***Thromboembolism.*.** Most arterial emboli (85%) originate from thrombus formation in the heart. Left ventricular thrombus formation resulting from myocardial infarction accounts for 60% to 70% of arterial emboli. Atrial thrombi associated with mitral stenosis and rheumatic heart disease account for only 5% to 10% of arterial emboli.[1] Coexisting atrial fibrillation is present in 60% to 75% of patients with peripheral arterial embolic events because atrial fibrillation predisposes patients to intracardiac clotting.[2]

Acute arterial emboli often cause distal tissue infarction. Clinical outcomes depend on the amount of collateral circulation, the size of the vessel, and the degree of obstruction. Patients with long-standing atherosclerosis have well-developed collateral circulation, whereas sudden occlusion of a normal artery without collateral pathways results in severe ischemia. After acute obstruction, the embolus can propagate proximally or distally, fragment and embolize further to distal vessels, or precipitate venous thrombosis by initiating a localized inflammatory reaction.

Because vessel diameters change abruptly at branch points, embolic occlusion most often occurs at major arterial bifurcations. The common femoral artery bifurcation is the most frequent site, accounting for 35% to 50% of all cases.[1] The smaller femoral and popliteal arteries are involved twice as often as the larger aortic and iliac vessels, reflecting the small size of most emboli.

Arterial emboli, causing arterial occlusion and subsequent ischemia, result in cell death and produce elevated concentrations of potassium, lactic acid, and myoglobin in the extremity distal to the occlusion. Revascularization may result in sudden release, which can produce life-threatening hyperkalemia, metabolic acidosis, and myoglobinuria. This myonephropathic-metabolic syndrome accounts for approximately one-third of the deaths from an arterial embolism after revascularization.[3]

***Atheroembolism.*.** *Atheroembolism* refers to microemboli consisting of cholesterol, calcium, and platelet aggregates dislodged from proximal complicated atherosclerotic plaques that lodge in distal end arteries. In the central nervous system, atheroemboli cause transient ischemic attacks and strokes. In the peripheral vascular system, atheroemboli characteristically cause cool, painful, and cyanotic toes, or the blue toe syndrome.[4]

Atheroemboli are caused by proximally located arterial lesions, usually atherosclerotic plaques or aneurysms. Bilateral distal extremity involvement implies an aortic source, whereas unilateral atheroemboli usually arise from sites distal to the aorta. Distal lesions are most common in the femoropopliteal arteries (60%) and the aortoiliac arteries (40%). Aortic lesions (e.g., aneurysms, polytetrafluoroethylene grafts) are a less common source of microemboli.[4]

Atheroemboli are small (100 to 200 μm in size). Single atheroembolic events seldom result in tissue loss, but atheroemboli tend to cluster. If unrecognized, repeated events ultimately result in the loss of collateral circulation, progressive symptoms, and extensive tissue infarction.[4]

Infectious emboli from bacterial endocarditis can produce septic infarcts that may convert to large abscesses. Rarely, cardiac and noncardiac tumors or foreign bodies may gain access to the arterial circulation and embolize. Primary or metastatic lung neoplasms, malignant melanoma, and bullet emboli have been reported. With cyanotic congenital heart disease (e.g., patent foramen ovale), venous emboli may pass directly to the arterial circulation (paradoxical emboli). Although rare, this possibility should be considered in any patient with simultaneous arterial and venous emboli, particularly if a source of the arterial embolus is not evident.

Arterial Thrombosis

Thrombosis is the in situ formation of a blood clot within the uninterrupted arterial vascular system. Complicated atherosclerotic plaques are usually responsible for the two major factors that cause in situ thrombosis: endothelial injury and alterations in normal blood flow. Less common causes include acute vasculitis and trauma. Thrombosis is rare in normal arteries.[5] Peripheral arterial thrombi are usually occlusive, firmly attached to the damaged arterial wall, and infrequently embolize. Clot propagation intensifies ischemia.

Aneurysms

A true aneurysm is an abnormal localized dilation of the intact vessel wall. With a pseudoaneurysm, the entire wall perforates or ruptures, and the extravasated blood is contained by the surrounding tissues, eventually forming a fibrous sac that communicates with the artery.

Mural and mechanical factors contribute to true aneurysm formation.[6] The major cause of aneurysms is a weakness or defect in the integrity of the arterial wall. The only aneurysms that develop in a normal arterial segment are poststenotic aneurysms, such as with coarctation. Acceleration of flow past a narrow point creates slower flow beyond the stenosis lateral to the jet stream, producing increased lateral pressure. Aneurysmal dilation accelerates, increasing the risk of rupture as diameter increases, as described by Laplace's law: tension (lateral pressure) in the wall of a hollow viscus varies directly with its radius (tension = pressure × radius).

The most common cause of aneurysms is severe atherosclerosis resulting from thinning and destruction of the tunica media. Atheromatous ulcers covered by mural thrombi are common. Mural thrombi form emboli that then lodge in distal vessels. When an entire aneurysm is filled with thrombus material, arterial occlusion results.

Aneurysms cause clinical symptoms through (1) rupture with subsequent hemorrhage, (2) impingement on adjacent structures, (3) occlusion of a vessel by either direct pressure or mural thrombus formation, (4) embolism from mural thrombus, and (5) a pulsatile mass.

Inflammation

Inflammatory arterial injury can be caused by drugs, irradiation, mechanical trauma, or bacterial invasion. The primary cause of arteritis is noninfectious systemic necrotizing vasculitis. Infectious arteritis is caused by direct invasion of the arterial wall. Septicemia, intravenous drug abuse, or infective endocarditis is most often responsible. Certain

fungal infections, particularly aspergillosis and mucormycosis, are frequently associated with vasculitis and thrombosis.

Trauma

Vascular trauma results in characteristic pathologic syndromes. Partial arterial lacerations continue to bleed because the intact portion of the vessel wall prevents retraction and closure of the arterial wound. This may form an expanding hematoma. Complete arterial transection usually has only moderate or insignificant bleeding because of arterial spasm of the transected ends and the formation of a temporary thrombus. Delayed hemorrhage results from relaxation of arterial spasm, liquefaction of the thrombus, or displacement of the thrombus by arterial pressure.

Blunt injury produces intimal disruption. Dissection then leads to progressive obstruction and thrombosis. Vasospasm can accompany injuries adjacent to traumatized blood vessels; spontaneous resolution always occurs in the absence of arterial disruption or intimal injury.

Vasospasm

Vasospastic disorders (Raynaud disease, Raynaud phenomenon, livedo reticularis, acrocyanosis, erythromelalgia) produce an abnormal vasomotor response in distal small arteries. The cause is unknown but may be related to the autonomic innervation of peripheral arterioles. Vasospastic disorders are characterized by the presence of ischemic symptoms and the absence of tissue loss. The arterial wall does not demonstrate any pathology. In contrast, patients with digital ulceration and gangrene always have fixed arterial occlusions in distal extremity arteries.

Arteriovenous Fistulae

Abnormal communication between arteries and veins may result from congenital defects, arterial aneurysm rupture into an adjacent vein, penetrating injuries, and inflammatory necrosis. The artery proximal and veins distal to the fistula become distended, tortuous, and aneurysmal. Proximal and distal veins respond to alterations in hemodynamics with intimal proliferation and fibrosis, followed by a decrease in the internal elastic lamina, resulting in distention, tortuosity, and aneurysm formation. Chronic venous hypertension causes dermatitis and ulceration of overlying skin. The size of the fistula generally increases with time.

Approximately 60% of arteriovenous fistulae are associated with a false aneurysm.[7] False aneurysm formation can occur as part of the fistulous tract or arterial or venous dilation.[7] Increase in cardiac output results in tachycardia, widened pulse pressure, or high-output failure.

CLINICAL FEATURES

History

Patients with peripheral arterial disease have pain and are at risk for tissue loss (ulceration or gangrene) or a change in sensation or appearance (swelling, discoloration, or temperature change). Related conditions suggest atherosclerosis, including cardiac disease, myocardial infarction, cardiac dysrhythmias (e.g., atrial fibrillation), stroke, transient ischemic attacks, and renal disease. Factors that increase the likelihood of atherosclerosis are cigarette smoking, diabetes, hypercholesterolemia, and hypertension. Intravenous drug use can lead to arterial injury. Risk factors unrelated to atherosclerosis include prior injuries or surgeries, a history of phlebitis or pulmonary embolism, autoimmune disease, arthritis, or coagulation abnormalities.

Physical Examination

A systematic assessment of the peripheral vascular system includes palpation of the pulse volume in the pairs of brachial, radial, femoral, posterior tibial, and dorsalis pedis arteries documented on a scale of 0 to 4+. It is important to note that approximately 10% of the population does not have one of the dorsalis pedis pulses.[8]

The lower extremities should be examined for signs of chronic and advanced ischemia. Muscular atrophy, particularly in the lower extremities, and loss of hair over the toes and feet with thickening of the toenails resulting from the slowness of nail growth are common signs of arterial insufficiency. As ischemia becomes more advanced, the skin becomes shiny, scaly, and "skeletonized" from atrophy of the skin, subcutaneous tissue, and muscle.

Test areas where ischemia is suspected by blanching with finger pressure; a delay in the return of normal color (compared with the unaffected extremity) implies reduced perfusion. Buerger sign provides reliable evidence of severe advanced ischemia. With the patient supine, the legs are elevated to 45 degrees to bring the feet more than 12 inches above the right atrium, and any pallor of the feet is noted. If the color does not change, the patient dorsiflexes the feet five or six times; pallor induced by exercise may also connote inadequate arterial flow. The patient is then moved to the sitting position with the feet hanging down. Within 10 to 15 seconds, color should return, and the veins should fill. Typically in the ischemic foot, the first return of color is cyanosis, transitioning to bright red as reactive hyperemia occurs. If the veins require more than 20 seconds to become distended, advanced ischemia is present. With severely restricted arterial inflow and chronic dilation of the peripheral vascular bed, the foot turns pale on elevation and intensely hyperemic after 1 minute of dependency. Localized pallor or cyanosis associated with poor capillary filling is usually a prelude to ischemic gangrene or ulceration.

Doppler ultrasonography should be used in patients with questionable or absent pulses. The ankle-brachial index (ABI) is made by comparing the systolic blood pressure at the level of the ankle with the brachial systolic pressure. Ankle systolic pressure can be accurately measured with a Doppler probe placed over the dorsalis pedis or posterior tibial artery. This pressure is normally 90% or more of the brachial systolic pressure; with mild arterial insufficiency, it is between 70% and 90%; with moderate insufficiency, between 50% and 70%; and with severe insufficiency, less than 50%.

The Allen test is helpful in assessing the patency of the radial or ulnar artery distal to the wrist. The patient initially opens and closes the hand and then clenches the fist to expel as much blood from the hand as possible; the examiner then compresses the radial and ulnar arteries. When the patient opens the fist, the hand is pale. The examiner then releases pressure from the radial artery but maintains it on the ulnar artery. If the radial artery is patent, the hand becomes pink rapidly; occluded, the hand remains pale. The maneuver is repeated maintaining pressure on the radial artery, releasing the ulnar artery. A comparison can be made with the opposite hand.

Inflammation

Inflammatory vascular disease manifests primarily as skin involvement. Skin lesions typically appear as palpable purpura; other cutaneous manifestations of vasculitis include macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. Skin lesions may be pruritic or painful, with a burning or stinging sensation. Lesions are common in dependent areas: lower extremities in ambulatory patients or sacral areas in bedridden patients. Edema and hyperpigmentation occur in areas of recurrent or chronic lesions.

Vasospasm

Vasospastic disorders cause a sharp border between ischemic and normal tissue. Raynaud disease is characterized by intermittent attacks of triphasic color changes: pallor, cyanosis, and then rubor.[9] The most

important element is pallor, and during which, the digits turn pale. Attacks last 15 to 60 minutes, and rewarming the hands restores normal color and sensation. Color changes do not occur above the metacarpophalangeal joints and rarely involve the thumb.

Livedo reticularis causes persistent cyanotic mottling of the skin with a typical "fishnet" appearance and may involve all parts of the extremities and trunk. Acrocyanosis, the least common vasospastic disorder, causes persistent, painless, diffuse cyanosis of the fingers, hands, toes, and feet. Cyanosis intensifies with exposure to cold and decreases with warming. The involved parts are cold, exhibit excessive perspiration, and have normal arterial pulses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis related to peripheral arteriovascular diseases is extensive, requiring consideration of dermatologic, neurologic, neurosurgical, orthopedic, cardiac, malignant, diabetic, infectious, and other unrelated diagnoses. The differential diagnosis for specific arteriovascular diseases is reviewed in detail in the following sections.

DIAGNOSTIC TESTING

An accurate diagnosis of peripheral arterial occlusive disease can be achieved in most patients by careful history and physical examination supplemented by bedside and radiographic testing.

Noninvasive Assessment

Doppler ultrasonography measures blood flow velocity, detecting the frequency shift of sound waves reflected from red blood cells moving toward and away from the transducer. Doppler waveform analysis detects occlusive disease but is less accurate in determining the exact location.

Ultrasound is useful in detecting and evaluating atherosclerotic plaques, mural thrombi, and in sizing aneurysms of the abdominal aorta, iliac, femoral, and popliteal arteries.[10] B-mode ultrasonography is noninvasive, painless, less expensive than other modalities, and universally available. It is the diagnostic procedure of choice for the initial evaluation of the size of peripheral artery aneurysms. Bedside ultrasound can lead to rapid diagnosis of life-threatening conditions and reduce the number of delayed or invasive diagnostic procedures.[11] B-mode duplex ultrasonography combines B-mode ultrasonography images and sophisticated online computer analysis of Doppler waveforms to allow simultaneous acquisition of both the image of a vascular structure and the characteristics of blood flow velocity within it. Duplex scanning permits noninvasive diagnosis of peripheral vascular, cerebrovascular, and venous disease.

Color imaging of blood flow combined with duplex scanning is known as *color-coded Doppler, Doppler angiography*, or *angiodynography.* The procedure of choice for most conditions, it allows noninvasive and accurate detection of atherosclerotic plaques and stenoses, their effect on intraluminal blood flow, and the presence of venous thrombosis.

Contrast Arteriography

Angiography is the definitive test of abnormal peripheral artery anatomy. The risk/benefit ratio of this procedure should be considered. Contrast media have direct toxic effects on vascular endothelium and can cause severe idiosyncratic and allergic reactions. The risk of acute kidney injury with contrast media is debated, but it may worsen renal function in patients with a preexisting decrement in the glomerular filtration rate. Catheter-related complications, including embolization, catheter breakage, and vascular disruption, vary with operator skill and anatomic location but average 0.5%. Overall mortality rate from angiography is 0.03%.[12] Emergency angiography may be necessary in the following circumstances: (1) acute arterial embolus or thrombosis if the clinical diagnosis is uncertain, (2) consideration of emergency vascular bypass grafting, and (3) characterization of vascular abnormality before emergency surgical correction. Otherwise, traditional angiography has largely been replaced by computed tomography angiography.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography angiography (CTA) is the most useful test for evaluating the abdominal aorta.[13] In the peripheral arteriovascular system, CTA has replaced invasive arteriography as the diagnostic procedure of choice for assessing peripheral arterial occlusive disease and is also useful for atherosclerotic, infected, and false aneurysms and the cerebral circulation. Magnetic resonance imaging (MRI) with angiography (magnetic resonance angiography) and has been beneficial in delineating cerebrovascular problems (see Chapter 101); use has expanded in the evaluation of peripheral vascular disease. MRI detects changes in tissues' relaxation variables before obvious structural changes, uniquely differentiating blood, thrombus, fat, and fibrosis.

MANAGEMENT

Noninvasive Therapy

Acute Anticoagulation with Heparin

For acute arterial embolism, acute arterial thrombosis, and subclavian vein thrombosis, heparin is indicated at standard intravenous doses (80 units/kg bolus, followed by a maintenance infusion of 18 units/kg/hr). Heparin minimizes clot propagation, which can intensify limb ischemia and jeopardize tissues. Relative contraindications include recent neurosurgery (especially within 2 weeks), major surgery within 48 hours, childbirth within 24 hours, a known bleeding diathesis, thrombocytopenia, a potentially hemorrhagic lesion, and active bleeding.

Fibrinolytic Therapy

Low-dose intra-arterial fibrinolytic therapy is increasingly used for acute arterial occlusion. Patients with limb-threatening ischemia are usually not candidates because they cannot tolerate the time to achieve clot lysis with this approach (6 to 72 hours) without risk of tissue or limb loss. Fibrinolytic therapy is reserved for patients with in situ thrombosis and non-limb-threatening ischemia.

Intra-arterial fibrinolytic agents induce clot lysis in small, distal runoff vessels, decreasing outflow resistance and enabling the native artery to remain open longer. Fibrinolysis often uncovers a critical stenosis that, untreated, may lead to recurrent thrombosis. After successful fibrinolytic therapy, most patients require secondary bypass grafting or angioplasty. Streptokinase, urokinase, and tissue plasminogen activator have all been used successfully. Intravenous administration of a fibrinolytic agent is less effective than direct administration into the clot. Clots more than 30 days old are less likely to achieve successful lysis.

Invasive Therapy

Fogarty Catheter Thrombectomy

Patients with limb-threatening ischemia from embolism should undergo emergency Fogarty catheter embolectomy.[14] Patients with limb-threatening ischemia from in situ thrombosis require direct or Fogarty catheter thrombectomy and vascular bypass grafting.

Thrombectomy alone often fails because of recurrent thrombosis. Patients who cannot be bypassed, have irreversible ischemia, or are too ill to tolerate revascularization are treated with primary amputation. The Fogarty catheter is most frequently used for iliac, femoral, and popliteal embolectomy, often with only local anesthesia. Aortic saddle embolus is removed by sequentially passing the Fogarty catheter through bilateral common femoral arteriotomies. Newly formed in situ thrombosis may often be successfully removed with the Fogarty catheter. An older thrombus adheres more firmly to the damaged vessel wall, requiring direct surgical thrombectomy. The Fogarty catheter is not used in the venous system because of valves.

A patient with non-limb-threatening embolism is also treated with Fogarty catheter embolectomy. Non-limb-threatening in situ thrombosis is often aggravated by emergency surgical intervention and is best managed nonoperatively with emergent systemic anticoagulation and consideration of intra-arterial fibrinolytic therapy (Fig. 73.1).

Peripheral Percutaneous Transluminal Angioplasty

The initial success and long-term patency achieved with angioplasty depend on the location of the lesion and the extent of atheromatous disease. Proximal larger arteries (e.g., iliac, femoropopliteal) have the best initial and long-term results. Discrete stenotic lesions (<5 cm) have better long-term patency rates than vessels with diffuse involvement. Balloon angioplasty is the accepted treatment for isolated stenoses in the renal, iliac, and superficial femoral vessels.

Transluminal angioplasty with intravascular stent placement is used in more distal vessels, including the popliteal and tibial circulation, in cases of more diffuse lesions, and for patients who are prohibitive surgical risks, although its value continues to be assessed.[15] Recanalization devices include the percutaneous atherectomy catheter, percutaneous angioscope, hot-tip laser, excimer laser, and high-speed rotating wire and drill.

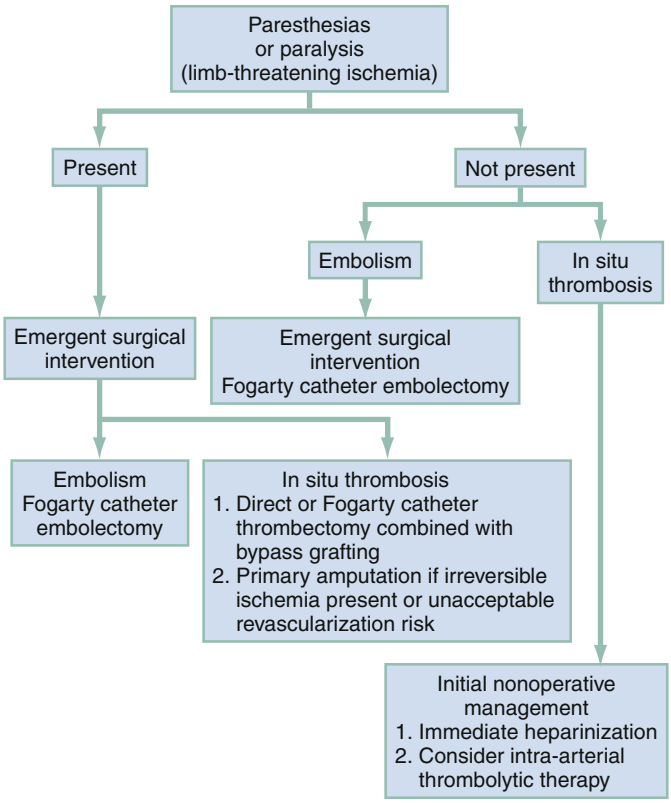

Fig. 73.1 Clinical presentation and management of acute arterial occlusion.

Grafting

Vascular grafting is associated with a variety of complications that can be diagnosed in the ED. Autogenous vein grafts (usually a reversed greater saphenous vein) provide excellent long-term patency for small arteries. They may develop atherosclerosis, which can lead to graft stenosis and thrombosis. False aneurysms can form along the suture line.

Polytetrafluoroethylene (Teflon) prosthetic grafts are used in medium and large arteries impossible to bridge with smaller vein grafts. Prosthetic grafts have higher rates of thrombosis than venous grafts. Distal emboli result from the poor fixation of luminal fibrin. Prosthetic grafts not adequately covered by viable tissue can erode into adjacent structures and hollow viscera. Prosthetic graft infection, a devastating complication, necessitates the removal of the entire graft.

Vascular grafts can be used to bypass arterial occlusions or reconstruct a diseased arterial bifurcation. They may also be interposed between sections of resected artery. The most common complications of both prosthetic and vein grafts are thrombosis or the development of a false aneurysm at one or more suture lines. Bypass grafting is most often used as palliative treatment for symptoms of atherosclerotic occlusive disease. Patients with localized unilateral stenosis may have comparable rates of success from angioplasty with or without stent placement.[16]

Patients with calf claudication from superficial femoral or popliteal occlusive disease can slow progression if they stop smoking and maintain an active exercise regimen. Patients who have progression of disease, significant rest pain, or tissue loss require surgical revascularization.

Hyperbaric Therapy

Scant objective evidence indicates that hyperbaric therapy alters the long-term course of chronic obliterative vascular disorders, presumably by accelerating the formation of fine vessels. More success has been achieved with healing chronic diabetic ischemic ulcers and salvaging ischemic skin grafts and flaps.[17] Referral to a hyperbaric unit for chronic therapy should be made by the patient's primary physician or vascular surgeon and not in the ED.

Disposition

Disposition of most patients with a suspected or confirmed peripheral arteriovascular diagnosis should be made in consultation with a vascular surgeon.

SPECIFIC ARTERIOVASCULAR DISEASES

Diseases of Chronic Arterial Insufficiency

Arteriosclerosis Obliterans

Arteriosclerosis obliterans (atherosclerotic occlusive disease, chronic occlusive arterial disease, obliterative arteriosclerosis) is the peripheral arterial presentation of atherosclerosis. Most often, arteriosclerosis obliterans affects the lower abdominal aorta, the iliac arteries, and the arteries supplying the lower extremities. Upper extremity manifestations are rare.

Arteriosclerosis obliterans is responsible for 95% of cases of chronic occlusive arterial disease. It is most common in persons older than 50 years, but as many as 19% of cases occur in patients 30 to 49 years old. Men are affected more often than women (5:1 to 10:1). Approximately one-third of patients with arteriosclerosis obliterans have coexistent coronary artery disease. The incidence of diabetes mellitus is 20% to 30%.[18]

Risk factors for arteriosclerosis obliterans include cigarette smoking, hyperlipidemia, and hypertension. Of patients with arteriosclerosis obliterans, 70% to 90% are smokers when first examined, 75% have hyperlipidemia, and 30% have hypertension.[18]

Clinical Features

History.. Acute arterial occlusion from embolism, thrombosis, or trauma is ruled out primarily by history. Chronic arterial insufficiency causes two characteristic types of pain: intermittent claudication and ischemic pain at rest. The location of arterial occlusion determines the location of claudication. Femoral and popliteal disease result in calf claudication, typically a cramping pain, reliably reproduced by the same degree of exercise and completely relieved by rest (usually 1 to 5 minutes). Aortoiliac occlusive disease causes claudication in the buttocks and hips, as well as the calves. The calf pain in aortoiliac disease is generally more severe than the buttock and thigh pain, which is more often described as an aching, discomfort, or weakness. Some patients do not have pain, noting only that the thigh or hip "gives out" with exercise. Bilateral hip or thigh pain indicate the possibility of aortoiliac occlusive disease. Aortoiliac occlusive disease severe enough to produce bilateral claudication is almost always associated with impotence in men (Leriche syndrome).

Chronic arterial insufficiency may progress to ischemic pain occurring at rest. Rest pain often begins in the feet and typically involves the foot distal to the metatarsals, awakening the patient from sleep. Ischemic rest pain is a severe, unrelenting pain aggravated by elevation and unrelieved by analgesics. Patients have prompt relief with any activity involving a standing position. Patients may sleep in a chair or with the leg dangling over the bed.

Physical Exam.. Atheromatous emboli from proximal ulcerated plaques or aneurysms cause small scattered ischemic lesions in the toes, feet, or legs, causing blue toe syndrome (Fig. 73.2). Peripheral pulses are present.

Fig. 73.2 Clinical presentation of atheromatous emboli, or blue toe syndrome. (Courtesy Gary R. Seabrook, MD.)

Approximately 5% of lower extremity ulcerations are caused by arterial insufficiency.[19] These are usually located distal to the ankle, typically at the terminal portion of the digits, around the nail beds, or between the toes, caused by friction of one toe on another. Less common locations include the metatarsal heads, heel, and malleoli. Arterial insufficiency ulcers are painful, but pain improves when the extremity is in a dependent position. They are associated with evidence of coexistent chronic arterial insufficiency (absence of hair growth on the dorsum of the feet, skin atrophy, absent pulses, and nail deformities). Ulcers are initially small, shallow, and dry. The base is gray, yellow, or black, with minimal or no granulation tissue. The rim of the ulcer is sharp and indolent, showing no signs of cellular proliferation or epithelialization.

Differential Diagnosis.. Exercise-induced claudication should be distinguished from nocturnal muscle cramps frequently seen in older patients. Aortoiliac occlusive disease can be differentiated from osteoarthritis of the hip, which tends to be more variable from day to day, is not relieved completely with rest, and is not reliably reproduced by the same amount of exercise. Pseudoclaudication from cauda equina syndrome is caused by narrowing of the lumbar canal from spondylosis, intervertebral disk disease, or spinal cord tumor. The symptoms mimic intermittent claudication but are less closely related to exercise and rest than true claudication.

The cause of lower extremity ulcers should be carefully determined. About 90% of lower extremity ulcers are caused by chronic venous insufficiency.[19] These occur proximal to or in the region of the ankle, especially near the medial malleolus. Venous stasis ulcers are mildly painful and improve with elevation of the extremity. Evidence of long-standing chronic venous insufficiency, including edema, prominent superficial veins, and stasis dermatitis, is present. Ulcers are moderate in size, with a weeping base and extensive granulation tissue. Rapidly developing ulcers are more suggestive of venous insufficiency.

Most of the remaining lower extremity ulcers are caused by diabetic neuropathy, alone or with arterial insufficiency.[19] The location reflects sites of repeated trauma, including the toes, heels, and plantar surface of the feet, especially the metatarsal heads. Neurotrophic ulcers are painless. Patients may have evidence of coexistent peripheral arterial insufficiency. The ulcers are deep and penetrating, often with suppurative drainage caused by an underlying infection or chronic osteomyelitis. Neurotrophic ulcers are usually surrounded by a rim of thick callus.

Hypertensive ulcers are rare and reflect long-standing, uncontrolled hypertension. These ulcers are typically near the lateral malleolus and start as painful, reddish-blue areas of infarcted skin. A hemorrhagic bleb develops and then breaks down into a superficial ulcer, which can reach a size of 5 to 10 cm. The ischemic ulcer has sharply demarcated borders, little granulation tissue, and minimal drainage. The pain is the most severe of all lower extremity ulcers.

Multiple ischemic ulcerations above and below the ankle suggest vasculitis or atheromatous embolization. Ulcers with regular edges in unusual locations may be factitial or may result from subcutaneous injection of illicit drugs. Thickened, rolled, and elevated edges with a central depression containing granulation tissue are characteristic of malignant ulcers.

Management.. The first step is to identify patients whose symptoms are the sole result of arteriosclerosis obliterans without coexistent thromboembolic disease. Treatment for symptomatic patients depends on whether patients have functional ischemia or limb-threatening ischemia.[20] Limb-threatening ischemia constitutes a surgical emergency. Computed tomography (CT) angiography should be arranged to identify sufficiently localized disease to permit emergency bypass grafting.[20] Patients with functional ischemia should have outpatient

arrangements for elective invasive or noninvasive vascular testing to determine treatment options.

Ischemic ulcers or skin lesions should be cultured in the emergency department (ED) and systemic antibiotics initiated to cover skin organisms if infection is present. Radiographs of underlying bones should be acquired when osteomyelitis is suspected. Patients with ischemic rest pain require hospitalization even if they are not surgical candidates. Bed rest, a warm environment, and maintenance of the limb in a dependent position usually relieve pain.

Buerger Disease (Thromboangiitis Obliterans)

Principles. First described by Buerger in 1908, thromboangiitis obliterans is an idiopathic inflammatory occlusive disease primarily involving the medium-sized and small arteries of the hands and feet.[21] Patients are usually men aged 20 to 40 years old who use tobacco, although recent reports indicate an increasing frequency of this disease in women. In the United States, the incidence is 20 per 100,000.[22] The exact pathogenesis is unknown, but virtually all patients are smokers.

Thromboangiitis obliterans is characterized by segmental acute and chronic inflammation in the smaller arteries of both upper and lower extremities. The initial arterial inflammatory process progresses to affect the adjacent veins and nerves, often leading to associated venous thrombosis and progressive fibrous encasement of these structures. These are painful, tender, or dark nodules over a peripheral artery with either a reduced or an absent pulse (phlebitis migrans).

Clinical Features. Clinical criteria for Buerger disease include (1) a history of smoking, (2) onset before the age of 50, (3) infrapopliteal arterial occlusive lesions, (4) either upper limb involvement or phlebitis migrans, and (5) absence of atherosclerotic risk factors other than smoking. A characteristic symptom of Buerger disease is foot or instep claudication caused by infrapopliteal arterial occlusion. Intense rubor of the affected extremity, particularly with dependency, is also characteristic. Foot pulses may be absent in the presence of normal femoral and popliteal pulses. Involvement of the hands is often bilateral and symmetrical, leading to the development of hand claudication or fingertip ulcers. Phlebitis migrans occurs early in the disease. Approximately 50% of patients experience Raynaud-type triphasic color response to cold. In the upper extremities, the digital arteries are usually more involved than the radial or ulnar arteries.[22]

Differential Diagnosis. Arteriosclerosis obliterans is most likely in patients older than 50 years old who have signs of peripheral ischemia. In young women, autoimmune diseases, such as scleroderma or systemic lupus erythematosus, should be considered.[22]

Diagnostic Testing. Adherence to diagnostic clinical criteria should suffice for ED diagnosis of Buerger disease. Noninvasive vascular laboratory testing confirms the diagnosis and extent of involvement. Rarely required, CTA demonstrates multiple segmental occlusions.

Management. Permanent complete abstinence from tobacco is the only effective treatment for Buerger disease. If a patient does not completely stop smoking, alternating periods of quiescence are followed by exacerbations of severe arterial insufficiency. Patients who quit smoking have a benign clinical course. Despite this, many individuals who have Buerger disease continue to smoke, incurring severe pain at rest, tissue loss, and eventually amputation.

With early symptoms without the threat of tissue loss, patient education and follow-up with a vascular surgeon are appropriate. Vascular surgery treatment options are varied for patients with severe symptoms or threatened tissue loss. Intractable pain can be controlled with epidural anesthesia. Intra-arterial or intravenous prostaglandin E_1 and antithrombotic agents, including aspirin and heparin, have been used successfully.[22] Patients with large-vessel arterial occlusion may benefit from arterial reconstruction. Sympathectomy is a potential treatment in advanced cases for cutaneous ulceration or relief of rest pain.[23] Because patients with Buerger disease have good healing, intensive conservative treatment is usually successful in avoiding amputation.

Diseases of Acute Arterial Occlusion

Arterial Embolism

Despite advances, acute arterial embolus continues to cause substantial morbidity and mortality. Approximately 50% of acute arterial occlusions are caused by arterial embolism, and the incidence is increasing. The other 50% are caused by in situ thrombosis.[1]

Clinical Features

History. Patients with acute arterial occlusion usually exhibit some variant of the five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Paresthesias and paralysis indicate limb-threatening ischemia requiring emergency surgical intervention regardless of the cause. A history of claudication is common with in situ thrombosis and rare with arterial embolism. Because acute arterial embolism usually occurs in patients without significant peripheral atherosclerosis or well-developed collateral circulation, it usually manifests as sudden limb-threatening ischemia. Patients describe a sensation of the leg's being "struck" by a severe shocking pain. Often, the patient has to sit or fall to the ground during the sudden event.

Physical Examination. The physical examination can help differentiate arterial embolism from in situ thrombosis. Sudden loss of a pulse is the hallmark of arterial embolism but may be difficult to recognize if prior pulse status is unknown or is abnormal because of atherosclerosis. A bounding pulse may be felt initially at the location of an embolus from transmitted pulsations through the fresh clot. Patients with arterial embolism have few physical findings suggestive of long-standing peripheral vascular disease. Tenderness to palpation may occur at the site of an embolic occlusion.

If arterial embolism is suspected, the physical examination should be directed toward identifying its source (a left ventricular mural thrombus [prior myocardial infarction] or a left atrial thrombus [mitral valve disease]). Coexistent atrial fibrillation is common. The limb distal to an embolic occlusion is initially pale. Because of the absence of blood in the sub-capillary venules, demarcation between ischemic and nonischemic tissue is sharp. With time, cyanosis appears from desaturation of blood with continued ongoing ischemia. Paresthesia or paralysis indicates limb-threatening ischemia. The presence of sensitivity to light touch is the best guide to the viability of the tissue. Complete anesthesia demands emergency surgical intervention. Paralysis represents severe muscle and neural ischemia, which may be irreversible. Involuntary muscle contracture with "woody" hardness represents irreversible ischemia.

Differential Diagnosis. Phlegmasia cerulea dolens is a massive iliofemoral deep venous thrombosis. The initial symptom is the acute onset of a swollen and painful leg. As swelling continues, secondary arterial insufficiency with associated pallor (phlegmasia cerulea albens) occurs. Early in acute arterial embolism, leg swelling is usually absent. Acute embolism produces a sharply demarcated pallor; phlegmasia cerulea dolens causes a cyanotic-appearing leg.

Aortic dissection may involve the arteries of the upper or lower extremity and may mimic acute embolus. Severe pain, the presence of aortic insufficiency, and involvement at multiple sites suggest dissection. Neurologic syndromes (e.g., transverse myelitis, spinal subarachnoid hemorrhage, ruptured intervertebral disk) may produce sudden onset of unilateral or bilateral lower extremity weakness or sensory loss that mimics an acute aortic saddle occlusion. Cold, blue extremities may result from low-output states, such as hypovolemia, decreased

cardiac output, and dehydration in patients with long-standing atherosclerotic disease.

Management. Acute arterial embolism is a surgical emergency. The likelihood of limb salvage decreases after 4 to 6 hours. On the basis of clinical diagnosis alone, full doses of intravenous heparin (80 units/kg bolus, followed by a maintenance infusion of 18 units/kg/hr) should be administered promptly to minimize clot propagation. Patients whose clinical findings clearly indicate an acute arterial embolism should undergo urgent Fogarty catheter embolectomy without prior angiography. In these patients, preoperative ultrasonography and angiography are rarely useful diagnostically and prolong the limb's ischemic time.

If the differentiation of acute embolism and in situ thrombosis is uncertain, CT angiography is usually diagnostic. Patients with acute emboli generally show minimal signs of atherosclerosis, occlusion at the site of an arterial bifurcation, sharply demarcated cutoffs, and lack of flow distal to the occlusion. In patients with in situ thrombosis, arteriography shows diffuse atherosclerosis, occlusion at sites other than arterial bifurcations, a tapered irregular cutoff, and well-developed collateral vessels (Table 73.1).

Intra-arterial thrombolytic therapy for acute embolism remains investigational. Present limb-threatening ischemia precludes consideration of treatment with thrombolytic therapy in most patients. Potential risks of thrombolytic therapy in arterial embolism patients with non-limb-threatening ischemia include partial clot lysis with distal embolization or recurrent embolic events from the primary source of the initial embolus.[24]

Atheroembolism (Blue Toe Syndrome)

Atheroemboli are microemboli consisting of cholesterol, calcium, and hemorrhagic debris that break off from proximal atherosclerotic plaques or aneurysms and lodge in distal end arteries. In the central nervous system, atheroembolism causes transient ischemic attacks and strokes. In the peripheral vascular system, atheroemboli are found in the lower extremities with cool, painful cyanotic toes in the presence of palpable distal pulses (Fig. 73.2).

Clinical Features. The typical presentation of atheroembolism is the sudden onset of a small, cyanotic, and tender area on the foot, typically the toe.[25] If bilateral, the distribution is not symmetrical. Posterior tibial and dorsalis pedis pulses are present. Physical examination should focus on a proximal source, such as an atherosclerotic aneurysm in the aorta or iliac, femoral, or popliteal artery.

TABLE 73.1 Differentiation of Embolus From Thrombosis

Clinical Findings	Embolus	Thrombosis
Identifiable source for embolus	Usual, particularly atrial fibrillation	Less common
History of claudication	Rare	Common
Physical findings suggestive of occlusive disease	Few; proximal and contralateral limb pulses normal	Often present; proximal or contralateral limb pulses diminished or absent
Demarcation of ischemia	Sharp	Diffuse
Arteriography	Minimal atherosclerosis; sharp cutoff; few collaterals	Diffuse atherosclerosis; tapered, irregular cutoff; well-developed collaterals

From Brewster DC, Chin AK, Fogarty TJ: Vascular surgery. Philadelphia, 1990, WB Saunders.

Differential Diagnosis. A variety of conditions can mimic blue toe syndrome. Acrocyanosis is painless, has a symmetrical distribution, and is located in the hands, nose, and lips. Poor peripheral perfusion from low cardiac output should be considered. Vasculitis typically causes palpable purpuric lesions and constitutional symptoms of low-grade fever and weight loss. Previous frostbite may leave the extremities sensitive to cold. Local injury to the diabetic foot is easily differentiated.

Management. Treatment is directed toward identifying and removing the proximal source of atheroembolism. CT angiography is the diagnostic procedure of choice for determining the source of emboli. If the source is an aortic aneurysm, vascular surgery should be consulted for consideration of an operative repair. Stenotic lesions in the iliac or femoral arteries can be treated with local endarterectomy, vascular bypass, or angioplasty.[15] Medical management with aspirin, dipyridamole, warfarin sodium (Coumadin), or steroids have variable results and are not routinely recommended.

Arterial Thrombosis

Approximately 50% of acute arterial occlusions are caused by in situ thrombosis.[1] Acute arterial thrombosis is almost always superimposed on a complicated atherosclerotic lesion but can be caused by vasculitis or trauma. With limb-threatening ischemia, CT angiography can be used to evaluate the feasibility of emergency bypass grafting. In non–limb-threatening ischemia, angiography may be required to distinguish acute embolism from thrombosis (see Table 73.1).

Physical Exam

Physical findings of in situ thrombosis are often accompanied by evidence of atherosclerotic occlusive disease. Proximal or contralateral limb pulses are usually diminished or absent. An embolic source, such as atrial fibrillation, is usually absent. Because of collateral circulation, demarcation of limb ischemia is less well defined in these patients (see Table 73.1).

Carotid, renal, and femoral arteries may have bruits, and there may be an abdominal aortic aneurysm. If occlusion of the upper extremity vessels is suggested, the subclavian artery should be palpitated for thrills and auscultated for bruits in the supraclavicular fossa.

A funduscopic examination may yield evidence of arteriosclerosis or hypertension. Hollenhorst plaques (atheromatous emboli containing cholesterol crystals in the retinal arterioles) may be detected. Roth's spots (round or oval white spots seen near the optic disk) may be present in patients with infective endocarditis.

Management. Heparinization (80 units/kg bolus, followed by a maintenance infusion of 18 units/kg/hr) should be started when the diagnosis is made. Patients with limb-threatening ischemia require emergency direct or Fogarty catheter thrombectomy combined with bypass grafting. Thrombectomy alone often fails due to rethrombosis. Patients who have atherosclerotic disease not amenable to vascular bypass, are too ill to tolerate revascularization, or have irreversible ischemia that require primary amputation.

Patients with non-limb-threatening ischemia are best treated nonoperatively. Endovascular options available to the vascular surgeon include catheter-directed thrombolysis, pharmacomechanical thrombolysis, catheter-directed thrombus aspiration, and percutaneous mechanical thrombectomy, involving a host of different catheters and devices, dependent on the medical condition and preference of the vascular surgeon.

Peripheral Arterial Aneurysms

A true aneurysm is an abnormal localized dilation of the intact vessel wall caused by mural weakness and hemodynamic forces. Aneurysms enlarge at a rate determined by the cause. Atherosclerosis etiologies

progress slowly over years; trauma or infectious causes enlarge over days, weeks, or months. The primary risk of central aneurysms (abdominal aorta, iliac arteries, and visceral arteries) is rupture (see Chapter 84). Peripheral arterial aneurysms rarely rupture; instead, they are complicated by thrombosis or embolism jeopardizing distal tissues.[26]

The etiology of an aneurysm is strongly associated with its anatomic location. Lower extremity aneurysms are most often atherosclerotic. Upper extremity aneurysms are usually caused by local trauma. Visceral aneurysms are from abnormal hemodynamics, atherosclerosis, or infectious causes.

Lower Extremity

Femoral and popliteal artery aneurysms almost always occur in older men with advanced atherosclerosis. Twenty-five percent of patients have distal atheroembolism or thromboembolism; an additional 15% have total aneurysmal occlusion from in situ thrombosis.[26] Popliteal aneurysms are the most common peripheral aneurysms, occurring bilaterally in 60% of patients.[26] Abdominal aortic aneurysm occurs in 80% of patients with bilateral popliteal aneurysms. Most patients have claudication, thromboembolic events, atheroembolic events, or gangrene. With aneurysmal dilation, venous compression and deep venous thrombosis occur. Femoral aneurysms are the second most common peripheral aneurysms and manifest similarly to popliteal aneurysms. Femoral aneurysm dilation can also compress the femoral nerve, producing anterior thigh pain or weakness.

Diagnosis of popliteal and femoral aneurysms is by palpation of a pulsatile mass. Plain radiographs may show unilateral or bilateral calcified aneurysms. Ultrasonography and CT are diagnostic. Arteriography yields definitive diagnosis and involvement of distal vessels. Patients with a lower extremity aneurysm should be evaluated for the presence of other aneurysms.

Asymptomatic patients can undergo elective surgical excision of the aneurysm and end-to-end anastomosis or graft interposition. Simultaneous repair of the coexisting abdominal aorta or contralateral extremity aneurysms combined with vascular bypass is typically done. Patients with limb-threatening thromboembolic events are first treated with Fogarty catheter embolectomy.[26]

Upper Extremity

Atherosclerosis generally spares the upper extremities, so peripheral arterial aneurysms in the upper extremities are rare and localized trauma is the most common cause. The causes of subclavian artery aneurysms are thoracic outlet obstruction, trauma, and, rarely, atherosclerosis. Subclavian aneurysms from atherosclerosis represent severe disease, and 30% to 50% of patients so afflicted also have aortoiliac or other peripheral aneurysms.[27] Symptoms depend on the aneurysm's anatomic location. Patients may have chest, neck, and shoulder pain from acute expansion. Compression of the right recurrent laryngeal nerve can lead to voice change. Compression of the trachea can lead to stridor or other respiratory complaints.

The chest radiograph may reveal a superior mediastinal mass and be confused with a neoplasm. The subclavian artery can be compressed by a complete cervical rib that articulates with the first rib, producing a poststenotic dilation from the proximal subclavian to axillary artery. This syndrome occurs more often in women and in the dominant upper extremity. Cervical ribs occur in 0.6% of the population.[28] Axillary artery aneurysms are caused by blunt trauma from inappropriate and prolonged use of crutches. Humerus fracture or anterior shoulder dislocation are uncommon causes.[27]

Subclavian, subclavian-axillary, and axillary artery aneurysms share complications of thromboembolism, limb-threatening ischemia, neuromuscular and sensory dysfunction from brachial plexus compression, and central nervous system ischemia from retrograde vertebral and right carotid thromboembolism. A systolic bruit and palpable thrill are common.

CT angiography to confirm the diagnosis and determine involvement of distal vessels is the diagnostic procedure of choice. Surgical treatment consists of aneurysm resection, vascular grafting, and reestablishment of arterial continuity.

The rare syndrome of ulnar artery aneurysm (hypothenar hammer syndrome) is associated with occupational trauma in which the heel of the palm is used to hammer, push, or twist objects.[29] Patients are often mechanics, carpenters, or machinists.

The ulnar artery fits snugly into the bony canal at the hypothenar eminence under the hook of the hamate bone. Long-term repetitive damage results in aneurysm formation.[29] The aneurysm may develop a mural thrombus that repeatedly embolizes to the superficial palmar arch or to a digital artery. Symptoms include paresthesias, pain, coolness, and cyanosis, most often in the little and ring fingers, occasionally in the middle and index fingers. The thumb is characteristically spared due to its radial artery blood supply.

Diagnosis is easily made by finding a pulsatile or non-pulsatile tender mass in the hypothenar eminence of the dominant hand. The Allen test may demonstrate occlusion of the ulnar artery. Angiography of the distal vessels is diagnostic. Proximal angiography may rule out the subclavian and axillary arteries as embolic sources. Surgical aneurysm resection is required to reestablish ulnar artery continuity. Adjunctive preoperative fibrinolytic therapy may be helpful.[29]

Viscera

Splenic Artery Aneurysms. Splenic artery aneurysms account for 60% of all visceral arterial aneurysms. They are the only aneurysms that are more common in women, with a female-to-male ratio of 4:1.[30] The cause of splenic artery aneurysms has been attributed to systemic arterial fibrodysplasia, portal hypertension, and increased splenic arteriovenous shunting that occurs in pregnancy.

Splenic artery aneurysms are most often asymptomatic. Symptomatic patients exhibit vague left upper quadrant or epigastric discomfort and occasional radiation of pain to the left shoulder or subscapular area. Because most splenic artery aneurysms are less than 2 cm in diameter, a pulsatile mass is not palpable. Occasionally, a systolic bruit can be heard.

Only 2% of splenic artery aneurysms result in life-threatening rupture.[30] More than 95% of ruptures occur in young women during pregnancy and can be confused with ectopic pregnancy or placental abruption. Splenic artery aneurysms are usually an incidental discovery on the abdominal radiograph as signet ring calcifications in the left upper quadrant. Ultrasonography, CT, and MRI can distinguish aneurysms from other cystic lesions in the left upper quadrant.[30] An angiogram is usually required to confirm the diagnosis. Symptomatic splenic artery aneurysms require urgent operative intervention, particularly in pregnant women or in women of childbearing age. The rate of maternal mortality from rupture during pregnancy is approximately 70%. In asymptomatic patients, transcatheter embolization is an alternative to surgery.[31]

Hepatic Artery Aneurysms. Hepatic artery aneurysms represent 20% of visceral artery aneurysms. The lesions are caused by atherosclerosis, infection (most often as a complication of intravenous drug abuse), major abdominal trauma, and polyarteritis nodosa. Hepatic artery aneurysms affect men twice as often as women and usually occur after 60 years of age.

Most aneurysms remain asymptomatic, but unruptured symptomatic aneurysms generally produce symptoms consistent with

cholecystitis: vague, persistent, right upper quadrant, or epigastric pain radiating to the back. Large aneurysms can cause severe upper abdominal discomfort, similar to pancreatitis. Hepatic artery aneurysms may rupture into the common bile duct, peritoneum, or adjacent hollow viscera, with a mortality rate of 35%.

An abdominal bruit or palpable pulsatile mass is usually not present on physical examination. Aneurysmal calcification may be seen on a plain abdominal radiograph, but the diagnosis can be made reliably by CT angiography. Ultrasonography and CT can detect asymptomatic hepatic artery aneurysms.[30]

Because of the high mortality rate with aneurysmal rupture, an aggressive approach to management is warranted. Surgical resection of the aneurysm is performed in operative candidates. Transarterial catheter occlusion can be used in patients who are high surgical risks.[32]

Superior Mesenteric Artery Aneurysms. Superior mesenteric artery aneurysms are the third most common visceral aneurysms. Nearly 60% are infected aneurysms caused by nonhemolytic streptococci from left-sided bacterial endocarditis. Atherosclerosis and trauma are much less common causes. Patients are usually younger than 50 years old; men and women are affected equally.

Patients generally have intermittent upper abdominal pain consistent with abdominal angina. Fifty percent have a pulsatile abdominal mass on physical examination. The stigmata of subacute bacterial endocarditis may be present. Plain abdominal radiographs may show a calcified aneurysm. Angiography is necessary to confirm the diagnosis. Management of superior mesenteric artery aneurysm should address any underlying infectious process. The surgical approach is difficult, varies with the condition of the patient, the shape of the aneurysm (saccular or fusiform), and the assessment of bowel viability.

Traumatic Aneurysms

Traumatic aneurysm refers to a pseudoaneurysm that follows perforation of the arterial wall with formation of a perivascular hematoma. Chronic traumatic aneurysms may or may not be associated with an arteriovenous fistula. *Pseudoaneurysm* is a synonym for *false aneurysm.* The usual presentation is a pulsatile mass found near the course of an extremity artery, with a history of trauma more than 1 month earlier.[33] The expanding aneurysm may compress associated peripheral nerves. Distal perfusion is usually well maintained, and thromboembolism is rare. A loud systolic and possibly a separate faint diastolic murmur are characteristic. Conventional angiography, digital subtraction arteriography, or CT confirms diagnosis. Surgical excision is indicated as soon as possible to decrease the risk of complications, including rupture, thrombosis, or neurologic dysfunction caused by continued expansion.

Infected Aneurysms

Mycotic Aneurysms. The term *mycotic aneurysm* is a source of confusion because there is no association with fungal disease. Although used to describe any infected aneurysm, it should be reserved for infected aneurysms resulting from bacterial endocarditis, as originally described in 1885 by Osler.[34,35]

Septic emboli from infective endocarditis implant in one of two ways. First, hematogenous seeding of bacteria can occur in non-aneurysmal arteries damaged by preexisting atherosclerosis. Second, septic emboli can become lodged in the vasa vasorum of larger vessels, causing vessel wall ischemia and infection. In smaller vessels, septic emboli tend to lodge at arterial bifurcations, arteriovenous fistulae, or sites of arterial stenosis. Mycotic aneurysms are most common in the aorta, superior mesenteric artery, intracranial, and femoral arteries.

The infecting organism in mycotic aneurysms reflects the bacteriology of infective endocarditis. Viridans streptococci are the most common organisms, although intravenous drug abusers are most often infected by *Staphylococcus aureus.* Patients who have mycotic aneurysms tend to be 30 to 50 years old. The mortality rate is 25% (Table 73.2).[34,35] Infective endocarditis is more completely discussed in Chapter 69.

Atherosclerotic Arteries. Currently, the most common cause of an infected aneurysm is sepsis with hematogenous spread of bacteria, such as *Salmonella, Staphylococcus,* and *Escherichia coli,* to atherosclerotic arteries. Large vessels (especially the aorta) rather than peripheral arteries are the most common site. Patients tend to be older than 50 and have well-established atherosclerosis. Perforation often occurs before diagnosis and carries a mortality rate of 75%.[34]

Preexisting Aneurysms. The incidence of infection in patients with preexisting atherosclerotic aneurysms is estimated at 3% to 4%, and patients with ruptured aneurysms have a higher incidence of positive bacterial culture results than those who have elective surgical treatment of an asymptomatic aneurysm. Gram-positive organisms, especially *Staphylococcus,* predominate (60%). The mortality rate is extremely high (90%) because of aneurysm rupture.[35,36]

Post-Traumatic Pseudoaneurysms. Post-traumatic infected pseudoaneurysms result from invasive hemodynamic monitoring, angiography, and intravenous drug use. The most common artery affected is the femoral because of its involvement in procedural cannulations.

TABLE 73.2 Clinical Characteristics of Infected Aneurysms

	Mycotic Aneurysm	Infection of Atherosclerotic Arteries	Infection of Existing Aneurysm	Post-traumatic Infected False Aneurysm
Cause	Endocarditis	Bacteremia	Bacteremia	Drug addiction Trauma
Age (years)	30–50	>50	>50	<30
Incidence	Rare	Most common	Unusual	Very common
Location	Aorta Visceral Intracranial Peripheral	Atherosclerotic Aortoiliac Intimal defects	Infrarenal Aorta	Femoral Carotid
Bacteriology	*Viridans streptococci*	*Salmonella*	*Staphylococcus*	*Staphylococcus aureus*
S. aureus	Others	Others	Polymicrobial	
Mortality	25%	75%	90%	5%

From Wilson SE, Van Wagenen P, Passaro E Jr: Arterial infection. Curr Probl Surg 15:1, 1978.

S. aureus is isolated in 30% to 70% of cases. Because of the more peripheral location and early identification, the mortality rate is low (5%).[36]

The clinical presentation of an infected aneurysm varies with anatomic location and underlying pathophysiologic process. Infected abdominal aneurysms are often misdiagnosed. Onset is usually insidious; low-grade fever may be present for several months. Common findings are fever (75%), back and abdominal pain (33%), and palpable aneurysm (53%). More peripheral aneurysms, especially infected femoral pseudoaneurysms, are characterized by a tender groin mass, some manifestation of sepsis, or bleeding.[37] Almost all are easily palpable. Although rare, fungal infections should be considered in patients who are chronically immunosuppressed, have been treated recently for disseminated fungal disease, or have diabetes mellitus.[37,38]

Positive blood cultures in a patient with a preexisting aneurysm should prompt treatment as an infected aneurysm until disproven. Bacteremia often is continuous, and blood cultures are positive in approximately 70% of cases, but negative blood cultures do not rule out this diagnosis. CT angiography should be performed when an infected aneurysm is suggested.[39] Indium-111-labeled white blood cells can confirm or rule out infected aneurysms.[36]

Treatment includes both antibiotics and surgical repair. Antibiotic therapy is usually continued for at least 6 to 8 weeks, although some physicians advocate lifelong treatment after successful surgical repair.[40] The most important intervention is timely repair.[37,38] Infected true and false peripheral aneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes is attempted; there is a high risk of prosthetic graft infection. Without surgery, aneurysm rupture with exsanguinating hemorrhage is inevitable.[36]

Vasospastic Disorders

Vasospastic disorders are characterized by an abnormal vasomotor response in the distal small arteries. Blood flow in the peripheral circulation is controlled by local, autonomic, and humoral mechanisms.[9] The cause of the increased vasospastic response is currently unknown.

Raynaud disease is the most common vasospastic disorder and occurs five times more often in women than in men. By definition, cases of Raynaud disease have no evidence of an underlying cause. The diagnosis is correct in 95% of cases that meet these criteria: (1) episodes are precipitated by cold or emotion; (2) symptoms are bilateral; (3) gangrene is absent or is minimal and confined to the skin; (4) no disease or condition that could cause a secondary Raynaud phenomenon is present; and (5) symptoms have been occurring for at least 2 years.[41]

The classic Raynaud attack is triphasic: the fingers become pale, then blue, and finally red. Initially, a complete closure of the palmar and digital arteries (and possibly arterioles) occurs, producing cessation of capillary perfusion. Slight relaxation of arterial spasm then occurs, with a slight return of rapidly deoxygenating blood into the dilated capillary bed, producing cyanosis. Arterial spasm then fully resolves, and reactive hyperemia produces a red extremity. Attacks are often precipitated by cold and emotional stress. Raynaud disease usually has a benign course. True histologic changes within the vessel wall are absent. Reassurance, education, and primary care follow-up are the only treatment necessary for true Raynaud's disease.

Raynaud phenomenon is the term given to Raynaud disease when there is an identifiable underlying causative disorder. Connective tissue disorders, including scleroderma, rheumatoid arthritis, and systemic lupus erythematosus, have the highest association with Raynaud phenomenon. Treatment should be directed toward identifying the underlying disorder and minimizing threatened tissue loss if present.[41]

Benign livedo reticularis is caused by spasms of the dermal arterioles. It is most common when skin is exposed to a cool environment, is never associated with histologic vascular abnormality, and quickly resolves when the exposed skin is covered or the environment is warmed. Other conditions, similar to the causes of Raynaud phenomenon, can have secondary livedo reticularis along with other peripheral vascular disease manifestations.[42]

Acrocyanosis is the least common of the vasospastic disorders and is characterized by persistent, painless, symmetrical cyanosis of the fingers, hands, lips, nose, and less often the feet. The disease is benign, unassociated with vascular abnormality or underlying disorder. Pain, trophic skin changes, and ulceration do not occur. It is more common in women, intensified by exposure to cold, and decreases with warming. The diagnosis is made by the bilateral and persistent nature of the findings, localized to the hands or feet in the presence of normal arterial pulses. The involved extremities are nearly always cold, and excessive perspiration is common. Except for reassurance and protection from cold, treatment is unnecessary.[42]

Primary erythromelalgia is a rare syndrome of paroxysmal vasodilation with burning pain, increased skin temperature, and redness of the feet and less often the hands. Secondary erythromelalgia can occur with underlying disease processes, most often systemic lupus erythematosus, myeloproliferative disorders, hypertension, venous insufficiency, or diabetes mellitus. Erythromelalgia is as common in children as adults, but in children, it is less likely to be associated with underlying systemic illness. Attacks are not triggered by cold and occur in modest ambient temperatures. Skin temperature of the involved digits is high compared with the patient's core temperature. Symptoms may remain mild for years or may become disabling. Tissue loss and trophic skin changes do not occur. Although elevation of the extremities, cold compresses, or immersion in ice can provide temporary relief, no consistently effective treatment has been found for the multiple, often daily episodes of pain that occur.[42]

Thoracic Outlet Syndrome

Thoracic outlet syndrome involves compression of the brachial plexus, subclavian vein, or subclavian artery at the superior aperture of the thorax. The subclavian artery courses over the first rib between the scalenus anticus muscle anteriorly and the scalenus medius muscle posteriorly, when passing under the clavicle to the axilla, where the brachial plexus lies posteriorly and laterally. Thoracic outlet syndromes were previously categorized by cause as scalenus anticus, costoclavicular, hyperabduction, cervical rib, and first thoracic rib syndromes. They are now most easily divided into three types—neurologic, venous, and arterial—depending on the predominant symptoms.

Compression of the brachial plexus causes the neurologic type of thoracic outlet syndrome and accounts for approximately 95% of all cases.[43] Symptoms begin between the ages of 20 and 50 years old, with women predominating at a ratio of about 3:1. Compression or thrombosis of the subclavian vein constitutes the venous type of thoracic outlet syndrome and is responsible for 4% of all cases. It occurs most often in men 20 to 35 years old. The arterial type of thoracic outlet syndrome is rare, occurring in approximately 1% of all cases, but is potentially the most serious of the three types. Fig. 73.3 demonstrates the relationship between anatomic abnormalities and neurovascular compression.

There are four basic concepts of thoracic outlet syndromes[44]: (1) patients who have a thoracic outlet syndrome develop an anatomic abnormality, predisposing them to symptoms under certain conditions; (2) brachial plexus compression or irritation constitutes approximately 95% of all thoracic outlet syndrome cases and is rarely caused by compression of the subclavian artery; (3) bedside testing for thoracic outlet syndrome based on positional compression of the

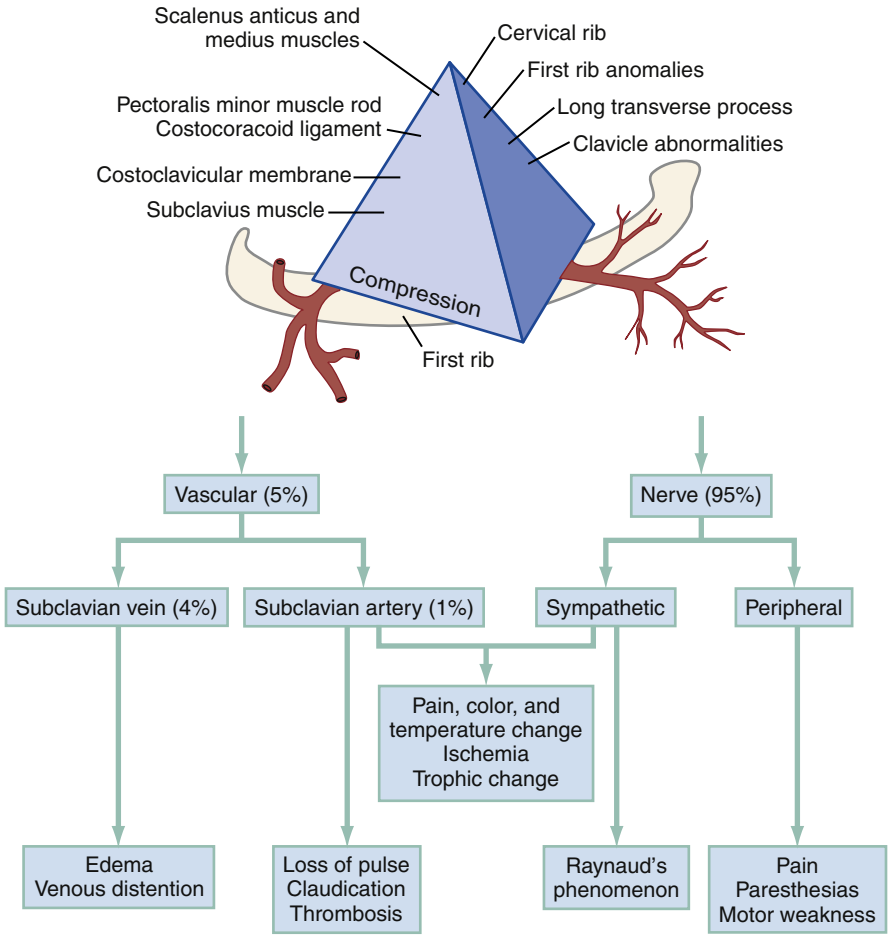

Fig. 73.3 Inter-relationships of muscle, ligament, and bone abnormalities in the thoracic outlet may compress neurovascular structures. (From Urschel HC Jr: Management of thoracic outlet syndrome. N Engl J Med 286:1140, 1972.)

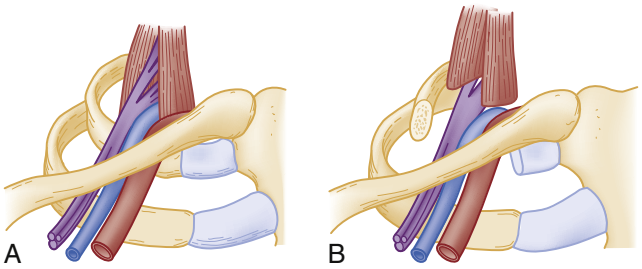

Fig. 73.4 (A) Thoracic outlet compression in costoclavicular space. (B) Decompression of thoracic outlet by resection of the first rib with disarticulation of the costochondral joint. (From Etheredge S, et al: Thoracic outlet syndrome. Am J Surg 138:175, 1979.)

subclavian artery is insensitive and unreliable; and (4) in advanced or refractory cases, the causative anatomic abnormalities are to be surgically corrected.

The neurologic and venous compression type of thoracic outlet syndrome can be associated with any underlying anatomic abnormality. Bony abnormalities (cervical rib, first thoracic rib, or clavicle) are the most common causes of the arterial type of thoracic outlet syndrome (Fig. 73.4A).

Clinical Features

Compression of the brachial plexus most often affects the lower two nerve roots, eighth cervical (C8) and first thoracic (T1), producing pain and paresthesias in the ulnar nerve distribution. The second most common pattern is the upper three nerve roots of the brachial plexus (C5, C6, and C7), with symptoms referable to the neck, ear, upper chest, upper back, and outer arm in the radial nerve distribution. Venous compression progresses to intimal damage and subclavian vein thrombosis, with venous engorgement and swelling of the affected extremity. Persistent subclavian artery compression results in poststenotic aneurysm formation and its sequelae.

Physical Examination. The most reliable test in screening for thoracic outlet syndrome is the elevated arm stress test (EAST).[44] With the patient sitting, the arms are abducted 90 degrees from the thorax and the elbows flexed 90 degrees, with the shoulders braced slightly behind the frontal plane. The patient is asked to open and close the fists slowly but steadily for a full 3 minutes and to describe any symptoms that develop. Normal patients perform this test without symptoms other than mild fatigue. The patient with thoracic outlet syndrome usually has early heaviness and fatigue of the involved limb, gradual onset of numbness of the hand, and progressive aching through the arm and top of the shoulder. Within the 3 minutes, the patient usually drops the hand to the lap for relief of the progressive, crescendo distress that becomes intolerable.

The EAST evaluates all three types of thoracic outlet syndrome: neurologic, venous, and arterial. Radial pulses can be palpated by the examiner during the test. The presence of a radial pulse and a positive EAST test result are strong indications that the basis of symptoms is neurologic involvement of the brachial plexus.

The hands should be observed for changes in skin color, warmth, moisture, or muscular atrophy. Triceps muscle strength (innervated by C7) should be tested bilaterally. Muscle strength of the interosseous muscles (innervated by C8 and T1) should be tested by asking the patient to spread the fingers apart against resistance. Gentle pressure with the thumb in the supraclavicular fossa over the brachial plexus may reproduce thoracic outlet symptoms. A blood pressure difference between the two arms is a reliable indication of arterial involvement.

Ancillary Evaluation. Cervical spine radiographs with oblique views and chest radiographs identify skeletal abnormalities (first rib, cervical rib, clavicle deformity), trauma, arthritis, scoliosis, Pancoast tumor, or other pulmonary disease. Electromyography, nerve conduction studies, and somatosensory evoked potentials are generally unreliable.[44] Patients thought to have cervical disk or spinal cord disease may require cervical CT or MRI.

CT angiography is recommended with (1) obliteration of radial pulse on the EAST, (2) blood pressure 20 mm Hg less than that of the opposite asymptomatic limb, (3) possible subclavian stenosis or aneurysm (bruit or abnormal supraclavicular pulsation), and (4) evidence of peripheral emboli in the upper extremity.[44] Duplex ultrasound is indicated for edema of the hand or arm, unilateral cyanosis, or a prominent venous pattern of the arm, shoulder, or chest.[45]

Differential Diagnosis

The differential diagnosis of thoracic outlet syndrome includes herniated cervical disk, cervical spondylitis, spinal cord tumor, ulnar nerve compression at the elbow, carpal tunnel syndrome, orthopedic shoulder problems, trauma, postural palsy, angina pectoris, and a variety of neuropathies, including those associated with multiple sclerosis, alcoholism, and diabetes.

