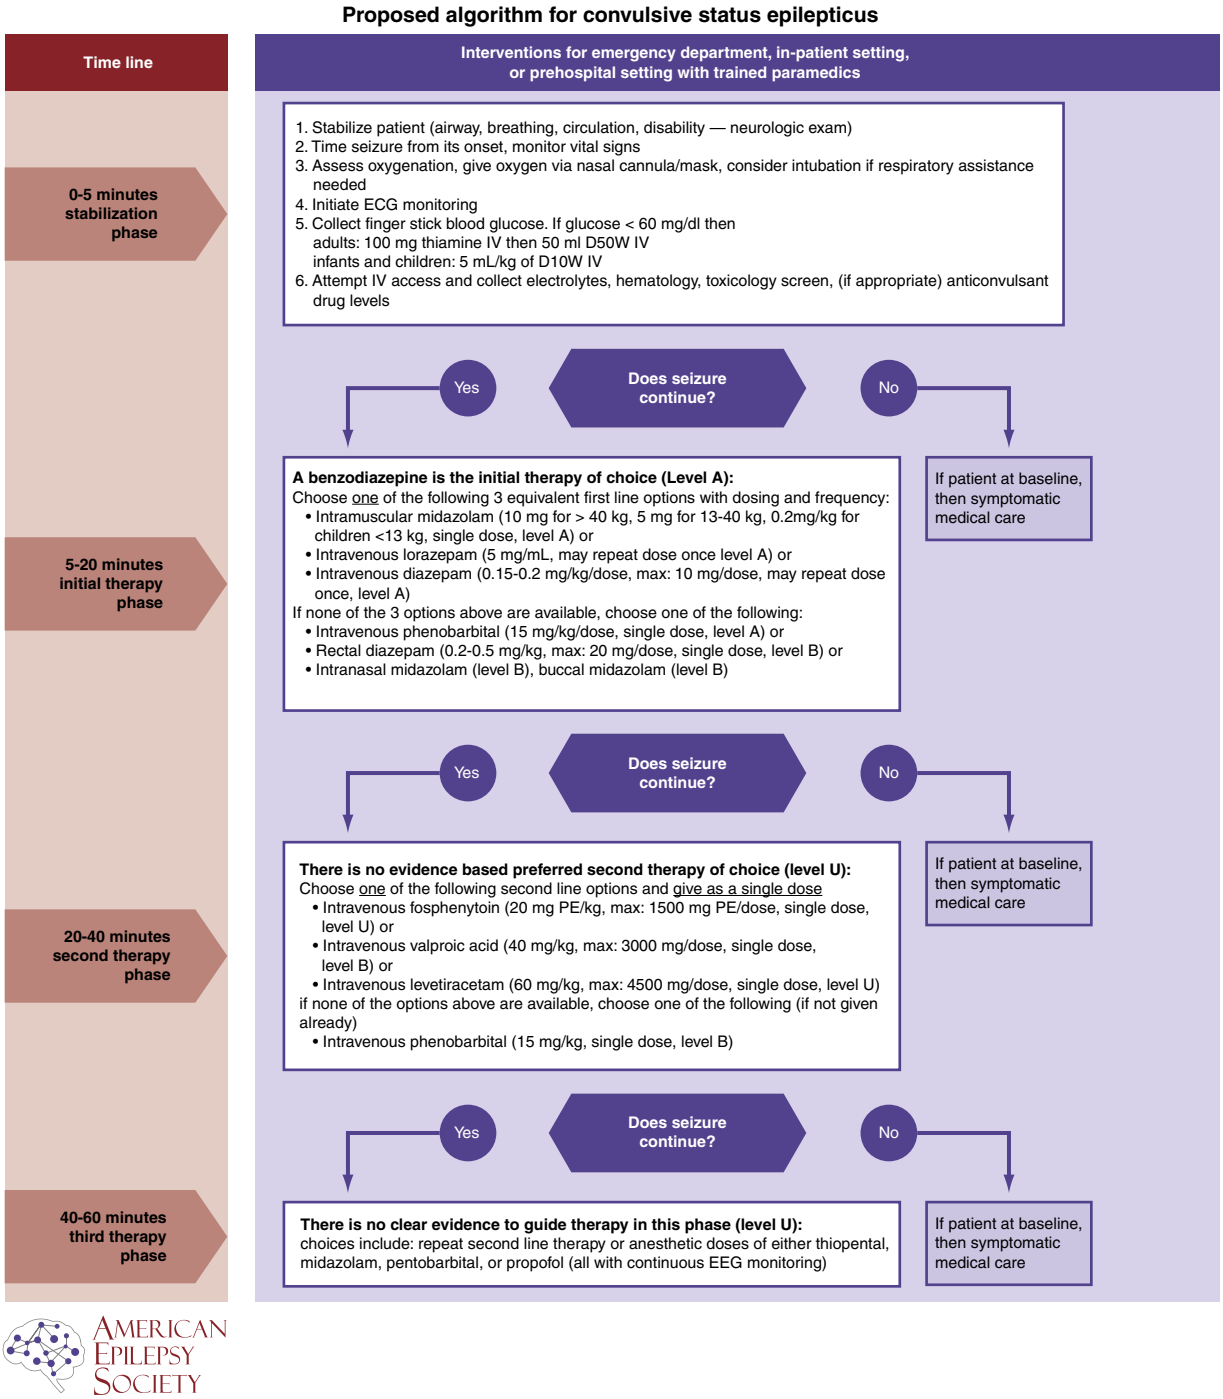

Fig. 169.3 Management of status epilepticus in infants >1 month of age and children. *IO,* Intraosseous; *IV,* intravenous. (Modified from: Glauser T, Shinnar S, Gloss D, et al. Evidence-based guideline: treatment of convulsive status epilepticus in children and adults: Report of the Guideline Committee of the American Epilepsy Society. *Epilepsy Curr.* 2016;16(1):48-61.)

afebrile seizures (2% to 5% or double the baseline risk), fever control, and emergency measures for seizure. Extensive anticipatory guidance and reassurance should be provided to the family with close follow-up with their pediatrician.

Afebrile Seizures

For infants and children older than 6 months who have had a first-time afebrile seizure and have returned to baseline, laboratory testing should be pursued in a targeted manner, based on clinical and historical findings. A seizure in the setting of recent vomiting, diarrhea or starvation may warrant examination of serum chemistries for possible electrolyte abnormalities. A toxicology screening history should be performed to explore any medications in the home and laboratory testing considered. A lumbar puncture should be considered for patients who present with unprovoked seizures and persistent abnormal mental status, do not return to baseline, or show signs of meningitis. An outpatient EEG may be appropriate in well-appearing children who have returned to baseline.

BOX 169.1 Common Causes of Neonatal Seizures[a]

Hypoxic ischemic encephalopathy
Central nervous system infection
Intracranial hemorrhage
Trauma (accidental and nonaccidental)
Metabolic derangements (e.g., hypocalcemia, hyponatremia)
Cerebral infarction
Chromosomal or congenital brain abnormalities
Inborn errors of metabolism
Drug withdrawal or intoxication

[a]Infants <1 month of age.

Emergent neuroimaging should be performed in infants and children with new focal neurologic deficits, persistent altered mental status (including status epilepticus), recent trauma, persistent headache, or partial seizures. Children with generalized unprovoked seizures and normal examination findings on presentation do not necessarily require emergent imaging. A focal abnormality on follow-up EEG may indicate a need for neuroimaging, which can be done on an outpatient basis. Children with a history of epilepsy do not need neuroimaging unless there is a change in clinical status or marked change in seizure pattern.

If imaging is indicated in the acute period, CT or MRI may be used. Although MRI provides superior anatomic detail, sedation may be needed, impeding assessment of the patient's mental status. When available, a rapid sequence MRI may provide sufficient information for the acute evaluation, with a full MRI planned for a later date.[12] Often the initial imaging study of choice, CT provides rapid imaging and is highly sensitive for the detection of acute blood and fractures.

Neonatal Seizures

The common underlying causes of neonatal seizures in infants <1 month of age differ from those in older children and adults (Box 169.1). In addition to congenital abnormalities, metabolic derangements, and birth-related injuries, neonatal seizures may be the only presenting sign of nonaccidental trauma. Diagnostic assessment of neonatal seizures is broad and includes metabolic testing (blood and urine), CSF analysis, and neuroimaging. Glucose, calcium, magnesium, and electrolyte levels (basic chemistry, including sodium, potassium, chloride, bicarbonate, blood urea nitrogen [BUN] and creatinine), and CBC should be obtained; lactic acid, ammonia, ketones, and pH determinations should be considered to assess for inborn errors of metabolism. Clinical assessment for meningitis is not reliable in young infants; thus, a LP should be performed and fluid sent for cell, protein, and glucose determinations, culture, and herpes simplex PCR assay. Head CT or MRI should also be performed when the neonate is stabilized. In the unstable neonate, a head ultrasound may be performed at the bedside to evaluate for a neurosurgical emergency until more definitive imaging can be obtained.

Empirical antibiotic coverage should be initiated if an LP is suggestive of bacterial meningitis. Antiviral therapy should be administered if there are clinical concerns for herpes encephalitis, including skin or mucosal findings, continued seizures with no other clear cause, or concerning maternal history; CSF red cells are a late and ominous finding. Electrolyte abnormalities, including hypoglycemia, hypomagnesemia, and hyponatremia, should be promptly corrected as described previously. If seizures are refractory to medical treatment, empirical treatment with pyridoxine, 15–30 mg/kg/day (not to exceed 500 mg/day), should be considered for the potential for a deficiency, and this dose can be repeated over the course of 30 minutes. This should be done with EEG monitoring, as clinical seizure detection in neonates is not reliable..

Phenobarbital is the usual drug of choice for neonatal seizures. However, there is increasing evidence of phenobarbital-induced neuronal apoptosis, even with a single dose, and evidence of memory and learning difficulties in rat models.[13] Due to its potential harm, other potential first-line agents for the treatment of neonatal seizures are currently being investigated. If seizures continue, fosphenytoin may be loaded. Refractory seizures may be treated with a benzodiazepine infusion. Neonates with a first-time seizures should be admitted for continuous cardiorespiratory monitoring and evaluation by a neurologist.

Disposition

Hospitalization is unnecessary for most children after a first unprovoked brief seizure, as long as the neurologic examination is normal and follow-up evaluation arranged. Electroencephalography and imaging studies can be performed on an outpatient basis in consultation with a neurologist. Children who have had a prolonged seizure, or who are not back to their baseline within a few hours, should be admitted to the hospital. Hospitalization should also be considered if adequate follow-up evaluation cannot be arranged or in the case of extreme parental anxiety.

Anticonvulsant Therapy at Discharge

The decision to start anticonvulsant prophylaxis should be done in consultation with a pediatric neurologist, balancing the risk of recurrent seizures against potential complications associated with long-term medication use. Two-thirds of children with a first unprovoked seizure never experience a recurrence. The risk for recurrence is increased with the presence of neuroimaging or electroencephalographic abnormalities, developmental delay, family history of epilepsy, remote symptomatic seizure, first seizure occurring during sleep, and Todd paralysis. If none of these risk factors are present, the 5-year recurrence risk is only 21%. There is no evidence that early treatment with anticonvulsant medications after a single seizure alters the risk of epilepsy, nor is there evidence to show that a single self-limited seizure causes neurologic sequelae. In light of these considerations, anticonvulsants are generally started after a second unprovoked seizure. The ED provider should only initiate a seizure medication upon discharge in consultation with a pediatric neurologist and is dictated by the seizure type and the side effect profile of the agent (Table 169.5). Patients with acute symptomatic seizures associated with a risk factor for recurrence (e.g., cerebral hemorrhage, meningitis, or contusion) should be treated in the hospital with prophylactic anticonvulsants under the guidance of a neurologist; the decision to continue treatment should be made once the patient is stable.

ALTERED MENTAL STATUS

Foundations

Altered mental status is a common and challenging pediatric presentation. Groupings of possible causes include vascular events (e.g., stroke, arteriovenous malformation with bleed), infection (e.g., meningitis, sepsis, encephalitis), trauma, toxic ingestion, anatomic or structural abnormality (e.g., intracranial mass or tumor), headache syndromes (e.g., acute confusional migraines, postconcussive syndrome), metabolic derangements, (e.g., DKA, hypoglycemia), intussusception, or subclinical seizures (see Table 169.1). Individual diagnoses associated with altered mental status will not be explored in full detail in this chapter. However, a guideline for approaching and managing pediatric patients in the ED with altered mental status will be presented.

Clinical Features

Altered mental status in children has a varied spectrum of clinical presentations and may include abnormalities in cognition, behavior, or memory. In children, these are manifested as an altered level of

TABLE 169.5 Commonly Used Anticonvulsants in Children

Drug	Seizure Type	Typical Daily Dose (mg/kg)	Therapeutic Level (μg/mL)
Carbamazepine (Tegretol)	Partial, GTC	10–20 (max 1000 mg/day)	4–12
Ethosuximide (Zarontin)	Absence	15–30 (max 1500 mg/day)	1.5–10
Phenobarbital	Partial, GTC	3–6	15–40
Phenytoin (Dilantin)	Partial, GTC	4–10	10–20
Valproic acid (Depakene, Depakote)	Atonic, GTC	15–40	40–120
Lamotrigine (Lamictal)	Partial, GTC, absence, Lennox-Gastaut syndrome	5–15 (1–5 if taking valproic acid)	Not routinely measured
Levetiracetam (Keppra)	Partial, GTC, myoclonic	20–60	Not routinely measured
Topiramate (Topamax)	Partial, GTC, myoclonic, Lennox-Gastaut syndrome	5–9	Not routinely measured
Clonazepam (Klonopin)	GTC, atonic, myoclonic	0.05–0.2	Not routinely measured

Starting doses for each drug may be lower than typical daily dose, and typical daily doses may fall outside the ranges noted in accordance with the child's underlying medical conditions and other medications.

GTC, Generalized tonic-clonic.

consciousness, excessive sleepiness, irritability, lethargy, or abnormal behavior. The nature of the altered mental status (e.g., lethargy versus coma), as well as the time course and concurrent findings (e.g., fever or focal neurologic signs), should guide evaluation. Information obtained in the history may be critical to diagnoses of trauma, toxic ingestion, atypical migraine, or infection.

During the initial assessment of an altered infant or child, vital signs can be essential to understanding the underlying diagnosis. Heart rate, blood pressure, and respiratory rate, for example, may provide information about conditions such as toxic ingestion (e.g., hyperpnea with salicylate ingestions), elevated intracranial pressure (e.g., Cushing triad), or metabolic derangements, such as diabetic ketoacidosis (often presenting with tachycardia and hyperpnea). Level of consciousness may be readily assessed using the AVPU scale: ***a***lert (alert and spontaneously interactive), ***v***erbal (responds to verbal cues), ***p***ainful (responds only to painful stimuli), ***u***nresponsive (unresponsive to all external stimuli). Additionally, identifying focal neurologic deficits and the presence or absence of fever will aid in the diagnostic evaluation.

Special consideration should be given to conditions that need emergent treatment or can lead to substantial morbidity or mortality. Examples include meningitis, intracranial bleed, toxic ingestion, and stroke. In infants less than one month old, the absence of fever does not eliminate the possibility of a serious bacterial infection and these infants often demonstrate vague findings: decreased tone, poor feeding, weak suck, increased sleepiness, or fussiness, with or without abnormal vital signs. In the ill-appearing or altered infant, clinical signs are often nonlocalizing and, therefore, can present a diagnostic challenge. In this age group, there are few distinguishing features to differentiate sepsis from meningitis, metabolic derangements, or an acute abdomen.

Differential Diagnoses

The breadth of differential diagnoses associated with altered mental status in children involves a broad spectrum of potential management interventions in the ED. The mnemonic AEIOUTIPS, as outlined in Box 169.2, can assist the emergency clinician in the differential diagnosis and determining priorities for management. With the recent legalization of marijuana in many states, there has been an increase in the presentation of altered mental status due to cannabinoid ingestion in infants and children.[14] With the current opioid epidemic, ingestion or cutaneous exposure to opioids should be considered in all pediatric cases of altered mental status.

Diagnostic Testing

After evaluation and stabilization of the airway, breathing, and circulation, priorities include obtaining a bedside glucose test, rapid IV access, and laboratory testing. A point-of-care electrolyte test or blood gas can quickly assess pH, sodium, and lactate levels. Toxicology screens are warranted when a toxidrome or a risk of exposure are identified, but should not delay empiric treatment. Emergent imaging by CT or MRI should be obtained when focal neurologic deficits are present in conjunction with a history suggestive of an acute intracranial process (headaches, trauma). When inflicted head injury is suspected as an etiology of altered mental status in an infant, a head CT should be obtained. The need for a LP should be considered based on vaccination history, exposures, immunologic state, and physical exam. Antibiotic and antiviral therapy for the patient with suspected bacterial meningitis should not be delayed by a LP. If the history or physical examination raises any concern for an acute abdominal process, abdominal ultrasound should be performed to evaluate for intussusception, as its presentation is often nonspecific and can present as altered mental status alone.

Management

After the initial resuscitation, including stabilization of the airway, breathing, and circulation, data obtained by the history, physical examination, and point of care labs often dictate the first steps in management. If lab values indicate hyperglycemia, hypoglycemia, or other electrolyte imbalances, early measures should be aimed at correcting these. If the abdominal examination reveals significant tenderness, a

radiograph or ultrasound should be obtained to evaluate for surgical etiologies, including intussusception, perforation or obstruction. In ill-appearing children for which a surgical cause is suspected, we recommend emergent surgical consultation. Head imaging may also help guide early management. If there is a concern for toxic ingestion, efforts will quickly be directed at the correction of perturbations associated with the offending agent (e.g., naloxone for opioids).

When bacterial meningitis is in the differential diagnosis of altered mental status, but not highly suspected, it is reasonable to consider risk stratification of the patient to determine if antibiotics can be withheld until obtaining further information (e.g., CSF, white cell count). Finally, acyclovir should be administered to an ill or febrile infant with a history of maternal herpes simplex virus (HSV) infection, presence of vesicles on the skin, seizures, or focal neurologic signs. If a child lives or has visited an area that is endemic with infections associated with altered mental status, further evaluation and treatment should be considered (e.g., malaria, Lyme disease).

Disposition

All patients with persistent altered mental status should be admitted to the hospital for additional evaluation and monitoring for improvement or worsening. In selected cases, when the altered mental status is self-limited, the patient may be observed and discharged home with close follow-up with a primary care provider.

HEADACHES

Foundations

Headache is a common problem in children and adolescents, with 40% of children experiencing a headache by 7 years, and 75% by 15 years of age. Migraine, one of the most common causes of headache in childhood, has a prevalence of up to 20% by 15 years of age. Although most pediatric patients have benign causes of headaches, a thorough history and physical examination should be conducted to evaluate for serious and time-sensitive underlying pathologies. The history and physical should guide decisions related to the need for emergent neuroimaging.

Clinical Features

Headaches can be classified into five temporal patterns—acute, acute recurrent, chronic progressive, chronic nonprogressive, and mixed. An acute headache is new in onset and different from previous headaches; it can herald a broad range of conditions, ranging from a viral illness to subarachnoid hemorrhage. An acute headache with weakness, seizures, speech difficulty, ataxia, or neurologic deficits should prompt evaluation of time-sensitive conditions, such as a stroke.[15] Acute recurrent headaches are periodic events separated by pain-free intervals. Chronic progressive headaches continue over weeks to months. They can signify serious medical disorders, such as brain tumors or arteriovenous malformations. Chronic nonprogressive headaches usually occur for years and are classified as primary headaches (as opposed to secondary symptomatic headaches, which are caused by an underlying medical problem). Mixed headaches are acute recurrent headaches (e.g., migraines) superimposed on a pattern of daily chronic nonprogressive headaches.

The primary goal of the ED evaluation is to differentiate life-threatening causes of headaches, such as strokes or brain tumors, from primary headaches, such as migraines or tension headaches. The child's history is the most important component to an accurate diagnosis. The patient and family members should be asked about specific factors related to the headache, such as time of onset, duration, location, laterality, quality (e.g., sharp, dull, throbbing, or aching), relieving and exacerbating factors, precipitating factors (e.g., poor sleep, hunger, or specific foods), and associated symptoms (e.g., nausea, vomiting, or photophobia).

The emergency clinician should focus on a detailed history of the neurologic system to identify any related symptoms (e.g., vomiting, lethargy, ataxia, seizures, weakness, or visual disturbances) and a general review of other organ systems. Warning signs of secondary headaches include sudden onset, occurrence with straining or exertion, association with neurologic symptoms, worsening in a recumbent position, headache pattern change, nocturnal awakening, and bilateral occipital headaches. Additional information related to the past medical history (e.g., history of recent head trauma, neurologic or psychiatric disorders, hospital admissions, medications) should also be obtained, as well as any family history of headache syndromes. For those patients with a history of loss of developmental milestones, serious causes including central nervous system tumors should be considered.

The physical examination should be thorough to evaluate for infectious, toxic, and structural causes for the headache (e.g., strep pharyngitis, cannabinoid ingestion, tumor). Height, weight, and head circumference should be compared with standard percentiles and the child's previous growth history; a change in the rate or direction of head growth may indicate an intracerebral mass or hydrocephalus. The blood pressure should be carefully measured, with the use of age-appropriate cuff size and percentiles for age; hypertension may be a sign of increased ICP. An infant's fontanelle should be palpated for size and fullness, as well as auscultated for bruits associated with arteriovenous malformations. A skin examination should be performed to look for stigmata of neurocutaneous disorders, such as neurofibromatosis (café-au-lait spots; see Fig. 169.1) or tuberous sclerosis (ash leaf spots; see Fig. 169.2). The neurologic examination should begin with assessment of the child's mental status and overall development. For infants, observing their level of alertness, age-appropriate social interaction, overall tone, and general vigor is an essential component of the initial neurologic evaluation. Nonspecific findings such as irritability, fussiness, or poor feeding may be the only presenting signs in infants with headache. The neurologic examination should include a complete assessment: cranial nerves; gait analysis (when possible); cerebellar, sensory, and motor function testing; and evaluation of deep tendon reflexes. The ophthalmologic examination should include pupillary reactivity, visual acuity, extraocular movements, and funduscopic evaluation for papilledema or retinal hemorrhages. Observation of interactions between the patient and family may provide clues to potential family problems, depression, anxiety, or child abuse.

Differential Diagnoses

Headaches may be primary (e.g., migraines and cluster headaches) or secondary to an underlying disease process. The list of differential considerations for secondary headaches is extensive and should be considered in the context of the child's history and physical examination (Table 169.6).

Acute Headache

The acute headache is a common problem in children and adolescents and accompanies many infectious processes. In the absence of other signs of CNS involvement (e.g., nuchal rigidity, alteration in level of consciousness, or focal neurologic findings), headaches in febrile children usually do not constitute evidence of CNS infection; nonspecific viral illnesses or dehydration represent the most common diagnoses in children presenting to the ED with an acute headache.

Although far less common, arteriovenous malformations can be a trigger for a new severe headache. Intracranial arteriovenous malformations are structurally unstable and thus susceptible to spontaneous rupture. In children, the abrupt onset of a severe headache in the absence of trauma (especially when accompanied by focal neurologic findings) suggests an acute intracranial bleed, and a head CT should be

TABLE 169.6 Differential Diagnosis for Secondary Headache

Cause	Features

	Influenza
	Pyelonephritis
	Group A streptococcal pharyngitis
Toxic	Medication
	Ingestion

performed. Localized acute headaches without focal neurologic findings may be due to sinusitis, otitis media, dental disorders, or traumatic head injury. Headache associated with trauma should be carefully investigated for the possibility of subdural or epidural hematomas, fractures, and leptomeningeal cysts (a "growing" skull fracture, usually in a child <3 years of age, with a history of recent trauma). Ophthalmologic problems, such as astigmatism, refractory errors, eye strain, and squint, are occasionally responsible for headaches in children.

Chronic Progressive Headache

Chronic progressive headaches in children often signify underlying pathology. The development of increased ICP can be caused by brain tumors, hydrocephalus, impaired venous drainage, brain abscess, or intracranial bleeding. Headache that awakens the child from sleep (related to increased CSF production in the later hours of sleep), is present on first awakening, or is associated with early morning emesis is a classic symptom of increased ICP and suggests an intracranial mass or hydrocephalus. In the setting of an abnormal intracranial entity, such as a mass or CSF obstruction, impaired venous outflow in the supine position leads to excess volume inside the skull, generating elevated pressure. The physical examination may show signs of increased ICP—vital sign changes, including hypertension, bradycardia, and irregular respirations (i.e., Cushing triad); papilledema; brisk reflexes; cranial nerve deficits; positive Babinski sign; or decreased level of consciousness—as well as focal symptoms related to the location of the lesion (e.g., hemiparesis, ataxia, visual field deficits).

Headaches are more likely to be the first symptom of a brain tumor in older children, but may be a later finding in younger children. Frequently, there are associated symptoms: nausea, vomiting; visual effects, problems with walking, weakness, loss of developmental milestones, changes in personality or school performance, or speech changes. As symptoms progress and evolve, the diagnosis of a brain tumor is often made after one or more clinical visits for headache. Loss of developmental milestones can be a potential sign of a brain tumor in infancy and childhood. Neurologic findings in children newly diagnosed with brain tumors may include papilledema, abnormal eye movements, ataxia, abnormal tendon reflexes, abnormalities on the visual examination, or less specific signs of increased ICP.

Clinical findings of pseudotumor cerebri (i.e., idiopathic intracranial hypertension or benign intracranial hypertension) are secondary to the increased ICP and include papilledema (with or without sixth cranial nerve palsy) and visual field deficits. Idiopathic intracranial hypertension (i.e., pseudotumor cerebri) is more common in females and obese individuals, and in younger children can be associated with medications (e.g., vitamin A, steroids, birth control pills, tetracycline). Neuroimaging is normal in idiopathic intracranial hypertension and the LP usually demonstrates elevated pressure, greater than 25 cm H_2O, and normal CSF protein and glucose levels. Neuroimaging should precede LP when increased ICP is suspected. We suggest any neuroimaging performed in the evaluation of idiopathic intracranial hypertension to include imaging of the venous sinuses, as cerebral sinovenous thrombosis (CSVT) can present similarly. Treatment is usually with diuretics, with or without an initial LP for therapeutic removal of CSF.

Brain abscess can result from meningitis, head trauma, chronic otitis media, sinusitis, or septic embolization in children with congenital heart disease. Focal neurologic signs, as well as fever and headache, may be present, but the patient may look surprisingly well. CT of the head without contrast enhancement is not sufficiently sensitive when an abscess is considered in the differential, but may be obtained; CT with and without contrast enhancement or MRI should be performed. CSF findings usually include a mild leukocytosis (10–200 leukocytes/mm^3), slightly elevated protein level, and normal glucose level. The CSF smear and culture do not usually reveal any organisms.

A subdural hematoma, epidural hematoma or intraparenchymal bleed are associated with head trauma. Headaches in these patients may evolve and progress over a relatively short time period. Symptoms include those associated with increased ICP, seizures, and focal neurologic deficits. The diagnosis is confirmed by neuroimaging.

Chronic progressive headache also can be a symptom of systemic diseases, such as hypertension, collagen vascular disease, hypothyroidism, Lyme disease, mononucleosis, or inborn errors of metabolism.

Migraine Headache

The diagnosis of migraine is based on symptoms of recurrent headaches separated by pain-free intervals. Migraine headaches are multifactorial in cause, with environmental and genetic contributions. The principal mechanism of migraine headaches is thought to involve a primary dysfunction of the brain in which a wave of spreading cortical neuronal depression is accompanied by vascular changes. Derangement of the trigemino-vascular reflex results in alterations of regional blood flow, and this neurovascular interaction is thought to contribute to neurogenic inflammation and the development of migraine headaches. Serotonin (5-hydroxytryptamine [5-HT]) may be a key mediator in this cascade of events, and serotonin agonists have been shown to relieve migraine pain.

Pediatric migraines may last from 2 to more than 72 hours and are more often bilateral than unilateral, which is more common in adults. Photophobia and phonophobia may be more difficult to assess in the young child or infant. Occipital headaches are rare and should raise clinical suspicion for a diagnosis other than migraine. Migraine headaches are classified primarily into migraine with and without an aura. Migraine without an aura, also known as common migraine, is the most frequent type of pediatric and adolescent migraine and includes the following criteria: more than 5 attacks that last 2 to 72 hours (untreated or unsuccessfully treated), accompanied by nausea, vomiting, photophobia or phonophobia, and including a minimum of 2 of the following criteria: unilateral or bilateral location, pulsing quality, moderate to severe intensity, and aggravated by routine physical activities.

Migraine with an aura, previously known as classic migraine, is diagnosed when at least two attacks fulfilling the diagnosis of migraine

occur accompanied by a variety of sensory warning symptoms, such as flickering lights (scintillations), obscuration or loss of vision (scotoma), and tingling or numbness (paresthesias). The aura typically develops over 5 or more minutes and completely resolves within 60 minutes.

Migraine variants or atypical migraines are more common in children. Hemiplegic migraine is characterized by the sudden onset of hemiparesis or hemiplegia, along with headache in the contralateral hemisphere. Even though symptoms usually last for hours or even days, patients are rarely left with permanent deficits. These patients often receive imaging on initial presentation to exclude other diagnoses. Ophthalmoplegic migraine is characterized by severe unilateral eye pain and headache, followed by ipsilateral third nerve palsy of variable degree. Rarely, the fourth or sixth cranial nerve, rather than the third nerve, may be affected. Basilar artery migraine, also common in children, is manifested with a combination of visual symptoms (e.g., transient bilateral blindness, blurred vision) and visual hallucinations, vertigo, ataxia, loss of consciousness, and drop attacks. An acute confusional state can be associated with migraines and is characterized by changes in personality, orientation, or behavior. The so-called Alice in Wonderland syndrome includes perceptions of distortion in body images and shapes; objects appear much larger (macropsia) or smaller (micropsia) before, during, or after the headache.

Migraine variants are not uncommon and can be misdiagnosed. Abdominal migraine is characterized by recurrent abdominal pain, nausea, vomiting, and recurrent headaches. Benign paroxysmal vertigo of childhood (distinct from benign paroxysmal positional vertigo) is manifested as headache accompanied by the sudden onset of vertigo, pallor, and nystagmus. Paroxysmal torticollis is defined as recurrent episodes of head tilt associated with headache, nausea, and vomiting. Of note, this is a diagnosis of exclusion; children with a head tilt, vomiting, and headache should first be evaluated for a posterior fossa lesion. Ocular migraine is characterized by transient monocular visual blurring to blindness with bright flashes of light.

The incidence of seizures is higher in patients with migraine than in the general population. Although epilepsy and migraine headache are distinct clinical syndromes, they share several characteristics, such as aura, vertigo, nausea, pallor, loss of consciousness, drowsy postictal state, confusion, and transient focal neurologic deficits. Headache as the sole manifestation of a seizure is uncommon; however, headaches frequently follow tonic, tonic-clonic, and brief complex partial seizures. Bilateral frontal throbbing headaches may follow episodes of status epilepticus. Further neurologic evaluation, including electroencephalography, may occasionally be necessary to distinguish between these two syndromes.

Chronic Nonprogressive Headache

Chronic nonprogressive headache is commonly seen in the adolescent population. Included in this category are muscle contraction and conversion headaches. The International Headache Society classification of headaches refers to these types of headaches as tension headaches. This type of headache includes the following symptoms: bilateral or unilateral, nonthrobbing, pressing, or bandlike tightness of mild to moderate intensity, and the absence of nausea, vomiting, and aura. Tension headaches are further classified as episodic (10–15 episodes/month lasting 30 minutes to 7 days) or chronic (>15 episodes/month for more than 6 months).

Cluster Headache

Cluster headache is a distinctive headache syndrome that is more common in males and rare in those younger than 10 years. Cluster headache is characterized by one to several attacks recurring each 24 hours, during several weeks to months. Headache-free periods between clusters may last months to years. The pain is throbbing, severe, and unilateral; occurs over the same orbito-temporal region, and is associated with ipsilateral scleral injection, lacrimation, nasal stuffiness, and sometimes a partial Horner's syndrome (enophthalmos, ptosis, miosis, and anhidrosis, unilateral, affecting sympathetic innervation of the eye). The pain lasts 30 minutes to several hours and can occur at any time of day or night.