Patients with a herniated cervical disk have more severe persistent pain radiating in a sharply demarcated dermatomal distribution (usually C4 to C5 or C5 to C6) and often have localized tenderness of the cervical spine at the affected level. Carpal tunnel syndrome is characterized by nocturnal symptoms of pain and paresthesias and an associated Tinel sign. Brachial plexus compression can be confused with other vascular conditions, such as Raynaud disease, vasospastic disorders, vasculitis, or arterial ischemia. Unilateral symptoms suggest thoracic outlet syndrome, whereas bilateral symptoms suggest a systemic process. Subclavian or axillary venous thrombosis from thoracic outlet syndrome should be differentiated from thrombophlebitis or mediastinal venous obstruction from a benign or malignant process (e.g., Pancoast tumor).

Management

Treatment depends on whether the involvement is neurologic, arterial, or venous. Brachial plexus involvement with minimal signs and symptoms often responds to conservative treatment with physiotherapy and shoulder girdle exercises. Patients with thoracic outlet syndrome who have cervical ribs, arterial involvement, or neurologic symptoms require surgical decompression, removal of anomalous fibromuscular bands, or resection of the cervical rib if present. First rib or anomalous muscle or fibrous tissue resection provides consistent relief of symptoms and minimal morbidity (see Fig. 73.4B).

Patients with arterial complications of thoracic outlet syndrome (thrombosis, thromboembolism, or acute ischemia) require immediate heparinization (80 units/kg bolus, followed by a maintenance infusion of 18 units/kg/hr) and CT angiography; Fogarty catheter embolectomy, if appropriate; and emergency or urgent surgical exploration. Patients with axillary and subclavian vein thromboses also require emergent heparinization and venography and are treated with surgical thrombectomy or systemic fibrinolytic therapy.[45] Subclavian and axillary aneurysms are treated with resection and end-to-end anastomosis or graft interposition.

Disposition. The correct diagnosis of thoracic outlet syndrome can be achieved in more than 90% of patients with a careful history, physical examination, and bedside testing alone.[44] Neurologic, orthopedic, or vascular surgery consultation is indicated according to the pathologic condition.

Peripheral Arteriovenous Fistulae

Arteriovenous malformations and fistulae, although rare, should be distinguished from vascular stenoses or aneurysms. Acquired peripheral arteriovenous fistulae are most often caused by trauma (gunshot wounds, stab wounds, or surgery), with malignancy, infection, and arterial aneurysms as less common causes. Patients seek care months after an invasive surgical procedure or penetrating injury.

Physical Exam

True aneurysms and arterial stenoses are associated with a systolic murmur. Pseudoaneurysms have a loud systolic and sometimes a separate faint diastolic murmur. Arteriovenous fistulae have a constant systolic and diastolic (to-and-fro) murmur associated with a palpable thrill, similar to a dialysis arteriovenous fistula. Arteriovenous fistulae can occur at prior operative or trauma sites. Skin overlying the lesion may be warm, but distally, the temperature is decreased. Peripheral veins are distended and varicose. Large arteriovenous fistulae produce high cardiac output and widened pulse pressure. Digital pressure on the artery leading to the fistula may decrease the tachycardia (Branham sign).

Differential Diagnosis

An arteriovenous fistula diagnosis can be made with clinical examination alone. A constant systolic and diastolic (to-and-fro) murmur with associated palpable thrill is characteristic. Sixty percent of arteriovenous fistulae have a coexisting false aneurysm. Patients with peripheral venous disease may have similar cutaneous manifestations (varicose veins and stasis pigmentation) but lack vascular bruits. Infection may complicate large fistulae.

Management

Acquired peripheral arteriovenous fistulae usually increase in size with time if surgery is delayed. Vessel dilation, peripheral ischemia, and cardiac output increase.[46] Surgical treatment of peripheral arteriovenous fistulae requires interrupting the fistula tract and restoring both arterial and venous continuity with end-to-end anastomosis or graft interposition. Transcatheter embolization with detachable balloons and liquid acrylic tissue adhesives (e.g., isobutyl 2-cyanoacrylate) is used for surgically inaccessible fistulae.[47]

Vascular Abnormality Caused by Drug Abuse

Principles

Parenteral drug use causes intravenous or intra-arterial injuries, including arterial ischemia, infected pseudoaneurysms, lymphatic obstruction, or neurologic injury. Acute arterial ischemia results from direct drug effects or endogenous catecholamine release after injection. Endothelial wall damage stimulates platelet aggregation and thrombus formation. Precipitated crystals, talc, or foreign body emboli cause arterial occlusion. Necrotizing arteritis produces ischemia, especially in patients who abuse methamphetamines.

Infected pseudoaneurysms associated with arteriovenous fistulae result from a through-and-through puncture of the artery with simultaneous bacterial contamination. These fistulae are the most common vascular lesions resulting from intravenous drug abuse. Secondary

infection of the vascular structure may be covered by a surrounding soft tissue infection (cellulitis or abscess). Infected aneurysms at sites distant from the injection can occur.

Patients who inject intravenous drugs can develop unilateral hand edema or "puffy hand syndrome" due to gradual obliteration of the superficial venous vessels and chronic lymphatic obstruction. Direct injury to adjacent nerves, polyneuritis, and ischemic neuritis can result. Coexisting infections include cellulitis, septicemia, and bacterial endocarditis.[48]

Clinical Features

Patients may not be comfortable discussing the use of intravenous drugs, but objective evidence such as track marks may be present. Distal ischemia after intra-arterial injection occurs in the upper extremity after injection of the brachial or radial artery. The immediate onset of severe, burning pain at the time of injection is a characteristic hallmark.[49] Patients have a painful, edematous upper extremity with patchy blue-purple skin discoloration. Distal pulses are generally present, but the skin temperature of the involved extremity is decreased. Because patients tend to seek attention early, the site of injection may be identifiable over the radial or brachial artery. Evidence of gangrene, pre-gangrenous changes, or neuromuscular deficits may accompany this syndrome.

Patients with infected pseudoaneurysms have a painful mass several days to weeks after injection, with resultant bleeding. The mass is pulsatile, and 50% have an associated bruit.[48] Infected pseudoaneurysm should be considered in the differential diagnosis of cutaneous abscess in a patient who injects intravenous drugs. Infected pseudoaneurysms are most often encountered in the lower extremities (80%). A peripheral vascular examination with auscultation for bruits should be performed. A radiograph can detect subcutaneous needle fragments. CT angiography is the diagnostic procedure of choice for suggested pseudoaneurysm or distal ischemia. Ultrasonography is often unable to distinguish an aneurysm from an abscess or cellulitis.

Management

Therapeutic considerations for acute ischemia from intra-arterial injection are primarily conservative. Intra-arterial vasodilators, heparin, low-molecular-weight dextran, fibrinolytic therapy, analgesics, systemic warming to stimulate vasodilation, antibiotics, elevation of the affected limb to promote venous drainage, and physical therapy have not significantly altered the outcome or amputation rate in this patient population. Surgical treatment is reserved for delayed amputation. Gradual resolution without surgical intervention is the most common outcome.

Patients with infected pseudoaneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes may require an extensive surgical approach.[48] Methicillin-resistant *S. aureus* and gram-negative rods are increasing in frequency as the causative agents. Broad spectrum coverage with vancomycin 5 to 20 mg/kg q8h to q12h and cefepime 1 to 2 g IV q8h should be initiated as soon as the diagnosis is considered and then tailored to the appropriate organisms as soon as possible.

CHAPTER 73: QUESTIONS AND ANSWERS

1. Where do most arterial emboli originate?
   - **a.** Abdominal aorta
   - **b.** Femoral artery
   - **c.** Left ventricle
   - **d.** Left atrium
   - **e.** Thoracic aorta

Answer: c. Eighty-five percent of arterial emboli originate in the heart. Of these, left ventricular thrombus formation after myocardial infarction (MI) accounts for 60% to 70%. Atrial thrombi account for only 5% to 10% of all peripheral arterial emboli.

2. What is the most frequent site of acute arterial embolic occlusion?
   - **a.** Carotid artery
   - **b.** Common femoral artery
   - **c.** Mesenteric artery
   - **d.** Popliteal artery
   - **e.** Renal artery

Answer: b. The bifurcation of the common femoral artery accounts for 35% to 50% of acute arterial occlusion due to arterial embolism. Embolic occlusion most often occurs at major arterial bifurcations because of the sudden change in vessel diameter at these locations.

3. A 63-year-old male presents with acute onset of left leg pain while walking. He describes it as a shock-like sensation that made his knee buckle. Past history is remarkable for hypertension, diabetes (diet controlled), tobacco use, and a recent lateral wall myocardial infarction. Current medications are aspirin, metoprolol, and lisinopril. Vital signs are temperature, 37.0°C oral; heart rate, 98 beats per minute; blood pressure, 160/105 mm Hg; respiratory rate, 20 breaths per minute; and oxygen (O2) saturation, 96%. Physical examination is remarkable for left lower extremity pallor with decreased light touch sensation, nonpalpable left foot pulses, and minimal capillary refill. What would be the most appropriate next step in the diagnosis and management of this patient?
   - **a.** Abdominal ultrasonography
   - **b.** Arteriogram
   - **c.** Serum lactate level
   - **d.** Thoracolumbar magnetic resonance imaging (MRI) scan
   - **e.** Vascular surgery consultation

Answer: e. This patient has acute limb ischemia from an acute arterial embolus, most likely originating from his left ventricle secondary to a recent myocardial infarction. Loss of light touch sensation on physical examination indicates jeopardized tissue viability, requiring immediate vascular surgery consultation for emergent Fogarty catheter embolectomy. Reliable diagnosis of an acute arterial embolism can almost always be made by history and physical examination alone. Any additional diagnostic evaluation constitutes an unnecessary delay. Serum lactate level, abdominal ultrasonography, and thoracolumbar magnetic resonance imaging (MRI) scan would not provide useful information. An arteriogram before going to the operating room is an unnecessary delay and may further exacerbate limb ischemia.

4. A supine patient is asked to raise his foot 12 inches above the estimated level of the right atrium and dorsiflex the foot five or six times. He is then brought to a sitting position with his feet hanging. In the absence of severe advanced ischemia, venous filling of the foot should return in less than how many seconds?
   - **a.** 1
   - **b.** 5
   - **c.** 10
   - **d.** 15
   - **e.** 20

Answer: e. This bedside test is Buerger sign and can provide reliable evidence of advanced ischemia. In the absence of severe advanced ischemia, the lower extremity veins should fill within 20 seconds after being placed in the dependent position.

5. A 73-year-old man presents with acute onset of right lower extremity pain. He has a long history of tobacco use, hypertension, and a several-year history of moderate calf claudication at 50 yards walking. Physical examination reveals signs of chronic atherosclerotic occlusive disease of the bilateral lower extremities, including muscular atrophy, loss of hair over the toes and feet, and thickening of the toenails. Examination of the distal right lower extremity reveals pallor, absent popliteal and foot pulses, and decreased sensation to light touch of the right foot. The cardiac examination is unremarkable, and the 12-lead electrocardiogram (ECG) reveals only normal sinus rhythm. Based on the most likely diagnosis, what is the most appropriate definitive therapy?
   - **a.** Acute hyperbaric oxygen therapy
   - **b.** Arteriogram to determine the presence of embolus versus in situ thrombosis
   - **c.** Intra-arterial thrombolysis
   - **d.** Surgical referral for Fogarty catheter embolectomy
   - **e.** Surgical referral for Fogarty catheter embolectomy with vascular bypass grafting

Answer: e. This patient has a history and physical examination consistent with long-standing peripheral atherosclerotic occlusive disease, no evidence of a proximal source for embolism, but acute onset of ischemic symptoms and loss of light touch in the affected extremity. The most likely diagnosis is a large, in situ thrombosis precipitating acute limb-threatening ischemia. When limb-threatening ischemia is present, emergent surgical referral for Fogarty catheter embolectomy is indicated, whether caused by acute in situ thrombosis or embolus. With limb-threatening ischemia caused by in situ thrombosis, simple Fogarty catheter embolectomy is insufficient and usually requires additional bypass grafting. Acute hyperbaric oxygen therapy has no role in the treatment of limb-threatening ischemia due to in situ thrombosis or embolism. An arteriogram to determine the presence of embolus versus in situ thrombosis is unwarranted, represents an unnecessary delay, and may further exacerbate ischemia. Intra-arterial thrombolysis takes 6 to 72 hours to work and is contraindicated in cases of limb-threatening ischemia.

6. What percentage of patients presenting with arteriosclerosis obliterans are younger than 50 years old?
   - **a.** 1%
   - **b.** 5%
   - **c.** 10%
   - **d.** 20%
   - **e.** 40%

Answer: d. Peripheral arteriovascular disease can occur in younger patients. Nineteen percent of patients presenting with atherosclerosis obliterans are between the ages of 30 and 50 years old. Of all arteriosclerosis patients, 33% have coexistent coronary artery disease, and 70% to 90% are smokers. The non-smokers have other risk factors including significant hypertension and hyperlipidemia.

CHAPTER 73: QUESTIONS AND ANSWERS—cont'd

7. A 49-year-old woman presents with severe left ankle pain. She describes a fairly sudden development of a left lateral malleolus hemorrhagic blister that transitioned to a painful superficial ulcer over 48 hours. She has no prior history of extremity ulcers, and her only significant past medical history is hypertension. She has a long-standing history of noncompliance with her hypertensive medications and smokes two packs of cigarettes per day. She has no history of myalgias, joint pain, fever, or systemic symptoms. Vital signs are: temperature, 36°C oral; heart rate, 90 beats per minute; blood pressure, 210/125 mm Hg; respiratory rate, 20 breaths per minute; and O2 saturation, 96%. Physical examination reveals a thin black female in distress because of pain. Cardiopulmonary examination is unremarkable. Abdominal, neurologic, and extremity examinations are likewise unremarkable except for a well-demarcated, shallow 4 × 3 cm ulcer over the left lateral malleolus. There is mild erythema but no evidence of active infection. Distal pulses and capillary refill are normal. What would be the most appropriate intervention?

a. Analgesics and admission for vasculitis evaluation
b. Surgical consultation for possible embolectomy
c. Wound care and blood pressure control
d. Wound care and tapering dose of prednisone
e. Venous Doppler scans and surgical consultation for possible skin grafting

Answer: c. This patient has a hypertensive ulcer, which is the most painful of lower extremity ulcers. They typically occur over the lateral malleolus, as opposed to venous stasis ulcers, which are more common anteriorly and medially. Ischemic arterial ulcers are more common distally over the digits. Although vasculitis or a collagen vascular disease are possible, the lack of any other systemic symptoms or prodrome argues against this.

74

Pulmonary Embolism and Deep Vein Thrombosis

Christopher Kabrhel

KEY CONCEPTS

- Hallmarks of deep venous thrombosis (DVT) include unilateral limb pain and swelling, though these findings can be subtle and nonspecific.
- Patients with low pretest probability (PTP) can have DVT ruled out in the ED with a negative D-dimer or venous ultrasound (US), patients with high PTP can have DVT ruled out in the ED with a negative D-dimer and venous US.
- Three-point US evaluates the leg veins proximal to the knee and has a sensitivity of 95% and specificity of 95% for proximal DVT when performed by a certified sonographer. A negative three-point ultrasound in a patient with a moderate or high PTP for DVT should have a D-dimer test or repeat venous ultrasound within 7 days. A single, whole-leg ultrasound excludes DVT in all pretest probabilities.
- Anticoagulation for DVT and pulmonary embolism (PE) can be achieved with a direct-acting oral anticoagulant (DOAC), low-molecular-weight heparin (LMWH), unfractionated heparin or, in rare cases, an alternative anticoagulant. For DVT and most PE, DOACs are as effective as and safer than the combination of heparin and warfarin.
- The treatment of isolated calf vein DVT is controversial, and it is reasonable to withhold anticoagulation in favor of a repeat venous ultrasound within 7 days and close follow-up.
- Distal superficial vein thrombophlebitis can adequately be treated with nonsteroidal antiinflammatory drugs and warm compresses, but proximal superficial vein thrombophlebitis should be treated with anticoagulation.
- Most patients with DVT distal to the iliofemoral region can be safely treated as outpatients as long as close follow-up and access to anticoagulant medications is assured.
- PE can present asymptomatically, with dramatic clinical symptoms, or with sudden cardiac death. Even the most common symptom, dyspnea, is absent in a quarter of patients.
- The first step in the evaluation of possible PE is determining whether testing for PE is indicated.
- The patient's pretest probability for PE, as determined by clinical gestalt or a validated score (e.g., the Wells Score) dictates the approach to objective testing for PE.
- Patients with low gestalt pretest probability and a negative PERC rule may incur more harm than benefit if testing for PE (including D-dimer) is performed.
- Patients with non-high pretest probability (e.g., Wells Score ≤ 6) can have PE ruled out with a negative D-dimer.
- The D-dimer threshold can be adjusted according to the patient's age or the pretest probability of PE. The formula for age adjustment is Age × 10 ng/mL. Using an adjusted D-dimer threshold reduces the need for imaging by about 10% to 15%.
- Patients with high pretest probability or a positive D-dimer require imaging. For most patients, including pregnant women, computer tomography pulmonary angiography (CTPA) is the imaging test of choice.
- For pregnant women, the decision to undergo any testing for PE should be shared with the patient. To minimize fetal radiation exposure, diagnostic testing for PE should start with a combination of D-dimer and bilateral lower extremity venous ultrasound.
- For patients diagnosed with PE, typical resuscitative measures can be harmful. Endotracheal intubation and positive-pressure ventilation can decrease preload and precipitate cardiac arrest. Excessive intravenous fluid administration can lead to worsening right ventricular distention and left ventricular compression.
- Patients with PE should be risk stratified using a combination of vital signs, CTPA, echocardiography, and troponin. High-risk PE is defined by hemodynamic instability, intermediate-risk by right ventricular dysfunction, and low-risk by the absence of either.
- Patients with high-risk PE should be treated with thrombolysis or thromboembolectomy unless contraindicated.
- Patients with intermediate-risk PE are usually not candidates for thrombolysis but may be candidates for catheter-directed or low-dose systemic thrombolysis.
- About 25% of patients with low-risk PE can be treated as outpatients.

FOUNDATIONS

Background and Importance

Each year more than 500,000 people are diagnosed with venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and pulmonary embolism (PE). PE is the third most common cause of cardiovascular death in the United States. PE and DVT occur equally in women and men, and while PE and DVT can occur in any age group, older patients have a much higher incidence, at 1/10,000 in people 20 to 30 years old and 1/100 in people greater than 80 years old. However, even this high incidence grossly understates the importance of PE and DVT to the practice of emergency medicine. Because the clinical presentations of PE and DVT are highly variable, with symptoms and signs that overlap with many common ED diagnoses, PE and DVT are frequently on the differential diagnosis for patients who present with chest pain, dyspnea, syncope, tachycardia, hypoxemia, leg pain, edema,

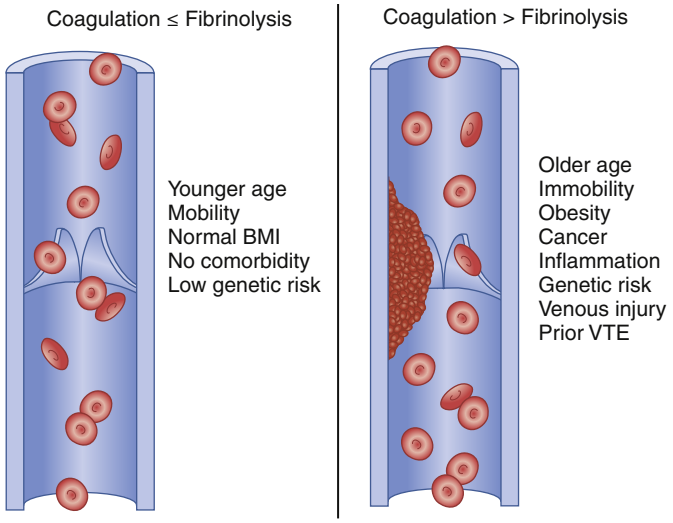

Fig. 74.1 Diagram of clotting in a lower extremity vein. Note how the clot forms in and around the cusps of the valve. (Illustration courtesy of Sadie A. Kabrhel.)

and other nonspecific complaints. The wide demographic range and nonspecific clinical presentation of PE and DVT is why as many as 1 in 10 emergency department (ED) patients are evaluated for possible DVT or PE. Emergency clinicians must, therefore, be knowledgeable and judicious in their approach to PE and DVT.

As illustrated in Figure 74.1, venous thrombosis occurs when the propensity of blood to coagulate overwhelms endogenous anticoagulant and fibrinolytic systems. Numerous factors associated with the classic triad of venous injury, venous stasis, and hypercoagulability have been associated with an increased risk of VTE in epidemiologic studies (Table 74.1). Emergency clinicians should be aware of factors that might increase a patient's propensity to clot and should consider these factors when determining whether a patient's clinical presentation warrants an evaluation for VTE. Important factors include older age, prior history of VTE, active cancer, recent surgery or trauma, recent hospitalization longer than three days, limb immobility, and estrogen use (especially if initiated in the past three months). Thus, the age and comorbid illness of the population served by an ED determine the frequency of VTE diagnoses.

However, not all epidemiologic risk factors are associated with an increased likelihood of an ED diagnosis of VTE (Table 74.1). For example, pregnant women are five times as likely to develop VTE as nonpregnant women of the same age, but only 4% of pregnant women tested for VTE in the ED have the diagnosis, compared to 12% of nonpregnant patients. This is because emergency clinicians have a low threshold to test pregnant patients for VTE. Similarly, travel is associated with a small increase in the absolute risk of VTE, but a history of travel often leads emergency clinicians to test for VTE, so travel does not seem to be associated with VTE in patients tested in the ED.[1] The decision to initiate an evaluation or treatment for VTE should be based on an analysis of the risk PE poses to the patient weighed against the risk imparted by testing and treatment.

As many as 50% of patients diagnosed with PE have no apparent clinical risk factors for PE or DVT at the time of diagnosis. However, the lack of a risk factor known at the time of the ED diagnosis does not mean that an occult risk factor does not exist. Between 4% and 11% of patients with PE or DVT will receive a new cancer diagnosis within 1 year of VTE diagnosis, depending on whether the VTE event is provoked or idiopathic. Genetic or acquired hypercoagulable states are often unknown until a patient has their first thrombotic event. Patients who develop PE or DVT after exposure to heparin may have heparin-induced thrombocytopenia, a hypercoagulable state leading to VTE. While the presence of an occult risk factor may only become known after a patient leaves the ED, a thorough history may suggest occult cancer (e.g., unintentional weight loss) or recent exposure to heparin that would enable the emergency clinician to adjust their assessment of a patient's risk of PE or DVT.

Anatomy, Pathology, and Pathophysiology of VTE

The venous anatomy of the lower extremity is divided into the deep and superficial systems (Fig. 74.2). The superficial venous system consists primarily of the greater and short saphenous veins and perforating veins. Distal greater saphenous vein thrombi are often referred to as superficial thrombosis, but greater saphenous clots near the connection with the femoral vein should be referred to as DVT. The deep venous system includes the anterior tibial, posterior tibial, and peroneal veins, collectively called the calf veins. Venous thrombi isolated to the calf veins are referred to as distal DVT. The calf veins join together at the knee to form the popliteal vein, which extends proximally and becomes the femoral vein at the adductor canal. Venous thrombi in the popliteal or more proximal veins are referred to as proximal DVT. The femoral vein (previously known as the superficial femoral vein), is joined by the deep femoral vein and then the greater saphenous vein to form the common femoral vein, which subsequently becomes the external iliac vein at the inguinal ligament. Venous thrombi in the proximal femoral and iliac veins are known as iliofemoral DVT.

Knowledge of the venous anatomy is also important for the performance and interpretation of ultrasound of the leg veins. Compression ultrasound, including point-of-care ultrasound, is typically limited to the common femoral, femoral, and sometimes popliteal veins. Duplex ultrasound includes compression ultrasound of the proximal veins as well as Doppler ultrasound of the calf veins. The anatomic location of a DVT also influences prognosis because proximal DVT are less likely to lyse spontaneously, more likely to embolize, and are associated with a greater risk of long-term complications such as post-thrombotic syndrome.

Although 90% of DVT form in leg veins, clots can also form in the arm, around venous catheters, pacemaker wires, or other foreign bodies such as inferior vena cava filters. Other sites of venous thrombosis rarely encountered in the ED include the jugular, ovarian, mesenteric, renal, portal, hepatic, cerebral, and retinal veins.

DVT formation typically begins when monocytes expose blood to tissue factor on their surfaces. This process overwhelms natural anticoagulant and fibrinolytic mechanisms and leads to the aggregation of red blood cells, platelets, and fibrin in the venous sinuses or cusps of the lower extremity deep veins. The formation of a DVT causes vascular congestion which, in turn, causes veins to dilate and valves to become incompetent. The lack of forward venous blood flow leads to venous stasis and further thrombus propagation.

When a DVT embolizes, it flows proximally through the venous system toward the vena cava and the heart. In 3% of cases, a portion of the clot will remain in the right atrium or ventricle, a condition known as clot-in-transit. Clots that pass through the heart and enter the pulmonary arterial circulation are called PE. A PE can be described as saddle if the clot is visualized across the bifurcation of the main right and left pulmonary arteries (Fig. 74.3A). More distal PE are typically described according to their anatomic location. Clots may lodge in a main pulmonary artery (Fig. 74.3B), or in a lobar (Fig. 74.3C), segmental (Fig. 74.3D) or subsegmental pulmonary artery branch. PE may extend from a proximal artery into distal branches, and PE frequently fragment, lodging in multiple arterial branches simultaneously.

TABLE 74.1 Epidemiologic Risk Factors and Physiologic Findings for Pulmonary Embolism in the Emergency Department Setting

Risk Factor from Epidemiologic Study	Mechanism	Strength of Association With PE or DVT in ED Patients
Surgery (within past 4 weeks, requiring general anesthesia)	Inflammation Venous Injury Stasis	++++
Trauma within past 4 weeks requiring hospitalization	Inflammation Venous Injury Stasis	+++
Older age	Hypercoagulability Stasis Association with other diseases of aging (e.g., cancer, surgery)	+++
Prior PE or DVT	Hypercoagulability Stasis (due to valvular damage)	++
Active cancer	Hypercoagulability	++
Inherited or acquired thrombophilia	Hypercoagulability	++
Limb or generalized immobility	Stasis	++
Estrogen	Hypercoagulability	++
Pregnancy or postpartum	Hypercoagulability	+
Recent travel	Stasis	Minimal
Connective tissue disease	Inflammation	Unknown
Inactive cancer (considered in remission)	Hypercoagulability	Not significant
Smoking	Inflammation and hypofibrinolysis	Not significant
Family history of VTE	Hypercoagulability (inherited predisposition)	Not significant
Symptoms	Mechanism	Strength of association with PE or DVT in ED Patients
Hemoptysis	Infarction	+++
Pleuritic chest pain	Lung infarction	+
Dyspnea	V/Q mismatch	+
Syncope	Obstruction of pulmonary outflow tract	+
Sudden onset of symptoms	Vascular obstruction	Not significant
Substernal chest pain	Presumed cardiac ischemia	Not significant
Signs		
Unilateral leg or arm swelling	Venous obstruction	++++
Unexplained hypoxemia (Sa_{O_2} < 95% [sea level])	$\dot{V}/\dot{Q}$ mismatch	+++
Pulse rate > 100 beats/min	Cardiac stress, baroreceptors	++

Note: Differences between epidemiologic risk factors and risk factors for a diagnosis of PE or DVT in the ED reflect the ability of these factors to differentiate patients who present with symptoms consistent with PE or DVT who are ultimately diagnosed with PE or DVT from those who have PE or DVT excluded after their ED workup.
PE, Pulmonary embolism; *DVT*, deep vein thrombosis; *ED*, emergency department; $\dot{V}/\dot{Q}$, ventilation/perfusion ratio; Sa_{O_2}, saturation of oxygen measured on pulse oximetry.

The physiologic effect of an obstruction in the pulmonary vasculature is variable. Small, subsegmental PE often lyse spontaneously and may be clinically inconsequential. Subsegmental thrombi that do not spontaneously lyse but obstruct blood flow to the lung's periphery can cause pulmonary infarction, necrosis, pleural inflammation, and severe pleuritic pain. The right ventricle normally pumps through a pulmonary vascular tree with a low resistance to flow, and young individuals without cardiopulmonary disease can tolerate at least 30% obstruction from a clot with minimal symptoms or signs. Larger PE can cause an acute increase in pulmonary artery pressure due to a combination of mechanical obstruction and chemically mediated vasoconstriction of unobstructed pulmonary arteries. Increased right ventricular (RV) afterload (i.e., when the pulmonary artery systolic pressure exceeds 40 mm Hg) can lead the thin-walled right ventricle to dilate and become hypokinetic. As illustrated in Figure 74.4, with normal PA pressures, the systolic RV is crescentic in cross-section and the left ventricle (LV) is circular. However, with increased PA pressures, the systolic RV dilates asymmetrically towards the intraventricular septum, compressing the LV into a "D" shape on cross-section. This can lead to underfilling of the left ventricle, decreased cardiac output, decreased coronary artery perfusion, myocardial ischemia, circulatory collapse, and death.

DEEP VEIN THROMBOSIS

Clinical Features

Hallmarks of DVT include unilateral limb pain and swelling, though these findings can be subtle and nonspecific. Patients may report only mild cramping or a sense of fullness in the calf. The clinical signs of DVT may include edema, erythema, and warmth of the affected extremity, tenderness to palpation along the distribution of the deep

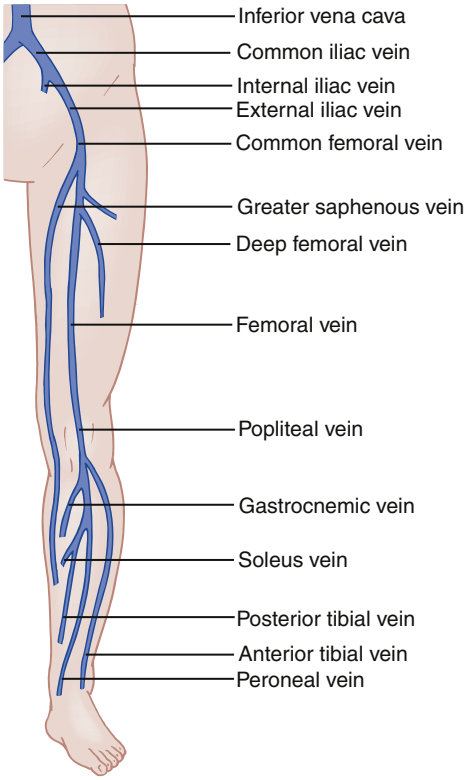

Fig. 74.2 Diagram of the leg vein anatomy relevant to the diagnosis of deep vein thrombosis. A three-point ultrasound includes the common femoral, femoral and popliteal veins. A whole-leg ultrasound adds the greater saphenous, posterior tibial, peroneal veins and the gastrocnemius vein. (Illustration courtesy of Sadie A. Kabrhel.)

venous system, dilation of superficial collateral veins, and rarely a palpable venous cord. Figure 74.5A shows a patient with a left leg DVT. To illustrate the difficulty of differentiating DVT from alternative diagnoses based on clinical examination, Figure 74.5B shows a patient with a ruptured Baker cyst in the left leg. Fever suggests an alternative diagnosis, such as cellulitis. Because the left iliac vein is vulnerable to compression by the left iliac artery (May-Thurner syndrome), leg DVT occurs with a slightly higher frequency on the left. Bilateral leg DVT is found in fewer than 10% of ED patients diagnosed with DVT.

More than 90% of upper extremity DVT occur in the presence of an indwelling catheter or similar device. Therefore, arm pain or swelling in the same arm as a catheter, infusion device, or pacemaker wire should raise suspicion for DVT. In the absence of a device, upper extremity DVT tends to occur in the dominant arm of young athletes, a condition known as Paget-Schroetter syndrome. Paget-Schroetter syndrome is an effort-induced form of thoracic outlet syndrome. Repetitive motion of the arm in the setting of hypertrophied scalene muscles or congenital cervical ribs causes compression of the subclavian vein and DVT.

Differential Diagnosis

Box 74.1 lists differential diagnoses for DVT. Venous insufficiency that causes congestion and inflammation is a common alternative diagnosis for DVT, especially since venous insufficiency increases the risk of DVT. Cellulitis is another common consideration. However, in a patient with clinical evidence of cellulitis, the frequency of concurrent DVT is only about 3%. Injuries to the gastrocnemius muscle or Achilles tendon can mimic the pain and swelling of DVT but are usually distinguished by history. Enlargement of the synovial membrane (Baker cyst) can cause popliteal pain and rupture of the cyst into the calf muscles causes inflammation that appears clinically similar to DVT. Spontaneous calf muscle hematomas can also cause pain and inflammatory changes. Many patients with systemic edema (e.g., from heart failure) will have asymmetrical swelling that raises concern for DVT.

Diagnostic Testing

Pretest Probability Estimation

Diagnosis of DVT (and PE) starts with an estimation of the pretest probability (PTP). PTP estimation helps guide the choice of diagnostic tests, the interpretation of results, and the need for follow-up testing. However, in the eyes of many clinicians the noninvasive, nonionizing nature of testing for DVT makes PTP estimation for DVT less critical than it is for PE. PTP estimation may be accomplished by the clinical gestalt of an experienced clinician or in conjunction with a clinical decision tool.

The most commonly used and well-validated clinical decision tool for DVT is the Wells DVT score (Table 74.2). Because the components of the Wells DVT score have been incorporated into clinical gestalt over the years since the score was developed, Wells DVT score and clinician gestalt have approximately equal diagnostic accuracy, and either method is acceptable. Although the Wells DVT score can categorize patients as low, intermediate or high PTP, the decision to test with a highly sensitive D-dimer or venous US is dichotomous. Therefore, it is easiest and appropriate to combine low and intermediate probability groups and consider the PTP of DVT to be low (−2 to 2 points) or high (≥3 points).

The Wells DVT score has not been validated in pregnant women, but the LEFt score has been validated in a study of 157 pregnant women. It consists of 1 point in case of left (*L*) leg suspicion, 1 point for edema (*E*), and 1 point if the suspicion occurred during the first trimester (*Ft*) of pregnancy. A LEFt score of 0 or 1 indicates low PTP. Although not validated, an approach that substitutes the LEFt score for the Wells score in pregnant women is reasonable.

Laboratory Evaluation

The D-dimer test measures the enzymatic breakdown of cross-linked fibrin from any intravascular thrombus. A normal quantitative D-dimer concentration in a patient with a low PTP (e.g., Wells score −2 to 0) excludes proximal DVT with a sensitivity of approximately 92% and a specificity of 45%.[2] This sensitivity is slightly lower than the sensitivity for PE, possibly because DVT tend to be subacute, and therefore less prone to release D-dimer, when diagnosed. Box 74.2 lists conditions other than PE and DVT that elevate the D-dimer. The specificity, and therefore the clinical usefulness, of the D-dimer may be low in patients with these conditions.

The US Food and Drug Administration (FDA) has cleared numerous D-dimer assays to aid in the diagnosis and exclusion of VTE, mostly using a cutoff of greater than 500 ng/mL to define abnormal. However, some D-dimer assays have cutoffs other than 500 ng/mL, so it is important for emergency clinicians to know the threshold considered positive in their practice setting.

Studies find that the need for venous US can be decreased by 5% by using a threshold for a positive D-dimer that is adjusted according to the patient's age using the following formula:[2-5]

$$\text{Age} \times 10\ \text{ng/mL}$$

Thus, an 80-year-old patient with a PE unlikely or non-high PTP can have DVT (or PE) excluded with a D-dimer concentration less than 800 ng/mL. This strategy maintains a diagnostic sensitivity near 95% but increases the percentage of patients who can have DVT excluded without venous ultrasonography. The safety of this strategy has not been tested with D-dimer assays with abnormal thresholds different than 500 ng/mL.

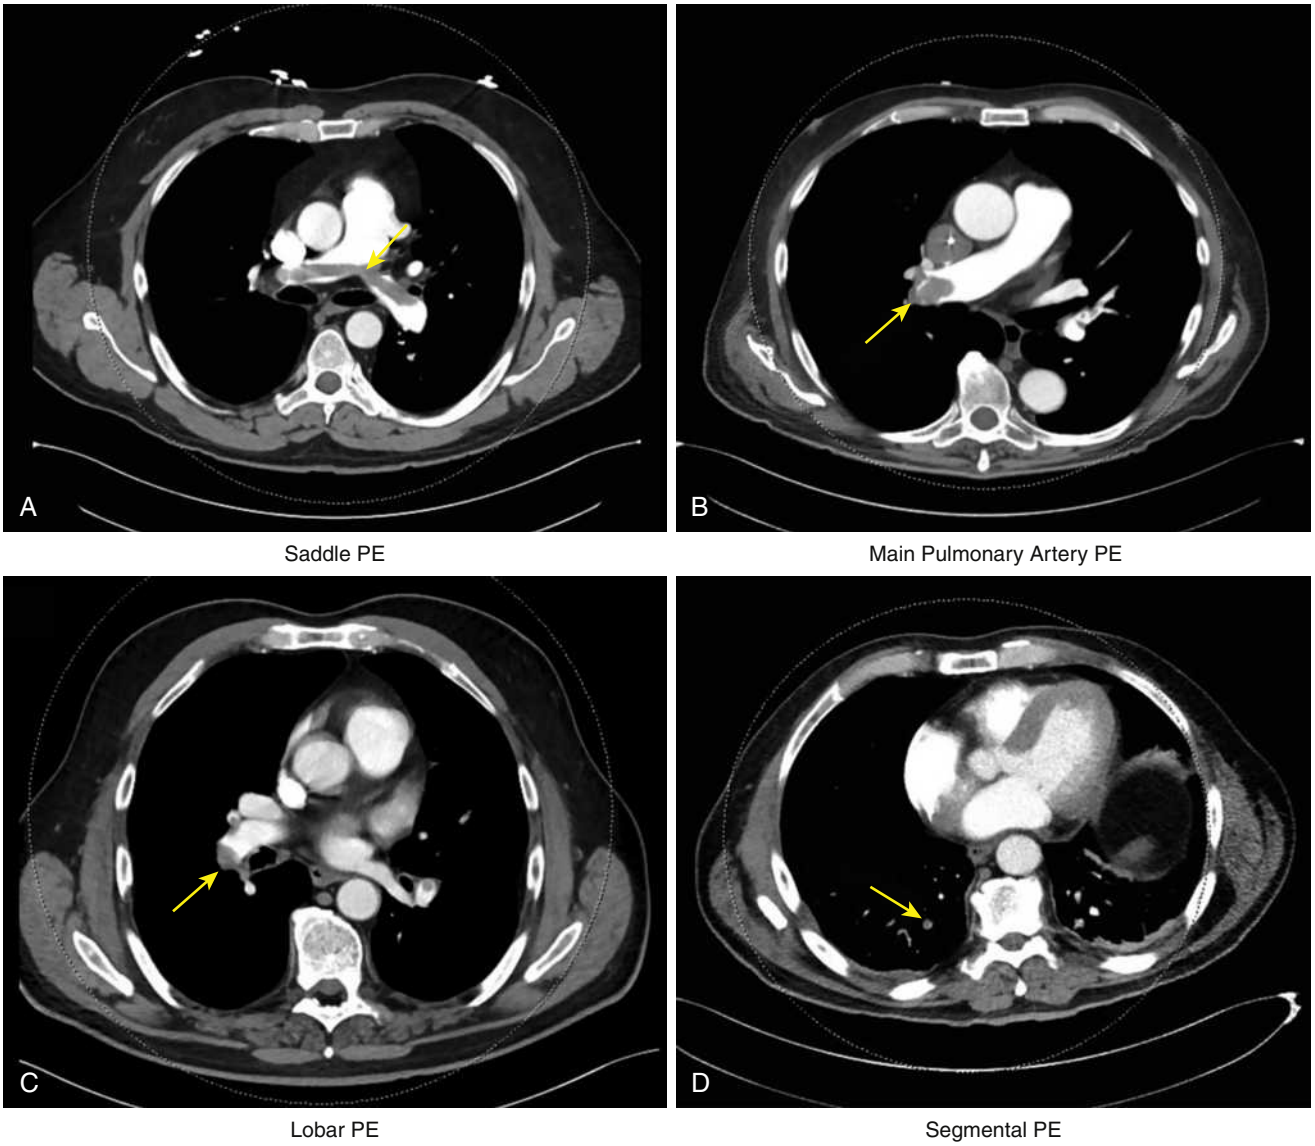

Fig. 74.3 Diagnostic computed tomography pulmonary angiography (CTPA) scans showing: (A) saddle PE, (B) right main pulmonary artery PE, (C) right lobar PE, (D) right segmental PE. The pulmonary arteries are enhanced by contrast, but PE appear as filling defects, as indicated by the yellow arrows.

An alternative to age adjustment is to apply a Bayesian approach, by which the threshold for a positive D-dimer is increased based on PTP. Using this strategy, patients with low PTP can have DVT ruled out using a threshold of 1000 ng/mL (for a test that normally uses 500 ng/mL). This approach has been shown to safely increase the proportion of patients with a negative D-dimer results from 50.9 % to 56.1%.[6]

Radiographic Evaluation

An expertly performed and interpreted positive venous ultrasound is sufficient to confirm the diagnosis of DVT. Several approaches to performing venous US are commonly used, and the emergency clinician should be aware of the US protocols used in their practice setting. Whole-leg US is the criterion standard and combines compression US of the proximal veins with ultrasound of the calf and saphenous veins. Whole-leg US is associated with a venous thromboembolism event rate at 3 months of 0.5%. A single normal whole-leg ultrasound excludes DVT regardless of PTP.

Three-point US, also called compression US, images the common femoral, femoral, and popliteal veins. Three-point US, when performed by a certified sonographer and interpreted by a board-certified radiologist, has a sensitivity of 95% and specificity of 95% for DVT. A negative three-point venous duplex ultrasound excludes the diagnosis of DVT in patients with low PTP. However, for patients at high risk, a negative three-point ultrasound is inadequate to exclude DVT as a single test. Patients with high PTP can have DVT ruled out in the ED with a combination of a negative three-point ultrasound and a negative D-dimer. A patient with high PTP, an elevated (or not performed) D-dimer, and a negative three-point ultrasound should be referred for a repeat venous US in 5 to 7 days to ensure their symptoms are not due to a distal (calf vein) DVT that later propagates proximally.

Bedside point-of-care ultrasound (POCUS) performed by a trained emergency clinician is 90% to 95% accurate compared to radiology-performed US.[7-9] Test characteristics are highest for femoral veins and lowest for saphenous and popliteal veins. POCUS of the upper extremity is not well studied and should be performed by radiology when necessary.

Ultrasound cannot be used to rule out iliac or pelvic vein thrombosis. For this, venography (typically CT) is needed. When duplex ultrasound is not available, the decision to empirically anticoagulate while awaiting the availability of ultrasound imaging should be based on the

PTP of DVT, and the risk anticoagulation poses to the patient. Generally, patients with low PTP do not need empirical anticoagulation while they wait for diagnostic imaging.

Magnetic resonance imaging (MRI) can evaluate the pelvic vasculature and inferior vena cava (IVC), which is not possible with ultrasound. Although CT venography can also visualize the pelvic veins and IVC, the accuracy varies across studies, and CT exposes patients to ionizing radiation. MRI does not produce ionizing radiation. Thus, MRI is a reasonable option to evaluate the pelvic veins of patients at high risk for pelvic vein thrombosis (e.g., a patient with gynecologic malignancy and bilateral leg swelling). Its use is limited by cost, availability, and patient tolerance. In only about 20% of patients with pelvic DVT is the clot isolated to the pelvic veins. Therefore, even when pelvic vein DVT is suspected, venous US is still the recommended first test.

Figure 74.6 provides a diagnostic flowchart for DVT that incorporates PTP. Patients with low PTP can have DVT ruled out in the ED with a negative D-dimer or venous US. Patients with high PTP can have DVT ruled out in the ED with a negative D-dimer and venous US. Patients with high PTP, a positive D-dimer, and a negative venous US of the proximal veins should have a follow-up ultrasound one week after ED discharge to look for the propagation of a distal DVT that might not have been detected during the initial ED visit.

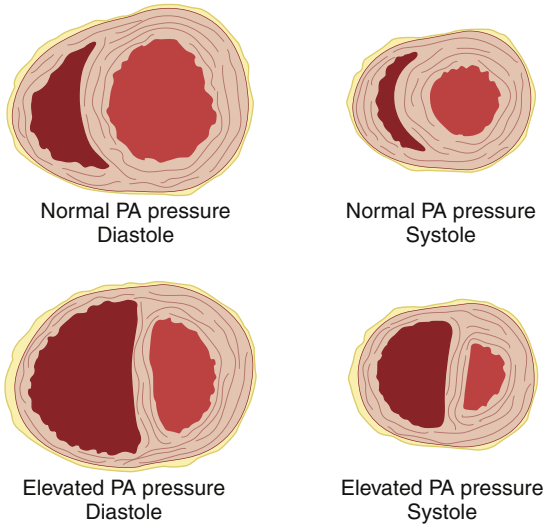

Fig. 74.4 Diagram showing the relationship of the right ventricle (RV) and left ventricle (LV) under conditions of normal pulmonary artery (PA) pressure and elevated PA pressure (i.e. in the setting of an acute PE). Note how, in the bottom right illustration, when PA pressure is elevated the RV dilates asymmetrically compressing the left ventricular septum. This can lead to decreased filling, decreased cardiac output, myocardial ischemia, hypotension and death. (Illustration courtesy of Sadie A. Kabrhel.)

Management

Patients with a positive ultrasound and patients with high PTP for whom imaging will be delayed (e.g., until the next day) should have anticoagulation initiated in the ED at the time of diagnosis, unless contraindicated.

Therapeutic anticoagulation for PE and DVT is the same. Options for initial anticoagulation are listed in Table 74.3. Direct-acting oral anticoagulants (DOACs) are as effective as warfarin at preventing recurrent VTE and are associated with fewer bleeding events, and in particular, intracranial bleeding events. They are well tolerated by patients and do not require injections or monitoring. The DOACs

BOX 74.1 Differential Diagnosis for DVT

- Venous insufficiency causing congestion and inflammation
- Cellulitis
- Muscle or tendon injury
- Baker cyst (including ruptured synovial membrane)
- Hematoma
- Arterial insufficiency and claudication
- Asymmetrical edema (e.g., due to congestive heart failure or liver disease)

Fig. 74.5 Clinical photograph showing patients with (A) deep vein thrombosis of the left leg and (B) ruptured Baker cyst of the left leg. Note the similar clinical appearance with both patients presenting with leg pain and swelling.

rivaroxaban and apixaban do not require bridging with low-molecular-weight heparin (LMWH) and are the first-choice anticoagulants for most patients with DVT.[10-12]

TABLE 74.2 Wells Score for Deep Vein Thrombosis

Clinical Feature	Score
Active cancer (treated within the previous 6 months or currently receiving palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden (for ≥3 days or major surgery within 12 weeks requiring general or regional anesthesia)	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than on the asymptomatic side (measured 10 cm below the tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep vein thrombosis	1
Alternative diagnosis at least as likely as deep vein thrombosis	–2

A score < 2 indicates that the probability of deep vein thrombosis is low. Adapted from: Wells PS, Anderson D, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet*. 1994;350:1795-1798.

For patients with active cancer, LMWH is associated with a lower risk of VTE recurrence than warfarin, but emerging evidence suggests that DOACs are also safe and effective in this population.[13,14] Concern about the ability to reverse anticoagulation should not dissuade an emergency clinician from starting DOAC therapy. Reversal agents are available for all DOACs (Box 74.3), and bleeding that does occur on DOAC therapy tends to be less severe than bleeding on warfarin.[15,16] However, DOACs are either contraindicated or not studied for the treatment of DVT associated with pregnancy, severe renal failure, liver failure, antiphospholipid antibody syndrome, and high-risk PE.

BOX 74.2 Factors Other Than VTE Associated With Positive D-Dimer Results

- Female sex
- Advanced age
- Black or African American race
- Cocaine use
- Immobility (general, limb, or neurologic)
- Hemoptysis
- Hemodialysis
- Malignancy (active)
- Rheumatologic disease (rheumatoid arthritis, systemic lupus erythematosus)
- Sickle cell disease
- Pregnancy and postpartum state
- Recent surgery (within 1 month)

Note: Warfarin use is associated with false-negative D-dimer results

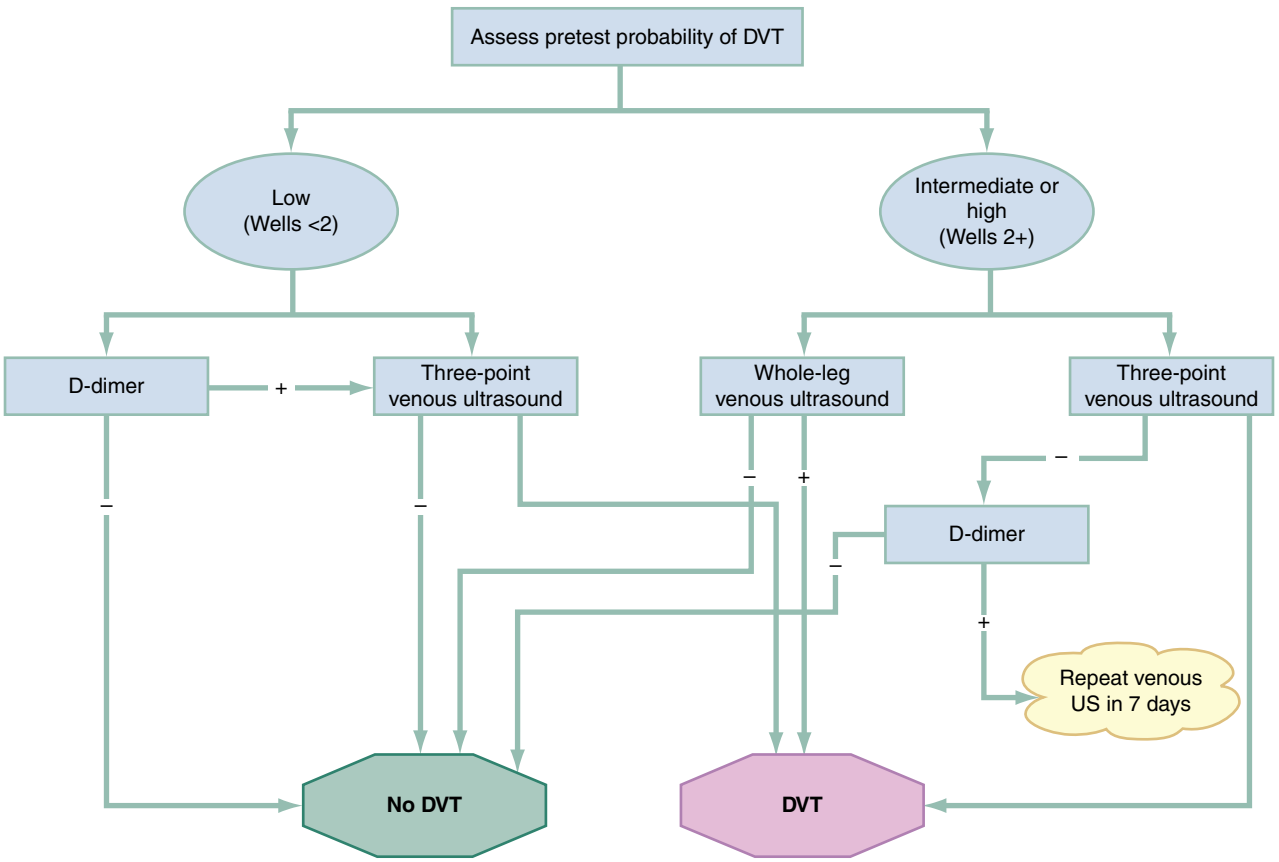

Fig. 74.6 Flowchart algorithm showing the diagnostic approach to a patient with possible acute deep vein thrombosis. *DVT*, Deep vein thrombosis; –, test negative; +, test positive; *US*, ultrasound.

TABLE 74.3 Anticoagulant Options for the Initial Treatment of DVT or PE

Anticoagulant	Initial Dose	Restriction	Time to Peak
Unfractionated heparin	70–80 U/kg, then 17–18 U/kg/h, IV	Heparin-induced thrombocytopenia	1 hour
Enoxaparin	1 mg/kg q12h or 1.5 mg/kg q24h subcutaneously	Creatinine clearance < 30 mL/min	3 hours
Dalteparin	200 unit/kg daily or 100 unit/kg q12h subcutaneously	Creatinine clearance < 30 mL/min	4 hours
Fondaparinux	5–10 mg subcutaneously	Creatinine clearance < 30 ml/min	3 hours
Rivaroxaban	5 mg by mouth q12h for 21 days with food	Creatinine clearance < 30 mL/min	2–4 hours
Apixaban	10 mg by mouth q12h × 7 days followed by 5 mg by mouth q12h with or without food	Creatinine clearance < 30 mL/min	3–4 hours

DVT, Deep vein thrombosis; *PE*, pulmonary embolism.

BOX 74.3 Reversal Agents for Anticoagulants

Anticoagulant	Reversal Agent
Heparin	Protamine sulfate
Warfarin	Fresh frozen plasma
	4-Factor prothrombin complex concentrate
	Vitamin K
Dabigatran	Idarucizumab
Rivaroxaban, Apixaban	Andexanet alfa

BOX 74.4 Contraindications to Anticoagulation

Absolute contraindications to anticoagulation include:

- Active bleeding into a critical organ or uncontrolled site
- Severe bleeding diathesis
- Recent, planned, or emergency high-bleeding-risk surgery or procedure
- Recent major trauma
- Recent intracranial, spinal or ocular hemorrhage

Relative contraindications to anticoagulation include:

- History of gastrointestinal major bleeding
- Intracranial or spinal tumors
- Previous bleeding into a tumor
- Large abdominal aortic aneurysm with concurrent severe hypertension
- Stable aortic dissection
- Recent, planned, or emergent low-bleeding-risk surgery/procedure

BOX 74.5 The VTE-BLEED Score

- Active cancer, 2 points
- Male patient with uncontrolled hypertension, 1 point
- Anemia, 1.5 points
- History of bleeding, 1.5 points
- Renal dysfunction (creatinine clearance 30–60 mL/min), 1.5 points
- Age ≥60 years, 1.5 points

Thrombolysis, whether systemic or catheter-directed, for DVT not associated with limb ischemia has not been shown to improve mortality or post-thrombotic syndrome (pain, paresthesia, induration, swelling, discoloration, and ulceration of the leg after DVT) but does increase the risk of bleeding.[17,18]

Compression stockings can no longer be advocated routinely for DVT, as the data do not support a reduction in post-thrombotic syndrome. However, the reduction in post-thrombotic syndrome may depend on how soon after DVT diagnosis the patient starts wearing the stockings, and some studies do show an improvement in quality of life, so some patients may find them beneficial.[19,20] Patients should be encouraged to ambulate after anticoagulation for DVT to reduce the incidence of post-thrombotic syndrome.

Assessing Bleeding Risk

Prior to initiation of anticoagulation for VTE, emergency clinicians should assess the patient's risk of bleeding. This is particularly important for patients with calf vein DVT without PE or isolated subsegmental PE without DVT, for whom withholding anticoagulation may be reasonable. Absolute and relative contraindications to anticoagulation are listed in Box 74.4. Bleeding risk can also be assessed using the validated VTE-BLEED score (Box 74.5). Patients with less than 2 points have a 0.5% risk of major bleeding, compared to 2.0% in patients with scores of 2 or more points.[21-23]

Superficial Vein Thrombophlebitis

Distal superficial vein thrombophlebitis can adequately be treated with nonsteroidal antiinflammatory drugs and warm compresses. The rate of DVT or PE within three months of superficial thrombophlebitis is about 3%, so patients with superficial vein thrombosis should be scheduled for a repeat ultrasound in 7 days to rule out progression. Based on the results of a large randomized controlled trial, patients with superficial thrombophlebitis involving the greater saphenous vein that extends above the knee are at risk for progression to DVT via the saphenous-femoral vein junction. In these patients, an abbreviated 45-day course of prophylactic-dose anticoagulation reduced clot extension, PE, and DVT, though the absolute rates of PE were less than 1% regardless of treatment allocation. If a greater saphenous vein clot is proximal (within 3 cm of the connection with the femoral vein; see Fig. 74.2), the risk of extension to the deep venous system is about 25% so therapeutic (full dose) anticoagulation is warranted for at least 30 days.

Isolated Calf Vein Thrombosis

The optimal management strategy for thromboses isolated to the calf veins remains controversial. About 15% of untreated isolated calf-vein DVT will extend into the popliteal vein or more proximally. Anticoagulation lowers the rate of proximal propagation and embolization.[19] However, it is not known whether the benefit of anticoagulation outweighs the risk, nor is it known whether anticoagulation is superior to a strategy

of serial venous ultrasound with anticoagulation reserved for DVT that propagate proximally. Several factors should lead the emergency clinician to favor anticoagulation, including: ongoing thrombotic risk (e.g., active cancer, immobility), severe symptoms, DVT longer than 5 cm, DVT close to proximal veins, or a history of prior VTE.[11] High bleeding risk favors surveillance without anticoagulation. When treatment with anticoagulation is used for isolated calf vein thrombosis, the dosing regimen is the same as for proximal DVT (see Table 74.3).

Phlegmasia Cerulean and Alba Dolens

Massive iliofemoral vein occlusion results in swelling of the entire leg, with extensive vascular congestion and associated venous ischemia, producing a painful cyanotic extremity. There may be associated arterial spasm resulting in phlegmasia alba dolens (painful pale leg), which may mimic an acute arterial occlusion. Elevated compartment pressures can also lead to limb ischemia. Phlegmasia is a limb-threatening emergency. Early diagnosis and prompt treatment with catheter-directed thrombolysis, percutaneous thrombectomy, or open surgical thrombectomy may be limb-salvaging. These procedures all require interventional-suite or operating-room capabilities. Therefore, emergency clinicians caring for patients with evidence of phlegmasia in hospitals without these resources immediately available should transfer to a capable center as soon as possible.

Upper Extremity Venous Thromboses

DVTs of the upper extremity have become more common in association with the increased use of indwelling venous catheters and wires for electronic cardiac devices. About half of all upper extremity DVTs are associated with an indwelling catheter, with peripherally inserted central catheters (PICCs) imposing the highest risk. Upper extremity DVT, especially axillary-subclavian vein thrombosis, occurring in the dominant arm of relatively young, physically active, patients is called Paget-Schroetter syndrome or "effort DVT." This is a form of thoracic outlet syndrome and may be secondary to compression of venous structures by hypertrophied scalene muscles or a cervical rib. While the data are not as robust as for lower extremity DVT, a similar diagnostic approach that combines pretest probability assessment, D-dimer testing, and ultrasound appears to exclude upper extremity DVT safely.[24]

Upper extremity DVT can cause PE, and all patients with DVT above the elbow require definitive treatment with anticoagulation prescribed at the same doses as lower extremity DVT (see Table 74.3). Acute PE from an upper extremity DVT occurs in 5% to 8% of patients, although the PE secondary to upper extremity DVT tend to be less severe. The recommended duration of anticoagulation for upper extremity DVT remains variable, but most published guidelines recommend at least 3 months.[11] In the absence of pain or infection, catheter-associated DVT does not automatically warrant catheter removal. The ability to anticoagulate the patient and the clinical necessity of the catheter should be considered. Optimal treatment of isolated brachial vein thrombosis, often the result of a recent intravenous infusion (infusion phlebitis), is uncertain. No study has demonstrated clear benefit for systemic anticoagulation of brachial vein thrombosis. It is reasonable to treat these clots similarly to superficial thrombophlebitis of the leg.

Complications

The most feared complication of DVT is fatal PE. However, DVT also damages venous valves, leading to venous insufficiency, varicose veins, and the post-thrombotic syndrome in 20% to 50% of patients.[25] The post-thrombotic syndrome includes persistent swelling, pain, burning sensation, varicose veins and skin changes, and nonhealing ulcers in 5% to 10% of cases.[25] Compression stockings may provide pain relief for patients with post-thrombotic syndrome, but for patients with a new diagnosis of DVT, compression stockings do not reduce the incidence of post-thrombotic syndrome.[20,26]

Disposition

Most patients with acute DVT can be discharged from the ED as long as reliable systemic anticoagulation can be established, including ensuring that the patient can obtain and pay for their anticoagulant, and follow-up with primary care, an anticoagulation clinic, or other appropriate specialty is available. Protocols that use monotherapy with a DOAC can facilitate outpatient management.[27,28] Patients without reliable follow-up or with challenges to complying with a treatment regimen should have care coordination and education in the ED, observation unit, or inpatient floor prior to discharge. Patients with severe pain may require admission. Patients with iliofemoral DVT are at higher risk for PE, especially when mobile thrombus is visualized on ultrasound, and admission is generally recommended for these patients as well. Patients with possible phlegmasia should be admitted.

PULMONARY EMBOLISM

Clinical Features

Symptoms

The clinical presentation of PE can vary from asymptomatic to sudden cardiovascular collapse. In fact, virtually any ED visit related to shortness of breath, chest pain, palpitations, dizziness, syncope, fatigue, weakness, nonspecific malaise, or functional deterioration could represent a potential PE. However, this does not mean that every patient with these symptoms should be evaluated for PE. Each patient's symptoms need to be considered in the context of the entire clinical picture, including the likelihood of alternative diagnoses.

The most common symptom of PE is dyspnea. If asked in a detailed way, 75% to 80% of patients with PE will report some sensation of dyspnea. Conversely, this means that the most common symptom of PE is absent in nearly one-fourth of patients, so clinicians should be wary of ruling out PE simply because the patient does not have dyspnea (or any particular symptom). A patient with PE typically presents with 2 to 3 days of constant or worsening shortness of breath, though symptoms can be sudden. The dyspnea may be constant or intermittent and perceived only with exertion. It may also be quite vague and described as fatigue or a feeling of not being able to take a complete breath.

Chest pain is the second most common symptom of PE. When chest pain is present, it may be described as pleuritic, achy, dull, or only as a vague discomfort. As many as one-third of patients with PE have no chest pain. Pleuritic pain is a severe, sharp pain that reproducibly halts respiration. When asked, many patients say that their pain is worse with deep breathing, but this is not necessarily pleuritic pain. While pleuritic pain is classically described, it is only present in 20% of patients with PE and is typically only associated with pleural inflammation from peripheral PE that causes pulmonary infarction and inflammation.

When PE causes pulmonary infarction, symptoms can be clinically similar to lobar pneumonia, including pleuritic chest pain, cough, hemoptysis, and fever. However, fever due to PE is typically low grade, and a temperature greater than 101.5°F (38.6°C) suggests infection rather than infarction. Moreover, the presence of several days of a cough productive of sputum suggests pneumonia rather than PE.

Unexplained, unilateral leg swelling is uncommon (<30%) in patients with PE, but when present along with dyspnea or chest pain, should raise suspicion for PE because this symptom is relatively specific.

Overall, fewer than 5% of patients who present with syncope have PE.[29-31] However, unexplained syncope, especially in a patient with PE risk factors, should be considered as a potential presentation of PE even in the absence of dyspnea or chest pain.[32]

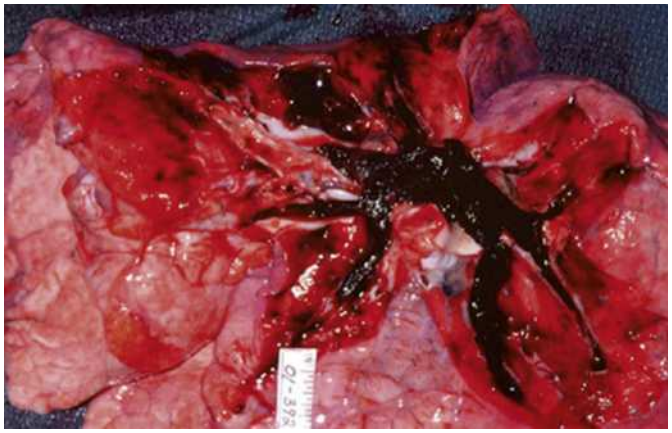

Fig. 74.7 Clinical autopsy photograph from showing a pulmonary embolism completely occluding the right ventricular outflow system.

In its most extreme form, PE can obstruct the entire right ventricular outflow system (Fig. 74.7), leading to sudden cardiovascular collapse and cardiac arrest. Approximately 25% of sudden cardiac deaths are thought to be due to PE. Prior to cardiac arrest, patients with PE typically have a heart rate higher than their systolic blood pressure (i.e., shock index >1),[33] overt respiratory distress, syncope or seizure-like activity, and significant anxiety. With impending cardiac arrest some patients manifest slow agonal rhythms, possibly due to septal wall tension leading to ischemia on the atrioventricular node and infranodal conducting pathways. Pulseless electrical activity ([PEA], >20 depolarizations/min, without palpable pulses) is the most common electrocardiographic (ECG) finding in patients with cardiac arrest due to PE. PEA manifests from right ventricular outflow obstruction and impaired right ventricular contractility. The survival rate from cardiac arrest from PE is about 20%, even if the arrest is witnessed and bolus fibrinolytic medication is given.

Vital Signs

The most common vital sign abnormality in PE is tachycardia, and about half of all patients with PE have a heart rate greater than 100 beats/min. Tachycardia may only be present or may be significantly worsened with ambulation. Tachycardia is associated with more severe PE and worse prognosis. About half of patients have an elevated respiratory rate (>20 breaths/min), though respiratory rate measurement is often variable in the ED. Hypotension (systolic blood pressure < 90 mm Hg) occurs in about 10% of patients but is the single most important predictor of PE mortality, associated with a four-fold increase in risk of death.[33] PE should be on the differential diagnosis for any patient with hypotension unexplained by an initial ED evaluation. Hypotension from PE is due to compression of the left ventricle by the deviated right ventricular septum. Left ventricular compression leads to decreased filling, decreased cardiac output, poor coronary perfusion, and a spiral of cardiac failure. Most studies evaluating the prognostic value of ED vital signs use the patient's worst vital signs (e.g., lowest blood pressure, highest heart rate). Significantly, normalization of a vital sign does not reduce the probability of PE.

Pulmonary embolism can produce hypoxemia (pulse oximetry reading <95% at sea level or <92% at higher elevations), but the degree of hypoxemia is unpredictable. Approximately half of all patients with PE have no evidence of hypoxemia, so a normal oxygen saturation, although reassuring, cannot rule out PE. However, hypoxemia that cannot be explained by a known disease process increases the likelihood of a PE diagnosis. When PE is diagnosed, the severity of hypoxemia represents a significant independent predictor of outcomes.

Physical Examination

Most patients with PE have no obvious abnormality on physical examination. The only finding that reliably increases the probability of a PE diagnosis is evidence of a DVT, such as unilateral leg asymmetry, unilateral edema, or tenderness along a deep vein.[1] On the other hand, the physical examination can provide clues to alternative diagnoses. Wheezing, or a prolonged expiratory phase on lung auscultation, suggests the alternative diagnosis of bronchospasm, which reduces the probability of PE. Bilateral rales suggest the diagnosis of left ventricular failure, although localized rales can also be heard over infarcted lung tissue.

Some clinical findings can also make the diagnosis of PE more difficult. A diagnosis of PE is more likely to be delayed in patients with baseline dementia, altered mental status, and multiple comorbidities. Additionally, symptoms, signs, and radiographic findings that support a diagnosis of pneumonia can lead to a missed or delayed PE diagnosis. Emergency clinicians may be prone to miss small, distal PE that produce pleuritic pain, rales, and peripheral densities on chest radiographs.

Differential Diagnosis

The differential diagnosis for PE includes any thoracic process associated with chest pain, dyspnea, or lightheadedness. Alternative diagnoses include pneumonia, acute coronary syndromes, aortic dissection, pericarditis, pleural or pericardial effusion, pulmonary hypertension, pneumothorax, acute decompensated congestive heart failure, asthma, chronic obstructive pulmonary disease, gastroesophageal reflux, dyspepsia, musculoskeletal pain, and nonspecific chest pain. Most alternative diagnoses can be ruled out with a thorough history, physical examination, chest radiographs, ECG, cardiac troponin testing, and echocardiography.[34,35] In ED patients evaluated for possible PE, pneumonia is the most common alternative diagnosis suspected by clinicians, and the most common alternative diagnosis found on computed tomography pulmonary angiography (CTPA), present on 5% to 10% of scans.

Diagnostic Testing

Figure 74.8 provides an algorithmic approach to PE diagnosis.

Bedside Assessment

The first step in the evaluation of possible PE is determining whether testing for PE is indicated at all. Each year, more than 16 million patients, or 12% of all patients who present to the ED, have chest pain or dyspnea. Not all of these require an evaluation for PE. Most ED patients have at least one risk factor for PE (e.g., advanced age, obesity, hormone use), so epidemiologic risk factors for PE do not necessarily mandate a workup for PE. Emergency clinicians currently evaluate 1% to 2% of all ED patients for PE with CTPA. Even more patients undergo D-dimer testing, the overuse of which has been shown to increase the use of CTPA. Because CTPA imposes risks to patients, including exposure to ionizing radiation, IV contrast, and the risk of a false-positive interpretation, it is essential to weigh the risk of a PE diagnosis against the potential risks of testing. The decision to pursue a diagnosis of PE should be based on each patient's presentation.

Determining whether objective testing is indicated requires the clinician to estimate the patient's probability of a PE diagnosis. The "test threshold" represents the point below which testing is more likely to harm than benefit the patient. For PE, the test threshold is from 1.5% to 2%. Patients with less than 1.5% to 2% probability of PE are more likely to be harmed by testing than to benefit, so testing is best avoided in these very low pretest probability patients. Conversely, patients with greater than 2% probability of PE are more likely to benefit from testing for PE than to be harmed. These patients should undergo objective

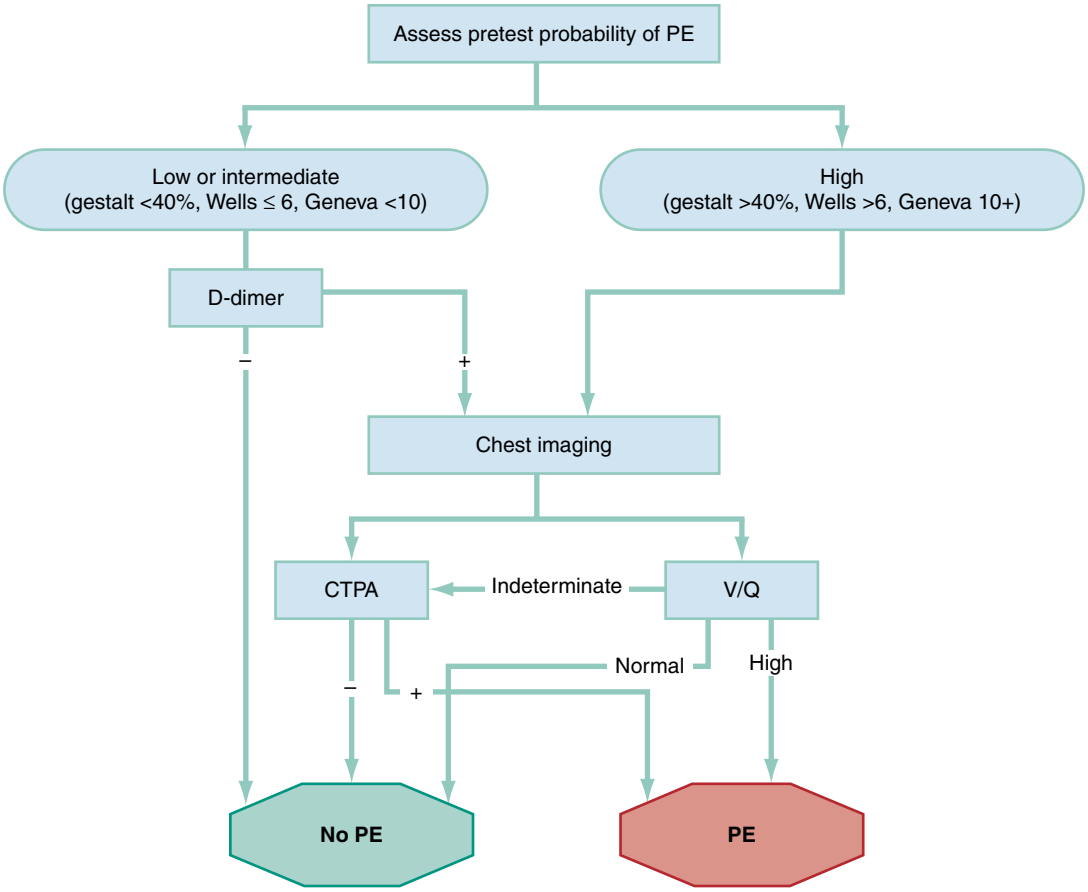

Fig. 74.8 Flowchart algorithm showing the diagnostic approach to a patient with possible pulmonary embolism. This algorithm starts with the assessment of pretest probability and includes a combination of D-dimer testing and pulmonary vascular imaging. In most cases, computed tomography pulmonary angiography (CTPA) will be the imaging test of choice, but ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning is also appropriate for patients with normal chest radiographs and a contraindication to CTPA. *PE*, pulmonary embolism; *–*, test negative; *+*, test positive; *CTPA*, computed tomography pulmonary angiography; *$\dot{V}/\dot{Q}$*, ventilation/perfusion.

testing for PE unless there is a viable alternative diagnosis, as the presence of an alternative diagnosis significantly decreases the likelihood of PE in an ED patient.

It follows then that tests that demonstrate alternative diagnoses can affect the need for a PE workup, and most patients who present with symptoms suggestive of PE will have at least some testing that provides information on alternative diagnoses. Chest radiography, although nonspecific for PE, can provide evidence of pneumonia, congestive heart failure, or pneumothorax. However, chest radiographs must be interpreted carefully, as pulmonary infarction may be visible on chest x-ray as a pleural-based, wedge-shaped infiltrate, "Hampton's hump," which can be confused for peripheral pneumonia.

Like a chest x-ray, a 12-lead ECG provides more information about the presence of alternative diagnoses (e.g., pericarditis, cardiac ischemia) than the presence of PE. When PE does cause ECG changes, it is usually a result of acute or subacute pulmonary hypertension and associated right ventricular dysfunction. The most common finding of PE on the ECG is tachycardia. Symmetric T-wave inversion in the anterior leads (V_1–V_4), the McGinn-White S1Q3T3 pattern, and incomplete or complete right bundle branch block (Fig. 74.9) indicate acute cor pulmonale and are associated with more severe PE.[36] Although these findings are nonspecific, especially in the presence of preexisting lung disease, the presence of any one of them approximately doubles the probability of PE in a symptomatic patient.

Biomarkers including cardiac troponin, B-type natriuretic peptide (BNP)/N-terminal pro-B-type natriuretic peptide (NT-pro-BNP), and lactate can all be elevated in PE. An elevated troponin indicates myocardial injury and is associated with higher mortality after PE.[37] The degree of troponin elevation predicts the degree of RV strain and mortality from PE. The appropriate use of high-sensitivity troponin assays is not well defined for PE.[38] BNP and NT-pro-BNP are released from cardiac myocytes in the setting of myocardial distention and increased pressure. Individuals with PE and high BNP or NT-pro-BNP levels are at increased risk of a complicated in-hospital course and 30-day mortality after PE. However, isolated elevated BNP is a nonspecific finding, and these results must be interpreted in the context of the complete clinical picture. PE can cause end-organ hypoperfusion, and normotensive PE patients with elevated plasma lactate (≥2 mmol/L) have significantly higher mortality, are more likely to develop of shock or hypotension, require intubation, or CPR.[39]

Bedside ultrasound can be useful when PE is suspected. The presence of acute DVT on bedside venous ultrasound in a patient with new symptoms of PE is equivalent to a PE diagnosis and sufficient to initiate treatment. Emergency clinician–performed venous ultrasound is 86% to 96% sensitive and 93% to 97% specific compared to radiology-performed ultrasound.[40] However, emergency clinicians must keep in mind that fewer than half of patients with PE have no ultrasound evidence of DVT, so a negative ultrasound is not sufficient to rule out PE.

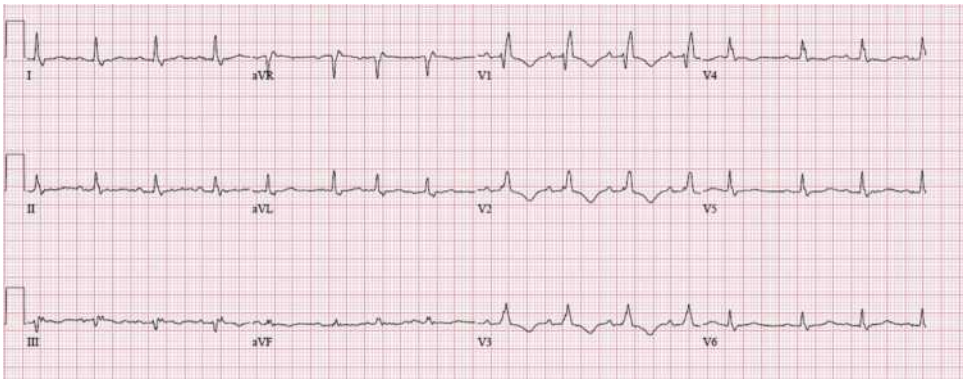

Fig. 74.9 Electrocardiogram from a patient who presented with PE in the right main pulmonary artery (see Fig. 74.3B). The presence of deep T-wave inversions in leads $V_{1–3}$, a new complete right bundle branch block, and the S1Q3T3 pattern all indicate right ventricular dysfunction (acute cor pulmonale) and are associated with poor prognosis.

TABLE 74.4 Wells Score for Pulmonary Embolism

Clinical Feature	Score
Previous PE or DVT	1.5
Heart rate > 100 beats per min	1.5
Recent surgery or immobilization (within 4 weeks of presentation)	1.5
Clinical signs of DVT (swelling or tenderness on palpation of the calf)	3
Hemoptysis	1
Active cancer (treated within the previous 6 months or currently receiving palliative treatment)	1
An alternative diagnosis is less likely than PE	3

A score <2 indicates that the probability of deep vein thrombosis is low, 2–6 intermediate, and >6 high.
PE, Pulmonary embolism; *DVT*, deep vein thrombosis.

TABLE 74.5 The Revised Geneva Score for Pulmonary Embolism

Clinical Feature	Score
Age >65 years old	1
Previous PE or DVT	3
Recent surgery or immobilization (within 4 weeks of presentation)	2
Active cancer (treated within the previous 12 months or currently receiving palliative treatment)	2
Unilateral leg pain	3
Hemoptysis	2
Heart rate	<75 = 0 75–94 = 3 >95 = 5
Pain on palpation and unilateral edema of the leg	4

A score <4 indicates that the probability of deep vein thrombosis is low, 4–10 intermediate, and >10 high.
PE, Pulmonary embolism; *DVT*, deep vein thrombosis.

Point-of-care echocardiography showing RV dilatation (a ratio of the RV to LV internal diameter in diastole [RV : LV ratio] >1 : 1) should also increase the clinical suspicion of PE, especially in a patient with no previous lung disease.

Pretest Probability Assessment

Once the decision to initiate a PE evaluation has been made, the next step is determining the patient's PTP of PE. The PTP guides what (if any) objective testing for PE should be performed and whether empirical therapy should be initiated. There are several acceptable methods for estimating PTP. An experienced emergency clinician can accurately assess PTP using their clinical experience, or "gestalt."[35] In fact, clinical gestalt has been shown to be the most accurate method of PTP assessment. Clinicians can also use one of several clinical scoring systems. The Wells Score (Table 74.4) and the Revised Geneva Score (Table 74.5) are both well-validated.

For the purposes of determining further testing, the Wells score can be divided into non-high (0–6 points) or high (>6 points) probability. A three-tiered interpretation of the Wells score is also accepted, but the intermediate-risk middle category is less easily adapted to binary ED decision making. The Wells score includes a subjective question that asks whether PE is the most likely diagnosis. This empowers the clinician to include elements that may be uncommon yet important to consider in the PTP assessment, such as inherited clotting disorders. However, the subjective component seems to power most of the predictive value of the Wells score and may introduce intrarater variability.

The Revised Geneva Score (and a simplified version of the score), includes only objective elements. Patients with 0 to 3 points are defined as low probability, 4 to 10 points as intermediate probability, and greater than 10 points as high probability. Several studies have found the Wells score and Geneva score perform similarly in clinical practice, and both of these systems can be built into clinical decision support systems to guide testing. Importantly though, when used alone, none of these methods reproducibly identify the very low-risk population whose PTP lies below the 2% test threshold.

Pulmonary Embolism Rule-Out Criteria

To identify the patients in whom PE can be safely excluded without objective testing, emergency clinicians should use the PE rule-out criteria, or "PERC rule" (Box 74.6).[41-43] When the clinician's unstructured PTP assessment (i.e., clinical gestalt) for PE is low, and each of the eight elements of the rule is satisfied, the PERC rule identifies patients whose probability of PE is below the 2% test threshold. For these patients, laboratory testing or imaging for PE is more likely to expose the patient to harm than to provide benefit, so testing should not be performed. The PERC rule has been validated in large studies in the United States and Europe.[41,43] When calculating the PERC, it is important that PTP be

BOX 74.6 Pulmonary Embolism Rule-Out Criteria (PERC Rule)

- Age < 50
- Pulse < 100
- Sao_2 > 94%
- No unilateral leg swelling
- No hemoptysis
- No recent trauma or surgery
- No prior PE/DVT
- No hormone use

determined using the clinician's gestalt, as the PERC rule contains similar elements to both the Wells and Geneva scores, so may not perform as well in combination with these methods of PTP assessment.

D-Dimer Testing

D-dimer assays are 95% to 98% sensitive and 40% to 55% specific for PE.[2,44] Therefore, patients with a non-high PTP (gestalt PTP < 40%, Wells score <6, or Revised Geneva score <5) can have PE excluded with a normal D-dimer concentration with negative predictive value of 99% to 100%. Large, real-world studies have shown that many ED patients still undergo CTPA despite a negative D-dimer. However, emergency clinicians should recognize that a false-positive CTPA is actually more likely than a false-negative D-dimer, so ordering imaging "to be safe" exposes the patient to unnecessary risk.

When false-negative D-dimer results do occur, it may be because the PE is subacute or chronic. The half-life of circulating D-dimer is less than 8 hours. However, the clinical relevance of the circulating half-life is unknown, because large PE continue to release D-dimer as they lyse over time. False-negative D-dimer measurements may also be seen with severe lipemia and ongoing warfarin therapy. Isolated subsegmental PE seen on CTPA may also be associated with negative D-dimer results, but in these cases the emergency clinician will need to determine whether the D-dimer is a false negative or the CTPA is a false positive.

Many conditions elevate the D-dimer other than PE and DVT (see Box 74.2). Because a positive result often necessitates diagnostic imaging, emergency clinicians should consider the likelihood of a positive D-dimer before ordering the test. This is especially true when CTPA carries additional risk to the patient (e.g., pregnant women, renal insufficiency) or is contraindicated (e.g., anaphylaxis with contrast dye).

The threshold for a negative D-dimer can vary by assay and local laboratory. In many laboratories, the threshold below which D-dimer is considered negative is 500 ng/mL. When the 500 ng/mL cutoff is used, the threshold for a positive D-dimer can safely be adjusted according to the patient's age using the following formula:[2-5]

$$\text{Age} \times 10\ \text{ng/mL}$$

This strategy maintains a sensitivity greater than 95% and negative predictive value greater than 98%, but increases the percentage of patients who can have PE excluded without pulmonary vascular imaging by 5% to 6% overall and 10% to 20% in patients greater than 70 years old.[5] The safety of this strategy has not been tested with D-dimer assays with abnormal thresholds different than 500 ng/mL.

As with DVT, emergency clinicians can also apply a Bayesian approach by which the threshold for a positive D-dimer is increased based on PTP. Using this strategy, patients with low PTP can have DVT ruled out using a threshold of 1000 ng/mL (for a test that normally uses 500 ng/mL).[45] A study of 2017 patients evaluated for PE found that this approach was associated with no missed PE diagnoses on follow-up and reduced the need for chest imaging by 17%.

The YEARS algorithm is another approach that uses three questions from the Wells score (clinical signs of DVT, hemoptysis, alternative diagnosis less likely than PE) to identify low PTP patients for whom the higher D-dimer threshold can be used.[46] YEARS has been validated in a large multicenter study and decreased the need for CTPA by 14%.[47] However, in the validation study, the same result was achieved using only the subjective question of the Wells score, "Are alternative diagnoses less likely than PE?," as the criteria for low PTP. The YEARS criteria have also been adapted for use in pregnant women.[48] In a study of 512 pregnant women suspected of having PE, CTPA was avoided in 195 (39%) patients, and 20 women were diagnosed with PE. However, the efficiency of the score varied significantly according to the trimester of pregnancy. Imaging was deemed not indicated for 65% of women in the first trimester of pregnancy, but for only 32% in the third trimester.

Computed Tomography Pulmonary Angiography

When the PTP is high or the screening D-dimer is positive, pulmonary vascular imaging is advised. Most centers use CTPA as the primary imaging method for evaluating possible PE. CTPA is readily available, minimally invasive, and can identify alternative processes that might explain the patient's symptoms.

Many PE, especially central PE, can be easily visualized by the emergency clinician. PEs appear as hypodensities in contrast-filled pulmonary arteries. Most PE will be in the central part of the lumen near the bifurcation of a vessel. Filling defects that appear peripheral or concentric may be chronic or may represent alternative processes or artifacts. A PE that extends across the bifurcation of both main pulmonary arteries is called a saddle PE. Although they tend to be large clots, many saddle PE are not occlusive, so patients may be minimally symptomatic. PE that extend into the pulmonary arteries may lodge in a main pulmonary artery, intralobar, lobar, segmental or subsegmental artery (see Fig. 74.3). PE are typically described according to their most proximal location, so a clot that extends from the lobar pulmonary artery into a segmental branch is described as lobar. While radiologists may describe a PE as "massive" based on the size of the clot, emergency clinicians should remember that "massive PE" is a physiologic diagnosis based on hemodynamic instability, and clot burden on CT has only a loose association with mortality. Due to this confusion, the term *high-risk PE* is a preferred term to describe the PEs resulting in hemodynamic instability.

A technically adequate CTPA scan, performed on a multidetector row scanner, has sensitivity and specificity of 90% to 95%. Technical adequacy requires more than 200 HU of contrast opacification in the main pulmonary artery and absence of motion artifact. Scans that are not technically adequate are less sensitive and specific for PE. Although the sensitivity of CT can be improved slightly by extending the scan to include the leg veins (CT venography), the technical reliability of this technique is limited and the additional radiation required is substantial, so most centers do not routinely perform "run-off" venography. As with any test, the probability of PE after CTPA should be based on a combination of the patient's pretest probability and the CTPA results. A negative CTPA in a patient with high pretest probability should be interpreted with caution because the negative predictive value in this population is only about 60%. Further testing such as leg ultrasound may be indicated to rule out PE. Similarly, an isolated subsegmental filling defect on CTPA in a patient with low pretest probability and no DVT on leg ultrasound is likely to be a false positive. In these cases, treatment should be based on shared decision making with the patient. The increased detection of isolated subsegmental filling defects on more thinly collimated CTPA images, combined with increased CTPA use, has led to the overdiagnosis of PE.

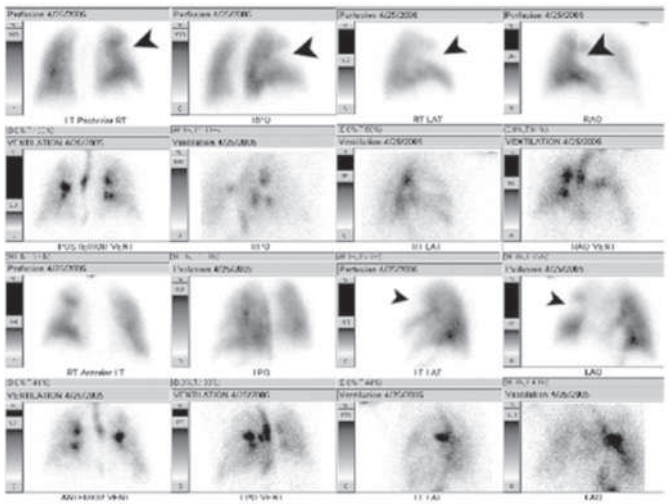

Fig. 74.10 Diagnostic ventilation/perfusion (V̇/Q̇) scan. These images are high probability for acute pulmonary embolism based on the criteria defined in the prospective investigation of pulmonary embolism diagnosis (PIOPED). The first and third rows project the perfusion phases of the examination, and the second and fourth rows show the ventilation phases. The black arrowheads point to wedge-shaped defects in the perfusion images. Comparison with the corresponding ventilation view immediately below shows relatively homogeneous scintillation activity in the anatomic segments that lack perfusion.

Ventilation/Perfusion Scan

The V̇/Q̇ scintillation scan remains a viable diagnostic option for patients with contraindications to iodinated intravenous contrast and vulnerable kidney function. The accuracy and precision of the V̇/Q̇ scan were shown in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, which compared the results of V̇/Q̇ scanning with the most accurate criterion standard test available at the time, catheter pulmonary angiography. Figure 74.10 shows the results of a high-probability V̇/Q̇ scan. A high-probability V̇/Q̇ scan confirms the diagnosis of PE, and a normal scan (i.e., no perfusion defect) excludes PE. However, only one-third of V̇/Q̇ scans fall into either the high-probability or normal categories. The remaining two-thirds of scans are read as either low probability or intermediate probability. These categories indicate indeterminate scans that are essentially nondiagnostic. Many patients, therefore, require additional diagnostic testing after an indeterminate V̇/Q̇ scan. When feasible, these patients should undergo CTPA, though negative bilateral venous ultrasonography of the legs can also be used to rule out PE in patients with a low PTP and a low-probability V̇/Q̇ scan.

V̇/Q̇ scanning is generally associated with lower fetal radiation exposure than CTPA. When the perfusion portion of the V̇/Q̇ scan is performed first, and the scan is normal, the ventilation portion of the scan may be avoided, further reducing the radiation exposure to the woman and the fetus. However, for technical reasons, most institutional protocols perform the ventilation portion of the scan first. In addition, because many women will require CTPA after an indeterminate V̇/Q̇ scan, and will be exposed to two doses of radiation, many institutions now recommend shielded, low-radiation CTPA rather than V̇/Q̇ scanning as the first test for pregnant women.

Pregnant Women

Pregnancy is a hypercoagulable state, and when combined with mechanical compression of the pelvic veins by the gravid uterus, increases the risk of PE, especially in the third trimester and postpartum period. However, when studied in ED patients undergoing diagnostic testing for PE, pregnancy does not appear to increase the risk of a VTE diagnosis.[1] This is because emergency clinicians tend to be conservative in their approach to the pregnant woman with signs or symptoms of PE and have a much lower threshold to order diagnostic testing. Most pregnant women whom emergency clinicians test for PE have a low clinical probability, though there is significant variation in the threshold to test because clinical decision rules, including the Wells score and PERC rule, have not been validated in pregnant women.

VTE in pregnancy is relatively rare, so even the largest studies are limited to a few dozen positive cases.[48] Because D-dimer levels are increased in pregnancy, the lower threshold to test employed by emergency clinicians results in many pregnant women being referred for imaging. However, pregnant women are justifiably cautious about fetal radiation exposure and may not choose to undergo CTPA when it is recommended. Emergency clinicians should have a predefined strategy for diagnostic testing of pregnant women with possible PE. Guidelines vary in their recommendations, and there is no single, data-driven approach to testing.

Before initiating any testing for PE, it is prudent to explain the diagnostic options to the patient, including the risks and benefits of different approaches, obtain her preferences, and document these stated preferences. Pregnant women should be given the opportunity to consider their testing preferences free from the bias associated with knowing D-dimer or other test results.

When the decision is made to pursue testing, it is best to begin with noninvasive, nonionizing testing. In a study of 395 pregnant women (28 [7.1%] with PE), bilateral lower extremity ultrasound and D-dimer testing were performed as first-line tests to either rule in or rule out VTE.[49] A positive lower extremity ultrasound for DVT in a pregnant woman suspected of having PE is sufficient to confirm the diagnosis of PE and to initiate treatment. When the conventional threshold for a positive D-dimer used for nonpregnant patients is applied (e.g., <500 ng/mL), a normal D-dimer excludes PE in pregnant women as reliably as in the nonpregnant population. However, most women will have a positive D-dimer and negative venous ultrasound results. In the previously mentioned study, 83% of women required CTPA or V̇/Q̇ scanning. Therefore, before pursuing this approach, pregnant women should be informed that imaging is likely to be needed. This will inform their shared decision to pursue a PE workup.

One reason a small proportion of women can be ruled out with noninvasive testing is that D-dimer levels fluctuate and steadily increase throughout pregnancy until they peak on the first day after delivery.[50] The proportion of women with normal D-dimer values is 50% to 85% in the first trimester, decreases to 23% to 33% in the second trimester, and to 0% to 4 % in the third trimester. Pregnancy-specific threshold values for each trimester have been suggested to help increase the proportion of women who can have PE ruled out without imaging. One model suggests using a threshold of 750 ng/mL in the first trimester, 100 ng/mL in the second trimester and 1250 ng/mL in the third trimester. However, outcome data supporting this approach are limited to studies with fewer than 20 pregnant women with VTE, so the safety of D-dimer adjustment based on pregnancy trimester has not been validated.

The YEARS approach has been modified for use in pregnancy, with a screening venous ultrasound performed first, followed by PTP-adjusted D-dimer based on the same three Wells score criteria used in the original study.[48] Among 498 women, 4 had DVT on screening ultrasound, and 16 were diagnosed with PE based on a combination of PTP adjusted D-dimer testing and chest imaging. Nearly one-third of women in the third trimester had PE ruled out without imaging, and only one subject was diagnosed with DVT after having PE ruled out in the ED. However, as with other studies of pregnant women, the small

TABLE 74.6 Fetal and Maternal Radiation Exposure Associated With Diagnostic Tests for PE

Imaging Method	Fetal Exposure (mSv)	Maternal Exposure (mSv)
Chest x-ray (two view)	<0.01	<0.01
Ventilation lung scan	0.1–0.3	<0.01
Perfusion lung scan	0.1–0.6	0.2–1.2
CTPA	0.01–0.66	7–70
Catheter pulmonary angiogram	3–6	15–20
CT venogram of the iliac veins	10–50	10–50

CTPA, Computed tomography pulmonary angiography; *CT*, computed tomography.

number of PE events makes it difficult to recommend this approach confidently.

For pregnant women for whom PE cannot be ruled in with ultrasound or ruled out with D-dimer, chest imaging is indicated. In this case, women often have questions about radiation exposure and the safety of the fetus. For comparison, the fetal radiation exposures of various tests for PE are presented in Table 74.6. The average dose of naturally occurring background radiation is 0.5 to 1.0 mSv over a normal gestation. Exposure to radiation doses lower than 50 mSv has not been shown to be associated with different pregnancy outcomes.[51] In the first two weeks after conception, a radiation dose of 50 to 100 mSv can cause the failure of blastocyst implantation and spontaneous miscarriage. Assuming the blastocyst implants, radiation effects are unlikely because blastocyst cells are omnipotent and damaged cells can be replaced (the "all-or-none period"). The embryo is most vulnerable to radiation between the eighth and fifteenth weeks of gestation. A definitive threshold has not been determined, but it is estimated that the risk of congenital malformations, intrauterine growth restriction, intellectual disability, and pregnancy loss increase at radiation doses beyond 100 to 200 mSv. The risk of cancer associated with fetal radiation exposure is difficult to predict, but even with higher radiation doses many times higher than those used for CTPA, the increase in lifetime cancer due to in-utero radiation exposure from diagnostic imaging seems to be negligible.[51]

Data comparing fetal radiation exposure do not clearly favor $\dot{V}/\dot{Q}$ or CTPA. Regardless of the approach, efforts should be made to minimize radiation exposure to the developing fetus. Because ^{99}Tc is excreted in the urine, prehydration with intravenous saline, frequent postscan urination, and insertion of a urinary catheter are unproven steps to reduce fetal exposure to radiation associated with $\dot{V}/\dot{Q}$ scanning. When CTPA is performed, shielding of the abdomen and tube voltage modulating technology may reduce fetal radiation exposure. Thus, while high-probability (i.e., diagnostic) or normal (i.e., exclusionary) $\dot{V}/\dot{Q}$ scanning may be associated with lower fetal radiation exposure than CTPA, the difference in radiation exposure of the two tests is minimal. However, many women have nondiagnostic $\dot{V}/\dot{Q}$ scans and need to undergo CTPA that will expose them to more radiation than if a CTPA had been performed first. Therefore, CTPA seems the best first test for most pregnant women.

Clinical Course

The clinical course of patients with obstructive PE can be unpredictable. The mortality of high-risk PE is greater than 25%,[52] but many patients with high-risk PE remain stable in the ED after initial resuscitation. In otherwise stable patients, clinical deterioration can occur rapidly due to embolization of clot material, release of mediators of pulmonary vasospasm, sudden dysrhythmias, or respiratory failure. Of ED patients without hypotension, 1% to 3% experience cardiac arrest while in the ED or die within 24 hours. Factors independently associated with clinical deterioration after PE diagnosis include ED hypotension, hypoxemia, prior coronary artery disease, residual deep vein thrombosis, and right heart strain on echocardiogram. Clues to oncoming cardiopulmonary decompensation include worsening respiratory distress and hypoxemia, increasing tachycardia and shock index, or a change in mental status. Deterioration in the ECG from a narrow-complex tachycardia to an incomplete right bundle branch block to a complete right bundle branch block also suggests life-threatening pulmonary hypertension.

Management

The treatment of acute PE depends on the risk that the PE poses to the patient (Table 74.7). PE are classified as high risk, or "massive," intermediate risk or "submassive," and low risk. These risk categories are defined by the hemodynamic status of the patient and the presence of right ventricular dysfunction, not by the size of the thromboembolism. Therefore, to avoid confusion sometimes associated with the term "massive" and "submassive" we use the terms high, intermediate, and low risk.

High-risk PE result in hemodynamic instability, defined as a systolic arterial pressure (SBP) less than 90 mm Hg that is sustained for 15 minutes and not caused by dysrhythmia or other etiology.[57] Patients who have a drop in their baseline SBP of greater than 40 mm Hg, who require vasopressors, or who have profound bradycardia (<40 bpm) can also be considered high-risk PE. It is also reasonable to require that the patient's PE be large enough to conceivably cause the patient's hemodynamic instability.

Intermediate-risk PE requires that the patient be hemodynamically stable and have evidence of RV dysfunction on echocardiogram or a positive troponin. Echocardiographic evidence of RV dysfunction includes RV dilatation, hypokinesis, or bowing of the intraventricular septum toward the left ventricle (LV). RV dilatation on CT (defined as an RV : LV ratio >1) is 88% sensitive for RV dysfunction on echocardiogram, but is only 39% specific.[58] CT evidence of RV dysfunction should, therefore, be confirmed with echocardiography. Some guidelines also use a clinical risk model (i.e., the pulmonary embolism severity index [PESI]) and troponin values to subcategorize patients as intermediate-low or intermediate-high risk.[59]

Low-risk PE are hemodynamically stable with no evidence of RV dysfunction. These risk categories are important because the mortality increases from less than 1% to 3% (low risk) to 3% to 15% (intermediate risk) to 15% to 50% (high risk). Accordingly, advanced therapies like thrombolysis or thromboembolectomy are not recommended

TABLE 74.7 Risk Stratification and Treatment Recommendations for Acute PE

Category	Criteria	Action
Low-Risk PE	Hemodynamically stable	Initiate anticoagulation (DOAC preferred)
	No right ventricular dysfunction	Safe for outpatient treatment based on Figure 74.12 or negative Hestia criteria
	Troponin negative	Optional admission to inpatient service or observation unit
Intermediate-Risk PE	Hemodynamically stable	Initiate anticoagulation (DOAC or heparin)
	Any of the following:	Thrombolysis or thromboembolectomy in a minority of cases
	• Right ventricular dysfunction on echocardiogram or CTPA	Activate PERT
	• Troponin positive	Admission to monitored bed or ICU
	• BNP/NT-pro-BNP positive	
High-Risk PE	Hemodynamically unstable	Initiate anticoagulation (heparin if thrombolysis or thromboembolectomy planned)
		Activate PERT
		Thrombolysis or thromboembolectomy unless contraindicated
		Admission to ICU

for low-risk patients, sometimes recommended for intermediate-risk patients, and recommended for high-risk patients.

Figure 74.11 presents a comprehensive management plan for diagnosed PE. This algorithm includes the spectrum of treatment options, including some that may only be available in a large tertiary care service hospital. Emergency clinicians should be familiar with the treatment options where they practice. Pathways similar to this have been adopted by multidisciplinary PE response teams (PERT).[52,60-62] At the left-most side of the algorithm, patients can be discharged to home from the ED. At the right side, patients with a massive PE and no contraindications receive thrombolysis or are referred for emergent thromboembolectomy.

Airway, Oxygenation, and Ventilation

Hypoxemia is common in PE and hypoxemic vasoconstriction may worsen acute pulmonary hypertension, so supplemental oxygen should target pulse oximetry above 90%. However, intubation and positive-pressure ventilation increase intrathoracic pressure, lower preload, and can worsen RV compression of the LV. This may precipitate hemodynamic collapse and cardiac arrest in patients with severe PE. Intubation should, therefore, be avoided whenever possible. When intubation is necessary, the emergency clinician should optimize pre-intubation hemodynamics, including with vasopressors, prior to induction.[53]

Hemodynamic Resuscitation

For patients who present with actual or pending hemodynamic instability, the first priority is resuscitation. For hypotensive patients, small volume boluses (such as 250–500 mL) can improve cardiac output.[12] However, excessive administration of intravenous fluids can worsen RV distension and compression of the left ventricle by the intraventricular septum. Figure 74.5 shows that with increased pulmonary artery pressures, the dilated RV distends towards the intraventricular septum, which can decrease left ventricular volume. This, in turn, decreases cardiac output, increases myocardial ischemia, and can precipitate cardiac arrest.

If the administration of intravenous fluids is contraindicated or no longer beneficial, vasopressors should be administered, and norepinephrine should be the initial agent in blood pressure support.[12] Dobutamine is useful as an adjunct but may worsen hypotension unless coadministered with norepinephrine.

Extracorporeal membrane oxygenation (ECMO) can unload the right ventricle, increase cardiac output, and provide a bridge to thrombolysis or thromboembolectomy for patients with high-risk PE.[54] ECMO requires institutional infrastructure and expertise which is only available in specialized centers. Survival of patients with PE who require ECMO is about 70%.[54,55]

Pulmonary Vasodilators

Inhaled nitric oxide and epoprostenol have been shown to decrease pulmonary vascular resistance and pulmonary arterial pressure in case series. However, a clinical trial failed to show benefit of inhaled nitric oxide in hemodynamically stable patients with PE and right ventricular dysfunction.[56]

Standard Anticoagulation

Patients with imaging confirming DVT or PE should receive anticoagulation using one of the agents in Table 74.3, administered in the ED as soon as the diagnosis is confirmed. Patients with a high PTP, no contraindication to anticoagulation, and evidence of hemodynamic instability, including recent syncope, hypotension, hypoxemia, or right heart dysfunction, should receive empirical anticoagulation while awaiting pulmonary vascular imaging. Direct-acting oral anticoagulant medications apixaban or rivaroxaban are now considered first-line therapy for most PE.[11] These drugs specifically inhibit one enzyme in the clotting pathway, are orally available, and provide therapeutic anticoagulation effect as rapidly as subcutaneous LMWH. Clinical trials support the use of apixaban and rivaroxaban without prior or concomitant use of heparin. By obviating the need for twice-daily subcutaneous injections and blood monitoring, these drugs can also facilitate outpatient treatment of PE and DVT.[28] DOAC medications have not been extensively tested in patients with severe PE, pregnant women with PE, or in patients with hypercoagulable states like antiphospholipid antibody syndrome. For these patients, LMWH is preferred. Compared to unfractionated heparin, meta-analyses show that LMWH is associated with lower rates of major hemorrhage, heparin-induced thrombocytopenia, and recurrent VTE, and has similar cost. Most hematologists, internists, and obstetricians prefer that pregnant patients with VTE receive twice-daily LMWH. Both DOAC and LMWH effects can be unreliable in patients with severe renal impairment. For these patients, unfractionated heparin is usually preferred. Patients with a history of

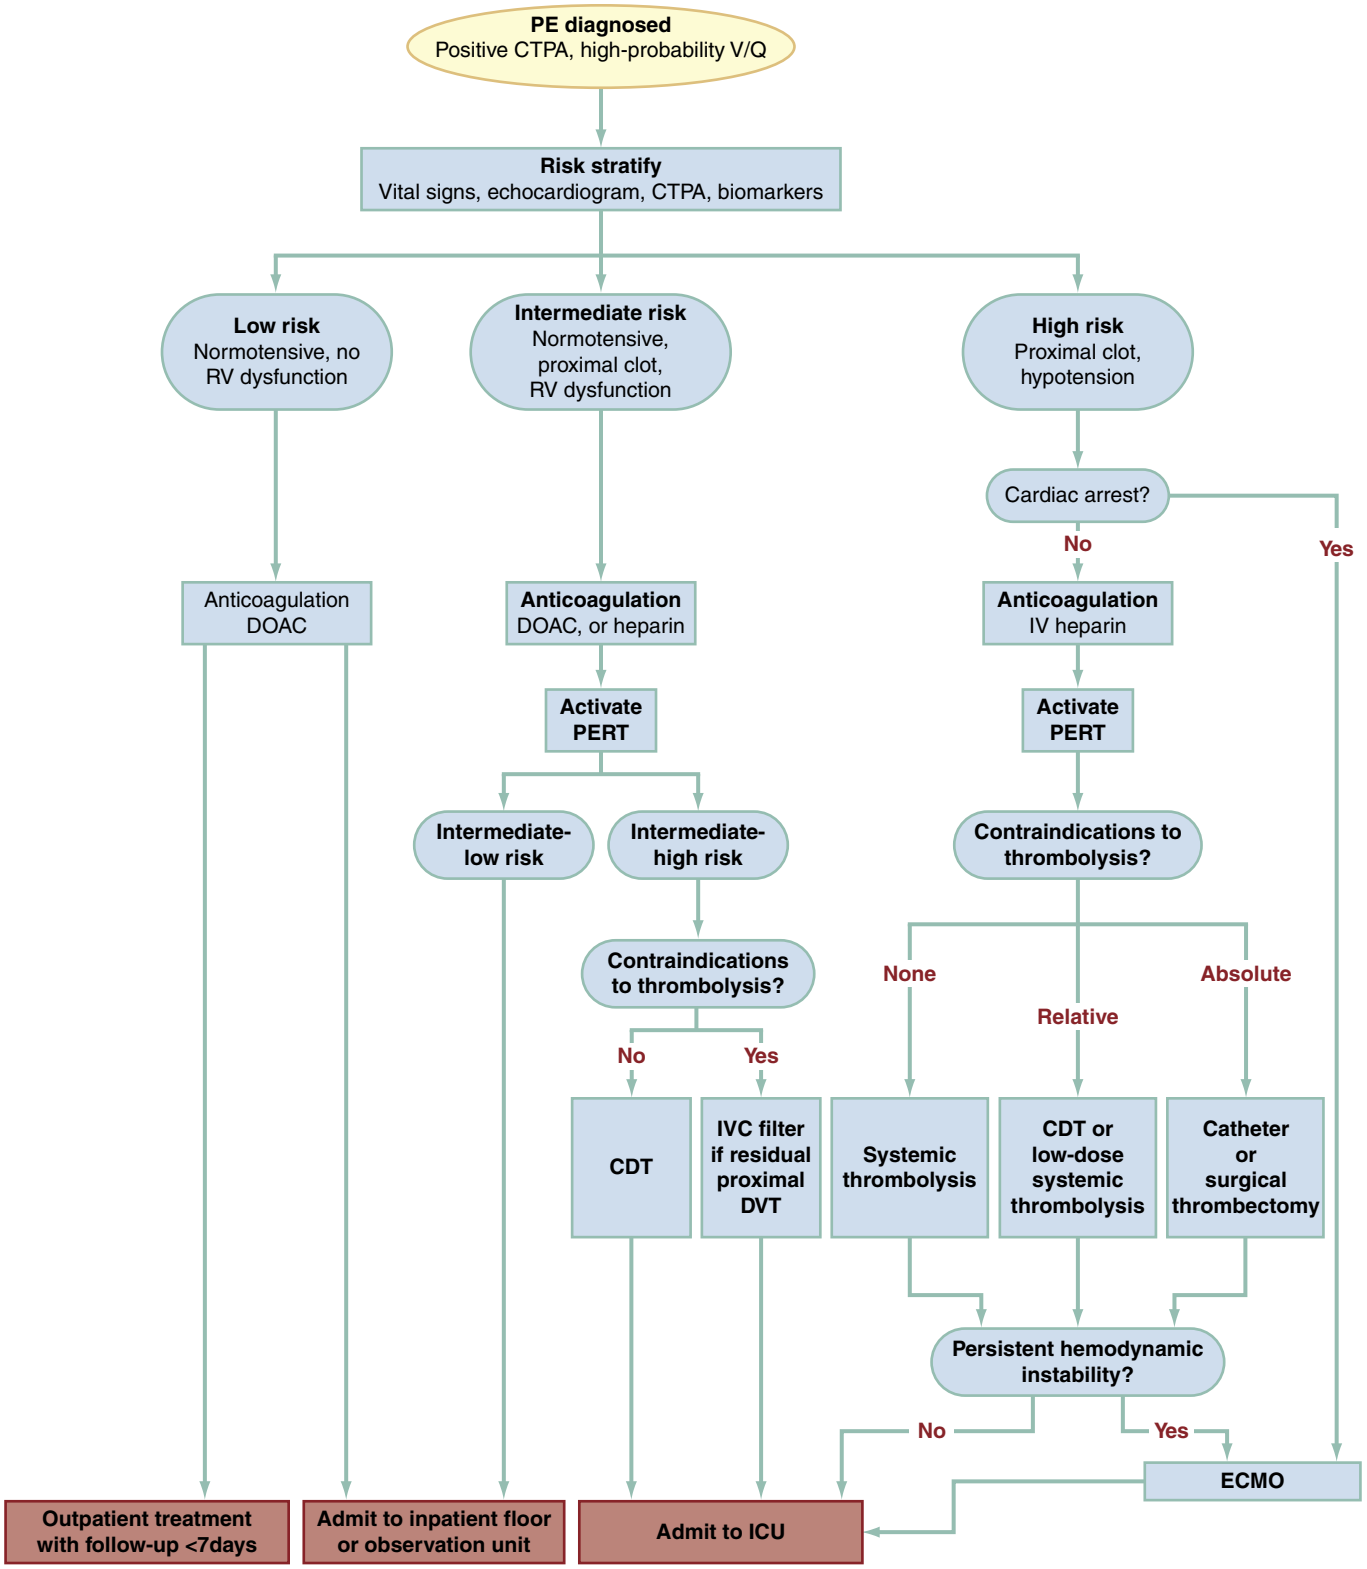

Fig. 74.11 Flowchart algorithm showing the treatment approach to patients diagnosed with acute pulmonary embolism (PE) in the emergency department of a full-service, tertiary-care hospital. This algorithm focuses on PE-specific treatment, rather than acute resuscitation. Low-risk PE are hemodynamically stable with no evidence of RV dysfunction. Intermediate-risk PE are hemodynamically stable but have evidence of RV dysfunction on echocardiogram or a positive troponin. Echocardiographic evidence of right ventricular (RV) dysfunction includes echocardiographic RV dilatation, hypokinesis or bowing of the intraventricular septum towards the left ventricle (LV) or RV : LV ratio >1 on CT. High-risk PE are hemodynamically unstable, defined as a systolic arterial pressure (SBP) < 90 mm Hg that is sustained for 15 minutes and not caused by a dysrhythmia or other etiology, a drop in baseline SBP of > 40 mm Hg, vasopressors, or profound bradycardia (<40 bpm). For dosing of anticoagulation, see Table 74.3. Pulmonary embolism response teams (PERT) can expedite the care and access to advanced therapies for patients with intermediate- and high-risk PE. Absolute contraindications to thrombolysis include: (1) gastrointestinal bleeding within previous 30 days; (2) active hemorrhage in any of the following sites at the time of enrollment—intraperitoneal, retroperitoneal, pulmonary, uterine, bladder, or nose; (3) head trauma causing loss of consciousness within previous 7 days; (4) any history of hemorrhagic stroke; (5) ischemic stroke within the past year; (6) history of intraocular hemorrhage; (7) known or suspected intracranial

metastasis; (8) liver failure with prothrombin time abnormal (international normalized ratio [INR] > 1.7); (9) surgery that required opening of the chest cavity, peritoneum, skull, or spinal canal within the previous 14 days; (10) subacute bacterial endocarditis under treatment; (11) pregnancy; (12) large pericardial effusion. Relative contraindications to thrombolysis include: age > 75 years; dementia; surgery more than 30 days but less than 60 days prior; any prior stroke; symptoms suggesting transient ischemic attack in the past 30 days; any prior gastrointestinal bleeding; concurrent use of a thienopyridine (e.g., clopidogrel); INR > 1.7 from warfarin use; any metastatic cancer, recent fracture, recent fall with head strike, history of hematuria, recent dental extraction, or orthopedic surgery. Systemic thrombolysis dosing regimens: alteplase (recombinant tissue plasminogen activator, rtPA) 100 mg IV over two hours, reteplase 10 units IV over two minutes and then repeated 30 minutes later or tenecteplase as a single weight-based bolus dose over 5 to 10 seconds. Low-dose thrombolysis dosing regimen: alteplase 25–50 mg IV over two hours. *PE*, Pulmonary embolism; *CTPA*, computed tomography pulmonary angiography; $\dot{V}/\dot{Q}$, ventilation perfusion; *RV*, right ventricle; *DOAC*, direct acting oral anticoagulant; IV, intravenous; *CDT*, catheter-directed thrombolysis; *DVT*, deep vein thrombosis; *ECMO*, extracorporeal membrane oxygenation; *ICU*, intensive care unit.

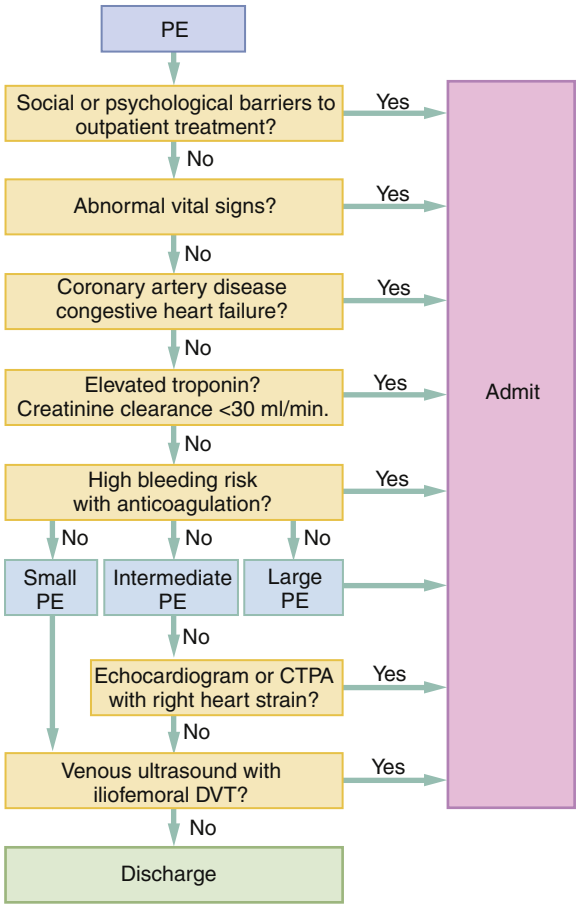

Fig. 74.12 Flowchart showing a validated algorithm for the identification of low-risk patients with acute PE who are candidates for outpatient treatment and discharge from the emergency department (or ED observation unit). Key to this approach is the availability of early follow-up and the ability of patients to obtain their prescribed anticoagulants after discharge. Abnormal vital signs include any hypotension or hypoxemia requiring oxygen therapy. Patients may be discharged with mild tachycardia, but patients with severe tachycardia should be observed in the hospital. Renal insufficiency (creatinine clearance < 30 mL/min) is not itself an indicator of higher risk PE, but severe renal impairment is a contraindication for both direct-acting anticoagulant (DOAC) and low-molecular-weight heparin (LMWH) anticoagulation. *PE*, pulmonary embolism; *CTPA*, computed tomography pulmonary angiography; *DVT*, deep vein thrombosis.

heparin-induced thrombocytopenia should receive fondaparinux, argatroban, apixaban, or rivaroxaban.

For patients in whom thrombolysis, surgery, or another advanced intervention is being considered, intravenous unfractionated heparin may be preferable because it has a short half-life, and anticoagulation should be discontinued prior to thrombolysis or a procedure. However, intravenous heparin provides unreliable anticoagulation, and many patients remain subtherapeutic throughout the first 24 to 48 hours of treatment.[63] As soon as it is decided that the patient will not receive thrombolysis or thrombectomy, it is best to convert to LMWH or a DOAC.

Anticoagulation therapy for patients with isolated subsegmental PE is controversial. If a patient has no evidence of DVT on bilateral lower extremity ultrasonography, no signs of right heart dysfunction, and no ongoing major risk for thrombosis (e.g., active malignancy, cast immobilization), it is reasonable to withhold anticoagulation. The decision to proceed with anticoagulation in this situation should be guided by individual patient risk profiles and preferences.[10,11]

Reversal of Anticoagulation. All anticoagulants commonly used in the ED, including the DOACs, now have effective reversal agents. The anticoagulant effect of unfractionated heparin can be almost completely and rapidly reversed with protamine sulfate, whereas LMWH can only be 50% neutralized with protamine. Protamine has no effect on fondaparinux, rivaroxaban, or apixaban. Andexanet alfa, a modified recombinant inactive form of human factor Xa, is now available to reverse anticoagulant effect (anti-factor Xa activity) in patients with life-threatening or uncontrolled bleeding on rivaroxaban and apixaban.[64,65] Although most patients treated in the single-arm trial achieved good hemostasis, the lack of a comparison (e.g., placebo) group makes it difficult to assess the effectiveness of andexanet alfa in reducing clinically important bleeding. The effectiveness of factor Xa inhibitor reversal using four-factor activated prothrombin complex, 50 U/kg IV, is limited and one meta-analysis concluded that these treatments may not result in more rapid reversal of anticoagulation than simply discontinuing the DOAC.[66-71]

Thrombolytic (Fibrinolytic) Therapy

Thrombolytic therapy in PE remains a controversial treatment. It is generally agreed that patients with arterial hypotension (systolic blood pressure < 90 mm Hg or > 40-mm Hg drop from baseline) should receive thrombolysis. Appropriate regimens for full-dose thrombolysis include alteplase (recombinant tissue plasminogen activator, rtPA) given as a 100-mg IV bolus over two hours, reteplase given as 10 units IV over two minutes and then repeated 30 minutes later, and tenecteplase given as a single weight-based bolus dose over 5 to 10 seconds. Practically speaking, two IV boluses of 50 mg separated by 15 minutes may be more realistic than a two-hour infusion of alteplase for an unstable patient. We recommend thrombolytic therapy for high-risk PE patients without contraindications, but specific regimens will vary by institution, availability, and pharmacy protocols.

For patients with intermediate-risk PE, data and clinical guidelines are conflicting. The PEITHO study randomized 1005 patients with intermediate-risk PE, defined as right ventricular dysfunction on echocardiogram and a positive troponin. Thrombolysis with tenecteplase was associated with significant reduction in the composite endpoint of clinical deterioration and 7-day mortality, but no decrease in mortality alone. There was, however, a significant increase in risk of intracranial hemorrhage, particularly in patients more than 65 years old. Subsequent meta-analyses of randomized trials that compared thrombolysis

plus heparin to heparin alone have reached different conclusions about mortality benefit, with one study finding significant improvement[72] and another no difference.[73] This difference seems to be mostly due to the definition of intermediate-risk PE used to characterize studies in the meta-analyses.

The benefit of thrombolysis for long-term outcomes in patients with intermediate-risk PE is also questionable. In the TOPCOAT trial of 88 patients with intermediate-risk PE, thrombolysis improved functional capacity and subjective perception of wellness. However, in PEITHO, thrombolysis had no effect on long-term mortality, residual dyspnea, or RV dysfunction.[74] Overall, we do not recommend full-dose intravenous thrombolysis for intermediate-risk PE except in carefully selected patients at high risk for clinical deterioration and low risk of bleeding. Intravenous thrombolysis for low-risk PE or DVT without PE is not indicated.

Thrombolytic regimens that use a lower dose (i.e., 50 mg of alteplase) thrombolysis have also been examined to determine whether lower thrombolytic doses reduce major bleeding associated with thrombolysis. While studies report low rates of intracranial hemorrhage, methodological issues and the outcome definitions used in the studies have tempered enthusiasm for this approach until further data are available.

Empirical thrombolysis has not shown benefit in undifferentiated cardiac arrest, but thrombolysis is recommended in cardiac arrest due to presumed PE, when there are no apparent contraindications. Both alteplase and tenecteplase may be given as a 50-mg bolus. To promote circulation of the thrombolytic medication, CPR should be continued for at least 60 minutes before terminating resuscitation.[75]

The primary risk of thrombolysis is bleeding. Studies suggest rates of major bleeding between 9% to 22%, and intracranial bleeding between 1.5% to 3%. The risk of intracranial hemorrhage appears to be highest in patients older than 65 years. One clinical prediction score for intracranial hemorrhage after thrombolysis for PE includes peripheral vascular disease, age greater than 65 years, prior cerebrovascular accident, and prior heart attack, though this study awaits external validation.[76]

Catheter-Directed Interventions

Catheter-directed interventions include catheter-directed thrombolysis and percutaneous thromboembolectomy. The advantages of catheter-directed thrombolysis include relatively low doses (4–24 mg of tPA over 12–24 hours) and delivery of thrombolytic medication near or directly into the PE.[77-79] Catheter-directed thrombolysis appears to be as effective as systemic thrombolysis in high-risk PE with a lower risk of bleeding[77-79] and may be superior to anticoagulation alone in intermediate-high risk PE, though, to date, only one small randomized clinical trial has compared catheter-directed thrombolysis to heparin alone. This study of 58 patients showed catheter-directed thrombolysis improved RV function at 24 hours, though there was no difference at 90 days. Single-arm studies have found similar results.[77-79]

Other catheter-directed interventions include clot maceration and suction thrombectomy. Clot maceration physically breaks up the clot, and may be used with thrombolysis, but can increase pulmonary hypertension through the release of vasoactive mediators. Suction thrombectomy devices mechanically withdraw clot from the pulmonary artery and have the benefit of not requiring thrombolysis or anticoagulation. While results are promising, there is no current evidence that catheter-directed interventions offer a survival advantage over systemic thrombolysis or anticoagulation alone.

Surgical Embolectomy

Surgical thromboembolectomy can be life-saving for patients with severe refractory hypotension or free-floating thrombi in the right heart ("clot-in-transit"), especially if the clot crosses a patent foramen ovale.[51] The perioperative mortality is highest for patients who require CPR before surgery, and lowest for stable patients who have an inferior vena cava (IVC) filter placed before surgery, so emergency physicians should involve an experienced cardiothoracic surgeon as early as possible in the care of a potential thromboembolectomy patient. Surgical embolectomy may be the best option for patients who have severe PE with a contraindication to fibrinolysis; however, extracorporeal perfusion requires intensive heparin anticoagulation, and the patient's mental status cannot be monitored during surgery—a key concern in patients with a high risk of intracranial hemorrhage. The administration of fibrinolytic therapy does not absolutely preclude surgical intervention. Patients treated with a fibrinolytic agent can undergo sternotomy or thoracotomy for thromboembolectomy and survive without fatal hemorrhage, but the decision to perform an open thromboembolectomy ultimately resides with the cardiothoracic surgeon.

Inferior Vena Cava Filters

For the vast majority of ED patients, placement of an inferior vena cava (IVC) filter is not indicated. However, for a patient diagnosed with PE in the presence of an absolute contraindication to anticoagulation, such as a recent cerebral hemorrhage, large cerebral infarction, or brain metastases, the appropriate consultant should be contacted for urgent placement of an inferior vena cava filter. Patients with a central PE who are unlikely to survive embolization of a proximal (e.g., iliofemoral), mobile DVT should also be referred for urgent IVC filter placement. The judgment that a patient is unlikely to survive an additional embolization is based on clinician experience and should be made alongside interventional radiology or cardiology consultants.

Pulmonary Embolism Response Teams (PERT)

PERTs are rapid response teams composed of multidisciplinary specialists, including emergency physicians, that can be mobilized to provide real-time expertise and expedite the care of patients with life-threatening PE. Approximately 60% of PERT activations originate in the ED.[58] PERTs have been shown to facilitate access to advanced therapies such as catheter-directed interventions, surgery, and extracorporeal membrane oxygenation, reduce disposition times, and improve overall care.[60,61] For patients with life-threatening PE, guidelines now recommend the involvement of a PERT.[12]

Mortality and Morbidity

For hemodynamically stable patients with PE, a multicenter registry of 1880 patients diagnosed with PE in the ED found 1.1% mortality directly attributable to PE and 5.4% all-cause mortality. In contrast, the mortality of hemodynamically unstable patients is 25% to 50%.[52] Approximately half of PE survivors will have exercise intolerance and dyspnea that degrades their quality of life,[80,72] and 40% to 50% of patients with DVT will have long-term symptoms consistent with post-thrombotic syndrome.[25,73] The etiology of exercise limitation after PE is not well understood but may have more to do with deconditioning than decreases in cardiac or pulmonary function.[80]

DISPOSITION

Approximately 20% to 30% of patients with PE can safely be discharged from the ED, usually with DOAC therapy and close outpatient follow-up.[27,28,81-84] Figure 74.12 shows a validated system for identification and risk stratification of patients with PE. This system has been shown to facilitate the outpatient treatment of up to 29% of ED patients with PE, with less than 1% all-cause 30-day mortality and 0.5% 30-day major bleeding.[28] The Hestia Criteria (Box 74.7) can also be used to identify patients who are safe for outpatient treatment.[82] The pulmonary

BOX 74.7 Hestia Criteria for the Outpatient Treatment of PE

Low-risk PE safe for outpatient treatment if:

- Systolic blood pressure > 100 mm Hg
- No thrombolysis needed
- No active bleeding
- Oxygen required to maintain oxygen saturation > 94%
- Not already anticoagulated
- Absence of severe pain requiring > two doses of intravenous narcotics
- Other medical or social reasons to admit
- Creatinine clearance > 30 mL/min
- Not pregnant, severe liver disease, or heparin-induced thrombocytopenia

embolism severity index (PESI) and its simplified version (sPESI) can be used to quantify patients' risk of all-cause mortality after PE, but these scores are less well suited to identify ED patients who require hospitalization.

Patients with PE who do not meet criteria for discharge should be admitted to an inpatient floor. Most patients should be admitted to a monitored (telemetry) bed, though low-risk patients can be admitted to an unmonitored bed or the ED observation unit. Patients with evidence of right ventricular dysfunction on echocardiogram, ECG, CTPA, or positive troponin assays should be admitted to a monitored bed. Patients who were hemodynamically unstable during any part of their ED stay should be admitted to a step-down or intensive care unit (ICU).

CHAPTER 74: QUESTIONS AND ANSWERS

1. A deep vein thrombosis localized to which of the following veins can safely be treated without anticoagulation and early follow-up with a repeat venous ultrasound?
- **a.** Popliteal vein
- **b.** External iliac vein
- **c.** Anterior tibial vein
- **d.** Common femoral vein

Answer: C. See Figure 74.2. The popliteal, external iliac, common femoral, and deep femoral veins are all proximal veins. Proximal DVT should be treated with anticoagulation. DVT isolated to a calf vein like the anterior tibial vein can be observed, without anticoagulation, so long as a follow-up ultrasound can be performed within 7 days to look for propagation.

2. In which of the following patients would the D-dimer level likely be elevated (e.g., >500 ng/mL)?
- **a.** 52-year-old female with a history of breast cancer in remission
- **b.** 18-year-old male with an acute febrile illness
- **c.** 79-year-old male with a history of hypertension
- **d.** 24-year-old female with a history of obesity

Answer: C. See Box 74.2. Active cancer increases D-dimer levels, but inactive cancer (in remission) does not. Febrile illness, obesity, and long-haul travel do not increase D-dimer levels. While hypertension does not increase D-dimer levels, D-dimer levels do increase with advancing age. The specificity of the D-dimer test in a patient 79 years old is about 10% to 15%.

3. A 29-year-old woman, G2P1, 28 weeks pregnant presents with a brief episode of left-sided chest pain and vague cramping of her left leg. She agrees that she would like to pursue a workup for PE. Which combination of tests is the most appropriate first step?
- **a.** CTPA and bilateral venous ultrasound
- **b.** Ventilation/perfusion scan and echocardiogram
- **c.** D-dimer and CTPA
- **d.** D-dimer and bilateral venous ultrasound

Answer: D. While the radiation doses from both CTPA and ventilation perfusion scanning are lower than the minimum dose known to affect pregnancy outcomes, it is still best to minimize radiation exposure when possible. Therefore, a diagnostic testing strategy that starts with D-dimer, which can rule out PE if negative, and bilateral venous ultrasound, which can rule in VTE when positive, may obviate the need for imaging with ionizing radiation.

4. What is the preferred anticoagulant for a patient with low-risk PE?
- **a.** A direct acting oral anticoagulants (DOAC)
- **b.** A nonsteroidal anti-inflammatory drug (NSAIDs)
- **c.** Unfractionated heparin
- **d.** Warfarin

Answer: A. See Figure 74.11. For most patients, and especially for patients with low-risk PE, direct-acting oral anticoagulants (DOACs) are the treatment of choice. The DOACs apixaban and rivaroxaban are approved for the initial treatment of DVT and PE and are associated with lower rates of major hemorrhage than the combination of heparin and warfarin. Nonsteroidal antiinflammatory drug (NSAIDs) can be used to treat superficial thrombophlebitis, but not PE.

5. A 46-year-old woman presents to a tertiary-care hospital with syncope and hypotension. Her oxygen saturation is 88% on room air. Her systolic blood pressures are between 75 to 88 mm Hg during her 30 minutes in the ED. Her CTPA shows acute, bilateral main pulmonary artery PE and right ventricular dilatation. Three weeks ago, she had surgery to resect a glioma from the left cerebral hemisphere. The most appropriate next step is:
- **a.** 2 L normal saline bolus and endotracheal intubation.
- **b.** Consult cardiac surgery to consider surgical thromboembolectomy.
- **c.** Low-dose alteplase, 50 mg IV over two hours.
- **d.** Anticoagulation with rivaroxaban.

Answer: B. See Figure 74.11. This patient has high-risk, or "massive," PE. She has persistent hypotension and a large central clot with evidence of right ventricular dysfunction. She also has an absolute contraindication to thrombolysis having recently undergone resection of a brain tumor. Patients with right ventricular dilatation from PE may clinically decompensate with excessive IV fluid resuscitation and intubation. Fluid boluses, when given, should be small (250–500 mL). Intubation should be avoided if possible. DOACs like rivaroxaban have not been extensively studied in high-risk PE and, because of their long half-life, should not be used in patients who may undergo thrombolysis or invasive treatment for their PE. Because this patient is not a candidate for thrombolysis, the best first step is to consult a cardiac surgeon to consider open thromboembolectomy.

75

Esophagus, Stomach, and Duodenum

Adam M. Nicholson and Jamie M. Hess

KEY CONCEPTS

Dysphagia

- Dysphagia can be caused by obstructive lesions (e.g., esophageal neoplasm), motility disorders (e.g., achalasia), or neuromuscular disorders that can be vascular (e.g., cerebral vascular accident), immunologic (e.g., myasthenia gravis, multiple sclerosis [MS]), infectious (e.g., botulism), or metabolic in nature.
- The incidence of achalasia increases with age, presenting insidiously with equal frequency for solids or liquids.
- Dysphasia can be the initial presentation of myasthenia gravis.
- Treatment of dysphagia is directed toward the underlying cause (e.g., myasthenia gravis, MS).
- An outpatient barium swallow or upper gastrointestinal endoscopy is indicated for most patients with dysphagia.

Upper Gastrointestinal Foreign Bodies

- Structural abnormalities of the esophagus are a major risk factor for foreign body obstruction; thus patients who obtain relief of foreign body sensation symptoms should be referred to a gastroenterologist for follow-up evaluation.
- Immediate intervention is indicated for button batteries, food boluses causing high-grade obstruction, or patients in significant distress (e.g., vomiting, gagging, choking, stridor, or inability to tolerate oral intake).
- Urgent (<24 h, and ideally <12 h) intervention is indicated for low-grade obstructions caused by sharp objects, coins lodged in the proximal esophagus, or food boluses.
- Urgent intervention is also recommended for gastric foreign bodies wider than 2.5 cm or longer than 5 cm.
- Flexible endoscopy with procedural sedation is the preferred therapeutic intervention to remove most proximal foreign bodies that can be reached by the scope.

Esophageal Perforation

- Iatrogenic causes, such as a complication of endoscopy, remain the most common cause of esophageal perforation.
- Water-soluble contrast should be used for initial diagnostic imaging studies when esophageal perforation is suspected.
- Admission with broad-spectrum antibiotics (e.g., intravenous vancomycin 15 mg/kg plus piperacillin 3.375 g) and early surgical consultation should occur in the majority of cases of esophageal perforation.
- Select stable patients with small, contained esophageal perforation may be managed conservatively by keeping the patient nothing per os (NPO), by administering broad-spectrum antibiotics and parenteral nutrition, and with a surgeon readily available.

Esophagitis

- Gastroesophageal reflux disease (GERD) is a diagnosis of exclusion in patients who present with chest pain. It is critical to first rule out other diagnoses, such as acute coronary syndrome (ACS).
- Empirical treatment of GERD with lifestyle modifications, H2 antihistamines, or proton pump inhibitors (PPIs) is appropriate, but if there is no improvement with these measures, patients should be referred for further evaluation.
- Sucralfate (1 g qid) can be safely used in pregnant patients with GERD.
- Eosinophilic esophagitis commonly presents as solid food dysphagia. Once food impaction is ruled out, a PPI should be initiated and the patient referred to a gastroenterologist.
- Infectious esophagitis primarily occurs in immunocompromised patients, and endoscopy may be helpful in differentiating among causal agents.
- Patients with pill esophagitis typically present with sudden onset retrosternal pain and odynophagia in the setting of taking medications without water; the diagnosis can often be made on the history alone.
- Medications associated with pill esophagitis include doxycycline, aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and potassium chloride.