BOX 169.3 Indications for Radiologic Imaging in Patients With Headache

Strongly Indicated If:

- Abnormal neurologic examination findings
- Signs and symptoms of elevated intracranial pressure
- Meningeal signs plus focal neurologic findings or altered mental status
- Progressive or new focal neurologic signs
- Significant head trauma
- Severe nocturnal headaches that awaken the patient from sleep or are present on awakening
- Severe (characterized by patient as "worst headache of my life") headaches; new or of increasing frequency and duration
- Presence of ventriculoperitoneal shunt
- Chronic progressive headache

Consider If:

- Headache or vomiting on awakening
- Unvarying location of headache, especially occipital
- Persistent headache plus no family history of migraine
- Neurocutaneous syndrome
- Age < 3 years (limited verbal skills)

Diagnostic Testing

Although many patients presenting to the ED with headache do not require neuroimaging or laboratory evaluation, if neuroimaging is obtained, MRI provides superior anatomic detail compared with CT, and is particularly useful in the detection of abnormalities in the sella turcica, posterior fossa, and cervicomedullary junction. MRI/A is also better for detecting arteriovenous malformations and low-grade tumors. CT scanning, however, is superior to MRI for the detection of acute blood and skull fractures, and therefore is often the modality of choice in the ED. Indications for the use of neuroimaging are presented in Box 169.3.

An LP is indicated for the diagnosis of an infectious process, subarachnoid hemorrhage not detected by CT, or idiopathic intracranial hypertension. In general, radiologic imaging should precede an LP on any patient with a headache or other red flags (e.g., early morning headaches and vomiting, progressively worsening headaches, or focal neurologic findings).

Chronic progressive headaches may be a symptom of a systemic disease. Guided by the history and physical examination, laboratory tests may include CBC, urinalysis, erythrocyte sedimentation rate, antinuclear antibody testing, liver function studies, thyroid function studies, serum lipid assay, serum magnesium concentration, lactate concentration, pyruvate concentration, and Lyme disease titers.

Management

Treatment of primary childhood headaches includes attention to initial pharmacologic management, as well as reassurance, removal of potential triggers, and initiation of a behavioral management program. The most important aspect of management is a thorough history and physical examination, past medical history of migraines or systemic disease, and targeted diagnostic evaluation for potentially life-threatening causes.

In addition to the use of standard oral analgesics, abortive treatment for children presenting to the ED with migraine headaches generally involves IV fluid hydration with a normal saline bolus, nonopioid analgesics (e.g., ibuprofen or IV ketorolac), and antiemetic (e.g., metoclopramide or prochlorperazine).[16] When migraines are refractory to traditional treatments or last over 72 hours, a neurologic consultation and admission should be considered.

Disposition

Children with primary headaches do not usually need hospitalization unless the diagnosis is uncertain and a serious cause of secondary headache is being considered. On discharge from the ED, patients may be given a variety of treatment recommendations while stressing the importance of close follow-up with a primary care provider for ongoing management of migraines.

Nonmedical interventions may have some impact and should be strongly considered. These include avoidance of triggers, placement of the child in a darkened room (with minimal or no extraneous noise), avoidance of hypoglycemia by feeding during a migraine, avoidance of caffeinated beverages (except for possible use as a migraine medication during an episode), application of a cool compress on the forehead, use of a gentle fan, breathing exercises, and relaxation techniques. Patients should be encouraged to keep a headache diary after discharge to track the duration, triggers, medication effects, and other characteristics of their headaches. Common triggers include insufficient or irregular sleep patterns, dehydration, missed meals, various psychosocial stressors, and certain foods (e.g., chocolate, processed meats, alcohol, hard cheeses, red wine, monosodium glutamate, yeast extracts, nuts, figs, aspartame, and sauerkraut).

In general, there are several outpatient treatment options available for acute migraine or other headache syndromes in children. For most patients, symptom relief can be achieved by oral analgesics such as acetaminophen or ibuprofen, along with rest, hydration, and avoidance of triggers. In other cases, additional abortive or prophylactic agents are needed, and the decision to initiate these agents should be deferred to a follow-up visit with the primary provider or neurologist. Treatment may include vasoconstrictors, sedatives, triptans, caffeine, dopamine antagonists, antiemetics or combination therapies. The placebo effect of many medications is high in children with migraines.

PEDIATRIC ATAXIA

Foundations

Ataxia comes from the Greek word *ataktos,* meaning "lacking order," and describes a pathologic abnormality of organization or modulation of movement. Congenital ataxia is associated with CNS macro or micro structural abnormalities. Acquired ataxia can be acute, episodic, or chronic. The chronic ataxias are usually caused by inherited metabolic or genetic disorders. Usually, ataxia is caused by cerebellar dysfunction, but lesions in the corticospinal tract or dorsal columns of the spinal cord may also be causative.

Clinical Features

Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or sudden development of a wide-based so-called drunken gait. The history should identify any recent infection, injury, inadvertent drug ingestion, or other family members with similar symptoms. Mental status is usually normal in cases of postinfectious ataxia; if abnormal, the possibility of ingestion, acute disseminated encephalomyelitis, or stroke should be considered. Nystagmus is common if the cerebellum is affected. Papilledema or cranial nerve palsies suggest hydrocephalus or a CNS lesion.

BOX 169.4 Causes of Childhood Ataxia

Acute cerebellar ataxia
Acute postinfectious demyelinating encephalomyelitis
Brainstem encephalitis
Drug ingestion
Guillain-Barré syndrome
Metabolic disorders
Aminoacidopathies
Mitochondrial disorders
Organic acidopathies
Urea cycle disorders
Migraine headaches
Multiple sclerosis
Neoplasm
Opsoclonus-myoclonus syndrome
Recurrent and chronic genetic ataxias
Seizures
Stroke
Vertebral artery dissection

Differential Diagnoses

Box 169.4 delineates common causes of pediatric ataxia. Approximately 40% of ataxia cases in children are caused by acute cerebellar ataxia. Boys are more commonly affected, with the highest incidence at the ages of 2 to 4 years. A history of recent illness with multiple causative agents is seen in 70% of patients, but varicella virus is the most common, associated with up to 26% of cases. The disease is thought to be due to an autoimmune phenomenon leading to cerebellar demyelination. Symptoms and signs are maximal at the onset, with the extremities more seriously affected than the trunk, and range from unsteadiness and wide-based gait to complete inability to walk. Mental status is normal, and nystagmus is common. Fever and seizures are uncommon outcomes.

Acute postinfectious demyelinating encephalomyelitis can also cause ataxia and occurs in the recovery phase of a viral illness or vaccination. It is distinguished from acute cerebellar ataxia by alteration in consciousness and multifocal neurologic deficits, as well as by fever and frequent occurrence of seizures. Brainstem encephalitis can involve the cerebellum, causing ataxia in association with focal neurologic abnormalities and respiratory irregularities. Potential causative agents include Epstein-Barr virus, *Listeria monocytogenes,* and enteroviruses.

Acute childhood ataxia can also be due to pharmacologic drug toxicity (e.g., anticonvulsants, benzodiazepines, alcohol, or antihistamines), or less commonly, from exposure to organic chemicals or heavy metals. The ataxia is usually accompanied by lethargy, confusion, and inappropriate speech or behavior, and nystagmus may be present.

Over half of all childhood brain tumors arise in the brainstem or cerebellum and can be manifested with slowly progressive ataxia. Acute decompensation can occur, with the development of hydrocephalus or hemorrhage into the lesion.

Head injuries with cerebellar contusion or hemorrhage can cause ataxia. Posterior circulation strokes are rare in children but should be considered after neck trauma, with possible vertebral artery dissection as a cause of the ataxia. Spontaneous vertebral artery dissections have also been reported in children.

The opsoclonus-myoclonus syndrome—ataxia; rapid, chaotic, multidirectional eye movements; and myoclonic jerks of the extremities, head, trunk, and face—is usually a presenting manifestation of neuroblastoma or ganglioneuroblastoma. Ataxia is thought to be due to a

paraneoplastic autoimmune phenomenon involving cross-reactivity of tumor and cerebellar antigens.

Ataxia can be seen in patients with basilar migraine and can be associated with vertigo, hemiparesis, cranial nerve dysfunction, nausea, vomiting, or headache. Loss of sensory input to the cerebellum can cause a sensory ataxia. Clinical manifestations include a Romberg sign, decreased deep tendon reflexes, and impaired proprioception and vibration sense. Of patients with Guillain-Barré syndrome (GBS), 15% have sensory ataxia. In the Miller-Fisher variant of GBS, the triad of ataxia, areflexia, and ophthalmoplegia of vertical gaze is characteristic.

Transient ataxia can be present in the ictal or postictal phase of seizures. Repeated attacks of ataxia can be the presenting manifestation of multiple sclerosis. Inborn errors of metabolism can also manifest with ataxia, acutely or intermittently, depending on dietary intake or the presence of other illness. Inborn errors of metabolism should be considered when ataxia is accompanied by lethargy, encephalopathy, vomiting, diarrhea, loss of muscle tone, or unusual body odor, as in urea acid cycle defects (e.g., aminoacidurias) or defects in pyruvate and lactate metabolism. Ataxia is associated with other inherited diseases such as Niemann-Pick, Tay-Sachs, and Wilson diseases.

The two most common genetic disorders associated with ataxia are Friedreich ataxia and ataxia-telangiectasia. Friedreich ataxia is a disorder of autosomal recessive inheritance characterized by progressive gait and limb disturbance. Affected patients demonstrate dysarthria, lower limb areflexia, proprioceptive sensory loss, and high-arched feet (pes cavus). Ataxia-telangiectasia is a disorder of recessive inheritance manifested as a truncal ataxia in infancy that leaves most patients wheelchair-bound by the age of 12 years. Oculocutaneous telangiectasias usually appear by the age of 3 to 5 years. These patients also demonstrate dysarthria, nystagmus, dystonic posturing, myoclonic jerks, and accelerated aging.

Diagnostic Testing

An accurate diagnosis for pediatric ataxia is dependent on a complete history and thorough physical examination, including testing of gait and cerebellar function. Urine and serum toxicology studies are the highest yield laboratory studies and should be performed on all patients.[17] CT and MRI findings are usually normal in patients with postinfectious ataxia, but demyelination, tumor, hydrocephalus, or traumatic injuries may be identified. Neuroimaging should be ordered if a patient has focal neurologic deficits in the setting of ataxia, but may be deferred in other patients if they have close follow-up.[18,19] CSF analysis may show mild pleocytosis or lymphocytosis in acute postinfectious ataxia; findings are normal in most other cases.

Admission for electroencephalography should be considered in patients with altered consciousness and fluctuating clinical signs of ataxia. Urinary catecholamine levels can be assayed for diagnosis of neuroblastoma. Additional testing may include a CBC, liver function tests, glucose, ammonia, lactate, pyruvate, and ketone levels, and determination of acid-base status. The four most high-yield tests are for levels of glucose, lactate, ketones, and ammonia. If all four of these are normal, it is unlikely that there is an inborn error. Any other laboratory tests should be ordered in consultation with a specialist and may include plasma and urinary amino acids, urine organic acids, CSF lactate, or serum biotinidase levels.

Management

Children with ataxia can be managed, depending on the cause, as outpatients with consultation with the primary care physician and/or pediatric neurology. Management of these patients often requires consultation in the ED by infectious disease or neurology specialists. Most children with acute postinfectious cerebellar ataxia recover completely, and treatment is supportive. Improvement is typically seen within 1 week, and the vast majority recover completely within 2 to 4 weeks. Some children exhibit persistent gait disturbances, ataxia, and delayed speech development.

Disposition

Children with persistent ataxia usually need hospital admission and consultation with a pediatric neurologist to identify causes of the ataxia not evident on the ED evaluation.

PEDIATRIC VERTIGO

Foundations

Vertigo, also discussed in Chapter 15, is defined as an illusion of movement, a sensation that the external world is revolving around an individual (objective vertigo) or that the affected person is revolving in space (subjective vertigo). Vertigo is well recognized to occur in the pediatric age group and has many potential causes. Disease processes that affect the balance of the vestibular, visual, and proprioceptive systems can cause vertigo by impairing the neural activity of the vestibular nucleus. Diseases of the ear, eighth cranial nerve, neck, brainstem, or eye can lead to vertiginous symptoms. Vertigo is characterized as central or peripheral, depending on whether the cause is in the CNS.

Clinical Features

Vertigo is often described as dizziness. There may be a history of sudden falls, grasping for support, or unwillingness to move. A review of systems should include those related to the ear, such as otalgia, hearing loss, and tinnitus. Other important historical features that should be determined include headache, loss of consciousness, head trauma or barotrauma, and family history of migraine or seizure disorders.

Diagnostic Testing

Patients can be divided into those who have hearing loss and those who have normal hearing. In the group with hearing loss, further characterization of the loss as conductive or sensorineural (using the Weber and Rinne tests) can help localize the peripheral lesion to the middle ear, labyrinth, or eighth cranial nerve.

Differential Diagnoses

Although vertigo is not as common in the pediatric age group as in adults, it has many potential causes (Box 169.5). It usually is helpful to separate conditions that cause vertigo into those with and without associated hearing loss.

Benign paroxysmal vertigo of childhood is defined by the repeated occurrence of vertiginous episodes lasting seconds to minutes, with occasional vomiting. In addition to being pale and diaphoretic, preverbal children may appear fearful, grasping onto a caregiver's leg for stability. This entity usually remits spontaneously within months to years. The most frequent cause of benign paroxysmal vertigo of childhood is a migraine headache, with vertigo occurring as the aura of an episode.

Patients with basilar artery migraines may also present with vertigo, hemiparesis, ataxia, palsies of the third, sixth, or seventh cranial nerve, drop attacks, and blindness in various combinations, followed by migraine headache. Children with benign paroxysmal vertigo of childhood or basilar migraines usually have a family history of migraine headaches.

Benign paroxysmal positional vertigo is rare in children, but can occur spontaneously as well as after trauma. It may present as early as in the second decade of life. It is believed to be due to otoliths that have moved out of their normal positions in the utricle and is corrected by canalith repositioning maneuvers (e.g., the Epley maneuver).

BOX 169.5 Causes of Pediatric Vertigo

Central Vertigo
Atrioventricular malformations
Brain abscess
Chiari malformations
Demyelinating disorders
Encephalitis
Meningitis
Migraine headaches
Neoplasm
Seizures
Trauma

Peripheral Vertigo
Alport syndrome
Benign paroxysmal torticollis
Benign paroxysmal vertigo of childhood
Benign positional vertigo
Cholesteatoma
Diabetes mellitus
Labyrinthine dysplasia or aplasia
Labyrinthine concussion
Labyrinthitis
Lyme disease
Otitis media, suppurative and serous
Ototoxins
Ocular disorders
Pendred syndrome
Perilymphatic fistula
Stenosis of the internal auditory canal
Syphilitic inner ear disease
Thyroid disease
Trauma
Usher syndrome
Vestibular neuronitis
Waardenburg syndrome (genetic disorder associated with deafness, wide-spaced eyes)

Ménière disease, caused by hydrops of the semimembranous labyrinth, is a syndrome of vertigo, fluctuating hearing loss, and tinnitus, and is responsible for up to 4% of cases of pediatric vertigo. Vestibular neuronitis, thought to be caused by viral infections, is manifested as vertigo without hearing loss. A preceding cold is found in 60% of patients. It is manifested with severe vertigo that resolves in a few days, after which the child will have vertigo only with rapid head movements, which persists for weeks or months until central compensation occurs.

Labyrinthitis is an inflammatory process involving the inner ear membranous labyrinth; it manifests with vertigo, hearing loss, and tinnitus. Cytomegalovirus, rubella virus, and rubeola viruses are common causative agents. Bacterial labyrinthitis usually occurs in association with meningitis and should be suspected in any ill child with vertigo and high fevers, especially in combination with a perforated tympanic membrane. Neurofibromatosis can be manifested with vertigo if it involves the superior vestibular nerve. Other genetic syndromes such as Alport syndrome are also associated with vertigo (see Box 169.5).

Ototoxic drugs, such as aminoglycosides and chemotherapeutic agents, can cause vertigo, usually in association with hearing loss. Cerebellar and brainstem lesions can also cause vertigo. Cranial nerve deficits associated with vertigo may indicate a brainstem lesion or tumor. Vertigo is the presenting symptom in up to 10% of cases of multiple sclerosis.

For most patients, the cause of vertigo cannot be established during their ED visit. A complete physical examination, including an otologic and neurologic evaluation, should be performed, including evaluation for nystagmus and cerebellar testing. Having the child hop and stand from a seated position on the floor, with eyes open and closed, can reveal vestibular dysfunction. Signs of other disease processes, such as café-au-lait spots in neurofibromatosis, may aid in the diagnosis.

Laboratory tests in the vertiginous patient should be dictated by the history and physical examination, and may include glucose and electrolyte levels, thyroid function tests, and viral titers or serologic studies (e.g., for Lyme disease or syphilis). CT or MRI is indicated for patients with a suspected underlying CNS abnormality (i.e., central vertigo).

Management

Management of the vertiginous patient depends on the underlying cause, which may not be evident in the ED. For acute symptomatic relief, vestibular suppressants such as meclizine and diazepam may be helpful. Patients with a positive Dix-Hallpike test should receive canalith repositioning maneuvers.

Disposition

Patients with suspected CNS infection, focal neurologic deficits, abnormal mental status, or inability to ambulate or tolerate oral fluids or medications should be admitted. Patients should follow up with their primary care provider and a neurologist or otolaryngologist for follow-up testing if vertigo persists.

MOTOR DYSFUNCTION

Acute weakness or motor abnormalities in the pediatric patient can result from pathology at a variety of levels in the neural axis. A complete neurologic assessment can indicate the location of pathology—upper motor neuron (i.e., motor neurons originating in the cerebral cortex or brainstem) or lower motor neuron (i.e., spinal cord anterior horn cells, peripheral nerves, neuromuscular junction, and the muscle itself). Generally, upper motor neuron pathology creates spasticity, increased tone, hyperreflexia, and no fasciculations. Lower motor neuron abnormalities result in decreased tone, poor reflexes, and muscle fasciculations.

STROKE

Foundations

Stroke is characterized by the acute and persistent onset of focal neurologic deficits. Less common in children than adults, pediatric strokes often go unrecognized, leading to delays in diagnosis and treatments. Often the cause of focal neurologic symptoms in children are stroke mimics (e.g., atypical migraine); however, the emergency clinician must always consider stroke in this differential, especially in those children with risk factors for stroke. Underlying conditions that predispose children to stroke include sickle cell disease, structural cardiac anomalies, homocystinuria, and moyamoya disease (Box 169.6). Vascular malformations, such as arteriovenous malformations, may cause hemorrhagic stroke or subarachnoid hemorrhage.

Strokes are classified as ischemic or hemorrhagic. In ischemic stroke, there is an interruption of blood supply to a particular area of the brain, resulting in hypoxic injury. In hemorrhagic stroke, the rupture of a blood vessel or an abnormal vascular structure causes focal damage. Hemorrhagic strokes are more common in children than adults, and often stem from unstable arteriovenous malformations.

BOX 169.6 Risk Factors for Pediatric Stroke

Cardiac
Congenital heart defects
Valvular heart disease
Right-to-left shunts
Cardiomyopathy
Endocarditis, myocarditis
Arrhythmia
Cardiac tumors
Cardiac surgery

Hematologic Disorders and Coagulopathies
Anemia
Sickle cell disease
Dehydration
Idiopathic thrombocytopenia purpura (ITP)
Thrombotic thrombocytopenic purpura (TTP)
Hemolytic uremic syndrome (HUS)
Thrombocytosis
Polycythemia
Disseminated intravascular coagulation
Leukemia or other neoplasm
Congenital and acquired coagulation disorders
Pregnancy and the postpartum period
Vasculitis, vasculopathies
Systemic lupus erythematosus
Polyarteritis nodosa
Takayasu arteritis
Kawasaki disease
Moyamoya syndrome, disease

Infection
Meningitis, encephalitis
Mastoiditis, otitis media
HIV
Varicella
Syphilis
Tuberculosis
Systemic infection

Metabolic, Miscellaneous
Homocystinuria
Fabry disease
Organic acidemia
Hyperlipidemia
Mitochondrial encephalopathy with lactic acidosis and strokelike episodes syndrome
Menkes disease

Other Vascular
Vasospasm (subarachnoid hemorrhage)
Migraine
Carotid ligation (e.g., extracorporeal membrane oxygenation)
Fibromuscular dysplasia
Cervicocephalic arterial dissection
Arteriovenous malformation
Arteriography
Hereditary hemorrhagic telangiectasia
Sturge-Weber syndrome
Intracranial aneurysm

Trauma (Including Nonaccidental)
Blunt and penetrating cervical trauma

Brain Tumor

Drugs
Cocaine
Amphetamines
Oral contraceptives
L-asparaginase

Clinical Features

Manifestations of stroke in infants and children are widely variable due to the potential affected areas of the brain, as well as the child's age and developmental level. Unlike adults who typically present with hemiparesis or localizable focal neurologic deficits, children often present with less specific symptoms such as headache, seizures, or altered level of consciousness. Seizures at stroke onset occur in 20% of pediatric cases, especially in those younger than 6 years of age.[20] The middle cerebral and anterior cerebral arteries are usually affected in children with stroke, generating upper extremity hemiplegia and lower extremity weakness, respectively. The posterior circulation, although less commonly involved, may produce ataxia, nystagmus, or vertigo, along with hemiparesis and hemianopsia.

Diagnostic Testing

Imaging of the brain can confirm the diagnosis of stroke in infants and children. A non-contrast head CT scan can reveal the presence of a bleed, but may not show evidence of ischemia if the stroke took place in the preceding 24 hours. Early consultation with a pediatric neurologist is prudent in children with a suspected stroke. Urgent MRI and MR angiography (MRA) are indicated if there is no evidence of hemorrhage on head CT and clinical suspicion for stroke remains high. If the child does not have a predisposing condition for stroke, additional laboratory evaluation may be helpful, including a CBC and coagulation studies, inflammatory markers, chemistry and lipid panels, and toxicology screen. Electrocardiography and echocardiography can reveal structural abnormalities associated with intracardiac shunts and clots.

Management

Initial pediatric stroke management is directed at stabilization of the airway, breathing, and circulation and controlling any seizure activity. To prevent secondary brain injury, hypoxemia and hypotension should be avoided. When present, hypertension should be managed with consideration of possible increased ICP, particularly in the setting of a hemorrhagic stroke. Blood pressure should be slowly reduced while maintaining cerebral perfusion pressure. The metabolic demands of the brain should be minimized by controlling seizures, fevers, pain, and agitation. Any hyperglycemia or hypoglycemia should be corrected, particularly in the setting of an ischemic stroke.

Additional therapy and definitive treatment of stroke in children are ultimately dictated by the type and extent of the stroke. Although data are limited for the use of thrombolytics and thrombectomy in pediatric stroke, effective utilization has increased in the last decade. When the clinical suspicion for acute ischemic stroke is high and the patient is presenting within the window for consideration of thrombolysis (currently 4.5 hours) or thrombectomy (currently 24 hours),[21]

the patient should be transferred emergently to a stroke center that has the capacity to effectively manage pediatric stroke. In the case of hemorrhagic stroke, neurosurgical intervention is often needed for intracranial decompression, blood evacuation, or control of active bleeding. For children with sickle cell disease, blood transfusion or exchange transfusion should be considered, in consultation with a hematologist and neurologist, to decrease the circulating level of hemoglobin S.

DISORDERS OF THE SPINAL CORD

Foundations

Disorders of the spinal cord may arise from within the spinal cord itself or from extrinsic causes, such as trauma or malignancy. Acute compression of the spinal cord is a medical emergency; rapid accurate assessment of children with acute spinal cord abnormalities can directly affect patient outcomes. Trauma, spinal masses, and infection or inflammation can all cause acute spinal cord compression. The mechanism of compression may be due to direct mass effect (e.g., from a tumor) or related to edema or hemorrhage from infection or trauma. Epidural abscesses are a common infectious cause of acute spinal cord compression and are typically caused by hematogenous spread of bacteria.

Infection or inflammation may also affect the spinal cord intrinsically. Transverse myelitis is an inflammation of the full width of the spinal cord (involving variable lengths of the cord) that manifests with demyelinating lesions at any level of the cord. It is thought to be autoimmune-mediated, often following a recent infection. Transverse myelitis typically evolves over hours to days, but may develop over a few weeks. Specific infections associated with transverse myelitis include Epstein-Barr virus, cytomegalovirus, measles, *Campylobacter jejuni,* and *Mycoplasma pneumoniae*.

Clinical Features

Regardless of the cause of acute spinal cord dysfunction, patients will present with certain characteristic findings, including paraplegia, hyporeflexia, and sensory deficits (complete sensory loss or paresthesias) below the level of the spinal cord lesion. Also, if the distal portion of the cord is affected, patients will have bowel and bladder incontinence. In the case of transverse myelitis, the thoracic region is usually affected. Children may demonstrate lower extremity paresthesias or pain with progressive weakness, which may be asymmetric, over a period of hours to days, and possibly urinary retention. There is often a history of a recent viral-like illness. An acute onset of local back pain with neurologic deficits suggests spinal cord compression due to a bleed, trauma, or infection. With infectious causes, pain may be the first sign, before fever, neurologic deficits, or other systemic signs. With oncologic processes such as spinal tumors, children may have a more insidious onset of symptoms and have evidence of spinal cord compression in the absence of pain.

Diagnostic Testing

A thorough history and physical examination can help diagnose children with acute spinal cord compression. A careful neurologic examination should include strength, deep tendon reflexes, sensation, and evaluation of anal sphincter tone. In suspected spinal cord compression, priority should be on emergent neuroimaging with MRI of the spine while immobilizing the patient. The use of gadolinium assists in identifying acute infectious and inflammatory lesions. CT is less helpful, and plain spine radiographs are of little value. An LP should not be performed when spinal cord compression is suspected. LP can be helpful in evaluating transverse myelitis, but should be performed only after confirmed by MRI.

Management and Disposition

Initial management steps for the patient with spinal cord trauma include immobilization of the spine and immediate neurosurgical consultation. Children with an epidural abscess identified on MRI should receive IV antibiotics and neurosurgical consultation for decompression or drainage. Corticosteroids should be administered only in select cases and in conjunction with neurosurgical consultation.

S. aureus is the most common pathogen in epidural abscesses; thus, initial IV antibiotic therapy in the ED should include vancomycin to cover methicillin-resistant *S. aureus* (in addition to methicillin-sensitive *S. aureus* [MSSA]) and coverage of gram-negative bacilli with a third- or fourth-generation cephalosporin, such as ceftazidime, ceftriaxone, or cefepime. Consideration of additional anaerobic coverage is warranted for higher risk individuals (e.g., associated sinus disease). Patient-specific conditions such as recent surgery or hospitalization may warrant additional coverage.

Surgical drainage in conjunction with IV antibiotic therapy is the mainstay of treatment of epidural abscesses. For spinal masses, neurosurgical intervention is needed to decompress the cord and further elucidate the diagnosis. Supportive care is the underpinning of treatment for transverse myelitis; these children should be hospitalized for observation, IV corticosteroid therapy, and consideration of additional immunotherapy. Initiation of IV corticosteroid therapy in the ED and its specific dosing and timing for children with transverse myelitis should be discussed with a neurologist. Although there are no randomized controlled trials to demonstrate the efficacy of IV corticosteroids in transverse myelitis, consensus favors their use.

GUILLAIN-BARRÉ SYNDROME

Foundations

Guillain-Barré syndrome (GBS) is an acute, demyelinating polyneuropathy that typically presents as transient, symmetric, ascending paralysis. GBS is thought to be autoimmune-mediated—a recent infection triggers an immune response, which, in turn, provokes acute peripheral nerve demyelination. Classically, patients with GBS have both motor and sensory nerve demyelination.

Children of all ages may be affected; however, it is uncommon in young toddlers and infants. Often, there is a history of a preceding minor viral or gastrointestinal illness in the weeks prior to presentation. *Campylobacter jejuni* is the most common infectious agent associated with GBS. The differential diagnosis for GBS is broad; a careful history and detailed neurologic examination will help localize the pathology to the peripheral nerves rather than to the brainstem, brain, spinal cord, neuromuscular junction, or muscle itself. The relatively acute and typically symmetrical nature of GBS paralysis helps distinguish this diagnosis.

Clinical Features

Lower extremity pain, paresthesias, and weakness in any combination may be the initial presenting symptoms of GBS, followed by progressive ascending weakness of the lower extremities. The weakness may progress rapidly over hours to involve the trunk and the muscles of respiration. Deep tendon reflexes are typically diminished or absent at the time of presentation. Cranial nerve abnormalities may also be present; in the Miller-Fisher variant of GBS, they represent the main findings, with oculomotor palsies, ataxia, and areflexia in the absence of extremity weakness.

Fig. 169.4 Infant with hypotonia, as seen with botulism. (From: Arnon SS, Schechter R, Maslanka SE, et al. Human botulism immune globulin for the treatment of infant botulism. *N Engl J Med.* 2006;354:462-471.)

Diagnostic Testing

The diagnosis of GBS is largely clinical; however, a lumbar puncture can be helpful. CSF typically reveals an elevated protein level, with normal glucose, and white blood cell count, known as albumin cytologic dissociation.

Management and Disposition

Given the potential risk of respiratory compromise associated with progressive demyelination and weakness, patients with GBS should be admitted to the hospital for monitoring and supportive care. Bedside respiratory evaluations, such as forced vital capacity and negative inspiratory force trends, may be useful in predicting respiratory compromise. Treatment with plasma exchange and IV immunoglobulin may be used in severe cases.

INFANT BOTULISM

Foundations

Infant botulism typically affects infants younger than 6 to 8 months. It results from intestinal colonization with *Clostridium botulinum*. A neurotoxin produced by *C. botulinum* impairs acetylcholine release from the presynaptic membrane, thereby affecting skeletal muscle, smooth muscle, and autonomic function. Infants develop constipation and poor feeding, with subsequent hypotonia and weakness (Fig. 169.4), which may require respiratory support. Most United States cases of infant botulism are thought to arise from ingestion of environmental dust particles containing *C. botulinum* spores and may be associated with active construction areas in which there is disruption of the ground. Canned foods and honey are also potential reservoirs for *C. botulinum* spores.

Clinical Features

Infant botulism typically has an insidious onset of symptoms, commonly starting with constipation. Over time, infants develop poor feeding, lethargy, hypotonia, and weakness. On examination, infants may have decreased deep tendon reflexes, cranial nerve findings such as poor suck and gag, weak pupillary reflexes, or ptosis.

Diagnostic Testing

The diagnosis of botulism may be confirmed through isolation of botulinum toxin in the stool; however, this process may be delayed because infants are often constipated and laboratory processing times may be hours to days. As such, treatment should be initiated while awaiting confirmation of the toxin in a stool sample. Characteristic electromyography (EMG) findings of low-amplitude motor potentials of reduced duration can rapidly suggest the diagnosis.

Management and Disposition

Infants with botulism should be admitted to the hospital for supportive care, mechanical ventilation for depressed respiratory reflexes, and possibly nasogastric feeding. Botulism immune globulin is safe and effective and should be given IV as early as possible when the diagnosis is highly suspected, without awaiting confirmatory stool sample results. Initial dosing for botulism immunoglobulin in infants less than 1 year of age is 50 mg/kg of body weight in a single IV infusion.

MYASTHENIA GRAVIS

Foundations

Myasthenia gravis is an autoimmune disorder characterized by autoantibodies directed against the acetylcholine receptor of the neuromuscular junction. This action produces intermittent and fatigable weakness. Myasthenia gravis is usually seen in adults; however, there are three types that affect children—neonatal (transient), congenital, and juvenile. The juvenile form of myasthenia gravis presents similarly to the adult form and will be discussed here. Children with juvenile myasthenia gravis are more commonly female and of early school age.

Clinical Features

Patients typically have waxing and waning weakness of the skeletal and facial muscles, exacerbated by repetitive use of these muscles. Facial weakness with bilateral ptosis that fatigues throughout the day is a common initial presenting sign. Oculomotor, truncal, and extremity weakness may also be seen.

Diagnostic Testing

A history of fatigable weakness with predominantly facial muscle findings is suggestive of myasthenia gravis. Bedside testing using edrophonium is no longer available. Serologic testing for autoantibodies can aid in the diagnosis but will not be available in the ED. Electrophysiologic studies can be obtained upon admission or as an outpatient.

Management and Disposition

Myasthenia gravis may be life-threatening. Ventilatory support should be provided in the event of marked truncal weakness and respiratory failure, particularly in the setting of a concurrent illness which can exacerbate symptoms. In patients without risk of respiratory failure and in consultation with a neurologist, treatment may occur on an outpatient basis, with close symptom monitoring and oral cholinesterase inhibitor therapy.

CHAPTER 169: QUESTIONS AND ANSWERS

1. Which of the following clinical findings of bacterial meningitis is more common in newborns compared with infants and children?
   - **a.** Hypothermia
   - **b.** Neck ache
   - **c.** Rash
   - **d.** Shaking chills
   - **e.** Tachycardia

Answer: A. Hypothermia is more commonly found in newborn infants with bacterial meningitis compared with older infants and children with a similar disease.