Gastritis and Peptic Ulcer Disease

- Although gastritis cannot be definitively diagnosed based on clinical features alone, a clinical history such as recent NSAID use or alcohol ingestion in the setting of classic symptoms supports a presumptive clinical diagnosis of gastritis.
- The most common cause of gastritis is *Helicobacter pylori* infection.
- First-line treatment of *H. pylori* infection is a PPI (e.g., omeprazole 20 mg bid), amoxicillin (1 g bid), and clarithromycin (500 mg bid) for 14 days.
- The most serious complications of peptic ulcer disease (PUD) include hemorrhage, perforation, penetration, and gastric outlet obstruction.

Gastric Volvulus

- Acute gastric volvulus often presents with the combination of severe epigastric pain, distention, and vomiting, followed by violent nonproductive retching.
- Volvulus has a very high morbidity and mortality. Nasogastric tube reduction can be attempted in the emergency department, but ultimately these patients need emergent surgical intervention.

DYSPHAGIA

Foundations

Anatomy and Pathophysiology

Swallowing (also known as deglutition) is a complex phenomenon requiring voluntary and involuntary skeletal muscle activity coordinated by the swallowing center in the medulla. The cranial nerves provide afferent sensory inputs as well as efferent motor activity.

Swallowing is divided into oral, pharyngeal, and esophageal phases. Precise motor control of the act of swallowing is necessary to ensure that food is successfully transferred from the mouth through the

esophagus into the stomach. Failure at any one of these levels results in **dysphagia**, which literally means "difficulty swallowing."

Although dysphagia at any age is abnormal, it is particularly common in elders, with up to 60% of assisted living and nursing home patients having reported difficulty feeding.[1] Dysphagia is classified as two types, oropharyngeal and esophageal. Oropharyngeal dysphagia, also termed *transfer dysphagia*, involves difficulty transferring a food bolus from the oropharynx to proximal esophagus. Esophageal dysphagia involves difficulty in transporting material down the esophagus.

Oropharyngeal Dysphagia

Neuromuscular Disorders. Neuromuscular disease causes approximately 80% of cases of oropharyngeal dysphagia, with most remaining causes being localized structural lesions. Most neuromuscular causes of dysphagia result in misdirection of the bolus, sticking, and the need for repeated swallowing attempts. Liquids, especially at extreme temperatures, cause dysphagia more commonly than solids, and symptoms are often intermittent. Strokes resulting in pharyngeal weakness with failure of the cricopharyngeus muscle to relax are the most common cause of neuromuscular dysphagia. Weakness of the tongue may occur, resulting in poor transfer of the bolus, or weakness of the buccal muscles may produce drooling and difficulty prompting the swallowing process.

The second most common cause of neuromuscular dysphagia is inflammatory myopathy, such as polymyositis or dermatomyositis. These disorders are characterized by inflammatory and degenerative changes in striated muscle that can produce dysphagia from weakness of the palate, pharynx, and upper esophagus. Dysphagia may be a presenting symptom of patients with these disorders.

Myasthenia gravis is an important cause of oropharyngeal dysphagia. At least 40% of patients with myasthenia gravis have dysphagia, and it is the presenting symptom in up to 15% of patients. The dysphagia becomes progressively worse with repeated swallowing attempts and is temporarily reversible with edrophonium.

Structural Disorders. Congenital anomalies of the aortic arch may cause dysphagia in children and adults. In children, respiratory symptoms are usually present and commonly predominate. In adults, an anomalous right subclavian artery is the most common vascular cause for dysphagia, often termed *dysphagia lusoria.* Patients often do not become symptomatic until the fourth decade of life, and the most common symptoms are dyspnea on exertion and dysphagia. Vascular compression of the esophagus causing dysphagia may also occur with aneurysms of the aortic arch and great vessels. Bronchogenic carcinoma can cause dysphagia by direct involvement of the esophagus or by compression from enlarged lymph nodes.

Esophageal Dysphagia

Mechanical Disorders. Esophageal dysphagia is caused by mechanical lesions or a motility disorder. Mechanical lesions may be intrinsic or extrinsic to the esophagus. Intrinsic lesions include strictures, webs, rings, tumors, esophagitis, postsurgical changes, and esophageal foreign bodies. Pressure from extrinsic lesions such as osteophytes, mediastinal masses, or aortic aneurysms can also cause dysphagia.

An esophageal web is a thin structure composed of mucosa and submucosa usually found in the middle or proximal esophagus. Although webs can occur in isolation, they are also seen in Plummer-Vinson syndrome, which is characterized by anterior webs, dysphagia, iron deficiency anemia, cheilosis, spooning of the nails, glossitis, and thin friable mucosa in the mouth, pharynx, and upper esophagus. Most patients with Plummer-Vinson syndrome are women between 30 and 50 years of age. Patients usually report dysphagia that is initially intermittent and worse with solids. If untreated, it may progress and become constant. Rarely, motility disorders and surgical changes after a gastric bypass can also cause an esophageal obstruction.

Extrinsic compression of the esophagus can occur in a variety of conditions. In the neck, thyroid enlargement from goiter or carcinoma may cause dysphagia. Symptoms may also be seen with a pharyngoesophageal or Zenker diverticulum, a progressive outpouching of the pharyngeal mucosa as a result of increased pressure generated by failure of proper relaxation of the cricopharyngeus muscle. Noisy deglutition, dysphagia, halitosis, and a palpable compressible mass in the neck may be present. Laryngotracheal aspiration when the patient is supine results from the emptying of contents from the diverticulum.

Motor Disorders. Patients with esophageal dysphagia who have no readily identifiable mechanical cause may have a motor disorder. Intrinsic motor disorders of the esophagus include **achalasia**, diffuse esophageal spasm, nutcracker esophagus, and hypertensive lower esophageal sphincter (LES). Systemic connective tissue diseases, such as scleroderma or CREST (***c***alcinosis, ***R***aynaud phenomenon, ***e***sophageal dysmotility, ***s***clerodactyly, and ***t***elangiectasia) syndrome, Chagas disease, or a paraneoplastic syndrome may cause secondary motor disorders.

Achalasia is a disorder of unknown etiology in which the resting pressure of the LES is markedly increased, and peristalsis is absent in the body of the esophagus. The incidence increases with age.

Diffuse esophageal spasm is another type of intrinsic motor disorder. When it is severe and prolonged, with associated high-intensity peristaltic waves, it is termed *nutcracker esophagus*.[2] Nonspecific motor disorders include repetitive esophageal contractions, nontransmitted esophageal contractions, and low-amplitude esophageal contractions.

Clinical Features

A careful history helps to differentiate oropharyngeal from esophageal dysphagia in up to 85% of patients (Box 75.1). The history focuses on determining the anatomic level involved (oropharyngeal vs. esophageal), types of food leading to symptoms (liquids, solids, or both), and whether the symptoms are intermittent or progressive. Associated pain, prior gastrointestinal (GI) history, and family history are also helpful in determining the cause.

The examination should include a thorough evaluation of the head and neck and a detailed neurologic examination. The patient should be observed while swallowing. It is helpful to note difficulty in initiating the swallow, misdirection of the bolus with regurgitation or aspiration, or unusual posturing of the patient when swallowing. Many patients with neuromuscular disorders depend on gravity to swallow, and having the patient swallow in the prone position may be helpful in rendering a diagnosis.

Oropharyngeal Dysphagia

Oropharyngeal dysphagia is characterized as an inability or excessive delay in initiation of swallowing, aspiration of the ingestate, nasopharyngeal regurgitation, or residual ingestate within the pharyngeal cavity following a swallowing event. This may be caused by misdirection of the food bolus, pain, or sticking and worsened with multiple swallowing attempts. Symptoms may include discomfort or pain in the cervical region, coughing, choking, drooling, or nasal regurgitation.

Tongue weakness can result in oral regurgitation. Inability to seal the nasopharynx because of obstruction or muscular weakness can cause nasal regurgitation. Inefficient laryngeal elevation from muscular weakness or a fixed larynx can result in laryngotracheal aspiration. Delayed aspiration can occur with pharyngeal weakness and with pooling of food in the piriform recesses or in a diverticulum. Inability

to contract the pharyngeal muscles is often compounded by failure of the cricopharyngeus muscle to relax, which causes misdirection of the food bolus or necessitates repeated swallowing attempts. Inflammatory lesions of the tongue or oropharynx can result in odynophagia, which may impede swallowing.

Esophageal Dysphagia

Dysphagia from upper esophageal lesions is usually perceived 2 to 4 seconds after the initiation of swallowing. Dysphagia that the patient localizes to the substernal or retrosternal area may be anatomically accurate, but localization to the neck may be referred from anywhere in the esophagus.

Dysphagia is the most common presenting symptom of achalasia and usually begins insidiously, with equal frequency for solids and liquids. Patients may report that maneuvers that increase esophageal pressure (e.g., raising arms above the head, standing erect with back straight) help pass the food. Odynophagia from esophageal spasm may also be seen early in the course of achalasia. The symptoms are often worse with rapid eating and during periods of stress. The patient may also report chest pain as a symptom. As dilation occurs above the sphincter, retention of undigested food in the esophagus occurs, and the patient may be aware of gurgling while eating. Regurgitation of the undigested material can occur after a meal, prompting consideration of the diagnosis of an eating disorder, or with changes in position or vigorous exercise. The regurgitated food usually has no acid taste unless bacterial contamination causes fermentation of the undigested food. Laryngotracheal aspiration may occur, especially at night, and may cause nocturnal coughing. The physical examination is usually unremarkable, except for weight loss. Radiographically, a dilated esophagus is seen proximal to a narrowed gastroesophageal junction that has a "beaklike" appearance.

Esophageal spasm may be precipitated by swallowing very hot or cold liquids. Symptoms include chest pain, dysphagia, or both. Manometrically, simultaneous prolonged strong esophageal contractions are noted to be interspersed over normal peristaltic waves.

If a barium swallow is performed during a spasm, findings such as corkscrewing, or curling, of the esophagus may be noted.

Differential Diagnoses

The differential diagnosis of esophageal dysphagia includes acute coronary syndrome (ACS). Substernal chest pain is the main symptom in 80% to 90% of patients with esophageal motility disorders. The chest pain can be similar to angina, described as crushing or squeezing, with patterns of radiation similar to those of cardiac chest pain. Nitroglycerin may also relieve the pain of spasm, making the distinction between the two entities even more difficult.

Symptoms that suggest an esophageal cause of chest pain include pain that is prolonged and nonexertional, pain that interrupts sleep, pain related to meals, relief with antacids, and presence of other symptoms of esophageal disease, such as heartburn, dysphagia, or regurgitation. Given the considerable overlap in symptoms, a cardiac diagnosis should be excluded before attributing chest pain to an esophageal cause.

Diagnostic Testing

The history and physical examination direct the need for testing. Nasopharyngoscopy may be used to assess for upper structural

abnormalities. The decision and timing of swallowing studies (e.g., video esophagography), barium swallows, manometry, and impedance monitoring are best coordinated with consultants. These studies are rarely indicated in the emergency department (ED).

Management

Achalasia is the only motility disorder for which reasonably reliable studies support specific treatment. Previously, pharmacologic therapies such as nitrates and calcium channel blockers have been used with the goal of decreasing tone of the LES. More recently, surgical interventions such as peroral endoscopic myotomy (POEM) have been used as first-line therapy in patients with achalasia who are able to tolerate surgical intervention.[3] Pharmacologic therapy remains available as a bridge to more definitive intervention or in patients who are unable to tolerate an invasive procedure. Endoscopic botulinum toxin injection remains available as an acceptable treatment option in patients, although as with other medical therapies is commonly reserved for patients unable to tolerate more invasive procedures.

Medical therapy for esophageal motility disorders is limited, and clinical impacts are typically minimal. Anticholinergic drugs such as hyoscyamine sulfate or dicyclomine have been used because they decrease the amplitude of esophageal peristalsis and LES pressure. However, because these drugs delay gastric emptying and decrease esophageal peristalsis, they may exacerbate reflux symptoms. Other therapies include the use of calcium channel blockers, which decrease LES pressure and the amplitude of esophageal contractions.

Disposition

Patients at risk of aspiration or who are unable to maintain hydration may require hospitalization for expedited work-up and management. Otherwise, prompt outpatient evaluation by a gastroenterologist is indicated.

FOREIGN BODIES

Foundations

Background

Patients with esophageal foreign bodies are generally classified into four major groups: (1) pediatric patients; (2) psychiatric patients or prisoners (typically intentional ingestion); (3) patients with underlying esophageal disease; and (4) edentulous adults. Pediatric patients account for more than 75% of cases, with the peak incidence occurring in those between the ages of 18 and 48 months. Swallowing coins accounts for most cases of pediatric ingestion, whereas most adult impactions involve food, particularly meat or bones. Patients with underlying structural abnormalities of the esophagus are at greater risk for foreign body impaction. Edentulous adults are also at increased risk because of impaired oral sensation, which may contribute to their risk of accidental ingestion of a dental prosthesis.

Anatomy and Physiology

The esophagus begins in the hypopharynx, approximately at the level of the cricoid cartilage. On either side of this cephalad slit are the piriform recesses, which are blind pouches that may occasionally harbor a foreign body. There are four natural areas of narrowing where most foreign bodies become entrapped: The cricopharyngeus muscle (which is a component of the upper esophageal sphincter [UES]), aortic arch, left mainstem bronchus, and LES at the diaphragmatic hiatus. Pediatric entrapment occurs most commonly at the level of the cricopharyngeus muscle in the UES given the anatomic features present in young children, whereas adult entrapment occurs most commonly at the LES (Fig. 75.1).

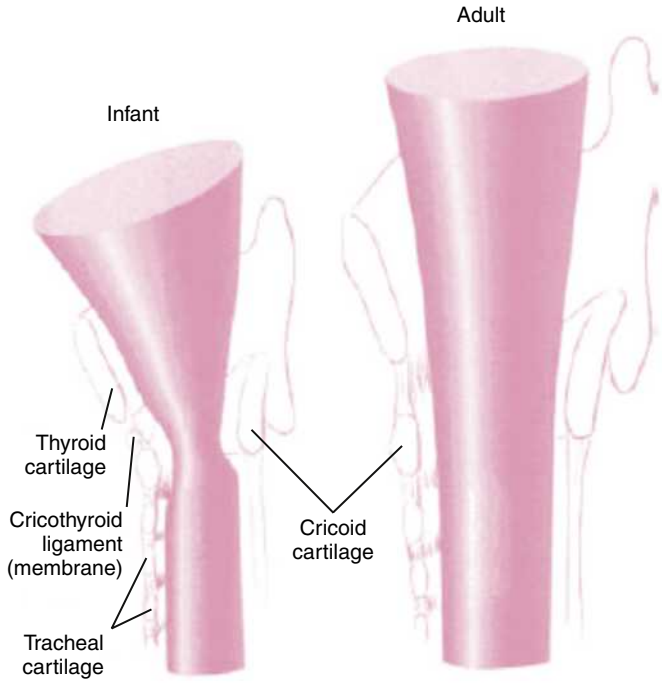

Fig. 75.1 Anatomic Differences Between Infant and Adult Airways.

The esophagus comprises two main bands of muscle, an inner circular layer and outer longitudinal layer. The resting tone of these muscles causes the inner epithelium to fold in on itself, effectively obliterating the lumen. Elastic fibers enable the esophageal lumen to expand and allow passage of a food bolus. The upper third of the esophagus, including the cricopharyngeus muscle, contains striated muscle to allow for the voluntary initiation of swallowing. The middle portion of the esophagus is a mixture of skeletal and smooth muscle, and the distal third is composed only of smooth muscle. Although it is relatively fixed at its origin, the esophagus becomes mobile as it traverses the mediastinum and can be easily displaced by adjacent structures. An enlarged left atrium or ventricle, goiter, or mediastinal tumor may cause enough displacement of the esophagus to impede the passage of a food bolus or foreign body.

Pathophysiology

Although obstruction may occur in a patient with a normal esophagus, preexisting structural abnormalities such as strictures (peptic or malignant), distal esophageal mucosal rings, or eosinophilic esophagitis are identified in nearly 90% of patients with an esophageal obstruction. Schatzki ring is a specific type of mucosal abnormality present in 15% of the population and characterized by a fibrous, diaphragm-like stricture near the gastroesophageal junction.

Clinical Features

Patients with an esophageal obstruction have a wide range of symptoms that typically begin minutes to hours following ingestion. Most adults are able to describe the precipitating event and commonly complain of dysphagia, odynophagia, and neck or chest pain. Patients are often able to localize retained foreign bodies due to somatic innervation of the upper esophagus. In contrast, entrapment in the lower esophagus causes more visceral-type generalized chest and epigastric discomfort. The obstruction may be partial or complete. The patient with complete obstruction is unable to swallow oral secretions. Large proximal impactions can impinge on the trachea, leading to airway compromise that manifests as cough, choking, or stridor.

Pediatric patients are often brought to the ED after a witnessed ingestion. However, up to 35% of children with proven esophageal foreign body impactions are asymptomatic at the time of presentation. Symptoms that should prompt consideration of unwitnessed foreign body ingestion include fever, wheezing, stridor, rhonchi, or poor feeding.

A so-called *café coronary*, which is a proximal esophageal obstruction caused by food (usually an incompletely chewed piece of meat), is characterized by sudden cyanosis and collapse as a result of airway obstruction. Similarly, *steakhouse syndrome* results when a large piece of food, usually improperly chewed, is swallowed and causes esophageal obstruction in the distal esophagus.

Patients may present to the ED with sharp throat pain and concern about swallowing a fish bone after eating fish. Despite the discomfort and concern of a retained fish bone foreign body, this rarely results in true esophageal obstruction.

Differential Diagnoses

Esophageal foreign bodies should be distinguished from those in the airway. This distinction can be especially difficult in small children because respiratory symptoms may be the only clue to the esophageal foreign body with associated tracheal compression. Patients with esophageal obstruction may have retrosternal pain that can appear similar to that of a patient presenting with ACS. The presence of odynophagia suggests an underlying mucosal lesion such as an abrasion, laceration, or perforation.

Diagnostic Testing

In most cases, the patient's history will be all that is necessary to confirm the diagnosis and initiate therapeutic intervention. Imaging studies may be necessary in unknown or equivocal cases, or in patients who are unable to provide a reliable history. Anteroposterior (AP) and lateral radiographs of the neck, chest, and abdomen are indicated when a radiopaque foreign body is suspected. Flat objects in the esophagus such as coins or button batteries typically orient in the coronal plane and appear as a circular object on an AP projection (Fig. 75.2). Button batteries can be differentiated from coins by a characteristic radiographic double-density appearance. Small bones or radiopaque objects may occasionally be visualized. Radiographs are typically unreliable in detecting a fish bone.

Nasopharyngoscopy can be useful in differentiating a retained foreign body from a mucosal abrasion. In the vast majority of patients with symptoms following ingestion of fish, no fish bone foreign body is identified. Air in the tissues may be present if perforation has occurred. However, failure to demonstrate a foreign body on radiographs does not rule it out. Persistent or concerning symptoms in a patient without evidence of a radiographic foreign body can be further evaluated by laryngoscopy and upper GI endoscopy.

Contrast studies with barium or gastrografin are rarely performed to evaluate for a foreign body because they present a risk for aspiration and can obscure visualization if subsequent endoscopy is necessary. Computed tomography (CT) may be used in equivocal cases to identify and localize foreign bodies before endoscopy. CT is more sensitive (90% to 100%) than radiography for identifying foreign bodies, including chicken or fish bones or other nonorganic objects. CT scans have the additional value of visualizing changes associated with perforation in the surrounding tissues.[4]

Management

Overview

Treatment for esophageal foreign bodies depends on the type and location of the object and clinical status of the patient. Flexible endoscopy using procedural sedation is recommended in most cases of complete esophageal obstruction, because rigid endoscopy requires general anesthesia and has a higher complication rate.

Urgent intervention (2 to 6 hours) is indicated for button batteries, magnets, large or sharp objects, coins lodged in the proximal esophagus, impactions that impair the handling of secretions, and food boluses causing signs of high-grade esophageal obstruction. Factors associated with a heightened risk of complications include a longer duration of impaction, bone, or other larger foreign bodies.

Although it is acceptable to delay endoscopy briefly in stable patients without symptoms of high-grade obstruction to allow a trial of spontaneous passage, the American Society for Gastrointestinal Endoscopy has recommended that food boluses causing incomplete obstruction be removed within 24 hours. Any object remaining in the esophagus for more than 24 hours carries a higher risk of complications, including perforation, aorto-enteric fistula, tracheoesophageal fistula, or abscess. These complications may occur in the near term or years after the ingestion. Follow-up endoscopic evaluation after an esophageal obstruction is necessary to assess for underlying pathologic conditions as up to 25% of patients will have an identifiable esophageal disorder.[4]

A recent retrospective review of patients who ingested sharp objects who had normal physical examination had a very low incidence of requiring surgical intervention. This suggests that perforation and obstruction rates may be less than traditionally thought, and careful observation may be appropriate in select cases.[5]

Upper Esophagus

Oropharyngeal foreign bodies can often be removed with a Kelly clamp or Magill forceps under direct visualization. Smooth upper esophageal foreign bodies such as coins can often be removed with a Foley catheter. This procedure requires an experienced clinician, cooperative patient, and fluoroscopic guidance. The patient is placed in a prone position, and the catheter is passed into the esophagus past the point of the foreign body impaction. The balloon is then inflated and the catheter withdrawn, pulling the foreign body with it. The literature reports that up to 80% of foreign bodies are successfully removed with this technique, and an additional 8% advance into the stomach. Failure rates are highest with infants younger than 1 year. Controversy exists regarding the safety of this technique because there is no direct control of the foreign body. However, large studies have shown complication rates to be less than 1% when patients are carefully selected for the procedure.

Foley catheter removal should not be used for a foreign body that has been impacted for more than 1 week, for objects that are not smooth, for patients with radiographic evidence of esophageal perforation, or for patients with any underlying structural esophageal abnormalities. This technique has a significant economic advantage when compared with the costs of general anesthesia in an operating room for the performance of rigid endoscopy.

Another technique is bougienage, which has been shown to be safe and effective in coin removal. In this technique, an esophageal dilator is passed through the mouth into the esophagus to advance the coin into the stomach; the dilator is then quickly removed. In a large study, this procedure had a significantly shorter duration to discharge when compared to endoscopy.[6]

Lower Esophagus

Lower esophageal obstruction is usually the result of an impacted food bolus. Anecdotally, intravenous (IV) administration of 1 mg of glucagon, up to a total of 2 mg, can cause enough relaxation of the esophageal smooth muscle to allow passage of a food bolus into the lower esophagus. However, a recent systematic review of the literature found no difference in efficacy of glucagon compared with placebo but did show an increased risk of adverse events with glucagon administration such as vomiting and potential aspiration.[7] Based on lack of evidence and the potential risks, we do not recommend using glucagon in the management of esophageal foreign bodies. IV benzodiazepines have anecdotally been used as a first-line approach for stable patients with a meat impaction, although the evidence supporting their benefit is sparse and suggests that effectiveness is not better than placebo.

Small studies have examined the role of effervescent agents in treating food bolus impaction. They have shown no clear evidence of benefit, and there is a theoretical risk of inducing perforation in the case of complete obstruction with associated distal esophageal ischemia. Similarly, the use of meat tenderizer (papain) to soften a food bolus is potentially dangerous and should not be used.

Endoscopy should be performed immediately for patients experiencing distress or for children with impaction of an alkaline button battery. Button batteries lodged in the esophagus can cause severe tissue damage in just 2 hours. Damage is primarily related to localized corrosive effects and occurs by three main mechanisms—leakage of an alkaline electrolyte, pressure necrosis, and generation of an external current that causes electrolysis of tissue fluids, thus generating hydroxide at the battery's negative pole and causing alkaline damage of the mucosa. Larger batteries carry a greater risk of impaction and leakage. Delayed complications include esophageal perforation, tracheoesophageal fistula, esophageal strictures, and exsanguination after the development of a fistula with a major blood vessel. In a review of more than 8000 battery ingestions that were reported to the National Battery Ingestion Hotline, outcomes have significantly worsened over the past decade. This is primarily attributable to the newer 20-mm-diameter lithium cell batteries that now account for 92% of fatal ingestions.

Batteries that pass into the stomach should be followed radiographically and clinically to ensure passage. Assistance with the management of a patient with button battery ingestion can be obtained through the National Button Battery Ingestion Hotline (1-202-625-3333) or at www.poison.org/prevent/battery.asp.

Stomach

Conservative outpatient management is appropriate for the vast majority of foreign bodies that have entered the stomach. However, certain foreign bodies that pass into the stomach still require endoscopic retrieval. Objects longer than 5 cm or wider than 2.5 cm in diameter (e.g., toothbrushes, spoons) rarely pass the duodenum. All sharp and pointed foreign bodies (e.g., toothpicks, bones) should be removed before they pass out of the stomach because there is a risk of intestinal perforation. Smaller objects that pass into the stomach can be followed with stool inspections and serial radiographs, if necessary, to confirm passage. Surgical removal should be considered for objects that remain in the stomach for more than 3 to 4 weeks or that remain in the same intestinal location for more than 1 week.

Disposition

The patient with an esophageal or stomach foreign body frequently requires a gastroenterology consult and consideration for upper endoscopy for foreign body removal. Discharge from the ED should follow foreign body removal, or consideration of the risks and benefits of a trial of spontaneous passage. Patients who undergo endoscopy should

be observed until awake from sedation and able to tolerate oral intake. These patients should be discharged with a proton pump inhibitor (PPI), and referral for further evaluation of structural abnormalities. If no foreign body is identified, and the patient is able to swallow liquids, they may be safely discharged with outpatient follow-up.

ESOPHAGEAL PERFORATION

Foundations

Background

Esophageal perforation can result from a rapid increase in intraesophageal pressure related to forceful vomiting or any Valsalva-like maneuver, including childbirth, coughing, or heavy lifting. Iatrogenic esophageal perforation can result during manipulation of the esophagus, such as during endoscopy, nasogastric tube placement, or endotracheal intubation. Other causes of perforation include foreign body ingestion, caustic substance ingestion, severe esophagitis, carcinoma, or direct injury related to blunt or penetrating trauma. Spontaneous rupture occurs because of a rapid increase in intraluminal esophageal pressure against a closed LES.

Anatomy and Physiology

More than 90% of spontaneous esophageal ruptures occur in the distal esophagus. In contrast, rupture resulting from blunt trauma to the neck or thorax usually occurs in the proximal or middle third of the esophagus. Most iatrogenic injuries occur at the pharyngoesophageal junction because the wall in this area is thin, there is no serosal layer to reinforce it, and force is frequently used to pass a tube or scope beyond the level of the cricopharyngeus muscle. Another site of frequent iatrogenic injury is the esophagogastric junction. In this area, the esophagus curves anteriorly and to the left as it enters the abdomen, and an endoscope has a greater likelihood of perforating the posterior wall. This usually occurs during therapeutic dilation for strictures or achalasia.

Clinical Features

Clinical presentations of esophageal perforation vary and depend on the cause, location, size, and degree of contamination. Symptoms related to iatrogenic perforation may not appear until several hours after the procedure. Patients with an upper esophageal perforation usually have neck or chest pain, dysphagia, respiratory distress, or fever. Odynophagia, nausea, vomiting, hoarseness, or aphonia may also result. Mackler triad of subcutaneous emphysema, chest pain, and vomiting is considered pathognomonic for spontaneous esophageal rupture. However, the complete triad is seen in less than 50% of cases.

Patients with perforation of the lower esophagus may have abdominal pain, pneumothorax, hydropneumothorax, and pneumomediastinum. The pain may radiate to the back, left side of the chest, and left or both shoulders. Physical findings include epigastric or generalized abdominal tenderness, often with involuntary guarding and rigidity. Up to 30% of patients develop mediastinal or cervical emphysema, which may be noted by crepitus on palpation or by the pathognomonic Hamman sign, with a crunching sound heard during auscultation. Patients with severe mediastinitis may present in fulminant shock.

Differential Diagnoses

Misdiagnosis occurs in more than 50% of patients with esophageal perforation or rupture because of the broad differential diagnosis of chest and abdominal pain. This includes pulmonary embolism, acute myocardial infarction, aortic dissection, perforated ulcer, pneumothorax, lung abscess, pericarditis, or pancreatitis, among others. The associated morbidity and mortality of patients with esophageal perforation increases significantly over time, so every effort should be made to quickly confirm the diagnosis.

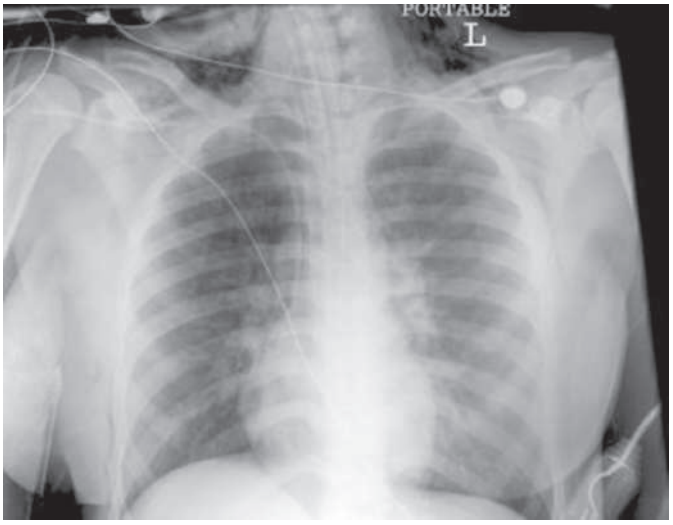

Fig. 75.3 Pneumomediastinum due to esophageal perforation following forceful vomiting.

Diagnostic Testing

Chest and upright abdominal radiography is generally the first diagnostic study performed in patients suspected of an esophageal perforation. Radiographic abnormalities may be detected in up to 90% of patients with esophageal perforation (Fig. 75.3). Patients with upper esophageal injuries commonly have chest radiographs that show pneumomediastinum alone with or without a right-sided pleural effusion, whereas radiographs in patients with distal esophageal perforations may demonstrate a left-sided effusion. Other radiographic abnormalities include subcutaneous emphysema, mediastinal widening, or pulmonary infiltrates. These radiographic changes are often not present in the first few hours after perforation; thus a normal early radiograph should not be used to exclude the possibility of esophageal perforation.

Patients with suspected perforation should undergo contrast enhanced radiographic studies. Barium sulfate is superior for identifying small perforations but may incite an inflammatory response in tissues. Water-soluble agents (e.g., Gastrografin) may be safer, but they are less dense and therefore may not demonstrate an abnormality. In addition, pneumonitis may result if these agents are aspirated because of their hypertonicity. We recommend an initial attempt with a water-soluble agent for patients who are not at risk for aspiration. If a perforation is not identified and suspicion remains high, a repeat study with barium is recommended.

CT of the chest may be considered if a contrast study does not demonstrate a clinically suspected perforation. It can also be used in patients who are intubated or cannot complete esophagography, or when alternative diagnoses are also being considered. Findings such as mediastinal air, extraluminal contrast material, or fluid collections or abscesses adjacent to the esophagus can confirm a perforation.

Flexible esophageal endoscopy is useful in directly visualizing the perforation, especially in cases of penetrating external trauma, with a sensitivity of 100% and specificity of 83%. This technique is not recommended for other situations because insufflation could potentially enlarge a small transmural opening.

Laboratory studies are not usually helpful soon after a perforation, although systemic leukocytosis may be noted.

Management

Clinically unstable patients with esophageal perforation require rapid resuscitation and treatment. There are no current randomized

controlled trials regarding antiinfective management of esophageal perforation, and as such, no definitive recommendation can be made regarding optimal antibiotic regimen to treat esophageal perforation. Common organisms found in the esophagus include gram-positive, gram-negative, anaerobic organisms, and at times fungal species as well.[4] Broad-spectrum IV antibiotics should be initiated early. We recommend IV vancomycin 15 mg/kg q8h to q12h plus IV piperacillin-tazobactam 3.375 g q6h, with consideration to add empiric antifungal coverage (fluconazole 400 mg IV daily) if patient has significant risk factors for fungal colonization. Patients should receive nothing by mouth (NPO), and early surgical consultation is warranted. Treatment within the first 24 hours has been found to improve survival when compared with delayed treatment.

There is evidence that some iatrogenic perforations in select patients at low risk can be managed conservatively. These patients must be clinically stable, have minimal symptoms, and have no signs of sepsis. In addition, they must have a perforation contained within the neck, and a surgeon must be available in the event of decompensation. Operative management in these patients has been reported to result in worse outcomes compared with nonoperative management including close monitoring, NPO status, broad-spectrum antibiotics, and parenteral nutrition. Other so-called palliative interventions, including endoscopic stent placement, drainage gastrostomy, feeding jejunostomy, and tube thoracostomy, have become more common.

Traumatic, noniatrogenic etiology of esophageal perforation is infrequent and associated with high morbidity and mortality. Factors associated with worse outcome include thoracic location of esophageal injury and more extensive esophageal damage. Early surgical treatment for these injuries improves survival rates.[8]

Disposition

Patients with esophageal perforation are at risk for rapid deterioration and require close monitoring in a hospital setting, often in an intensive care unit. Early surgical consultation is recommended.

ESOPHAGITIS

Foundations

Esophagitis is an inflammation of the esophagus. The most common cause is gastroesophageal reflux disease (GERD). Other important causes include eosinophilic infiltration, infection, foreign body, toxic ingestion, or radiation. Chapter 143 discusses esophagitis caused by caustic substance ingestion.

Gastroesophageal Reflux Disease

Asymptomatic reflux of gastric contents from the stomach into the esophagus often occurs several times a day as a normal physiologic phenomenon. GERD occurs when reflux becomes symptomatic or causes histopathologic alterations in the upper GI or respiratory tract. In the United States, symptomatic reflux in the form of heartburn occurs in 10% to 20% of the population.[9]

The primary mechanism that enables reflux of gastric contents into the esophagus is inappropriate relaxation of the LES. This can occur because of general hypotension of the LES, increased intra-abdominal pressure, or transient LES relaxation. Multiple risk factors can decrease LES pressure and lead to reflux, including medications (e.g., nitrates, calcium channel blockers, anticholinergics, albuterol), fatty meals, and chocolate. Other mechanisms that may contribute to GERD include esophageal motility abnormalities, increased intragastric pressure (e.g., obesity, pregnancy), acid hypersecretion, gastric outlet obstruction, and conditions that cause delayed gastric emptying (e.g., gastroparesis, neuromuscular disease).

Repetitive exposure to acid can lead to changes in the esophageal mucosa. Continued reflux can lead to thinning of the normal stratified squamous epithelial layer. With the development of esophagitis, an inflammatory response occurs in the mucosa and submucosa, with infiltration of polymorphonuclear leukocytes. The inflammatory response is the result of chemical irritation of the esophageal mucosa from reflux of gastric acid, pepsin, and bile acids. Both acid and alkaline refluxes produce the same pathologic changes. Continued exposure can lead to further endoscopically visible changes of erosion, ulceration, and scarring. Ultimately, stricture formation may result. The most severe histologic consequence of GERD is replacement of the normal stratified squamous epithelium with metaplastic columnar epithelium in a condition termed *Barrett metaplasia*. In patients with reflux undergoing endoscopy, approximately 10% to 15% are found to have Barrett esophagus. There is a strong correlation between the development of Barrett metaplasia and adenocarcinoma of the esophagus.

Eosinophilic Esophagitis

Eosinophilic esophagitis results from an eosinophilic infiltration within the esophageal mucosa or deeper tissues. Initially thought to be a disease of children, it is being diagnosed in adults with increasing frequency with a prevalence rate now approaching 3%.[10] The cause is unknown, although there is an association with food allergens, especially in the younger age group. More than 50% of patients have associated atopic disorders, such as asthma or eczema. The criteria necessary for diagnosis include clinical symptoms of esophageal dysfunction, more than 15 eosinophils in one high-power field on esophageal biopsy, and lack of responsiveness to high-dose PPI therapy.

Infectious Esophagitis

Esophageal infections primarily occur in immunocompromised hosts. When they occur in healthy patients, there is usually an underlying esophageal abnormality or local area of immune compromise, as might occur with the use of inhaled steroids. Iatrogenic alterations in host defenses through the use of immunosuppressive agents, potent chemotherapeutic agents, or broad-spectrum antibiotics can predispose an individual to the development of an esophageal infection. Other systemic diseases that weaken immunologic defenses in otherwise normal hosts can predispose the esophagus to infection, including diabetes mellitus, alcoholism, underlying malignancy, use of corticosteroids, or advanced age. The *Candida* species (primarily *Candida albicans*) are the most common esophageal pathogens.

Human immunodeficiency virus (HIV) is a risk factor for infectious esophagitis, but rates have decreased since the advent of highly active antiretroviral therapy (HAART). Patients with acute HIV seroconversion syndrome that occurs 2 to 3 weeks after primary exposure to HIV can develop esophageal ulcerations and severe odynophagia.

As empirical antifungal prophylaxis in immunosuppressive states has become more common, viral esophagitis has become more prominent. Herpes simplex virus 1 (HSV-1) and cytomegalovirus (CMV) are the most common viral pathogens. Human papillomavirus has been implicated as well. Bacteria, mycobacteria, other fungi, and parasitic organisms such as *Trypanosoma cruzi*, *Cryptosporidium,* and *Pneumocystis* are uncommon causes of infectious esophagitis and are usually diagnosed by culture or biopsy.

Pill Esophagitis

The incidence of pill esophagitis is unknown as most cases are unrecognized and therefore unreported. The condition results when a pill or capsule fails to pass into the stomach and remains in contact with the esophageal mucosa for a prolonged period. This results in inflammation and injury of the esophageal mucosa.

Pill esophagitis has been reported in all age groups. Predisposing factors include advanced age, decreased esophageal motility, or extrinsic compression. Large pills are more likely to be retained because these are coated with gelatin. Pills can stick to a normal esophagus, especially when taken without water or by a patient in the supine position. Any area of the esophagus can be affected, although sites of natural compression may be more susceptible. Sustained-release compounds may be more damaging than standard preparations. Injury can range from minor irritation to frank ulceration, hemorrhage and, ultimately, stricture formation. Some of the more common offending medications include antibiotics (especially the tetracycline family) and antivirals, aspirin and other NSAIDs, potassium chloride, quinidine, ferrous sulfate, alendronate, and pamidronate.

Radiation-Induced Esophagitis

Patients undergoing radiation treatment for underlying malignancy may develop esophagitis. The degree of injury is related to the total dose of radiation received. The mucosa becomes inflamed and friable. Agents used during sclerotherapy can also cause esophagitis.

Clinical Features

Esophagitis, regardless of cause, usually manifests with dysphagia or odynophagia. Chest pain is frequently present, and esophageal bleeding can occur, ranging from localized oozing as a result of inflammation to frank hemorrhage. Ulceration and perforation can result in mediastinitis.

Gastroesophageal Reflux Disease

The most common clinical manifestation of GERD is heartburn, defined as a burning sensation that begins in the subxiphoid area and radiates toward the neck. Reflux may also cause a dull discomfort, localized pressure, or severe squeezing pain across the middle of the chest. The patient may appear comfortable or may have associated diaphoresis, pallor, nausea, and vomiting, leading to the consideration of ACS. A detailed history is often helpful in differentiating cardiac chest pain from reflux, although the distinction may be difficult in the ED.

Other symptoms of GERD include regurgitation (spontaneous appearance of an acid or bitter material in the mouth or pharynx) and water brash (a vagally mediated hypersalivation response that may produce as much as 10 mL of saliva in 1 minute). Dysphagia and odynophagia may also be presenting complaints and may be associated with more serious complications.

Any condition or agent that decreases LES pressure, decreases esophageal motility, or prolongs gastric emptying predisposes patients to reflux (Box 75.2). Body positions that place the esophagus dependent to the stomach or increase intra-abdominal pressure tend to precipitate reflux. Stooping, bending, leaning forward, performing Valsalva-type maneuvers, or assuming a supine position are common precipitants.

GERD can manifest itself in extraesophageal locations. Reflux-induced asthma may result from microaspiration of gastric contents into the lung or activation of a vagal reflex arc from the gut to the lung. GERD has been identified in up to 80% of asthmatic patients based on pH probe monitoring, but up to 50% of these patients have no reflux symptoms. However, studies have shown no benefit in treating poorly controlled asthmatic patients with PPIs in the absence of GERD symptoms.

If the refluxate reaches the proximal esophagus, otolaryngologic manifestations may result, even in the absence of esophageal symptoms. Reflux can cause hoarseness, chronic laryngitis, refractory sore throat, and globus sensation. Refluxate that enters the oropharynx may lead to gingivitis, halitosis, or dental problems, such as erosion of the lingual sides of the teeth as a result of acid exposure. Otalgia and hiccups can also result from reflux.

BOX 75.2 Agents and Conditions Related to Gastroesophageal Reflux

Decreased Lower Esophageal Sphincter Pressure
Anticholinergic drugs
Benzodiazepines
Caffeine
Calcium channel blockers
Chocolate
Estrogen
Ethanol
Fatty foods
Nicotine
Nitrates
Peppermint
Pregnancy
Progesterone

Decreased Esophageal Motility
Achalasia
Diabetes mellitus
Scleroderma

Increased Gastric Emptying Time
Anticholinergic drugs
Diabetic gastroparesis
Gastric outlet obstruction

Eosinophilic Esophagitis

The most common symptom of eosinophilic esophagitis in adults is solid food dysphagia. In addition to dysphagia, patients may present with nausea and vomiting, food impaction, or heartburn. Children may present with more vague symptoms, such as vomiting, regurgitation, nausea, epigastric or abdominal pain, chest pain, water brash, or decreased appetite. Children with eosinophilic esophagitis have a higher rate of atopy, immunoglobulin E (IgE)-mediated food allergies, or family history of allergies. This diagnosis should be considered in patients who have severe GERD symptoms despite the use of acid suppression medications or in patients with chronic unexplained dysphagia or recurrent esophageal food impaction. The diagnosis is confirmed by biopsy during endoscopy.

Infectious Esophagitis

Infectious esophagitis usually causes severe odynophagia. Dysphagia of solids and liquids may be present. Pain may be so severe that the patient refuses to eat or drink. Heartburn and nausea may be presenting symptoms, although the pain is not improved by antacid therapy. Immunocompromised patients may have fever or bleeding, without dysphagia or odynophagia. Many patients with esophageal candidiasis also have oral candidiasis, but it is possible to have esophageal manifestations only, which makes it more difficult to diagnose.

Pill Esophagitis

Patients with pill esophagitis commonly present with chest pain (72%), odynophagia (39%), and dysphagia (30%). Most patients have no prior history of esophageal disease and experience sudden onset of pain worsened by swallowing. Dysphagia may be present. Although some patients complain that a pill has become stuck, the history of

pill ingestion can be difficult to obtain because symptoms may begin hours after the offending pill was taken. Atypical presentations include a burning type of pain, suggesting GERD as the cause.

Differential Diagnoses

Acute cardiac ischemia should be considered as a possible cause of chest pain in adults. It is difficult to differentiate between ischemic coronary disease and GERD based only on features of the pain, location, or radiation. Radiation of pain can be a feature in esophageal and cardiac chest pain. The occurrence of reflux after meals is another important feature in the history. A feeling of fullness after meals occurs commonly in reflux and is helpful in differentiating it from coronary artery disease.

Relief of chest pain from reflux by antacids may be a key point in the history, although it is not evidence against a cardiac cause. The relief is often short lived, and pain may recur in a short time. Esophageal pain may be provoked by swallowing. Other GI disorders such as gastritis, esophagitis, peptic ulcer disease (PUD), and biliary tract disease should be considered in the differential.

Diagnostic Testing

GERD is a common problem, and additional diagnostic testing in the ED is rarely necessary, assuming that other, more serious causes of the patient's symptoms have been excluded. Patients with dysphagia, odynophagia, or bleeding should be referred for further evaluation.

Endoscopy can be used to evaluate pathologic changes, but there is no direct correlation between symptoms and endoscopic features. With infectious esophagitis, direct visualization may reveal characteristic signs of infection, such as white plaques of *Candida* or herpetic vesicles. Definitive diagnosis can be made through brushings or biopsies. Radiographic studies are usually not helpful because the findings are nonspecific.

Management

Gastric Reflux

Lifestyle modification solely as an initial approach to GERD has little therapeutic benefit without concomitant medical management. Lifestyle modifications to reduce GERD symptoms include avoidance of foods that can precipitate reflux (e.g., caffeine, alcohol, chocolate, fatty foods) and avoidance of acidic foods that can cause heartburn (e.g., citrus products, spicy foods). In addition to these dietary changes, other behavioral modifications include weight loss, smoking cessation, elevation of the head of the bed, and avoidance of a recumbent position for several hours after eating. The only lifestyle recommendations that have evidence-based support include weight loss and head of bed elevation, although others can be useful adjuncts in select patients.

The pharmacologic therapy of GERD includes agents that neutralize acids, decrease acid production, act on the LES or affect motility, and protect the mucosa. The most effective treatment for GERD is reduction of acid production. Many patients self-medicate with antacids, over-the-counter (OTC) type 2 histamine receptor (H2)–receptor antagonists, or PPIs. A Cochrane systematic review concludes that PPIs are more effective than H2 blockers in eliminating symptoms and healing mucosal damage. However, H2 blockers are an acceptable alternative for patients with mild to moderate GERD. These agents do not stop the reflux but rather reduce the potency of the refluxate. Choices of H2 blockers and PPIs are listed in Tables 75.1 and 75.2. All these agents are generally regarded as safe and effective.

Another agent that may be of benefit in refractory cases of symptomatic esophageal reflux is sucralfate, which can be used with other agents such as PPIs and H2 blockers. The dose is 1 g every 6 hours. Sucralfate is a mucosal protectant that binds to inflamed tissue to create a protective barrier. It blocks the diffusion of gastric acid and pepsin across esophageal mucosa and can limit the erosive action of pepsin and bile. It has limited side effects and can be safely used in pregnant women.

Prokinetic agents treat GERD by increasing LES pressure. They may also be used for patients whose symptoms suggest a superimposed motility disturbance (e.g., regurgitation, choking, abdominal distention). In addition to improving the propulsive activity of the stomach and small and large intestines, the increase in esophageal peristalsis and LES tone is an effective therapy for reflux by improving the clearance of refluxate. Metoclopramide (10-mg dose) may be used, but its efficacy has not been conclusively demonstrated and prolonged use can cause significant irreversible extrapyramidal side effects such as tardive dyskinesia.

Patients with clinically suggested GERD who do not improve with empirical therapy and those who are at high risk for complications should be referred to a gastroenterologist for confirmation of the diagnosis and follow-up care. In these cases, further diagnostic evaluation may be necessary. Patients who are intolerant of acid-suppressive medications may be candidates for surgical therapy with laparoscopic fundoplication. Less invasive endoscopic therapies include thermal ablation to narrow the esophagus at the LES, suturing to create a plication at the LES, or injection or implantation techniques to fortify the LES.

Eosinophilic Esophagitis

These patients usually are seen after standard antireflux measures have failed or they have developed a food impaction. Once food

TABLE 75.1 Summary of Histamine Receptor Antagonists

Agent	GERD	PUD[a]
Cimetidine	800 mg bid or 400 mg qid	800 mg qhs or 400 mg bid
Famotidine	20 or 40 mg bid	40 mg qhs or 20 mg bid
Nizatidine	150 mg bid	300 mg qhs or 150 mg bid

[a]Maintenance dose for PUD is half the qhs dose.
GERD, Gastroesophageal reflux disease; *PUD*, peptic ulcer disease; *qhs*, at bedtime.

impaction is eliminated as the presenting problem, empirical treatment by initiation of a daily PPI and referral to a gastroenterologist for urgent endoscopy is recommended. Untreated eosinophilic esophagitis can lead to esophageal remodeling and stricture formation in up to 40% of adult patients. Although consensus has not yet been reached regarding an optimal treatment regimen, success has been reported with the use of topical (swallowed) corticosteroids. Additional therapies that are considered in patients with eosinophilic esophagitis include leukotriene receptor antagonists, mast cell stabilizers, azathioprine, 6-mercaptopurine, and biologic immunomodulators. These medications have been trialed with some success, although may be of limited utility due to side effects.[10] Pediatric studies have also shown efficacy of the use of oral viscous budesonide.

Infectious Esophagitis

For infectious esophagitis, therapy is directed at the causative organism. Patients with normal immune systems and mild cases of oropharyngeal candidiasis can be treated with clotrimazole troches (10 mg dissolved in the mouth, five times daily for 1 week) or nystatin (400,000 to 600,000 million units orally [PO] four to five times/day for 2 weeks). Patients with moderate to severe esophageal candidiasis should be treated with oral fluconazole (400 mg as a loading dose and then 100 to 400 mg daily for 14 to 21 days). In patients unable to tolerate oral medication, fluconazole can be given by the IV route.

Herpes esophagitis is generally a self-limited process that resolves within 1 to 2 weeks. Immunocompromised patients should be treated with antivirals, such as acyclovir (400 mg PO, five times/day for 7 to 14 days, or 5 to 10 mg/kg IV tid for 10 to 14 days), famciclovir (500 mg PO, tid for 10 to 14 days), or valacyclovir (1 g tid for 10 to 14 days). For CMV, initial treatment can begin with ganciclovir (5 mg/kg IV bid) or foscarnet (60 mg/kg IV tid or 90 mg/kg IV bid), although optimal duration of therapy is not currently clear.[11]

Pill Esophagitis

If a patient with suspected pill esophagitis has persistent symptoms, endoscopy may be necessary. It also helps determine alternative causes. No data support a specific treatment, although, intuitively, antacid medication may prevent further erosion of damaged mucosa. Symptoms may take up to 6 weeks to resolve.

The best treatment for pill esophagitis is prevention. Patients should be instructed to drink at least 4 ounces of liquid with any pill. All medications should be taken when the patient is in an upright position, and they should remain upright for several minutes after medication ingestion. Patients with underlying esophageal abnormalities or who are bedridden should avoid the use of pills whenever practical.

Disposition

Treatment of esophagitis is largely symptom based and supportive. Patients who cannot eat or drink because of injury to the esophagus should be considered for admission for IV fluid therapy. Treatment of GERD is directed at symptom management. GERD can be safely managed on an outpatient basis. ED disposition decisions are largely based on the ability to rule out other more serious causes of the patient's complaints, such as ischemic coronary disease. For infectious esophagitis, if the causative organism cannot be identified or the patient is severely debilitated, hospitalization may be required. In addition to therapy directed at the infecting organism, treatment with antacids, topical anesthetics, or sucralfate may provide symptomatic relief.

Patients discharged from the ED should receive appropriate follow-up with the relevant specialist (e.g., gastroenterology, infectious disease).

GASTRITIS AND PEPTIC ULCER DISEASE

Foundations

Background

Gastritis and PUD are often difficult to differentiate based on history alone. Strictly speaking, gastritis is a histologic diagnosis denoting inflammation of the gastric mucosa. Hence the diagnosis of gastritis can be made only by endoscopy and biopsy. However, it is common practice for clinicians to use the term *gastritis* to refer to symptoms of dyspepsia. To confuse the picture further, gastroenterologists frequently use the term to refer to the endoscopic finding of an edematous friable mucosa. However, without accompanying inflammation, this is more appropriately termed *gastropathy* rather than gastritis. This section considers gastritis and gastropathy together as one entity because the distinction has little importance to emergency care. Gastric and duodenal ulcers are often grouped together as PUD because of the similarity in their pathogenesis and treatment.

Pathophysiology

The most common cause of gastritis is infection with *Helicobacter pylori.* Although most patients are asymptomatic at the time of initial exposure, acute infection with *H. pylori* can cause severe gastritis and PUD. The identification of *H. pylori* has dramatically shifted our notion of PUD from an acid-related to an infectious disease–mediated process.

H. pylori is a spiral, flagellated, gram-negative rod whose natural habitat is the human stomach, between the epithelial cell surface and overlying mucus. It is estimated that up to 95% of patients with duodenal ulcer and up to 70% of patients with gastric ulcer are infected with *H. pylori.*[12] It is more prevalent in lower socioeconomic groups and in developing countries. It is most likely spread person to person by an oral-oral route, although the fecal-oral route and iatrogenic transmissions have also been hypothesized.

It is estimated that up to 40% of the US population is infected with *H. pylori.* It is found in people of all age groups, although infection is typically acquired during childhood. Its presence is believed to cause mucosal inflammation that disrupts the normal defense mechanisms and leads to ulceration. It also increases the risk of gastric carcinoma and, less often, lymphoma. Although there is a strong association between *H. pylori* and PUD, only 5% to 10% of infected patients develop ulcers. It is unclear what role environmental and host factors, such as diet, play. It is now broadly accepted that nearly all non–NSAID-related ulcers are caused by *H. pylori*. Eradication of infection with *H. pylori* results in more rapid healing of ulcers, fewer episodes of relapse, and a diminished rate of ulcer complications. It is also more cost-effective than chronic antisecretory therapy.

Suppurative gastritis, also known as acute phlegmonous gastritis, is a rare and often fatal disease that results from an acute bacterial infection of the stomach wall. *Streptococcus* bacteria species are involved in nearly 75% of cases. Patients usually have an underlying mucosal abnormality such as cancer, ulcer, or preexisting gastritis. Less common infectious causes of gastritis include mycobacterial, viral, parasitic, or fungal organisms.

Use of aspirin and other NSAIDs is the second most common cause of PUD. Up to 25% of chronic NSAID users develop ulcer disease, and 2% to 4% of these patients have serious complications, including perforation or bleeding. The cause of NSAID-related ulcers is suppression of

BOX 75.3 Risk of Gastrointestinal Complications From Nonsteroidal Antiinflammatory Drugs

Highest Risk
Indomethacin (relative risk [RR], 2.25)
Naproxen (RR, 1.83)

gastric prostaglandin synthesis. Prostaglandins promote mucosal integrity by maintaining mucosal blood flow, promoting mucosal mucus and bicarbonate formation, and reducing mucosal acid secretion. It is believed that the inhibition of cyclooxygenase (COX) by NSAIDs leads to a diminished level of protective prostaglandins in the stomach. In addition, the antiplatelet aggregation effect of NSAIDs may increase the amount of bleeding associated with NSAID-induced ulcers.

NSAIDs differ in their ulcerogenic potential. Studies have shown a higher risk of upper GI bleeding with ketorolac and piroxicam, particularly if their use extends beyond 5 days. The COX-2–specific inhibitors (e.g., celecoxib, rofecoxib, valdecoxib) were initially thought to have a more favorable GI safety profile than traditional NSAIDs. However, further studies have refuted this belief and noted an increased risk of cardiovascular side effects, including myocardial infarction and stroke. As a result, rofecoxib (Vioxx) and valdecoxib (Bextra) were withdrawn from the market. Celecoxib (Celebrex) is still available in the United States as a treatment for arthritis and familial polyposis but has a black box warning regarding an increased incidence of GI side effects as well as increased cardiovascular risk (Box 75.3).

Patients older than 60 years, those with a prior history of an ulcer or hemorrhage, those receiving higher doses of NSAIDS, and patients concurrently taking glucocorticoids or anticoagulants are at higher risk for NSAID-induced gastroduodenal toxicity. These patients should be considered for ulcer prophylaxis with a PPI or misoprostol.

Other drugs with ulcerogenic potential include 5-fluorouracil, mycophenolate mofetil, and the bisphosphonates. Other drugs implicated in causing gastritis are potassium preparations and iron supplements. Gastritis can result from short- and long-term exposure to ethanol.

Any condition that causes hypovolemia or hypotension can lead to gastritis. Ulcer formation may ultimately result. This may be a major causative factor in the development of gastritis and upper GI bleeding in intensive care unit patients. Other causes of gastritis include radiation, autoimmune reactions, Crohn disease, or sarcoidosis.

Many mechanisms can protect the gastric mucosa from the digestive effects of the hydrochloric acid, proteolytic enzymes, bile, and other deleterious substances to which it is exposed. Normally, a gastric mucosal barrier to intraluminal gastric acid is present and prevents the back-diffusion of hydrogen ions from the gastric lumen. Sodium ions are prevented from moving in the opposite direction. This ionic impermeability protects the gastric mucosa from gastric secretion-induced damage. Damage to the gastric mucosal barrier from any cause (Box 75.4) allows hydrogen ions and digestive enzymes to make contact with the gastric mucosa, leading to inflammation, bleeding, and potential ulceration.

H. pylori infection and use of NSAIDs account for the vast majority of PUD cases. Only 1% of PUD is caused by acid hypersecretion. Zollinger-Ellison syndrome is an acid hypersecretion syndrome caused by increased levels of circulating gastrin from gastrin-secreting tumors. Gastrin stimulates the parietal cells of the stomach to secrete more acid and causes parietal cell hyperplasia. Thus these patients have increased parietal cell mass and hypersecretion of acid, leading to ulcer formation.

PUD also occurs in infants and children. Infants with PUD usually demonstrate poor feeding, vomiting, or failure to thrive. Up to 25% of children have isolated hematemesis or melena as presenting signs. Toddlers and preschool children may have abdominal pain, vomiting, or bleeding. Of ulcers in this age group, 80% are stress ulcers associated with systemic illness such as sepsis, head trauma, burns, or sickle cell disease. Older children and adolescents usually have primary PUD, with presentations similar to those of adults.

Clinical Features

Acute gastritis and PUD may cause epigastric abdominal pain, nausea, and vomiting. By definition, gastritis or gastropathy cannot be diagnosed based on clinical features alone. However, a good clinical history such as recent NSAID use or alcohol ingestion in the setting of the epigastric burning pain supports a presumptive clinical diagnosis.

Patients with phlegmonous gastritis usually appear toxic. Patients with gastritis as a result of decreased mucosal blood flow may have symptoms of abdominal pain and upper GI bleeding in addition to those of their underlying disease. Complications of gastritis include perforation or gastric outlet obstruction.

The classic presenting symptom of PUD is epigastric pain described as burning or gnawing. However, up to 2% of patients with endoscopically proven PUD are asymptomatic. Patients may also present with atypical symptoms, including pain in other areas of the abdomen, chest, or back, and may describe the pain as vague or crampy. Associated symptoms include fullness, nausea, early satiety, and abdominal distension. Pain usually occurs 2 to 5 hours after a meal or at night. Having symptoms that awaken a patient from sleep between midnight and 3 AM is a classic indicator of ulcer disease, because in most people gastric acid output is highest at approximately 2 AM. Ulcer pain is usually not present on awakening in the morning because gastric acid output is at its lowest. Colicky pain is rarely gastric or duodenal in origin. Well-defined periods of exacerbation and remission are usually present with a duodenal ulcer and aid in the diagnosis. A constant pain lasting from weeks to months is uncommonly caused by ulcer disease. Relief of pain after eating is another feature of gastric or duodenal ulcer. The pain from a duodenal ulcer is usually worse immediately before a meal.

Although some patients with ulcers may vomit, alternative diagnoses such as gastric volvulus, gastric outlet obstruction, small bowel obstruction, pancreatitis, or biliary tract disease should be considered in patients

with epigastric pain and vomiting. Relief of abdominal pain with antacids is an important aspect of the history. Antacids usually afford relief of pain in PUD and gastritis. More than 90% of patients with PUD and 75% with gastritis experience pain relief with antacids. Patients with duodenal ulcer usually experience pain relief within 5 minutes.

Physical findings in patients with PUD are usually minimal. Mild epigastric tenderness may be elicited. A positive stool guaiac test may be evidence of a slowly bleeding ulcer, but other causes of occult bleeding should also be considered.

Complications

The most serious complications of PUD include hemorrhage, perforation, penetration, and gastric outlet obstruction. Hemorrhage is the most common complication, occurring in 15% to 20% of patients. Ulceration into an artery can lead to life-threatening hemorrhage. Patients older than 60 years are at greater risk. Approximately 2% to 10% of patients experience perforation, which occurs when an ulcer erodes through the wall and leaks air and digestive contents into the peritoneal cavity. Duodenal ulcers account for 60% of all perforations, followed by antral gastric ulcers (20%) and gastric body ulcers (20%). Penetration is pathologically similar to perforation, except that the ulcer erodes into another organ such as the liver (usually from a gastric ulcer) or pancreas (usually from a duodenal ulcer). Gastric outlet obstruction occurs in 2% of ulcer patients as a result of edema and scarring near the gastroduodenal junction. Symptoms may manifest as gastroesophageal reflux, early satiety, weight loss, abdominal pain, or vomiting.

Pain patterns may be helpful in diagnosing some of the complications of PUD. Pain from a perforated duodenal ulcer is usually appreciated first in the epigastrium but becomes generalized within a short time. Vomiting is present in 50% of patients, and peritoneal findings usually result. Pneumoperitoneum commonly occurs after duodenal ulcer perforation, and the accumulated air under the diaphragm may cause referred pain to the shoulder. One or both shoulders may be involved, depending on the location of the free air.

A history of ulcer-like anterior abdominal pain that begins to radiate into the back suggests penetration of a duodenal ulcer. The pain is usually described as steady and is perceived at the level of the lower thoracic and upper lumbar vertebrae. The pain becomes refractory to treatment with antacids and food. In addition, the pain may radiate to the chest, right upper quadrant, or left upper quadrant in up to 20% of patients. The sudden onset of pain, especially if unrelated to eating, suggests ulcer perforation or gastric volvulus.

Differential Diagnoses

Many other disorders can produce epigastric pain that mimics the pain of gastritis or PUD. Before either of these diagnoses can be made, other diseases that cause nausea, vomiting, and upper abdominal pain should be excluded, such as pancreatitis, biliary tract disease, or small bowel obstruction. Esophageal disorders such as GERD, esophagitis, or esophageal spasm include similar abdominal symptoms. Mesenteric ischemia should be considered, especially in elders and those with underlying vascular disease or atrial fibrillation. The possibility of ACS should also be considered.

It can be difficult to distinguish between gastritis and PUD. The discomfort associated with gastritis is often mild to moderate in severity and described as a hot burning pain or bloating. In particular, burning pain is twice as common in gastritis as in PUD.

Diagnostic Testing

Because the diagnosis of gastritis is made clinically, no specific diagnostic tests are necessary. Ancillary tests should be ordered as clinically indicated to rule out other possible diagnoses or to assess for complications of gastritis, such as bleeding, obstruction, or perforation.

Upper endoscopy is the procedure of choice for confirming the diagnosis. This is not typically performed in the ED unless it is necessary to treat complications of PUD, such as acute bleeding.

Abdominal and chest radiographs should be ordered if obstruction, perforation, or penetration is suggested or if a pulmonary cause is being considered, although negative radiographs do not definitively rule out these diagnoses. Newer studies show that careful multiplanar CT interpretation may visualize deep ulcers, secondary mural, and extraluminal signs of peptic gastroduodenitis. This can be helpful in facilitating expedited endoscopic evaluation to initiate appropriate treatment.[13]

Electrocardiography should be considered in any patient with the potential for a cardiac cause of pain. A pregnancy test should be considered in woman of childbearing age.

Patients can be tested for *H. pylori* by invasive or noninvasive methods. These include a urea breath test, serum antibody testing, stool antigen testing, and direct mucosal biopsy during endoscopy. None of these methods are practical in the ED; thus patients should be referred to primary care providers to facilitate additional testing.

Management

Therapy should be directed toward treating the suspected underlying cause. Acid suppression may improve symptoms of dyspepsia in patients taking NSAIDs. Patients with persistent symptoms should be referred to a primary care doctor or gastroenterologist for further diagnostic evaluation.

For NSAID-related ulcers, treatment should begin with discontinuation of the offending agent combined with initiation of PPI therapy. For ulcers not related to NSAIDs, treatment for *H. pylori* infection is recommended.

Recommended regimens combine antibiotics with acid-suppressing agents for treatment of *H. pylori* infection (Box 75.5). Commercially available combination products may also be prescribed that may assist in compliance (e.g., Prevpac, which contains lansoprazole, amoxicillin, and clarithromycin, and Helidac, which contains bismuth subsalicylate,

BOX 75.5 Suggested Treatment Regimens for *Helicobacter pylori*

Triple Therapy (10- to 14-day treatment regimen)
Clarithromycin, 500 mg bid
Plus
Amoxicillin, 1 g bid
Or
Metronidazole, 500 mg bid (if penicillin-allergic)
Plus
A PPI

Quadruple Therapy (10- to 14-day treatment regimen)
Bismuth subsalicylate (Pepto-Bismol), 525 mg PO qid
Plus
Metronidazole, 250 mg PO qid
Plus
Tetracycline, 500 mg PO qid
Plus
A PPI

PO, Orally; *PPI*, proton pump inhibitor.

metronidazole, and tetracycline). Continued therapy with antisecretory agents following completion of an antibiotic-containing regimen is recommended.

Antacids

By the time most patients seek treatment for upper GI complaints, they have likely already tried some form of antacid therapy because many of these agents are readily available OTC. Antacids afford relief of pain symptoms for most patients with PUD and promote ulcer healing. Antacids also work by binding bile acids or inhibiting pepsin.

The choice of antacid should be individualized. The magnesium-containing antacids can produce diarrhea in up to 25% of patients. Magnesium-containing antacids can also lead to an increase in serum magnesium levels and should be used with caution or avoided altogether in patients with impaired renal function. Aluminum-containing antacids may cause constipation, and prolonged use may lead to phosphate depletion. Calcium-containing antacids have been marketed as acid neutralizers and as a means of calcium supplementation, particularly for postmenopausal women. Calcium-containing antacids have traditionally been believed to cause the highest incidence of acid rebound, a paradoxical increase in gastrin secretion and acid production. Calcium antacids can also lead to constipation, and their excess consumption can lead to hypercalcemia, alkalosis, and renal insufficiency—the milk-alkali syndrome.

Antacids can decrease the absorption of warfarin, digoxin, and some anticonvulsants and antibiotics. It is recommended that antacids be administered 1 to 3 hours after meals and at bedtime. Antacids are the least expensive drugs available to treat PUD, but their use is limited by efficacy, side effects, and inconvenient administration schedules.

Histamine Blockers

Histamine is the primary stimulus to gastric acid secretion. It binds to the histamine-2 (H2) receptor located on the basolateral portion of the parietal cell to stimulate the release of hydrochloric acid. The discovery of the ability of H2 blockers to inhibit gastric acid production was a major advance in antiulcer therapy because ulcers are not prone to develop in the absence of acid. These drugs are highly selective competitive inhibitors of histamine for the H2 receptor on parietal cells and reduce the volume of gastric juice and its hydrogen ion concentration. All of the currently available H2 blockers are rapidly absorbed after an oral dose, with peak levels reached within 1 to 2 hours. All have half-lives of approximately 2 to 3 hours, so their effects last for approximately 6 hours. Most are now available OTC in lower dosage strength than prescription forms.

H2 blockers are effective in treating duodenal ulcer and, to a lesser extent, gastric ulcer, although they are not as effective as the PPIs. They are widely prescribed for symptoms of dyspepsia and work well in patients with episodic heartburn. All H2 blockers are mainly metabolized hepatically and renally, with the exception of nizatidine, which is almost exclusively metabolized renally. Dosages of these agents should be reduced in patients with renal failure.

H2 blockers are safe and generally well tolerated. Side effects are rare but include central nervous system effects, such as somnolence, dizziness, and confusion. Transient increases in liver enzyme levels may be noted. Some patients may exhibit abnormalities in cardiac conduction as the heart contains H2 receptors. Cimetidine has been shown to cause gynecomastia. Dosages of the various agents are summarized in Table 75.1.