2. A 15-month-old child is seen with a history of one 10-minute tonic-clonic event, which was nonfocal and accompanied by a temperature of 39°C (102.2°F) and period of illness preceding this event. Two hours after the event, the child is still unresponsive to external stimulation. Which of the following is the next step in the management of this child?
   - **a.** Admit to the inpatient service for antibiotics after blood cultures are drawn.
   - **b.** Admit to the inpatient service for continued observation.
   - **c.** Carry out imaging by obtaining an MRI of the brain.
   - **d.** Obtain a complete blood count (CBC) and urinalysis if the child does not improve in 1 hour.
   - **e.** Order neuroimaging, a lumbar puncture, complete blood count, and blood and urine cultures to evaluate for infectious causes.

Answer: E. Additional diagnostic testing should be obtained because this child has exhibited a prolonged postictal period and has not returned to baseline.

3. What is the appropriate treatment for a 12-year-old boy with a history of epilepsy and brought from home by emergency medical services to the emergency department (ED) after multiple seizures within the 15 minutes. The child is still unconscious and seizing. Which of the following is the next step in the management of this child on arrival at the ED?
   - **a.** Benzodiazepine
   - **b.** Electroencephalography (EEG) and CT scan of the head
   - **c.** Intubation using etomidate and vecuronium
   - **d.** Methohexital
   - **e.** Propofol

Answer: A. If the airway cannot otherwise be maintained, there is respiratory failure, or there is evidence of increased intracranial pressure, the patient should be intubated. Do not paralyze the patient unless absolutely necessary. If needed, consider short-acting neuromuscular blockers such as succinylcholine and vecuronium. The three most commonly used agents to treat convulsive status epilepticus are benzodiazepines, fosphenytoin, and levetiricam.

CHAPTER 169: QUESTIONS AND ANSWERS—cont'd

4. A 3-year-old boy is seen for seizure-like activity at home. He has no prior history of epilepsy and no family history of seizures. His fever has been as high as 39°C (102.2°F), and his parents have been watching him at home. Seizure activity has ceased and the history and physical examination are normal; the child is fully immunized for age. Which of the following statements is *not* consistent with appropriate counseling of parents regarding their 3-year-old?
   a. Although acetaminophen may make him feel better, it will not prevent recurrence.
   b. He is at a substantially higher risk for developing epilepsy later in life.
   c. It is safe for him to go home with the parents.
   d. Seizures with fever are common in young children and do not lead to brain damage.
   e. There is no need to start any antiepileptic medication.

Answer: B. In general, a child between 6 months and 5 years who has a normal neurologic examination and has had a brief seizure in the setting of fever can be assumed to have a simple febrile seizure. Future epilepsy is not predicted and is unlikely in children with simple febrile seizures.

5. Which one of the following statements best describes the signs and symptoms associated with pediatric brain tumors?
   a. At the time of diagnosis, most patients with brain tumors have associated symptoms, such as nausea, vomiting, visual effects, problems with walking, weakness, changes in personality or school performance, or speech changes.
   b. Headaches are never the first symptom of a pediatric brain tumor.
   c. Most pediatric brain tumors are diagnosed within the first month after symptom onset.
   d. Papilledema is one of the least common neurologic findings in children with brain tumors.

Answer: A. Of patients with brain tumors, most have some of the associated signs or symptoms noted in choice A. Headaches may be the first symptom of a pediatric brain tumor, although the frequency of this presentation increases with age. Papilledema is one of the more common neurologic findings, along with abnormal eye movements, ataxia, abnormal tendon reflexes, and abnormalities on the visual examination. CT scanning is usually not performed with the first sign of a headache unless clinically indicated.

6. A 10-year-old boy is brought in by his mother for gait imbalance. He is alert and oriented to person, place, and time, and he has a negative drug and alcohol screen. He has a persistent wide-based unsteady gait. What should be the next step in management?
   a. Head imaging, admission, and neurologic evaluation
   b. Discharge home if CT scan is negative
   c. Perform a lumbar puncture
   d. Reassurance and primary care referral
   e. Start sepsis evaluation

Answer: A. Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or the sudden development of a wide-based "drunken" gait. History should include recent infection, injury, inadvertent drug ingestion, or other family members with the same problem. Children with ataxia usually need admission for a complete evaluation. Consultation with a pediatric neurologist should be sought for patients in whom the cause of the ataxia is not evident on ED evaluation.

7. A 14-year-old girl with a history of migraines presents to the ED with the complaint of being unable to move her left side following a severe right-sided headache. Which of the following statements best describes her management?
   a. Imaging, analgesics, and admit to the hospital because symptoms may last for days.
   b. Immediate evaluation with neuroimaging for a stroke
   c. Inpatient vasculitis evaluation is indicated.
   d. She can be safely discharged home, and the symptoms will resolve in an hour.

Answer: B. Hemiplegic migraine is characterized by the sudden onset of hemiparesis or hemisensory loss followed by headache in the contralateral hemisphere. This type of migraine is seen more frequently in children than adults, but imaging should be obtained to rule out the diagnosis of stroke. Although symptoms usually last for hours or days, affected individuals are rarely left with permanent deficits.

8. A mother brings in her 4-year-old son for periods of lip smacking that occur multiple times per week and last several minutes. During these episodes, he may turn his head to her when she calls, but he does not speak. You suspect which of the following conditions?
   a. Complex partial seizure
   b. Generalized seizure
   c. Infantile spasm
   d. Lennox-Gastaut syndrome
   e. Simple partial seizure

Answer: A. In complex partial seizures, the patient has a change in level of awareness and may exhibit bizarre behaviors including staring, lip smacking, wandering, or picking at clothing. In simple partial seizures, the patient has no change in mentation. Lennox-Gastaut syndrome is characterized by mental retardation, multiple seizure types, and a classic EEG pattern of slow spike and wave. Infantile spasms manifest during the first year of life and consist of rapid, jackknife flexor or extensor spasms that appear in clusters.

Pediatric Musculoskeletal Disorders

William B. Prince

KEY CONCEPTS

- The pediatric physis is the weakest part of the bone and more likely to separate before adjacent tendon or ligament tears, occurring more frequently during periods of rapid growth.
- Displaced supracondylar fractures are at greater risk for neurovascular injury and compartment syndrome. A lateral elbow radiograph with an elevated fat pad is suspicious for occult fracture.
- Transient synovitis has a peak presentation between 3 and 6 years of age. History, physical examination, radiographs, and laboratory values can help distinguish from septic arthritis and Lyme arthritis.
- Slipped capital femoral epiphysis (SCFE) is the posterior and inferior slippage of the proximal femoral epiphysis on the metaphysis, occurring through the epiphyseal plate. This condition affects boys at twice the rate of girls, occurring more commonly between 8 and 15 years of age. This prevalence is changing due to the increasing obesity rate.
- Lyme arthritis typically presents as mono-arthritis in two-thirds of cases, involving the knees 90% of the time. The knee tends to be swollen with limited range of motion, but pain varies and patients can usually still ambulate with a limp. Approximately 50% to 60% of patients not treated for early stages of Lyme will go on to develop Lyme arthritis, which can be their presenting symptom of the disease.
- Little League elbow describes a group of elbow injuries, including apophysitis, medical epicondylitis, and osteochondritis dissecans of the radial head and capitellum. The pediatric elbow is vulnerable to overuse injury, because it has multiple muscle and ligamentous attachments as well as six ossification centers that close at different ages of skeletal maturity.
- Apophyseal injuries of the hip occur at the multiple sites of muscle origination or insertion including on the pelvis. Athletes most at risk are dancers, distance runners, and those participating in kicking sports.
- Gymnast wrist is a chronic wrist pain affecting almost 80% of pediatric gymnasts at some point. Compressive loading and shearing forces cause physeal microfractures at the hypertrophic zone, causing physeal widening and metaphyseal irregularity in almost three-fourths of patients.

FOUNDATIONS

Anatomy and Physiology

Due to the dynamic developmental state occurring in growing children, the pediatric skeleton is unique compared to adults. The most unique feature of pediatric bones is the presence of the physis. This growth plate is composed of proliferating cartilage cells between the epiphysis and metaphysis. The physis is the weakest part of the bone and allows for distinctly different fracture patterns and injury mechanisms compared to adults. The physis can separate or fracture before the adjacent ligaments and tendons tear; similar injury mechanisms in adults which result in sprained ligaments can cause physeal injuries in children. These injuries are most common during periods of rapid growth and represent up to 18% of pediatric fractures.

The pediatric periosteum is thicker and stronger than mature periosteum, which can result in a reduction of fracture displacement. It is also physiologically active which allows for rapid healing and increased stability, making nonunion unlikely. Children have tremendous remodeling potential which allows for greater degrees of angulation or misalignment. If the child has at least 2 years of growth potential remaining, a fracture adjacent to a joint will remodel acceptably if the angulation is less than 30 degrees in the plane of motion.

Fracture Patterns

Immature bones are more porous and pliable, resulting in fracture patterns seen uniquely in pediatric injuries:

- Plastic deformity results in bowing of the bone without cortical disruption.
- Torus (buckle) fractures tend to occur from linear compression and result in buckling of bone without cortical disruption. These injuries are common at the metaphyseal-diaphyseal junction (Fig. 170.1).
- Greenstick fractures disrupt the cortex unilaterally, with periosteum on the compression side remaining intact (Fig. 170.2). The degree of acceptable angulation without reduction is age dependent. Children under 5 years of age can have up to 35 degrees of angulation on lateral radiograph and less than 10 degrees of angulation on AP views, whereas children 5 to 10 years old can tolerate up to 25 degrees on lateral and less than 10 degrees on AP view without need for reduction. Children older than 10 years of age can tolerate 5 to 20 degrees of angulation on lateral x-ray, presuming no angulation on AP view. Treatment for greenstick fractures generally involves casting for 4 to 6 weeks.
- Complete fractures transect both cortices of the bone; these include transverse (Fig. 170.3), spiral (Fig. 170.4), oblique, and comminuted (Fig. 170.5).
- Physeal fractures are not specific to pediatrics but are more likely during periods of rapid bone growth. The Salter-Harris classification is commonly used to delineate fracture patterns as they relate to the physis (Table 170.1). Concern for physeal injury stems from the potential for growth arrest and limb-length abnormalities. Nondisplaced Salter-Harris type I and II fractures (Fig. 170.6 and Fig 170.7) are generally low risk for these complications because the germinal layer of the physis is not commonly involved. These fractures can be splinted or casted with orthopedic follow-up within 1 week. Salter-Harris type III, IV, and V fractures (Fig. 170.8 through 170.10) are at greater risk for damage to the growth plate and are commonly unstable, requiring prompt orthopedic consultation. Types III and IV involve the joint surface and commonly require open reduction to maintain joint stability. Type V fractures are

Fig. 170.1 Buckle fracture of the distal end of the radius.

Fig. 170.2 Greenstick fracture of the radius.

followed closely, as the risk for premature growth plate closure is high and surgical intervention is often needed.

SPECIFIC DISORDERS

Clavicle Fracture

Clavicle fractures are common in childhood but generally heal without complication. Most fractures occur between the middle and distal third of the bone. Mechanisms include birth trauma, direct trauma to the bone itself, and falls onto the shoulder. The bone's superficial lie allows for easy palpation when evaluating for pain or deformity. A clavicle fracture may be detected later in a neonate when a visible callus has formed around day 10 or per parent history of crying when being picked up.

The patient with a clavicle fracture commonly complains of pain at the clavicle and shoulder, often with neck and arm movement. An anteroposterior radiograph of the clavicle is sufficient for diagnosis

Fig. 170.3 Transverse fractures of the radius and ulna.

Fig. 170.4 Spiral fracture of the femur.

Fig. 170.5 Comminuted fractures of the tibia and fibula.

(Fig. 170.11). Displacement of the affected shoulder along with crepitus and edema may be present upon inspection. The proximity of the clavicle to the subclavian vessels as well as the brachial plexus warrants a thorough neurovascular examination, especially in the setting of a displaced fracture. Complications can be seen in the setting of proximal fractures or posterior sternoclavicular displacement which can injure the trachea, esophagus, or cause pneumothorax.

Most children and adolescents with clavicle fractures only require supportive care and immobilization involving sling and swath for 4 to 6 weeks. However, recent studies suggest adolescents after 12 years of age have limited clavicular growth potential remaining and some surgeons have begun to use operative indications for adult patients in their pediatric population. Figure-of-eight splinting is not recommended due to risk of brachial plexus palsy with prolonged use. Newborns generally require no treatment following clavicle fractures from birth. Orthopedic consult should be obtained for clavicular fractures that are open, associated with neurovascular compromise, evidence of a floating shoulder (when associated with a scapular fracture), or with significant skin tenting.[1] An orthopedic referral should be considered in fractures that are comminuted, have a substantial degree of displacement, or in high-level athletes as surgery may facilitate a faster return to activity.

Supracondylar Fractures of the Humerus

Supracondylar humerus fractures are the most common fractures involving the elbow in pediatric patients. During childhood, the tensile strength of the ligaments surrounding the joint exceed that of the weaker bones themselves, which increases the likelihood for fractures rather than ligamentous injury. Typically the patient history involves a fall onto an extended arm, forcing the distal bone superiorly and posteriorly.

Radiographic evaluation of elbow injuries include an AP view of extended elbow (if possible), oblique view, and lateral flexed view. The elbow joint contains 6 cartilaginous ossification centers which can be easily mistake for fracture lines (Fig. 170.12). An acronym for remembering the order of appearance of the ossification centers is CRITOE (Table 170.2).

TABLE 170.1 Salter-Harris Fracture Classification

Type	Description	
I	Fracture extends through the physis	II	Fracture extends from the physis into the metaphysis (away from the joint space)	
III	Fracture extends from the physis into the epiphysis (toward the joint space)	IV	Fracture extends from the physis into the metaphysis and epiphysis	
V	Crush injury of the physis	
Injury mechanisms involving impact on flexed elbow result in anterior displacement of the distal fragment. Supracondylar fractures are classified as either flexion or extension injuries, of which the latter is more common. An AP and lateral radiograph are required to evaluate the degree of displacement and continuity of the cortex as defined by the Gartland classification (Table 170.3). Because subtle fractures can be difficult to visualize, the anterior humeral line can be used as indirect evidence of fracture (Fig. 170.13). A true lateral view should demonstrate a figure-of-eight appearance of the distal humerus, with intersection of the anterior humeral line with the posterior two-thirds of the capitellum. If this line intersects the anterior one-third of the anterior capitellum or is anterior to this structure, then a supracondylar fracture with posterior displacement of the distal fragment is suggestive. The Baumann angle, normally 70 to 75 degrees, can be helpful in detecting subtle fractures and is formed by a line drawn to follow the growth plate of the capitellum intersected with a line drawn down the center of the humerus (Fig. 170.14).

Fig. 170.6 Salter-Harris type I fracture of the fibula. Radiographic findings include soft tissue swelling over the growth plate and minimal physeal widening.

Fig. 170.7 Salter-Harris type II fracture of the radius.

Fat pads are markers for joint effusions or hemorrhage and raise suspicion for occult fracture. On a lateral radiograph with the elbow flexed at 90 degrees, the anterior fat pad demonstrates radiolucency anterior to the coronoid fossa. When thin, this can be a normal finding in children, but is considered a "sail" sign of occult fracture when bulging. The posterior fat pad is posterior to the distal humerus and always represents a pathologic effusion (Fig. 170.15).

Fig. 170.8 Salter-Harris type III fracture of the middle phalanx.

Fig. 170.9 Salter-Harris type IV fracture of the proximal phalanx.

The injured patient presents with a painful swollen elbow and typically holds the extremity in extension and slight pronation. Puckering, dimpling, or anterior bruising are indications that reduction may be difficult, as the anteriorly displaced fragment may have penetrated the brachialis muscle. Immediate assessment should include evaluating for neurovascular compromise by assessing capillary refill and palpating both radial and ulnar pulses. Signs of arterial compromise include the 5 "Ps": pain, pallor, pulselessness, paralysis, and paresthesias. Worsening

TABLE 170.3 Gartland Classification of Extension-Type Supracondylar Fractures

Type	Description
I	Nondisplaced fracture
II	Displaced fracture with intact posterior cortex
III	Displaced fracture with no cortical contact
IIIA	Posteromedial rotation of the distal fragment
IIIB	Posterolateral rotation of the distal fragment

Adapted from: Gartland JJ. Management of supracondylar fractures of the humerus in children. *Surg Gynecol Obstet*. 1959;109:145.

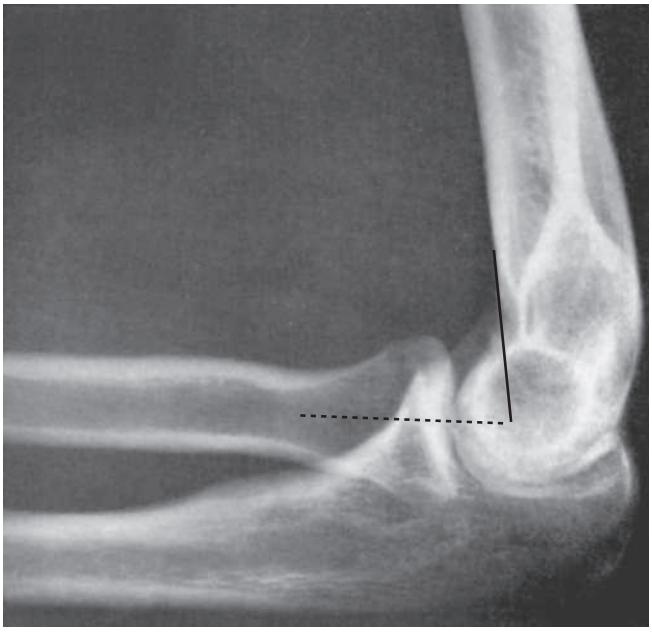

Fig. 170.13 Lateral radiograph demonstrating the bone relationships in a normal elbow. The anterior humeral line (*solid line*) and proximal radial line (*dashed line*) bisect the capitellum. (From: Weissman BN, Sledge CB. *Orthopedic Radiology*. Philadelphia: WB Saunders; 1986.)

pain or pain with passive extension of the fingers is a concerning sign of limb ischemia and can lead to Volkmann ischemic contractures. Emergent consultation with an orthopedic surgeon should be initiated and fracture reduced expeditiously in an attempt to restore blood flow (Fig. 170.16). Perfusion should be confirmed via radial artery signal by Doppler following closed reduction attempts; if reperfusion is unsuccessful, emergent vascular exploration is warranted to assess for and repair brachial artery injuries.

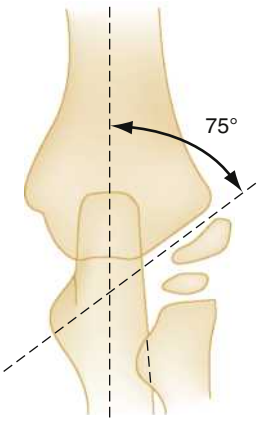

Fig. 170.14 Baumann angle in a normal elbow (anteroposterior radiograph). (From: Worlock P. Supracondylar fractures of the humerus: assessment of cubitus varus by the Baumann angle. *J Bone Joint Surg Br*, 1986;68:755.)

Fig. 170.15 Lateral radiograph of a supracondylar fracture with an anterior fat pad sail sign and posterior fat pad.

Because major nerves and arteries lie in proximity to the supracondylar region, a full motor and sensory function should evaluate for possible associated injury or entrapment. Major structures include radial, ulnar, and median nerves (Table 170.4). The median and radial nerves are commonly injured in extension injuries when the distal fragments are displaced posterior-laterally and posterior-medially, whereas the ulnar nerve is commonly affected with flexion injuries.

Supracondylar humerus fractures are the most common fractures treated surgically by pediatric orthopedic surgeons.[2] Management of Gartland type I fractures can be placed in a posterior long arm splint with the elbow flexed at 90 degrees and either neutral or pronated position. These patients should follow up with an orthopedist with 24 hours for evaluation and casting. Gartland type II and III fractures require emergent evaluation by an orthopedic surgeon. Type II fractures require closed reduction, but if greater than 90 degrees of flexion is required to maintain reduction, then stabilization with percutaneous pinning is advised. Treatment of type III supracondylar fractures includes admission and should include operative reduction and pinning, because they are prone to neurovascular compromise.

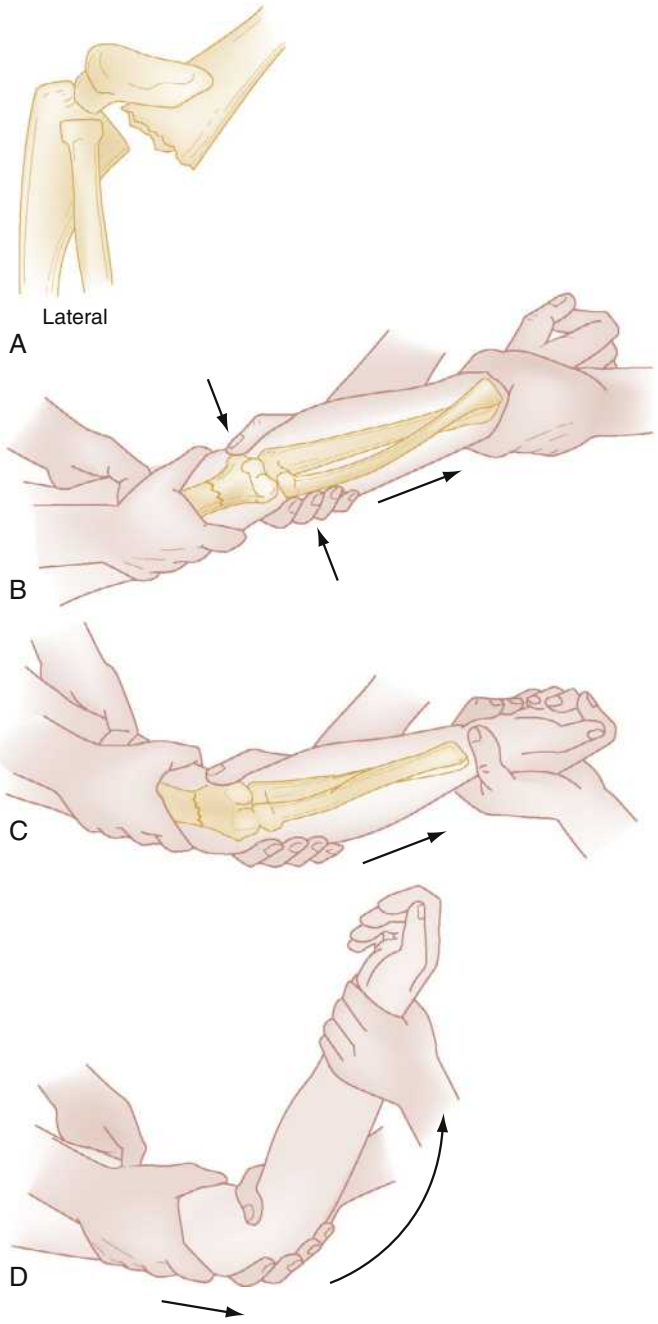

Fig. 170.16 Steps in reduction of a displaced supracondylar fracture. (A & B) The assistant fixes the arm of the patient while the emergency clinician grasps the patient's wrist and applies steady traction in line with the long axis of the arm while keeping the forearm in the neutral, thumb-up position. (C) If the distal fragment is displaced laterally, it is pushed inward with the emergency clinician's other hand. If it is displaced medially, it is pushed outward. Throughout manipulation, traction is maintained. (D) After length is restored and the medial and lateral displacement is corrected, the emergency clinician's thumb is placed over the anterior surface of the proximal fragment, with the fingers behind the olecranon, and the elbow is gently flexed. The arm is then immobilized with the forearm pronated; laterally displaced fractures are immobilized with the forearm supinated. (From: Geiderman JM, Magnusson AR. Humerus and elbow. In Rosen P, Barkin R, eds. *Emergency Medicine: Concepts and Clinical Practice*, ed 4. St. Louis: CV Mosby; 1998.)

Monteggia and Galeazzi Fracture-Dislocations

Monteggia fracture-dislocation represents a fracture of the proximal third of the ulna plus dislocation of the radial head (Fig. 170.17). Isolated ulna fractures are uncommon in children and can present as a plastic deformity of the ulna without obvious fracture. The radiocapitellar line, drawn down the radial shaft, should pass through the center of the capitellar ossification center on lateral elbow radiograph; radial head dislocations will disrupt this line (Fig. 170.18). In contrast, the Galeazzi fracture is characterized as a fracture of the distal radius and disruption of the distal radioulnar joint.

For both fracture types, orthopedic consultation is needed for closed reduction and casting. Management of the Monteggia fracture is predicated on recognizing the radial head dislocation, and reduction and stabilization of the ulnar fracture generally results in radial head reduction.[2] Failure to reduce the radial head over time can result in valgus instability of the elbow, arthritis of the elbow, and restricted forearm pronation.[2]

TABLE 170.4 Neurologic Examination of the Distal Upper Extremity

	EXAMINATION COMPONENT	
Nerve	**Motor**	**Sensory**
Radial	Wrist extension	Thumb and first finger web space
Ulnar	Wrist flexion and adduction	Little finger
Median	Wrist flexion and abduction	Thumb, index, and middle fingers
Thumb opposition	Radial aspect of palm of hand	
Anterior interosseous	Distal phalanx flexion (thumb and first finger)	None

Nursemaid's Elbow

Nursemaid's elbow (i.e., radial head subluxation) occurs when the head of the radius is displaced from the annular ligament; it represents approximately 20% of pediatric upper extremity injuries, with a peak incidence between two and three years of age.[3] The typical mechanism occurs when axial traction is placed on the forearm, causing extension of the elbow and pronation. This movement permits subluxation of the radial head via partial tearing or entrapping of the annular ligament between the radial head and capitellum (Fig. 170.19).[3]

Patients generally present with unwillingness to use the affected arm, which is typically held against the body, slightly flexed at the elbow with the arm pronated. Edema, ecchymosis, or deformity are typically absent. Gentle palpation usually does not illicit pain of the long bones or elbow joint, although ranging the extremity can cause distress. The diagnosis of nursemaid's elbow is made clinically; AP and lateral radiographs of the elbow should be obtained if there is focal bony tenderness, ecchymosis, joint swelling, or a traumatic mechanism.

Two common techniques for reduction are supination/flexion and hyperpronation maneuvers. Both methods involve the examiner supporting the child's arm at the elbow by placing pressure with a finger on the radial head. In the supination/flexion maneuver, the examiner holds the forearm with their other hand and provides gentle traction while fully supinating and flexing the elbow in one motion. With hyperpronation, the examiner holds the affected arm's hand in a handshake grip and grips the elbow with the other hand. Hyperpronation of the forearm usually results in a palpable click over the radial head if reduction is successful.

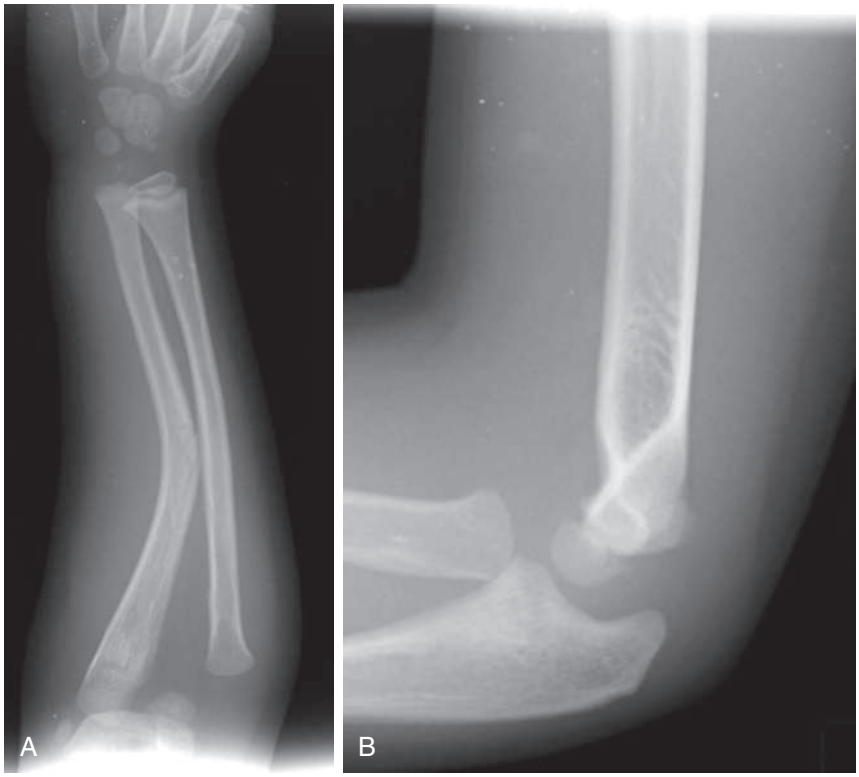

Fig. 170.17 (A) Anteroposterior view of the elbow revealing a distal ulna fracture with radial head dislocation. The radial head should align with the capitellum in all views. (B) Lateral view of the elbow demonstrating poor alignment of the radial head, with the capitellum consistent with Monteggia fracture-dislocation. (Courtesy Dr. Micheal Diament, Pediatric Radiology, Harbor-UCLA Medical Center, Torrance, CA.)

Both methods are effective, however, meta-analysis of randomized control trials have shown that hyperpronation is more effective, with a lower first attempt failure rate.[3] Recurrence is common and parents should be cautioned to avoid lifting the child by the arm or wrist, but may be taught to perform the maneuver themselves if it recurs.

Children typically begin using the arm normally within 15 minutes. If the child fails to move the extremity, repeat maneuvers may be attempted. However, if unsuccessful, radiographs should be obtained and the extremity placed in a long arm splint at 90 degrees. Pediatrician follow-up should be arranged within next 24 hours.

Toddler's Fracture

The toddler's fracture is a nondisplaced oblique fracture of the distal tibia that is the result of a minor fall or twisting mechanism, with a peak incidence between 1 and 4 years of age. Clinical diagnosis may be difficult, as the history may be vague and the physical examination is commonly nonspecific to a local injury. Typically, guardians report the child is limping or unwilling to bear weight; there may be a report of a minor fall. Tenderness may be elicited with palpation, but obvious swelling or deformity is uncommon. Gentle twisting of the lower leg may provoke pain.

Lower leg AP and lateral radiographs may reveal a subtle oblique lucency through the distal tibia terminating medially (Fig. 170.20). Because children have robust periosteum, any displacement can be minimal, making identification on radiograph difficult, and the fracture is often not initially visible. If suspicion for a toddler fracture is high, immobilization and reevaluation 2 weeks later will show callus formation on repeat radiographs from new periosteal growth. If available, ultrasound can be considered as an imaging modality to evaluate for fracture. Traditionally, immobilization involved a posterior long leg cast for 3 to 4 weeks, but recent studies have shown no differences in the clinical outcomes between various immobilization methods: casting, splinting, or a cast boot.[4] Casts should not extend above the knee on young toddlers, who are at risk for cast migration. Children are allowed to bear weight as tolerated after immobilization.

Nonaccidental Trauma

The National Child Abuse and Neglect Data System reported more than 680,000 children were victims of maltreatment and 1670 children died of abuse and neglect in 2015.[5] Of all these childhood fatalities 43.9% were victims of physical abuse exclusively or in combination with another maltreatment type and 74.8% of these children were less than 3 years of age.[5] Diagnosis of physical abuse can be elusive and missed identification can lead to additional injuries. An estimated 25% of children diagnosed with nonaccidental trauma (NAT) have a sentinel injury before their abuse diagnosis.[5] These data underscore the necessity for a thorough evaluation when there is a concerning history or physical findings for NAT. See Chapter 172 for a complete discussion on the evaluation of NAT.

Developmental Dysplasia of the Hip

Foundations

Developmental dysplasia of the hip (DDH) denotes a wide spectrum of clinical severity: neonatal instability, acetabular dysplasia, hip subluxation, and true dislocation of the hip. Laxity within the acetabulum refers

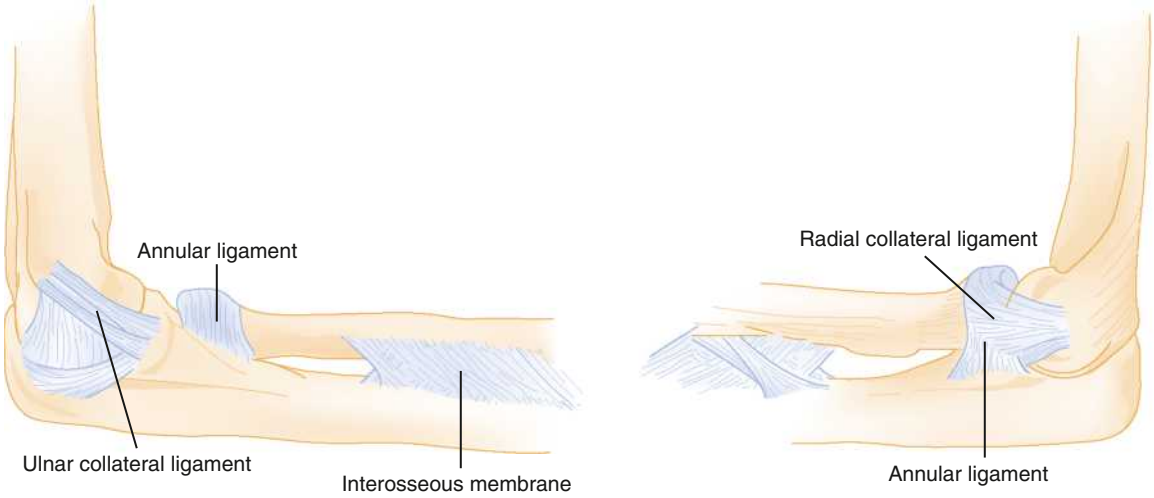

Fig. 170.19 Nursemaid's elbow. In a nursemaid's elbow injury, the annular ligament around the radial head is dislodged as an axial force is applied. The ligament is then partially dislocated into the radiocapitellar joint when the arm is released. (From Simon R, Koenigsknecht S: *Emergency orthopedics, the extremities*, ed 2, Norwalk, CT, 1987, Appleton & Lange.)

Fig. 170.20 Toddler's fracture.

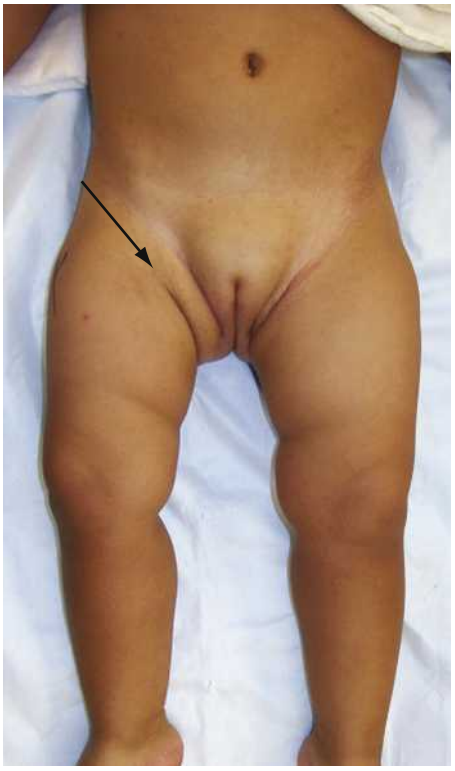

Fig. 170.21 A 21-month-old child with right hip dislocation. Note the asymmetrical skinfolds in the upper thigh (*arrow*). (From: Storer SK, Skaggs DL. Developmental dysplasia of the hip. *Am Fam Physician*. 2006;74:1310-1316.)

to instability, whereas dysplasia indicates some morphologic change in the acetabulum or proximal. With a subluxed hip, articular surfaces are in contact, but not concentrically aligned. With a hip dislocation, articular surfaces of the acetabulum and proximal femur are not in any contact.

Clinical hip instability occurs in 1% to 2% of term infants; up to 15% have findings on imaging studies.[6] Risk factors include breech presentation, female gender, family history, and incorrect lower extremity swaddling; risk factors are additive, with frank breech presentation and family history the two most important risk factors.[6]

Clinical Features

Signs of DDH may be present at birth or develop as the baby grows. Diagnosis is usually made during regular screening and surveillance by physical exams up to 6 months of age. Instability is the primary sign of DDH in the neonatal period; however, this quickly diminishes as muscle strength increases, leaving abduction asymmetry as the main clinical sign.

At less than 3 months of age, screening of newborns involves Ortolani and Barlow maneuvers. The Barlow test is done with the hip in 90 degrees of flexion and adduction; lateral pressure is put on the hip. In hip instability, a clunk can be felt as the femoral head falls out the back of the acetabulum, effectively dislocating. The Barlow test has no proven predictive value for future hip dislocation, and if performed frequently or forcefully, can create instability.[6] The AAP, in its 2016 clinical report on DDH, recommends that no posterior-directed force be applied during this procedure.[6] From a similar starting position, the Ortolani maneuver should transition smoothly from hip adduction into gentle anterior pressure on the trochanter while the hip is abducted; a clunk is felt if the hip locates into the socket.

Benign "hip clicks" without instability are clinically insignificant. This finding, which is secondary to soft tissue snapping over bony prominences, should be distinguished from "hip clunks," as detected in a positive Ortolani maneuver. A dislocated hip becomes fixed by 3 months of age, after which the usefulness and sensitivity of the Barlow and Ortolani tests are limited.[6]

Fig. 170.22 A 3-year-old child with a left hip dislocation. Note the limited abduction. (From: Storer SK, Skaggs DL. Developmental dysplasia of the hip. *Am Fam Physician*. 2006;74:1310-1316.)

Restricted asymmetrical hip abduction may be found on physical examination. Limb length discrepancy (Galeazzi test), asymmetrical thigh or gluteal folds (Fig. 170.21), and limited or asymmetrical abduction (Fig. 170.22) raises suspicion for DDH. A positive Galeazzi test can be detected with the hips and knees flexed to 90 degrees, observing the vertical level of the knees (Fig. 170.23). Asymmetrical groin, thigh, and gluteal folds can be seen in up to 25% of normal infants and alone are not pathognomonic.[7] Once a child is walking, a dislocated hip may manifest as an abnormal gait.

Diagnostic Testing

Infants older than 4 weeks of age suspected of having DDH should undergo ultrasound, also recommended to diagnose clinically silent

Fig. 170.23 Galeazzi sign in a 7-month-old girl with left hip dislocation. Apparent inequality of femur length is manifested as asymmetry in the level of the patient's knees. (From: Storer SK, Skaggs DL. Developmental dysplasia of the hip. *Am Fam Physician*. 2006;74:1310-1316.)

DDH in the high-risk infant from 6 weeks to 6 months of age.[6] Once the ossifying nucleus of the femoral head appears around 4 to 6 months of age, radiographs are more diagnostic than ultrasound. An AP radiograph of the pelvis with both legs extended in neutral position is sufficient to make the diagnosis (Fig. 170.24).

Management

Early detection of infants with suspected DDH and referral for bracing or casting can prevent the need for reconstructive surgery. Infants with suspected DDH should be referred after 4 weeks of age. An isolated positive Barlow result up to 2 weeks of age will generally stabilize on its own and can be followed with surveillance for an additional 4 to 6 weeks. Because 96% of pathologic changes found on ultrasound resolve spontaneously within the first 6 weeks of life, treatment can be safely delayed until that time if the hip is stable and not dislocated.

The treatment goal of DDH is concentric reduction and stabilization of the hip joint. If not treated, long-term consequences can include arthritis, back pain, and aseptic necrosis of the femoral head. If the hip is dislocated, the Pavlik harness (PH) is first-line treatment for reduction (Fig. 170.25). The PH is a safe and effective option during infancy for hips that are dislocated, located but unstable, or dysplastic.[8] The harness holds the hips in a flexed and abducted position, allowing for the femoral head to be reduced within the acetabulum. The P4 has a success rate of approximately 85% if treatment is initiated before 6 months of age.[8] If reduction with PH is not successful or in children older than 6 to 8 months, children should receive reduction in the OR followed by spica cast immobilization. Most children beyond 18 months of age require surgical reconstruction.

Pediatric Hip Pain

Children are susceptible to a number of hip disorders of varying degrees of severity (Box 170.1). Some of the conditions discussed can affect other joints in the body as well.

Transient Synovitis

Transient synovitis is a self-limited inflammatory process with a peak incidence between the ages of 3 and 6 years old, and more common in boys than girls. Caused by a benign nonpyogenic inflammatory response, it affects up to 3% of children, and is the most common hip disorder causing atraumatic limp in children.[9] The symptoms

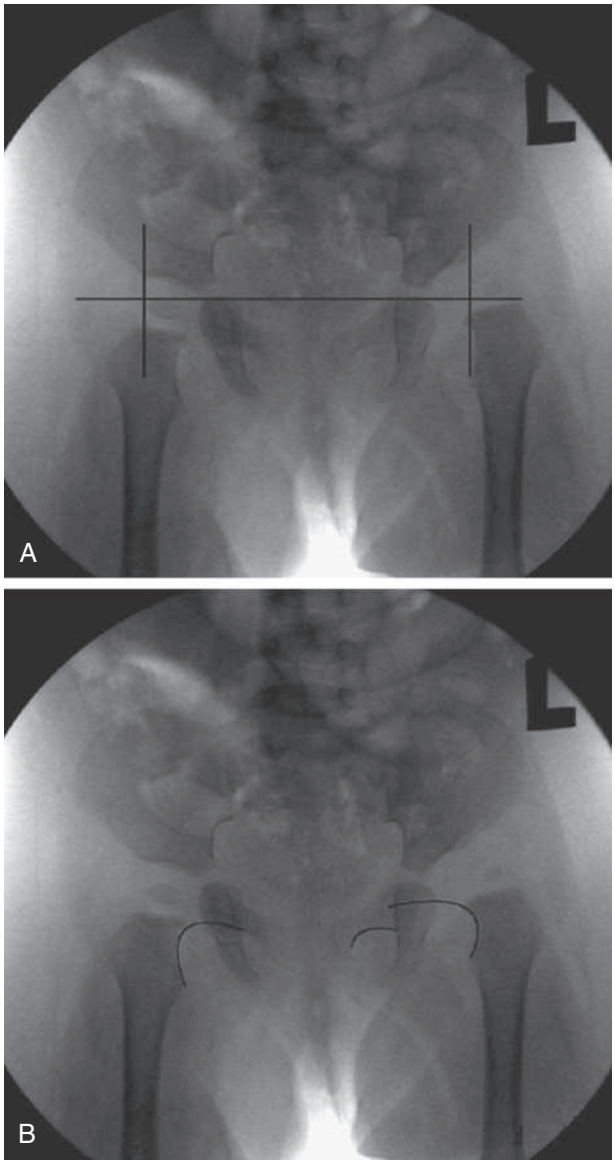

Fig. 170.24 Anteroposterior radiographs obtained in a 7-month-old girl with developmental dysplasia of the left hip. (A) The horizontal line is the Hilgenreiner line; the vertical lines are Perkin lines. Note that the femoral head on the right (normal) side lies in the inferomedial quadrant formed by those lines. The left hip is dislocated; its femoral head lies in the superolateral quadrant. (B) Shenton line is disrupted on the left (dislocated) hip. (From: Storer SK, Skaggs DL. Developmental dysplasia of the hip. *Am Fam Physician*. 2006;74:1310-1316.)

of transient synovitis often follow a viral respiratory illness, minor trauma, or allergic hypersensitivity. This condition may affect the hips or knees.

In a child presenting with a limp, transient synovitis should be distinguished from septic arthritis, because the latter can cause joint destruction if diagnosis is delayed. Generally, patients with septic joints have fevers and are unwilling to bear weight, whereas children with transient synovitis are rarely febrile and may limp but bear some weight. The leg of either condition is generally held in some flexion, slightly abducted and externally rotated due to the presence of an effusion. Transient synovitis often presents after a viral illness and the child may have no other symptoms; children with septic joints can appear ill.

Transient synovitis is a diagnosis of exclusion, involving history, physical examination, screening labs, and imaging to rule out a septic

Fig. 170.25 Pavlik harness. (From: Clarke N, Taylor C. Diagnosis and management of developmental hip dysplasia. *Paediatr Child Health*. 2012;22(6):235-238.)

joint. Because clinical features for these two entities can overlap, a set of four independent predictors of septic arthritis (Kocher criteria) can help evaluate the likelihood for septic joint: fever of 38.5°C or greater, inability to bear weight; erythrocyte sedimentation rate (ESR) of 40 mm/hr or greater; and peripheral white blood cell (CBC) count of 12,000 cells/μL or greater. The Kocher study found that the probability of septic arthritis in patients with one predictor was 3%; two predictors, 40%; three predictors, 93%; and all four, nearly 100%. Validation studies found a 2% chance of septic arthritis in patients with zero out of four predictors. Although not part of the original Kocher criteria, C-reactive protein (CRP), commonly used for additional risk stratification, has shown to be a better negative than a positive predictor of the disease. A CRP less than 1.0 mg/dL carries an 87% probability of *not* having septic arthritis. Inflammatory markers tend to be normal to mildly elevated in transient synovitis.

If septic arthritis cannot be reliably excluded in the differential, then we recommend ultrasound for initial hip imaging, because it is noninvasive and highly sensitive for detecting hip effusions. A hip ultrasound that is negative for joint effusion generally rules out septic arthritis; however, the presence of a hip effusion is nonspecific. Radiographs of the hip have limited utility in ruling in or out transient synovitis but can identify other pediatric hip disorders causing symptoms.

If transient synovitis is suspected, treatment includes symptomatic relief with nonsteroidal antiinflammatory drugs (NSAIDs) and joint rest. Return to activity is allowed as tolerated with improvement of pain. Close follow-up with primary care within 24 hours is recommended for continued monitoring for signs of septic arthritis. Symptoms of transient synovitis last 1 week or less in 67% of patients, and less than 1 month in an additional 21% of patients.

Acute Septic Arthritis

Septic arthritis is a bacterial joint space infection that can result in acute and chronic disability. Boys are affected twice as often as girls, and the lower extremities are most commonly involved; hips, knees, and ankles account for 80% of cases. Predisposing factors include trauma, preceding viral infection, immunodeficiency, hemoglobinopathy, hemophilia-induced hemarthroses, diabetes, intraarticular injections, surgery, and IV drug use.

The pediatric joint is most commonly infected through hematogenous inoculation via transphyseal vessels, as the blood flow is sluggish in metaphyseal capillaries. Contiguous spread of infection from osteomyelitis into the joint space is more common in infants and young children. The infection's inflammatory response leads to a high local cytokine concentration, which induces the host to release matrix metalloproteinases, which are collagen degrading enzymes. Bacterial toxins and lysosomal enzymes further damage the articular surface as soon as 8 hours after inoculation. Pressure ischemia and avascular necrosis cause additional joint destruction from increased capsular pressure.

Common bacterial etiologies for septic arthritis tend to be age specific (Table 170.5). The organisms most likely to cause bacteremia in a child are the most common organisms isolated from pediatric joint infections, including both methicillin-sensitive and methicillin-resistant *Staphylococcus aureus*. Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) is isolated in up to 63% of cases. Some strains of CA-MRSA have been found to contain a gene encoding for the cytotoxin Panton-Valentine leucocidin (PVL), which is associated with complex infections, higher rates of septic shock, prolonged hospital stays, increased surgical interventions, and longer durations of antibiotic therapy.

In neonates, group B *Streptococcus* and gram-negative enteric organisms are common causes of infections. Neonates and adolescents share a risk for *Neisseria gonorrhoeae*, whereas children with sickle cell are at a greater risk for *Salmonella* infections. Other frequently isolated species include group A hemolytic *Streptococcus* and *Streptococcus pneumoniae*.

Septic arthritis can present similarly to transient synovitis, with a combination of fever, malaise, and immobility from pain when ranging the affected joint. Local erythema, warmth, and swelling may be noted in joints other than the hip. Hip infections commonly present with the

TABLE 170.5 Septic Arthritis Pathogens and Treatment

Age	Organism	Treatment
Birth–3 mo	Group B streptococcus (*Streptococcus agalactiae*) *Staphylococcus aureus* Gram-negative organisms *Neisseria gonorrhoeae*	Nafcillin 75–150 mg/kg/day q6h or oxacillin 75–100 mg/kg/day q6-8h, and cefotaxime 100–150 mg/kg/day q8h or cefepime 100 mg/kg/day q12h
3 mo–5 yr	*S. aureus* *Streptococcus pneumoniae* *Streptococcus pyogenes* *Kingella kingae* *Haemophilus influenzae*	Nafcillin, 150–200 mg/kg/day q6h or oxacillin 100–200 mg/kg/day q4–6h, and ceftriaxone, 50–100 mg/kg/day q12h[a]
5 yr–12 yr	*S. aureus* *S. pyogenes*	Nafcillin 150–200 mg/kg/day q6h or oxacillin 100–200 mg/kg/day q4–6h, and ceftriaxone 50–100 mg/kg/day q12h[a]
>12 yr	*S. aureus* *N. gonorrhoeae*	Nafcillin 150–200 mg/kg/day q6h or oxacillin 100–200 mg/kg/day q4–6h, and ceftriaxone 50–100 mg/kg/day q12h[a]

[a]Consider vancomycin, 45–60 mg/kg/day q6–8h, if methicillin-resistant *S. aureus* (MRSA) accounts for >10% local *S. aureus* isolates. Clindamycin 40 mg/kg/day q6–8h can be substituted for vancomycin if local *S. aureus* resistance to clindamycin is <10%.

joint in flexion, abduction, and external rotation. Patients may limp or refuse to bear weight. Infants may be irritable, lethargic, have pain when being handled, and refuse to feed. Neonatal hip infections commonly present with the joint in flexion and abduction with internal rotation.

Diagnosis of septic arthritis is made by history and physical examination, supported by laboratory studies and imaging, and confirmed by arthrocentesis. Initial blood work should include complete blood count with differential, CRP, ESR, and blood cultures. As discussed previously, some of these studies are included in the Kocher criteria, which helps differentiate between transient synovitis and septic arthritis. In septic arthritis, the ESR generally rises greater than 24 hours after the onset of infection symptoms, whereas the CRP rises quickly and is a better independent predictor of infection.

Kingella kingae arthritis deserves special mention, because the presentation is atypical for septic arthritis. *Kingella kingae* is an oral gram-negative bacterium, most commonly linked to septic arthritis in children less than 4 years of age. *K kingae* infections are often preceded by upper respiratory infections and tend to have a milder presentation than the typical septic arthritis, including lower to absent fever. *K. kingae* septic arthritis can present with a normal white blood cell count and normal acute-phase reactants, similar to transient synovitis. *K. kingae* patients are commonly colonized and oropharynx PCR assay for the RTX toxin should be obtained if suspected.

In septic arthritis, plain radiographs of the affected joint are less likely to be helpful. In the acute setting, only soft tissue swelling may be noted. Radiographic changes including destruction of the articular cartilage and joint space narrowing can be seen in a chronic process, but not readily until 7 to 10 days after the infection has commenced. Ultrasound is a rapid and noninvasive method for detecting the presence of a joint effusion. This is particularly helpful when evaluating the hip or shoulders, which are not easily palpated for effusion. A negative ultrasound of the hip with absence of fluid generally rules out septic arthritis. MRI with and without gadolinium contrast is the optimal imaging modality for bone infections, which can help identify nearby osteomyelitis or pyogenic myositis. Between 15% and 50% of osteoarticular infections involve the joint *and* bone.

Definitive diagnosis of septic arthritis hinges on the evaluation of aspirated synovial fluid sent for Gram stain, cell count with differential, and aerobic and anaerobic cultures. Synovial fluid samples with WBC greater than 50,000/μL of which greater than 75% are polymorphonuclear cells (Table 170.6) is considered positive for septic arthritis. The synovial glucose concentration may be low (synovial fluid glucose/blood glucose ratio < 0.5). Culturing synovial fluid in aerobic blood culture bottles can improve detection of *K. kingae*.

Joint aspiration should be performed and treatment not delayed when septic arthritis is suspected. Empirical antibiotic therapy for septic arthritis is directed against the most likely organisms, as dictated by the patient's age and comorbid conditions (see Table 170.5). To improve bacterial identification, synovial and blood cultures should precede antibiotics; however, antibiotics should not be delayed in patients exhibiting signs of sepsis. Antibiotics have good penetrance into the joint, and synovial fluid concentrations are equivalent to serum concentrations within one hour. When treating gram-positive cocci, initial therapy is a penicillinase-resistant penicillin; however, in areas with high rates of CA-MRSA, therapy should include vancomycin or clindamycin (depending on local resistance patterns). Ceftriaxone should be added for gram-negative bacterial coverage, as well as *K. kingae, Gonococcus, Salmonella*, and *Borrelia burgdorferi* (Lyme disease). Optimal length for intravenous antibiotic treatment is generally 2 to 4 days, followed by transition to oral therapy if clinical symptoms are improving and CRP levels declining.

Timely decompression of the joint via open arthrotomy, irrigation, and débridement is the recommended treatment for septic arthritis. Due to risk of avascular necrosis, urgent intervention is particularly

Fig. 170.26 Crescent sign (subchondral lucent zone) in early Legg-Calvé-Perthes disease. (Courtesy Dr. Marianne Gausche-Hill.)

indicated for septic arthritis of the hip. Less invasive cannula irrigation techniques are performed in some centers, but an open procedure is still recommended if concurrent bone infection or subperiosteal abscess is present.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes Disease (LCPD) is an idiopathic necrosis of the capital femoral epiphysis and a form of osteochondrosis. The disorder is more common in boys, has a peak incidence in children aged 3 to 11 years, and presents with bilateral disease in 10% to 15% of patients.[7] The later the onset of the disease, the less favorable the outcome; patients older than 8 years old have poor outcomes.[7] The disease process involves a predominance of femoral head resorption compared to reformation, resulting in femoral head deformity and mechanical weakening.

Most children with LCPD present with a limp and may have the Trendelenburg sign, limited internal rotation and abduction of the hip. Early in the disease, hip motion is generally good. Pain is typically insidious in onset, experienced in the hip, or referred to the groin, thigh, or knee. Pain is worse with activity and relieved by rest. Disease progression can be variable but may include muscular atrophy of the buttocks, thigh, and calf, as well as limb length discrepancy up to 2.5 cm.[7]

Imaging of the hip should include AP pelvis and frog leg lateral radiographs. Early in the illness, the radiographs may be normal, but subtle changes may vary depending on the disease progression. If initial radiographs are normal, but symptoms concerning for LCPD persist for more than 6 weeks, then an MRI is recommended.[7] There are four phases of the disease: initial, fragmentation, reossification, and healed. In the initial phase, the femoral head loses blood supply. As bone dies, the medial joint space widens as the femoral head becomes less round due to subchondral collapse (Crescent sign) (Fig. 170.26). The hip joint becomes painful, stiff, and inflamed. In the fragmentation phase the epiphysis begins to fragment as new bone begins to form, reshaping the femoral head. The reossification phase includes continued bone density repair as the femoral head continues to reshape. In the healed stage, radiographs of the proximal third of the femur and femoral head may demonstrate residual deformities.

Children with concern for LCPD should be evaluated by an orthopedic surgeon. The goal of management is to keep the femoral head within the acetabulum. Treatment includes restriction of activity, physiotherapy, bracing, or surgery. The choice varies with the stage and onset of the disease.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is defined as the posterior and inferior slippage of the proximal femoral epiphysis on the metaphysis, occurring through the epiphyseal plate (growth plate). This condition affects boys at twice the rate of girls, occurring more commonly between 8 and 15 years of age. The average age at diagnosis is 13.5 years for boys and 12 years for girls, presenting bilaterally in 18% to 50% of patients, although in most patients the second slip occurs within 18 months after the initial presentation.[7] SCFE is the most common hip disorder of adolescents, with a prevalence of 10.8 cases per 100,000 children. This prevalence is changing due to the increasing obesity rate, which data suggest is a contributing factor—63% of affected patients have weight in the 90th percentile or higher.[7]

The etiology of SCFE is felt to be multifactorial: obesity, periods of rapid growth, and endocrine disorders. Adolescent growth spurts and obesity contribute to the mechanical factors predisposing to epiphyseal sliding. Although increased mechanical load tends to increase bone strength, endocrine-related changes with obesity lead to a decreased overall bone mass. The most commonly observed endocrine abnormalities in SCFE patients are hypothyroidism, growth hormone deficiency, and chronic renal failure. Skeletal maturation is delayed in many SCFE patients.

Patients with SCFE generally present with limping and poorly localized pain to the hip, groin, thigh, or knee. Patients may have an antalgic gait or be unable to bear full weight on the affected leg. Limited internal rotation of the hip is common. Patients may have Drehmann sign, obligatory external rotation when the affected hip is flexed. Although the differential diagnosis for pediatric hip pain is broad, SCFE should be considered because a delayed diagnosis may result in a poorer prognosis.

Traditionally, SCFE is classified as preslip, acute slip, chronic slip, and acute on chronic slip. This classification is based on history, duration of symptoms, physical examination, and radiographs. Currently, however, a more clinically relevant method of classification is preferred based on stability of the physis and risk of avascular necrosis (AVN).[8] A SCFE is considered stable (90% of all slips) if the patient is able to ambulate with or without crutches; however, if the patient is unable to ambulate even with crutches, it is considered unstable.

If a stable SCFE is suspected on examination, then diagnostic radiographs should include anteroposterior and frog leg lateral views of both hips; for an unstable SCFE, anteroposterior and cross-table lateral views are recommended. Early in the course of the SCFE, the initial slippage is posterior and the AP view is generally normal in appearance or shows widening of the physis, whereas the lateral view is more diagnostic (Fig. 170.27). Signs of slippage on AP radiographs include evaluating the Klein line, a line drawn along the superior margin of the femoral neck. In a normal hip, the lines intersect with the epiphysis symmetrically; in a SCFE, the line does not intersect with the epiphysis (Fig. 170.28). MRI may be useful in diagnosing low-displacement forms of SCFE.

Slip severity can be graded using the Wilson method, which measures the relative displacement of the epiphysis on the metaphysis in a frog leg lateral radiograph. A mild slip involves epiphysis displacement less than one-third of the width of the metaphysis; a moderate slip shows displacement of one-third to one-half of the width; and a severe slip involves displacement greater than one-half of the width. Additional measurement of slippage can be made on a frog leg lateral radiograph with the epiphyseal shaft angle of Southwick (Fig. 170.29). This measurement involves drawing a line between the anterior and posterior tips of the epiphysis at the physeal plate level. A second line is drawn perpendicular to the epiphyseal line. A third line is then drawn along the midshaft of the femur. The epiphyseal shaft angle is formed by the intersection of the perpendicular and femoral shaft lines. The

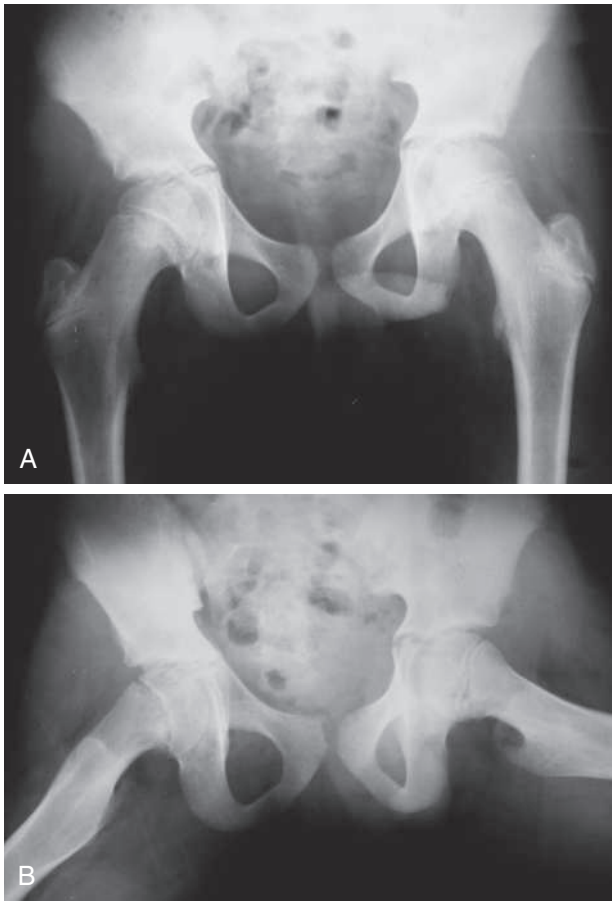

Fig. 170.27 (A) Anteroposterior radiograph of the pelvis with a unilateral slipped capital femoral epiphysis. Note widening of the physis on the right compared with the left. (B) Early inferior and posterior slippage is evident on the lateral view. (Courtesy Dr. Marianne Gausche-Hill.)

Fig. 170.28 Anteroposterior radiograph of the pelvis with a slipped capital femoral epiphysis. Note widening of the physis on the left and a greater distance from the lateral edge of the femoral epiphysis to the Klein line on the right than is seen on the left. A difference of more than 2 mm is diagnostic.

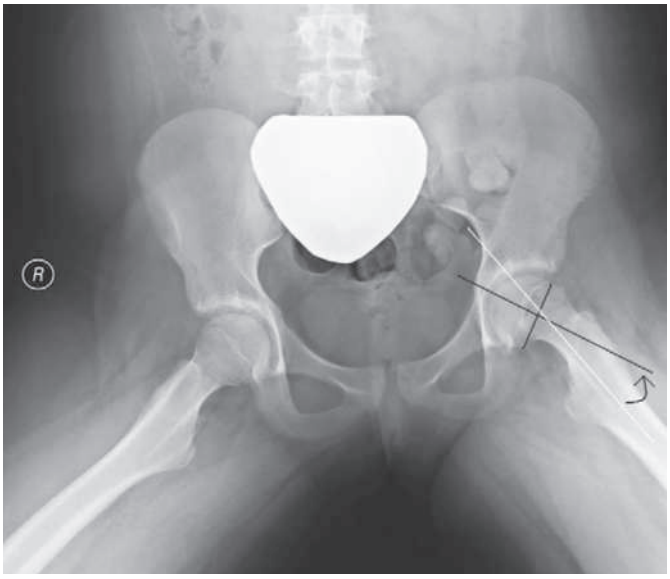

Fig. 170.29 Epiphyseal shaft angle of Southwick. On a lateral radiograph, a line is drawn from the anterior to the posterior epiphyseal edges and a second line is then drawn perpendicular to this line. A third line is drawn down the femoral diaphysis. The intersection between the perpendicular line and femoral shaft line is the epiphyseal shaft angle. The magnitude of slip displacement is the angle of the involved hip minus the angle of the normal hip. (From: Pinkowsky GJ, Hennrikus WL. Klein line on the anteroposterior radiograph is not a sensitive diagnostic radiologic test for slipped capital femoral epiphysis. *J Pediatr*. 2013;162f:804-807.)

degree of slip displacement is the angle of the involved hip minus the angle of the normal hip. A mild SCFE involves displacement of less than 30 degrees, a moderate slip is between 30 degrees and 50 degrees, and severe displacement is great than 50 degrees.[10]

Children diagnosed with SCFE should be made non-weightbearing and admitted or transferred for orthopedic intervention to prevent further slippage. The standard treatment for SCFE is in situ fixation with a single screw performing an epiphysiodesis. Fixation treatment goals are similar in stable and unstable SCFE; however, there is controversy regarding timing of surgery and value of reduction in the unstable type.

Secondary to blood supply disruption or hematoma formation, a vascular necrosis of the femoral epiphysis occurs in 20 to 50% of patients with unstable SCFE and is more common in severe displacement. Chondrolysis, the acute loss of articular cartilage, can be a complication of SCFE surgery, most often from pin penetration of the femoral head, causing joint stiffness and pain. The incidence of chondrolysis has decreased from 7 to 1% as SCFE surgical techniques have improved. Premature closures of the epiphyseal plate, as well as early onset degenerative changes, are common complications from SCFE.

Lyme Arthritis

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is now considered the most common vector-borne illness in North America and Europe, with a threefold increase in annual cases since 1992.[11] The primary vector is the *Ixodes* tick while in its nymph stage. The nymph stores the spirochetes in its midgut, which migrate to the salivary glands after the gut is engorged. An infected nymph must feed for at least 72 hours in order to transmit the disease.

The geographic distribution of Lyme disease has increased primarily into locations adjacent to recognized endemic areas, including New England, the Mid-Atlantic States, and Wisconsin (Fig. 170.30).[12] Two-thirds of cases

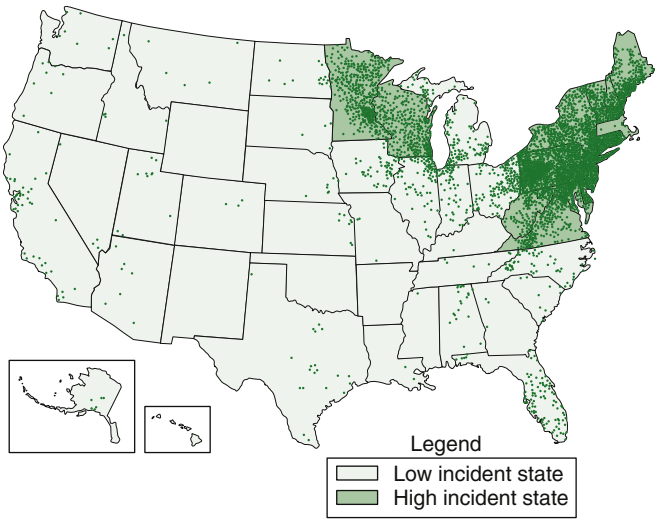

Fig. 170.30 Reported cases of Lyme disease in the United States, 2018. Each dot represents one case of Lyme disease and is placed randomly in the patient's county of residence. (From: Centers for Disease Control and Prevention. Reported Cases of Lyme Disease-United States, 2018. Retrieved from https://www.cdc.gov/lyme/datasurveillance/maps-recent.html.)