Proton Pump Inhibitors

The H^+,K^+-ATPase (proton pump) is located on the apical portion of the parietal cell and is responsible for the production of hydrogen ions in gastric acid. PPIs are the most potent inhibitors of gastric acid secretion. They work by irreversibly binding to stimulated proton pumps to block the secretion of hydrogen ions. Although they have no effect on the volume of gastric juice produced, production of acid can be reduced by up to 95%. Both basal and stimulated gastric acid secretions are reduced. The antisecretory effects last up to 72 hours.

PPIs should be administered before the first meal of the day because the number of proton pumps is maximized after a fasting state. At the cellular level, additional proton pumps are continually recruited to produce more acid in response to stimulation; therefore several doses of a PPI are necessary for the maximal antacid effect to be achieved. The use of these medications on an as-needed basis would not be expected to provide an adequate clinical response; H2 blockers are more suitable for this purpose.

PPIs are hepatically metabolized; thus dosage should be modified in patients with hepatic failure. Side effects are usually minimal, and the long-term safety of these drugs has been shown in multiple studies. PPIs may be used at significantly higher dosages in patients with Zollinger-Ellison syndrome. Dosages of the various agents are summarized in Table 75.2. Lansoprazole, pantoprazole, and esomeprazole are available as IV formulations.

PPIs have been linked to inhibition of the effects of thienopyridines used to treat cardiovascular disease. Retrospective observational studies have suggested a potential increase of reinfarction and hospitalization when clopidogrel was used in combination with PPIs; however, this has not been shown in prospective studies. Two prospective randomized control trials have been performed, and both failed to show an increased cardiovascular risk for patients using both clopidogrel and PPIs.[14] Overall, the data are mixed, and further research is needed to determine if there is an important clinical effect on patients taking both clopidogrel and PPIs.[15] We recommend using PPIs and clopidogrel together with caution, and only when the benefits of PPIs outweigh the potential risks. An additional risk of PPIs in elders is a significant association with hip fracture when compared with H2 blocker therapy. As such, we recommend caution when initiating PPIs in patients at high risk for hip fracture.[16]

Prostaglandins

Prostaglandins exert protective effects on the gastric mucosa by inhibiting acid secretion and decreasing the amount of cyclic adenosine monophosphate generated in response to histamine. Inhibition of gastric acid secretion, increased secretion of mucus and bicarbonate, and stimulation of mucosal blood flow have all been demonstrated. Misoprostol is an analogue of prostaglandin E_1, with a longer duration of action and greater potency than endogenous prostaglandins. It should be used only for the prevention of NSAID-induced gastric ulcers in patients at high risk. The dose is 200 μg qid PO with food, but crampy abdominal pain and diarrhea may necessitate the use of a somewhat less effective dose of 100 μg PO qid. Misoprostol is an abortifacient and therefore is contraindicated in any female patient of childbearing age who is not using contraception.

Other Agents

Sucralfate binds to epithelial cells, especially to ulcerated surfaces, providing a protective layer that inhibits further acid damage. Its mechanism of action is not completely understood, although it has been shown to enhance epithelial growth, suppress acid secretion, and inhibit the growth of *H. pylori*. The usual dose is 1 g PO qid given 30 to 60 minutes before meals. This can be an appropriate and safe choice to use during pregnancy, although there are currently preferred options with longer duration of action and higher efficacy that should be considered as first line for most patients.

Bismuth compounds such as bismuth subsalicylate decrease pepsin activity, increase mucus secretion, and form a barrier to further acid damage in ulcer craters. They also increase prostaglandin synthesis and retard hydrogen ion diffusion through the mucosal barrier. Bismuth may also help to heal ulcers through its bactericidal action on *H. pylori*. Bismuth compounds are not approved for the treatment of peptic ulcers.

Disposition

Referral to a gastroenterologist is suggested if any of the following signs or symptoms are present: Age 55 years or older with new-onset dyspepsia, dysphagia, progressive unintentional weight loss, persistent vomiting, iron deficiency anemia, or an epigastric mass. Most patients with PUD can be safely managed as outpatients, with referral to gastroenterology for confirmation of diagnosis with an esophagogastroduodenoscopy (EGD). Further evaluation is recommended for patients with high-risk clinical features (e.g., anemia, report of GI bleeding, intractable pain, signs of gastric obstruction) prior to discharge.

GASTRIC VOLVULUS

Foundations

Gastric volvulus is a rare cause of severe abdominal pain that occurs when the stomach rotates on itself more than 180 degrees, creating a closed loop obstruction. It is a rare condition with a true incidence that remains unknown as some types of volvulus are intermittent and resolve spontaneously. Gastric volvulus may be classified according to cause (primary vs. secondary), anatomy (axis of rotation), or onset (acute vs. chronic).[15]

The stomach is fixed at only two points, the esophagocardiac junction and pylorus. The remainder of the organ is relatively distensible and mobile and can occupy various positions within the abdomen. When a person is supine, the stomach lies entirely above the umbilicus, whereas it descends below the umbilicus when a person is in the erect position. Regardless of its position, the stomach maintains its familiar morphology because of ligamentous attachments to surrounding organs. A primary (or subdiaphragmatic) volvulus accounts for approximately one-third of cases and occurs when the stabilizing ligaments are too lax or are congenitally abnormal in such a way that the stomach is able to twist on itself.

Secondary (or supradiaphragmatic) volvulus occurs in patients with diaphragmatic defects such as a paraesophageal hiatal hernia, elevated diaphragm, gastric ulcer or carcinoma, diaphragmatic paralysis, extrinsic pressure on the stomach from other organs, or abdominal adhesions. The combination of one or more of these factors, as well as ligamentous laxity, makes a volvulus more likely.

Gastric volvulus can also be classified on the basis of its axis of rotation. The most common form is organoaxial volvulus, which occurs when the stomach twists on its long axis. Less commonly, in approximately one-third of cases, the stomach folds on its short axis from its lesser to greater curvature and is classified as a mesenteroaxial volvulus.

Clinical Features

Gastric volvulus typically occurs in persons 40 to 50 years of age and is often associated with the presence of a paraesophageal hernia. Approximately 20% of cases occur in infants younger than 1 year, frequently associated with a congenital diaphragmatic defect.[15]

The presenting features of a gastric volvulus vary, depending on the type. Primary volvulus may arise with the sudden onset of severe abdominal pain. The upper abdomen may demonstrate marked distention. Patients with secondary volvulus may experience predominant symptoms in the chest, with pain radiating to the back or shoulders, along with accompanying dyspnea. The abdominal examination may be unremarkable. Nonbilious vomiting is usually present and may be persistent and severe. The combination of severe epigastric pain and distention, vomiting followed by violent nonproductive retching, and inability to pass a nasogastric tube (Borchardt triad) increases the likelihood of a gastric volvulus and is present in up to 70% of patients. Up to 25% of children with acute gastric volvulus present with life-threatening events that necessitate resuscitation, including apnea, cyanosis, or acute respiratory distress.

A volvulus may be chronic if the rotation is minimal and there is no vascular compromise. Symptoms usually consist of mild intermittent upper abdominal pain. Early satiety, dyspnea, bloating, eructation, or upper abdominal distension may be present. It is unknown how often a chronic volvulus can lead to an acute volvulus.

Complications

If an acute volvulus is not identified and corrected early, it may lead to gastric ischemia, perforation, and death. The mortality rate from acute gastric volvulus has been reported to be as high as 50%. Fortunately, the frequency of gastric infarction is low (reportedly 5% to 28% for organoaxial volvulus) because of the redundant blood supply of the stomach. Other complications include ulceration, perforation, hemorrhage, pancreatic necrosis, or omental avulsion.

Differential Diagnoses

The differential diagnosis of gastric volvulus includes any disease that can arise with sudden upper abdominal pain and vomiting. Perforated peptic ulcer, gastric outlet obstruction, biliary tract disease, or acute pancreatitis should be considered. Symptoms of a volvulus may be similar to those of ACS.

Diagnostic Testing

A plain abdominal radiograph is often the initial diagnostic test, which can help quickly confirm the diagnosis if typical findings are seen. The classical x-ray will show a large, gas-filled loop of bowel in the abdomen or chest with an air-fluid level, often with an associated lack of air in the distal bowel (Fig. 75.4). A barium swallow may help

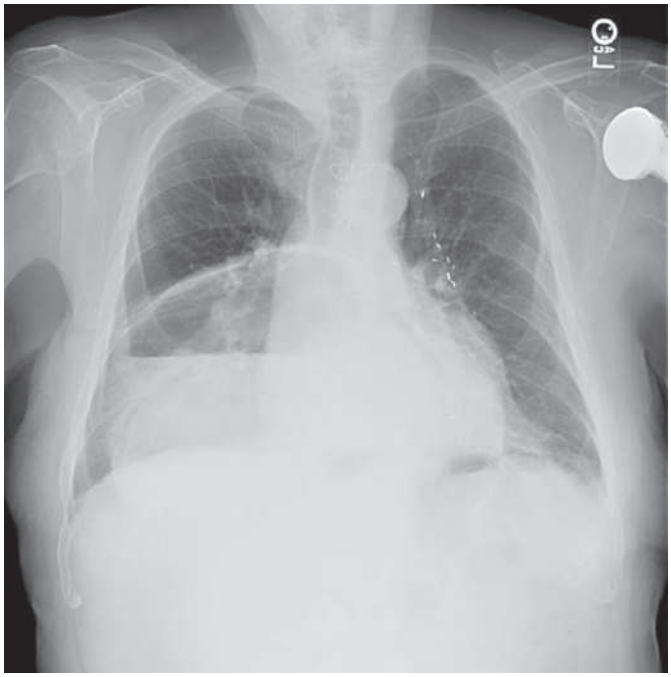

Fig. 75.4 Organoaxial Gastric Volvulus. (Courtesy Radiopaedia.org: Gastric volvulus. http://radiopaedia.org/cases/gastric-volvulus.)

visualize the abnormality, and CT can be used for confirmation in equivocal cases. There are no laboratory findings specific for volvulus, although elevations in amylase and alkaline phosphatase levels have been reported.

Management

The goal of treatment of an acute gastric volvulus is reduction. Mortality rates increase with delayed diagnosis because of ischemic complications. Acutely, clinicians should attempt immediate passage of a nasogastric tube, which may occasionally reduce the volvulus. Although somewhat controversial, patients without signs of gastric infarction may undergo an attempt at endoscopic reduction. Ultimately, treatment is a surgical emergency, with the goal of reducing the volvulus and preventing recurrence by fixating the stomach within the abdomen. Surgical repair of predisposing diaphragmatic defects is also recommended to prevent recurrence.

Disposition

Patients with an acute gastric volvulus require admission and surgical consultation due to the high morbidity and mortality associated with the condition.

CHAPTER 75: QUESTIONS AND ANSWERS

1. Which of the follow drug regimens is appropriate first-line treatment for *Helicobacter pylori* infection?

a. Bismuth subsalicylate, famotidine, and clarithromycin
b. Metronidazole and sucralfate
c. Omeprazole, amoxicillin, and clarithromycin
d. Omeprazole and bismuth subsalicylate
e. Famotidine, omeprazole, and amoxicillin

Answer: c. The recommended triple-treatment regimen for *H. pylori* infection is a proton pump inhibitor (PPI) (e.g., omeprazole, 20 mg bid), amoxicillin (1 g bid), and clarithromycin (500 mg bid) for 14 days. Quadruple therapy with Pepto Bismol, metronidazole, tetracycline, and a PPI is an alternative option. See Box 75.5.

2. What percentage of esophageal foreign bodies require a nonoperative intervention to facilitate removal?

a. <5%
b. 10% to 20%
c. 50%
d. 75%
e. >90%

Answer: b. Most foreign bodies pass spontaneously. Approximately 10% to 20% require intervention, but less than 1% require surgery for removal.

3. A 5-year-old child is brought to the emergency department (ED) by his mother after a possible ingestion of a plastic Lego piece. He has had no pulmonary symptoms but reports difficulty swallowing and declines to drink liquids that are offered. What would be the intervention of choice?

a. Contrast-enhanced CT scan of the chest
b. Endoscopy
c. Non–water-soluble barium swallow
d. Posteroanterior and lateral chest radiography
e. Water-soluble barium swallow

Answer: b. Because the patient is symptomatic, endoscopy is indicated. A CT scan of the chest is useful for organic and inorganic materials. A basic chest radiograph cannot reliably exclude a foreign body. Barium swallow is difficult in pediatric patients, particularly in a child who is refusing oral fluids. Water-soluble media administration risks development of pneumonitis if aspirated. Non–water-soluble materials risk increased inflammation if leakage occurs into the mediastinum. Barium may also obscure subsequent endoscopic visualization.

continued

CHAPTER 75: QUESTIONS AND ANSWERS—cont'd

4. Which of the following statements regarding the use of glucagon in esophageal obstruction from a food bolus is true?
   a. Glucagon should be administered by the oral route.
   b. Glucagon has antiemetic properties.
   c. Glucagon can facilitate passage of a food bolus localized anywhere in the esophagus.
   d. Glucagon is relatively contraindicated with sharp-edged foreign bodies.
   e. The success rate of glucagon approaches 90% when used with a few hours of food bolus impaction.

Answer: d. Glucagon is a smooth muscle relaxant, so it is theoretically useful only for distal esophageal foreign bodies. There are only anecdotal reports of success with glucagon, but a literature review shows no statistical benefit of glucagon in treating esophageal foreign bodies. There are many adverse effects, including flushing, nausea, and vomiting, that can potentially increase the risk of aspiration. It is contraindicated for use with sharp or damaging foreign bodies. There is only low-level evidence to support the use of effervescent agents, and they are relatively contraindicated after 24 hours because of perforation concerns.

5. Which of the following is an indication for urgent endoscopy?
   a. Button battery in the stomach
   b. Chest pain due to foreign body
   c. Coin in the proximal esophagus
   d. Nausea and vomiting
   e. Object failing to pass out of the esophagus after 12 hours

Answer: c. A coin that remains lodged in the proximal esophagus should be removed. Other indications are inability to handle secretions, sharp objects, esophageal button battery (alkaline), and impactions that fail to pass after 24 hours.

6. Ulcers in which portion of the upper GI tract are most likely to perforate?
   a. Hypopharyngeal
   b. Esophageal
   c. Gastric—antrum
   d. Gastric—body
   e. Duodenal

Answer: e. Duodenal ulcers account for 60% of all perforations, followed by antral gastric ulcers (20%) and gastric body ulcers (20%). Various upper gastrointestinal (GI) symptoms may lead to esophageal ulcerations and severe odynophagia, although perforation is infrequent.

7. A 32-year-old otherwise healthy man presents with acute onset of epigastric pain radiating to his chest that woke him from sleep at 2 AM. It was a burning pain associated with water brash. There were no associated pulmonary symptoms. His past medical history is unremarkable except for tobacco use and heartburn. His electrocardiogram and upright chest radiograph are normal. Vital signs and physical examination findings are unremarkable. He is currently pain free. His troponin level is normal. What is the most appropriate intervention?
   a. Cardiology consultation for catheterization
   b. Contrast-enhanced CT scan of the chest
   c. Discharge on aspirin, 325 mg once daily
   d. Serial troponins
   e. Trial of twice-daily proton pump inhibitor therapy

Answer: e. Peak gastric acid secretion occurs during the early morning hours between 1 AM and 3 AM, with a typical scenario of causing awakening from sleep. The shared afferent neural pathway makes the pain of gastroesophageal reflux disease (GERD) similar to that of pain of cardiac origin. Gastric acid secretion is lowest at approximately 6 AM; thus awakening in the morning with pain from GERD is unusual.

8. A 45-year-old woman presents several hours after an upper endoscopy with severe chest pain and neck discomfort. She is awake and alert, but rates pain as "10 of 10." What is the most appropriate test to confirm the diagnosis?
   a. Abdominal x-ray
   b. Barium contrast esophagography
   c. Gastrografin (water-soluble) contrast esophagography
   d. Ultrasound
   e. Upper endoscopy

Answer: c. We recommend an initial attempt with a water-soluble agent in patients who are awake and alert and are not at risk for aspiration. Barium sulfate is superior for identifying small perforations; however, it may incite an inflammatory response in tissue and should be used only if no initial perforation is identified with water-soluble contrast. Endoscopy is generally not recommended except in cases of penetrating trauma because insufflation could potentially enlarge a minimal transmural opening. CT imaging is a reasonable alternative.

76

Liver and Biliary Tract Disorders

Elizabeth J. Haines and Holly Thompson

KEY CONCEPTS

Viral Hepatitis

- The clinical presentation of viral hepatitis is highly variable, and many cases may be asymptomatic, particularly in children.
- Hepatitis A is transmitted through oral fecal spread, whereas hepatitis B and C are spread through parenteral or intimate contact.
- Highly effective immunizations exist against hepatitis A and B viruses.
- Postexposure, passive immunization exists for hepatitis A and B viruses, though its use is primarily in the setting of hepatitis B exposure in nonimmunized individuals.
- Direct-acting antiviral regimens using nucleoside inhibitors have revolutionized hepatitis treatment.
- Viral hepatitis may be a reportable disease dependent on jurisdiction.

Alcoholic Hepatitis

- Alcohol-induced liver disease may progress from steatosis to steatohepatitis to cirrhosis, and finally to hepatocellular carcinoma. It is estimated that 8% to 20% of patients with steatosis will eventually progress to cirrhosis. The risk for hepatocellular carcinoma (HCC) in decompensated alcohol-induced cirrhosis approaches 1% per year.
- With cessation of alcohol intake, steatosis may reverse within 2 weeks.
- Laboratory tests may help distinguish alcoholic hepatitis from viral hepatitis, with the former associated with milder transaminase level elevations and a relative predominance of AST to ALT.
- Hypoglycemia is common in patients with alcoholic hepatitis secondary to caloric insufficiency, chronically depleted glycogen stores, and suppressed gluconeogenesis.
- Management of alcoholic hepatitis is guided by severity scoring; Maddrey discriminant function (MDF) is the most commonly utilized and incorporates coagulopathy and bilirubin levels.
- Patients with alcoholic hepatitis and a MDF over 32 should be treated with prednisone, 40 mg PO daily, or methylprednisolone, 32 mg IV daily.

Cirrhosis

- Patients with cirrhosis most often present with complications resulting from loss of hepatocytes, including ascites, variceal bleeding, hepatorenal syndrome, or hepatic encephalopathy.
- The targeted platelet count should generally be greater than 50,000/mm^3 prior to the performance of invasive procedures in patients with cirrhosis. Management of coagulopathy may need to precede major diagnostic or therapeutic interventions.
- An elevated INR or thrombocytopenia is not a contraindication to paracentesis in patients with cirrhosis.
- Albumin, 8 g per L of ascitic fluid removed, should be administered when volumes over 5 L are removed by paracentesis.
- Upper GI bleeding in patients with cirrhosis, often from esophageal varices, carries a 10% to 15% mortality.
- When treating liver-associated coagulopathies in a patient with active bleeding, cryoprecipitate, 1 unit/10 kg body weight, is preferred over fresh-frozen plasma.
- Angiotensin-converting enzyme inhibiting drugs or angiotensin receptor blocking drugs should be avoided in patients with decompensated cirrhosis or ascites because plasma drug concentrations may increase, renal clearance may be markedly decreased, leading to impaired renal function.
- In patients with cirrhosis, mean arterial pressure (MAP) is an independent predictor of mortality.
- Hepatorenal syndrome is heralded by an increasing creatinine level in the setting of liver failure, and is associated with a high rate of mortality.

Hepatic Encephalopathy

- Hepatic encephalopathy is a state of cerebral and neuromuscular dysfunction secondary to an increased ammonia level and its effect on cerebral metabolism. However, the severity of hepatic encephalopathy does not directly correlate with the measured serum ammonia level.
- Underlying conditions that can precipitate encephalopathy in patients with cirrhosis include GI bleeding, hypokalemia, infection, and dehydration.
- Management of hepatic encephalopathy includes correction of underlying electrolyte abnormalities, dietary guidance, administration of lactulose (30–60 g/day), and rifaximin (400 mg PO every 8 hours).
- In addition to lactulose and rifaximin, infusion of branched chain amino acids has shown benefit without increased mortality in patients with hepatic encephalopathy.

Spontaneous Bacterial Peritonitis

- Spontaneous bacterial peritonitis (SBP) is an acute infection of ascitic fluid that should be considered in any patient with ascites and abdominal pain, fever, or unexplained clinical deterioration.
- SBP is most commonly caused by *E. coli* and *Klebsiella.*
- The diagnosis of SBP is dependent on obtaining ascitic fluid for analysis.
- An ascitic fluid granulocyte count greater than 250 cells/mm^3 (100 cells/mm^3 in peritoneal dialysis patients) is generally an indication for antibiotic treatment.
- Treatment of SBP includes cefotaxime 2 g IV every 8 hours for 5 days.

Hepatic Abscesses

- Abscesses may be amoebic or pyogenic in nature. Abdominal ultrasound or CT are the diagnostic imaging modalities of choice.
- Chest radiography may reveal a right lower lobe pleural effusion
- Imaging does not distinguish pyogenic from amebic abscesses.
- Treatment is initiated prior to abscess drainage.

- Treatment regimens for pyogenic abscess include:
  - Cefotaxime 2 g IV q8h + metronidazole 500 mg IV or PO every 8 hours
  - Ampicillin 2 g IV q4h + gentamycin 5– 7 mg/kg IV daily + metronidazole 500 mg IV or PO every 8 hours
  - Ciprofloxacin 400 mg IV q12h or 500 mg PO q12h or levofloxacin 750 mg IV or PO every 24 hours or moxifloxacin 400 mg IV or PO daily + metronidazole 500 mg IV or PO every 8 hours
  - Piperacillin-tazobactam 3.375 g or 4.5 g IV every 6 hours or imipenem-cilastatin 500 mg IV every 6 hours or meropenem 1 g IV every 8 hours + metronidazole 500 mg IV or PO every 8 hours
- Definitive treatment for abscesses larger than 3 to 5 cm includes image-guided percutaneous drainage.

Amebic Abscess

- Symptom onset with amebic abscess usually occurs approximately 12 weeks following exposure.
- Although similar in many ways to pyogenic abscess, the diagnosis of hepatic amebic abscess is made via stool analysis or ELISA testing.
- Most patients will have elevation in alkaline phosphatase and aminotransferase levels.
- Ultrasound may reveal specific findings unique to an amebic abscess, including a peripherally located, ovoid abscess with a well-circumscribed border and a homogeneous, hypoechoic center.
- Definitive treatment of amebic abscess is amebicidal therapy with IV or oral metronidazole (750 mg every 8 hours for 7–10 days).
- Percutaneous drainage is rarely needed.

Cholelithiasis

- Biliary colic should be considered in patients with nausea, vomiting, and right upper quadrant (RUQ) abdominal pain.
- Diagnosis with ultrasound of the biliary system or laboratory abnormalities including leukocytosis, elevated liver tests or pancreatic enzymes when present, suggests obstruction of the biliary tree.
- Initial management of cholelithiasis is supportive, with the goal of treating pain and correcting fluid or electrolyte abnormalities.
- Patients without findings of infection who are tolerating oral intake are typically managed in the outpatient setting.
- Definitive care requires outpatient surgical referral for cholecystectomy.

Cholecystitis

- Most patients with cholecystitis have gallstones, but approximately 8% have acalculous disease.
- Despite an unclear relationship between the pathophysiology and bacterial infection in cholelithiasis, antibiotic therapy is recommended. First-line treatment includes piperacillin-tazobactam 3.375 gm IV every 6 hours
- Patients with acalculous or emphysematous cholecystitis are at increased risk for gangrene or perforation and often require emergent cholecystectomy.

Cholangitis

- Cholangitis is an emergency condition resulting from extrahepatic bile duct obstruction and bacterial infection. Most commonly, the obstruction is secondary to gallstone impaction.
- The classic (Charcot) triad of cholangitis consists of RUQ pain, fever, and jaundice.
- Initial management of cholangitis requires prompt fluid resuscitation and administration of broad-spectrum antibiotics. First-line treatment choice of antibiotics should take into consideration individual risk factors and community versus health care–associated pathogens.
- Definitive management of cholangitis includes hospitalization and early biliary tract decompression, which can be achieved surgically, transhepatically, or by endoscopic retrograde cholangiopancreatography (ERCP).

HEPATIC DISORDERS

Hepatic disorders may be acute or chronic. Although acute disease is often self-limiting, it can progress to scarring, fibrosis, cirrhosis, or cancer. In the United States (US), acute hepatic disease prevalence has remained stable for the last three decades in contrast to chronic liver disorders which have increased, attributed primarily to a doubling of nonalcoholic fatty liver disease (NAFLD).[1] Etiologies of newly diagnosed chronic liver disease include: hepatitis B, hepatitis C, hepatitis C in combination with alcohol-related liver disease, alcohol-related liver disease, NAFLD, or alternative/undetermined etiologies. Hepatitis C is the most common etiology in the US. Overall mortality and anticipated cost burden is projected to increase with an aging patient cohort previously infected with hepatitis C.[2]

HEPATITIS

End organ inflammatory damage to the liver defines *hepatitis*. Although it commonly results from viral infection or toxic alcohol exposure, other etiologies include chemical or medication exposure; bacterial, fungal or parasitic infection; genetic disorders; or immune mediated pathology.

Viral Hepatitis

Foundations

Many viral infections are associated with some degree of measurable liver inflammation. However, the most significant and potentially severe cases of viral hepatitis are caused by type A, type B, type C, or delta viruses. The Epstein-Barr virus, the causative agent of mononucleosis, is also a common cause of hepatitis, although it is more important clinically for its nonhepatic effects.

Hepatitis A. Hepatitis A virus (HAV), is an RNA enteroviral picornavirus. It is spread by the fecal-oral route directly or through fecally contaminated water or food. Transmission by blood is possible though exceedingly rare. HAV can occur sporadically or more commonly in association with epidemics generally linked to common source outbreaks. HAV infection is common worldwide; serologic evidence of previous infection exists in nearly 100% of the adult population in some regions (Fig. 76.1). In the US, close to 50% of all urban-dwelling adults are seropositive for antibody for HAV.[3] High rates of seropositivity in association with the relatively small number of reported episodes support the notion that many cases may be subclinical or asymptomatic altogether. Occult disease appears to be more common in children with upwards of 70% of those infected

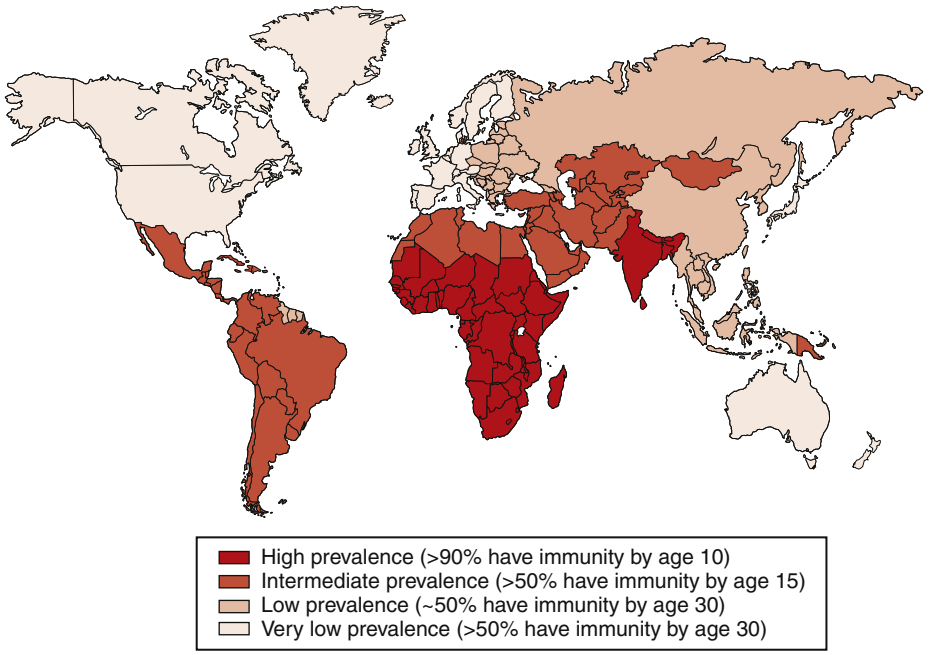

Fig. 76.1 Worldwide distribution of hepatitis A. (From Jefferies M, Rauff B, Rashid H, et al. Update on global epidemiology of viral hepatitis and preventive strategies. *World J Clin Cases*. 2018;6(13):589-599.)

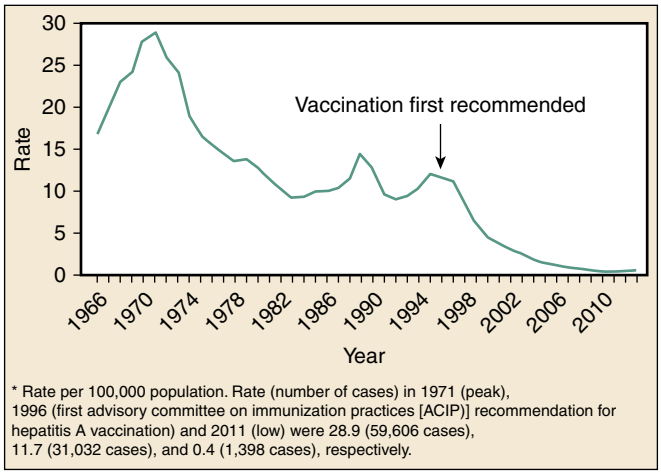

Fig. 76.2 Incidence of hepatitis A denoting 1995 approval of vaccination. (From Centers for Disease Control and Prevention (CDC). Progress toward eliminating hepatitis A disease in the United States. *MMWR Morb Mortal Wkly Rep*. 2016;65(1):29-41.)

asymptomatic.[3] The hepatitis A vaccine was approved in the US in 1995. Widespread vaccination has contributed to a profound shift in reported new cases to adults (Figs. 76.2 and 76.3). Travel to endemic areas is the most common risk factor for hepatitis A in persons more than 15 years of age.

The incubation period for hepatitis A ranges from 15 to 45 days (typically, 30 days), with a relatively short duration of viremia that is most prominent before the onset of symptoms. Most commonly, symptoms occur between 2 to 6 weeks after exposure.[4] Fecal shedding and maximum infectivity occur before the onset of symptomatic disease and generally have waned by the time jaundice appears (Fig. 76.4). HAV is not associated with a chronic carrier state.

Hepatitis B. Hepatitis B virus (HBV) is a virion that envelopes DNA polymerase, hepatitis B surface antigen (HBsAg), and hepatitis B core antigen (HBcAg). Hepatitis Be antigen (HBeAg) is not incorporated into the virion; rather, it is secreted from cells into the serum of infected patients. In contrast to HAV, for which there is only a single antigenic variety, several genotypes of HBV are recognized as defined by surface antigen. HBV is transmitted principally by parenteral exposure and also can be transmitted through intimate contact or body fluids. Transmission by blood transfusion, previously a common source of infection, has essentially been eliminated secondary to modern blood screening techniques. In contrast to HAV which has decreased, the incidence of hepatitis B has remained relatively stable despite increased rates of immunization. This is postulated in relation to increasing injection drug use and the ongoing opioid crisis in the United States, with 22,000 new HBV infections estimated annually[5] (Figs. 76.5 and 76.6). HBsAg has been detected in a variety of bodily fluids, including saliva, semen, stool, tears, urine, and vaginal secretions. The virus is highly stable and can survive outside of the body up to seven days with ongoing infective capacity.[6]

The mean interval between exposure and onset of clinical illness is 120 days; however, serologic markers of infection generally appear within 1 to 3 weeks (Fig. 76.7). Chronic hepatitis is typically defined as the presence of HBsAg in serum for longer than 6 months. Additional tests for HBV replication, HBeAg, serum HBV DNA, and ALT should be performed to determine if the patient is a candidate for antiviral therapy. Approximately 10% of adults, and 90% of infected neonates with immature immune systems, will become asymptomatic chronic carriers of HBsAg. Similar to HAV, children are more likely to have asymptomatic infections. The likelihood of becoming chronically infected with HBV varies inversely with the age at which infection occurs. In other words, there exists an age-dependent protection against contracting chronic HBV.[7] HBV transmitted from HBsAg-positive mothers to their newborns results in HBV chronic carriage in up to 90% of infants, whereas only 6% to 10% of acutely infected adults become chronic carriers. This has led to strict prenatal screening and prophylaxis practices in the United States.

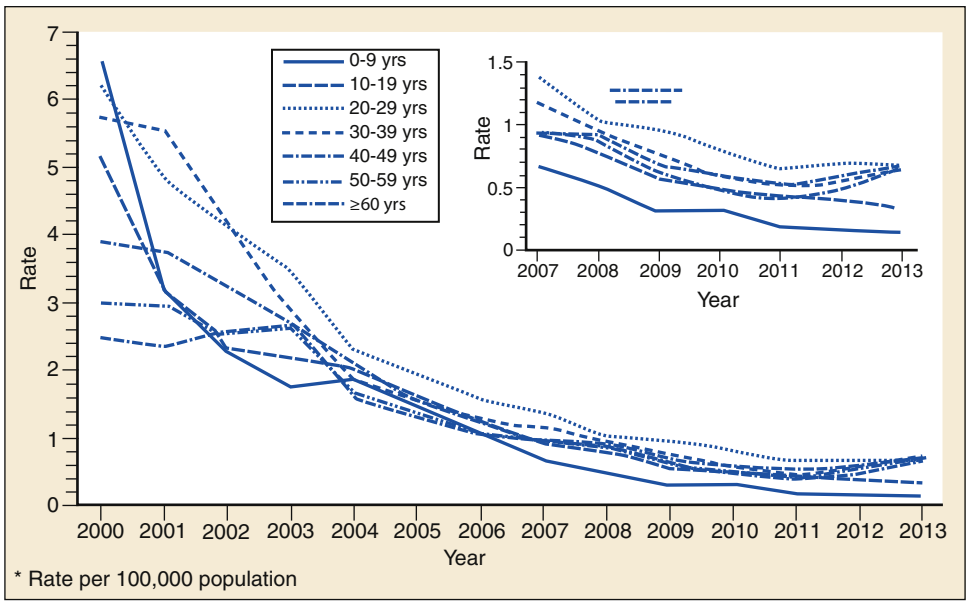

Fig 76.3 Incidence of hepatitis A by age group. (From Centers for Disease Control and Prevention (CDC). Progress toward eliminating hepatitis A disease in the United States. *MMWR Morb Mortal Wkly Rep.* 2016;65(1):29-41.)

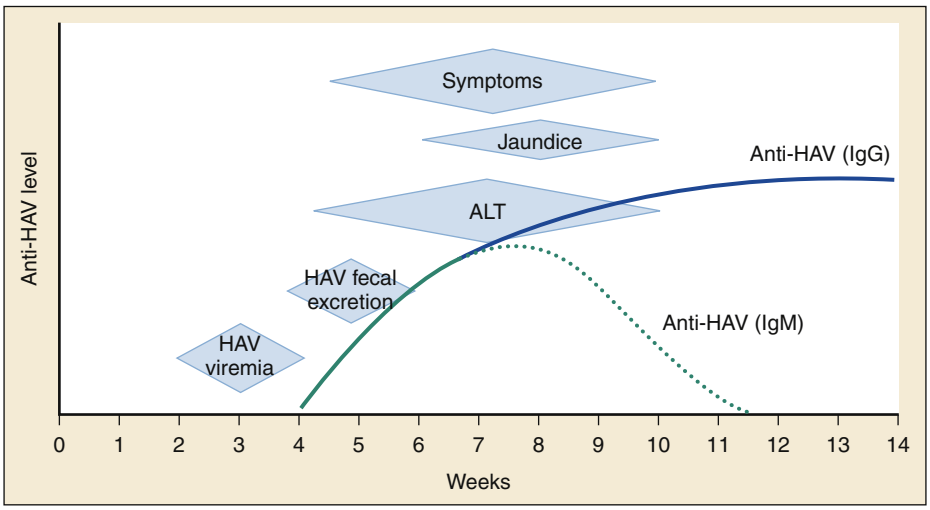

Fig. 76.4 Acute hepatitis A virus (HAV) infection. *ALT,* Alanine aminotransferase; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M. (From Oyama LC. Disorders of the liver and biliary tract. Anesthesia key: fastest anesthesia & intensive care & emergency medicine insight engine. Available at: https://aneskey.com/disorders-of-the-liver-and-biliary-tract/. Accessed May 10, 2021.)

Hepatitis C and E

Historically termed "non-A, non-B hepatitis," hepatitis C and E are caused by at least two distinct RNA viruses, hepatitis C virus (HCV) and hepatitis E virus. In the US, hepatitis C infection is currently the leading cause of cirrhosis, accounting for over 42% of cases of chronic liver disease.[2] Worldwide, HCV remains highly prevalent. The World Health Organization (WHO) in 2020 reported an estimated 71 million cases worldwide.[8] Hepatitis C is the most commonly reported bloodborne infection in the US. Data from the National Health and Nutrition Examination Survey (NHANES) estimates a prevalence of 1.2% to 2.0% among the US population.[9] Prior to 1992 and the advent of improved screening with antibody, PCR nucleic acid amplification, and aminotransferase (surrogate marker) testing, transmission by blood transfusion or solid organ transplant was common. Current risk of transfusion-acquired hepatitis C is less than 1 in 2 million units of blood transfused.[10,11]

Both in the United States and worldwide, the strongest risk factor for HCV infection is a history of intravenous drug use (IVDU). A 2017 study noted an HCV prevalence in the US of 53% among persons who inject drugs.[12] Another study estimates that the rate is closer to 75% among injection drug users coinfected with HIV.[13] Patients coinfected with HIV and HCV generally have a more aggressive course of both diseases. In upwards of 57% of patients with HCV, no source of infection is identified. The mean incubation period for hepatitis C is 50 days. Following the incubation period, a self-limited acute phase begins.[14] The acute phase persists for up to 12 weeks and is rarely associated with hepatic failure. Approximately 90% of HCV infections progress to chronic hepatitis. Over a 20- to 30-year period, clinical liver disease

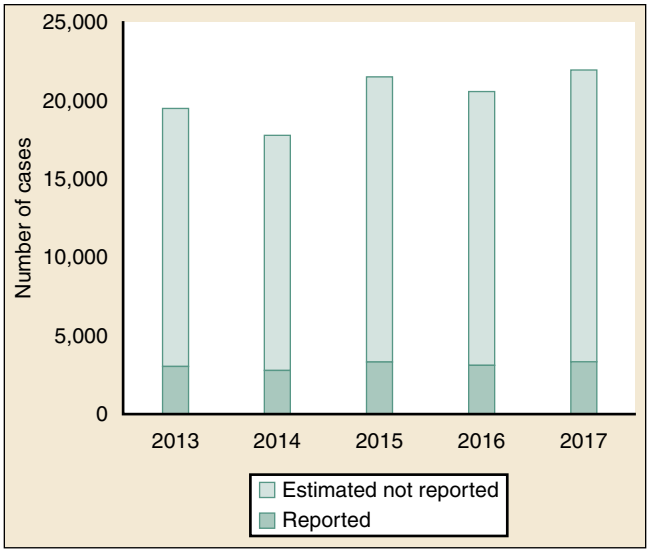

Fig. 76.5 Incidence of hepatitis B in the United States. (From Centers for Disease Control and Prevention. Viral hepatitis surveillance—United States, 2017. Atlanta: US Department of Health and Human Services, Centers for Disease Control and Prevention; 2019. Available at: https://www.cdc.gov/hepatitis/statistics/2017surveillance/index.htm)

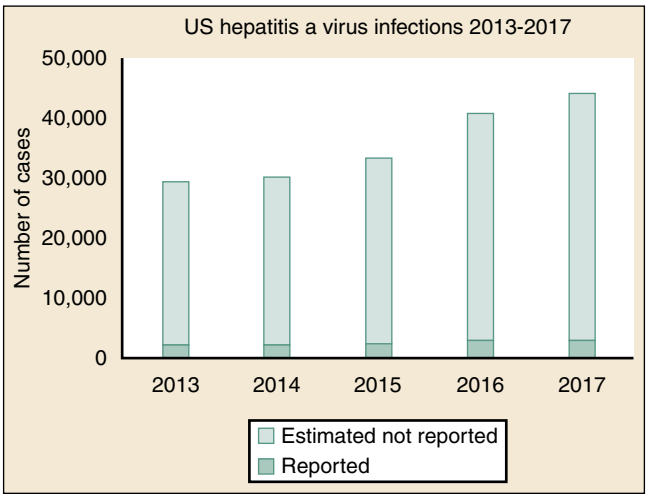

Fig. 76.6 Incidence of hepatitis A in the United States. (From Centers for Disease Control and Prevention. Viral hepatitis surveillance—United States, 2017. Atlanta: US Department of Health and Human Services, Centers for Disease Control and Prevention; 2019. Available at: https://www.cdc.gov/hepatitis/statistics/2017surveillance/index.htm)

or cirrhosis develops in roughly 10% to 20% of those infected. Patients with cirrhosis are at elevated risk for development of hepatocellular carcinoma.[15] In the US, it has been estimated that 2.1 million persons are infected with HCV. Unlike HAV and HBV, HCV incidence has continued to increase. Antiviral treatments can reverse damage and effectively cure many patients with HCV.

Hepatitis D. Hepatitis delta virus (HDV) is a defective RNA virus that can infect only patients who are actively producing HBsAg (HBV disease), which is required for its viral coating. Worldwide, the prevalence of hepatitis D in those with hepatitis B is 5%.[16] As a result of HBV control in the US, the prevalence is lower. Given its association with chronic HBV infection, it is likely that many cases of HDV infection are misdiagnosed as acute or reactivated hepatitis B.

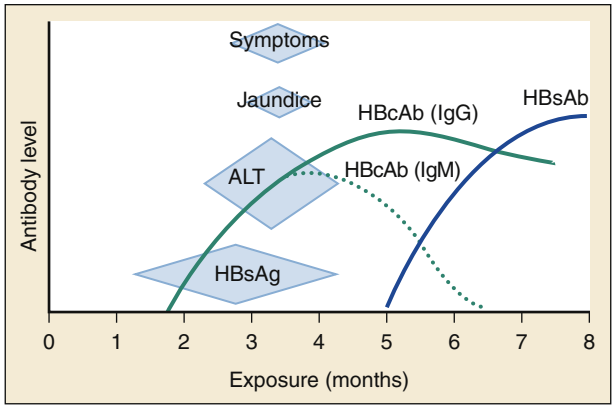

Fig. 76.7 Acute hepatitis B virus infection. *Ab,* Antibody; *Ag,* antigen; *ALT,* alanine aminotransferase; *HBc,* hepatitis B core; *HBs,* hepatitis B surface; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M. (From Oyama LC. Disorders of the liver and biliary tract. Anesthesia key: fastest anesthesia & intensive care & emergency medicine insight engine. Available at: https://aneskey.com/disorders-of-the-liver-and-biliary-tract/. Accessed May 10, 2021.)

HDV is spread in a manner similar to that of hepatitis B. Infection with HDV can occur concomitantly with HBV (coinfection) or subsequent to an existing HBV infection (superinfection), as HDV can only replicate in the presence of HBV. Cases of superinfection may present as acute self-limited disease to fulminant hepatitis or chronic infection. Fulminant hepatitis is more often observed with HBV-HDV coinfection than with HBV mono-infection. HDV further aggravates and worsens the disease course for patients with HBV.[17]

Hepatitis E and G. Hepatitis E, which is associated with fecal-oral transmission, is encountered most often in Asia, Africa, or Russia. Hepatitis E has an incubation period of 15 to 60 days. The most recently described hepatitis virus is hepatitis G (HGV). HGV is also referred to as hepatitis GB virus type C (GBV-C). It is an RNA virus that is transmitted through blood transfusion, parenteral exposure to blood products, or possibly during intimate contact. The virus has been identified in patients with acute and chronic hepatitis. Similar to HDV, it is believed to be a bystander virus, with disease manifestations attributable to coinfection with another hepatitis virus.

Clinical Features

The clinical presentation of viral hepatitis is highly variable, with a significant number of asymptomatic infections. The hepatitis viruses (A, B, C, D, E, G) are often clinically nondistinct. Common findings include malaise, fever, or anorexia, followed by nausea, vomiting, abdominal discomfort, or diarrhea. Stools may be described as pale or clay colored. The initial finding that may prompt further evaluation is jaundice. A small number of patients with hepatitis B may experience a prodromal illness characterized by arthralgia, arthritis, and dermatitis. The joint involvement typically is polyarticular; the small joints of the hands and wrists are usually affected. The characteristic dermatitis associated with HBV is urticarial though may be macular, papular, or petechial.

Fulminant hepatitis is characterized by an acute onset illness that progresses to hepatic failure and encephalopathy over a period of days characterized by altered mentation and spontaneous mucosal bleeding. Although most often encountered with HBV and HDV coinfection, fulminant hepatitis can occur in association with all the causative viruses (1% to 2% of all cases).

Physical findings may include fever, scleral or cutaneous icterus, and abdominal tenderness. There may be vomiting and dehydration

resulting in tachycardia or hypotension. Hepatomegaly may occur and is characterized by a smooth, homogeneous, tender liver surface. Even if liver enlargement is not appreciated, tenderness to percussion over the lower right ribs may be present. Scleral icterus is generally noticeable earlier than cutaneous discoloration. Muddy sclera, commonly found among African American patients, may obscure or confuse this finding; sublingual or subungual surfaces are alternative examination sites. Scleral icterus usually occurs once the serum bilirubin level is above 2.5 mg/dL. Spider angiomata and splenomegaly, although more often associated with chronic cirrhosis, may be features in acute presentations as well.

Differential Diagnosis

The generalized findings associated with hepatopathy, often heralded by an elevation in transaminases, renders the differential diagnosis broad in scope. In addition to nonhepatic viral illnesses (such as EBV or others) or biliary tract disease, various other infectious, chemical, or immunologic causes of hepatic inflammation should be considered. Many medications, herbal and dietary supplements, or other toxins are associated with hepatopathy. Common medications that can cause hepatopathy include acetaminophen (most common cause of acute liver failure in the US), antimicrobial drugs (such as amoxicillin-clavulanate, isoniazid, nitrofurantoin, and dapsone), anticonvulsive drugs (such as phenytoin and carbamazepine), and statins, among many other drugs. Herbal and dietary supplements that are associated with liver injury include weight-loss or fat-burning products (such as Hydroxycut), anabolic steroids, Indian and Chinese herbal medications (Ayurvedic compounds), green tea, and pyrrolizidine alkaloids. Chemical toxins that are associated with liver injury include organic solvents (toluene, dimethylformamide, carbon tetrachloride, and chloroform, among many others), vinyl chloride, aflatoxin, and polycyclic aromatic hydrocarbons.[18-21]

A viral cause may be suggested by the medical history and serologic tests provide confirmation. Alcoholic hepatitis is associated with a history of excessive or chronic alcohol consumption, less marked elevation of hepatic transaminase levels, and AST levels elevated above those of ALT. Extrahepatic obstruction, cholecystitis, and cholelithiasis are rarely associated with significant elevation of aminotransferase levels. Abdominal ultrasound or computed tomography (CT) imaging may be helpful in the evaluation of potential alternative diagnoses.

Diagnostic Testing

Laboratory findings are critically important in diagnosing hepatitis and determining the specific cause, including measurements of serum hepatic aminotransferase and bilirubin levels. Typically, hepatitis is associated with elevations (10- to 100-fold) of serum AST and ALT levels, with the ALT level generally elevated in excess of AST. The serum bilirubin level may be moderately increased (5–10 mg/dL), and occasionally is markedly elevated (15–25 mg/dL). Hyperbilirubinemia typically emerges several days to 1 week or more after the onset of clinical symptoms. Direct and indirect bilirubin levels are typically elevated in nearly equal proportions. Alkaline phosphatase and lactate dehydrogenase levels may be elevated, though rarely more than 2 to 3 times normal.

The prothrombin time (PT) or international normalized ratio (INR) is useful in assessing the degree of hepatic synthetic dysfunction. Elevation of the PT or INR may be the first clue to a complicated course. The white blood cell (WBC) count generally is not useful in the diagnosis because values range from leukopenia with a lymphocytic predominance to marked polymorphonuclear leukocytosis. Although determining the precise cause of hepatitis can rarely be achieved in the ED, serologic testing should be initiated as soon as feasible (Table 76.1) because results impact prognosis and may have public health importance.

TABLE 76.1 Serologic Markers in Hepatitis

Serologic Marker	Abbreviation	Interpretation
Antibody to HAV	Anti-HAV	Combination of IgG and IgM antibody defining infection with HAV, acute or past
IgM antibody to HAV	Anti-HAV IgM	Antibody to HAV, indicating acute infection
Hepatitis B surface antigen	HBsAg	Surface antigen associated with acute or chronic HBV infection
Hepatitis Be antigen	HBeAg	Antigen associated with active infection, acute or chronic, and indicative of high infectivity
Antibody to B surface antigen	HBsAb	Antibody indicative of acute or past infection or immunization
Antibody to B core antigen	HBcAb	Combination of IgG and IgM antibody defining infection with HBV, acute or past
IgM antibody to B core antigen	HBcAb-IgM	Antibody to B core antigen, indicating acute infection with HBV
Antibody to Be antigen	HBeAb	Antibody to e antigen, possibly representing resolving HBV infection and decreased infectivity
Antibody to HDV	Anti-HDV	Antibody defining infection with HDV; HBsAg is also likely to be present
Antibody to HCV	Anti-HCV	A new antibody that defines infection with HCV, acute or past

HAV, Hepatitis A virus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV,* hepatitis delta virus; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

From: Oyama LC. Disorders of the liver and biliary tract. Anesthesia key: fastest anesthesia & intensive care & emergency medicine insight engine. Available at: https://aneskey.com/disorders-of-the-liver-and-biliary-tract/. Accessed May 10, 2021.

Acute hepatitis A is diagnosed by the presence of immunoglobulin M (IgM) HAV antibody, whereas previous infection is determined by detection of an IgG antibody. Acute hepatitis B is characterized by the presence of HBsAg and IgM antibody to HBcAg. HBsAg alone does not establish the diagnosis of acute hepatitis B because it can be absent late in the course of acute disease or present chronically. Anti-HBcAg antibody generally is the best indicator of previous HBV infection, whereas anti-HBsAg antibody is the best marker for immunity to HBV. Figure 76.8 demonstrates the temporal relationships among infection, clinical symptoms, and serologic responses for the two most common causes of viral hepatitis, HAV and HBV.

Due to its prolonged incubation period, early diagnosis of hepatitis C is based on the exposure history and elimination of other causes. Screening is through serologic detection of hepatitis C antibodies. Due to delayed appearance of antibodies, confirmation by a polymerase chain reaction (PCR) assay that detects HCV RNA

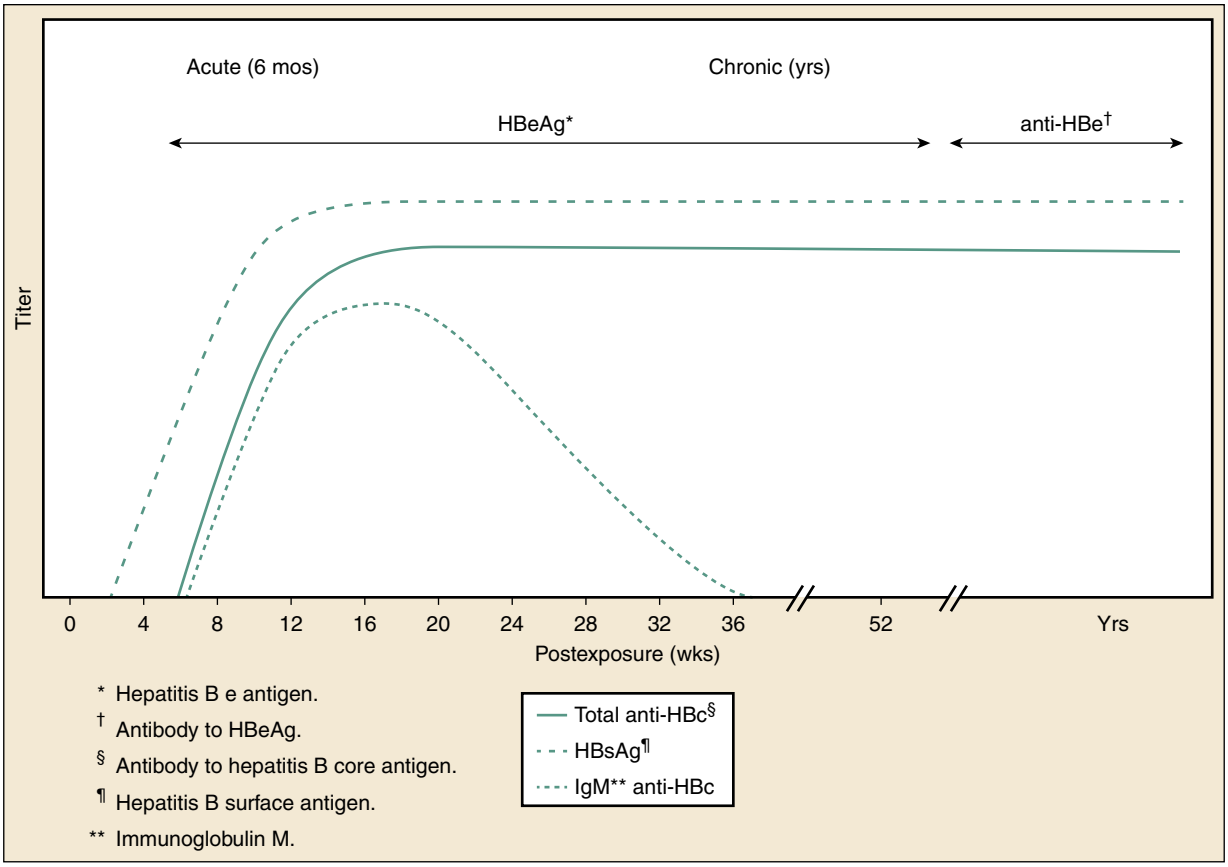

Fig 76.8 Serologic markers and symptom timing for hepatitis B. (From Centers for Disease Control and Prevention (CDC). Recommendations for identification and public health management of persons with chronic hepatitis B virus infection. *MMWR Morb Mortal Wkly Rep*. 2008;57:1-20.)

facilitates definitive diagnosis. HCV antibody testing does not distinguish acute from chronic infection. Repeat PCR testing at 6 weeks can be used to differentiate acute versus chronic hepatitis. Variable low levels of HCV RNA suggest acute infection, whereas nonvariable, higher HCV RNA levels are more consistent with chronic hepatitis C infection. Also, the presence of hepatic fibrosis assessed by histologic (biopsy) analysis or noninvasive serum and ultrasonographic testing can assist in evaluating for the presence of a chronic state. Among those in the US testing positive for hepatitis C, the majority are unaware of their infection.[22] Coupling this lack of awareness with the high prevalence of undiagnosed HCV has led many public health advocates to successfully implement HCV screening programs in the ED setting.[23]

Due to coinfectivity, diagnosis of HDV infection with a serologic test for the antibody to HDV (anti-HDV) requires a thorough testing approach because it may readily be mistaken for acute or chronic HBV infection. The presence of anti-HDV in conjunction with IgM antibody to HBcAg suggests coinfection with HDV and HBV. Anti-HDV in association with IgG antibody to HBcAg supports the diagnosis of superinfection.

Management

Most patients with viral hepatitis have self-limited disease, with symptomatic and histologic resolution in 2 to 4 weeks. ED management is primarily supportive with attention to fluid or electrolyte imbalances resulting from poor oral intake or excessive diarrhea or vomiting. Antiemetics may be helpful and fluid intake should be encouraged, with gradual advancement of diet. Medications with primarily hepatic metabolism should be dose adjusted or discontinued only in the setting of significant hepatic dysfunction, as indicated by elevated serum aminotransferase and bilirubin levels, encephalopathy, or rising PT or INR levels. Nonessential drugs with hepatotoxic potential should be avoided. Alcohol consumption should be completely discontinued until signs of liver injury have dissipated. Due to the lack of evidence, we do not recommend a role for corticosteroids in the treatment of acute viral hepatitis.

Complications include fluid or electrolyte imbalance or refractory emesis. Severe vomiting can result in upper gastrointestinal (GI) bleeding from an esophageal tear. The most severe complication of acute disease is the development of liver failure, usually heralded by hepatic encephalopathy.

Although hepatitis A is self-limited and does not progress to a chronic state, isolation precautions, hand hygiene, and attention to other hygienic practices is prudent, in both the inpatient and home setting. Patients are contagious during the incubation period and remain contagious until 1 week after the appearance of jaundice.

Prevention and Postexposure Management. Effective preexposure and postexposure prophylaxis for HAV and HBV are available. For HBV exposure in an unimmunized patient, passive immunization with immune globin may prevent disease. The window to effectively prevent HBV seroconversion is about 2 weeks from time of exposure. Owing to the self-limited nature of HAV disease, hepatitis A immune globulin is reserved for use as preexposure prophylaxis in nonimmune individuals who are at high risk of exposure to hepatitis A, immunocompromised patients, those who are less than 6 months of age, have chronic liver disease, or have demonstrated an allergy to hepatitis A vaccination.

Emergency health care workers are at increased risk for exposure to all types of hepatitis given frequent contact with bodily fluids, blood, or interaction with high-risk patients.

ED personnel involved in patient care or related activities should be vaccinated against HBV for occupational reasons. A safe and effective vaccine for HAV is available, though routine immunization for health care workers is not generally recommended, unless in the setting of an outbreak. The vaccines are highly effective and are associated with rare acute or delayed toxicity. A complete three-injection series of vaccine—to the deltoid muscle for optimal immunologic response—produces protective antibody approximately 95% of the time. Hepatitis B immune globulin (HBIG) is recommended for immediate passive immunization of those not previously immunized who have been exposed to potentially infective material. Immune globulin diminishes the risk of HBV infection by 75%. The exposed, nonvaccinated patient should receive HBIG, 0.06 mL/kg intramuscularly (IM), in addition to the HBV vaccine. Figure 76.9 outlines an approach for managing health care workers exposed to blood or other potentially infectious secretions.

The risk of seroconversion after percutaneous exposure from an HCV-positive source is approximately 1.8%. Despite the theoretic risk of blood-borne HCV exposure among health care workers (HCWs), the prevalence of HCV infection in this group is approximately the same as in the general population. No effective vaccine for HCV is currently available, one reason we continue to see rises in hepatitis C relative to hepatitis A and B. Figure 76.10 Previously, it was thought that the use of peginterferon alfa-2b may decrease seroconversion in HCWs exposed to blood from HCV-infected individuals. However, low transmission rates, coupled with no additional benefit to prophylactically treated HCWs, has resulted in no accepted preexposure or postexposure prophylaxis (PEP) regimen for HCV prevention following occupational exposure. Though some studies have considered employment of direct acting antiviral (DAA) agents in postexposure prophylaxis, there is insufficient evidence to support their use in a postexposure capacity.[24] Universal precautions—the use of gloves, masks, protective eyewear, and gowns—constitute the first and best means of defense for persons who work in proximity to potentially infective bodily fluids. Occupationally exposed individuals should be tested within 48 hours to establish baseline presence or preexistence of disease, as well as again at 6 months post exposure.[24]

Disposition

Hospitalization is rarely required for the management of viral hepatitis and generally is reserved for patients with a fluid or electrolyte imbalance, or complete oral intolerance. Patients with less severe illness may require hospitalization for concomitant medical problems or if suitable living arrangements are not available. Altered sensorium, a PT more than 5 seconds, or an INR more than 1.5 may suggest fulminant disease or an increased likelihood of a complicated course, necessitating consideration of hospitalization. Transfer to a facility that can offer liver transplantation should be considered in the setting of emergence of fulminant disease.

Treatment of chronic hepatitis C has improved greatly in recent years. Current therapy involves genotype-specific DAA regimens using nucleoside polymerase inhibitors (e.g., simeprevir, sofosbuvir, ledipasvir). The goal endpoint is a sustained virologic response (SVR), defined as absence of HCV RNA by PCR testing at 3 to 6 months following treatment. Treatment regimens take into account various patient factors, including naïveté to treatment, prior relapse, prior partial or null response (lack of quantified decline in viral load at 4 weeks), or history of protease inhibitor failure. DAA regimens demonstrate sustained virologic response rates that exceed 95%. Evidence supports reversal of hepatic fibrosis, scarring, and metabolic function with DAA use in patients with chronic HCV.[25,26] There are numerous effective combinations of orally administered DAA agents. Combinations are chosen in relation to disease genotype to optimize outcomes and avoid adverse drug events. Treatment regimens should be considered in conjunction with a hepatologist.[27]

Referral to a hepatic disease specialist for virus genotyping, treatment initiation, and ongoing surveillance is recommended. Communicability concerns may affect the ease of disposition. Patients with possible HAV infection should be advised to practice meticulous personal hygiene, not to share toiletries, and ensure thorough cleaning of utensils and kitchenware between uses. In children, caretakers should be counseled on hand washing around feeding and diapering. In patients with suspected HBV or HDV infection, the relatively low risk of transmission by intimate personal contact should be emphasized, in order to ease anxiety. In the US, the Centers for Disease Control and Prevention (CDC) aggregates data weekly for surveillance posting. Though underreported, the CDC provides adjusted predictions on the number of acute infections.[28]

Viral hepatitis is generally a reportable disease requiring notification of the local health department. Immuno-prophylaxis should be provided to the patient's family members and close personal contacts (if not previously immunized) pending serologic determination (see Fig 76.9; Tables 76.1 and 76.2). Patients with HAV infection who process or handle food must not return to work while potentially infectious. Although infectivity is greatly diminished by the time jaundice emerges, it is advisable to delay return to work until after the jaundice has cleared.

Alcoholic Hepatitis

Foundations

Alcoholic hepatitis is rising in incidence. It is the most extreme manifestation of ongoing alcoholic liver disease and requires specialized medical care. It results from long-term alcohol consumption and is defined by the syndromic appearance of hepatic decompensation or failure. Disease continuum exists from mild to life-threatening. In relation to estrogen effects, women are at higher risk.[29]

Alcohol and its metabolites are toxic to most organ systems and are largely eliminated by metabolic hepatic degradation; up to 15% of alcohol is excreted unchanged in the urine or expired air. Physiologically, alcohol stimulates fatty acid synthesis and inhibits fatty acid oxidation. This allows the accumulation of fat within the liver. Additionally, alcohol increases intestinal permeability. This, in turn, makes patients vulnerable to bacterial translocation and peritonitis.

Although susceptibility to liver damage varies based on genetic heterogeneity, a gross correlation is recognized between the amount of ethanol ingested and risk of developing liver disease. The risk of liver injury increases as daily consumption exceeds 80 g of ethanol daily in men or 20 g in women. For men, this is equivalent to a six-pack of beer, four to six glasses of wine, or three to four mixed drinks daily. Fatty infiltration appears to depend on the duration and amount of alcohol consumed and, in general, is reversible when the patient stops drinking.

The most common variety of alcohol-induced liver disease is steatosis. Fatty infiltration of the liver is most likely a consequence of altered fatty acid metabolism resulting from a diminished NAD^+/NADH ratio, which favors triglyceride production. Beyond enlargement of the liver, which usually is painless, this tends to be a benign process.