Fig. 170.31 Erythema migrans (EM) rash of the left inner thigh. EM is the most common early localized symptom of Lyme disease. (Courtesy Dr. William Prince, MD.)

of early Lyme disease occur in June, July, or August; however, because Lyme arthritis is a late manifestation (occurring weeks to months after initial infection), presentation is greatest in fall and winter months.[11]

Patients with Lyme disease have signs or symptoms correlating with disease progression: early localized, early disseminated, or late Lyme disease. Early localized disease is characterized by the erythema migrans (EM) lesion, the most common manifestation of Lyme disease in children.[13] This lesion begins as a red macule that expands over days to weeks to form an erythematous annular lesion with partial central clearing. The classic "bull's-eye" rash is seen less commonly (Fig. 170.31). Early disseminated disease may include multiple EM lesions, cranial nerve palsies (most commonly cranial nerve VII), lymphocytic meningitis, radiculitis, and carditis (AV block). Early disseminated disease may also include systemic symptoms such as low-grade fever, arthralgia, myalgia, headache, and fatigue. Approximately 50% to 60% of patients not treated for early stages of Lyme will go on to develop Lyme arthritis, which can be their presenting symptom of the disease. Late Lyme disease in children most commonly presents as arthritis.[13]

Lyme arthritis presents as monoarthritis in two-thirds of cases. If presenting as oligoarthritis, the knee is often involved; joint involvement is generally asymmetrical, involving a knee and another joint, such as the hip, shoulder, ankle, elbow, temporomandibular joint, or wrist. Patients can have acute joint swelling or intermittent and migratory arthralgias. The knee tends to be swollen, with limited range of motion, and the joint may be erythematous and warm to the touch. Pain varies, but patients can usually still ambulate with a limp.

Diagnosis of early Lyme disease can be difficult, because the immune system takes several weeks to develop antibodies after exposure to *B. burgdorferi*. Because the skin lesion is generally clinically identifiable, serology is not recommended for diagnosis in Lyme endemic areas. In fact, patients can still be seronegative, even after an erythema migrans rash develops.[12] However, by the time the late-stage symptoms of Lyme arthritis develop, immunoglobulin G serology for *B. burgdorferi* should be positive and is considered diagnostic in a patient from an endemic area with monoarthritis or oligoarthritis. Immunoglobulin M may wane and be negative at 30 days. Initial testing is performed using an ELISA screening followed by confirmatory Western blot test. A positive immunoblot result is defined as the presence of at least two 2 IgM bands or 5 IgG bands.[13]

In contrast to septic arthritis or rheumatic fever, the joint swelling, effusion, and stiffness in Lyme arthritis are disproportionate to the relatively mild degree of pain. Because of its insidious onset and subtle infectious symptoms, Lyme arthritis is commonly overlooked and mistaken for traumatic injury. Differentiating between Lyme arthritis, septic arthritis, and transient synovitis in the acute setting can be difficult, because many clinical symptoms overlap. Similar to delineating between septic arthritis and transient synovitis, a complete blood count with differential, ESR, and CRP can be helpful when determining risk for Lyme arthritis in an endemic area. Compared to Lyme arthritis, septic arthritis is more likely to have a history of fever, increased serum WBC count, and elevated CRP.[11] ESR levels are similar between Lyme arthritis and septic arthritis, and both are significantly elevated compared to transient synovitis.[14] Ultimately, serum markers for leukocytosis and inflammation alone are not reliable markers for distinguishing Lyme arthritis from transient synovitis or septic arthritis.[14]

To determine need for antibiotics or surgical intervention, children should undergo synovial fluid testing to rule out septic arthritis. Standard synovial fluid analysis includes cell count, Gram stain, culture, and, if indicated and available, *B. burgdorferi* PCR. Lyme arthritis elicits a synovial WBC count ranging between 10,000 to 50,000 cells per microliter, whereas septic arthritis is typically greater than 50,000 cells per microliter (see Table 170.6). PCR synovial fluid testing is often positive (40% to 96%) prior to antibiotic therapy but given the high specificity and sensitivity of serologic testing in late Lyme disease, it may not add any additional clinical value.

Antibiotic treatment for Lyme arthritis hastens resolution of symptoms and prevents long-term joint damage. Antibiotic recommendations for Lyme disease were updated in 2018 by the Infectious Disease Society of America, primarily pertaining to prophylaxis and treatment with doxycycline in children with early localized disease.[13] Doxycycline was previously not recommended in children less than 8 years of age due to

TABLE 170.7 Recommended Treatment of Lyme Disease in Children

Manifestation	First-Line Drugs	Alternative Drugs	Second-Line Drugs
Erythema migrans (single or multiple)	Amoxicillin 50 mg/kg/day TID PO × 14 days Doxycycline 2–4 mg/kg/day BID PO × 10 days	Cefuroxime 30 mg/kg/day BID × 14 days	Azithromycin 10 mg/kg daily × 10–14 days
Facial palsy	Amoxicillin 50 mg/kg/day TID PO × 14 days Doxycycline 2–4 mg/kg/day BID PO × 14 days		Azithromycin 10 mg/kg daily × 10–14 days
Meningitis	Ceftriaxone 100 mg/kg/day daily IV × 14 days Cefotaxime 180 mg/kg/day q8h IV × 14 days		
Carditis	Amoxicillin 50 mg/kg/day TID PO × 14–21 days Doxycycline 2–4 mg/kg/day BID PO × 14–21 days Ceftriaxone 100 mg/kg/day daily IV × 14-21 days Cefotaxime 180 mg/kg/day q8h IV × 14–21 days		
Arthritis	Amoxicillin 50 mg/kg/day TID PO × 28 days Doxycycline 2–4 mg/kg/day BID PO × 28 days		
Persistent arthritis after course of therapy	Retreat with one of above oral regimens	Ceftriaxone 100 mg/kg/day daily IV × 14–28 days Cefotaxime 180 mg/kg/day q8h IV × 14–28 days	

Adapted from: Sood S, Krause P. (2019). Lyme Disease. *Feigin and Cherry's textbook of pediatric infectious diseases*, 140;1246-1252.e2

the risk of dental staining. Evidence now suggests that doxycycline for 10 days, in the setting of early localized disease, is safe. However, the recommended oral antimicrobial treatment of Lyme arthritis calls for 28 days of doxycycline, and there are limited safety data on its use for greater than 21 days in children younger than 8 years old.[13] Treatment options for Lyme arthritis in children are listed in (Table 170.7). Patients with incomplete resolution of arthritis symptoms or relapse soon after treatment may be given a second 28-day course of oral therapy, or ceftriaxone parentally for 14 to 28 days if arthritis worsens.[13] The Infectious Disease Society of America recommends several months of observation after treatment due to anticipated slow resolution of inflammation.

Approximately 10% to 15% of patients treated for Lyme arthritis will have persistent synovitis for months to years, despite multiple courses of antibiotics.[13] This chronic arthritis is considered a postinfectious inflammatory process, with negative Lyme PCR from their synovial fluid; these patients may benefit from referral to a rheumatologist. Nonsteroidal antiinflammatory medications are reasonable for pain control; systemic steroids are not recommended.

Apophyseal Injuries

The apophysis is a cartilaginous structure on growing bones that serves as a site for tendon insertion. This site has a growth plate, with a slower rate of growth than the nearby epiphyseal plate. The apophysis is two to five times weaker than the surrounding structures, including the muscle tendon complex, ligaments, and bones. Rapid bone growth before adequate muscle lengthening contributes to increased tension at the apophysis. Although the age of onset varies, this injury is seen most commonly in the immature skeleton. Apophysitis results from a traction injury to the cartilage and bony attachment of tendons, most often as an overuse injury in children. Specific sports and activities have a predilection for specific apophyseal locations and may be secondary to a single trauma versus repetitive microtrauma.

Because many children are consistently playing year-round sports and nearly 44 million participate in more than one sport, overuse injuries in youth sports are increasing in prevalence.[15] Many children and adolescents will not recognize overuse injuries, due to insidious onset or misinterpretation of symptoms as simple fatigue or performance decline.

Osgood-Schlatter Syndrome

Osgood-Schlatter disease (OSD) is a condition in which the patellar tendon insertion on the tibial tubercle ossification center becomes inflamed due to repetitive tensile stress. It is more commonly seen in boys around 10 to 15 years of age and between 8 and 12 years in girls. Bilateral knees are affected in 20% to 30% of cases, but intensity of symptoms can vary in each knee.

Patients typically complain of a bony prominence and pain over the tibial tuberosity that is exacerbated by physical activity like running, jumping, and climbing stairs. Symptoms generally resolve without any treatment after natural closure of the physis, but some symptoms may persist if bone fragments do not fuse. Nonunion can occur in almost 10% of patients and generally results in anterior knee pain after minor activity, especially kneeling.

Diagnosis is based on history and clinical findings. Radiographs are not necessary but may aid in ruling out other causes of knee pain. A lateral knee radiograph may show blurred margins of the patellar tendon in the acute stage. After three to four months, bone fragmentation at the tibial tuberosity may be visible, and may later fuse during the chronic stage. Ultrasound may show pretibial swelling, fragmentation of the ossification center, insertional thickening of the patellar tendon, and excessive fluid collection in the infrapatellar bursa. Infrapatellar bursitis may be difficult to distinguish from OSD clinically, because the location of pain is similar; however, OSD should have tenderness with palpation of the tibial tuberosity.

Management of OSD focuses on reduction of pain and swelling over the tibial tuberosity. Activities that exacerbate pain should be limited for several months until symptoms resolve. Conservative management includes NSAIDs, ice, and exercises for the improvement of the quadriceps, hamstrings, and gastrocnemius muscles. In some cases, immobilization in a cast for 3 to 6 weeks may be necessary.

Sever Disease

The most common cause of heel pain in pediatric patients is calcaneal apophysitis, commonly called Sever disease. Similar to other overuse injuries, it is a result of repetitive microtrauma and inflammation at the site of the Achilles tendon insertion. Pain is felt at the posterior aspect of the calcaneus. This condition is primarily seen in pediatric athletes between 8 and 15 years of age, when the calcaneal physis is still an open growth plate. Bilateral involvement is seen in about 60% of cases. Sever disease can be associated with running and jumping sports.

Patients generally have no history of specific injury. Patients often report limping or walking on their toes to avoid putting weight on their heels. Physical examination includes tenderness at the lateral and medial aspects of the calcaneus. Compression of these sites can be diagnostic and is called the "squeeze test." X-rays of the heel may appear normal in the disease but radiographic findings can show increased density and fragmentation of the calcaneal apophysis.

Treatment for calcaneal apophysitis is universally conservative, including ice, NSAIDs, activity restriction, stretching, and heel cups. Stretching of the calf muscle is recommended, as it provides traction to the Achilles tendon, which may benefit from stretching during times of rapid bone growth. Arch taping has also been shown to decrease associated pain during ambulation. Recovery time varies according to the causative factors and treatment compliance. Activity restriction is recommended until the patient is pain free; full recovery is expected once skeletal maturity is reached.

Little League Elbow

Little League elbow is a term commonly used to describe a group of elbow injuries, including apophysitis, medial epicondylitis, and osteochondritis dissecans of the radial head and capitellum. The pediatric elbow is vulnerable to overuse injury because it has six ossification centers, closing at different ages of skeletal maturity, as well as multiple muscle and ligamentous attachments.[15]

Twenty-eight percent of youth pitchers report a history of elbow pain. Examination reveals localized tenderness and swelling over the medial epicondyle, and pain with resisted wrist flexion and forearm pronation. This condition is described as a valgus overload syndrome stemming from repetitive throwing imparting tensile force on the medial epicondyle and a compressive force at the lateral epicondyle. Medial injuries are most common, as the medial epicondyle is usually the last apophysis in the elbow to fuse.[15] Lateral epicondylitis of the elbow is felt to be tendinosis, worsened by wrist and finger extensor and supinator muscle contraction against resistance.

Radiographs may be normal in appearance, but commonly show focal lucency or sclerosis at the subchondral bone in the anterior aspect of the capitellum. Images may demonstrate fragmentation at the condyle, apophyseal avulsion, or widening at the medial epicondyle ossification center. MRI is the study of choice to fully delineate the extent of the injury.

The most important key to treatment is preventative, through adhering to proper pitch count guidelines by age and teaching proper mechanics.[16] Conservative treatment consists of ice, NSAIDs, and activity modification. Throwing can resume after symptoms have resolved, usually after 4 to 6 weeks. Operative intervention is indicated for displaced fractures > 5 mm, incarcerated fragments, or when associated with elbow dislocation.

Fig. 170.32 Avulsion of the right anterior superior iliac spine in a child with hip pain after kicking a soccer ball. (Courtesy Dr. William Prince, MD.)

Apophysitis and Avulsion Fractures of the Hip

Apophyseal injuries of the hip occur at sites of muscle origination or insertion: iliac crest, anterior superior iliac spine, anterior inferior iliac spine, greater trochanter, lesser trochanter, ischial tuberosity, and pubic symphysis. Athletes most at risk include dancers, distance runners, and those in kicking sports. Patients most commonly present with pain at the tendinous insertion, which is commonly tender to palpation.

Radiographs may appear normal but can show mildly displaced avulsion fractures of the apophysis (Fig 170.32). Treatment for apophysitis includes activity restriction and stretching of associated muscles because this is a self-limited disorder that resolves by improving flexibility or when the apophyseal centers fuse when skeletal growth is complete. Avulsion fractures are generally treated conservatively with immobilization and slow resumption of activities. Surgery may be recommended for fragment displacement greater than 2 cm or for rapid rehabilitation of an athlete. Gradual return to pain-free activity may take several weeks to months.

Gymnast Wrist

Distal radial epiphysitis, also known as "gymnast wrist," is a chronic wrist pain affecting almost 80% of pediatric gymnasts at some point.[17] This injury is common to gymnasts who frequently bear weight through their upper extremities during events, such as the pommel horse and back handsprings. The overall weight load to the wrist ranges from 2 to 16 times the athlete's body weight, leading to distal radial growth plate injury in skeletally immature gymnasts.[17]

Compressive loading and shearing forces cause physeal microfractures at the hypertrophic zone. This leads to temporary ischemia which inhibits normal physeal calcification, causing physeal widening and metaphyseal irregularity. These radiographic abnormalities are seen in almost three-fourths of patients with the clinical diagnosis of gymnast wrist.[17]

Physical examination of the wrist is notable for tenderness over the distal radial physis, although range of motion of the wrist is generally normal.[15] Initial radiographs of the wrist may demonstrate widening of the distal radial physis, but a lack of bony edema, as this injury is due to chronic repetitive microinsults to the region (Fig 170.33).[15]

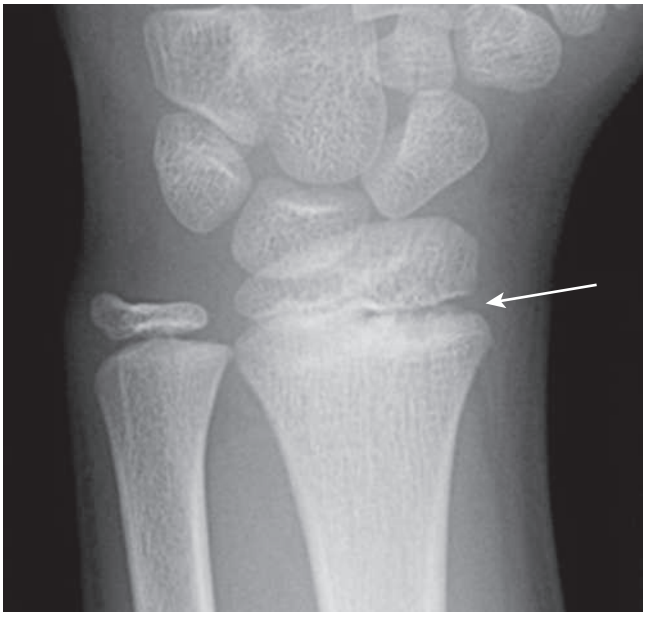

Fig. 170.33 Radiograph of 12-year-old female gymnast demonstrating mild physeal widening (*arrow*) of the distal radius with metaphyseal irregularity. (From: Paz DA, Chang GH, Yetto JM Jr, Dwek JR, Chung CB: Upper extremity overuse injuries in pediatric athletes: clinical presentation, imaging findings, and treatment. *Clin Imag*. 2015;39(6):954-964.)

Conservative treatment includes cessation from weightbearing activities until pain resolves, bracing of the wrist, and physical therapy. Premature closure of the distal radius physis can progress to bony deterioration, instability, and chronic arthritis if left untreated.[15]

CHAPTER 170: QUESTIONS AND ANSWERS

1. An 8-year-old boy presents with left wrist pain after fall off a trampoline. Wrist radiograph shows a fracture at the distal left radius extending through the epiphysis, physis, and metaphysis. According to the Salter-Harris classification, what fracture pattern is described?

a. Salter-Harris type I
b. Salter-Harris type II
c. Salter-Harris type III
d. Salter-Harris type IV
e. Salter-Harris type V

Answer: D. Salter-Harris type IV fractures involve the growth plate extending from the physis into both the epiphysis and metaphysis. The risk of growth plate damage is higher in type IV and requires orthopedic consult and commonly open reduction to stabilize.

2. A 13-year-old overweight male presents with a complaint of insidious left hip pain that now radiates down to his knee. No trauma is noted on history and the patient is not athletic. On examination the patient walks with a limp and is unable to fully range his left hip due to pain but has full range of motion of the knee. Radiograph of the left hip is likely to show what finding?

a. Inferiorly and posteriorly displaced femoral epiphysis relative to the metaphysis on a cross-table lateral view of the hip
b. Femoral neck fracture
c. Avulsion fracture at the ischial tuberosity
d. Femoral head fragmentation

Answer: A. The patient's history and examination are consistent with a slipped capital femoral epiphysis (SCFE). The diagnosis of SCFE is made with AP and lateral radiographs of both hips as it can be present in 18% to 50% of patients. Femoral head fragmentation is consistent with Legg-Calvé-Perthes. Medial joint space widening can be seen with a joint effusion in the setting of septic arthritis, transient synovitis, or Lyme arthritis.

3. Which of the following statements regarding Lyme arthritis is true?

a. Lyme arthritis is an early localized sign of Lyme disease.
b. Synovial fluid WBC count ranges between 50,000 and 100,000 cells per microliter.
c. Azithromycin is the treatment of choice.
d. Monoarthritis is noted in two-thirds of cases, involving the knee 90% of time.

Answer: D. Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is now considered the most common vector-borne illness in North America and Europe. The primary vector is the *Ixodes* tick. Lyme arthritis is a finding in late Lyme disease. Synovial fluid WBC count ranges are typically 10,000 to 50,000. Treatment recommendations depend on prior treatment failures and additional Lyme manifestations.

4. Which of the following statements regarding gymnast wrist are true?

a. Initial radiographs of the wrist demonstrate a distal radius Salter-Harris II fracture.
b. Gymnast wrist only affects about 10% of gymnasts.
c. Radiographic evidence is seen in almost three-fourths of patient's with the clinical diagnosis.
d. The weight load to the athlete's wrist is generally greater than 30 times their body weight.

Answer: C. Distal radial epiphysitis, also known as "gymnast wrist," is a chronic wrist pain affecting almost 80% of pediatric gymnasts at some point. Radiographs demonstrate widening of the distal radial physis. This condition is commonly seen in gymnasts who bear weight through their upper extremities, increasing the weight load to their wrist from 2 to 16 times their body weight. Treatment is generally conservative with cessation from weightbearing activities.

Pediatric Drug Therapy

Laurie Seidel Halmo and George Sam Wang

KEY CONCEPTS

- Awareness of differences in pediatric pharmacokinetics and specific drug toxicities is of critical significance for the safe and effective use of medications in children.
- Avoid prescription and over-the-counter (OTC) cough and cold medications in children because these agents have limited efficacy data and may cause harm.
- Counsel parents about the management of fever and appropriate indications and proper use of antipyretics.
- Perform a risk assessment (for prescription drug abuse and diversion) prior to prescribing opioid analgesics and, when indicated, limit prescribing to the lowest duration and amount possible.
- A multifaceted approach using clinical support systems and readily available reference tools is essential for the delivery of optimal emergent pediatric care.

FOUNDATIONS

Emergency clinicians are tasked with treating not only a wide age range of pediatric patients but also a wide spectrum of disease.[1,2] Nearly 75% of visits are associated with some form of pharmacotherapy during the visit or in the form of a prescription at discharge. Children may present to the emergency department (ED) with an acute life-threatening illness or injury. Although many children presenting for emergency care are otherwise healthy, children with complex medical needs and chronic illness account for an increasing number of ED encounters, many requiring some form of pharmacotherapy. At one tertiary care pediatric facility, 20% of their ED visits in a 2-year time frame were for children with chronic conditions. Pediatric patients are at high risk for medication errors and adverse drug events in the ED for a variety of reasons, including unique pharmacokinetic characteristics, lack of standard pediatric drug dosing and formulations, and weight-based dosing.[2]

PHARMACOKINETIC CONSIDERATIONS IN CHILDREN

Absorption

Absorption is the process in which a drug is transported from the site of administration (i.e., the GI tract for oral administration) to the systemic circulation. Children have unique differences that may lead to changes in drug absorption.[3] Figure 171.1 illustrates many of the key factors that account for pharmacokinetic differences between children and adults. For example, young children have higher gastric pH levels, which affects the bioavailability of acid-labile drugs (such as penicillins) to be absorbed in the stomach. They have decreased gastric emptying times, which prolongs exposure to medications before they pass the pylorus and may impact time to achieve peak concentrations. Variations in the intestinal tract also result in pharmacokinetic differences. The activity of drug-metabolizing enzymes on the intestinal border vary as development occurs, and differences in gut flora can impact drug absorption in young infants. One commonality between children and adults is that drug absorption is often impaired in the setting of critical illness.

Absorption of drugs via a non-oral route can also vary significantly in children compared to adults. The topical route can result in increased absorption in children due to their relatively larger body surface area and increased skin vascularity. Additionally, children's skin contains more water and has a thinner stratum corneum. These factors make children more prone to increased absorption and risk for systemic toxicity from dermally applied drugs. Children have less muscle mass with associated weaker muscle contraction and reduced muscle blood flow. This can result in erratic absorption of intramuscular medications in young children.[3] Absorption of rectally administered medications also varies widely, depending on the age of the child and chemistry of the drug involved. However, this route can be used for medications when children are unable to tolerate or are refusing oral administration, such as for acetaminophen and diazepam. The ability to administer medications via the pulmonary route is particularly desirable in pediatric populations, given the high prevalence of respiratory conditions, such as asthma. At the same time, younger children may be less able to coordinate the use of a metered-dose inhaler to deliver these medications properly; parental assistance and adjunct devices such as spacers maximize efficacy by minimizing drug deposition in the oropharynx. There has been increasing experience in the use of intranasal preparation of analgesic, sedative, and anxiolytic medications in children. Medications that can be used intranasally include fentanyl, ketamine, dexmedetomidine, and midazolam.[4-9] This relatively noninvasive route of administration provides rapid absorption and clinical effect for circumstances requiring immediate pain control or sedation.

Distribution

Drug distribution is the movement of the drug after entering systemic circulation to the tissues of the body. Drug distribution can be impacted by circulation, proteins, extracellular fluid, and body composition. The

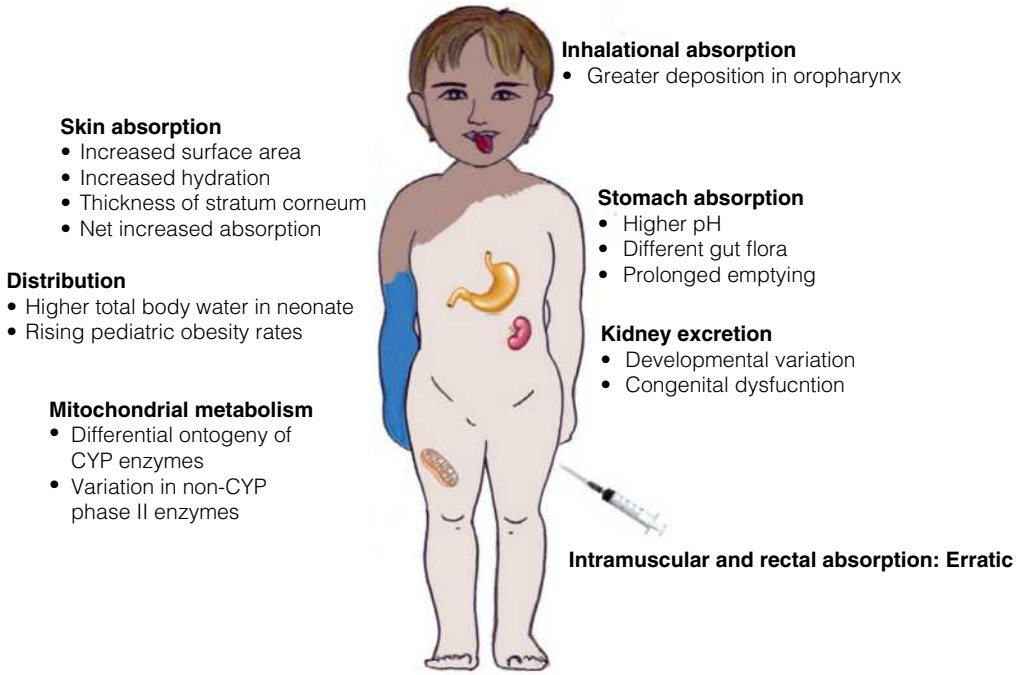

Fig. 171.1 Major pharmacokinetic considerations in the pediatric patient. (Courtesy Voyo Wu.)

specific drug composition can also impact drug distribution greatly. Distribution can differ significantly in children, which has important clinical implications. Neonates and infants have higher total body water and larger volumes of distribution and extracellular fluid; therefore, dosing of medications such as aminoglycosides will differ in this age group, and drug concentrations should be closely monitored. The larger volume of distribution (Vd) may impact hydrophilic drugs and result in larger weight-based doses to achieve sufficient systemic concentrations. Free drug concentrations are also affected by relatively lower concentrations of plasma proteins (albumin, glycoprotein, globulins, etc.) in infants and young children. A consideration specific to neonates is the displacement of bilirubin from protein-binding sites by drugs such as ceftriaxone, which can lead to kernicterus. Consequently, these medications should be avoided until the blood-brain barrier matures. Table 171.1 presents examples of other commonly used medications in the practice of emergency medicine that carry pediatric-specific toxicities as a result of pharmacokinetic and other idiopathic differences.

Body composition can impact drug pharmacokinetics. Childhood obesity has reached epidemic proportions in the United States and worldwide, and significant knowledge gaps have led to a lack of guidance on how medications should be dosed in an obese pediatric patient.[10] Drugs should be cautiously administered in this patient population, especially for high-risk medications such as opioid analgesics and sedatives. Additionally, childhood obesity has resulted in more children being placed on medications, more commonly used in adults, for chronic conditions, such as anti-hypertensives and diabetes medications. Because these medications have been traditionally prescribed for adults, there are few guidelines and a significant paucity of safety and efficacy data in children, which can predispose them to adverse drug events.

Metabolism

Drugs are metabolized through various organs—most commonly the liver, but also in the kidneys and gastrointestinal mucosa. Phase 1 metabolism often involves oxidation or hydrolysis (often by cytochrome P450 enzymes [CYP]), whereas phase 2 metabolism includes conjugation reactions such as glucuronidation and sulfation. Drug metabolism in neonates and infants can be diminished because of immature drug-metabolizing enzymes (Box 171.1). An example of toxicity due to differences in drug-metabolizing enzymes is the neonatal gasping syndrome. Benzyl alcohol, a common preservative for parenteral medications, is metabolized to benzoic acid, which is detoxified by glycine conjugation. Glycine conjugation is decreased in neonates and therefore benzoic acid accumulates when they are given drugs containing benzyl alcohol, leading to metabolic acidosis, respiratory distress, and cardiovascular collapse. As children approach adolescence, drug metabolism is generally the same as in adults.

Elimination

The two primary sites of drug excretion and elimination are the kidneys and liver. They rely on active and passive transport processes to clear drugs. However, the impact of age on many of these transporters remains unclear. Any underlying congenital or acquired hepatic or nephrotic disease will certainly impair drug clearance and drug interactions. In the neonate and infant, there is decreased renal blood flow and glomerular filtration for the first 6 months of life; tubular secretion is decreased for the first year. This pathophysiologic difference may impact renally eliminated drugs. An important example is gentamicin, where it has been demonstrated that using dosing regimens designed for older children and adults has resulted in significant toxicity.

OTHER CONSIDERATIONS

Drug Therapy in the Neonate

As previously mentioned, neonates are the subgroup of pediatric patients that differ the most with regard to physiology and drug pharmacokinetics; however, there is also the greatest paucity of pharmacologic data on this population. Emergency clinicians caring for neonates should consult drug references for specific prescribing information because dosing recommendations, administration, and

TABLE 171.1 Common Emergency Department Medications With Pediatric-Specific Toxicities

Medication	Pediatric-Specific Toxicity
Codeine	Ultrarapid CYP2D6 metabolism implicated in deaths in post-tonsillectomy patients and from breast milk excretion in infants. Not recommended for use in pediatrics
Antipyretics	Dosing errors led to 2011 US Food and Drug Administration (FDA) guidelines to reduce confusing labeling and package directions, elimination of infant formulation of acetaminophen
Aspirin	Reye syndrome associated with use during viral illness
Cough and cold medicines	FDA and Joint Advisory Panel warning for children <2 yr; expanded to 2–4 yr
Phenothiazines	Apnea risk (severe respiratory depression at wide range of doses)
Ceftriaxone	Calcium precipitation in patients <28 days, kernicterus
Doxycycline	Tooth discoloration
Trimethoprim-sulfamethoxazole	Bilirubin displacement may result in kernicterus in patients <2 mo

BOX 171.1 Maturation of Functioning Enzymes in the Pediatric Patient in Phase 1 and 2 Drug Metabolism

Phase 1 Drug Metabolism
- Birth: Cytochrome P450 (CYP)2D6 and CYP2C9
- 1 year: CYP3A4
- 10 years: CYP1A2

Phase 2 Drug Metabolism
- Birth: Glutathione S-transferase alpha 1 (GSTA1)
- 3–6 months: UDP glucuronosyltransferase family 1 member A1 (UGT1A1)
- 18 months: Glutathione s-transferases (GST)

contraindications differ in this age group. Early consultation with a neonatologist may be warranted, depending on the clinical scenario.

Neonates can also be exposed to and experience subsequent toxicity from pharmaceuticals via lactation. For example, the postpartum use of codeine in lactating mothers has been associated with toxicity in the newborn. This phenomenon has been linked to maternal CYP2D6 polymorphisms, which result in ultrarapid metabolism of codeine to morphine. High concentrations of morphine are excreted in the breast milk, which can cause toxicity in the infant. Although many medications are safely administered during breast-feeding, this underscores the importance of obtaining a complete maternal medication history when evaluating a breast-fed infant, as well as consulting a lactation reference when prescribing medications to nursing mothers. This can be difficult because there are limited human data regarding medication use in pregnancy, and multiple factors need to be considered, including maternal comorbidities, therapeutic alternatives, and preferences for continued breast-feeding. The National Library of Medicine maintains a Drugs and Lactation Database (LactMed) summarizing available evidence on medications and illicit drugs and their impact on the breast-feeding infant.[11]

Use of Antipyretics in Children

Fever is one of the most common presenting complaints for pediatric ED and urgent care visits.[12] An important distinction exists between fever, a controlled physiologic increase in body temperature that occurs when the hypothalamic temperature set point is increased in response to pyrogens, and hyperthermia, a pathophysiologic increase in body temperature that occurs when physiologic thermoregulatory mechanisms fail. Unlike fever, hyperthermia has the potential to cause serious harm and can be fatal; thus, hyperthermic children should be rapidly cooled and the underlying cause of their hyperthermia addressed. Antipyretics are not generally useful in managing hyperthermia, because antipyretics do not mechanistically address the underlying thermoregulatory dysfunction.

In contrast to hyperthermia, there is no evidence that fever is dangerous or detrimental to children. Fever as a response to infection has been conserved across vertebrates for hundreds of millions of years, and a growing body of evidence suggests that fever confers a survival benefit to hosts fighting an infection.[13] Even so, a recent survey study of parents found that most felt fever conferred no benefit to their child and that there were risks associated with being febrile.[14] This so-called "fever phobia" often leads to unnecessary administration of antipyretics which, unlike the fever itself, does confer some risk. Aside from the known adverse effects associated with antipyretics and with nonsteroidal antiinflammatory drugs in particular, therapeutic errors and accidental exploratory ingestions of antipyretics in children are relatively common.[15] Even when administered in a health care setting, antipyretic use in children can have unintended consequences; one study found that children with a temperature between 38°C and 39°C with otherwise normal vital signs who were given an antipyretic in the emergency department had a significantly longer length of stay compared to those who did not receive an antipyretic.[16]

Given the risks associated with antipyretic use and the lack of risk associated with fever, current recommendations focus on maintaining patient comfort and not on normalizing temperature. Even in patients who are critically ill with sepsis—to whom an antipyretic is often given because of a concern for the increased metabolic demands associated with being febrile—antipyretic administration was not associated with a decreased ICU length of stay in a randomized, placebo-controlled trial in adults; the same was true in a small pilot randomized, placebo-controlled trial in children.[17,18] As such, the primary goal of antipyretic administration should be to improve the patient's comfort. When emergency clinicians do prescribe an antipyretic in the ED, they should counsel parents regarding the safe and appropriate use of these medications on discharge. Ibuprofen should be avoided in infants younger than 6 months because of pharmacokinetic differences and ongoing renal development in this age group. Combined regimens or alternating therapy with acetaminophen and ibuprofen may be slightly more effective in alleviating discomfort and lowering body temperature; however, this approach is also more complicated and may predispose to medication errors, with small clinical benefit.[19] Table 171.2 presents manufacturer-recommended dosing for commonly used antipyretics and analgesics; Box 171.2 provides counseling points for parents regarding fever and antipyretic use.

Over-the-Counter Cough and Cold Medications

Cough and cold symptoms are complaints commonly encountered in pediatric ED patients, and over-the-counter (OTC) cough and cold medications containing various combinations of antitussives, antihistamines, decongestants, expectorants, and antipyretics have been widely used in children for decades. In 2007, a series of initiatives was launched to curb the use of these medications in young children due to a lack of efficacy data and mounting safety concerns.

TABLE 171.2 Common Antipyretics and Analgesics

Agent	Indication	Dose	Maximum
Acetaminophen	Analgesic, antipyretic	10–15 mg/kg PO, PR, q4–6h	75 mg/kg/day, never to exceed 3 g
Ibuprofen	Analgesic, antiinflammatory, antipyretic	10 mg/kg PO, q6–8h	40 mg/kg/day, never to exceed 3200 mg; not recommended for children <6 mo
Fentanyl	Analgesic	1 to 3 μg/kg IV, IO, IM, IN, SC	N/A
Morphine	Analgesic	0.1 mg/kg IV, IO, IM, SC	N/A

IM, Intramuscular; *IO,* intraosseous; *IV,* intravenous; *PO,* orally; *PR,* per rectum; *SC,* subcutaneous; *IN,* intranasal.

BOX 171.2 Counseling Tips for Parents and Caregivers for Safe Antipyretic Use

- Fever is a clinical sign that the body may be fighting infection and children should be monitored for signs of serious illness.
- Be sure the child maintains adequate hydration during febrile illness.
- Antipyretics should be given to minimize discomfort; if the child appears comfortable, he or she does not need an antipyretic.
- The use of combination products and alternating use of antipyretics can lead to dosing errors and therapeutic duplication.
- Do not use ibuprofen in children younger than 6 months.
- Do not use aspirin in children younger than 15 years due to the risk of Reye syndrome.
- Counsel caregivers and parents regarding appropriate weight-based dosing for the child.
- Recommend use of a calibrated measuring device to avoid dosing errors, showing milliliters ONLY.
- Store all medications, both OTC and prescription, out of the reach of children.

In October of that year, a joint panel meeting of the US Food and Drug Administration's (FDA) Nonprescription Drugs and Pediatric Advisory Committees voted to advise against the use of OTC cough and cold medications in children younger than 6 years. Later that month, the Consumer Healthcare Products Association (CHPA) issued a position statement and voluntarily withdrew OTC cough and cold products marketed for use in children younger than 2 years. In January 2008, the FDA formally recommended against the use of OTC cough and cold medicines in children younger than 2 years. The CHPA subsequently issued additional warnings against the use of these medications by children younger than 4 years. Currently, the American Academy of Pediatrics (AAP) advises against the use of OTC cough and cold medications in children younger than 6 years, and the FDA continues to review available data in consideration of changing the labeling for OTC cough and cold medications for all children aged 2 to 6 years.

Since these initial labeling changes were instituted, some studies have suggested that the use of OTC cough and cold medication in children under 6 years of age is declining. For example, one study found a significant decrease in the proportion of children under 2 years of age with bronchiolitis who had been given an OTC cough or cold medication in the week prior to their ED visit in 2007 to 2010 compared to 2004 to 2006.[20] Another study found that the national estimated number of ED visits for unsupervised exposures to cough and cold medications in children under 6 years of age decreased from 2010 to 2013 after having increased from 2004 to 2010.[21] There has also been a decrease in clinician recommendations for cough and cold medication use in children, though recommendations for use of antihistamines for cough and cold symptoms have increased.[22]

Despite this progress, numerous recent reports have documented that children under 4 years of age now consistently make up the largest proportion of children who suffer adverse events related to OTC cough and cold medication exposures in the years since the aforementioned labeling changes were introduced, despite the fact that the new labels state "do not use" in children under 4 years of age.[23-26] Emergency clinicians should be cognizant of current recommendations to avoid these medications in young children and educate parents regarding the dangers of OTC cough and cold medications; prescription cough and cold alternatives have similar safety and efficacy concerns. The most recent CHEST guidelines on this topic specifically recommend against the use of OTC cough and cold products for both children and adults with cough associated with the common cold.[27] Parents should also be counseled regarding alternative therapies, such as nasal suctioning and honey in children older than 1 year. Table 171.3 presents manufacturer-recommended dosing for commonly used medications in pediatric respiratory emergencies.

Opioid Analgesics

Opioid analgesics can be used safely and effectively in children for the management of moderate to severe pain in the ED and should not be withheld when indicated. However, the evolution of the opioid epidemic of the last 30 years has thrown into sharp relief the risks that opioid use—including therapeutic opioid use—can carry. Numerous studies have documented the large number of ED visits and hospital admissions for opioid-related adverse events in children over the past two decades, particularly in adolescents and in young children under 5 years of age.[28-31] In one study, there was no apparent deviation from the prescribed regimen in 71% of children presenting with an opioid-related adverse event.[30] Only in the last few years has the incidence of pediatric opioid exposures begun to fall; this decrease has mirrored the decrease in opioid prescriptions written for pediatric patients and likely reflects more conscientious opioid prescribing.[30-35]Among adolescents, risk factors that have been identified for development of adverse events related to opioid exposure include having a prescription for more than 30 days, concurrent benzodiazepine use, having a prescription for an extended-release or long-acting opioid, and having a preexisting mental health condition.[36,37] Several studies have also demonstrated that medical use of opioids during adolescence is associated with increased rates of opioid misuse later in life.[38,39] Opioid misuse during adolescence itself is not rare; one study found the prevalence of opioid misuse among high school seniors to consistently be between 10% and 15% from 2002 to 2013, and only recently has it begun to fall.[32] Another prospective study has further demonstrated that adolescents who nonmedically use opioids have higher odds of developing a formal substance use disorder at age 35.[39]

Certain opioids have additionally been described as having specific risks beyond the risks associated with opioid use in general. Codeine toxicity in those who are CYP2D6 ultrarapid metabolizers is a classic example. Codeine's analgesic effects are primarily due to its conversion

TABLE 171.3 Common Pediatric Emergent Respiratory Medications

AGENT	INDICATION	DOSE	MAXIMUM
Albuterol	Asthma	0.15 mg/kg (minimum dose 2.5 mg) INH 20 minutes for 3 doses, then 0.15–0.3 mg/kg up to 10 mg INH q1–4h PRN	Continuous dosing: • ≤10 kg: 7.5 mg/hr • 10–20 kg: 11.25 mg/hr • ≥20 kg: 15 mg/hr
Dexamethasone	Croup, Asthma	0.15–0.6 mg/kg PO, IV, IM	16 mg/dose
Diphenhydramine	Allergy, Urticaria	1–2 mg/kg PO, IV, IM	50 mg/dose
IM Epinephrine (1 mg/ml concentration)	Anaphylaxis	0.01 mg/kg IM	0.5 mg
Ipratropium	Asthma	250 μg INH if <20kg 500 μg INH if >20 kg	N/A
Magnesium	Severe asthma	50 mg/kg IV over 20 min	2 grams
Methylprednisolone	Asthma	1 to 2 mg/kg IV	80 mg/day
Prednisolone	Asthma	2 mg/kg PO	60 mg/dose
Racemic epinephrine	Croup	0.25–0.5 mL of 2.25% solution; as needed up to q30 min	N/A
Terbutaline	Severe asthma	0.01 mg/kg SC	0.4 mg/dose

IM, Intramuscular; *INH,* isoniazid; *IV,* intravenous; *PO,* orally; *SC,* subcutaneous.

to morphine by CYP2D6; ultrarapid metabolizers can therefore produce relatively large quantities of morphine in a short period of time and thus are at risk for toxicity. Toxicity, including death, has been documented in children who received codeine after a tonsillectomy or adenoidectomy for postoperative pain management; a black box warning was issued in 2013 for the use of codeine for postoperative pain in children who have undergone tonsillectomy or adenoidectomy.[40] In 2017, in response to these and other adverse events related to codeine exposure, the FDA formally stated that codeine was contraindicated for treatment of any pain or cough in children under 12 years of age, and added a new warning to codeine labels recommending against its use in children 12 to 18 years of age who are obese, have obstructive sleep apnea or have severe lung disease.[41] In 2018, the FDA went on to require that labels on prescription cough and cold medications containing codeine state that these products are contraindicated in children under 18 years of age. The FDA's mandate contraindicating the use of codeine-containing prescription cough and cold medications in children under 18 years of age was also extended to hydrocodone-containing products.[42] Hydrocodone, one of codeine's minor metabolites, was found in a recent study of pediatric adverse events related to exposures to hydrocodone- and codeine-containing cough and cold medications to be associated with a higher frequency of both fatal and nonfatal adverse events than codeine alone.[43]

Tramadol also deserves a special mention, because it has become increasingly implicated as one of the opioids associated with the highest risk of opioid toxicity among adolescents.[36,44] Tramadol is a prodrug like codeine and is similarly contraindicated for the treatment of pain in children under 12 years of age and for the treatment of postoperative pain in children under 18 years of age who have undergone tonsillectomy or adenoidectomy. It also carries the same warning as codeine recommending against its use in children 12 to 18 years of age who are obese, have obstructive sleep apnea or have severe lung disease. Both tramadol and codeine should be avoided in mothers who are breast-feeding because of the risk of serious adverse events, including death, in their breastfed infants.[41] Tramadol is additionally noteworthy for its well-described association with seizures in overdose.[45]

Unlike in adults, there is a paucity of guidelines for opioid use in the pediatric population. It is important for emergency clinicians to balance adequate analgesia with the risks associated with the use of prescription opioids. Use of nonpharmaceutical modalities and nonopioid alternatives (e.g., acetaminophen and nonsteroidal antiinflammatory drugs) should be used as primary therapy or as an adjunct to minimize the dose of opioids, including for conditions that historically were treated with opioids, such as fractures or acute pancreatitis. For example, a recent randomized, double blind, placebo-controlled trial of children 6 to 17 years old presenting to an ED with a musculoskeletal injury and a pain score of greater than 29 mm on a visual analog scale (VAS) found no difference in the proportion of children meeting the primary outcome of a VAS less than 30 mm, when comparing those who received morphine, morphine and ibuprofen, or ibuprofen alone. The only statistically significant difference found was in the mean reduction of VAS from baseline to 120 minutes after medication administration, which was significantly greater (a more reduced pain score) in children receiving ibuprofen alone compared to morphine alone.[46] There was also no significant difference in pain control among children treated with either morphine or ibuprofen for uncomplicated extremity fractures in an earlier randomized trial.

When an opioid is clearly indicated, clinicians should follow institution-based protocols, if available, for dosage and administration. Additional safeguards to mitigate risk of diversion and misuse include limiting prescriptions to the lowest effective dose for the shortest possible duration, and using the state prescription drug monitoring profile. Similarly, extended-release preparations should generally be avoided, as they are very rarely indicated for acutely painful conditions for which children present to emergency departments. While there are no national opioid prescribing guidelines for children, in 2016 the Centers for Disease Control and Prevention (CDC) published guidelines for opioid prescribing in adults, which state that clinicians "should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids.… Three days or less will often be sufficient; more than seven days will rarely be needed."[47] Emergency physicians who supervise trainees should be aware that both the odds of receiving an opioid prescription at discharge and the odds of receiving an opioid prescription for a prolonged duration of time are greater if that prescription was written by an emergency medicine resident.[48-50] Similarly, the odds of receiving an outpatient opioid prescription were higher if the child was seen in a general emergency department compared to a pediatric emergency department.[51] In adolescent patients, it can be beneficial to use screening tools such as the CRAFFT to identify high-risk adolescents who may need closer follow-up[52] (Box 171.3).

BOX 171.3 CRAFFT for Substance Use Disorder[a]

C: Have you ever ridden in a **CAR** driven by someone (including yourself) who was high or had been using alcohol or drugs?
R: Do you ever use alcohol or drugs to **RELAX**, feel better about yourself, or fit in?
A: Do you ever use alcohol/drugs while you are by yourself, **ALONE**?
F: Do you ever **FORGET** things you did while using alcohol or drugs?
F: Do your family or **FRIENDS** ever tell you that you should cut down on your drinking or drug use?
T: Have you gotten into **TROUBLE** while you were using alcohol or drugs?

BOX 171.4 Best Practices for Prescribing Opioid Analgesics in the Emergency Department

- Assess if there is an indication for an opioid analgesic; nonopioid therapies and pharmaceuticals should be optimized and used as adjuncts, whenever possible.
- Perform a risk assessment for nonmedical use, particularly in adolescent patients.
- Consult state prescription drug monitoring programs and prior medical and pharmacy records whenever available.
- Short-acting opioids are preferred versus extended-release formulations.
- Use caution when combining opioid analgesics with other central nervous system depressants, such as benzodiazepines.
- Prescribe the lowest effective dose and limit duration of therapy to the shortest possible time.
- Provide instructions for the safe disposal of any unused medication.
- Arrange for close outpatient follow-up.
- Counsel parents and caregivers regarding signs of prescription drug abuse.

General recommendations for safe prescribing practices for opioid analgesics are presented in Box 171.4.

Medication Safety and Adverse Drug Events

Medication errors and adverse drug events are common among children cared for in an ED, with error rates in several studies reaching upwards of 30%.[2] This is in part due to characteristics inherent to emergency care, such as a lack of familiarity with individual patients who may be medically complex, and a chaotic environment where verbal orders may be used. Other factors also contribute to pediatric medication errors in all care settings. Because of legislative restrictions in pediatric drug research, many medications are used off label, with dosing based on experience and estimations rather than formal clinical trials. In one study, over 10% of ED visits included at least one off-label use of a medication for a child.[53] Even when a medication has pediatric data shown on the drug label, this information is often not clearly presented and may offer little guidance. For example, the age range for which a medication is formally approved is often not listed in the indications section of the labeling. Approved pediatric-specific dosing information, when available, is listed in another section of the label. To further complicate matters, labels very rarely have dosing listed for obese children; in one study, only 8% of acute care drugs had dosing information for obese children on the label, despite the fact that nearly 1 in 5 children in the United States is obese.[54,55]

The lack of pediatric-specific formulations is also a contributor to adverse drug events and poor patient adherence. Because pediatric formulations are not available for many medications, parents and clinicians may have to split fixed-dose adult tablets, or liquid formulations may need to be extemporaneously compounded, which introduces the potential for compounding and concentration errors. In addition, the poor palatability of adult formulations can lead to noncompliance; oral solutions, suspensions, and rapidly disintegrating and chewable tablets are often preferred. Parents should be counseled regarding proper measurement and administration of prescribed medications, and a dosing syringe using milliliter units should be provided. Payer formulary alerts can direct prescribers to choose an inappropriate alternative if the intended prescription is not covered by the patient's insurance. In one study at a single institution, 27% of payer formulary alerts were found to be inappropriate, and there were 24 specific instances of prescribing errors that were ultimately attributed to these alerts.[56]

Several other factors also contribute to adverse drug events in children. Weight-based dosing and calculations required for children introduce additional error-prone steps, particularly with emergent medications. In a randomized simulation study of residents in an emergency department, the use of a reference book that provided precalculated medication doses (as opposed to a card listing milligram per kilogram dosing) was found to significantly decrease the rates of ten-fold dosing errors, as well as dosing errors for medications administered via continuous infusions.[57] Another common error is calculating weight-based dosing using a patient's weight in pounds instead of kilograms. Despite the fact that numerous professional societies—including the American College of Emergency Physicians and the American Academy of Pediatrics—recommend obtaining scales that exclusively display weights in kilograms, multiple studies have demonstrated inconsistent adoption of this recommendation.[58,59] Medication reconciliation in pediatric patients is also often inaccurate, which can contribute to suboptimal therapy and adverse drug events. Parents and caregivers should be specifically asked about all prescription medications, OTC medications, homeopathic preparations, and dietary supplements. Details regarding dosage and schedule should also be obtained.

Ongoing attempts to mitigate these risks include the use of clinical pharmacists in the ED, separation of pediatric and adult care locations, and increased use of human factors and information technology solutions. In one study, after instituting 24-hour pharmacist coverage of an emergency department, 17% of pharmacist-reviewed orders were found to lead to a clinical intervention that otherwise may not have occurred.[60] The advent of hand-held wireless technology and gradual adoption of inpatient electronic health record (EHR) systems have generated many new reference options for pediatric pharmacology. Decision support tools in the EHR system, such as computerized physician order entry, have repeatedly been shown to decrease adverse events, in part because many are related to simple weight-based calculation errors.[2] At the same time, EHRs can also precipitate errors when clinicians "copy and paste" without critically evaluating data. The ultimate responsibility for medication dosing rests with the ordering clinician, dispensing pharmacist, and administering nurse. Simulation training for nurses has also been shown to decrease medication administration errors; a single 2-hour training in one study decreased the rate of serious medication administration errors from 2.5 events per month to 0.86 events per month.[61] Table 171.4 presents a selection of different types of decision support tools that can serve as a reference to emergency clinicians.

In recent years, prescription drug shortages have emerged as a threat to public health. According to the American Society of Health Systems Pharmacists, there were over 200 current drug shortages in the United States as of the end of 2019.[62] Drug shortages can lead to delayed treatment or no treatment even when treatment is indicated.

TABLE 171.4 Selected Pediatric Drug References[a]

Reference	Description	Examples
App store	Apps with calculators for common pediatric dosing; dosing recommendations provided for reference only	PediStat, palmPEDi, EMRA Pediatric Airway, PediCalc
Web-based	Web-based clinical information suites with medication dosing and company-provided evidence-based recommendations	Micromedex, Epocrates
EHR-based	Decision support tools and institutional guidelines incorporated into CPOE	Cerner, Epic, Allscripts
Reference text	Classic bedside reference texts for decision support and dosing information	Redbook, Harriet Lane, Tarascon, Broselow Tape

[a]This list is not all inclusive, nor does it carry a formal endorsement.

Sometimes, alternative medications are substituted that may be more toxic or less effective, and medication errors can occur when clinicians are forced to use less familiar therapeutic alternatives.[63] The reasons for the rising rates of prescription drug shortages are multifactorial, and it is anticipated that shortages will continue as a problem in the foreseeable future, despite mitigation efforts. Emergency clinicians should be cognizant of current drug shortages that may affect their practice and work to design protocols for the ethical distribution of available supplies of medications in short supply, as well as for safer use of therapeutic alternatives.

CHAPTER 171: QUESTIONS AND ANSWERS

1. A 12-year-old girl is being discharged from the emergency department (ED) after having her displaced forearm fracture reduced. Which one of the following actions would be considered potentially dangerous?
   a. Prescribe codeine.
   b. Consult state prescription drug monitoring programs (PDMP) and prior medical and pharmacy records.
   c. Use a screening tool, such as CRAFFT, to evaluate for high-risk behaviors.
   d. Prescribe a minimum number of days to decrease risk for misuse and diversion.

Answer: A. Codeine is no longer recommended for pain in pediatric patients. This is due to the variation in pharmacogenomics (CYP 2D6) and metabolism to morphine, which can lead to either poor pain control or unintentional opioid toxicity. In adolescent patients, it is recommended that the patient be evaluated for high-risk factors that may lead to opioid use, misuse or diversion. This includes checking the state's PDMP and screening to evaluate the risk for drug abuse and addiction. There are currently no pediatric-specific guidelines for prescribing opioids, but it is generally recommended not to prescribe opioids for acute pain more than 3 to 7 days in duration. Providers should also emphasize a nonopioid, multimodal approach to pain control, including nonpharmacologic methods and adjunct medications such as nonsteroidal antiinflammatory drugs, acetaminophen, or neuroactive agents.

2. What is a unique pharmacokinetic property observed in the pediatric population?
   a. Infants have decreased absorption of topically applied medications.
   b. Neonates and infants have higher total body water and larger volumes of distribution and extracellular fluid.
   c. All drug metabolizing enzymes are at full capacity at birth.
   d. All maternal drugs should be considered not safe when breast feeding.

Answer: B. Young children can have significant differences in the pharmacokinetic properties based on their physiology. Absorption can be impaired and delayed based on gut pH and motility. Metabolizing enzymes mature at different rates during the first year of life. Young children have a higher total body water and larger volumes of distribution and extracellular fluid. There are several factors to consider when assessing the risk/benefit profile of taking medications while breast-feeding, including limited human data, maternal comorbidities, therapeutic alternatives, properties of the drug, and the benefits of continued breast-feeding, when possible. LactMed is an excellent resource to determine the safety of the drug during breast-feeding.

3. A healthy, fully vaccinated 11-month-old male infant presents to your department for evaluation of a fever of 38.4°C (101.1°F) this morning that responded to a dose of acetaminophen. The physical examination reveals a well-appearing, afebrile infant with clear lungs. The patient has an unremarkable evaluation and, during the discharge process, his parents ask for advice regarding fever management. Which of the following statements is correct?
   a. Aspirin should not be used in children younger than 15 years because of the risk of Reye syndrome.
   b. Cool water baths and creams should be used to supplement antipyretics, even if they cause some discomfort to the patient.
   c. Ibuprofen cannot be used in this age group because of ongoing renal development.
   d. Over-the-counter (OTC) antipyretics are standardized, contain similar products and formulations, and are thus interchangeable.

Answer: A. Counsel parents and caregivers about the management of fever and appropriate indications for and proper use of antipyretics. There is no need to cause discomfort with external cooling methods for fever control. Ibuprofen should not be used in children younger than 6 months because of ongoing renal development. The formulations and dosing of OTC antipyretics are varied and cannot be used interchangeably. The correct answer is A because of the risk of Reye syndrome with

CHAPTER 171: QUESTIONS AND ANSWERS—cont'd.

aspirin administration during a viral illness in children younger than 15 years.

4. Which of the following statements regarding pediatric pharmacokinetics is correct?
   - **a.** A thinner stratum corneum and increased body surface area contribute to a greater risk for systemic toxicity from dermally administered drugs.
   - **b.** Ceftriaxone administration in neonates results in increased bilirubin production.
   - **c.** Because of minimal differences in the volume of distribution and renal development, weight-based dosing of gentamicin without attention to age is sufficient.
   - **d.** Quicker gastric emptying and decreased gastric pH in neonates increase systemic absorption of enterally administered medications.

Answer: A. Awareness of differences in pediatric pharmacokinetics and specific drug toxicities is of critical significance for the safe and effective use of medications in children. The dosing of gentamicin needs to account for age-based differences in renal development in addition to weight-based differences in distribution volume. Decreased gastric emptying times and an increased pH can prolong exposure to medications before they pass the pylorus. An immature blood-brain barrier can result in kernicterus from bilirubin displacement by ceftriaxone. The correct answer is that a thinner stratum corneum and increased body surface area contribute to a greater risk for systemic toxicity from dermally administered drugs.

5. Which of the following steps can be taken to reduce pediatric dosing errors?
   - **A.** Adoption of electronic health records with clinical support tools to decrease weight-based dosing errors
   - **B.** Calculation of weight-based dosing for all emergent medications administered in code situations as opposed to using a validated quick reference guide
   - **C.** Limiting hospital pharmacist presence in the emergency department to avoid delays in bedside care
   - **D.** Medication reconciliation should occur with just the patient present to limit primary caregiver influence

Answer: A. A multifaceted approach using clinical support systems and readily available reference tools are essential for the delivery of optimal emergent pediatric care. Caregivers are an integral part of medication reconciliation. ED pharmacists have been proven to increase departmental accuracy in pediatric medication management. Validated quick reference guides for code drug administration have been shown to decrease errors and improve efficiency.

Child Abuse

Daniel Lindberg

PHYSICAL ABUSE

KEY CONCEPTS

- The ultimate determination of whether abuse has occurred can take days or weeks. Emergency clinicians should focus on recognizing possible abuse, treating medical injuries, and establishing a safe disposition for the child.
- Completely undress infants and preverbal children for the physical examination; pay particular attention to the skin, ears, mouth and oral cavity, scalp, fontanel, and genitalia.
- Consider abuse routinely for sentinel injuries in young children without an independently witnessed traumatic mechanism. Sentinel injuries include the following: bruising in children younger than 6 months old; bruising on the torso, ears, neck, jaw, cheek, or eyelid; oral injuries; patterned cutaneous injuries; subdural hematoma; long-bone fractures in infants; intra-abdominal injuries; and rib fractures.
- Consider abuse for children when family violence (child abuse, intimate partner violence, elder abuse, or animal abuse) is recognized in the child's home.
- The goal of diagnostic testing is to identify additional clinically or forensically significant injuries or medical entities that may present similarly to abuse.
- Use objective, nonaccusatory, matter-of-fact statements to communicate concern for abuse.
- Emergency clinicians in the United States, Canada, and many other countries are legally mandated to report reasonable concerns for abuse to public child protective services (CPS) agencies.

FOUNDATIONS

Child physical abuse is a leading cause of death and disability for young children. In the United States (US), more than 120,000 children are victims of physical abuse leading to more than 550 preventable deaths each year.[1] This means that large pediatric centers will see several cases of physical abuse each month, while smaller, general emergency departments (EDs) may go several months without a single case.[2] Physical abuse is also commonly missed—approximately 30% of abusive head trauma and 20% of abusive fractures are missed on initial presentation.[3] Physical abuse is especially difficult to identify, because it predominantly affects preverbal children, particularly those younger than 6 months old.[1,4] Caregivers frequently omit or obscure the true history, and key portions of the physical examination (e.g., neurologic and musculoskeletal examinations) are limited. Early recognition of abuse therefore often depends on identifying subtle, minor, or self-limited injuries.[5-7] With these challenges, current practices are highly variable, and children are frequently returned to abusive environments.[2,8]

Overcoming these challenges is essential for abused children and their families. Because violence is a disease that affects entire households, recognition of abuse is important not only for the children themselves, but also for their siblings, parents, elders, and even pets.[9-13] For abuse survivors and those who share a violent household, the long-term health effects of toxic stress are severe, diverse, and widespread.

Role of the Emergency Clinician

It is rarely possible and almost never necessary to definitively diagnose abuse in the ED. Care of abused children involves the cooperation of medical, social, and law-enforcement agencies over weeks and months. Emergency clinicians are responsible for raising the initial concern for abuse and working with other professionals (e.g., general and child abuse pediatricians, CPS) to stratify risk, ensure safety, and arrange for ongoing care.

Most injuries in childhood are not the result of abuse, and unusual events may produce unusual or unusually severe injuries.[14] Inevitably, some children who are evaluated for abuse will ultimately be determined to have an innocent explanation for their injuries. To facilitate the evaluation and preserve the doctor-patient relationship, emergency clinicians should use nonaccusatory statements to explain the need for testing (Box 172.1). A routine, standardized approach to testing and reporting can improve abuse recognition and decrease racial and social disparities.[15-17]

CLINICAL FEATURES

The clinical features of physical abuse are listed in Box 172.2.

Social and Demographic Risk Factors

Understanding psychosocial and demographic risks is most important for primary prevention efforts.[18,19] Despite increased data, these factors are relatively insensitive and nonspecific and should not be used to confirm or exclude abuse. Serious physical abuse has been reported in every socioeconomic setting, and even in households with several risk factors, the vast majority of caregivers do not physically abuse their children. Nevertheless, poor or African American families remain disproportionately likely to be evaluated and reported for abuse, while abuse is more likely to be missed in White or affluent families.[20]

Physical abuse is more likely to occur with male caregivers, especially with new caregiving arrangements, or when the caregiver is an unrelated boyfriend.[21] Prior involvement with CPS, intimate partner violence, substance use, mental illness, poverty, and criminal history have been associated with increased risk for abuse, as has the use of negative descriptors of children.[22-25]

History

Abuse is challenging to recognize when a child presents with nonspecific symptoms and without a recognized traumatic injury. Fractures,

BOX 172.1 Communication Strategies

When Interviewing a Child About Abuse

- Open-ended, non-leading questions: "Tell me more about that.", "How did your body feel?", "Then what happened?"
- "What happens at your house when kids (or pets) get in trouble?"
- Frequently explain and ask permission: "I am going to ask you some questions about your health to make sure I provide the safest treatment. Is that ok? I'm going to examine your body to make sure you are healthy. Is that ok?"

To Introduce the Genital Examination for Young Children

- "I'm also going to examine your whole body to make sure that you are healthy. I'm going to look at your nose, your ears, your belly-button, and even under your undies."
- "This examination is ok because I'm a doctor, because your mother is here, and because your mother says it's ok."

After the Examination

- "Your body looks completely healthy and normal. This does not make me doubt what you told me. It does mean that no one, not your spouse, your friends, or even a doctor like me will know what happened by looking at you." Or, "Your body has some signs of injury, but these will heal very quickly, and in a few days, you will be completely back to normal. No one, not even…"
- "Despite what many people believe, doctors usually can't tell whether someone has had sex by looking at their body. In fact, in one study of teens that were pregnant, almost 90% had completely normal examinations."
- "In my opinion, someone stops being a virgin when they *choose* to have sex."

Nonaccusatory Statements of Abuse Concern

- "The injuries we've identified are more than we would expect from the event you've described."
- "Whenever we see injuries like this, we test for other injuries and medical conditions to be sure we're not missing something that could affect your child's health."
- "I want to make sure that your child is safe/that no one is hurting your child."
- "Have you ever been concerned that someone might have been rough with or might have injured your child?"

BOX 172.2 Red Flags for Physical Abuse

Psychosocial Factors (Nonspecific, Do Not Use to Exclude Abuse)

- Unrelated caregiver (especially boyfriend) or new caregiver relationship
- Family violence
- Mental health disorders
- Substance use disorders
- Describing the child negatively

Historical Factors

- Significant injuries with no or minor trauma
- Significant inconsistencies in history
- Unexplained delay in seeking care
- Significant injury attributed to pets or young children

Physical Examination Factors

- Bruising, frenulum or conjunctival injury in children <6 months old, or who are not "cruising"
- Bruising on the torso, ear, neck, angle of the jaw, cheek, or eyelid
- Patterned bruising or burns
- Immersion or cigarette burns

TABLE 172.1 The Pittsburgh Infant Brain Injury Score (PIBIS)

Applies to	• Age 30–364 days • Well-appearing • Afebrile (T <38.3°C) • No history of trauma
Who present with	• ALTE/BRUE/apnea • Vomiting without diarrhea • Seizures or seizure-like activity • Bruises/scalp swelling • Nonspecific neurologic symptoms/lethargy/fussiness/poor feeding
Score	• Abnormal skin exam (2 points) • Age >3 months (1 point) • Head circumference >85th percentile (1 point) • Hemoglobin <11.2 g (1 point)

Total points: 5; neuroimaging is recommended for children with scores of 2 or more.

abdominal injuries, and mild brain injuries can have a smoldering course of mild symptoms, such as irritability, vomiting, or decreased appetite or activity.[6,26] In these cases, identifying abuse is difficult and usually involves prolonged symptoms, additional clues on physical examination, known social risk factors, or prior concern for abuse. The Pittsburgh Infant Brain Injury Score (PIBIS) can be used in these cases to determine the need for neuroimaging (Table 172.1).[6]

Although still nonspecific, certain complaints should prompt consideration of abuse. A small percentage of children presenting with a brief, resolved, unexplained event (BRUE; formerly known as apparent life-threatening event (ALTE)) will have retinal hemorrhages or other abusive injuries. Occult fracture should be considered in young or preverbal children who present with decreased use of an extremity, fussiness, and localized tenderness or refusal to bear weight.