As alcohol-related liver disease progresses beyond steatosis to fibrosis, cirrhosis and, in some cases, hepatocellular carcinoma may ensue (Fig. 76.11). In more than 90% of those who regularly consume

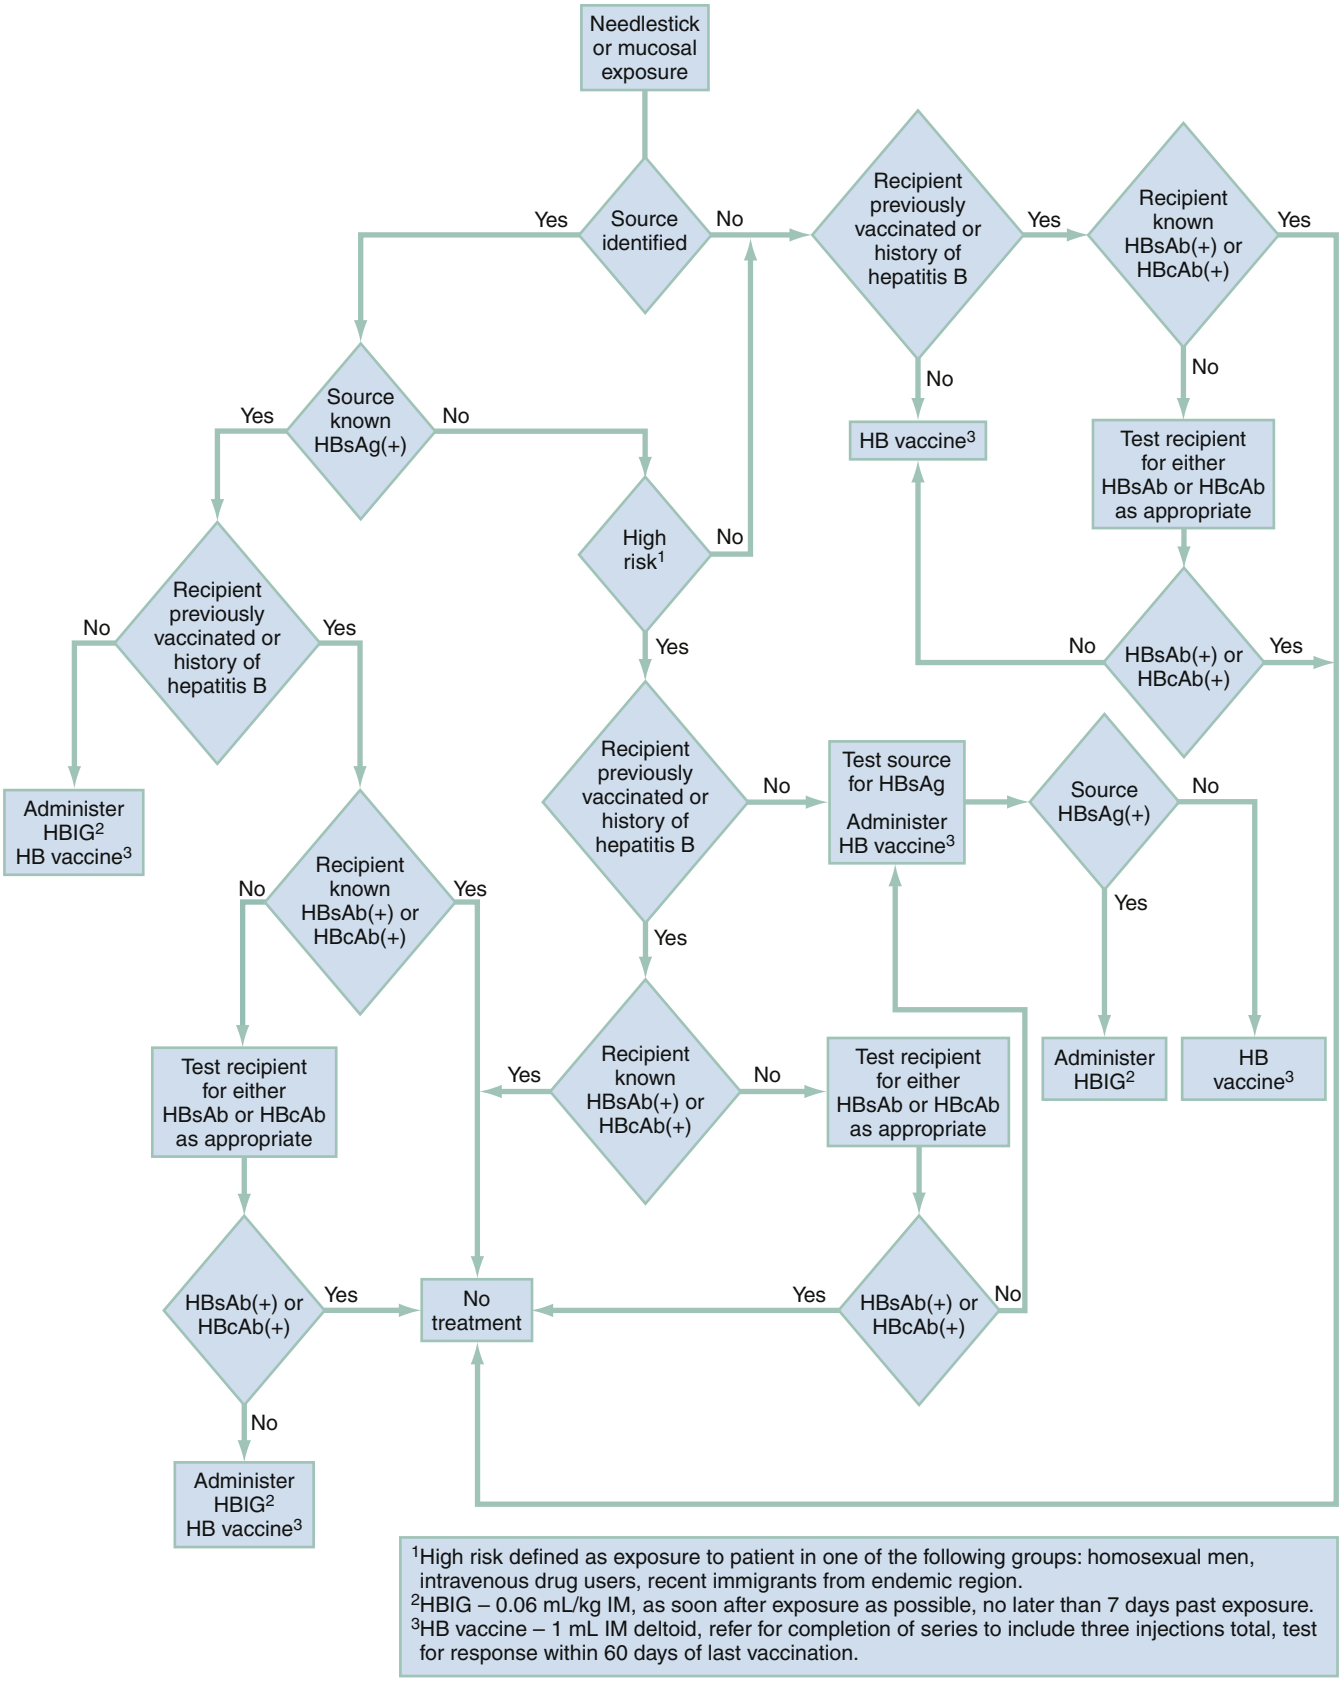

Fig. 76.9 Management of health care workers exposed to blood or other infectious secretions. *HB,* Hepatitis B; *HBIG,* HB immune globulin; *HBcAb,* hepatitis B core antibody; *HBsAb,* hepatitis B surface antibody; *HBsAg,* hepatitis B surface antigen; *IM,* intramuscularly. Fig 76.10 Reported cases of hepatitis 2010-2017 in the United States. (From Centers for Disease Control and Prevention (CDC). Surveillance for viral hepatitis—United States, 2017. Available at: https://www.cdc.gov/hepatitis/statistics/2017surveillance/index.htm. Accessed May 10, 2021.)

alcohol, steatosis can be seen as early as 2 weeks. Within 5 years, 8% to 20% of those with steatosis of the liver progress to cirrhosis. Comorbidities that contribute to the progression of disease include viral hepatitis, HIV, or hemochromatosis. Approximately 3% to 10% of chronic alcoholics will develop hepatocellular carcinoma.

Clinical Features

Alcoholic hepatitis is a potentially severe form of alcohol-induced liver disease. Most cases are likely subclinical and the spectrum of presentation can range from nausea, vomiting, and abdominal pain to acute liver failure. Physical findings may include tachycardia, fever, and supine or orthostatic hypotension. Abdominal tenderness usually can be elicited, especially in the right upper quadrant. Coexistent fatty infiltration may produce palpable hepatomegaly; cirrhosis from chronic disease may result in a small nonpalpable liver. The characteristic physical signs of cirrhosis may be present—gynecomastia, spider angiomata, muscle wasting, ascites, or palmar erythema (Figs. 76.12 and 76.13). Jaundice can be noted in patients with a bilirubin level of at least 2.5 mg/dL. As disease advances, peripheral edema, abdominal distention, hematemesis, or melena may be present. Patients with clinical signs of alcoholic hepatitis should be assessed for symptoms of gastritis or GI bleeding.

Differential Diagnosis

The differential diagnosis of alcoholic hepatitis is broad in scope and includes many other alcohol-related GI maladies (e.g., gastritis, pancreatitis). The clinical history and aminotransferase profile typically facilitate an accurate diagnosis as other potential causative disorders are considered. Mild aminotransferase level elevation and marked bilirubin level elevation are consistent with alcoholic hepatitis; abdominal ultrasonography will aid in differentiating from common bile duct obstruction. Serum can be sent for testing for anti-HAV IgM and hepatitis B core antibody (HBcAb) IgM, though findings will likely result following ED disposition.

Diagnostic Testing

Laboratory tests reveal moderate elevations of AST and ALT levels. Values in excess of 10 times normal are unusual, even in severe cases associated with eventual liver failure. Compared with viral hepatitis, a relative predominance of AST to ALT is expected. AST can be 2 to 6 times the normal range. Leukocytosis, hyperbilirubinemia, and coagulopathy are common. The PT and INR level provide a rough assessment of hepatic dysfunction. An acutely prolonged PT or elevated INR level in a patient not suspected to have chronic cirrhotic disease suggests a complicated course. Electrolyte or acid-base disturbances may develop with excessive vomiting or alcoholic ketoacidosis. For alcoholic hepatitis, liver biopsy remains the diagnostic and prognostic gold standard, with a sensitivity ranging from 85% to 95% depending on the level of hyperbilirubinemia present. However, biopsy may be challenging secondary to hematologic abnormalities or ascites.

Management

The management of alcoholic hepatitis is principally supportive. Fluid and electrolyte imbalances should be corrected, usually requiring parenteral fluid replacement; antiemetics may mitigate the need for IV treatment. Alcohol may suppress gluconeogenesis, thereby causing hypoglycemia. The blood glucose level should be measured and supplemented, as necessary. Many alcoholics are malnourished and, if thiamine deficiency is suspected, thiamine should be given at a dose of 100 mg IV. Ethanol-induced magnesium wasting may not be apparent on serum magnesium measurement, and replacement should be given empirically unless the patient has a contraindication, such as renal failure or known hypermagnesemia. Magnesium can be given as the sulfate salt in a dose of 1 g IV or IM or as an oxide, chloride salt, or amino acid conjugate for oral replacement therapy at a daily dose of 200 to 1000 mg PO. Finally, short-term abstinence may result in increased risk for withdrawal, which requires management with short-acting benzodiazepines.

The overall nutritional status of the patient should be addressed with the administration of a high-calorie, vitamin-supplemented diet. Protein content may require restriction if evidence of cirrhosis and incipient encephalopathy exists. Coexisting gastritis should be treated with histamine H_2 antagonists, proton pump inhibitors, or antacids. Variceal bleeding is associated with a 5-year mortality rate of 65%;

TABLE 76.2 Postexposure Hepatitis Prophylaxis

Nature of Exposure	Recommended Treatment
Hepatitis A	
Close personal contact	ISG, 0.1 mL/kg IM
Daycare center	ISG, 0.1 mL/kg IM
• Employee	ISG, 0.1 mL/kg IM
• Attendee	
School contacts	None
Hospital contacts	None
Workplace contacts	None
Food-borne source	ISG, 0.2 mL/kg IM
• Within 2 wk of exposure	None
• After 2 wk of exposure	
After common source outbreaks have begun to occur	None

Nature of Exposure	Source	Exposed Individual Unvaccinated	Exposed Individual Vaccinated
Hepatitis B			
Percutaneous or mucosal	HBsAg (+)	1. HBIG ×1 2. Hepatitis B vaccination booster	Test exposed person for anti-HBs; if titer is adequate, no treatment. If anti-HBs titer inadequate: 1. HBIG ×1 2. Initiate hepatitis B vaccination series.
	HBsAg (–)	Initiate hepatitis B vaccination series	No treatment
	Unknown source (Treat as if HBsAg [+].)	1. HBIG ×1 2. Initiate hepatitis B vaccination series	Test exposed person for anti-HBs; if titer is adequate, no treatment. If anti-HBs titer is inadequate: 1. HBIG ×1 2. Hepatitis B vaccination booster
Intimate sexual	HBsAg (+)	1. HBIG ×1 2. Initiate hepatitis B vaccination series	Test exposed person for anti-HBs; if titer is adequate, no treatment. If anti-HBs titer inadequate: 1. HBIG ×1 2. Hepatitis B vaccination booster
Hepatitis C			
Unknown benefit from prophylaxis; ISG, 0.06 mL/kg IM can be considered for parenteral exposures in patients with evidence of viral hepatitis and negative results on serologic studies.			
Hepatitis Delta			
Same as for hepatitis B			

HBIG, Hepatitis B immune globulin; *HBsAg,* hepatitis B surface antigen; *IM,* intramuscularly; *ISG,* immune serum globulin.
The HB vaccine recombinant dose comes in three formulations: pediatric, adult, and those on hemodialysis. The adult formulation (without preservative) comes in a concentration of 10 µg/mL. The dose is 1 mL for adults. Each 1-mL dose contains 10 µg of hepatitis B surface antigen.
From: Oyama LC. Disorders of the liver and biliary tract. Anesthesia key: fastest anesthesia & intensive care & emergency medicine insight engine. Available at: https://aneskey.com/disorders-of-the-liver-and-biliary-tract/. Accessed May 10, 2021.

acute bleeds require pharmacologic intervention that decreases portal blood flow, such as octreotide (50-µg IV bolus followed by 25–50 µg/h IV), somatostatin (250-µg IV bolus and 250 µg/h IV infusion), or vasopressin (0.2 to 0.4 unit/min up to a maximum of 0.8 unit/min [off label] continuous IV infusion).[25] Treatment should not be delayed while identification of the source of bleeding is undertaken. If bleeding persists or recurs, treatment options include endoscopic variceal ligation, endoscopic variceal sclerotherapy, transjugular intrahepatic portosystemic shunt (TIPS), or surgical shunt placement.

The American Association for the Study of Liver Disease (AASLD) has recommended that treatment be based on the assessment of disease severity. There are several severity scales. The most widely used is the Maddrey discriminant function (MDF) score based on coagulation and bilirubin levels. The score is calculated by multiplying the increase in PT (seconds) by 4.6 and then adding the serum bilirubin (mg/dL) for a total discriminant factor (DF) score. A DF score of greater than 32 correlates with poor prognosis in alcoholic hepatitis and identifies which patients could benefit from steroid therapy. In the absence of GI bleeding, hepatorenal syndrome, or sepsis, the AASLD recommends the initiation of corticosteroids (oral prednisolone, 40 mg PO daily, or parenteral methylprednisolone, 32 mg IV daily) for those with alcoholic hepatitis and an DDF score more than 32.[25] Pentoxifylline, an inhibitor of cytokines such as anti–tumor necrosis factor alpha, has been shown to provide mild benefit over placebo and may be used in the setting of contraindications to corticosteroids.[30] Compared to corticosteroids, however, pentoxifylline is not associated with improved 28-day survival.

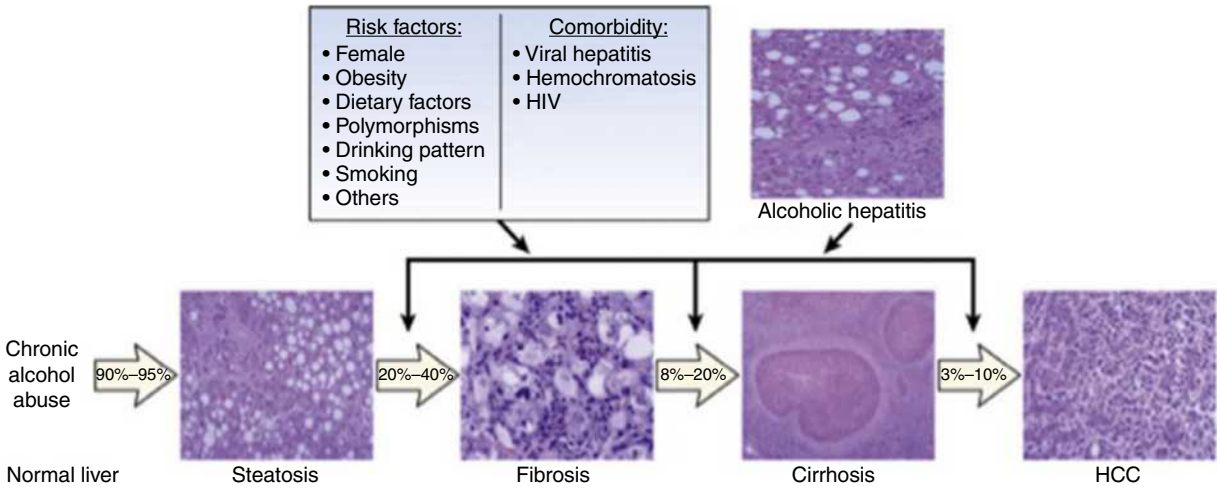

Fig. 76.11 Progression of alcoholic-related liver disease. *HCC,* Hepatocellular carcinoma.

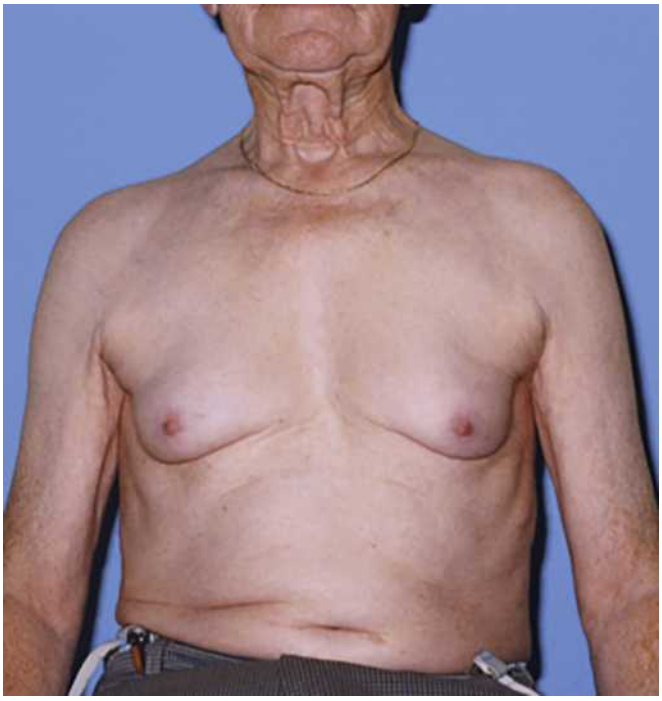

Fig. 76.12 Gynecomastia in a male patient with cirrhosis. (Biophoto Associates / Science Photo Library.)

Fig 76.13 Close up view of the central arteriole (punctum) of a spider nevus. (From Benign neoplasms and hyperplasias. In: Wolff K, Johnson R, Saavedra AP, et al., eds. *Fitzpatrick's color atlas and synopsis of clinical dermatology*, 8e. McGraw Hill; 2017. Accessed September 07, 2021. https://accessmedicine.mhmedical.com/content.aspx?bookid=2043&sectionid=154898019. Chapter 9, figure 9-21.)

Disposition

The disposition is determined by the patient's clinical state—degree of fluid and electrolyte abnormality, ability to retain oral intake, and any coexistent illnesses or complications—and socioeconomic circumstances. Hospitalization generally is not required. Patients should be advised to abstain from further alcohol ingestion and, ideally, provided with information regarding detoxification or alcohol dependency treatment.

Autoimmune Hepatitis

Foundations

Autoimmune hepatitis (AIH) results from antibodies targeted to hepatospecific antigens. At onset, AIH can be difficult to differentiate from other forms of acute hepatitis, cirrhosis, or acute liver failure. Inflammation to the liver results from circulating autoantibodies. AIH remains rare, affects all ages—though is predominantly bimodal with peaks in the second, fifth, and sixth decades—and is more common among females. The disease physiologically stems from a complex interaction of genetic, immunologic, and environmental factors within the host.[31] There are two diagnostic types, based on the individual's expression of autoantibodies. There is some degree of overlap with primary sclerosing cholangitis or primary biliary cirrhosis.[32] Overlap with other autoimmune disorders is also observed, including with autoimmune thyroiditis, type 1 diabetes, rheumatoid arthritis, inflammatory bowel disease, or lupus. A United Kingdom study noted earlier age at presentation, higher circulating IgG levels, and broader overlap with lupus in patients of African descent.[33]

Diagnosis

AIH is a diagnosis of exclusion. For patients with suspected disease, the workup may include a combination of biomarker serologic testing demonstrating presence of at least one autoimmune or globulin marker, elevated aminotransferase levels, histologic evidence on biopsy, imaging studies such as MRCP to exclude primary sclerosing cholangitis, and the absence of an alternative pathologic etiology of hepatitis such as alcohol, drug-induced, or viral hepatitis (Fig. 76.14).[32]

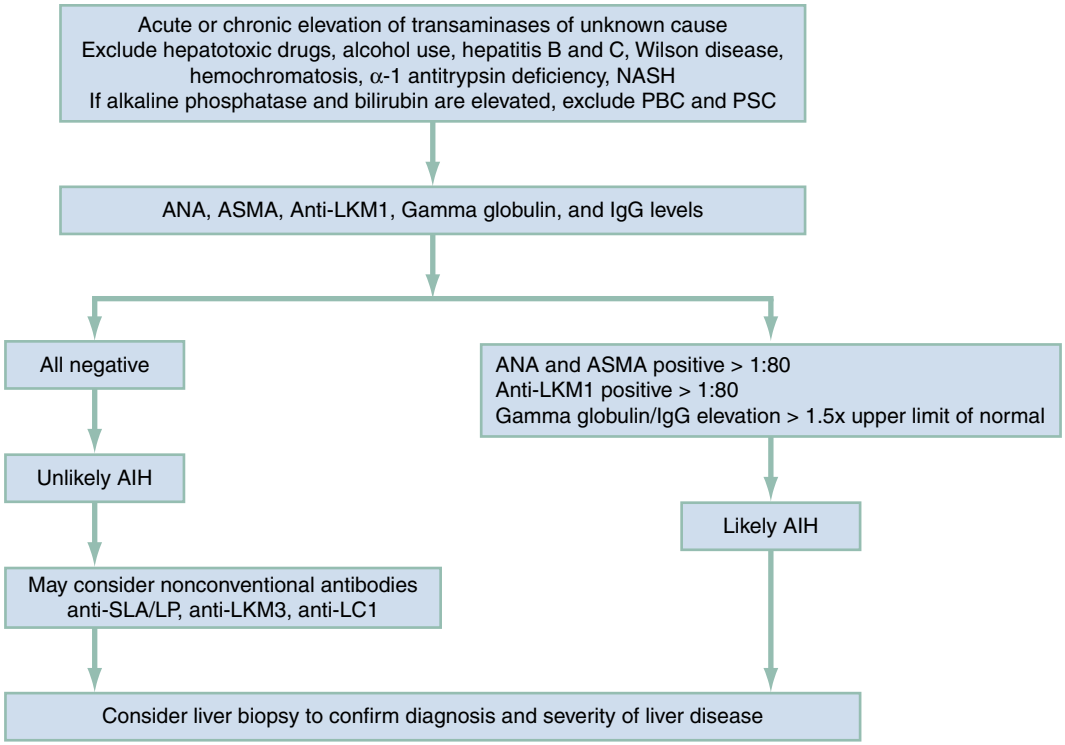

Fig 76.14 Diagnostic algorithm in autoimmune hepatitis. (From Cleveland Clinic Foundation Center for Continuing Education Disease Management Home. Fialho A. Autoimmune Hepatitis. Published July 2015. Accessed online at: http://www.clevelandclinicmeded.com/medicalpubs/diseasemanagement/hepatology/chronic-autoimmune-hepatitis/)

Differentiation into type I versus type II AIH is based on autoimmune serologic testing. Though management does not differ between the two, prognosis differs with type II AIH being more severe.[34]

Management

Immunosuppression with corticosteroids is the primary treatment modality for AIH. Early randomized trials comparing corticosteroids with placebo demonstrated a poor prognosis for untreated AIH. The aim of treatment is remission, defined as normalization of aminotransferases, serum bilirubin, and IgG levels and absence of clinical symptoms. Azathioprine is occasionally used alongside or in lieu of steroids. Those without treatment demonstrated a 5-year survival of approximately 32%.[34] However, the ten-year survival rate with treatment is approximately 90%, which highlights the need for prompt diagnosis. Second-line therapy includes mycophenolate mofetil as the most widely supported of the alternative agents. Medication alone is often successful in achieving remission. Ultimately, transplantation is considered for life-threatening AIH. Post transplantation, patients are at risk for recurrent disease. Novel immunotherapies targeting the T cell–mediated hepatitis are currently under development.[35]

Disposition

Disposition depends on the presenting severity. Criteria exist for differentiating two different induction pathways. For asymptomatic patients with aminotransferase levels under 10 times the upper limits of normal, low-dose induction therapy with prednisone is standard. Those who are either symptomatic or have marked elevations begin either higher dose prednisone monotherapy or prednisone in combination with azathioprine if other diseases are present that increase an individual's side effect risk profile.[36] Management of patients with AIH should be in conjunction with a hepatologist or specialist with expertise in liver disease.

CIRRHOSIS

Foundations

Cirrhosis is a generic term for end-stage chronic liver disease characterized by the destruction of hepatocytes with resulting deposits of fibrotic tissue and regenerative nodules. Laënnec cirrhosis is a diffuse process that involves the entire lobule, with 10% to 20% of chronic alcoholics developing this disorder. Postnecrotic cirrhosis usually is nonhomogeneous, characterized by regions of fibrosis and hepatocyte loss alternating with normal areas. It most often is a consequence of chronic hepatitis of various causes—infectious (viral, bacterial, fungal), drug-induced, or metabolic. Biliary cirrhosis is much less common and is a consequence of chronic extrahepatic biliary obstruction or is a primary disorder of autoimmune-mediated intrahepatic duct inflammation and scarring. Nonalcoholic fatty liver disease has become an increasingly recognized cause of cryptogenic cirrhosis. This poorly understood disease, with features similar to those of Laënnec cirrhosis, is more common in the setting of obesity or type 2 diabetes mellitus.

Clinical Features

The clinical manifestations of cirrhosis are related to loss of hepatocytes, leading to metabolic and synthetic dysfunction, or to fibrosis and altered hepatic architecture, resulting in impaired portal vein blood flow and portal hypertension. Typically, the patient with cirrhosis complains of chronic fatigue and poor appetite. With the exception of those with biliary cirrhosis, many patients with cirrhosis can be asymptomatic until complications develop, such as GI bleeding, ascites, or hepatic encephalopathy. Patients with biliary cirrhosis generally complain of pruritus or exhibit obvious jaundice before end-stage cirrhosis or complications develop. Primary biliary cirrhosis may be associated with other immune-mediated disorders; these patients may have signs

and symptoms characteristic of scleroderma or the CREST syndrome (***c***alcinosis cutis, ***R***aynaud phenomenon, ***e***sophageal motility disorder, ***s***clerodactyly, and ***t***elangiectasia).

Physical examination may reveal muscle wasting, thinning of the skin with patchy ecchymosis, spider angiomata, palmar erythema, Dupuytren contracture and, in men, gynecomastia or testicular atrophy. Jaundice generally is absent in mild cases or in those with early disease. The liver may not be palpable if it is extensively scarred, but a large regenerative nodule, tumor, or fatty infiltration can result in hepatomegaly. Complications of cirrhosis include ascites, hepatic encephalopathy, and variceal hemorrhage. Ascites is the most common of these, particularly in those with advanced disease, and may be present with abdominal wall vein distention known as caput medusa.

Diagnostic Testing

Laboratory tests are not specific. Aminotransferase levels are rarely more than minimally elevated. The bilirubin level may be increased but usually not until cirrhosis is far advanced. Elevation of the alkaline phosphatase level out of proportion to other liver enzyme levels is suggestive of biliary cirrhosis. Coagulation studies commonly show abnormalities, and the serum albumin level is low as a result of impaired hepatic synthetic function. Mild to moderate anemia and thrombocytopenia often are present in Laënnec cirrhosis. An elevated blood urea nitrogen (BUN) or creatinine level suggests dehydration or hepatorenal syndrome. Ascites can be detected on a carefully performed physical examination or ultrasound. Bedside ultrasound demonstrating a diffuse nodular surface, with or without the presence of ascites, is consistent with cirrhosis (Fig. 76.15).

In patients with ascites and fever or abdominal pain, diagnostic paracentesis should be considered to rule out spontaneous bacterial peritonitis (SBP). Nuclear scintigraphy or computed tomography (CT) imaging may reveal a hepatic or splenic appearance characteristic of cirrhosis and portal hypertension but, in general, these tests should be deferred to an elective setting.

Management

Treatment of cirrhosis in the ED is limited in the absence of acute complications. Oral tolerance should be confirmed, fluid and electrolyte imbalances should be corrected, and nutritional supplements should be provided. Most patients can be discharged with referral to a general internist or gastroenterologist for further evaluation and treatment. The complications of cirrhosis include ascites with or without infection, GI bleeding, hepatorenal syndrome, or encephalopathy. The Model for End-Stage Liver Disease (MELD) score is used to predict 3-month mortality of patients with end-stage liver disease. The MELD score is calculated using serum creatinine, total bilirubin, INR, and sodium. It is mainly used as one of the factors in determining liver transplantation priority and in predicting survival rate after a TIPS procedure.[37]

Ascites

Ascites is the accumulation of fluid within the peritoneal cavity. It is most often caused by cirrhosis but may have other etiologies, such as malignancy. In cirrhosis, ascites occurs as a consequence of portal hypertension, impaired hepatic lymph flow, hypoalbuminemia, and renal salt retention. When severe, it can cause respiratory compromise or significant discomfort. The treatment is therapeutic paracentesis, generally with removal of 2 L of ascitic fluid or more. Paracentesis improves patient comfort, decreases respiratory effort, allows improved oral intake, and decreases the risk for bacterial peritonitis. Removal of large quantities of ascitic fluid can result in body fluid and electrolyte abnormalities, intravascular volume depletion, and hemodynamic instability, commonly known as paracentesis-induced circulatory dysfunction. When removing over 5 L of ascitic fluid via paracentesis, colloid infusion is typically necessary to avoid adverse cardiovascular, renal, and neurohumoral responses. Standard IV dosing of albumin after large-volume paracentesis is 8 g/L removed. The AASLD has established guidelines for the management of ascites secondary to cirrhosis.

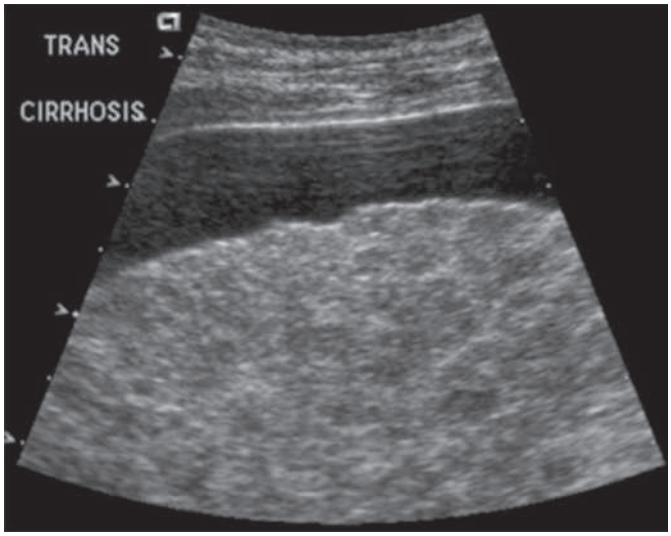

Fig. 76.15 Ultrasound of liver the demonstrating cirrhosis.

A low-sodium diet of less than 2000 mg of sodium, in conjunction with an aldosterone antagonist such as spironolactone 100 mg daily, may be of use in the chronic management of ascites. A low-dose regimen of a thiazide or loop diuretic (furosemide 40 mg PO daily) may accelerate resolution of ascites and is considered safe if the patient has coexistent peripheral edema and normal renal function. Furosemide should be given orally because IV dosing can result in a decline in renal function. The presence of peripheral edema allows the rate of diuretic-mediated fluid removal to be more precipitous than removal in those with ascites solely. To avoid brisk intravascular volume depletion and azotemia, those with ascites without accompanying peripheral edema should not exceed 500 mL of fluid removal/day. Finally, care should be taken to avoid medications such as angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II blockers (ARBs), or nonsteroidal antiinflammatory drugs (NSAIDs).

Gastrointestinal Bleeding

In patients with cirrhosis, acute upper GI bleeding carries a mortality of 10% to 15%.[38] GI bleeding is often related to esophageal or gastric varices, but over half of the cases result from another source (e.g., gastritis, duodenal ulcer). Coagulopathy and thrombocytopenia in conjunction with active bleeding should be considerations for platelet transfusion. The goal in this scenario is generally to correct the platelet count to greater than 50,000/mm^3. There is little support for the use of fresh-frozen plasma to correct asymptomatic abnormalities in PT and INR. Cryoprecipitate (1 unit/10 kg body weight) with a targeted fibrinogen level of more than 100 mg/dL may also be considered in active bleeding. Cryoprecipitate improves certain coagulopathies using a lower volume than fresh-frozen plasma. With uncomplicated prolongation of PT or INR in individuals with nutritional or gastrointestinal losses, treatment with oral vitamin K supplementation (10–20 mEq PO given every 6 hours to every 12 hours) may be used.

Mean arterial pressure (MAP) is an independent predictor of mortality in patients with cirrhosis. Lowering pressure may adversely affect survival. ACEIs, ARBs, and beta blockers, such as propranolol, should be used with caution.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is defined as renal dysfunction occurring in the setting of cirrhosis without obvious renal pathology. An elevated creatinine or blood urea nitrogen (BUN) level may herald the onset of hepatorenal syndrome and typically necessitates hospitalization for optimal fluid and electrolyte management. There are two classifications, type I HRS and type II HRS. Type I is the more severe and is associated with serum creatinine levels exceeding 2.5 mg/dL. Despite the use of albumin and vasoactive medications such as norepinephrine to increase the MAP, hepatorenal syndrome carries a high mortality.

HEPATIC ENCEPHALOPATHY

Foundations

Hepatic encephalopathy, also termed portal-systemic encephalopathy, is a clinical state of altered cerebral function resulting from the diseased liver's failure to perform its normal metabolic functions adequately. Ammonia, formed primarily in the GI tract by bacteria, is normally absorbed and converted to urea in the liver. In severe hepatic disease, ammonia accumulates, crosses the blood-brain barrier, and combines sequentially with α-ketoglutarate and glutamate to form glutamine, which is thought to disrupt the gamma-aminobutyric acid (GABA) receptors. Serum ammonia levels correlate inconsistently with the severity of encephalopathy, though there is an association of ammonia levels with cerebrospinal fluid (CSF) glutamine levels. Whether glutamine is itself toxic or simply represents a marker for disordered central nervous system (CNS) metabolism is unknown. Severity can be graded, I to IV, with grade I classified as mild confusion and slurred speech, and grade IV marked by coma and unresponsiveness to painful stimuli.

Clinical Features

The clinical manifestations of hepatic encephalopathy range from mild cognitive dysfunction, irritability, and confusion to profound coma. Asterixis, a low-amplitude, alternating flexion and extension of the wrist that occurs when the wrist is held in extension, is characteristic of the neuromuscular dysfunction seen in mild to moderate degrees of encephalopathy. A similar finding may be elicited in the dorsiflexed foot or with extension of the neck. Fetor hepaticus, a musty breath odor presumably from mercaptans (products of methionine metabolism by gut bacteria and cleared by the liver), may be detected in severe cases. Physical examination commonly reveals signs of cirrhosis—spider angiomata, testicular atrophy, muscle wasting, superficial bruising, gynecomastia, or ascites.

Differential Diagnosis

The differential considerations in patients with suspected hepatic encephalopathy include all causes of altered sensorium. The scope of the differential diagnosis can be narrowed if the patient's history includes previous episodes of hepatic encephalopathy or if the patient has severe underlying liver disease and its supportive physical signs. In patients without a previous history of encephalopathy, a more in-depth evaluation for altered mental status, including testing of electrolyte levels, evaluation for toxins, and possibly neuroimaging should be considered.

Diagnostic Testing

Liver function tests, including albumin and coagulation studies, are recommended, although the results may be normal. Serum ammonia levels generally are elevated but do not necessarily correlate with the severity of encephalopathy. Results of tests reflective of hepatic synthetic function (i.e., serum albumin, PT, INR level) are generally abnormal. Evaluation for underlying treatable causes (Box 76.1) is imperative. Serum chemistry tests to evaluate electrolyte and metabolic derangements may reveal precipitating factors.

BOX 76.1 Common Underlying Causes of Hepatic Encephalopathy in Patients With Known Liver Disease

- Gastrointestinal bleeding
- Electrolyte abnormalities including hypokalemia and alkalosis
- Venous thrombosis
- Ileus and constipation
- Sedative medications
- Dehydration and hypovolemia
- Acute or chronic kidney injury
- Infection

The presence of hypoalbuminemia must be considered in patients who require medications with high protein-binding profiles. Decreased protein binding in the setting of hypoalbuminemia enhances the potential for drug toxicity. Drugs circulating in the extracellular compartment carry the largest risk. Some commonly prescribed drugs with high protein-binding profiles include phenytoin, morphine, and antimicrobial medications, including β-lactams, vancomycin, dalvance, and daptomycin. Additional dosing consideration should be given to agents that normally undergo hepatic metabolism with large first-pass extraction. With decreased hepatic flow and shunting, these agents are more apt to increase their bioavailability and serum concentrations. Finally, glutathione reduction and decreased renal elimination, which are commonly present in cirrhosis, may predispose individuals to further medication toxicity and liver injury, necessitating dosing adjustments by the treating emergency clinician.

Management

Aggressive management of the patient with hepatic encephalopathy may reverse the condition. As with any comatose patient, the airway is assessed first, not only to determine the need for respiratory support but also to prevent aspiration. Affected patients generally are hemodynamically stable but have an increased incidence of GI bleeding. Hypokalemia, alkalosis, and GI bleeding contribute to increased ammonia production or absorption, and the cause must be addressed when detected. Relatively mild degrees of hyponatremia, hypoglycemia, azotemia, or dehydration often will have a disproportionate effect on cerebral function and thus will require correction. CNS depressants or mild sedatives should be avoided to the extent feasible.

After identifying the precipitating cause, treatment aims to lower the blood ammonia concentration. The current approach in hepatic encephalopathy is treatment with nonabsorbable disaccharides (e.g., lactitol, lactulose). Lactulose decreases the absorption of ammonia through its osmotic cathartic effects and by altering the colonic pH to trap ammonia as ammonium in the stool. The usual dose of lactulose is 30 to 60 g (oral) or 200 g (rectal) daily or in a quantity sufficient to result in several loose bowel movements daily. The principal adverse effect is excessive diarrhea, with resultant fluid and electrolyte imbalances. A recent noninferiority trial compared lactulose alone to lactulose in combination with polyethylene glycol and found 24-hour improvement in severity scoring of hepatic encephalopathy in the combination group compared to lactulose alone. The dosing of PEG recommended for adults is 280 g (oral) daily.[39]

Oral antibiotics including rifaximin, neomycin, vancomycin, or metronidazole may be utilized in combination with lactulose.

The antibiotics aim to reduce ammonia-producing enteric bacteria in patients with hepatic encephalopathy. Rifaximin is a minimally absorbed, oral antimicrobial agent that concentrates in the GI tract. It offers minimal systemic bioavailability and fewer detrimental side effects than neomycin. It is therefore the preferred antimicrobial to utilize in patients with hepatic encephalopathy. Neomycin, which is reserved for those unable to tolerate or with contraindications to rifaximin, is administered orally (PO) at an initial dose of 250 mg every 6 hours to every 12 hours (maximum, 4000 mg/day). Neomycin carries additional risks for ototoxicity or nephrotoxicity. In obtunded patients, lactulose and neomycin can be administered by nasogastric tube or rectal enema. Multiple trials have assessed the use of infused branched chain amino acids in the treatment of hepatic encephalopathy. Because these showed benefit without increased mortality or negative impacts on nutrition or quality of life, their use should be strongly considered in patients with hepatic encephalopathy.[40]

Less commonly used in the US, L-ornithine–L-aspartate (LOLA) has demonstrated benefit in lowering postprandial serum ammonia levels alone and following TIPS procedures (known to increase or exacerbate hepatic encephalopathy). Complementary therapies include probiotics such as *Lactobacillus acidophilus* (to increase non–urease-producing bacteria), eradication of *Helicobacter pylori* (urease-producing), and zinc replacement (metabolism of ammonia is dependent on zinc that is deficient in liver disease).

Cirrhosis is commonly a comorbid condition associated with overall poor nutrition. Protein restrictions are associated with increased mortality and therefore protein should not be restricted in patients with active hepatic encephalopathy. Patients should be instructed to eat small frequent meals that include complex carbohydrates. Fasting results in the production of glucose from amino acids, with resultant ammonia production, obviously deleterious to patients with hepatic encephalopathy.

Disposition

Although many patients with hepatic encephalopathy will require hospitalization, those with grade I or II encephalopathy without complicating factors and a supportive home environment are candidates for outpatient management. In addition to a prescription for lactulose and rifaximin, nutritional guidance to ensure adequate caloric intake and a maximum of 1.5 g/kg/day of protein is essential.

SPONTANEOUS BACTERIAL PERITONITIS

Foundations

Spontaneous bacterial peritonitis is an acute bacterial infection of ascitic fluid in patients with liver disease, without an apparent external or intra-abdominal focus of infection. It can occur in any patient with ascites. Diagnosis is correlated with presence of elevated polymorphonuclear (PMN) leukocytes within the peritoneal fluid aspirate (>250 cells/mm^3) and established with positive identification of organisms upon peritoneal fluid culture. The pathophysiology of SBP is related to a combination of impaired phagocytic function in the liver and to portal systemic hypertension, which can cause bowel mucosal edema, alterations in gut flora, and transmural migration of enteric organisms. Bacterial seeding may also occur from other sites in the abdomen, such as the bladder, as well as the lungs or bloodstream. Gram-negative enteric organisms, primarily *Escherichia coli* or *Klebsiella,* predominate in SBP. Modern treatments of cirrhosis, including variceal ligation, TIPS placement, and long-term antibiotic prophylaxis, have changed the type and cause of acute bacterial infections in cirrhosis. With improved cirrhosis care, the cause in outpatients with cirrhotic neutrocytic ascites has been found to be predominantly gram-positive organisms. Polymicrobial and anaerobic infections are uncommon.

BOX 76.2 Runyon Criteria for Spontaneous Bacterial Peritonitis[a]

Total protein > 1g/dL
Glucose < 50 mg/dL
LDH > the upper limit of normal for serum

[a]Requires 2 or more be present in the peritoneal fluid analysis.
From: Akriviadis E, Runyon B. Utility of an algorithm in differentiating spontaneous from secondary bacterial peritonitis. *Gastroenterol.* 1990;98(1):127-133.

Clinical Features

The clinical presentation of SBP is variable and may include acute onset of severe abdominal pain, insidious onset of abdominal discomfort, or encephalopathy. Objective or subjective fever may be present. Hemodynamic instability may be slow to develop. On physical examination, palpation of the abdomen may range from mild tenderness to abdominal rigidity and guarding with rebound tenderness. Although, by definition, ascites is essential for SBP to develop, free peritoneal fluid may not always be clinically apparent. One study has identified a positive peritoneal fluid culture rate of 3.5% among patients who were judged to have asymptomatic ascites. This observation underscores the exceptionally broad spectrum of manifestations and variability in physical findings, thus the diagnosis of SBP should be considered in any patient with severe liver disease who has abdominal pain or exhibits unexplained clinical deterioration.

Differential Diagnoses

The differential diagnosis for SBP is broad, and includes other causes of peritonitis or abdominal pain in patients with or without liver disease.

Diagnostic Testing

Diagnosis is made by culture of the ascitic fluid, with anticipatory treatment decisions in advance of culture results. An ascitic fluid granulocyte count greater than 500 cells/mm^3 correlates with positive cultures in more than 90% of cases; however, ED treatment for SBP should be initiated if the PMN count is greater than 250 cells/mm^3. Cultures of ascitic fluid guide the antibiotic choice. Also, fluid chemistry testing may aid in the diagnosis when the fluid neutrophil count is nondiagnostic or peritonitis secondary to another abdominal source (e.g., urinary tract infection, appendicitis) is suspected. Because cultures may be delayed, many advocate use of preliminary analysis of the peritoneal fluid to employ the Runyon criteria to assesses for SBP (Box 76.2). Determining peritoneal fluid total protein, lactate dehydrogenase (LDH), glucose, and alkaline phosphatase levels, as well as fluid Gram stain, assist in distinguishing SBP from other causes of peritonitis. An early indicator of SBP is a serum-ascites albumin fluid gradient (albumin in ascites subtracted from serum albumin level) greater than 1.1 g/dL. Serum laboratory parameters (e.g., aminotransferase and bilirubin levels, peripheral blood count) are not infrequently abnormal, although these findings are nonspecific and may be a consequence of underlying liver disease rather than SBP.

Testing of ascitic fluid prior to administering antibiotics is ideal, provided clinical stability and ability to rapidly obtain fluid. A single dose of antibiotic will produce negative cultures at 6 hours in 86% of patients with SBP.[41]

Management

Empiric antibiotics should be initiated in patients presenting with ascites and one or more of the following: temperature greater than 100°F, abdominal pain, abdominal tenderness, altered mental status, or peritoneal fluid containing greater than 250 cell/mm^3. Fever is the most

sensitive of these signs and symptoms.[37] The treatment of SBP requires IV antibiotics. The choice of agents is driven by the anticipated bacteriology. A third-generation cephalosporin, such as IV cefotaxime 2 g every 8 hours, is the agent of choice and is generally superior to two-drug regimens. In patients with contraindications to cephalosporins who are capable of oral therapy and who have not been on oral prophylaxis with cephalosporins, an alternative treatment is oral ofloxacin 400 mg PO every 12 hours. Unless an atypical response, risk profile, or resistant organism is identified, patients with SBP should be treated for a total of 5 days. Therapy may need to be tailored as guided by local antibiotic resistance patterns. Prevalence of multidrug resistance has been increasing among patients with decompensated cirrhosis.[42]

Peritonitis is a frequent complication in patients undergoing peritoneal dialysis (PD), and is associated with a high degree of morbidity and mortality. Similar to peritonitis in cirrhosis, peritonitis in patients undergoing peritoneal dialysis may be spontaneous or secondary to underlying urinary tract, GI, or lung disorders. The most common symptoms include abdominal pain and cloudy peritoneal effluent. The diagnosis is presumed with a dialysate WBC count of more than 100 cells/mm^3 with greater than 50% neutrophils, and is confirmed by culture. In patients with symptoms suggesting peritonitis, dialysate is collected for analysis and culture and treatment initiated. Consideration of catheter removal is also warranted. The most commonly isolated organisms are coagulase-negative staphylococcal species, with *S. aureus* and *S. epidermidis* accounting for over 50% of infections. Intraperitoneal antimicrobial administration is generally preferred over an IV regimen.[43] Current recommendations include empiric coverage with a third-generation cephalosporin (ceftazidime or cefepime) or an aminoglycoside (gentamycin, tobramycin or amikacin) along with vancomycin, covering gram-negative and gram-positive organisms, respectively.[44] Prophylaxis at the catheter exit site with topical application of mupirocin or aminoglycosides is associated with a reduced risk for infection.[45] PD patients or their caretakers will typically be facile in management of the PD catheter, including methods necessary for intraperitoneal antibiotic administration, once prescribed. Management decisions should occur in concert with input from the patient's nephrologist.

Disposition

Any patient with ascites is at risk for the development of SBP. This risk is markedly increased in patients with ascitic fluid protein levels less than 1 g/dL. Other important risk factors include serum bilirubin level greater than 3.2 mg/dL, platelet count less than 98,000/mm^3, or a previous history of SBP. Management with diuretics will help decrease the risk of developing SBP. Proton pump inhibitors (PPIs) may adversely alter acid secretion and gut flora thereby increasing SBP risk. However, some controversy remains regarding the use of PPIs; some studies have found an increased risk of SBP in patients using PPIs, though a recent prospective study demonstrated no increased SBP incidence.[46] We do not recommend the use of PPIs at this time. Beta blockers may increase risk secondary to resultant systemic hypotension.

Antibiotic prophylaxis for high-risk patients can reduce SBP incidence by 60% to 80% and can be cost-effective. Daily prophylaxis may consist of norfloxacin 400 mg PO daily, ciprofloxacin 500 mg PO daily or trimethoprim-sulfamethoxazole (TMP-SMX) 800/160 mg PO daily, however, these recommendations are not graded.

In patients with cirrhosis who are admitted for GI bleeding, prophylactic ceftriaxone (1 g IV daily) is recommended until the patient is taking food orally, at which time a switch to oral TMP-SMX is advised.

Long-term outpatient prophylaxis with either norfloxacin, ciprofloxacin, or TMP-SMX is recommended for patients who have cirrhosis, gastrointestinal bleeding, prior SBP or those with high-risk features including ascitic fluid protein less than 1.5 g/dL, serum BUN level greater than 25 mg/dL, serum creatinine greater than 1.2 mg/dL or serum sodium level less than 130 mmol/L.

Patients with diagnosed SBP typically require hospitalization. Many patients with SBP will not require repeat abdominal paracentesis. In those with inconsistent symptoms, abnormal treatment response, atypical organisms, or recent β-lactam exposure, repeat paracentesis may help differentiate secondary bacterial peritonitis potentially requiring surgical intervention.

HEPATIC ABSCESSES

Hepatic abscesses fall into two broad categories, pyogenic and amebic. Although there may be similarities in clinical presentation, the pathophysiology and treatment differ significantly. The multiple etiologies of hepatic abscess are summarized in Fig. 76.16.

Pyogenic Abscess

Foundations

Liver abscesses may be associated with biliary tract obstruction or cholangitis but can also be related to conditions that cause peritonitis and subsequent extension via the portal circulation, including: diverticulitis, pancreatic abscess, omphalitis, appendicitis, inflammatory bowel disease, or pneumonia. Pyogenic liver abscess as a consequence of liver trauma is possible, although rates have declined with the inception of nonoperative protocols for traumatic hepatic injuries.[47] Often no underlying cause for hepatic abscess is identified. Solitary and multiple abscesses occur with approximately equal frequency, usually in the right lobe of the liver. Patients with multiple lesions tend to be more severely ill, with less favorable outcomes. Causative organisms may be anaerobic and aerobic; *E. coli, Klebsiella, Pseudomonas,* and *Enterococcus* spp., anaerobic streptococci, or various *Bacteroides* spp. may be isolated.

Clinical Features

The clinical presentation is characterized by the onset of often high fever, chills, right upper quadrant (RUQ) pain, nausea, or vomiting. Patients generally have an acute presentation and appear generally ill, particularly if there is underlying cholangitis. Physical findings include elevated temperature, RUQ tenderness, hepatomegaly, and occasionally dullness to percussion or diminished breath sounds over the right lower chest. Jaundice may be apparent, especially if coexistent biliary tract obstruction is present.

Differential Diagnosis

The differential diagnosis of pyogenic hepatic abscess includes amebic liver abscess, hepatitis, cholangitis, and pancreatic or subphrenic abscesses, among others.

Diagnostic Testing

Laboratory findings include leukocytosis in 70% to 80% of cases, elevated alkaline phosphatase levels in up to 90%, and bilirubin level in excess of 2 mg/dL in 50% of patients. Although blood culture sensitivities are overall poor in patients with pyogenic abscesses, they should be obtained in advance of antimicrobial treatment if feasible and while awaiting definitive drainage from the abscess site. Serum aminotransferase levels commonly are elevated 2 to 4 times normal. Chest radiographs may reveal a right pleural effusion, basilar atelectasis, or an elevated right hemidiaphragm. The most useful, sensitive, and expeditious imaging modalities include ultrasonography and CT (Figs 76.17 and 76.18), with CT demonstrating higher sensitivity.

Management

The initial treatment of a pyogenic hepatic abscess is hemodynamic stabilization, IV antibiotics, and pain control. Pending definitive microbial identification, broad-spectrum antibiotic coverage should

Amebiasis and biliary infection. In: Blumgart LH, Fong Y, eds. *Surgery of the liver and biliary tract.* London: WB Saunders; 2000:1147-1166.)

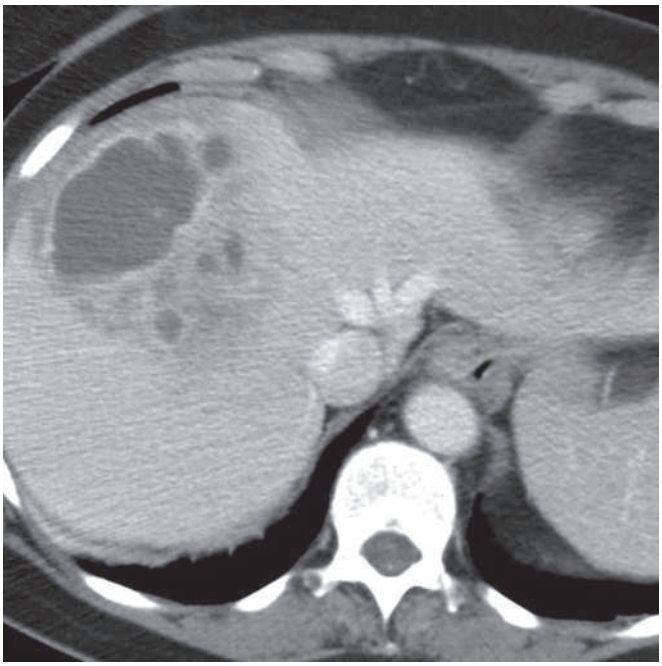

Fig. 76.18 Contrast-enhanced CT through the liver reveals the "cluster" appearance of a pyogenic hepatic abscess with several smaller peripheral abscesses that have coalesced. (From Vickers SM, Black SM, Prabhakaran S. Liver abscess. In: Yeo CJ, ed. *Shackelford's surgery of the alimentary tract*, 7th ed. Elsevier; 2013. Fig. 118-3.)

be promptly initiated, even in advance of a drainage procedure, and continued for up to 6 weeks, depending on the size of the abscess and patient response. Abscesses less than 5 cm are often treated with antibiotics alone, without drainage.[47] Although there has been no consensus on treatment regimens, IV antibiotic coverage targeting gram-negative bacilli, gram-positive cocci, and anaerobes is recommended. This may include cefotaxime 2 g IV every 8 hours; or ceftriaxone 2 g IV daily plus metronidazole 500 mg IV every 8 hours; or ampicillin 2 g IV every 6 hours in conjunction with gentamycin 1.7 mg/kg IV every 8 hours and metronidazole 500 mg IV or PO every 8 hours; or piperacillin-tazobactam 3.375 IV every 6 hours, imipenem 500 mg every 6 hours, or meropenem 1 gm every 8 hours in combination with metronidazole 500 mg IV or PO every 8 hours. The addition of vancomycin is indicated for an acutely ill or unstable patient, as well as any patient with gram-positive cocci on staining or when suspicion for enterococcal or staphylococcal organisms is high.

Definitive treatment for abscesses larger than 5 cm requires drainage. This usually is done percutaneously under imaging guidance, reserving open surgical drainage primarily for complex cases associated with intraperitoneal soiling, intestinal perforation, or biliary obstruction. Complications include rupture of the abscess into the peritoneal cavity or an adjacent anatomic structure (e.g., thoracic cavity, lung, pericardium). Aspirates containing bile should prompt further investigation of the biliary tract for sources of obstruction.[47]

Disposition

Patients with pyogenic hepatic abscess typically require hospitalization. Input from a general surgeon, gastroenterologist, or interventional radiologist may be helpful in determining optimal management.

Amebic Abscess

Foundations

Amebiasis related to the protozoan *Entamoeba histolytica* is one of the most common protozoal infections worldwide. Transmission generally occurs by the fecal-oral route, often as a consequence of ingesting contaminated water or food. Although intestinal disease is by far the most common manifestation of infection, extraintestinal disease can occur, with the liver most commonly affected. *Entamoeba histolytica* is the only ameba responsible for invasive disease, and only certain varieties of *E. histolytica* are pathogenic after invasion of the intestinal mucosa and transit through the portal venous circulation. As with a pyogenic abscess, involvement of the right hepatic lobe is more common.

Clinical Features

The clinical presentation generally is acute with fever, chills, nausea, vomiting, and abdominal pain. Median onset of symptoms is 12 weeks post exposure, although longer periods have been observed between exposure and occurrence.[48] Diarrhea is common in children though is present in less than one-third of adults. Careful questioning of patients without diarrhea often yields a history of intestinal illness several weeks prior to presentation. Many patients complain of cough, which may direct attention away from the liver. A chronic illness of several months' duration, although less common than the acute presentation, can occur. Physical findings include an elevated temperature, RUQ tenderness, hepatomegaly, and dullness, with decreased breath sounds over the right lower chest.

Differential Diagnoses

The differential diagnosis includes pyogenic abscess, biliary tract disease, hepatitis, pneumonia, appendicitis, or pancreatitis. Respiratory symptoms or abnormalities on the chest radiograph may cause confusion with pulmonary illnesses. Hepatic imaging is helpful in establishing the diagnosis; however, differentiation from pyogenic illness is difficult and requires additional laboratory testing. Amebiasis should remain high on the differential diagnosis in patients with supporting signs and symptoms and epidemiologically relevant history including travel to or residency in endemic areas including India, Africa, Mexico, Central or South America.

Diagnostic Testing

Laboratory findings are nonspecific. Neutrophilic leukocytosis is common. The alkaline phosphatase level is elevated in 75% of cases and aminotransferase levels in 50%. Hyperbilirubinemia is uncommon and, when present, is typically indicative of biliary obstruction. The chest radiograph may reveal a right pleural effusion, basilar atelectasis, or elevated right hemidiaphragm. Ultrasound examination of the liver may reveal specific findings unique to amebic abscess, specifically a peripherally based round or oval mass, with a well-circumscribed border and homogeneous hypoechoic center (Fig. 76.19). CT or magnetic resonance imaging (MRI) are alternative abdominal imaging modalities if ultrasonography is inconclusive. The diagnosis is supported by identification of a pathogenic protozoan in the stool, though even in cases of invasive intestinal disease, the yield may be low. Serologic antigen detection using enzyme-linked immunosorbent assay (ELISA) and counter-immune electrophoresis are the recommended diagnostic tests. The indirect hemagglutination test remains positive for an extended period and is therefore not helpful in establishing the presence of acute infection. At the time of presentation, nearly all patients with hepatic abscess will have antibodies present on serologic testing.

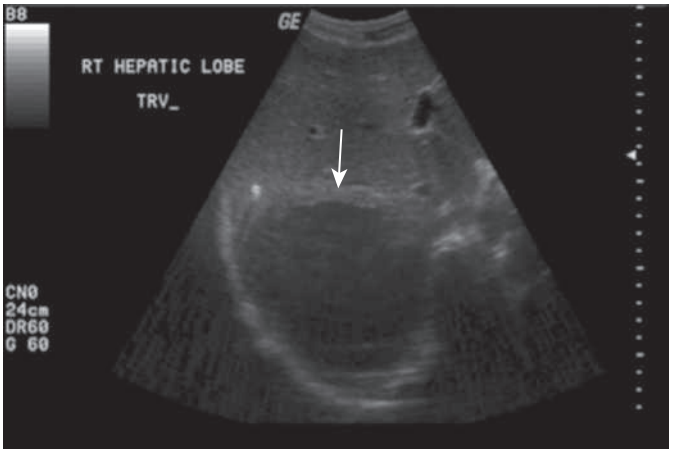

Fig. 76.19 Ultrasound of the liver demonstrating amebic abscess with a peripherally located abscess with a homogeneous, hypoechoic center (*arrow*).

Management

Management of an amebic abscess consists of supportive therapy and initiation of amebicidal therapy. Both tissue and luminal agents are required. Metronidazole, 500–750 mg PO every 8 hours for 7 to 10 days is the therapeutic tissue agent of choice. Following tissue therapy, clearance of luminal cysts is achieved with paromomycin 10 mg/kg PO every 8 hours for 7 days. Most patients will respond to this regimen with percutaneous catheter abscess drainage required only in refractory or complicated cases. The most serious complication of amebic liver disease is rupture into adjacent anatomic structures. Involvement of the lung occurs in 20% to 35% of cases of extrahepatic disease, often manifesting as a massive pleural effusion or consolidative pneumonia. With rupture into a bronchus, the patient can have cough productive of an anchovy paste–like substance, necrotic debris, or frank hemoptysis. Abdominal pain with peritonitis can result from rupture into the abdominal cavity. Involvement of the pericardium occasionally is seen with lesions in the left lobe of the liver and can be catastrophic, either acutely as a consequence of pericardial tamponade or chronically from constrictive pericarditis.

Disposition

Select patients with amebic liver abscess can be managed as outpatients. This approach is best suited for those with mild clinical disease, stable living circumstances, and adequate access to medications and follow-up care. In patients with more severe disease, evidence of complications, or questionable social circumstances, hospitalization is advised.

MISCELLANEOUS DISORDERS AND CONDITIONS OF THE LIVER

Liver Disease of Pregnancy

The incidence of liver disease in pregnancy (LDoP) is less than 1%, and can contribute to a range of maternal and perinatal morbidities, including maternal or fetal death.[49] The two primary hepatic disorders associated with pregnancy are benign cholestasis and acute fatty liver. Of note, LDoP often accompanies preeclampsia in the setting of the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, and as such should prompt further assessment of blood pressure, mental status, and urine or serum studies when LDoP is detected during pregnancy or the postpartum period.

Benign Cholestasis

Benign cholestasis during pregnancy is common and has a familial linkage. Onset is in the late second or third trimester and is heralded by the development of progressive pruritus. Resolution is with delivery. Circulating estrogens are thought to be causative, because onset mirrors estrogen peaks and pregnancies with multiple gestations have a higher incidence. The bilirubin level may be elevated though not dramatically, thus jaundice is uncommon. Laboratory tests reveal elevated alkaline phosphatase, serum aminotransferases, and total and direct bilirubin levels. Although the primary concern to the mother is discomfort from pruritus, bile acids cross the placenta into the amniotic fluid and can adversely impact the fetus, with an associated increased incidence in prematurity, stillbirth, or fetal distress. In Patients with cholestasis of pregnancy, treatment with ursodeoxycholic acid (UDCA) 300 mg PO every 8 hours until delivery is recommended.[50]

Acute Fatty Liver

Acute fatty liver of pregnancy can progress rapidly to maternal or fetal demise. It is treated as an obstetric emergency and requires prompt identification. The illness occurs in the latter part of the third trimester (usually after 30 weeks) and is more common in primigravidas and twin gestations.[46] Differentiation of acute fatty liver disease of pregnancy from HELLP can be difficult. Additional organ involvement, including pulmonary or renal, is more suggestive of acute fatty liver disorder. Early clinical features include fatigue, anorexia, nausea, or vomiting. Physical findings include mild jaundice and abdominal tenderness, most prominently in the midepigastrium and right upper quadrant. Physical examination may not allow thorough palpation of the liver secondary to the enlarged, gravid uterus.

Abnormal laboratory findings include moderate elevation of aminotransferase levels (5 to 10 times normal), hyperbilirubinemia, hypoglycemia, or evidence of disseminated intravascular coagulation—prolonged PT and partial thromboplastin time, hypofibrinogenemia, elevated fibrin split products, and thrombocytopenia. Swansea criteria have high sensitivity and may aid in diagnosing acute fatty liver disease of pregnancy (Box 76.3). Positive screening requires presence of at least 6 of the 15 criteria.[51] Early detection remains critical to prevention of mortality. Treatment involves prompt delivery of the fetus and supportive maternal care. A combination of interventions including aggressive fluid and electrolyte support, glucose administration, management of coagulopathy, ventilatory support for ARDS, or dialysis necessitate monitoring in a critical care setting. N-acetylcysteine (NAC) has been utilized clinically though is not uniformly recommended because evidence is lacking.[51] Liver disease in pregnancy generally resolves without permanent sequelae after delivery.

Budd-Chiari Syndrome

Budd-Chiari syndrome (BCS) is caused by hepatic venous outflow obstruction located anywhere above the level of hepatic venules. There are two types based on etiologic entities. Primary BCS is caused by thrombosis (Fig 76.20) or phlebitis, whereas secondary BCS is due to external compression of the venous outflow tract (hepatic vein or IVC). The primary disorder is typically associated with hypercoagulable states, such as factor V Leiden, protein S or C deficiency, thrombophilia, antithrombin III deficiency, myeloproliferative disorder, Behçet disease, paroxysmal nocturnal hemoglobinuria, or oral contraceptive use.

Symptoms usually develop over weeks to months. Presentation ranges from fulminant hepatic failure in acute high-grade obstruction to the insidious onset of jaundice or ascites in more subacute forms. Clinical symptoms correlate with the degree of venous obstruction and rate of venous occlusion. Fulminant disease is clinically indistinguishable from acute hepatic necrosis secondary to viral infection or other hepatocellular disease. Because treatment options differ significantly, it is important to make the distinction between these two classes of hepatic failure. Prompt intervention in patients with BCS offers the possibility of effective relief with a potentially favorable outcome. Doppler ultrasound imaging of the hepatic vein has a sensitivity of 85% to

BOX 76.3 Swansea Criteria for the Diagnosis of Acute Fatty Liver Disorder of Pregnancy

Abdominal pain
Ascites
Vomiting
Polydipsia or polyuria
Encephalopathy
Bilirubin > 0.8 mg/dL
Hypoglycemia < 72 mg/dL
Elevated urea > 950 mg/dL
Leukocytosis > 11 × 10^9/L
ALT > 42 U/L
Ammonia > 66 μmol
Cr > 1.7 mg/dL
Coagulopathy or PT > 14s
Bright liver on ultrasonography
Microvesicular steatosis on liver biopsy

Adapted from: Liu J, Ghaziani T, Wolf J. Acute fatty liver disease of pregnancy: updates in pathogenesis, diagnosis and management. *Am J Gastroenterol.* 2017;112(6):838.

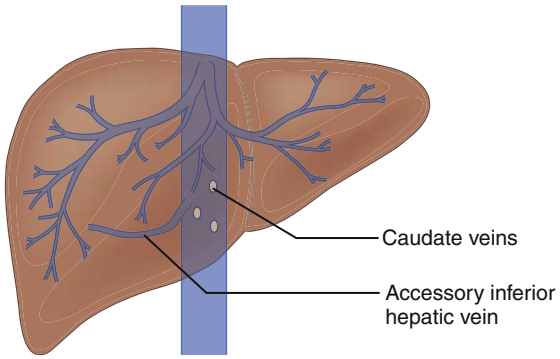

Fig. 76.20 Diagram of hepatic venous drainage depicts the small veins that drain from the caudate lobe and adjacent part of the right lobe directly into the inferior vena cava. The veins tend to be spared in hepatic venous occlusion in patients with Budd-Chiari syndrome, giving rise to hypertrophy of the caudate lobe and adjacent part of the right lobe. (Redrawn from: Khan AN, Chandramohan M, Amin Z. Budd-Chiari syndrome imaging. *Medscape.* 2020. https://emedicine.medscape.com/article/364420-overview)

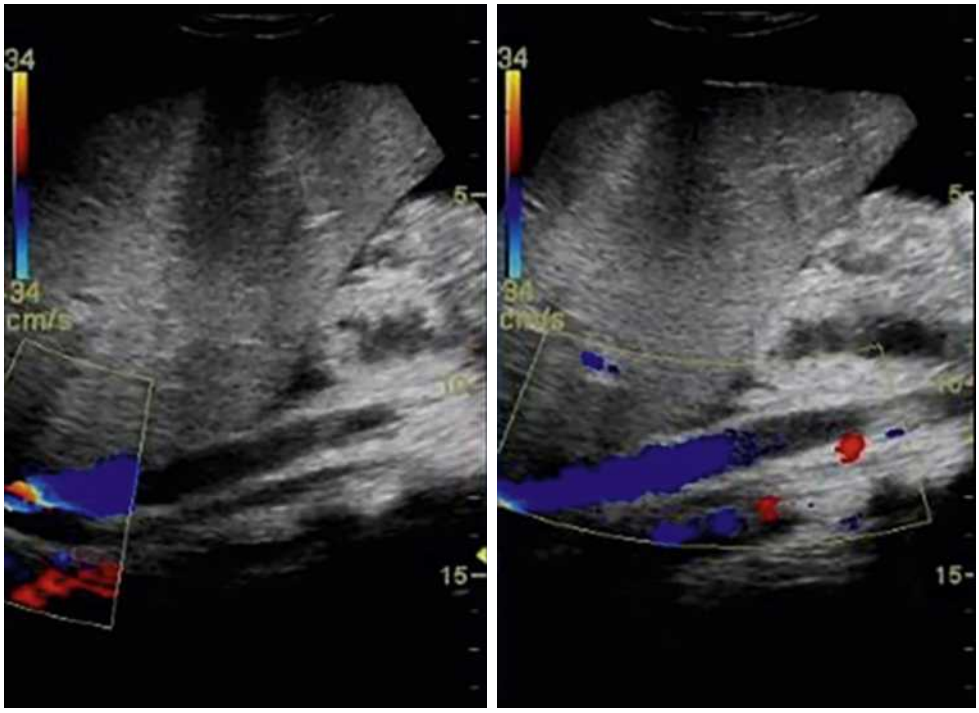

Fig. 76.21 Doppler ultrasound demonstrating patient IVC but no flow in the hepatic veins. (From: Khan AN, Chandramohan M, Amin Z. Budd-Chiari syndrome imaging. Medscape. 2020.)

95% for the diagnosis of BCS and emerges as the diagnostic modality of choice in the ED setting (Fig. 76.21). Venography with access through internal jugular, cephalic, or femoral veins is the most sensitive diagnostic modality. It is typically reserved for cases that remain highly suspicious despite nondiagnostic sonographic studies. Additionally, ascitic fluid analysis may help distinguish among etiologies of ascites, because the high portal pressure seen in BCS is associated with elevated serum-to-ascites protein gradients of greater than 1.1 g/dL.

The management of BCS relates to the severity and acuity of disease. Management focuses on relieving underlying disorders such as hypercoagulopathy as well as managing complications of portal hypertension. Newly diagnosed BCS with acute decompensation necessitates consideration of TIPS placement, percutaneous angioplasty, or thrombolytic therapy. Previously diagnosed disease with worsening ascites can be managed with modification of diuretics and therapeutic paracentesis, followed by referral to a primary care physician or gastroenterologist. In cases of primary BCS, anticoagulation is used to prevent clot propagation. Thrombolysis and stenting may be employed to restore flow. Portacaval surgical shunting or liver transplantation are options for disease refractory to medical or percutaneous interventions.

Liver Transplantation

Human orthotopic liver transplantation is an effective treatment option for patients with acute failure, end-stage disease or malignancy. Transplantation offers a 5-year survival rate of approximately 80%, though transplantation-related complications are common. Considerations for recipient selection include underlying disease, surgical risk, potential for recurrence, and risks of long-term immunosuppression. Early complications include bleeding, acute rejection, vascular or biliary tract issues, or infection. Delayed complications include recurrence of underlying disease, malignancy, infection, chronic rejection, medication toxicity, biliary complications, or renal failure. Many early complications will manifest during the immediate postoperative period. Delayed complications may occur 1 year or more after transplantation.

A combination of two to three immunosuppressive agents are utilized following liver transplantation to prevent rejection. Common regimens include a glucocorticoid such as prednisone along with a calcineurin inhibitor (e.g., cyclosporine or tacrolimus) plus either sirolimus, mycophenolate, or azathioprine. Corticosteroid toxicity includes potential for glucose intolerance, diabetes, osteoporosis, gastric ulceration, or muscle wasting. Cyclosporine and tacrolimus can cause renal impairment, which is the most common dose-limiting effect of these agents. Azathioprine can be hepatotoxic but is more often associated with bone marrow suppression, placing the patient at increased risk for infectious complications or bleeding diatheses.

As a result of their immunosuppression, liver transplant recipients are at increased risk for infections, which remain the leading cause of mortality in transplant recipients and occur frequently in the first three months following surgery, or may be delayed. Presenting signs and symptoms may be subtle secondary to immune suppression. Chronic rejection manifests with low-grade temperature elevation, fatigue, and jaundice. Expected laboratory abnormalities in rejection include elevated bilirubin and transaminase levels, prolonged PT or INR, and low serum albumin level. Evolving renal dysfunction may not be clinically apparent until the glomerular filtration rate has declined significantly. Routine serum creatinine level measurement is the best means of early identification.

Management of patients with complications related to their liver transplant is guided by the nature of the problem. Accordingly, assessment may include a CBC and determination of glucose, BUN, creatinine, serum electrolytes, transaminase, bilirubin and albumin levels, as well as coagulation studies. Hepatobiliary imaging is indicated if tumor, vascular occlusion, or biliary tract obstruction is suspected. Ultrasound studies with Doppler interrogation can be particularly useful in the ED setting. Serologic PCR testing for cytomegalovirus (CMV) is undertaken if patients are within the first three months of transplant or have a constellation of supportive symptoms including leukopenia, arthralgias, or fever. Engagement

of a transplantation specialist is recommended for any patient with a problem potentially related to the organ transplant or immune-modulating medications.

Management of the liver transplant patient is further discussed in Chapter 183.

BILIARY TRACT DISORDERS

CHOLELITHIASIS

Foundations

The principal cause of biliary tract disease is related to the development of gallstones, termed *cholelithiasis*. There are two categories of gallstones, cholesterol stones and pigmented stones. Stones are common in the US population, with a prevalence of 6% to 9%, with a female predominance. The majority of individuals with stones remain asymptomatic and may become aware of their cholelithiasis only incidentally upon imaging for other indications.

Cholesterol stones usually occur as a consequence of an elevated concentration of cholesterol in bile relative to the other principal constituents, bile acids and phospholipids. As cholesterol levels rise or bile acid and lecithin levels decline, cholesterol has an increasing tendency to form crystals. These crystals serve as a nidus for stone formation. Factors associated with an increased risk of cholesterol stone formation include increased age, female gender, obesity, rapid weight loss, cystic fibrosis, parity, drugs such as clofibrate or oral contraceptive agents, and familial tendency.

Pigmented stones are of two varieties, black and brown. Black stones occur exclusively in the gallbladder, contain a high concentration of calcium bilirubinate, and are usually encountered in older adults and those with intravascular hemolytic diseases such as sickle cell anemia or hereditary spherocytosis. Brown stones are associated with infection and can form in the gallbladder and intrahepatic or extrahepatic bile duct systems. All types of gallstones contain calcium bilirubinate and therefore may be visible on plain abdominal radiographs.

Clinical Features

The most common initial clinical manifestation of symptomatic cholelithiasis is biliary colic. The term *colic* can be misleading, because affected patients may report dull, steady pain, rather than intermittent or cramping discomfort. The pain most often is perceived in the RUQ but may be localized over a wide region of the upper abdomen. Radiation of pain, if it occurs, generally is to the base of the right scapula or shoulder. Associated signs and symptoms include nausea or vomiting, which may be severe enough to lead to fluid and electrolyte imbalances. Patients with biliary colic commonly report similar self-limited occurrences in the past and may offer an association between symptom onset and eating. Postprandial physiologic contraction of the gallbladder applying pressure to stones (or sludge, a mixture of particulate matter and bile, microlithiasis) against the cystic duct opening leads to elevated gallbladder pressure and transient wall inflammation. This cascade results in visceral pain. Physical findings include mild tenderness to palpation, without guarding or rebound in the RUQ or epigastric region. Patients with uncomplicated cholelithiasis usually appear well and without infectious or compensatory findings such as fever or tachycardia.

Differential Diagnosis

Differential considerations include cholecystitis, choledocholithiasis (with or without cholangitis), gallstone pancreatitis, peptic ulcer disease of the stomach or duodenum, or hepatitis. Cholelithiasis may occasionally lead to chest discomfort and as such it is prudent to consider cardiopulmonary syndromes as well. A compatible clinical history in conjunction with normal laboratory test values (ALT, AST, lipase, and alkaline phosphatase levels), gallstones on ultrasound, and minimal or no tenderness in the RUQ favor the diagnosis of uncomplicated cholelithiasis. If abnormalities are not visualized, a chest radiograph, electrocardiogram, or serum troponin levels in selected patients may help differentiate between cardiopulmonary and biliary pathology.

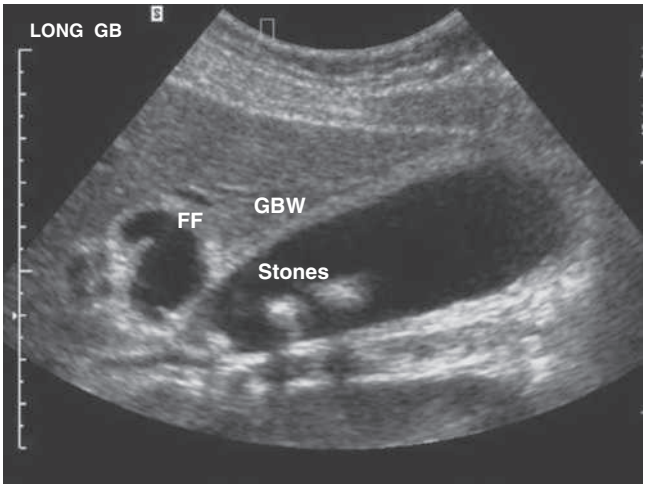

Fig 76.22 Gallbladder with gallstones (*Stones*), thickened gallbladder wall (*GBW*), and pericholecystic fluid (*FF*). Together with a sonographic Murphy sign, these findings constitute the sonographic findings in cholecystitis.

Diagnostic Testing

There is no pathognomonic test for cholecystitis. Results of commonly performed tests are often within normal limits. Important tests to perform include ALT and AST level measurements to evaluate for the presence of hepatitis, bilirubin and alkaline phosphatase level for common duct obstruction, and lipase level for pancreatitis.

The diagnosis of biliary colic is made clinically in conjunction with the demonstration of echogenic foci (stones) in the gallbladder. Transabdominal ultrasonography is the diagnostic modality of choice for investigating the gallbladder given that it can be performed rapidly, is highly sensitive, and also permits evaluation of local surrounding structures when necessary (Fig. 76.22). CT and MR imaging are alternative modalities when ultrasonography is not available or cannot be performed successfully. These alternative modalities have lower sensitivity than ultrasonography. Endoscopic ultrasonography, though invasive, has a higher sensitivity than transabdominal techniques and may detect smaller stones. Additionally, endoscopic ultrasound is performed in conjunction with endoscopic examination of the upper GI tract, which also serves to evaluate for alternative disorders.

Management

The initial management of biliary colic is correction of fluid and electrolyte disturbances and relief of symptoms. Vomiting is managed with antiemetics. Pain often can be controlled with nonsteroidal antiinflammatory drugs (NSAIDs) or opiate analgesic agents, as needed. The definitive management of symptomatic cholelithiasis usually involves surgical removal of the gallbladder. Alternative treatments include oral administration of bile acids (e.g., chenodeoxycholate, ursodeoxycholate) that can result in dissolution of small

to medium-sized stones over a period of months to years. Extracorporeal shock wave lithotripsy may be successful in a select, technically suitable set of patients who have functioning gallbladders and, ideally, have a small number of stones.

The most common complication of biliary colic is fluid and electrolyte imbalances secondary to vomiting. Other adverse consequences include Mallory-Weiss tears from uncontrolled emesis or cholangitis from unrecognized and persistent common bile duct obstruction.

Special Considerations

Biliary colic is an uncommon finding in children and is usually associated with an underlying hemolytic disorder such as sickle cell anemia or hereditary spherocytosis.

Cholelithiasis may be encountered in pregnant women, though the diagnosis is made more difficult by the common occurrence of nausea and vomiting, particularly in the first trimester, and the presence of an enlarged uterus in later pregnancy, which alters anatomic relationships and may interfere with abdominal examination. Ultrasound imaging is of considerable diagnostic use in this setting. ED management is the same for pregnant and nonpregnant patients; however, definitive therapy generally is delayed until after delivery.

Disposition

Hospitalization should be considered for unremitting pain, intolerance of oral intake, significant electrolyte abnormalities, or laboratory tests indicating obstruction or possible cholecystitis. In other patients, symptom control can often be achieved and electrolyte and volume depletion corrected such that the patient can be discharged home with antiemetics and agents for pain control after demonstrating tolerance for oral intake. Referral to a general surgeon as an outpatient for further evaluation and consideration of cholecystectomy should be considered in discharge planning.

CHOLECYSTITIS

Foundations

Acute cholecystitis is defined as sudden inflammation of the gallbladder. The risk factors for cholecystitis are similar to those for cholelithiasis—female gender, increasing age and parity, and obesity. Although gallstones play a prominent role in the pathogenesis of cholecystitis, a minority of cases occur without stones, termed *acalculous cholecystitis*.

Obstruction of the cystic duct appears to be the critical factor in the development of gallbladder inflammation. Gallstones are identified in 95% of patients with cholecystitis or may be located in the common bile duct. Causes of cystic duct obstruction unrelated to stone disease include tumor, lymphadenopathy, fibrosis, parasitic illness, or kinking of the duct, which leads to filling and distention of the gallbladder. The ensuing inflammatory reaction is related to mucosal ischemia from increased hydrostatic pressure as well as the action of cytotoxic products of bile metabolism (e.g., lysophosphatidylcholine). Although bacteria are isolated from the bile of inflamed gallbladders in most cases, the role of infection in the pathogenesis of cholecystitis is not completely understood. Coliforms such as *E. coli* represent the most common isolates, though anaerobes have been identified in as many as 40% of cases.

Clinical Features

The most common presenting symptom of cholecystitis is pain, usually in the right upper quadrant. Although the pain initially may be colicky, it near-uniformly becomes constant. A previous history of similar but less severe and self-limited symptoms is a valuable diagnostic clue, as is documentation of previous gallstones. Fever, nausea, and vomiting are typical features. Radiation of pain to the tip of the right scapula may be described.

Physical findings include tenderness in the RUQ or epigastric region, often with guarding or rebound. Murphy sign (tenderness and an inspiratory pause elicited by palpation of the RUQ during a deep breath) is compatible with, though not specific for, gallbladder inflammation.

Differential Diagnosis

Diagnostic considerations include hepatitis, hepatic abscess, pyelonephritis, right lower lobe pneumonia or pleurisy, pancreatitis, peptic ulcer disease with perforation or penetration, or appendicitis, among others. Accurate diagnosis often requires the use of sonographic or, less commonly, CT or hepatobiliary iminodiacetic acid (HIDA) scanning.

Diagnostic Testing

Leukocytosis or neutrophil predominance may be absent in nearly half of patients. Serum aminotransferase, bilirubin, and alkaline phosphatase levels may be mildly elevated but more often are within normal limits. An elevated lipase level should suggest the diagnosis of pancreatitis, instead of or in addition to cholecystitis. Plain abdominal radiographs rarely reveal calcified stones, gas in the gallbladder, or an upper quadrant sentinel loop, but are usually nondiagnostic.

Ultrasound imaging is the most useful test in the ED. Visualization of the gallbladder without identification of stones has an extremely high negative predictive value for cholecystitis, whereas the presence of stones, thickened gallbladder wall, pericholecystic fluid and a positive sonographic Murphy sign has a positive predictive value in excess of 90% (Fig. 76.23).

Hepatobiliary nuclear scintigraphy with technetium-99m–labeled HIDA generally is considered the most sensitive and specific imaging test for cholecystitis. The IV tracer is taken up by hepatocytes and secreted into the bile canaliculi. Failure to obtain an outline of the gallbladder within 1 hour of administration in the presence of hepatic and common duct visualization is consistent with cystic duct obstruction. In the appropriate clinical setting, this finding is diagnostic of cholecystitis. Conversely, visualization of the gallbladder and common duct within 1 hour of administration has a high negative predictive value. HIDA loses its sensitivity as the serum bilirubin level rises above 5 to 8 mg/dL; however, scintigraphy with diisopropyl iminodiacetic acid, or mebrofenin, allows visualization of the biliary tree in patients with total serum bilirubin as high as 20 to 30 mg/dL.

CT can identify cholecystitis with a sensitivity of 92% but much lower specificity.

Management

Definitive management of acute calculous cholecystitis includes cholecystectomy. Supportive measures include IV crystalloid administration to optimize volume status and antiemetics to manage emesis. Pain control can be addressed with NSAIDs or narcotic analgesics. Despite the questionable role of microbial infection in the pathogenesis of cholecystitis, initial antibiotics are recommended. Unless clinical evidence of sepsis exists, coverage with a single agent broad-spectrum antibiotic, such as IV piperacillin-tazobactam (3.375 g every 6 hours) is recommended.

Gangrene of the gallbladder is a significant complication, with necrosis and perforation. Localized perforation may lead to pericholecystic abscess or fistula formation, with the latter predisposing to gallstone ileus at a later date. Diabetics are at increased risk for bacterial invasion of the gallbladder wall and emphysematous cholecystitis (Fig. 76.24). In this case, complications related to delayed definitive surgical care include gangrene and perforation of the gallbladder, both of which are associated with significant mortality.

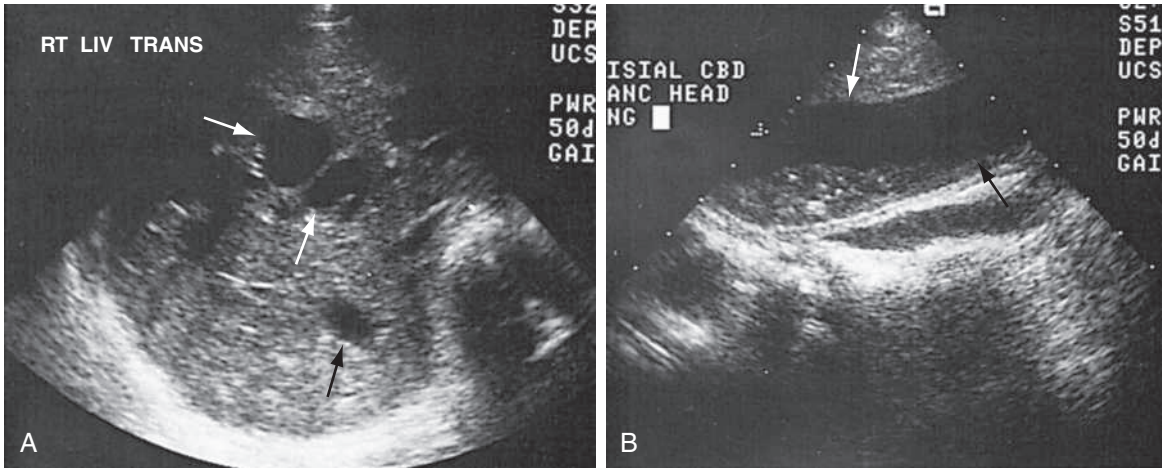

Fig. 76.23 Abdominal ultrasound images from a patient with common bile duct obstruction. (A) Multiple dilated intrahepatic ducts *(arrows)*. (B) Significant dilated common bile duct *(arrows)*. The duct measures 2 cm in diameter.

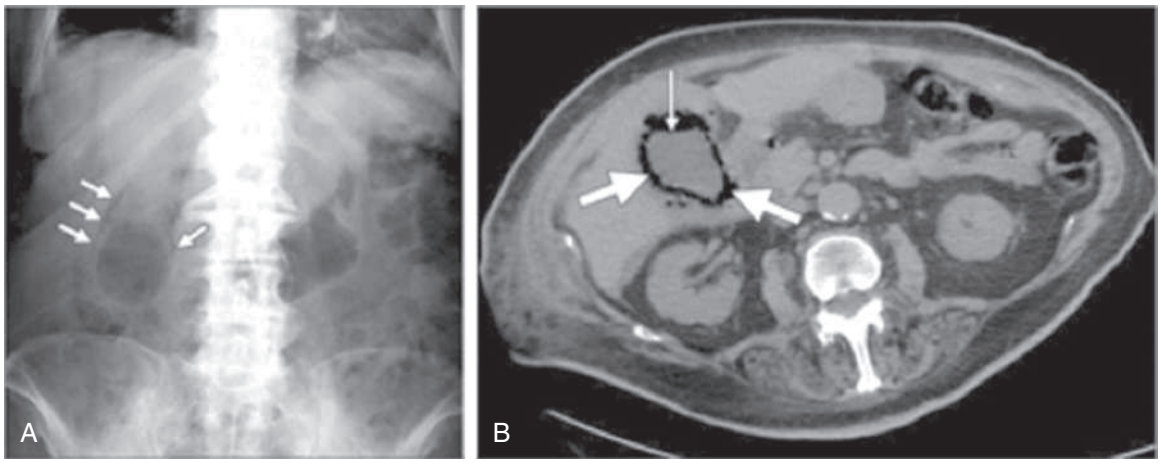

Fig. 76.24 (A) X-ray demonstrating air around the wall of the gallbladder and CT scan (B) demonstrating a luminal air-liquid level and air within the wall of the gallbladder.

Special Considerations

Cholecystitis is uncommon in children; however, when it occurs, it should be managed as for adult patients. Cholecystitis in the pregnant patient poses challenges in diagnosis and therapy. Initial therapy is identical to that for the nonpregnant patient, but the issue of surgical intervention necessitates discussion including surgery and obstetrics.

Acalculous Cholecystitis. Acute cholecystitis absent of stones is more common in older adults and is often found in patients who are recovering from non–biliary tract surgery. This disease should be considered in any critically ill patient presenting with either jaundice or sepsis of undifferentiated source. It is caused by inflammation in the gallbladder wall stemming from stasis and ischemia. Over the past decade, acalculous disease has been increasingly encountered as a complication of advanced AIDS, usually secondary to infection with cytomegalovirus (CMV) or *Cryptosporidium*. In comparison with calculous disease, acalculous cholecystitis tends to have a more acute and malignant course, with a high mortality rate. The same techniques are used to diagnose acalculous disease as for other forms of cholecystitis but are less sensitive and specific for this entity. Sonographic findings include thickening of the gallbladder wall, pericholecystic fluid, sonographic Murphy sign, intramural gas, sludge, and hydrops. HIDA findings are the same as for calculous disease.

Emphysematous Cholecystitis. This is an uncommon variant of cholecystitis, occurring in approximately 1% of cases. It is characterized by the presence of gas in the gallbladder wall, consequent to the invasion of the mucosa by gas-producing organisms such as *E. coli*, *Klebsiella* spp., or *Clostridium perfringens*. It is more common in diabetic patients, has a male predominance, and is acalculous in up to 50% of cases. Clinical presentation and physical findings are similar to those for cholecystitis. Plain radiographs or CT scans of the abdomen typically reveal gas in the gallbladder wall. Because of a high incidence of gangrene and perforation, emergency cholecystectomy is recommended. Antibiotic coverage should include ceftriaxone 1 to 2 g IV every 24 hours plus metronidazole 500 mg IV, every 8 hours, or monotherapy with a β-lactamase inhibitor such as carbapenem. The mortality rate for emphysematous cholecystitis is upwards of 15%.

Disposition

Patients are typically hospitalized for antibiotic therapy and pain management. Surgery is recommended for patients with cholecystitis, though the optimal timing for surgery is not well established. Surgery usually is performed after symptoms have subsided and while the patient is still hospitalized. Immediate cholecystectomy or cholecystostomy is typically reserved for the complicated case in which the patient has gangrene or perforation.

CHOLANGITIS

Foundations

Acute obstructive cholangitis is usually the consequence of common duct blockage by a gallstone but may be associated with structural compression by malignancy or a benign stricture. The key factors contributing to cholangitis include obstruction, elevated intraluminal pressure, and bacterial infection. Incomplete obstruction occurs more commonly than complete blockage. Bacteria may gain access to the obstructed common duct in a retrograde manner from the duodenum, by way of the lymphatics, or from portal vein blood. The most commonly encountered organisms are similar to those encountered in other varieties of biliary tract disease—*E. coli*, *Klebsiella, Enterococcus,* and *Bacteroides.*

Clinical Features

Patients most often experience fever, chills, nausea, vomiting, or abdominal pain. The classic triad of physical findings first described by Charcot consists of RUQ pain, fever, and jaundice. These findings are compatible not only with cholangitis, but also potentially with cholecystitis or hepatitis. Sepsis is a common complication and is evidenced by tachycardia, tachypnea, and frank hypotension. The presence of the Charcot triad along with the clinical signs of sepsis—hypotension and altered sensorium—is referred to as the Reynolds pentad.

Differential Diagnosis

Although patients with cholangitis generally have a higher fever and appear more ill than those with cholecystitis, considerable variability and overlap exist. The presence of jaundice is the clinical sign most helpful in differentiating between these two disorders. An elevated bilirubin level is characteristic of cholangitis and uncommon in cholecystitis. Ultrasonographic evidence of dilated common and intrahepatic ducts usually is required to distinguish cholangitis from cholecystitis.

Diagnostic Testing

Common laboratory abnormalities include leukocytosis, hyperbilirubinemia, elevated alkaline phosphatase level, and moderately increased aminotransferase levels. Blood gas measurements are useful to identify base deficit as an early sign of sepsis.

Sonography can be helpful if it demonstrates common and intrahepatic ductal dilation, whereas identification of stones in the gallbladder or common duct suggests the underlying cause of obstruction (see Fig. 76.22). Although nuclear scintigraphy (HIDA) scanning may not determine the cause, it is a more sensitive means to diagnose early obstruction. There is a high incidence of nonvisualization of the biliary tree with cholescintigraphy in patients with common duct obstruction when sonography fails to identify dilation.

Alternative imaging techniques include CT, percutaneous transhepatic cholangiography (THC), or endoscopic retrograde cholangiopancreatography (ERCP). Although these techniques may be more time-consuming, the latter two have the added benefit of offering potential therapeutic benefit. Endoscopic cholangioscopy can permit culture of bile, direct removal of obstructing stones, or decompression of the biliary tree through sphincterotomy or stent placement.

Management

Treatment of cholangitis includes hemodynamic stabilization with crystalloid fluid and, if necessary, vasopressors. Broad-spectrum antibiotic coverage should be initiated immediately after blood culture specimens have been obtained. The choice of antibiotics should be guided by local sensitivities and should provide coverage for enteric microbes. First-line single agents may include either ampicillin-sulbactam 3g IV every 6 hours or piperacillin-tazobactam 3.375 g IV every 6 hours. The key to successful treatment is early biliary tract decompression, which may be achieved with THC, ERCP, or surgery.

Disposition

Patients with cholangitis require hospitalization, preferably in a monitored setting. Prompt engagement of surgery, interventional radiology, or gastroenterology for biliary tract decompression is necessary.

SCLEROSING CHOLANGITIS

Sclerosing cholangitis is a chronic, idiopathic inflammatory disorder affecting the biliary tree characterized by progressive, diffuse fibrosis and narrowing of the intrahepatic and extrahepatic bile ducts as well as the extrahepatic biliary tree. It is commonly associated with inflammatory bowel disease, particularly ulcerative colitis; however, in 25% of cases, it appears as an isolated disorder. Patients usually report weight loss, lethargy, jaundice, or pruritus. Earliest symptoms include isolated fatigue and pruritis. Rarely, infective cholangitis may develop. Prompt diagnosis may be challenging because of the sclerotic nature of the bile ducts and absence of duct dilation on ultrasound imaging. Surgical exploration or ERCP often is required for diagnosis (Fig. 76.25). Sclerosing cholangitis is thought to be autoimmune in nature. Autoantibodies are often positive but are of unknown prognostic value. Of note, antimitochondrial antibodies may help distinguish sclerosing cholangitis from primary biliary cholangitis; they are often positive in primary biliary cholangitis but not present in sclerosing cholangitis.

The management of uninfected cases is primarily symptomatic. Cholestyramine, a bile acid sequestrant, may diminish pruritus. Elevations of bilirubin for more than 3 months from diagnosis correlates with poorer prognosis. Median survival after diagnosis is 9 to 10 years without liver transplantation.[52]

AIDS CHOLANGIOPATHY

Manifestations of advanced HIV disease, generally associated with CD4+ counts less than 200/mm^3, may include any one of a group of disorders collectively referred to as AIDS cholangiopathy. These disorders include bile duct stricture, papillary stenosis, or sclerosing cholangitis spurred by infectious etiologies. The pathophysiology is not completely understood but is related to infection with CMV, *Cryptosporidium,* microsporidia, or *Mycobacterium avium* complex. Cryptosporidium parvum is the most commonly isolated pathogen. The widespread use of highly active antiretroviral therapy has resulted in a declining incidence of AIDS-related cholangiopathy.

The clinical presentation is similar to that for other causes of cholangitis, with fever and RUQ pain, often with accompanying diarrhea related to the underlying pathogen. Laboratory tests include increased levels of alkaline phosphatase and minor elevation of transaminase levels. The bilirubin level is less commonly elevated than in other disorders that cause cholangitis. Ultrasonography generally is helpful in initially identifying bile duct stricture, thickening, or dilations. Secondarily, visualization using magnetic resonance cholangiopancreatography (MRCP) is helpful in identifying strictures and differentiating this entity from other causes of abdominal pain. Complications of longstanding AIDS-related cholangitis include sclerosis and liver failure. Management includes ursodiol (8–10 mg/kg/day by mouth every 8 or 12 hours) for patients with intrahepatic ductal disease. Isolated ductal stricture management involves endoscopic sphincterotomy or stent placement in conjunction with treatment of the underlying infection.

CHAPTER 76: QUESTIONS AND ANSWERS

1. Which of the following statements regarding hepatitis A is true?
- **a.** Fecal shedding and highest infectivity coincide with symptomatic disease.
- **b.** In the US, approximately 20% of urban-dwelling adults are seropositive.
- **c.** Occult disease is more common in children than in adults.
- **d.** The incidence is consistent across ethnic groups.
- **e.** The most common risk factor for children is travel.

Answer: c. Children are more likely to have occult disease (up to 70%). Adult seropositive rates approach 50% among urban-dwelling adults. The incidence varies widely across ethnic groups. In areas of pediatric vaccinations, increasing adult cases are seen among intravenous drug users (IVDUs) and males who have sex with males. The stage of highest infectivity precedes symptoms.

2. Which of the following statements concerning hepatitis D infection is true?
- **a.** Hepatitis D is spread primarily via the fecal-oral route.
- **b.** Infection with hepatitis D is an independent event with a course nearly identical to that of hepatitis A.
- **c.** It is common to see aspartate aminotransferase (AST) level elevations far in excess of alanine aminotransferase (ALT) level elevations.
- **d.** Many cases are misdiagnosed as acute or reactivated hepatitis B.
- **e.** Unconjugated bilirubin levels are 2 or 3 times higher than conjugated levels.

Answer: d. Hepatitis D virus infection can only occur with (coinfection) or after (superinfection) hepatitis B infection. It is spread via the parenteral route, such as by IV drug use. Many cases are misdiagnosed as acute or reactivated hepatitis B because HBV markers will be positive. There are no unique biochemical or laboratory patterns for any of the viral hepatitis infections. Hepatitis D appears to have a direct cytotoxic potential compared with other viral causes where the host immunologic response primarily leads to hepatopathy.

3. A 26-year-old man presents with complaints of pruritus and a raised rash for 7 days. The rash has been associated with nausea and painful symmetrical swelling of both wrists and metacarpophalangeal joints. He has no past medical history and takes no medications. He works in a retail store. Vital signs are normal, and the physical examination is remarkable for right upper quadrant tenderness, bilateral mild wrist effusion with minimal warmth and no erythema, and diffuse skin urticaria. The remainder of the examination is negative. Blood count, chemistries, and liver studies are remarkable for WBC of 11,800 cells/mm^3, AST of 212 IU/L, ALT of 395 IU/L, normal alkaline phosphatase level, and total bilirubin of 2.3 mg/dL. Which of the following diagnostic modalities would be most likely to yield the causative diagnosis?
- **a.** C-reactive protein level
- **b.** Hepatitis A antigen
- **c.** Hepatitis B surface antigen
- **d.** Joint aspiration
- **e.** Liver ultrasound

Answer: c. A small number of patients with hepatitis B develop a prodrome of arthralgias and arthritis (symmetric small joints) and dermatitis. The dermatitis is typically urticarial but may be macular, popular, or petechial.

4. Scleral icterus becomes clinically apparent at approximately which serum bilirubin level?
- **a.** 2 mg/dL
- **b.** 2.5 mg/dL
- **c.** 3 mg/dL
- **d.** 3.5 mg/dL
- **e.** 4 mg/dL

Answer: b. Icterus is often first noted in the sublingual or subungual areas when the serum bilirubin level is above approximately 2.5 mg/dL.

5. Which of the following statements regarding the typical laboratory profile for a patient with acute viral hepatitis is true?
- **a.** AST is generally elevated in excess of ALT.
- **b.** Direct and indirect bilirubin levels are elevated in almost equal proportions.
- **c.** Lactate dehydrogenase (LDH) levels are almost always normal.
- **d.** The alkaline phosphatase level is generally elevated 5 to 10 times normal.
- **e.** The WBC always shows a marked polymorphonuclear leukocytosis.

Answer: b. The alkaline phosphatase level is rarely elevated more than 2 or 3 times normal, and LDH levels are modestly elevated. The WBC count may range from low, with lymphocytic predominance, to a polymorphonuclear (PMN)-predominant leukocytosis. ALT is almost always elevated in excess of AST in the setting of acute viral hepatitis.

6. A 26-year-old woman returns for follow-up after initial evaluation for possible acute hepatitis. Her hepatitis panel has returned with the following results:

Hepatitis A IgM	Negative
Hepatitis A IgG	Negative
Hepatitis B surface antigen	Positive
Hepatitis B surface antigen IgG	Negative
Hepatitis B core antigen IgM	Positive
Hepatitis B core antigen IgG	Negative
Hepatitis C antigen	Negative

Which of the following is the most appropriate diagnosis?
- **a.** Acute hepatitis A
- **b.** Acute hepatitis B
- **c.** Immunity to hepatitis B
- **d.** Previous hepatitis A
- **e.** Previous hepatitis B

Answer: b. Acute hepatitis A is characterized by IgM to hepatitis A. Prior infection is determined by IgG antibody. Acute hepatitis B is characterized by the presence of surface antigen and IgM antibody to core antigen. Surface antigen alone may be absent late in the course of the disease or may present chronically unrelated to the current episode. IgG to the core antigen indicates previous infection. IgG to the surface antigen is the best marker for immunity.

CHAPTER 76: QUESTIONS AND ANSWERS—cont'd

7. A 39-year-old man presents with a 4-day history of abdominal pain and nausea. He has no significant past history and takes no medications. Vital signs include a temperature of 37.7°C (99.9°F) oral, pulse of 98 beats/min, respiratory rate of 20 breaths/min, and a blood pressure of 119/68 mm Hg. The physical examination reveals scleral icterus, a normal cardiopulmonary examination, moderate right upper quadrant tenderness without rebound, and guaiac-negative stool. Laboratory assessment reveals the following:

Total bilirubin	9.8 mg/dL
Conjugated bilirubin	4.6 mg/dL
Unconjugated bilirubin	5.2 mg/dL
AST	5300 IU/L
ALT	8400 IU/L
Alkaline phosphatase	750 IU/L
Albumin	3.9 mg/dL
INR	1.2
Hematocrit	42%
Platelet count	396,000/mm^3
WBC	9900/mm^3
Blood urea nitrogen (BUN)	53 mg/dL
Creatinine	0.9 mg/dL

Which of the following courses of action is most appropriate?

a. Admission for observation and GI consultation
b. CT scan of the abdomen with contrast
c. Gastrointestinal (GI) referral for interferon therapy
d. Reassurance
e. Tapering course of corticosteroids

Answer: a. Altered sensorium and prolongation of the PT beyond 5 seconds or INR beyond 1.5 suggests fulminant hepatic failure. Similarly, an unexplained elevation of the BUN or creatinine level may portend hepatorenal syndrome, which is associated with significant morbidity. The laboratory derangements warrant admission or transfer for hydration, close observation, and gastroenterology evaluation. Interferon has demonstrated some success in symptomatic hepatitis B patients but does not affect the early course. There is no role for corticosteroids.

8. The risk of liver injury in men increases as daily consumption of alcohol exceeds which of the following?

a. 10 g
b. 20 g
c. 40 g
d. 60 g
e. 80 g

Answer: e. 80 g of alcohol consumption is equivalent to a six-pack of beer, four to six glasses of wine, or three or four mixed drinks. For women, the risk increases with daily consumption of more than 20 g of alcohol.

9. A 63-year-old man with history of alcohol abuse presents with altered mental status. His family reports 3 days of decreasing ambulation and increasingly nonsensical conversation. He has no other known past medical history and takes no medications. Vital signs are unremarkable. Physical examination reveals a thin, unkempt man who is oriented to person only but is cooperative and follows commands. He falls asleep easily. There is no scleral icterus, and cardiopulmonary, abdominal, stool guaiac, and neurologic examinations are otherwise normal. A noncontrast CT scan of the head is negative for acute pathology. Pertinent laboratory findings are as follows:

Hematocrit (HCT)	34%
Hemoglobin	11.4 g/dL
Platelet count	108,000/mm^3
WBC	9300/mm^3
AST	148 IU/L
ALT	86 IU/L
Total bilirubin	2 mg/dL
Albumin	2.2 mg/dL
Alkaline phosphatase	158 IU/L
INR	1.8
BUN	38 mg/dL
Creatinine	2.1 mg/dL
Ethanol	0 mg/dL
Bicarbonate	30 mmol/L
Sodium	133 mEq/L
Potassium	3.6 mEq/L
Chloride	95 mEq/L

What is the most appropriate intervention?

a. Admission for lactulose, 30 to 60 g daily, titrated to modest diarrhea
b. Determination of further therapy, admission, and treatment based on serum ammonia levels
c. Discharge with the family; neomycin, 500 mg every 4 to 6 hours
d. Oral metronidazole, 250 mg PO every 6 hours
e. Oral vitamin K for 2 weeks

Answer: a. Ammonia accumulates in severe liver disease and crosses the blood-brain barrier to eventually form glutamine. Ammonia levels correlate poorly with encephalopathy. Lactulose is an osmotic cathartic that acidifies colonic contents, causing ammonia trapping. Neomycin is a poorly absorbed aminoglycoside that reduces colonic bacteria but is relatively contraindicated in cases of renal insufficiency. Therapies for hepatic encephalopathy that have been under clinical investigation include metronidazole, zinc, flumazenil, and eradication of *Helicobacter pylori*. Vitamin K would have modest benefit due to loss of hepatic synthetic abilities.

Continued

CHAPTER 76: QUESTIONS AND ANSWERS—cont'd

10. A 23-year-old G2P1 woman at 35 weeks of gestation presents with 3 days of fatigue, anorexia, nausea, and vomiting. She reports moderate epigastric and right upper quadrant pain. The physical examination is remarkable for icteric sclerae, slightly dry mucous membranes, and moderate tenderness in the right upper quadrant. She is afebrile and her uterus is not tender. Ultrasound shows a viable fetus at 34 weeks estimated gestation, with good cardiac activity, and liver and gallbladder ultrasound reveals no obvious gallstones or ductal dilations but moderate hepatomegaly. Laboratory analysis is remarkable for the following:

AST	1050 IU/L
ALT	1265 IU/L
Total bilirubin	9.9 mg/dL
Conjugated bilirubin	4.6 mg/dL
Unconjugated bilirubin	5.2 mg/dL
Alkaline phosphatase	328 mg/dL
Glucose	62 mg/dL
Hemoglobin	9.3 g/dL
Platelet count	105,000/mm^3
Serum electrolytes	Normal
Creatinine	0.6 mg/dL
Prothrombin time	14.8 sec
Albumin	3.1 g/dL

What is the most appropriate treatment?

- **a.** Clear liquids, antiemetics, and follow-up outpatient ultrasound in 48 hours
- **b.** Contrast CT scan of the abdomen
- **c.** Hydration, antiemetics, and discharge after symptom resolution
- **d.** Intensive care unit admission for monitoring for DIC
- **e.** Stabilization and urgent delivery

Answer: e. Acute liver failure of pregnancy typically presents in the later third trimester. Treatment involves aggressive fluid and electrolyte support, glucose administration, and immediate delivery. Liver disease generally resolves without sequelae. The illness is more common in primigravidas and twin gestations.

11. What is the most sensitive and specific imaging test for acute cholecystitis?

- **a.** Contrast CT scan
- **b.** Hepatobiliary nuclear scintigraphy with iminodiacetic acid (HIDA) scan
- **c.** Serum alkaline phosphatase level
- **d.** Serum bilirubin level
- **e.** Ultrasonography

Answer: b. Iminodiacetic acid administered IV is taken up by hepatocytes and secreted into bile canaliculi. Visualization of the gallbladder and common duct within 1 hour has a negative predictive value of 98%. Sensitivity of HIDA is diminished at bilirubin levels of 5 to 8 mg/dL.

77

Pancreas

Philippa Soskin

KEY CONCEPTS

- Acute pancreatitis represents a wide spectrum of disease, ranging from mild to severe life-threatening disease with a mortality rate as high as 30%.
- The most common causes of acute pancreatitis are gallstones and chronic alcohol consumption.
- Acute pancreatitis is diagnosed by the presence two of three criteria—characteristic abdominal pain, serum lipase or amylase levels greater than three times the upper limit of normal, and characteristic findings on abdominal imaging.
- Serum lipase level is preferred over the amylase level because of its greater sensitivity and specificity in diagnosing acute pancreatitis.
- Computed tomography (CT) scan is not routinely recommended in the diagnosis of acute pancreatitis. It should be used in cases of diagnostic uncertainty and assessing for complications.
- Abdominal ultrasound should be performed to evaluate for a biliary etiology of pancreatitis.
- Treatment of acute pancreatitis is mainly supportive with fluid resuscitation and pain management. Lactated Ringers is preferred over normal saline because it is more physiologic and may provide antiinflammatory effects. There is no evidence to support one analgesic agent over another.
- Prophylactic antibiotics are not indicated in the management of acute pancreatitis but should be used in cases of infected pancreatic necrosis or other clear evidence suggesting sepsis or infection.
- Endoscopic retrograde cholangiopancreatography (ERCP) is only indicated in cases of cholangitis or biliary obstruction.
- Most patients with pancreatitis require hospitalization for symptomatic control, monitoring of hydration and nutrition status, and management of complications.
- There are several scoring systems to aid in predicting severity and outcomes in pancreatitis, including Ranson criteria, Acute Physiology and Chronic Health Evaluation II (APACHE II), CT severity index (CTSI), and Bedside Index of Severity in Acute Pancreatitis (BISAP). They are similar in their predictive accuracy, and each has different strengths and weaknesses.
- Chronic pancreatitis is a progressive fibroinflammatory syndrome which impairs both exocrine and endocrine pancreatic function.
- Pancreatic cancer is the seventh most common cause of death from cancer globally with a 5-year survival rate of only 7%.
- Surgical treatment may improve survival in patients whose pancreatic cancer is diagnosed early without metastasis. Most patients have advanced disease at diagnosis.

PANCREATITIS

Anatomy, Physiology, and Pathophysiology

The pancreas is a retroperitoneal organ with endocrine and exocrine functions (Fig. 77.1). It contains three segments—head, body, and tail—that span across the upper abdomen. The pancreatic head sits within the concave C loop of the duodenum, located in the epigastrium. The body of the pancreas traverses posteriorly to the stomach, and the pancreatic tail abuts the hilum of the spleen in the left upper quadrant. A large main pancreatic duct (duct of Wirsung) courses within the pancreas from the tail to the head, where it meets the common bile duct to form the ampulla of Vater, which drains its contents into the duodenum via the sphincter of Oddi. The exocrine function of the pancreas is carried out by the excretion of various digestive enzymes, such as trypsinogen. The endocrine function of the pancreas includes secretion of the regulatory hormones insulin, glucagon, and somatostatin.

Injury to the pancreas begins with an inciting event, such as duct obstruction by a gallstone or exposure to a pharmacologic agent or a toxin such as alcohol. Cellular injury disrupts normal membrane trafficking and triggers the inappropriate activation of trypsinogen resulting in increased trypsin production which results in further cell injury and activation of other digestive enzymes. Autodigestion and the activation of the inflammatory cascade with the recruitment of macrophages and neutrophils lead to further destruction of pancreatic tissue. Cytokine release causes increased vascular permeability, which can result in complications such as edema, hemorrhage, and necrosis. The release of inflammatory mediators through a heightened autoimmune response may lead to systemic inflammatory response syndrome (SIRS), sepsis, and shock. Bacteremia can occur due to translocation of intestinal flora. Extrapancreatic organ dysfunction such as the development of pleural effusions, acute respiratory distress syndrome (ARDS), and renal failure may also occur.

Acute Pancreatitis

Foundations

Acute pancreatitis is an inflammatory condition leading to enzymatic autodigestion and the destruction of pancreatic tissue. Its presentation ranges widely from mild, self-limited disease to sepsis and multiorgan failure. Recurrent episodes of acute pancreatitis can result in the progressive fibrosis of chronic pancreatitis. Acute pancreatitis is the most common pancreatic disease worldwide and one of the top reasons for hospitalization due to gastrointestinal disease in the United States.[1,2] Mortality can run as high as 30% in severe cases; however, although

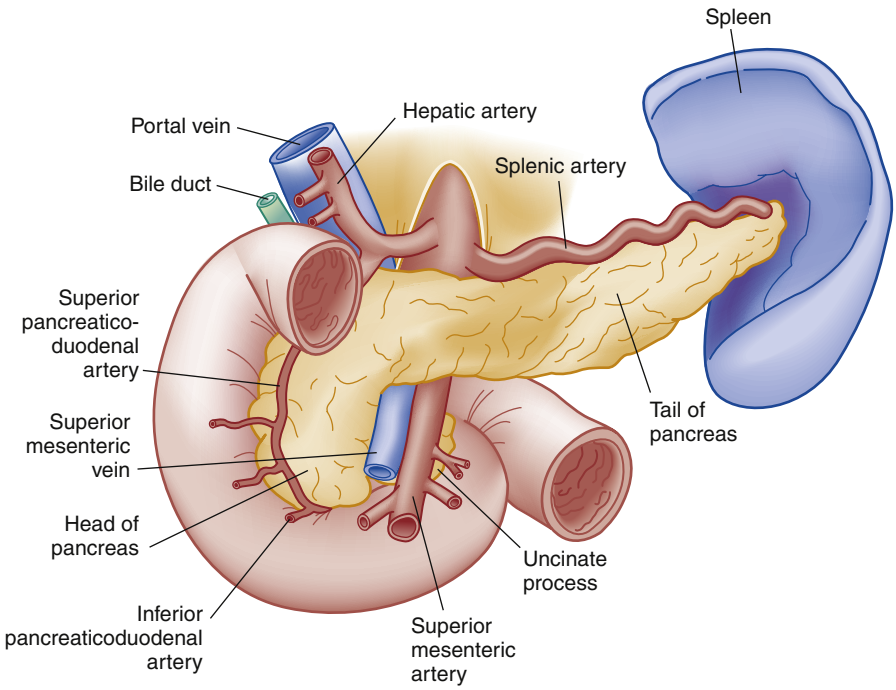

Fig. 77.1 Diagrammatic Representation of the Pancreas, Anterior View. (Redrawn from Feldman M, Friedman LS, Sleisenger MH, eds. *Sleisenger & Fordtran's Gastrointestinal and Liver Disease: Pathophysiology, Diagnosis, Management.* 7th ed. Philadelphia: Saunders; 2002.)

hospital admissions continue to increase, the overall mortality of acute pancreatitis has decreased.[3–5]

There are numerous causes of acute pancreatitis (Box 77.1), with gallstones (40% to 70%) and chronic alcohol consumption (25% to 35%) accounting for the majority of cases.[6–8] Other common causes include hypertriglyceridemia (serum triglyceride levels > 1000 mg/dL), complications from endoscopic retrograde cholangiopancreatography (ERCP), medications, trauma, and idiopathic. It is thought that many idiopathic cases may be due to occult to microlithiasis. Smoking and diabetes are independent risk factors for the development of pancreatitis.

Acute pancreatitis can be classified by type—interstitial edematous versus necrotizing pancreatitis—and by local complications. Most patients have the interstitial edematous type, which usually resolves within the first week of illness. Approximately 5% to 10% of patients develop necrotizing pancreatitis, which can involve the pancreatic parenchyma and surrounding tissue. Necrotic tissue may remain sterile, liquefy, or become infected. Infected lesions are associated with increased morbidity. Local complications usually occur after the first week and should be suspected in patients with prolonged or recurrent symptoms, secondary elevation of pancreatic serum markers, or signs of sepsis, such as fever and leukocytosis. The local complications of acute pancreatitis are summarized in Box 77.2.

Clinical Features

Patients with acute pancreatitis typically present with persistent epigastric or left upper quadrant pain that may radiate to the back, chest, or flanks. The pain is usually moderate to severe in intensity; however, the intensity of pain does not correlate with clinical severity. Associated symptoms include nausea, vomiting, and anorexia as oral intake may exacerbate pain. The pain may be alleviated by sitting up or bending forward.

Vital signs may be normal in cases of mild or early disease. Abnormalities commonly reflect patient discomfort or an existing inflammatory process, with rises in temperature, heart rate, or respiratory rate. Blood pressure may be slightly elevated secondary to pain, although in severe or complicated cases, hypotension and signs of shock may be present. Jaundice suggests an obstructive process such as a gallstone or tumor. Respirations may be shallow due to splinting from pain, and pulmonary auscultation may reveal decreased breath sounds or basilar crackles in the setting of pulmonary complications.

The abdomen can appear normal or distended. The classic clinical findings of Cullen sign (bluish periumbilical discoloration due to hemoperitoneum) and Grey Turner sign (reddish-brown discoloration around the flanks due to retroperitoneal bleeding) are rare and neither sensitive nor specific for acute pancreatitis but, when present, may confer a poor prognosis. Auscultation of the abdomen may reveal normal, diminished, or absent bowel sounds if the patient has concomitant ileus. Palpation of the abdomen often reveals epigastric tenderness with or without guarding and with rebound tenderness being a less common finding. Right upper quadrant tenderness and the presence of Murphy sign may be seen in cases of gallstone pancreatitis.

In addition to direct injury to the pancreas, patients may have local complications involving surrounding structures (e.g., bowel necrosis, splenic or portal vein thrombosis, gastrointestinal bleeding, or gastric outlet obstruction). Most of these tend to be late findings.

Systemic complications are related to the progression of local inflammation and may result in SIRS. Although in most cases these conditions resolve within days, if persistent there may be progression to fulminant sepsis, shock, and organ failure, especially if there is underlying chronic disease. The pulmonary, cardiovascular, and renal systems are the most important when assessing for organ failure. Increased microvascular permeability is the primary cause of pulmonary sequelae, although enzymatic degradation of surfactant may also play a role. Patients may develop ARDS, atelectasis, or pleural effusion, manifested as hypoxemia or respiratory distress. Pleural effusions are present in up to 50% of patients and tend to develop more frequently on the left side. Cardiovascular collapse, as evidenced by decreased mean arterial pressure or the need for inotropic support, may develop as shock results from fluid shifts and volume loss. Renal failure, demonstrated by an elevated creatinine level, may arise from a combination of hypoperfusion and the effects of inflammatory mediators.

In addition, coagulopathy occurs from cytokine-mediated activation of the coagulation cascade, potentially leading to thrombocytopenia or

BOX 77.1 Causes of Acute Pancreatitis

disseminated intravascular coagulation. Metabolic abnormalities are also common. Hyperglycemia results from decreased insulin production and hypocalcemia from low albumin and magnesium levels.

Differential Diagnoses

A number of disease processes have the ability to mimic the presentation of acute pancreatitis and should be considered in the differential diagnosis (Box 77.3). Inflammation of nearby intra-abdominal organs, such as the gallbladder, stomach, and duodenum, is often characterized by a similar pattern of epigastric or upper quadrant abdominal pain. Myocardial infarction, pneumonia, and aortic pathology may also present as lower thoracic or upper abdominal pain, with radiation to the back.

Diagnostic Testing

Acute pancreatitis is generally diagnosed by the presence of at least two of the following three criteria: (1) abdominal pain characteristic of acute pancreatitis, (2) serum lipase or amylase levels greater than three times the upper limit of normal, and (3) characteristic findings seen on abdominal imaging.

Laboratory Tests. Laboratory diagnosis of pancreatitis is made primarily by serum lipase and amylase levels. Lipase is an enzyme produced predominantly by the pancreas to aid in the breakdown of dietary triglycerides into free fatty acids. Amylase is an enzyme

BOX 77.2 Local Complications of Acute Pancreatitis

Interstitial Edematous Pancreatitis
- Acute peripancreatic fluid collection—homogeneous fluid collection adjacent to pancreas; seen within 4 weeks of symptom onset
- Pancreatic pseudocyst—homogeneous fluid collection with well-defined wall; seen >4 weeks from symptom onset

Necrotizing Pancreatitis
- Acute necrotic collection—heterogeneous collection of fluid and necrosis; intrapancreatic and/or extrapancreatic
- Walled-off necrosis—heterogeneous collection of fluid and necrosis with well-defined wall; intrapancreatic and/or extrapancreatic; seen >4 weeks from symptom onset

Adapted from Banks PA, Bollen TL, Dervenis C, et al. Classification of acute pancreatitis—2012: revision of the Atlanta classification and definitions by international consensus. *Gut.* 2013;62:102–111.

Diabetic ketoacidosis

produced by the pancreas and salivary glands, as well as multiple other organs to a smaller extent, to aid in the digestion of carbohydrates. Elevated lipase levels are both more specific and more sensitive than amylase levels in the diagnosis of acute pancreatitis. Although both enzymes begin to rise in the first few hours following symptom onset, amylase remains elevated for approximately 3 to 5 days compared with lipase which peaks more quickly and remains elevated for approximately 1 to 2 weeks.

Serum amylase levels may be high in a number of conditions, including macroamylasemia (a condition where amylase forms large molecular complexes with immunoglobulins resulting in decreased renal excretion), renal failure, salivary gland disease, liver disease, appendicitis, cholecystitis, intestinal obstruction, intestinal ischemia, peptic ulcer disease, and gynecologic diseases.[7] Elevated serum lipase

levels may also be seen in extrapancreatic conditions such as renal failure, appendicitis, and cholecystitis; however, it is generally recognized that elevated lipase levels have greater sensitivity and specificity for pancreatitis when compared with amylase levels. Amylase levels may be falsely negative in cases of alcohol and hypertriglyceridemia-induced acute pancreatitis, particularly early in the disease course. We recommend use of the lipase level in the diagnosis of acute pancreatitis. Testing for both enzymes does not improve diagnostic sensitivity or specificity. For both enzymes, three times the upper limit of normal is the most commonly used cutoff value because studies have demonstrated high sensitivity at this level. The degree of lipase or amylase level elevation does not correlate with disease severity or prognosis.

Alanine transaminase (ALT), aspartate transaminase (AST), and bilirubin levels should be drawn to evaluate for gallstones or another obstructive process as a cause of pancreatitis. ALT has been shown to be particularly specific for biliary pancreatitis, with a positive predictive value of 95%. Calcium and serum triglyceride levels, particularly in the setting of an absence of gallstones or significant history of alcohol use, may also be useful in determining an etiology (triglyceride levels >1000 mg/dL). A complete blood count (CBC) and basic metabolic panel (BMP) should be drawn to evaluate for SIRS and signs of organ failure.

Radiologic Tests. Abdominal imaging by computed tomography (CT) or magnetic resonance imaging (MRI) is not routinely recommended in the diagnosis of acute pancreatitis. CT is recommended only in the following three circumstances: (1) in cases of diagnostic uncertainty (e.g., atypical abdominal pain) or normal pancreatic enzyme levels in the setting of high clinical suspicion; (2) to rule out other suspected intra-abdominal pathology (e.g., bowel obstruction or aortic aneurysm); and (3) to assess for complications in patients who fail to respond to appropriate therapy after at least 48 to 72 hours.[3,7] The evaluation of complications of pancreatitis by CT is of most utility when done at least 3 to 7 days after presentation because CT findings of pancreatic necrosis are often not identified early on and abscesses and pseudocysts do not generally develop until several weeks after symptom onset. Studies show that patients undergoing early CT have increased costs and exposure to radiation with no additional diagnostic benefit or change in medical management.[9–11]

If CT is performed, it should be done with intravenous (IV) contrast. The CT scan is normal in 15% to 30% of patients with mild cases of pancreatitis. Contrast-enhanced CT has a greater than 90% sensitivity and specificity in the diagnosis of acute pancreatitis.[7] Abnormal findings include pancreatic parenchymal enlargement with lack of enhancement, loss of its typical texture and borders, and surrounding retroperitoneal fat stranding (Fig. 77.2). Pancreatic necrosis is suggested by areas demonstrating no enhancement (Fig. 77.3). In cases for which contrast is contraindicated, CT without contrast may still be useful; alternatively, MRI can be performed.

The diagnostic utility and radiologic findings of pancreatitis with MRI are similar to those of CT. MRI provides superior imaging of the gallbladder and biliary tract but is more costly and often has limited availability and accessibility. Direct pancreatic ultrasonography may show an edematous swollen pancreas, but the study image is often obscured by bowel gas, and of limited diagnostic and prognostic value. Abdominal ultrasound (US) has limited value in the direct diagnosis of pancreatitis but is noninvasive and sensitive for imaging the gallbladder and biliary tract and should therefore be obtained to evaluate for a biliary or obstructive etiology. Abdominal ultrasound may also help to determine the need for further advanced imaging of the biliary tract with magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound (EUS) as well as potential surgical or procedural management such as cholecystectomy or ERCP.[12] Abdominal

radiographs show primarily nonspecific findings and do not contribute to the diagnosis of pancreatitis. Chest radiography should be performed in the setting of an abnormal pulmonary exam or when pulmonary complications are suspected.

Predicting Disease Severity. Predicting the disease course in acute pancreatitis is challenging but important given the range in severity from mild cases to the critically ill. A number of classification schemes and severity scoring systems have been developed and these vary in their utility for use in emergency department (ED) management. The 2012 revision of the Atlanta Classification provides a framework to classify acute pancreatitis based on clinical and radiologic criteria

BOX 77.4 Revised 2012 Atlanta Classification of Acute Pancreatitis

Mild
No organ failure
No local or systemic complications

Moderately Severe
Transient organ failure (<48 h)
Local or systemic complications

Severe
Persistent organ failure (>48 h)
Local complications—acute peripancreatic fluid collection, pancreatic pseudocyst, acute necrotic collection, walled-off necrosis
Systemic complications—exacerbation of a preexisting comorbidity
Organ failure—defined as a modified Marshall score of 2 or more for the respiratory, cardiovascular, or renal system.

Data from Banks PA, Bollen TL, Dervenis C, et al: Classification of acute pancreatitis—2012: revision of the Atlanta classification and definitions by international consensus. *Gut*. 2013;62:102–111.

(Box 77.4). This classification delineates three degrees of severity: mild acute pancreatitis, moderately severe acute pancreatitis, and severe acute pancreatitis. Under this system, patients cannot be diagnosed with severe pancreatitis until 48 hours following presentation which limits its use in the ED. The oldest and most well-known scoring system to assess the severity of pancreatitis is the Ranson criteria, which uses a combination of clinical features, vital signs, and serum markers at both presentation and 48 hours after admission to predict mortality. Another well-known score is the Acute Physiology and Chronic Health Evaluation II (APACHE II) system, which consists of 15 variables designed for use in the intensive care unit (ICU) to predict mortality. The modified CT severity index (CTSI) is a classification system based on CT imaging. The CTSI allots points for pancreatic enlargement, inflammation, necrosis, fluid collections, and extrapancreatic complications. A Ranson score ≥3, APACHE II score ≥8, and an MCTSI ≥4 are considered high risk for severe disease.

The practicality and usefulness of these tools in ED management are limited by their complexity and reliance on post-admission data. The Bedside Index of Severity in Acute Pancreatitis (BISAP) is a more recently developed scoring system that may improve on this given its simplicity and ability to be calculated during a patient's ED evaluation. The BISAP score evaluates five factors: ***b***lood urea nitrogen (BUN) level, ***i***mpaired mental status, ***S***IRS, ***a***ge, and ***p***leural effusions. These scoring systems (summarized in Table 77.1) show similar predictive accuracy for evaluating the severity of acute pancreatitis.[13–17] The Harmless Acute Pancreatitis Score (HAPS) aims to identify mild cases of acute pancreatitis using just three factors: presence or absence of peritonitis (rebound tenderness or guarding), creatinine, and hematocrit. HAPS has been shown to be 97% specific for mild disease, although it is not sensitive.

Several isolated serum markers have also been proposed as indicators of severity. Procalcitonin has been shown to be a predictor of severe acute pancreatitis, as well as C-reactive protein (CRP); however, CRP is more useful 24 to 48 hours after admission.[18,19] An elevated BUN is linked to poorer outcomes, and hemoconcentration represented by an elevated hematocrit is associated with necrosis; these are included in BISAP and HAPS, respectively.[20]

Management

The treatment of acute pancreatitis is mainly supportive. Fluid resuscitation is important because patients with pancreatitis are often volume depleted from decreased oral intake, emesis, and increased vascular permeability with third-spacing of fluid due to the release of inflammatory mediators. There is some debate regarding how rapidly fluid resuscitation should be undertaken. Inadequate fluid resuscitation in the first 24 hours is associated with increased need for invasive interventions and incidence of SIRS, organ failure, pancreatic necrosis, and ICU admission. There is also some concern that overly rapid fluid resuscitation may result in increased need for mechanical ventilation, abdominal compartment syndrome, and earlier and more frequent development of sepsis.[21]

Although there is a consensus that fluid resuscitation is important, particularly in the first 24 hours of the disease process, recommendations regarding the volume and rate of administration vary.[3,7,22–24] The International Association of Pancreatology (IAP) in collaboration with the American Pancreatic Association (APA) recommends goal-directed fluid resuscitation of 5 to 10 mL/kg/h based on clinical targets of heart rate less than 120/min, mean arterial pressure 65 to 85 mm Hg, and urine output greater than 0.5 to 1 mL/kg/h.[3] The American College of Gastroenterology (ACG) recommends 250 to 500 mL/h.[7] More rapid fluid administration may be necessary in cases of severe volume depletion with significant tachycardia and hypotension. Response to fluid administration and the need for additional therapy should be closely monitored. Hematocrit, BUN, and creatinine can be used as surrogate markers for these goals.[3,7,21,24] Lactated Ringers (LR) solution is thought to have some benefit over normal saline (NS) as the preferred isotonic crystalloid solution for fluid resuscitation in acute pancreatitis and is generally recommended but the evidence for this is not strong.[21,25] Large volumes of NS can result in a hyperchloremic metabolic acidosis. Acidosis can worsen the systemic inflammatory response and activate trypsinogen, thereby making pancreatic acinar cells more prone to injury and exacerbating the disease process. LR may also provide antiinflammatory benefits in patients with acute pancreatitis.[26] Colloids have not been shown to improve outcomes when compared with crystalloids and are not generally recommended; however, colloid administration may be beneficial in cases with a hematocrit of less than 24 or albumin less than 2 g/dL. We recommend moderate fluid resuscitation based on hemodynamic assessment with

TABLE 77.1 Summary of Severity Scoring Systems

Ranson Criteria	APACHE II Variables	Modified CTSI	BISAP
At admission	Age	**Pancreatic inflammation**	BUN > 25 mg/dL
Age > 55 years	Temperature	0: normal pancreas	Impaired mental status
WBC > 16,000/mm^3	Mean Arterial Pressure	2: intrinsic pancreatic abnormalities ± inflammatory changes in peripancreatic fat	• disorientation, lethargy, somnolence, coma
Glucose > 200 mg/dL	Heart Rate	4: pancreatic or peripancreatic fluid collection or peripancreatic fat necrosis	≥ SIRS criteria
AST > 250 IU/L	Respiratory Rate	**Pancreatic necrosis**	Age > 60 years
LDH > 350 IU/L	PaO_2	0: none	Pleural effusion present
At admission (if biliary cause)	pH or HCO_3	2: 30% or less	
Age > 70 years	Serum sodium	4: more than 30%	
WBC > 18,000/mm^3	Serum potassium	**Extrapancreatic complications**	
Glucose > 220 mg/dL	Serum creatinine	2: one or more of pleural effusion, ascites, vascular complications, parenchymal complications and/or gastrointestinal involvement	
AST > 250 IU/L	Hematocrit		
LDH > 400 IU/L	WBC count		
At 48 h	Glasgow Coma Scale		
Hematocrit drop > 10%	Chronic health problems:		
BUN rise > 5 mg/dL	• Cirrhosis of the liver confirmed by biopsy		
Calcium < 8 mg/dL	• New York Heart Association Class IV		
PaO_2 < 60 mm Hg	• Severe COPD		
Base deficit > 4 mEq/L	• Hypercapnia, home O_2 use, or pulmonary hypertension		
Fluid needs > 6 L	• On regular dialysis		
At 48 h (if biliary cause)	• Immunocompromised		
Hematocrit drop > 10%			
BUN rise > 2 mg/dL			
Calcium < 8 mg/dL			
Base deficit > 5 mEq/L			
Fluid needs > 4 L			

APACHE, Acute Physiology and Chronic Health Evaluation; *AST,* aspartate transaminase; *BISAP,* Bedside Index of Severity in Acute Pancreatitis; *BUN,* blood urea nitrogen; *CTSI,* computed tomography severity index; *COPD,* chronic obstructive pulmonary disease; *LDH,* lactate dehydrogenase; *PaO2,* partial pressure of oxygen; *SIRS,* systemic inflammatory response syndrome; *WBC,* white blood cell.

LR at a rate of 5 to 10 mL/kg/h over the first 2 hours followed by 1.5 to 3 mL/kg/h for 12 to 24 hours with an overall goal of 2 to 4 L over the first 24 hours. If necessary, vasopressors (we recommend norepinephrine) should be initiated to maintain a map of 65 mm Hg.

As fluid status is being corrected, electrolyte levels may also need to be addressed. Hypocalcemia is frequently due to hypoalbuminemia, so calcium replacement is not necessary unless the ionized calcium level is low, in cases of QT prolongation or cardiac dysrhythmias, or when neuromuscular effects of hypocalcemia, such as Chvostek or Trousseau sign, are present. When concurrent hypomagnesemia is present, magnesium repletion should be done prior to correction of hypocalcemia. Hyperglycemia results from impaired insulin release, increased gluconeogenesis, and alterations in glucose uptake. Some patients will require exogenous insulin because untreated hyperglycemia may contribute to worsening pancreatitis and immune function.

Pain control is another important aspect of management. No specific analgesia strategy is found to be superior.[27] We recommend acetaminophen 1 g every 6 hours (650 mg PO every 8 hours in patients with liver disease or severe alcoholism) for initial pain control. Opioids should generally be avoided because they can promote ileus but may be required in some cases due to the severity of pain associated with pancreatitis. No particular opioid has been found to be more beneficial. Morphine is thought to possibly cause sphincter of Oddi spasm; however, there are no clinical studies showing that the administration of morphine causes or worsens pancreatitis or cholecystitis. Low-dose ketamine (0.1 to 0.3 mg/kg IV) is an opioid sparing alternative for parenteral pain management. Nonsteroidal antiinflammatory agents should be avoided in critically ill patients due to the increased risk of acute kidney injury. Antiemetics may also be needed for symptomatic relief.

Bowel rest by nothing per os (NPO) was once a standard part of the treatment of acute pancreatitis due to concern that oral or enteral nutrition would worsen disease by stimulating pancreatic secretions leading to autodigestion. It is now recognized that withholding enteral feeding may be detrimental because it can lead to gastrointestinal mucosal atrophy and bacterial overgrowth and translocation of gut bacteria. The alternative of total parenteral nutrition (TPN) is known to have many complications. Enteral nutrition provides nutritional support, can preserve gut function, and may help to regulate the systemic inflammatory response system.[28] In mild cases of acute pancreatitis, early oral feeding has found to be safe and may decrease length of hospitalization.[29]

Prophylactic antibiotics are not indicated in the treatment of acute pancreatitis because they have not been found to reduce the incidence of infected pancreatic necrosis.[3,7,30] Even in severe cases of pancreatitis, antibiotic prophylaxis has not been shown to improve mortality or the need for surgical intervention. Their use should be limited to toxic-appearing patients, those with infected necrotizing pancreatitis, and extrapancreatic infections such as cholangitis, pneumonia, and bacteremia. SIRS features such as tachycardia and tachypnea are common in acute pancreatitis but are nonspecific and do not necessarily portend sepsis or organ failure. Severe acute pancreatitis may be difficult to differentiate from sepsis during the ED presentation, and therefore antibiotics should be initiated if there is suspicion of an infectious source or sepsis. In cases of known infected pancreatic necrosis, the chosen antibiotic regimen should penetrate pancreatic tissue and cover gram-negative and gram-positive bacteria as well as anaerobes; carbapenems (meropenem 1 g, ertapenem 1 g, or imipenem-cilastin 500 mg) and quinolones with metronidazole (ciprofloxacin 400 mg with metronidazole 500 mg) are appropriate choices.[7]

ERCP in patients with gallstone pancreatitis without evidence of ongoing obstruction is not recommended because most gallstones will spontaneously pass into the duodenum. Early ERCP is indicated for patients with cholangitis or bile duct obstruction and is recommended within 24 to 48 hours of admission. Unstable patients who are unable to safely undergo ERCP may require biliary decompression with the placement of a percutaneous transhepatic gallbladder drainage tube. Suspicion of choledocholithiasis based on a dilated biliary tree on CT does not itself warrant ERCP. In the absence of cholangitis or clear evidence of biliary obstruction (e.g., jaundice, hyperbilirubinemia, and signs of sepsis), MRCP or EUS is preferred over ERCP because ERCP is a more invasive study and can itself trigger pancreatitis. No benefit of ERCP has been shown in patients with nonobstructive causes of pancreatitis regardless of severity.

Surgical intervention is rarely indicated at the time of presentation. It is recommended that patients with mild biliary pancreatitis undergo cholecystectomy during the index admission but not emergently. In cases of severe acute pancreatitis, surgical intervention is determined on a case-by-case basis, but cholecystectomy is generally delayed. Asymptomatic pancreatic necrosis and pseudocysts do not need treatment. Infected or symptomatic necrotizing pancreatitis often requires surgical, endoscopic, or radiologic intervention, but this is recommended after 3 to 4 weeks to allow better demarcation of the viable pancreatic tissue and area of necrosis.

Disposition

Discharge may be considered in well-appearing patients with mild presentations, adequately controlled symptoms, tolerance of oral intake, and no signs of complications. However, given the unpredictable course of pancreatitis and potential of decompensation and severity, inpatient management is typically warranted. Patients with severe symptoms, persistent pain, intolerance of oral intake, and gallstone disease and those who are older with comorbidities will likely require admission. ICU admission should be considered for patients with moderately severe and severe acute pancreatitis, persistent vital sign abnormalities, significant electrolyte abnormalities, older age and those deemed at high risk for deterioration. Patients who may require endoscopic, surgical, or interventional radiology procedures should be managed in or referred to a specialist center, defined as a high-volume center with daily access to these services.

Chronic Pancreatitis

Foundations

Chronic pancreatitis is a progressive fibroinflammatory syndrome of the exocrine pancreas. It is thought that pancreatitis is a continuum which is initiated with the inflammation of acute pancreatitis and progresses to chronic pancreatitis by repeated pancreatic injury due to recurrent episodes of acute pancreatitis. Recurrent inflammation of the pancreas leads to atrophy and fibrosis resulting in the destruction of acinar cells and the islets of Langerhans and thereby impairing both pancreatic exocrine and endocrine function. Approximately 36% of those with recurrent acute pancreatitis will go on to develop chronic pancreatitis.[31] Although both sexes have an equal risk of developing acute pancreatitis, men are twice as likely to progress to chronic pancreatitis compared with women.[31,32] Blacks are twice as likely to be diagnosed with chronic pancreatitis compared with White patients, in large part due to the prevalence of alcohol and tobacco use which are both significant risk factors.[31,33] Those with chronic pancreatitis are at higher risk of developing pancreatic cancer. Chronic pancreatitis can be classified as toxic-metabolic, idiopathic, genetic, autoimmune, related to recurrent and severe acute pancreatitis, and obstructive (Box 77.5).

BOX 77.5 TIGAR-O Causes of Chronic Pancreatitis

Toxic-Metabolic
Alcohol
Tobacco
Hypercalcemia
Hypertriglyceridemia
Chronic kidney disease
Medications

Idiopathic
Tropical chronic pancreatitis
Early onset
Late onset

Genetic
Autosomal dominant: hereditary pancreatitis
PRSS1 mutations

Autosomal Recessive/Modifier Genes
CFTR mutations
SPINK1 mutations
CTRC mutations
Other

Autoimmune
Type 1 (IgG4 related) and type 2

Recurrent and Severe Acute Pancreatitis
Postnecrotic (after severe necrotizing pancreatitis)
Vascular disease/ischemia

Obstructive
Pancreas divisum
Sphincter of Oddi disorders
Malignant pancreatic duct obstruction
Posttraumatic pancreatic duct scars and strictures

CFTR, Cystic fibrosis transmembrane conductance regulator; *CTRC,* chymotrypsin C; *IgG,* immunoglobulin G; *PRSS1,* cationic trypsinogen; *SPINK1,* serine protease inhibitor Kazal type 1.

Clinical Features

Patients with chronic pancreatitis often present similarly to those with acute pancreatitis: severe postprandial epigastric pain associated with nausea and vomiting that may radiate to the back and be helped by sitting forward. Exocrine pancreatic insufficiency may result in weight loss, steatorrhea, and signs of malnutrition and malabsorption. Endocrine pancreatic insufficiency may present in the form of diabetes and these patients are also at higher risk for hypoglycemia due to loss of counterregulatory glucagon and pancreatic polypeptide. Patients with alcoholic cirrhosis or biliary obstruction may be jaundiced. The abdomen is usually tender, and a palpable mass representing a pancreatic pseudocyst or tumor may be appreciated. Common complications of chronic pancreatitis include pseudocysts, pancreatic ascites, ductal strictures, duodenal stenosis, pleural effusions, pseudoaneurysms (splenic, hepatic, gastroduodenal, pancreaticoduodenal arteries), and portal and splenic vein thromboses.

Differential Diagnoses

The list of alternative diagnoses is similar to that for acute pancreatitis (see Box 77.3); however, chronic abdominal processes, such as peptic

ulcer disease, gastritis, biliary colic, pancreatic cancer, inflammatory bowel disease, and irritable bowel syndrome, should also be considered as alternative diagnoses for patients with recurrent episodes of upper abdominal pain. In addition, patients with chronic pancreatitis who are opioid dependent may have withdrawal symptoms that mimic an exacerbation of pancreatitis.

Diagnostic Testing

Clinical diagnosis of chronic pancreatitis may be challenging, particularly in its early stages. For acute exacerbations of chronic pancreatitis, the same diagnostic principles apply as for acute pancreatitis—clinical features, laboratory analysis, and imaging. However, laboratory tests are less helpful in chronic pancreatitis because serum lipase and amylase levels do not rise to the same degree and may be normal. Liver function test results (transaminase, alkaline phosphatase, bilirubin levels) may be elevated in patients with concurrent alcoholic liver disease or biliary duct obstruction. Hypocalcemia and hypoalbuminemia are common, and impaired pancreatic endocrine function may be reflected by hyperglycemia.

CT is the imaging modality of choice, and as with acute pancreatitis, it may be of limited utility in early or mild disease and is more helpful in evaluating later findings and complications. Intraductal pancreatic calcifications are the most specific finding on both CT and US. Other CT findings of chronic pancreatitis include pancreatic enlargement, dilated pancreatic ducts, pancreatic calcifications, atrophy, biliary duct dilatation, fluid collections, and changes in panpancreatic fat.[34] MRCP is superior at evaluating pancreatic duct abnormalities, and its ability to detect signal intensity changes in the pancreas may be useful in evaluating chronic pancreatitis at its early stages. Pancreatic stimulation with IV secretin may improve the diagnostic accuracy of MRCP.[35] CT, MRCP, EUS, and US have high diagnostic sensitivity for chronic pancreatitis and comparable diagnostic specificity.[36] US findings include pancreatic enlargement, calcification, and decreased echogenicity. EUS and ERCP have the highest diagnostic accuracy but are invasive tests, and ERCP is generally not recommended because it carries a 4% risk of precipitating pancreatitis. Although an abdominal radiograph is not necessary, up to 30% of patients have a characteristic finding of pancreatic calcification, which is pathognomonic for the disease. Abdominal imaging findings have not found to be predictive of pain pattern and severity.[33]

Management

The treatment of chronic pancreatitis is supportive and largely focused on pain management, correction of fluid and electrolyte imbalance, and lifestyle modification with the cessation of alcohol and tobacco use. Nonopioid pain medications such as acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are preferred as initial agents, although NSAIDs should be used judiciously due to their adverse effects on the gastrointestinal system and the predisposition of patients with chronic pancreatitis to peptic ulcer disease.[37,38] Given the severity of pain in chronic pancreatitis, it will likely be necessary to escalate to tramadol or more potent opioid analgesics; however, opioids should also be used with caution given the risk of misuse and dependence as well as adverse gastrointestinal effects such as opioid induced bowel dysfunction.[37,38] Adjunctive agents in the treatment of chronic pain such as tricyclic antidepressants, serotonin-reuptake inhibitors, and gabapentoids may also play a role in pain management.[38,39] In patients who fail traditional medical management, other pain control options with varying supportive evidence include oral enzyme replacement, octreotide, antioxidants, and celiac plexus block. Referral to a pain management specialist may be beneficial given the challenge of pain control, its chronicity, and risk of addiction.

Beyond ED care, endoscopy may be indicated for intraductal stone removal, stenting of ductal structures, and the drainage of symptomatic pseudocysts.[37,40] Surgical management is considered for duodenal or biliary obstruction, pancreatic drainage procedures, and in cases where cancer is suspected. Surgery is generally reserved for patients who have failed medical and endoscopic therapy, but some studies indicate that early surgery may be of benefit in the treatment of pain and improvement of pancreatic insufficiency.[40–43]

Disposition

Patients with chronic pancreatitis typically present to the ED with acute exacerbations of pain or complications of their disease. The prognostic indices used for acute pancreatitis can be applied to these patients. Most patients will require admission; chronic pancreatitis is emerging as the leading contributor of hospitalizations due to acute pancreatitis.[5]

PANCREATIC CANCER

Foundations

Pancreatic cancer is an aggressive and lethal disease which is the seventh most common cause of death from cancer globally.[44] Its incidence is greater in developed countries, and most patients are diagnosed older than 50 years of age, with peak incidence in the seventh and eight decades of life. Blacks have both a higher incidence and mortality when compared with Whites.[45–47] The median survival of patients with locally advanced disease is 6 to 9 months and only 3 months for those with metastatic progression. Pancreatic cancer carries an overall 5-year survival rate of just 7% owing to its often advanced stage at diagnosis, rapid progression of disease, and resistance to treatment options.[47] Risk factors for disease include tobacco use, alcohol abuse, obesity, type 2 diabetes mellitus, chronic pancreatitis, and a family history of pancreatic cancer.[48] The majority of pancreatic neoplasms are adenocarcinomas followed by neuroendocrine tumors such as gastrinomas (Zollinger-Ellison syndrome), insulinomas, and glucagonomas.

Clinical Features

Pancreatic cancer typically presents with epigastric pain often radiating to the back, unexplained weight loss, anorexia, nausea, and generalized weakness. Obstructing tumors may lead to cholestasis, jaundice, pancreatitis, and gastric outlet obstruction. Newly diagnosed diabetes is also a common presenting sign. Neuroendocrine tumors present with symptoms indicative of the hormone secreted by the tumor. For example, insulinomas are associated with hypoglycemia, glucagonomas with glucose intolerance, weight loss, and dermatitis, and gastrinomas with peptic ulcers, gastroesophageal reflux disease, and diarrhea. Most patients at the time of diagnosis have locally advanced disease, vascular involvement, and metastatic spread most commonly to the liver, peritoneum, and lungs.

Diagnostic Testing

Abdominal CT with IV contrast is the imaging modality of choice for diagnosis and guiding initial management. On CT, pancreatic carcinoma appears as an area of hypoattenuation. CT may also show secondary signs such as pancreatic duct cutoff, dilation of the pancreatic or common bile duct, atrophy, or border irregularities. Smaller tumors (<10 mm) are better detected on EUS than CT, and EUS guided fine-needle aspiration is often necessary to make a tissue diagnosis.[49]

Management

Treatment in the ED generally involves pain control and management of complications such as gastrointestinal bleeding, bowel obstruction, acute cholangitis, and venous thrombosis. In situations where the diagnosis of pancreatic cancer is made in the ED, the disease process may

be advanced, and patients may benefit from the emergency clinician expediting their evaluation and facilitating multidisciplinary involvement in the patient's case.

Surgical resection can be curative but is only possible in a very small subset of patients with no direct tumor extension. Ampullary masses, which make up a small percentage of cases, are associated with a better prognosis (up to 50% may be successfully resected) because they tend to cause biliary obstruction, leading to earlier presentation and diagnosis. The surgical management of pancreatic head tumors is usually a partial pancreaticoduodenectomy (also known as the Whipple procedure) with or without partial resection of the distal stomach. Tumors of the pancreatic tail generally require a distal pancreatectomy with splenectomy. Less than 20% of patients are diagnosed with resectable disease, and 80% of those who undergo surgical treatment and will relapse and ultimately die.[48] In patients with locally and systemically advanced disease, treatment is generally focused on slowing tumor progression and palliative care. Chemotherapy and radiation may prolong survival to a small extent. Identifying patients earlier in their disease course through risk determination and screening efforts may increase surgical treatment options and improve survival.[50,51]

CHAPTER 77: QUESTIONS AND ANSWERS

1. Which of the following statements regarding acute pancreatitis is true?
- **a.** Esophageal ultrasound is the diagnostic imaging of modality of choice for the diagnosis of acute pancreatitis.
- **b.** Hypertriglyceridemia is the likely etiology of acute pancreatitis in those with serum triglyceride levels greater than 1000 mg/dL.
- **c.** The most common cause of acute pancreatitis is alcohol abuse.
- **d.** Acute pancreatitis is the most lethal pancreatic disease globally.
- **e.** Pancreatic pseudocysts form within the first week of symptom onset.

Answer: b. Serum triglyceride levels greater than 1000 mg/dL with no other clear causes of acute pancreatitis points to hypertriglyceridemia as the etiology. Imaging is not routinely recommended in the diagnosis of acute pancreatitis. CT is the diagnostic modality of choice; endoscopic ultrasound (EUS) is invasive and not recommended as a first line imaging test. Although acute pancreatitis is the most common pancreatic disease globally, pancreatic cancer carries the highest mortality. Pancreatic pseudocysts generally form after 4 weeks from symptom onset.

2. Which of the following statements about serum lipase and amylase levels is true?
- **a.** Lipase is an enzyme which aids in the digestion of carbohydrates.
- **b.** In acute pancreatitis, amylase levels rise in 1 or 2 hours and normalize in 2 days.
- **c.** Higher lipase and amylase levels are correlated with more severe disease.
- **d.** Amylase is a less specific test than the serum lipase level for the diagnosis of pancreatitis.
- **e.** Testing for both lipase and amylase enzymes improves the diagnostic sensitivity and specificity for acute pancreatitis.

Answer: d. Lipase is more specific than amylase in the diagnosis of acute pancreatitis as amylase is produced by multiple organs other than the pancreas and lipase is produced predominantly by the pancreas. Lipase aids in the breakdown of dietary triglycerides into free fatty acids while amylase aids in the breakdown of carbohydrates. Levels rise within 6 to 24 hours and normalize in 3 to 7 days. Higher enzyme levels have not been found to correlate with disease severity. Testing for both enzymes has not been found to improve diagnostic sensitivity and specificity in the diagnosis of acute pancreatitis.

3. Which of the following statements regarding the use of radiographic studies for the evaluation of pancreatitis is true?
- **a.** Computed tomography (CT) is indicated in the evaluation of all cases of pancreatitis.
- **b.** Oral administration of a contrast agent for abdominal CT may aggravate pancreatitis.
- **c.** The initial study of choice in suspected gallstone pancreatitis is ultrasonography.
- **d.** CT and magnetic resonance imaging (MRI) of the abdomen are equally accurate for visualizing the biliary tract.
- **e.** Ultrasonography may help to differentiate pancreatitis from pancreatic pseudocyst.

Answer: c. Ultrasonography has a sensitivity of 94% for gallstones further imaging may be necessary to rule out biliary tract pathology. CT is not routinely recommended in the diagnosis of acute pancreatitis but is recommended in cases of diagnostic uncertainty, to rule out other diagnoses, and to assess for complications in patients who worsen or fail to improve. Oral contrast material does not aggravate pancreatitis. A non–contrast-enhanced helical scan may also be helpful if an oral contrast agent cannot be tolerated. MRI is superior to CT in visualizing the biliary tract although often more costly and less accessible. Ultrasonography is generally not helpful in assessing for pseudocysts.

4. A 28-year-old woman presents with recurrent pancreatitis. She is otherwise healthy and takes no medications. This episode of pain was preceded by several similar episodes of intermittent epigastric pain that lasted several hours at a time. A previous ultrasound examination of the liver, gallbladder, and pancreas was normal. She does not smoke, drink, or use over-the-counter medications. The physical examination is remarkable for moderate epigastric tenderness without rebound. Vital signs are normal. Laboratory evaluation reveals an elevated lipase level and moderate leukocytosis. Urinalysis and urine pregnancy test results are normal. What would be the most appropriate intervention?
- **a.** After stabilization, referral to a gastroenterologist for endoscopic retrograde cholangiopancreatography (ERCP)
- **b.** After stabilization, referral to a gastroenterologist for upper endoscopy
- **c.** CT scan of the abdomen to rule out pancreatic pseudocyst
- **d.** Repeated ultrasound examination of the liver, gallbladder, and pancreas
- **e.** Symptomatic treatment only unless her clinical picture worsens

Answer: a. Many cases of presumed idiopathic pancreatitis may be due to small stones or sludge that cannot be seen by ultrasound examination but may be seen by ERCP. Pancreatic pseudocyst is more likely in alcoholic pancreatitis and typically occurs gradually, several months after a severe episode.

CHAPTER 77: QUESTIONS AND ANSWERS—cont'd

5. A 68-year-old male presents with several months of epigastric pain, decreased appetite, weight loss, and weakness. Which of the following statements is true?

a. CT scan will rule out the diagnosis of pancreatic cancer.
b. His pancreatic adenocarcinoma is most likely to be confined to the pancreas.
c. Following the diagnosis of pancreatic adenocarcinoma, chemoradiation will be curative.
d. Chronic pancreatitis is a risk factor for developing pancreatic cancer.
e. Those residing in developing countries are at higher risk for pancreatic cancer.

Answer: d. Those with chronic pancreatitis are at higher risk of developing pancreatic cancer. Abdominal CT is the initial imaging modality of choice for the diagnosis of pancreatic cancer; however, smaller tumors (<10 mm) are better detected on EUS. Less than 20% of patients are diagnosed with localized and resectable disease. Chemoradiation is generally focused on slowing tumor progression and palliative therapy but is unlikely to be curative without resection. The incidence of pancreatic cancer is higher in developed countries.

Small Intestine

Chad E. Roline and Robert F. Reardon

SMALL BOWEL OBSTRUCTION

KEY CONCEPTS

- Small bowel obstruction (SBO) is a common clinical condition accounting for 2% of patients presenting to the emergency department with abdominal pain, leading to an estimated 300,000 hospitalizations annually in the United States.
- The most common cause of SBO is adhesions from prior abdominal surgery, which are found in approximately 60% of cases. Tumors and abdominal hernias account for another 20% and 10% of cases, respectively.
- The most common presenting symptoms of SBO include colicky abdominal pain, abdominal distention, nausea, or vomiting. However, no single component of the history or physical exam can reliably predict SBO.
- Initial evaluation should focus on identifying SBO patients in need of prompt surgical evaluation including findings concerning for peritonitis, bowel strangulation, or ischemia.
- For patients presenting with SBO likely due to adhesions, most can be successfully managed conservatively with bowel rest, pain control, intravenous fluid, and electrolyte replacement.

FOUNDATIONS

Background and Importance

Small bowel obstruction (SBO) is a common problem encountered in the emergency department (ED). Advances in imaging as well as operative techniques have greatly improved the prognosis for patients and have decreased the mortality rate from nearly 60% in 1900 to less than 8% today.

Anatomy, Physiology, and Pathophysiology

There are several different types of SBO. The term *mechanical obstruction* implies the presence of a physical barrier to the movement of the intestinal contents. Obstructions of this type can be further subclassified according to the cause of the obstruction relative to the intestinal wall (Box 78.1). Lesions external to the intestinal tract cause obstruction by compressing the gut. This is most commonly the result of post-operative adhesions, though hernias and intra-peritoneal neoplasms may also cause external obstruction. Lesions intrinsic to the intestinal wall itself can also cause mechanical obstruction, such as primary intestinal neoplasms, localized infection (e.g., intestinal wall tuberculosis), or trauma (e.g., a hematoma of the intestinal wall). Finally, lesions within the intestinal lumen can lead to obstruction, such as bezoars, ingested foreign bodies, or gallstone ileus.

Another important distinction of SBO is whether the obstruction is a *simple* or *closed loop* obstruction. A simple obstruction occurs at a single point. A closed loop–type obstruction involves obstruction at two locations, thus creating a segment of bowel with compromised blood flow proximally and distally. Closed loop obstructions are seen when a twist develops in the mesentery or, in the case of an internal hernia, when a loop of bowel becomes entrapped in a defect in the mesentery (Fig. 78.1). If not promptly recognized and relieved, a closed loop obstruction can quickly lead to intestinal infarction and necrosis, which has twice the mortality rate of simple small bowel obstruction.

In contrast to a mechanical obstruction, a *neurogenic* or *functional* obstruction occurs as a result of disruption of the normal coordinated peristaltic activity of the gastrointestinal (GI) tract in the absence of a physical blockage within the intestinal lumen, leading to dysfunction in the enteric propulsion. This is also commonly referred to as an adynamic ileus. The causes of adynamic ileus are listed in Box 78.2. It often occurs in patients who have undergone abdominal surgery and is usually transient in nature. Some degree of functional obstruction is considered normal after surgery and results from multiple factors, including an inflammatory response to intestinal manipulation, the release of several hormones and neurotransmitters triggered by surgery, and the effects of opioid analgesics. In addition to surgery, a number of medical conditions can lead to a functional SBO, including infection or metabolic abnormalities, particularly hypokalemia.

The term *pseudo-obstruction* refers to a poorly understood and complex syndrome in which the signs and symptoms of mechanical obstruction, including the appearance of dilated bowel on radiography, are present in the absence of a mechanical lesion. This is thought to involve disruption of intestinal pacemaker activity controlled by a specialized group of cells found in the GI tract called the interstitial cells of Cajal. These cells regulate the contractility of the intestinal smooth muscle and are under the influence of the enteric nervous and autonomic systems. Pathology at any one of these sites can lead to pseudo-obstruction. Causes include degenerative neuropathies, autoimmune or paraneoplastic disease including systemic lupus erythematosus, or scleroderma, as well as hereditary conditions. The symptoms of pseudo-obstruction are often chronic and respond poorly to treatment.

PATHOPHYSIOLOGY

Regardless of the etiology, with the development of an SBO the interruption of normal flow through the intestinal lumen triggers a cascade of physiologic changes that correlate with the progressive development of symptoms. In a mechanical obstruction, the bowel proximal to the blockage first becomes mildly dilated through the accumulation of partially digested food and normal intestinal secretions. These secretions are referred to as *succus entericus* and are secreted by cells lining the intestinal wall in response to mechanical stimulation. Increased intestinal dilation causes an increase in peristalsis throughout the intestines, which can trigger frequent and loose bowel movements early in the progression of the obstruction as well as episodes of nausea or vomiting.

BOX 78.1 Lesions Causing Small Bowel Obstruction Relative to the Intestinal Wall

External to Intestinal Wall
Postoperative adhesions
Hernias
Volvulus
Compressing masses (tumors, abscesses, hematomas)

Intrinsic to Intestinal Wall
Primary neoplasms
Inflammatory (e.g., Crohn disease, radiation enteritis)
Infectious causes (e.g., intestinal tuberculosis)
Intussusception
Traumatic (intestinal wall hematoma)
Intraluminal
Bezoars
Foreign bodies
Gallstones
Ascaris infestation

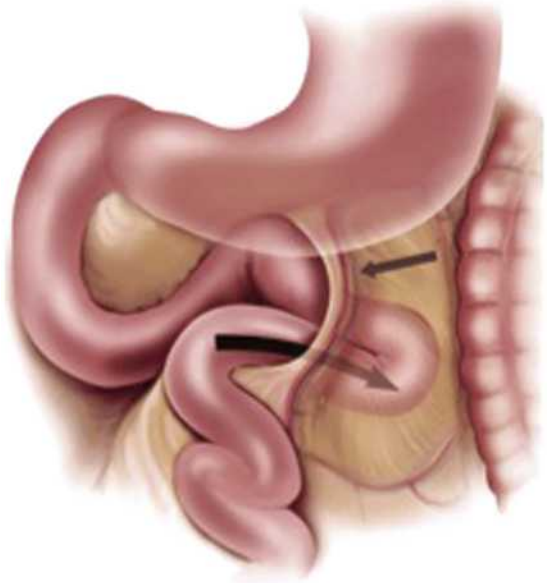

Fig. 78.1 Diagram of Internal Hernia. Note the formation of a closed loop, which creates a high risk for strangulation (*arrows*). (From Martin LC, Merkle EM, Thompson WM. Review of internal hernias: radiographic and clinical findings. *AJR Am J Roentgenol.* 2006;186:703–717. Reprinted with permission from the *American Journal of Roentgenology*.)

BOX 78.2 Causes of Adynamic Ileus

Metabolic disease (especially hypokalemia)
Medications (e.g., narcotics)
Infection (retroperitoneal, pelvic, intrathoracic)
Abdominal trauma
Laparotomy

As the process continues, the bowel wall becomes edematous and the normal absorptive function of the intestinal wall decreases, leading to further accumulation of contents in the intestinal lumen proximal to the obstruction. Owing to the loss of normal intestinal motility, bacterial overgrowth begins to occur in the proximal small bowel. It is this overgrowth in a location of the intestines that is normally relatively sterile that explains the feculent nature of the emesis observed in patients with SBO. As the obstruction continues, there is a transudative fluid loss into the peritoneal cavity, leading to worsening hypovolemia and dehydration. In addition, if the obstruction is proximal in location, continued bouts of emesis can lead to electrolyte abnormalities, metabolic alkalosis, severe hypovolemia, or shock.

Fig. 78.2 Small Bowel Adhesion. (Courtesy Edward Klatt, MD.)

In a closed loop obstruction, the escalation in intraluminal pressure occurs much more rapidly as the intestinal contents cannot flow retrograde. Intestinal venous congestion and then arterial obstruction can also progress quickly to intestinal ischemia and infarction, referred to as a *strangulation* obstruction. If not promptly relieved, necrosis and intestinal perforation can occur. The resulting leakage of the intestinal contents into the peritoneum can lead to peritonitis and sepsis.

In the developed world, the most common cause of SBO is postoperative adhesions, which account for approximately 60% of cases (Fig. 78.2). A large meta-analysis estimated the overall incidence of adhesive SBO following abdominal surgery at 2%.[1] These adhesions develop as a result of a process involving the interaction among numerous types of cells, cytokines, and coagulation factors caused by damage to the peritoneal surfaces, with a subsequent increase in fibrin formation.[2] Operations on the small intestine, colon, appendix and uterus appear to have a higher risk of adhesion formation than procedures in the upper abdomen involving the gallbladder, stomach or pancreas. Emergency surgery also appears to be a risk factor compared to elective procedures.[3] Over the last several years, numerous physical bioabsorbable barriers and pharmacologic agents have been evaluated as potentially useful in decreasing the formation of post-operative adhesions with mixed results. Although they appear to minimize the formation of postoperative adhesions, they have not been shown to improve clinical outcomes.

The second most common cause of SBO is tumors, which are responsible for roughly 20% of cases. This includes malignancies, such as adenocarcinomas, carcinoid tumors, lymphomas, or sarcomas, as well as benign conditions, including adenomas, leiomyomas, or lipomas. In addition to these primary GI tumors, gynecologic cancers, especially ovarian cancer, are a common cause of SBO. Metastatic disease is yet another tumor-related cause of SBO, including metastatic breast, skin, or testicular cancer.

Hernias are the third most common cause of SBO, found in approximately 10% of cases. Similar to their relative frequency in general, ventral and inguinal hernias are usually encountered, but femoral, parastomal, lateral ventral (also called *spigelian hernia*), and internal hernias may also lead to SBO. Although rare in the general population, internal hernias are a recognized complication of bariatric surgery,

Fig. 78.3 Gallstone Ileus of the Small Intestine at Laparotomy. (Courtesy J.C. Campbell, Plymouth, England; www.surgical-tutor.org.uk.)

especially when a Roux-en-Y type procedure has been performed. In this group, internal hernias have been described in up to 5% of patients and usually develop at the mesocolic window. Another rare type of hernia is the obturator hernia. This hernia develops into the obturator foramen and is especially common in older women who have recently lost a significant amount of weight. The female pelvis is wider and the obturator canal is more oblique in women than in men. This, in combination with a loss of preperitoneal fat in older, often emaciated patients, predisposes to the development of an obturator hernia. Because an external mass is absent, the diagnosis can be especially challenging, which explains why it carries the highest mortality of any abdominal hernia, nearly 70%, when it is incarcerated.

Gallstone ileus is a rare but important cause of mechanical SBO (Fig. 78.3). It is responsible for 1% to 4% of all cases of mechanical obstruction and is most frequently seen in older adults with underlying medical problems. The pathogenesis involves the entry of a gallstone into the intestinal tract through a biliary-enteric fistula. This arises from the localized inflammation of cholecystitis and, in most cases, entry occurs via a cholecystoduodenal fistula. After entering the intestinal lumen, the gallstone migrates distally. As a stone moves through the intestinal lumen, it often increases in size as bowel content sedimentation becomes attached. Eventually, the gallstone becomes lodged, usually in the ileum, which is the narrowest segment of the small bowel, and the patient then develops symptoms of obstruction.

Small bowel volvulus occurs infrequently but is a potentially catastrophic cause of SBO. This condition results from the abnormal twisting of a loop of small bowel around the axis of its own mesentery. Although it accounts for only 3% to 6% of SBO cases in the West, it is much more common in Africa, India, and the Middle East, where it is responsible for up to 20% of cases. Primary small bowel volvulus occurs in an otherwise normal abdominal cavity; secondary small bowel volvulus occurs when a congenital or acquired abnormality leads to the development of the volvulus.

A reported increase in primary small bowel volvulus during Ramadan has been attributed to eating a large amount of food bulk after prolonged fasting, causing the proximal jejunum to descend into the pelvis, displacing empty small bowel loops upward and initiating malrotation. Alterations in gut motility and increased small bowel length have also been suggested as possible predisposing factors.

Causes of secondary small bowel volvulus include intestinal malrotation caused by the arrest of normal rotation of the embryonic gut, or post-operative adhesions. In the case of congenital malrotation, more than 50% of affected children present for evaluation before 1 month of age with small bowel volvulus. Because a small bowel volvulus is a classic closed loop obstruction, prompt recognition and surgical treatment are imperative because the risk of strangulation is high.

The term *intussusception* describes the invagination or "telescoping" of a part of the small intestine into itself. This results in the development of venous and lymphatic congestion, with consequent intestinal edema, which can lead to intestinal ischemia and perforation. Intussusception occurs in patients of all ages but is most frequently seen in children younger than 2 years. It is the most common cause of intestinal obstruction in infants 6 to 36 months of age. Unlike ileocolic intussusception, which can often be treated nonoperatively by enema reduction, surgery is more often required in cases of intussusception limited only to the small bowel. In children, the cause is usually idiopathic, but several studies have shown an association with adenovirus infection. It has been postulated that enteric adenovirus infection may trigger stimulation of the lymphatic tissue in the intestinal tract, which may create a lead point for the intestine to be dragged into itself by the normal peristaltic activity of the intestines. In contrast to the idiopathic nature of intussusception in children, a mechanical cause is found in more than 90% of adult cases. Tumors, benign or malignant, are discovered as the initiating cause in more than 65% of adult cases. Adult intussusception has been reported in association with acquired immunodeficiency syndrome (AIDS) as a result of lymphoma or unusual infections, such as atypical mycobacterial infections.

CLINICAL FEATURES

History

Patients with SBO commonly report colicky abdominal pain, abdominal distention, nausea, vomiting, constipation, or the inability to pass flatus, but no single historical feature can reliably predict SBO.[4] The pain is often described as periumbilical in location and typically has a crescendo-decrescendo pattern. The recurrent waves of discomfort can last from seconds to minutes. In more proximal obstruction, symptoms of nausea and vomiting can be much more severe, and the onset of symptoms is often more abrupt. Distal obstructions typically cause the gradual onset of symptoms over 1 to 2 days and are frequently accompanied by increased abdominal distention. The colon requires up to 24 hours to empty after the formation of an SBO, and the associated small bowel distention stimulates peristalsis; consequently, flatus and the passage of stool may continue, even in the presence of a complete obstruction. A history of previous abdominal surgery, small bowel obstructions, GI malignancy or inflammatory bowel disease should be elicited. The use of medications (especially opioids) that may affect bowel function should be reviewed.

Physical Examination

The physical examination includes evaluation of the patient's hemodynamic status, degree of distress, and general condition. Thus, appropriate interventions, including intravenous (IV) fluids, can be initiated early. Inspection of the patient includes a careful search for abdominal distention and hernias including umbilical, inguinal and femoral locations, as well as the presence of surgical scars. Although bowel sounds in SBO are frequently described as high-pitched and tinkling in nature, studies have shown that they may often be decreased or absent. One study of physicians listening to recordings of bowel sounds demonstrated the ability to identify SBO correctly in only 42% of affected patients.

The presence of peritoneal signs usually indicates late obstruction with complications, including strangulation or bowel ischemia. However, abdominal palpation in the setting of bowel dilation can give the false impression of peritonitis, as quick compression-decompression of dilated bowel may elicit a significant pain response. For this reason, it may be

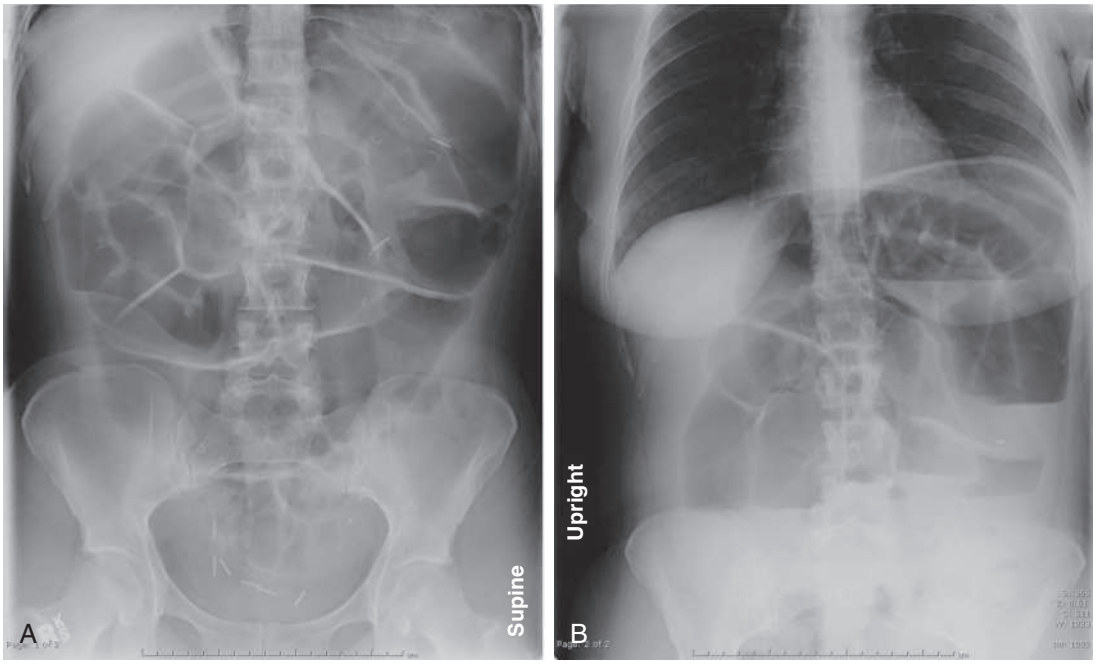

Fig. 78.4 (A) Supine plain film radiograph showing dilated loops of small bowel in a patient with small bowel obstruction. (B) Upright abdominal plain radiograph revealing multiple air-fluid levels and small bowel dilation, consistent with a diagnosis of small bowel obstruction.

helpful to determine the presence of pain with cough or gentle shaking of the patient's pelvis to more accurately investigate for true peritonitis.

DIFFERENTIAL DIAGNOSIS

The diagnosis of SBO should be considered in any patient with abdominal pain and vomiting, especially if there is a history of prior abdominal surgery. It may be difficult to differentiate SBO from nonobstructive intestinal motility disorders, such as adynamic ileus or intestinal pseudo-obstruction, by history and examination alone.

Other conditions to consider include gastroenteritis, mesenteric adenitis, constipation, cholelithiasis or nephrolithiasis, ectopic pregnancy, pancreatitis, peptic ulcer disease, atypical myocardial infarction, leaking abdominal aortic aneurysm (AAA), or mesenteric ischemia. These pathologies have typical signs, symptoms, and diagnostic findings that can help differentiate them from one another and from SBO, but this may be challenging, especially early in the course of illness.

DIAGNOSTIC TESTING

Laboratory

Although laboratory tests are of limited utility in diagnosing the presence of SBO, they can be useful in assessing the degree of dehydration and metabolic disruption resulting from the obstruction. Studies have evaluated the use of lactate and creatine phosphokinase (CPK) to identify strangulation complicating an SBO. Intestinal fatty acid-binding protein (I-FABP), which is released by necrotic enterocytes, has also been studied as a marker to identify strangulation. Unfortunately, all the biomarkers studied to date may be normal until very late in the process of intestinal strangulation. While recognizing this, an elevated lactate level should heighten clinical suspicion for strangulation.

Imaging

Traditionally, plain film radiographs have been the initial imaging test of choice in the diagnosis of SBO. Abdominal plain film radiographs should include supine and upright or decubitus views. An upright chest radiograph may also be obtained to evaluate for sub-diaphragmatic free air resulting from bowel perforation. Characteristic plain radiographic findings of SBO include distended loops of bowel, normally greater than 3 cm in diameter, often seen centrally in the radiograph (Fig. 78.4). In addition, unlike the haustra of the large intestine, which do not cross the full diameter of the bowel, the valvulae conniventes (or plicae circulares) of the small bowel cross the entire lumen of the small intestine, thus helping differentiate SBO from large bowel obstruction. In general, the greater the number of distended loops, the more distal the obstruction. No gas should be seen in the large bowel, unless the films are obtained early in the course of the obstruction or in the presence of a partial SBO. An adynamic ileus, on the other hand, tends to show extensive air-filled loops throughout the entirety of the GI tract without small bowel dilation. Unfortunately, plain radiographic studies have significant limitations in the evaluation of SBO. Plain radiographs are diagnostic in only 50% to 60% of cases, equivocal in 20% to 30%, and normal, nonspecific, or misleading in 10% to 20%. As a result, we do not recommend their use in the setting of suspected SBO.

Computed tomography (CT) has become an increasingly popular imaging modality for the evaluation of SBO, and is currently considered the gold standard for imaging in suspected SBO. CT detects SBO with a high degree of sensitivity and specificity. In addition, unlike plain radiographs, CT scans provide more information regarding the cause of obstruction by identifying the tumors. More important acutely, unlike plain radiographs, CT scans are highly sensitive for detecting strangulation, with a specificity of 96% and likelihood ratio of 9.3.[5] According to the American College of Radiology Appropriateness Criteria, the CT scan of choice for the evaluation of a suspected high-grade bowel obstruction is CT of the abdomen and pelvis with IV contrast and without oral contrast. This guideline states that "oral contrast will not reach the site of obstruction, wastes time, adds expense, can induce further patient discomfort, will not add to diagnostic accuracy, and can lead to complications, particularly vomiting and aspiration."[6]

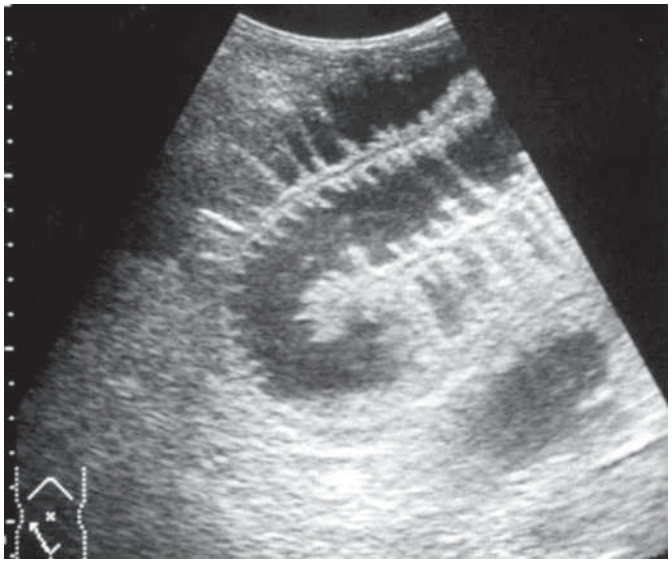

Fig. 78.5 Ultrasound Image of Fluid-Filled Dilated Small Bowel in Small Bowel Obstruction. (Courtesy Masaaki Ogata, Kobe, Japan.)

Historically, ultrasound had limited value in evaluating SBO due to significant artifact caused by gas within the GI tract. However, the improved resolution of newer scanning devices has made this modality much more attractive, with one recent meta-analysis finding that ultrasound performed with similar diagnostic characteristics to CT in identifying SBO, with the additional advantages of the potential for rapid performance at the bedside without exposure to ionizing radiation. Typical ultrasound findings in SBO include fluid-filled bowel with dilated loops greater than 2.5 cm in diameter with decreased or absent peristalsis with distally collapsed bowel (Fig. 78.5).[7] Abdominal free fluid between loops of dilated bowel (the Tanga sign) is suggestive of a high-grade obstruction.

In summary, CT scan with IV contrast is currently the preferred imaging test as it is the most sensitive and specific for detecting SBO, and is the most likely to identify both the cause and complications of the obstruction (specifically strangulation and bowel ischemia) with a high degree of sensitivity. Bedside ultrasound is quickly emerging as a useful tool in the diagnosis of SBO, though further research is needed with particular focus in the ED setting as well as the pediatric population.

MANAGEMENT

Hemodynamically unstable patients should be resuscitated with crystalloid solution via a large-bore catheter. Once SBO is diagnosed, if the cause is an abdominal hernia an attempt at bedside reduction is warranted. Clinical or imaging findings suggestive of bowel strangulation or ischemia should prompt rapid surgical consultation, as operative intervention is likely.[8] Although many emergency clinicians and surgeons consider the use of nasogastric decompression in all cases of SBO to be dogma, its effect in decreasing the duration of SBO has scant support in the medical literature, with some studies suggesting that nasogastric decompression may increase the risk of complications such as pneumonia.[9] We believe that it is reasonable to delay nasogastric tube insertion in the setting of a simple SBO suspected due to adhesions if nausea or vomiting can be adequately controlled with antiemetic medications (e.g., ondansetron 4 mg IV every 6 to 8 hours or metoclopramide 10 mg IV every 6 to 8 hours). However, in patients with persistent symptoms or large gastric volumes on imaging, a nasogastric tube attached to wall suction should be considered. There appears to be no benefit in using a long intestinal tube as an alternative to traditional nasogastric tube. Placement of a nasogastric tube is an uncomfortable procedure, and attempts should be made to anesthetize the patient's nasopharynx with topical anesthetic before insertion. In addition, the use of anxiolytics such as 2 mg of IV midazolam during insertion in appropriate patients, may reduce patient discomfort.[10]

Most simple SBOs related to adhesions will resolve with conservative treatment within 48 to 72 hours. Some surgical guidelines suggest administration of a water-soluble contrast medium at admission or after 48 hours of failed conservative treatment. Appearance of contrast in the colon within 24 hours of administration predicts nonoperative resolution of the obstruction.[11] The contrast media itself was once thought to have a therapeutic effect in resolving SBO, but recent studies have failed to show an effect.[12] A proposed approach to the management of SBO is shown in Fig. 78.6.

There is no convincing evidence to recommend the empiric use of antibiotics for the nonoperative management of a simple SBO. In patients in whom surgical exploration is planned or perforation is suspected, antibiotics are recommended and should provide coverage against the Gram-negative and anaerobic organisms that colonize the intestinal tract (e.g., a regimen with either a third-generation cephalosporin such as ceftriaxone 2 g IV daily or a fluoroquinolone such as ciprofloxacin 400 mg IV q12 hours, either combined with metronidazole 500 mg IV q8 hours. Single drug broad-spectrum options include piperacillin-tazobactam 3.375 g IV q6 hours or a carbapenem such as meropenem, 1000 mg IV tid).

SBO occurs in up to 30% of patients with colon cancer and in 50% of patients with ovarian cancer. Patients who may not qualify for surgical intervention because of intra-abdominal carcinomatosis, massive ascites, or poor overall health status may benefit from palliative relief with self-expanding metal bowel stents or the use of octreotide, 300 mcg/day IV given over three doses, or alternatively as a continuous infusion, to reduce GI secretions. A collaborative approach with the patent's oncologist and consulting surgeon can provide individualized treatment in this situation. In the setting of terminal metastatic disease, although surgery may provide temporary symptomatic improvement, it often comes at the cost of a significant proportion of the patient's remaining days being spent in the hospital.[13]

There are numerous potential serious complications associated with SBO. Persistent vomiting can lead to hypovolemia, metabolic alkalosis, and shock. If strangulation occurs, necrosis of the bowel can lead to perforation, and leakage of contaminated bowel contents into the peritoneal space can cause peritonitis, intra-abdominal abscess formation, and sepsis. Complications are more common in older adults and those with medical comorbidities. There are also several potential complications related to surgical intervention for SBO, including wound infection or short bowel syndrome. Unfortunately, the rate of recurrence of SBO is high; 40% for patients treated nonoperatively and 27% for those treated operatively. For patients with SBO secondary to adhesions, the relative risk of recurrence increases with the number of prior episodes of obstruction. For those with four or more episodes of adhesional SBO, the recurrence rate is more than 80%.

DISPOSITION

Patients with SBO routinely require inpatient admission to the hospital. One study has found that patients with SBO admitted to a surgical service for inpatient management had a shorter length of stay, lower hospital charges, and lower mortality compared to those admitted to a medical service. This was attributed largely to earlier identification of patients with failed conservative management and thus earlier surgical intervention. Regardless of the admitting service, patients with SBO need frequent reassessment to determine disease progression or resolution. Finally, although laparoscopic surgery was once considered inappropriate for the management of SBO, there has been a growing

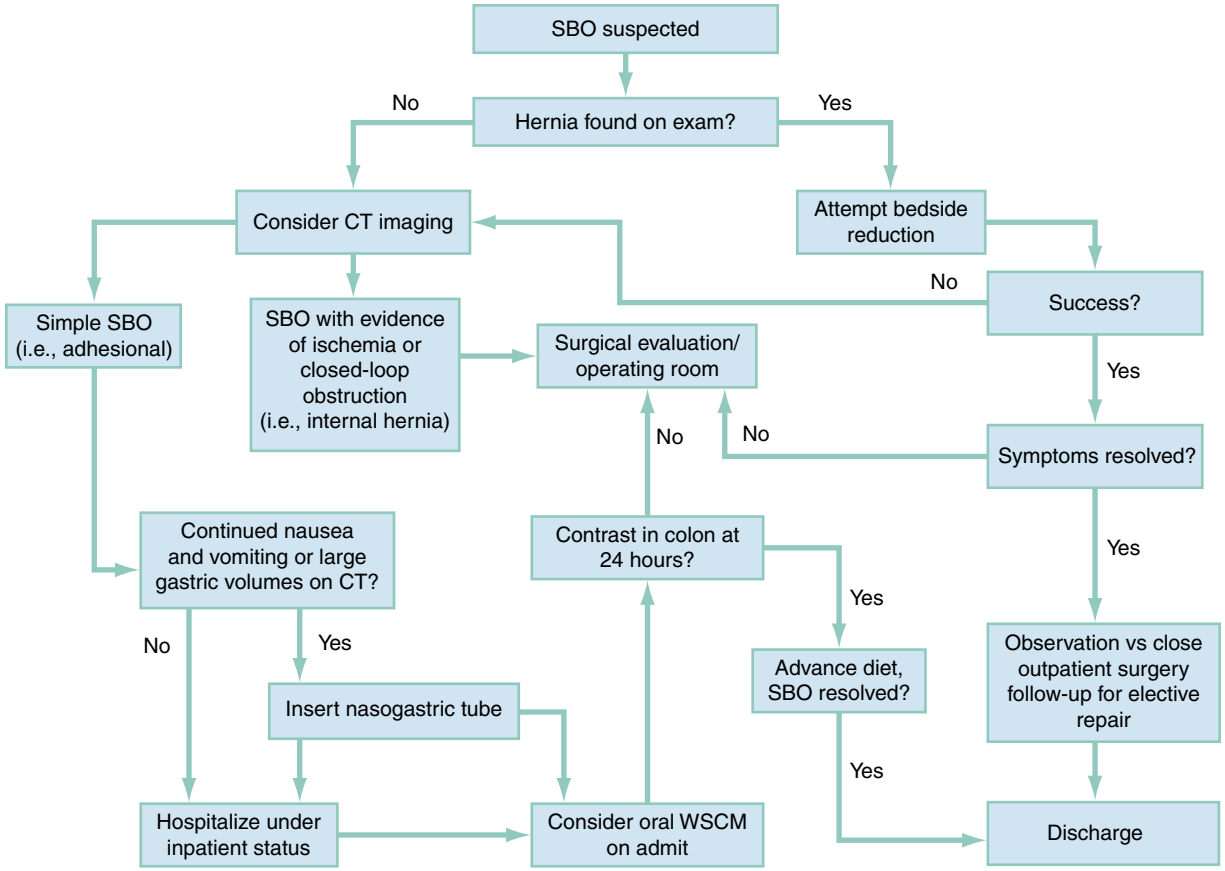

Fig. 78.6 Management Algorithm of Small Bowel Obstruction *(SBO). WSCM,* Water soluble contrast medium.

experience with its successful use, particularly those with obstructions caused by adhesions. Laparoscopy may decrease the incidence of subsequent obstructions, and several current guidelines suggest consideration of laparoscopy in stable patients in need of operative intervention for nonresolving SBO caused by adhesions.[14,15]

ACUTE MESENTERIC ISCHEMIA

KEY CONCEPTS

- Acute mesenteric ischemia (AMI) is a rare vascular catastrophe that involves the sudden reduction or loss of blood flow to the small bowel and possibly the right colon.
- Within the diagnosis of AMI are four distinct clinical entities with unique associated risk factors and treatments. These include:
  1. Mesenteric arterial embolism
  2. Mesenteric arterial thrombosis
  3. Nonocclusive mesenteric ischemia
  4. Mesenteric venous thrombosis
- CT angiography with IV contrast and thin axial images (1–3 mm) is currently the initial imaging study of choice in the evaluation of suspected AMI and has a very high level of accuracy.
- Successful management of acute mesenteric arterial embolism and thrombosis frequently requires multispecialty care including general or vascular surgery, interventional radiology, and critical care, with the goal of restoring mesenteric blood flow as quickly as possible.
- Unlike cases of arterial embolism or thrombosis, in the absence of peritonitis, mesenteric venous thrombosis is often successfully managed with anticoagulation alone.

FOUNDATIONS

Background and Importance

In his 1926 treatise on mesenteric vascular occlusion, A.J. Cokkinis wrote: "occlusion of the mesenteric vessels is apt to be regarded as one of those conditions of which…the diagnosis is impossible, the prognosis is hopeless, and the treatment almost useless." Since that time, significant advances in the understanding of this condition, as well as the development of endovascular approaches and surgical treatments have been made. Despite these advances, the mortality rate has remained as high as 60% to 80%, and the diagnosis and treatment of this vascular catastrophe has remained challenging.

Acute mesenteric ischemia (AMI) is the sudden reduction or loss of blood flow to the small bowel to a level that is insufficient to meet the metabolic demands of the small intestines.[16] This may at times involve the right colon. The left colon has a much higher degree of collateral blood flow and is less prone to mesenteric ischemia. When acute mesenteric ischemia occurs, rapid intestinal injury results. This condition should be clearly differentiated from chronic mesenteric ischemia (CMI), also referred to as *intestinal angina*, which often manifests as recurrent episodes of post-prandial abdominal pain resulting from insufficient intestinal blood flow during periods of increased metabolic demand, leading to food aversion and weight loss.[17] CMI does not usually require emergent therapy; however, it is also possible for acute mesenteric ischemia to develop in these patients.

Overall, AMI is a rare clinical problem. There are four specific clinical categories that make up the overwhelming majority of causes, each with distinct epidemiologic risk factors—mesenteric arterial embolus, mesenteric arterial thrombosis, nonocclusive mesenteric ischemia, and mesenteric venous thrombosis.

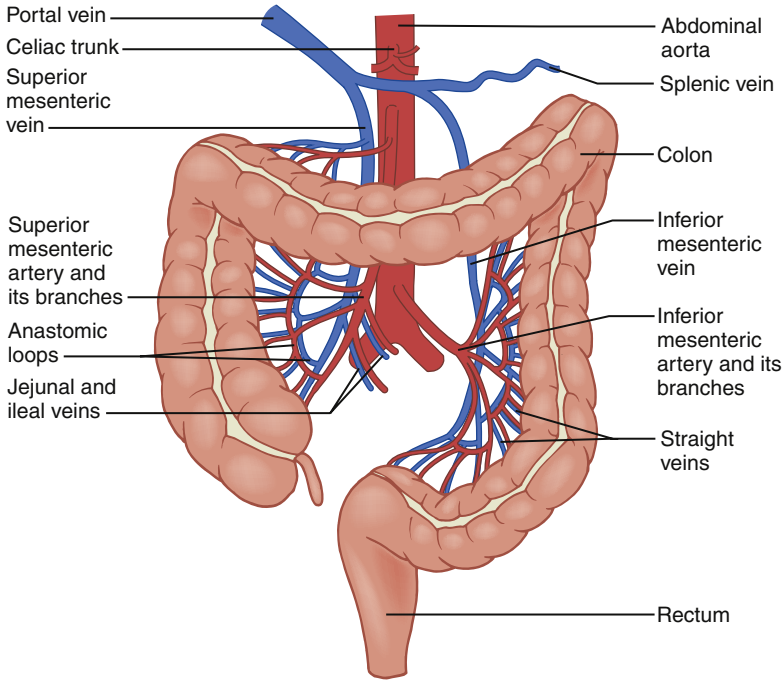

Fig. 78.7 Blood Supply of the Small and Large Intestine. (Reprinted with permission from Floch MH, Floch NR, Kowdley KV. *Netter's Gastroenterology*.)

Anatomy and Physiology

The mesenteric vessels arise from the primitive ventral segmental arteries. Although there is considerable individual variability, these vessels typically regress as embryologic development proceeds, with the exception of the 10th, 13th, and 21st segmental arteries. These become the celiac trunk, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA), respectively. The celiac trunk arises from the anterior aspect of the abdominal aorta and branches into the common hepatic, splenic, and left gastric arteries. These vessels supply the distal esophagus to the duodenum at the entrance of the bile duct. The SMA normally arises 1 cm below the celiac trunk and runs toward the cecum, terminating as the ileocolic artery. The SMA supplies the distal half of the duodenum to the proximal two-thirds of the transverse colon. The IMA originates approximately 6 to 7 cm below the SMA and gives rise to the left colic artery, sigmoid arteries, and hemorrhoidal arteries. Anatomically, this vessel provides blood flow to the distal third of the transverse colon to the rectum (Fig. 78.7). The gut receives 20% of cardiac output at rest and up to 35% after eating. Of this, up to 70% supplies the mucosa due to the high metabolic demands required for the absorptive function of this intestinal layer.

Intestinal blood flow is regulated by a complex combination of intrinsic and extrinsic mechanisms to match intestinal demands with blood supply. Intrinsic factors provide the moment-to-moment control of the intestinal circulation; they function independently from neural control. This intrinsic modulation has been proposed to involve the release of local metabolites produced as a result of mucosal ischemia. These metabolites then diffuse to the local arterioles, triggering relaxation in the smooth muscle and increased blood flow, thereby allowing for efficient adjustments to the intestinal blood supply. Smooth muscle relaxation can also be brought about directly by a decrease in the perfusion pressure in the arterioles themselves. These two mechanisms are referred to as the metabolic and myogenic pathways. Intestinal blood flow is also controlled extrinsically through neural and hormonal mechanisms. Increased sympathetic tone to the paired celiac ganglia located adjacent to the celiac trunk results in mesenteric and arteriolar vasoconstriction. Hormonal influences include the direct action of angiotensin II released as a result of decreased extracellular volume, as well as vasopressin, both of which cause mesenteric vasoconstriction.

Fig. 78.8 Gross Pathologic Image of Intestinal Ischemia and Infarction. Note mucosal hyperemia and hemorrhage. (From Gore RM, Yaghmai V, Thakrar KH, et al. Imaging in intestinal ischemic disorders. *Radiol Clin North Am.* 2008;46:845–875.)

PATHOPHYSIOLOGY

Although these mechanisms allow for the mesenteric circulation to adapt to wide variations in the metabolic needs of the gut and systemic perfusion, the bowel is quickly injured in the setting of acute compromise. Because of the high metabolic demands of the intestinal mucosa, structural damage to the intestinal villi can be observed histologically within 15 minutes of ischemia. If not corrected, mucosal sloughing occurs within 3 hours. After 6 hours, transmural necrosis is complete (Fig. 78.8). Complicating the situation, reestablishment of blood flow at this point results in the systemic release of several pro-inflammatory

Fig. 78.9 Coronal Abdominal CT Angiogram With Large Superior Mesenteric Artery Embolism *(Arrow).* (From Gore RM, Yaghmai V, Thakrar KH, et al. Imaging in intestinal ischemic disorders. *Radiol Clin North Am.* 2008;46:845–875.)

cytokines and toxic oxygen radicals caused by reperfusion, which can lead to multi-organ failure and death.

Mesenteric Arterial Embolism

Arterial emboli, the most common cause of acute mesenteric ischemia, are responsible for approximately 50% of cases. The median age of patients with mesenteric arterial emboli is 70 years, and in contrast to other vascular disorders, two-thirds are women. Emboli are usually cardiac in origin and arise from left atrial or ventricular mural thrombi or valvular lesions. Risk factors for the development of thrombi include myocardial ischemia or infarction, cardiomyopathies, ventricular aneurysms, endocarditis, or atrial dysrhythmias, specifically atrial fibrillation. Compared with the estimated annual risk of stroke of 2.3%, the annual risk of AMI caused by thromboembolism secondary to atrial fibrillation is 0.14%. The SMA is most frequently affected because of the large caliber of the vessel and its narrow takeoff angle from the aorta. The embolus typically lodges 3 to 10 cm distal to the origin of the SMA (Fig. 78.9). The jejunum is most often involved, as it is distant from the watershed collateral flow provided from the celiac and inferior mesenteric arteries.

Mesenteric Arterial Thrombosis

Mesenteric arterial thrombosis results from the progression of atherosclerotic disease of the mesenteric vasculature. Risk factors for development include advanced age, hypertension, diabetes, and tobacco use. Affected patients frequently have a history suggestive of CMI of several months or years duration. Unlike embolic occlusions, thrombosis usually occurs in the proximal SMA at the origin of the vessel.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia occurs as a result of mesenteric vasospasm in the absence of a physical obstruction. This vasospasm is triggered by mesenteric hypoperfusion or excessive sympathetic nervous system activity. Mesenteric hypoperfusion can result from a wide variety of conditions, including sepsis, severe dehydration, pancreatitis, or hemorrhagic shock. Excessive sympathetic activity can result from congestive heart failure, or the use of medications and drugs such as vasopressors, cocaine, or digoxin. Once initiated, this vasospasm often persists even after correction of the underlying condition, and repeated episodes of ischemia and reperfusion occur. Studies suggest that this recurrent pattern of ischemia and reperfusion may result in more severe histologic injury than a single episode of prolonged ischemia.

Fig. 78.10 Superior Mesenteric Venous Thrombus *(Red Arrow)* in a Patient With Nondescript Abdominal Pain. Hematologic evaluation revealed factor V Leiden thrombophilia. (From Gore RM, Yaghmai V, Thakrar KH, et al: Imaging in intestinal ischemic disorders. *Radiol Clin North Am.* 2008;46:845–875.)

Mesenteric Venous Thrombosis

Mesenteric venous thrombosis (MVT) is the least common cause of acute mesenteric ischemia, accounting for only 5% to 15% of all events. It usually involves the superior mesenteric vein and its branches (Fig. 78.10). In the vast majority of cases (>75%), an underlying inherited thrombotic disorder or inherited or acquired hypercoagulable state can be identified. The most common cause is factor V Leiden mutation, which is thought to account for 20% to 40% of cases. Other inherited prothrombotic states implicated in the development of mesenteric venous thrombosis include deficiency in antithrombin III, protein C, or protein S. Hematologic conditions predisposing to this condition include polycythemia vera and essential thrombocythemia. Oral contraceptive use accounts for 9% to 18% of the episodes of MVT in young women. Local intra-abdominal inflammation secondary to pancreatitis, malignancy, or inflammatory bowel disorders also increases the risk of mesenteric venous thrombosis. Finally, the venous stasis caused by portal hypertension is a recognized risk factor.

Box 78.3 summarizes causes of mesenteric venous thrombosis.

Unusual Causes of Mesenteric Ischemia

There are numerous case reports of unusual causes of mesenteric ischemia. These include SMA dissection leading to occlusion, tumor emboli, retroperitoneal fibrosis, and various types of vasculitis, including Buerger disease, polyarteritis nodosa, or Takayasu arteritis. Because these conditions involve a rare cause of an already rare condition, they frequently go unrecognized initially.

Clinical Features

History. The history at presentation of mesenteric ischemia is largely dependent on the nature of the underlying cause. The traditional historical triad of acute mesenteric ischemia is the sudden onset of poorly localized abdominal pain and gastric emptying (vomiting or

diarrhea) in a patient with cardiac disease. This is especially true in cases of SMA embolism or thrombosis, in which symptoms and clinical deterioration can rapidly occur. In cases of MVT, the symptoms are often slower in onset and have been present for several days by the time the patient seeks medical attention. Approximately one-third of patients with acute embolic mesenteric ischemia and 50% of patients with acute MVT have a personal history of an embolic event, such as a pulmonary embolism, deep vein thrombosis, or ischemic stroke. Patients with nonocclusive mesenteric ischemia are often already critically ill, making it difficult or impossible for them to provide historical details to the treating physician.

Physical Examination. The pain in acute mesenteric ischemia is typically described as being out of proportion to the physical examination findings. The patient may be writhing in pain but have a soft abdomen without guarding, especially early in the course of the event, when only the visceral structures are ischemic. However, as the parietal peritoneum becomes ischemic, the abdominal physical findings progress. If the ischemia progresses to infarction, peritonitis may be present. Heme-positive stools may also be noted. Hypotension, tachycardia, and tachypnea are all signs of severe ischemia and suggest a poor prognosis.

DIFFERENTIAL DIAGNOSIS

Other potentially devastating conditions to consider in the differential diagnosis of acute-onset severe abdominal pain include leaking AAA, perforated viscus, bowel obstruction, biliary disease, or atypical myocardial infarction.

Diagnostic Testing

Laboratory Tests

Initial laboratory results in patients with acute mesenteric ischemia are often nonspecific and may include leukocytosis, an elevated hematocrit secondary to hemoconcentration, or metabolic acidosis. Several serum biomarkers have been investigated as early indicators including I-FABP, α-glutathione S-transferase (α-GST), serum lactic acid, ischemia modified albumin (IMA), and citrulline levels. A meta-analysis has shown a pooled sensitivity of 71% and pooled specificity of 74% for serum lactic acid.[18] To date, no biomarkers have been found that are sufficiently sensitive and specific to diagnose or eliminate mesenteric ischemia. Recognizing these limitations, the serum lactic acid level is currently the most useful laboratory test available. In addition to its wide availability and rapid turnaround time, the short half-life of serum lactic acid (≈20 minutes) may be useful to allow for serial measurements, especially early in the course of suspected acute mesenteric ischemia.

Imaging

CT angiography has become the initial imaging study of choice for the evaluation of suspected acute mesenteric ischemia. Several studies have shown that with the emergence of multi-detector CT scanners, the sensitivity and specificity for mesenteric ischemia are approximately 94% and 95%, respectively.[19] Duplex sonography has a specificity 92% to 100% for the detection of AMI but its sensitivity is only 70% to 89% due to limited evaluation beyond the proximal main vessels. It is also unable to provide information regarding complications of acute mesenteric ischemia, including bowel infarction or perforation. Plain abdominal radiographs are usually nonspecific and of little use. Later in the disease course, plain radiographic findings may show so-called thumbprinting, in which multiple, round, smooth soft tissue densities project into the intestinal lumen because of mucosal and submucosal edema and hemorrhage. More specific but very late plain radiographic findings indicating infarction include pneumatosis intestinalis and portal venous gas.

Management

Once AMI has been diagnosed, the goals of treatment are to restore mesenteric blood flow as rapidly as possible, manage underlying conditions, treat persistent mesenteric vasospasm if present, and mitigate the risk of further clot propagation. Initial interventions should focus on fluid resuscitation and hemodynamic stabilization. Unless contraindicated, patients should be anti-coagulated with intravenous unfractionated heparin (80 units/kg bolus followed by an 18 units/kg/h infusion).[20] Because these patients are often older adults with cardiac comorbidities, invasive monitoring may be indicated. If vasopressors are required, dobutamine, low-dose dopamine, or milrinone are recommended, because these have been shown to have less of a vasoconstrictive effect on the mesenteric vasculature than other agents (see Chapter 5). With evidence of infarction, perforation, or peritonitis, antibiotics suitable for enteric coverage, such as ceftriaxone 2 g IV qd, or ciprofloxacin 400 mg BID, in combination with metronidazole 500 mg IV TID, is recommended. Single drug options include piperacillin-tazobactam 3.375 g IV q6 hours, or a carbapenem such as meropenem 1000 mg IV TID).

The optimal care of this challenging condition often requires multispecialty coordination involving general surgery, vascular surgery, interventional radiology and critical care experts. Previously, the standard approach was emergent open surgery. If signs of intestinal infarction or perforation with peritonitis are present, prompt laparotomy is still recommended. The benefit to this approach is that it also allows the surgeon to assess the viability of the bowel at the time of the operation, which is not possible with endovascular treatment alone, and to resect necrotic bowel if needed. Open repair can also involve surgical embolectomy, or bypass grafting as well as an approach referred to as the hybrid technique, which includes intra-operative retrograde revascularization.[21] This approach involves open surgical evaluation of the bowel, as well as concurrent retrograde stenting of the occluded vessel,

thus combining the benefits of rapid revascularization with surgical evaluation of the bowel (Fig. 78.11). If bowel viability is questionable during the first laparotomy, a second-look procedure 24 to 48 hours later has been recommended.[22]

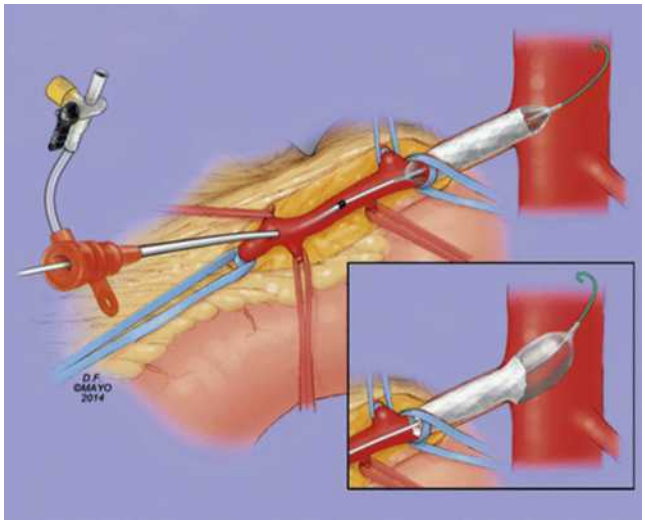

Fig. 78.11 Hybrid Technique With Retrograde Open Mesenteric Stenting. (From