Regardless of the injury, unreasonable delay in seeking care should prompt concern for abuse. No precise time period defines an "unreasonable" delay, and physicians should consider the child's symptoms and progression of disease. A delay of several hours is not uncommon for children with nonabusive fractures or abdominal injury. Conversely, even a brief delay can be concerning in children with obvious signs and symptoms such as seizures, coma, or substantial burns.

Serious injury without a history of trauma, or with a history of only mild trauma (e.g., caused by the child themselves, a young sibling, or a pet) should raise a high level of concern for abuse. Nontrivial intracranial hemorrhage is extremely uncommon from short falls (e.g., from a bed or a couch) and does not result from choking on formula or saliva.[27-29] Abdominal and thoracic injuries rarely result from household falls, even with increased height or falls down stairs.

Physical Examination

To identify subtle signs of abuse, infants (i.e., children <12 months old) should be completely undressed during physical examination. The fontanel, scalp, ears, oropharynx, skin, and genitalia should be specifically examined. A growth chart can identify sudden increase in head circumference (a sign of intracranial injury) or failure to thrive.

Although bruises are very common in ambulatory children, *any* bruising in a child less than 6 months old, or that is not yet able to ambulate with assistance or "cruise," is highly concerning for abuse.[7,30]

Fig. 172.1 Bruising to the helix of the ear is very concerning for abuse. (Courtesy John Melville, MD.)

Fig. 172.2 Subtle bruising behind the child's ear can represent direct trauma or traction injury and should raise the level of concern for abuse. (Courtesy Daniel Lindberg, MD.)

Of children younger than 6 months old referred for an abuse evaluation with apparently isolated bruises, 50% had additional injury (fracture, brain injury, abdominal injury) identified.

Even in children old enough to cruise, bruises to the TEN-4-FACESp regions (*T*orso, *E*ar, *N*eck, *A*ngle of the jaw, *C*heek, or *E*yelid, or *F*renulum or *S*cleral injury, or injury that is *p*atterned in children younger than 4 years old) should raise concern for abuse (Figs. 172.1 to 172.3).[31] Common patterns include bruises in the shape of a cord, belt, or hand (Figs. 172.4 to 172.6). Human bite marks are patterned bruises

Fig. 172.3 Bruising to the neck and under the chin of an abused child. (Courtesy Carol Berkowitz, MD.)

Fig. 172.4 Slap mark. The parallel, linear bruising results when capillaries rupture outward between fingers. (Courtesy John Melville, MD.)

Fig. 172.5 Loop marks demonstrate contact injury from a looped cord. (Courtesy John Melville, MD.)

Fig. 172.6 Patterned bruising from a woven belt. (Courtesy Daniel Lindberg, MD.)

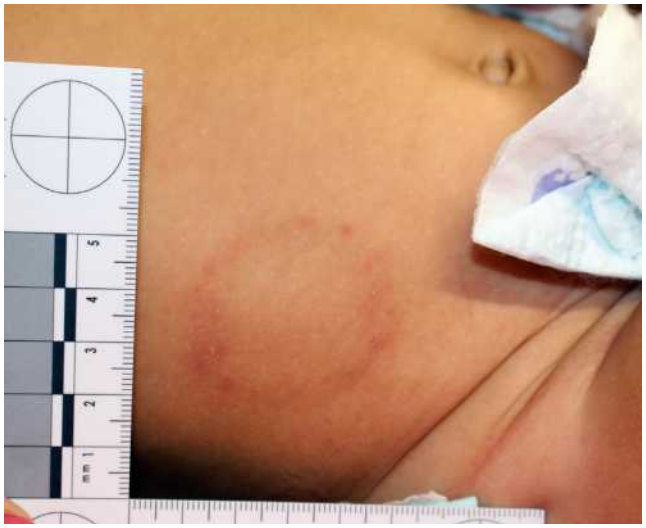

Fig. 172.7 Bite marks should be swabbed for DNA. (Courtesy John Melville, MD.)

in circular or paired semilunar rows (Fig. 172.7) and can be caused by adults or children. The ability of bite mark analysis to identify a biter is limited, so human bite marks should be swabbed to identify assailant DNA. Forensic evidence collection kits ("rape kits") used for sexual assault can be used to obtain, document, store, and transmit samples.

Abusive burns generally fall into three categories: immersion burns, contact burns, and cigarette burns. Immersion burns should be distinguished from pull-down scalds, which are very common in toddlers. Although pull-down scalds principally involve the upper body, immersion burns tend to involve the perineum or have a symmetric, stocking/glove distribution (Figs. 172.8 and 172.9). Abuse should also be considered when scalds affect a large body surface area, when sparing patterns suggest that the child was held in place, or when the incident is reported in the context of a toileting accident. For scald burns, CPS or law enforcement can measure the home's peak water temperature and the delay until peak temperature occurs. Although it takes several minutes to sustain a partial thickness burn from water at 120°F, the same burn can occur in seconds at 150°F.

As with bruises, emergency clinicians should consider abuse for young children with burns that take on the shape of an implement

Fig. 172.8 Immersion burn. (Courtesy EMSC Slide Set, National EMSC Resource Alliance.)

Fig. 172.9 Immersion burn of the feet after débridement. (Courtesy John Melville, MD)

(e.g., hair curler, grate, or lighter). Cigarettes can cause accidental or inflicted burns. Because the burning end of a cigarette can be more than 1000°F, inflicted burns are rarely superficial, and commonly result in crusted or ulcerated lesions between 8 to 10 mm (Figs. 172.10 and 172.11). Glancing or accidental contact with a cigarette can also cause superficial, linear burns.

Oropharyngeal injuries are also concerning in young children without a history of accidental trauma to the mouth or throat (Fig. 172.12). Tears of the lingual or labial frenula, or injuries to the lips, teeth, or soft palate should prompt an evaluation for abuse in children who are not yet walking and should increase concern, particularly when identified in evaluating children with other concerns of abuse.

Fig. 172.10 Cigarette burns. (Courtesy EMSC Slide Set, National EMSC Resource Alliance.)

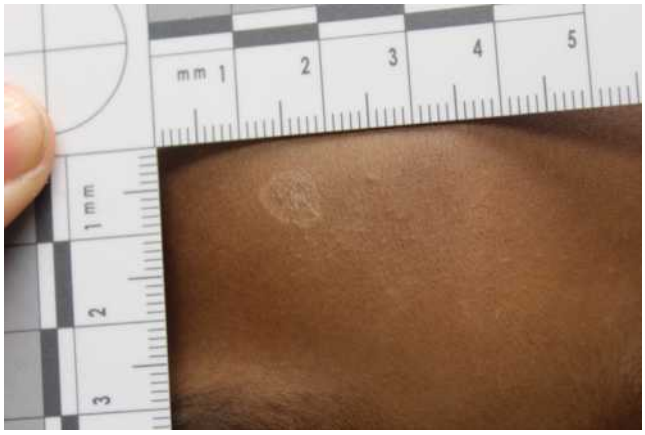

Fig. 172.11 Healing cigarette burn. (Courtesy of John Melville, MD)

Sentinel Injuries

For many children, the concern for abuse is first raised by the unexpected or incidental identification of a traumatic injury. Abuse should routinely be considered when young children present with these injuries unless there is an independently verifiable history of major trauma (e.g., a motor vehicle collision).

Serious traumatic brain injury should prompt a concern for abuse in children younger than 3 years old, where abuse is the source of approximately one-third to one-half of all injuries excluding traffic collisions.[32,33] Subdural hematomas, parenchymal injuries, and multifocal injuries are especially concerning for abuse, whereas epidural hematomas and isolated intraventricular hemorrhages are more likely to be nonabusive.[32,34,35]

Long-bone fractures are concerning in infants; abuse is diagnosed in 30% to 60% of infants with radius, ulna, tibia, fibula, femur, or humerus fractures. Rib fractures (Fig. 172.13) are even more concerning, with abuse identified in more than 25% of children up to 36 months old, and more than 67% of infants.[36,37] Less common, fractures to the hands, feet, spine, pelvis, sternum, or scapula should be considered highly concerning for abuse in young children without a specific, independent history of significant trauma.

Classic metaphyseal lesions (CMLs) are subtle metaphyseal fractures that occur in the severely abused infants (Fig. 172.14). CMLs appear radiographically as chips or bucket handle lesions around the growth plate and are most commonly seen in the femur, humerus, and tibia.[38] No fracture is more specific for abuse than the CML, and identification should prompt a thorough evaluation for other injuries.[39-41]

Fig. 172.12 Torn upper labial frenulum. (Courtesy John Melville, MD.)

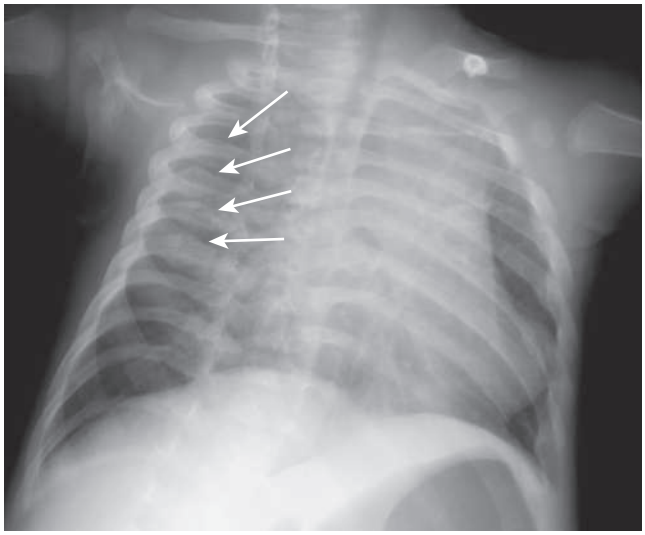

Fig. 172.13 Healing, posterior rib fractures. Right-sided, posterior rib fractures are indicated by the white arrows. Left-sided, lateral and posterior fractures are also present, and are better demonstrated by other views. (Courtesy Daniel Lindberg, MD.)

Skull fractures in infants commonly raise the concern for abuse but, relative to the injuries listed earlier, are much less specific. Even in infants, linear, parietal skull fractures can result from very minor falls. Because skull fractures do not show signs of healing, birth-associated skull fractures can be clinically subtle and difficult to differentiate from acute injury. In series of infants with apparently isolated skull fractures, occult fractures were identified by skeletal survey in up to 5% of cases. Complex skull fractures–multiple fracture lines, fractures that cross suture lines, and those with substantial depression or widening—require more force or multiple impacts and are therefore more concerning. It is possible, however, for bilateral parietal fractures to result from a single impact to the cranial vertex.

Although spiral fractures were once thought to have high specificity for abuse, available data do not support this.[42] Indeed, spiral fractures of the tibia *in children learning to walk* (toddler's fractures) are among the few fractures in young children that do not require routine skeletal survey, even without a clear mechanism of trauma (see Chapter 170).

Intra-abdominal injuries in young children are concerning for abuse if not sustained as a result of a motor vehicle collision, accidental direct blow, or significant fall. Although hepatic injuries are the most

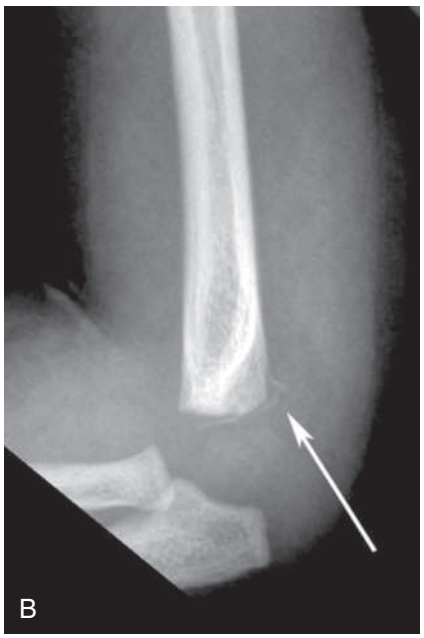

Fig. 172.14 (A) Classic metaphyseal fracture. In this anteroposterior view, the fracture assumes the "bucket handle" conformation. (B) In the lateral projection, the classic metaphyseal fracture appears as a chip. (Courtesy Daniel Lindberg, MD.)

common abusive injury identified, small bowel perforation and pancreatic injury are especially specific for abuse.[43]

TABLE 172.2 Differential Diagnoses (Not Exhaustive)

Presenting Injury	Diagnoses	Signs
Any	Accidental trauma	Minor injuries, walking children, history
	Birth trauma	Young infants
Fractures/bony injury	Osteomalacia of prematurity	Former significantly premature infants
	Osteogenesis imperfecta	Blue-gray sclera, family history
	Osteomyelitis	Fever (even minor)
	Congenital syphilis	Rash
Bruising/hemorrhage	Congenital coagulopathy	Abnormal PT/PTT/platelets, family history
	Other cutaneous lesions	Failure to resolve with time
Burns	Phytophotodermatitis	Typical history
	Irritant burn	Exposure to senna, laxatives, irritants

Universal Screening

In an effort to reduce rates of missed physical abuse, some centers have implemented processes of "universal screening," in which the primary nurse documents whether there is concern for abuse in every child at the time they present for care. Nurses are prompted to consider historical and physical findings and to completely undress young children. In several large, population-based samples, universal screening has been shown to be feasible, to identify children with higher risk for abuse, and to increase reporting, but it has not yet been shown to decrease rates of missed abuse.[44-46]

DIFFERENTIAL DIAGNOSES

Because the diagnosis of abuse has a profound impact on a child, their family, and the alleged abuser, a variety of traumatic and medical conditions have been suggested to explain signs and symptoms of physical abuse (Table 172.2). These range from sincere attempts to distinguish abuse from rare but well-described medical entities, to the invention of new medical entities invoked only in legal settings or the lay press.[27,28,47-50] It is usually beyond the scope of an emergency clinician to test for such rare diseases or hypothetical entities unless there are specific signs or symptoms (e.g., the blue sclera of osteogenesis imperfecta) or a specific family history.

The most common entity to be differentiated from abuse is accidental injury. With few exceptions (e.g., the CML), most traumatic injuries that have been reported in the setting of abuse can also be seen with other severe forms of trauma. Isolated injuries reported in the context of an accidental trauma mechanism should be evaluated on a case-by-case basis to determine whether the identified injury matches the reported mechanism. Young children who have started to cruise or walk frequently may have unobserved short falls from standing height or furniture. Although the vast majority of these falls are benign, they can produce injury: isolated bruising to shins, elbows, or other hard body surfaces; linear skull fractures; toddler's fractures, buckle fractures of the distal femur; and clavicle fractures.

In the youngest infants, injuries from birth should be considered, because symptoms may only be recognized weeks after the child is discharged from the hospital. Skull fractures, cephalohematomas, and clavicle fractures are the most commonly identified, whereas asymptomatic subdural hematomas, rib fractures, and other extremity fractures are rarer. Retinal hemorrhages occur in approximately one-third of normal births and persist for 1 to 3 months.[51,52]

Bone fragility disorders should be considered in children with exclusively bony injuries. *Osteomalacia of prematurity* occurs in roughly 30% of extremely low-birth-weight infants and is commonly associated with fractures in the absence of significant trauma. Risk factors include exposure to prolonged parenteral nutrition, steroids or furosemide, and those with cholestasis or chronic lung disease. Minor forms of *osteogenesis imperfecta* can present with multiple unexplained fractures. Although the diagnosis can be made early in children with a family history or severe disease, some cases are only diagnosed in the course of an evaluation for abuse. Be alert for blue-gray sclera, especially if they persist beyond infancy, or family history of unexplained fractures, fragile teeth, congenital hearing problems, or short stature. Osteomyelitis and congenital syphilis can cause metaphyseal abnormalities and should be considered in children with even mild fever or rash.

In children whose injuries are confined to problems of bruising or bleeding, emergency clinicians should consider an undiagnosed coagulopathy. The American Academy of Pediatrics (AAP) has published guidelines for coagulopathy testing that will identify the vast majority of bleeding disorders.[53] Briefly, these children should have prothrombin time and international normalized ratio (PT/INR), partial thromboplastin time (PTT), Factors VIII and IX, and complete blood count (CBC).[53,54] Those with intracranial hemorrhage should have testing for D-dimer and fibrinogen. Because coagulopathy testing can take weeks or months, and because abuse is the more common etiology in children with isolated bruising and concern for abuse, the coagulation evaluation should not delay the evaluation for abuse, reporting to CPS, or safety planning.

Atraumatic cutaneous findings may be confused for isolated bruising, including congenital dermal melanosis (formerly "Mongolian spots"), other birthmarks, or even blue dye from clothing (diagnose and "cure" this with an alcohol wipe). Because bruising resolves over a few days, follow-up examinations with photo documentation can reliably distinguish most findings. In cases where an immediate decision is needed, preliminary data suggest that transcutaneous bilirubin testing might be useful.[55]

When children present with lesions concerning for abusive burns, emergency clinicians should consider phytophotodermatitis and irritant burns. Phytophotodermatitis is a skin reaction caused by sun exposure in the setting of photo-sensitizing substances such as citrus, parsnip, or celery juices. It can cause well-demarcated, patterned, burn-like, blistering lesions and the typical history can usually be elicited. Irritant burns can be caused by prolonged exposure to mild skin irritants, such as household bleach, which may not be uncomfortable to the child. Prolonged contact with stool in diapered children, especially after the use of Senna or other laxatives, can cause contact burns that look identical to immersion burns.[56]

DIAGNOSTIC TESTING

Protecting a child from an abusive caregiver may require proving that the child's injuries are the result of abuse. Identification of additional traumatic injuries suggests abuse, particularly when not explained by the initial history. Concomitant injuries may have important *forensic* significance, even when they do not require specific treatment. The clinical examination is insensitive, especially in very young children, for forensically significant injuries, such as healing fractures, CMLs, abdominal injuries, and even milder abusive head trauma.[57] To decrease testing disparities and improve abuse recognition, we recommend a routine testing strategy based on the level of concern for abuse and the child's presenting injuries (Table 172.3).[14,31,58,59]

Skeletal Survey

The radiographic skeletal survey is the oldest and most commonly used diagnostic test to identify occult traumatic injuries when there is concern for physical abuse. Depending on the population, skeletal surveys identify additional fractures in approximately 10% to 25% of cases, with very low radiation exposure.[38,60] Guidelines recommend skeletal survey for all children younger than 24 months old with suspicion for abuse.[8,14,59,61,62] Skeletal surveys may be reasonable in children 24 to 60 months old, especially for those with limited mobility, decreased ability to communicate, and those 24 to 36 months old. Skeletal surveys require specialized technique, including at least 21 separate films and interpretation by an experienced radiologist.[63] A child should be transferred to an experienced center for skeletal survey rather than have an incomplete or inadequate series. There is no role for a single exposure "baby-gram" to identify occult fractures. A follow-up skeletal survey, repeated after at least 14 days, frequently identifies additional missed fractures and may clarify indeterminate findings (Box 172.3).

TABLE 172.3 Recommendations for Occult Injury Testing

Diagnostic Test	Indications (With Concern for Abuse)
Skeletal survey	All patients <24 months old Consider in 24-60-month-olds
Neuroimaging (CT or MRI)	Signs/symptoms of traumatic brain injury History of assault to head or violent shaking <6 months old PIBIS score >1 (see Table 172.1)
Retinal examination	Patients with traumatic brain injury
AST/ALT	Patients <60 months old with significant injury (e.g., brain injury, torso injury, long-bone fracture)
Abdominal CT	History of assault to abdomen Signs/symptoms of abdominal injury AST or ALT >80 IU/L
Siblings and contacts	Skeletal survey for <24-month-old contacts of injured, abused children. Interview verbal children capable of participating
Toxicology testing (evidence is limited)	Altered mental status Evidence of substance use in the environment Abusive burns

ALT, Alanine transaminase; *AST,* aspartate transaminase; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

Neuroimaging (Computed Tomography or Magnetic Resonance Imaging)

Abusive head trauma is both the leading cause of death and disability in abused children, and the abusive injury most frequently missed by clinicians.[3] Head computed tomography (CT) or magnetic resonance imaging (MRI) should be undertaken in children with signs of brain injury—decreased mental status, external signs of impact to the head, bulging fontanel, seizure, coma, or focal neurologic findings.[57] We recommend neuroimaging also be performed in children younger than 6 months old when there is concern for abuse, even when the child is neurologically asymptomatic. In infants with nonspecific signs and symptoms, such as lethargy, seizure-like activity, or vomiting without fever or diarrhea, the PIBIS score should guide neuroimaging decisions (see Table 172.1). Because of the need to identify forensically significant injuries, the Pediatric Emergency Care Applied Research Network (PECARN) decision rule should not be used to identify children at low risk of injury when there is concern for abuse[57,64] See Chapter 160 for a discussion on nonabusive pediatric head injury evaluation.

Because it is widely available, fast, and accurate, CT is currently the most widely used modality to diagnose abusive head trauma. Head CT should routinely include three-dimensional reformatting to identify

subtle skull fractures that may be missed in the plane of the scan. These reformats do not require additional radiation exposure but do require reformatting before data are expunged.

Recently, MRI using faster, more motion-tolerant MRI sequences (fast MRI) has come to replace CT as the initial test for abusive head trauma in several centers.[65-69] In order to decrease radiation exposure, we recommend, as resources allow, rapid MRI in favor of CT for clinically stable children who do not require other CT imaging. Because rapid MRI is marginally less sensitive for skull fractures than CT, we recommend that a complete skeletal survey with skull radiographs be performed in children who undergo rapid MRI for concerns of abuse. Cranial ultrasound is not sufficiently sensitive to identify occult abusive injuries and is not recommended as an initial study for children with concern for abuse. In children with identified abusive head trauma, MRI of the brain and cervical spine is frequently performed several days after the initial CT scan to further delineate and assess progression of injury.[70]

Retinal Examination

Retinal hemorrhages identified in a child with head injury can significantly increase the recognition of abuse.[51] Although a wide range of diseases can cause mild retinal hemorrhages, numerous (>20), multilayered and extensive hemorrhages, or those associated with macular retinoschisis, are strongly associated with abusive head trauma (Fig. 172.15). Dedicated retinal examination by an experienced ophthalmologist is recommended for children with concern for abusive head trauma to characterize the hemorrhages and improve sensitivity.[51] Conversely, without radiographic evidence of brain injury, significant retinal hemorrhages are rare, and transfer or referral for specialty retinal examination should be considered optional in this group. Even in severe cases of abusive head trauma, retinal hemorrhages are absent in approximately 15% of cases; retinal examination should therefore not be used as an initial screening test to determine the need for neuroimaging.

Abdominal Injury Testing

Intra-abdominal injuries, ranging from obviously life-threatening to completely asymptomatic, are present in approximately 3% of children evaluated for physical abuse. Abdominal bruising, tenderness, or distention of the abdomen are present in approximately 50% of children with abusive abdominal injuries. In children with concern for abuse and aspartate transaminase (AST) or alanine transaminase (ALT) greater than 80 IU/L, at least 20% had an intra-abdominal injury identified by CT scan or other definitive testing. Amylase and lipase have been recommended by some authors to increase sensitivity for abdominal injuries, but have not been shown to significantly improve yield beyond clinical examination plus AST and ALT. Although ultrasound can identify abdominal injuries, it is relatively insensitive; CT should be used to characterize injuries identified by ultrasound.

To assess for intra-abdominal injury, we recommend AST and ALT testing for children with concern for abuse unless there is obvious abdominal injury or history of direct abdominal trauma, in which case a CT scan should be performed. We also recommend CT scan with intravenous (IV) contrast be performed for those with AST or ALT greater than 80 IU/L. Because AST and ALT rapidly normalize, even in children with hepatic lacerations, trending of transaminases over time should not be used to determine the need for imaging. For this reason, it is also important that testing be completed during the initial evaluation.

Fig. 172.15 Too numerous to count retinal hemorrhages in all layers that extend to the periphery—characteristic of abusive head trauma. (Courtesy of Daniel Lindberg, MD.)

Toxicology Testing

Children can ingest illicit drugs via malicious poisoning or neglectful exposure.[71-73] Centers with routine testing strategies identify illicit substances in approximately 5% to 10% of children with high levels of concern for abuse.[71] Because data are limited and the epidemiology of drug use is highly variable, there are currently no widely accepted guidelines for drug testing when there is concern for abuse. Currently, we recommend drug testing when children with high concern for abuse present with burns, altered mental status, or when substance use disorders are identified in the child's environment. Because rapid drug screens based on ELISA methodology are subject to high rates of false negatives, we recommend use of comprehensive testing based on mass spectroscopy.[71]

MANAGEMENT

Compared to children with nonabusive traumatic brain injury, as a group, children with abusive head trauma tend to have more severe injury, longer ICU stays, and higher mortality. Nonconvulsive seizures are identified in more than 30% of children with abusive head trauma, prompting some to recommend routine electroencephalogram (EEG) monitoring.[4,74] Otherwise, medical management of children with abusive traumatic injuries is generally the same as for nonabused children.

Beyond the management of the acute injuries themselves, management of abuse largely consists of protecting the child from further abuse.

Household Contacts

Violence is a disease that affects an entire household.[10,13,75,76] We recommend that emergency clinicians identify any other children who share a home where child abuse (or other forms of family violence) is identified.[9,12,59,75] Conversely, when child abuse is recognized, emergency clinicians should consider whether other family members or companion animals may be at risk and use the expertise of CPS to assist in bringing those at risk for evaluation. Contacts younger than 24 months, especially twins and other multiple births, should have a skeletal survey.[14] Older, verbal children should be interviewed about any reported trauma history, and to identify abusive disciplinary practices. In cases where there is significant concern for genetic diseases that mimic abuse, evaluation of biological siblings can help to establish the correct diagnosis.

Timing

Determining the age of an injury can affect the plausibility of an offered history and can assist law enforcement in identifying the perpetrator. In young children, multiple injuries of different ages are highly concerning for abuse. In many cases, the best way to determine the timing of an injury is based on when the child developed symptoms, independent witness reports, or images of visible injuries.

The best evidence for injury dating comes from fractures of endochondral bones (most bones except the skull). Signs of healing (e.g., periosteal reaction and callus formation) are rarely evident before 7 days and commonly seen within 10 to 14 days. Experienced radiologists can sometimes offer more nuanced estimates of fracture age. Multiple fractures of different ages are highly concerning for abuse.

Recent data suggest that the finding of too-numerous-to-count intraretinal hemorrhages reliably resolves within a few days. Thus, we recommend dedicated retinal examination occur within 24 to 48 hours in cases with concern for abusive head trauma; the patterns of retinal hemorrhages may be useful in estimating the time of injury.[77]

Conversely, emergency clinicians should be cautious not to estimate the age of bruises based on their appearance. Previously used dating systems were based on scant data and have poor accuracy when prospectively used to estimate bruise ages in children with known times of injury. Similarly, the CT appearance of subdural hematomas or other intracranial hemorrhages is of limited utility in estimating the age of injury. Although hyperdense "bright" blood is often thought to signify acute hemorrhage (and vice-versa), hyperacute bleeding, re-bleeding and mixing of blood and cerebrospinal fluid (CSF) probably account for their poor accuracy. Mixed density subdural hematomas have been described in several cases with a single traumatic episode, and therefore are not strong evidence for multiple episodes of trauma. In cases of severe traumatic brain injury, the onset of a child's symptoms is probably the most useful determination of timing of injury, especially when a child who had been acting normally suddenly becomes comatose.

Mandated Reporting

In the United States, Canada, and several other jurisdictions, emergency clinicians are mandated to report a reasonable concern of child maltreatment to public CPS agencies or law enforcement. These reports can mobilize social resources for family, expand the investigation of abuse beyond the hospital, and facilitate testing or protection for other children in the abusive environment. A final diagnosis of abuse is not required to trigger the mandate, and reporters generally have legal protection for reports made in good faith, even if a child is ultimately determined not to have been abused. In cases where there is reasonable concern for abuse, but where the final diagnosis is pending, emergency clinicians should be reassured that a mandated report need not automatically trigger the removal of a child from their home or the instigation of criminal proceedings. In many jurisdictions, the mandate to report can be satisfied by reporting to a designated child protection team who will complete the evaluation and determine the need for reporting.

Hospital social workers can assist with the reporting process. The exact procedure for reporting varies by jurisdiction, but instructions are usually accessible via an internet search for "report child abuse [location]." In preparing to report, gather the child and family's contact information, the identity and ages of any other children in the home, and the location where the abuse may have occurred (to determine reporting jurisdiction).

DISPOSITION

Many children with physical abuse will require hospital admission for treatment and stabilization of their injuries or identification of a safe environment. Children with concern for physical abuse may be discharged if: (1) injuries have been medically stabilized; (2) reasonable concerns for abuse have been reported as required by statute; and (3) a safe environment has been identified. In children who are otherwise stable for discharge, CPS should establish a temporary safety plan until testing can be completed.

Should caregivers attempt to leave the ED prior to the completion of an evaluation for abuse, emergency clinicians should follow their typical practice for parents seeking to leave against medical advice. If a caregiver demonstrates the capacity to make medical decisions, and has received the clinician's best advice, emergency clinicians and hospital staff should not seek to forcibly prevent them from leaving. Reasonable concerns for abuse should be reported in these circumstances as required by local statutes to CPS or law enforcement, which have the ability to implement secondary prevention.

SEXUAL ABUSE

KEY CONCEPTS

- ED evaluation of pediatric sexual assault should focus on time-dependent medical treatment and evidence collection. The ultimate determination of abuse likelihood can be deferred pending the forensic interview and additional investigation.
- A normal examination neither confirms nor excludes the possibility of abuse, and patients should be reassured that their body is normal and healthy.
- A genital examination should not be forced on a child. Most children can be referred for an examination when they are rested and prepared.
- Likelihood of obtaining forensic evidence decreases with time from assault. Evidence collection may be performed up to 7 days after sexual assault, depending on jurisdiction.
- Emergency contraception should be offered to pubertal females up to 120 hours after sexual assault.
- Prophylactic or empirical treatment for gonorrhea, chlamydia, and trichomonas should be offered to pubertal children, but treatment should be deferred in pre-pubertal children until infection is confirmed.
- When an investigation for sexual abuse is ongoing, caregivers and emergency clinicians should provide a believing, supportive environment if a child reports abuse or has questions but should not attempt to elicit a detailed narrative outside the context of the forensic interview.

FOUNDATIONS

Sexual abuse of children is common and under-recognized.[78] When surveyed as young adults, roughly 25% of women and 5% of men report some form of sexual abuse, with adolescents being at highest risk. These are likely under-estimates given the limitations of self-reporting. Perpetrators of sexual abuse are overwhelmingly male and can include family members, acquaintances, or strangers.

Especially in adolescents, the loss of control inherent in sexual abuse can be profoundly damaging. A trauma-informed approach can decrease anxiety and facilitate the evaluation. In school-aged or adolescent children (and adults) who have experienced sexual assault, emergency clinicians should seek to re-establish a sense of control whenever possible. For example, we recommend frequently explaining the purpose of each step of the process and asking for permission (examples, see Box 172.1). Respect a child's right to decline any part of the evaluation.

As with physical abuse, the bulk of the investigation in cases with concern for sexual abuse can occur outside of the ED. Urgent interventions include stabilization of medical injuries, evidence collection, post-exposure prophylaxis (PEP), arrangement of a safe environment, and CPS reporting. Evaluation of children more than 72 hours after possible abuse (or another period if mandated by law) can be deferred from the ED to an outpatient setting.[79] Completion of a full evidence collection kit can require more than an hour of undivided attention, and emergency clinicians responsible for multiple potentially unstable patients may benefit in partnering with a sexual assault/forensic nurse examiner (SANE/FNE) program or a subspecialty child abuse pediatrician.

Misconceptions about normal pediatric female genital anatomy (Figs. 172.16 and 172.17) are widespread among both patients and clinicians. The pre-pubertal hymen is thin, with a smooth edge. Normal configurations include annular or ring-shaped, crescent-shaped, and tulip-shaped, among many others. Although imperforate hymens exist and can cause symptoms in pubertal children, this is a rare abnormality. During puberty, the hymen becomes thickened and redundant (see Fig. 172.17).

Trafficking

Trafficking, or commercial sexual exploitation of children, occurs when someone engages a minor in any sex act that involves the exchange of something of perceived value, and can include the prostitution of children by others, "survival sex," or pornography.[80] Although reliable statistics on the prevalence and epidemiology of trafficking are limited, available evidence suggests that the large majority of trafficked children and adolescents in the United States are female and are US citizens.[81] Early data suggest that trafficking is more likely among adolescents who have history of substance use, run away from home, have been involved with law enforcement, had a traumatic injury (i.e., broken bone, loss of consciousness, significant wound), had an STI, or had more than 5 sexual partners.[80,82,83] When two or more of these risk factors are identified, clinicians should ask if anyone has asked or forced the patient to do something sexual with someone else, to do some sexual act in public (like dance in a strip club), to pose sexually for a photo or video, or if the patient has traded sex for something they needed.[84] Clinicians should take steps to ask these questions privately, because traffickers may pose as relatives, friends, or employers. The National Human Trafficking Resource Center maintains a hotline (1-888-3737-888) that can provide region-specific resources to clinicians or patients when there is concern for trafficking.

CLINICAL FEATURES

In contrast to physical abuse, most sexual abuse evaluations will be prompted by a patient or caregiver report. Genital bleeding or discharge should prompt consideration of sexual abuse even when no concern is raised in the history, and in pre-verbal children. Pregnancy or sexually transmitted infections (STIs) (gonorrhea, chlamydia, syphilis, trichomonas, or human immunodeficiency virus [HIV]) demonstrate evidence of sexual contact.[79,85-87] A diagnosis of pregnancy or STI in a young adolescent should prompt nonjudgmental questions about the child's sexual partners; some victims perceive abuse as consensual sexual activity with a boyfriend or girlfriend.

Caregivers sometimes bring children for evaluation based on concern for abnormal appearance of a child's genitalia (redness, size, or shape of vaginal or rectal orifices). Without other indications of abuse, these findings are extremely nonspecific and do not increase the likelihood of abuse.[88] In young children (2 to 6 years old), some sexual behaviors that are concerning to caregivers (e.g., touching genitals in public) are part of normal development, whereas others (e.g., inserting objects into the genitals) should prompt concern for sexual abuse. The AAP has published guidelines for the evaluation of several such

sexual behaviors. In general, behaviors are less concerning if they are transient, few, and distractible. They are more concerning if they are persistent and resistant to parental distraction. When children engage in sexual actions or activity with each other, sexual abuse should be distinguished from sexual play by the presence of a significant difference in age or development, or the presence of coercion. Laws defining the age of consent for sexual activity and the age difference that constitutes statutory rape differ by jurisdiction.

History

Most cases of sexual abuse do not have diagnostic findings on physical examination, laboratory testing, or forensic evidence collection. Therefore, a child's history is usually the most important factor to determine social or legal interventions in cases of alleged sexual abuse. Forensic interviews, conducted by CPS, law enforcement, child advocacy centers, or child protection teams, are conducted to avoid suggestive or coercive questions. In most cases, these forensic interviews can take place after the initial ED evaluation, allowing emergency clinicians to limit their history to the information needed to identify medically significant injury or illness.

Forensic interviewing requires substantial training and ongoing peer review, and repeated interviews could "contaminate" evidence. For these reasons, we recommend that emergency clinicians, parents, and caregivers not attempt to obtain detailed narrative needed for prosecution outside the formal forensic interview.[79] However, adults should provide a safe, supportive, listening environment if the child approaches them with information or questions. Outcomes for sexually abused children are improved when they are believed and supported by their caregivers. Clinicians should transparently communicate that their ability to keep information confidential is limited in some cases by the legal mandate to report reasonable concerns for child abuse.[89]

In cases where a caregiver reports the initial concern for abuse, emergency clinicians should obtain the caregiver's history separated from the child. Document whether the child reported abuse; and if so, whether the report was spontaneous, or in response to questioning by the caregiver. Identify any additional children ("contact children") who share the environment where abuse may have occurred. If interviewing a child, avoid leading questions, and document both the question asked and the child's response.

Interviews should be conducted at an appropriate developmental level; most children younger than 4 years old will have limited ability to participate in the interview. Younger school-aged children may have difficulty with "when" questions, limiting the ability to determine the time elapsed from the last episode of abuse (needed to determine the need for an acute examination, evidence collection, or HIV PEP). Consider asking "where," "what," or "who" questions to understand the timeline. For example, a child who does not know what time or day something occurred may know whether it was day or night, a school day or a weekend, or during a specific holiday, event, or visit to a different home. It may be helpful to elicit the terms used by the child to describe different body parts.

Physical Examination

Most children who present to the ED with concern for sexual abuse should be offered a dedicated physical examination of the genitalia and rectum. With proper preparation, this examination need not be painful or distressing to the child (see Box 172.1). Conducting the examination on the lap of a trusted caregiver and in the context of other painless examination maneuvers (inspecting the nose, heart, and belly-button) can reassure the child. Limit exposure of the child's body to the area being examined.[89]

The pre-pubertal (non-estrogenized) hymen is exquisitely sensitive; touching it will almost certainly end the useful portion of your examination. For this reason, collection of internal vaginal and cervical swabs is not indicated in a pre-pubertal child and a speculum examination should not be conducted.[89]

To avoid additional trauma, a genital examination should not be forced on a reluctant child. In most cases, a child can return for an outpatient examination after food, rest, and preparation.[89] In the rare cases of substantial bleeding or concern for a medically unstable injury, a gynecologist should perform an examination under anesthesia.

To best expose the hymen and other relevant anatomy, pull the labia majora out (off the table or toward the examiner—not laterally) with the same force you would use to retract the cheek to examine the teeth. The posterior hymen, if not sufficiently visualized in this position, can sometimes be better seen in the "knee-chest" position, where the child is placed in a prone position on the examination table with her hips flexed so that the knees and chest are resting on the table. The posterior hymen is then visualized by laterally retracting the buttocks.[79]

If manipulation of the hymen is absolutely necessary, consider using the mucosal surface of the contralateral labia. Alternatively, a few drops of sterile saline can be used to "float" the posterior rim of the hymen and expose an area of interest. A colposcope can be useful to magnify, illuminate, and document examination findings. Data do not support the use of toluidine blue to identify mucosal injuries not apparent to the naked eye.[79] If photo-documentation is conducted, images should be maintained in a confidential format separate from the normal electronic medical record.

Even when concern for sexual abuse is high, most children will not have physical signs of genital or anal injury.[85] A wide array of nonspecific findings (e.g., erythema, periurethral bands, and bumps and notches of the hymen) should not be confused with evidence of sexual contact. (Table 172.4). Injuries that are indicative of trauma include bruising, petechiae, or abrasions on the hymen; acute lacerations of the hymen; vaginal lacerations; or complete transection of the hymen between 4 o'clock and 8 o'clock (Figs. 172.18 and 172.19). In adolescents capable of consensual sexual activity, no examination finding can distinguish consensual sexual activity from assault or rape.

Although the vast majority of physical examinations will be normal, even when performed soon after acute sexual assault, a normal examination does not exclude abuse. Children and families can be reassured that they are healthy and normal and that no one in the future (e.g., doctors, spouses) will know from looking at them that abuse has occurred. Some families have concern for an anatomic definition of virginity, although they are reluctant to broach the issue. Providers should emphasize that the child is anatomically normal and that the definition of virginity should depend on when someone *chooses* to have intercourse.

DIFFERENTIAL DIAGNOSES

Strep infection of the perineal skin and genitalia can produce redness, inflammation, and fissures. Vaginitis from infection or poor hygiene can result in vaginal discharge or dysuria. Isolated vaginal bleeding can be the result of urethral prolapse (beefy red protrusion inferior to clitoral hood) or lichen sclerosis (pale, irritated, thin, hypopigmented skin surrounding the genitalia; Figs. 172.20 and 172.21). Straddle injuries can produce bruising of the external genitalia (labia, perineum, and peri-urethral tissues) and are usually accompanied by a history of injury. In boys who are toilet training, a falling toilet seat can produce dorsal and ventral penile bruising similar to a bite mark.

TABLE 172.4 Significance of Genital Findings for Abuse

Normal Findings	Conditions Mistaken for Abuse	Findings Caused by Trauma and/or Sexual Contact
• Normal hymen variants (annular, crescentic, imperforate, micro-perforate, septate, redundant, with tissue tags, with bumps or mounds) • Hymenal notches or clefts between 3 and 9 o'clock • Superficial notches below 3 and 9 o'clock • Periurethral bands • Intravaginal ridges or columns • External hymenal ridge • Linea vestibularis • Diastasis ani • Perianal skin tags • Hyperpigmentation of the skin of the labia minora or perianal tissues in children of color • Dilated urethral orifice Findings commonly caused by other medical conditions: • Erythema • Increased vascularity • Labial adhesions • Friability of posterior fourchette • Vaginal discharge • Molluscum contagiosum • Anal fissures • Venous pooling • Anal dilatation from constipation, anesthesia, impaired muscular tone or post mortem	• Urethral prolapse • Lichen sclerosus • Vulvar ulcers • Erythema, inflammation or fissures from bacterial, viral, fungal, parasitic infection • Perineal groove • Rectal prolapse • Post mortem lividity	• Acute laceration(s) or bruising of labia, penis, scrotum, perianal tissues, or perineum • Acute laceration of the posterior fourchette or vestibule • Perianal or posterior fourchette scars (difficult to diagnose without documentation of the acute laceration) • Bruising, petechiae, or abrasions on the hymen • Acute laceration of the hymen • Vaginal laceration • Perianal laceration with exposure of tissues below the dermis • Healed hymenal transection/complete hymen cleft—a defect in the hymen between 4 and 8 o'clock that extends to the base of the hymen with no hymenal tissue discernible at that location • Evidence of female genital mutilation or cutting • Gonorrhea (genital, rectal or pharyngeal) • Syphilis • Chlamydia (genital or rectal) • Trichomonas • HIV (excludes transmission from blood transfusion) • Pregnancy • Semen found by forensic specimens

HIV, Human immunodeficiency virus.

DIAGNOSTIC TESTING

The goal of diagnostic testing in the ED is to identify transient evidence of sexual assault or sexually transmitted diseases (Table 172.5). Beyond the history and physical examination, a forensic evidence collection kit ("rape kit") can provide evidence of sexual contact and identify the assailant if DNA is isolated. Evidence is more likely to be obtained soon after the assault with the majority of positive kits obtained within 24 hours, especially in pre-pubertal children. Forensic evidence collection is recommended for cases of assault with possibility of DNA transmission (semen, blood, or saliva) up to 72 hours from the assault, although some practitioners or jurisdictions are moving to a threshold of up to 7 days based on newer polymerase chain reaction (PCR)-based techniques.[89] Beyond 24 hours, specimens from the child's clothing are the most likely to retain evidence. Obtaining the child's underwear (even if not worn at the time of the assault) can recover DNA evidence beyond 24 hours and is relatively noninvasive. Although many kits require documentation of whether a child has eaten, defecated, urinated, or wiped prior to evidence collection, children should not be asked to defer these activities in service of evidence collection, and these considerations should not impact the decision to collect evidence.

Pregnancy testing is routinely obtained in pubertal females because emergency contraception (levonorgestrel or ulipristal; Plan B) is ineffective for established pregnancies. STI testing is undertaken for symptomatic patients or in cases with potential for subacute or chronic abuse. Determining which tests to obtain depends on the details of the child's potential exposure and their physical examination, as well as local disease prevalence, patient and parent preferences, and the availability of timely follow-up. In cases with concern for drug-facilitated sexual assault, blood (within 24 hours) or urine (within 120 hours), samples should be obtained and included in the evidence collection kit.[90] Emergency clinicians may benefit from case-by-case consultation with child abuse pediatrics or infectious disease colleagues.

Fig. 172.20 Urethral prolapse. (Courtesy John Melville, MD.)

In adolescents and adults, the prevalence of STIs is high enough to warrant routine screening for gonorrhea, chlamydia, and trichomoniasis using nucleic acid amplification testing (NAAT) methods, if acceptable to the patient. NAAT has improved sensitivity, lower cost, and can be collected more easily, relative to traditional cultures.[85,86,91] NAAT testing for gonorrhea and chlamydia has been endorsed by the Centers for Disease Control and Prevention (CDC) for urine or vaginal specimens in girls.[79,86] STI prevalence in pre-pubertal assault victims is lower (5% to 8%). The AAP recommends NAAT testing for gonorrhea, chlamydia, and trichomoniasis in pre-pubertal children when there is:[85-87,92]

- Penetration of the vagina or anus
- Abuse by a stranger
- Known STI or high-risk behavior (IV drug use, men who have sex with men, multiple sexual partners) in the perpetrator
- Contact of a child with a known STI
- Signs or symptoms of STI
- Prior diagnosis of another STI
- Reasonable need by the patient or family for reassurance

Currently, there are no guidelines to direct testing for syphilis, hepatitis B or C, or HIV in children following sexual assault. We recommend testing in children with any of the above risk factors, or with high community prevalence or incomplete hepatitis B vaccination. Initial screening for syphilis should be by rapid plasma reagin (RPR); hepatitis B screening should include hepatitis B surface antigen and hepatitis B virus (HBV) immunoglobulin M (IgM) core antibody. Testing for HIV and hepatitis B and C should be repeated 6, 12, and 24 weeks after sexual contact.[86]

MANAGEMENT

ED management should focus on the most time-dependent interventions: mandated reporting and PEP for pregnancy and HIV. When there is a reasonable concern for sexual abuse, reporting to CPS is mandatory for emergency clinicians in the United States, Canada, and many other countries. Some caregivers may strongly desire a report, even when the

TABLE 172.5 Indications to Offer Testing and Treatment in Cases With Concern for Sexual Abuse

Test/Intervention	Indication
Pregnancy testing	Pubertal females
Gonorrhea/chlamydia/trichomonas testing (NAAT)	All pubertal children Report of vaginal or anal penetration Physical examination findings of sexual contact or ejaculation Abuse by a stranger Symptoms of STI, or diagnosed STI in the patient or a contact child Known STI or risk in suspected assailant Patient or parent request
HBV, HCV, HIV, syphilis testing	As for gonorrhea (above) *or:* Absent or incomplete vaccination for hepatitis B High community prevalence
Forensic evidence collection ("rape kit")	Potential for DNA transmission (blood, semen, saliva) Abuse within 72 hours (or longer depending on local statutes)
Levonorgestrel (Plan B)	Non-pregnant, pubertal females <72 hours from assault
Ulipristal (Ella)	Non-pregnant, pubertal females <120 hours from assault
Empirical treatment for gonorrhea/chlamydia/trichomonas	Pubertal children Avoid treatment in pre-pubertal children without confirmation of infection
HIV PEP	Depends on local prevalence and case-specific details Consider consultation with infectious diseases or CDC hotline (800-933-3413)
Report to children's services	Reasonable concern for abuse

HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PEP,* post-exposure prophylaxis; *STI,* sexually transmitted infection.

findings do not meet the threshold of a reasonable concern for abuse (as when the child presents for isolated nonspecific redness of the genitalia without a disclosure of abuse). Should the emergency clinician opt not to report these cases, caregivers can be advised that they have the option to report their concerns to CPS directly, independent of the health care provider.

Levonorgestrel (Plan B) should be offered to pubertal females within 72 hours (3 days) or ulipristal within <120 hours (5 days) of sexual assault. When taken within 72 hours, it can prevent up to 50% of pregnancies, although there is some potential to prevent pregnancy up to 120 hours after sexual assault. Because it works by suppressing ovulation, patients can be reassured that it will not terminate an established pregnancy.

The decision to offer PEP for HIV is complex and depends on the nature, timing, and likelihood of the sexual assault; local prevalence of HIV; and likelihood that the perpetrator is HIV positive. Although rates of HIV transmission in the course of sexual abuse are probably low, cases of HIV in children whose only risk factor is abuse have been reported.[86] Post-exposure prophylaxis is not effective if administered more than 72 hours after the assault. Consultation with infectious diseases specialists may be useful, and the CDC maintains a national telephone consultation service (1-800-933-3413) to provide real-time expert consultation to emergency clinicians with questions about HIV PEP.

Prophylaxis or empiric treatment for gonorrhea, chlamydia, and trichomonas should be offered to pubertal children but should be deferred for pre-pubertal children.[16] In pre-pubertal children, consensual sexual activity is impossible by definition, rates of STD are low, ascending infection is very uncommon, and follow-up is usually obtainable. For these reasons, the medical consequences of delayed treatment are low, but the forensic significance can be profound. Because infection with gonorrhea, chlamydia, or trichomonas is usually strong evidence of sexual abuse in pre-pubertal children, proof of infection can be essential to ensure the child's protection from ongoing abuse. Treatment prior to obtaining proof of infection can limit confirmatory testing and thwart protection efforts.

DISPOSITION

The vast majority of children evaluated for sexual abuse in the ED can be discharged to follow-up as outpatients. Follow-up is needed to arrange subsequent STI testing, ensure completion of HPV or hepatitis B vaccination, assess tolerance of HIV PEP, and arrange for mental health care. Medically stable patients can be discharged to a safe environment after obtaining appropriate testing and evidence collection. When the alleged assailant is a member of the child's household, CPS can arrange safety planning to ensure that a child has a safe place for discharge or that the alleged assailant is removed from the child's home.

CHAPTER 172: QUESTIONS AND ANSWERS

1. A 12-month-old girl is referred to the emergency department (ED) because her daycare noticed that she cries whenever she is picked up and there was crepitus in the left side of the chest. They deny any witnessed trauma in the daycare facility. The mother arrives and appears concerned. On physical examination, you find some circular contusions on the inner aspects of both her upper arms. The mother states this occurred from a fall a week ago. Which of the following should be the next step(s) in the patient's management?
   - **a.** Conduct a skeletal survey, and report to child protective services (CPS).
   - **b.** Determine whether the arm contusions are of the same age.
   - **c.** Perform a dedicated retinal examination to determine if the child has retinal hemorrhages and, if she does, perform a head computed tomography (CT) scan.
   - **d.** Perform a humerus x-ray to determine if there is a humerus fracture.

Answer: A. Contusions on the inner aspect of the upper arm are atypical injuries in light of the mother's claim of a fall for the child. This pattern of injury is often related to being held tightly around the arm. Chest wall pain in a child could indicate a rib fracture. Chest x-ray is insensitive for rib fractures, which are very uncommon at this age unless caused by inflicted trauma. This should raise your suspicion of child physical abuse. In general, children younger than 2 or 3 years old with suspected inflicted injuries should be evaluated with a skeletal survey.

2. A 6-year-old, pre-pubertal girl presents to the emergency department (ED) at midnight after her parents noticed malodorous vaginal discharge over the last 3 days after visiting her grandfather 2 weeks ago. The patient is tired and irritable at the time of presentation. Which of the following are indicated in the ED?
   - **a.** Empiric treatment for gonorrhea and chlamydia
   - **b.** Obtain a forensic interview.
   - **c.** Post-exposure prophylaxis for HIV.
   - **d.** Report to child protective services (CPS)

Answer: D. Genital discharge can be caused by both sexually transmitted and non-sexually transmitted infections, as well as other inflammatory processes. Several days of discharge implies a subacute timeframe for a potential abusive exposure. For subacute sexual abuse, ED management should include fulfilling the mandate to report to CPS and ensuring that the child has a safe disposition. A genital examination may be attempted in a cooperative patient and can assist in assuring the child that they are normal and healthy, but the examination should not be forced on the child if they are reluctant; it is unlikely to identify transient evidence of sexual contact. The detailed forensic interview should be conducted by a trained interviewer and may be deferred until the patient is rested. HIV PEP is unlikely to be effective 2 weeks after the assault. Empiric treatment for gonorrhea or chlamydia should not be given to pre-pubertal children until a sexually transmitted illness is definitively confirmed.

3. Which of the following implies multiple episodes of trauma at different times?
   - **a.** Bruises that are different colors.
   - **b.** Mixed density subdural hematoma on head CT.
   - **c.** Rib fractures with robust periosteal reaction are identified the day after a child presents with sudden coma and subdural hematoma.
   - **d.** Too numerous to count intraretinal hemorrhages and liver laceration with elevated hepatic transaminases

Answer: C. Periosteal reaction and other signs of fracture healing are not visualized until approximately 1 week after injury, and persist for weeks or months, whereas sudden coma implies an acute, traumatic event. Mixed-density subdural hematomas can be observed in the acute, subacute, and chronic phases. The color of bruises is affected by several factors in addition to the age of a bruise, including the child's complexion, depth of the bruise, natural variation, and even the perceptions of the observer. Too numerous to count intraretinal hemorrhages do not persist beyond a few days, but this could be consistent with a hepatic laceration.

4. Which of the following is very concerning for sexual abuse in a pre-pubertal child?
   - **a.** A new history of constipation and dilated anal sphincter (>1 cm)
   - **b.** An 8-year-old girl whose anogenital exam is completely normal reports that her camp counselor "put his wee-wee in my butt."
   - **c.** Erythema of the hymen and posterior fourchette.
   - **d.** Thin, fragile epithelium surrounding the labia with petechiae and subcutaneous bleeding.

Answer: B. A child's report of sexual abuse is highly concerning and is often the strongest evidence of abuse. A normal exam neither confirms nor excludes the possibility of sexual abuse, even with penetration. Dilation of the anal sphincter is nonspecific, especially in the setting of constipation. Like many mucosal tissues, erythema can occur for many reasons, including trauma, foreign bodies, lack of hygiene or even normal variation. "Cigarette-paper" skin with petechiae or hemorrhage suggests the presence of *lichen sclerosis et atrophicus*.

5. In a 2-week-old infant that is not yet crawling, which of the following is most highly concerning for abuse?
   - **a.** Clavicle fracture with callous
   - **b.** Lateral rib fracture with callous
   - **c.** Parietal skull fracture without callous
   - **d.** Torn lingual frenulum with scant bleeding

Answer: D. Lingual frenulum tears are very concerning for abuse in pre-mobile infants. These injuries heal quickly, and the presence of bleeding excludes the possibility of birth injury. Several self-limited injuries can result from the birth process, even in deliveries that are not recognized as particularly traumatic. These injuries can be clinically subtle and are not-uncommonly missed in the newborn nursery. Rib fractures are uncommonly seen from birth and are more common in larger infants or difficult deliveries. The presence of obvious callous on the rib fractures is consistent with a fracture that is at least 7 to 14 days old. Clavicle and skull fractures are not uncommon parturitional injuries. Unlike other fractures, skull fractures do not develop callous and their age cannot be estimated.

173

Complications of Pregnancy

Megan C. Henn and Michelle D. Lall

KEY CONCEPTS

- Miscarriage is defined as the spontaneous termination of pregnancy before 20 weeks of gestational age.
- Approximately 25% of women experience some bleeding during pregnancy.
- Most miscarriages are due to uterine malformations or chromosomal abnormalities.
- Beta hCG discriminatory levels for detecting intrauterine pregnancy are usually considered to be 6500 mIU/mL for transabdominal ultrasonography and 1000 to 2000 mIU/mL for transvaginal ultrasonography.
- Treatment of the patient with incomplete miscarriage includes expectant management, medical management, or surgical evacuation.
- All patients with pregnancy loss require patient education, return precautions, and support through the grieving process.

Acute complications of pregnancy can appear in all trimesters and pose challenges in diagnosis and management for the emergency clinician. Life-threatening disorders, such as ectopic pregnancy in early pregnancy, pregnancy-induced hypertension in mid to late pregnancy, and abruptio placentae in late pregnancy, are relatively common. Emergency clinicians must consider the signs and symptoms, stage of pregnancy, and hemodynamic stability of the patient in developing diagnostic and treatment strategies.

PROBLEMS IN EARLY PREGNANCY

Miscarriage Foundations

Miscarriage, the most common serious complication of pregnancy, is defined as the spontaneous termination of pregnancy before 20 weeks of gestation. Fetal demise after 20 weeks of gestation or when the fetus is more than 500 g is considered premature birth. Early pregnancy loss is defined as a nonviable, intrauterine pregnancy with either an empty gestational sac or gestational sac containing an embryo or fetus without fetal cardiac activity within the first 12 weeks and 6 days of gestation.

Early pregnancy loss is common, with 80% occurring in the first trimester, and it is seen in 10% of recognized pregnancies.[1] This estimation is likely low because it is difficult to measure those pregnancies lost before clinically confirmed but still recognized by the patient. Embryonic and fetal loss after implantation occur in up to one-third of detectable pregnancies. The risk of miscarriage rises with increasing maternal age (a fivefold increase in those >40 years compared with those 25 to 29 years), increasing paternal age, alcohol use, increased parity, history of prior miscarriage, poorly controlled diabetes mellitus and thyroid disease, obesity, low pre-pregnancy body mass index, maternal stress, smoking, alcohol, and caffeine consumption, and history of vaginal bleeding.

Approximately 25% of pregnant patients experience some bleeding. It is estimated that up to 50% of all women who have bleeding during early pregnancy miscarry before 20 weeks' gestation, although the risk is probably higher in the emergency department (ED) population.[2] Patients who have an intrauterine pregnancy with fetal cardiac activity visualized on ultrasound examination have a much lower risk of miscarriage (3% to 6%), although vaginal bleeding is a high-risk indicator, even when a viable fetus is present.[3] Those with a history of bleeding in singleton pregnancies who do not miscarry may have otherwise normal pregnancies, although they have an increased risk for preterm premature rupture of membranes, abruption, previa, stillbirth, and congenital abnormalities.[2]

Pathophysiology

Most miscarriages are due to uterine malformations or chromosomal abnormalities, which account for the majority that occur within 10 weeks of gestation. In some cases, the ovum never develops (anembryonic gestation). In most early miscarriages, fetal death precedes clinical miscarriage, often by several weeks. Although clinical symptoms of miscarriages are most common between 8 and 12 weeks of gestation, sonographic evidence in most cases demonstrates death before 8 weeks; if fetal viability can be demonstrated by cardiac activity and a normal sonogram, the subsequent risk of fetal loss decreases significantly.

Maternal factors that increase the risk of miscarriage include age greater than 30 years, congenital anatomic defects, uterine scarring, leiomyomas, and cervical incompetence. Other conditions associated with increased miscarriage rates include toxins (e.g., alcohol, tobacco, and cocaine), autoimmune factors, endocrine disorders, a prior history of miscarriage, and maternal infections.

Terminology

Miscarriage is broadly divided into four categories. The first is a *threatened miscarriage*, in which the patient presents with vaginal bleeding but is found to have a closed internal cervical os. The risk of miscarriage in this population is estimated at 35% to 50%, depending on the patient's risk factors and severity of symptoms. The second category is

an *inevitable miscarriage* when the internal os is open. The third is an *incomplete miscarriage*, where the products of conception are present at the cervical os or in the vaginal canal. The last category is a *completed miscarriage*, which occurs when the uterus has expelled all fetal and placental material, the cervix is closed, and the uterus is contracted. A gestational sac should be visualized for diagnosis because the cervix may close after an episode of heavy bleeding and clot passage without or after only partial expulsion of the products of conception. Unless an intact gestational sac is passed and recognized, a completed miscarriage is diagnosed only after dilation and curettage (D&C) with pathologic confirmation of gestational products, demonstration by sonography of an empty uterus with a prior known intrauterine pregnancy (IUP), or reversion to a negative pregnancy test result. This may take up to several weeks after the initial presentation.

Missed abortion is a relatively obsolete term referring to the clinical failure of uterine growth over time. Instead, the terms *anembryonic gestation* (when no fetus is visualized on ultrasound), *first-* or *second-trimester fetal death* (failure to see fetal cardiac activity with at least a 5-mm crown-rump length), and *delayed miscarriage* are more appropriate.

Clinical Features

Patient history should include the estimated length of the gestation, time since the last menstrual period, symptoms of pregnancy, including evolution or loss of pregnancy symptoms, degree and duration of bleeding, presence of cramps, pain, or fever, and attempts by the patient to induce miscarriage. Although the history is important, it is not helpful in the classification of the type of miscarriage. In addition, the severity of symptoms does not correlate well with the risk of miscarriage, although cramping and passage of clots are thought more likely to occur as the miscarriage becomes inevitable.

The assessment of the patient who experiences first-trimester vaginal bleeding includes a careful abdominal examination to evaluate for tenderness or peritoneal irritation from a potential ectopic pregnancy and to determine the size of the uterus, which should not be palpable abdominally. A pelvic examination is performed to evaluate whether the cervix is closed or open, look for clots or the products of conception, determine the degree of vaginal bleeding, and assess uterine size and tenderness.

In the patient with second- and third-trimester bleeding, cervical probing should not be done because the uterus is more vascular, and the organized placenta may overlie the cervical os. Parous women normally have an open or lax external os, which is a finding of no significance. The adnexa may be enlarged, often unilaterally, because the corpus luteum is cystic or because the pregnancy is ectopic. Adnexal or uterine tenderness should always raise the possibility of an ectopic pregnancy. Much less commonly, pelvic inflammatory disease can cause uterine and adnexal tenderness during early pregnancy.

Differential Diagnoses

Ectopic pregnancy can masquerade as a miscarriage in the early stages of pregnancy and should always be considered in the differential diagnosis. Even in the patient with painless vaginal bleeding, the diagnosis of ectopic pregnancy must be considered. Early ultrasonography is indicated to locate the pregnancy in the patient who has bleeding or pain.

A small amount of bleeding occurs at the time of implantation of the blastocyst into the endometrium and, occasionally, at the time of the first missed menses. Molar pregnancy is also characterized by vaginal bleeding, usually during the late first trimester or second trimester. This condition can be identified by ultrasonography. Cervical and vaginal lesions can also cause local bleeding and can usually be seen on vaginal inspection.

TABLE 173.1 Landmarks for Gestational Age and β-hCG Level by Transvaginal Ultrasonography

Finding	Weeks From LMP	β-hCG (mIU/mL)
Gestational sac (25 mm)	5	1000
Discriminatory zone	5–6	1000–2000
Yolk sac	6	2000
Upper discriminatory zone	6–7	3000
Fetal pole	7	5700
Fetal heart motion	6–7	7000

β-hCG, Beta subunit of human chorionic gonadotropin; *LMP*, last menstrual period.

Bedside ultrasonography for obstetric and gynecologic emergencies. *Crit Care Clin*. 2014 Apr;30(2):207-226.

BOX 173.1 Sonographic Criteria for Abnormal Pregnancy With Transvaginal Ultrasonography

- No gestational sac at β-hCG level of 3000 mIU/mL
- No yolk sac with gestational sac of 13 mm (or at 32 days since last menstrual period)
- 5-mm crown-rump length, with no fetal heart tones
- No fetus, with gestational sac of 25 mm mean diameter
- No fetal heart tones after gestational age of 10–12 wk

Diagnostic Testing

A hemoglobin level is useful to provide a baseline measurement and evaluate the degree of blood loss in women whose bleeding persists. In addition, the Rh type should be determined. Ultrasonography is the primary means of evaluating the health of the fetus as well as its location (Table 173.1). Because historical and clinical estimations of gestational age are often inaccurate, ultrasonography is useful to provide an accurate measure of fetal age and viability (Box 173.1).

Serial quantitative hCG levels are used to assess the health of the fetus if sonographic findings are indeterminate or if the gestational age is less than 6 to 7 weeks. The sonographic discriminatory zone is defined as the quantitative hCG level at which a normally developing IUP should reliably be seen. Discriminatory levels are operator- and equipment-dependent and vary by individual patient characteristics, but are usually considered to be 6500 mIU/mL for transabdominal ultrasonography and 1000 to 2000 mIU/mL for transvaginal ultrasonography. Ultrasonography can be performed or repeated when hCG levels rise to 1500 to 3000 mIU/mL. If hCG levels are level or decline, or if sonographic criteria for fetal demise are demonstrated (Box 173.1), the patient should be referred to an obstetrician for follow-up to ensure miscarriage completion and to assess for subsequent complications. Expectant management may be sufficient in the stable patient with threatened miscarriage, as long as ectopic pregnancy has been excluded.

Management and Disposition

Threatened Miscarriage. After assessment of hemodynamic status and management of blood loss, a patient with a threatened miscarriage requires very little specific medical treatment. Though expert opinions vary as to whether anti-D immune globulin should be administered to Rh-negative patients after a threatened or spontaneous miscarriage, we recommend administering anti-D immune globulin in the ED to all pregnant patients with bleeding. If anti-D immune globulin is administered, a 50-µg to 120-µg dose is used during the first trimester and a full 300-µg dose after the first trimester. Once evaluated for ectopic pregnancy, the need for a follow-up routine ultrasonogram should be discussed with the patient; the patient should be made aware that the potential for ectopic pregnancy exists until it is excluded by identification of an IUP. In the patient who is planning pregnancy termination, prompt referral should be encouraged and chorionic villi confirmed at the time of uterine evacuation.
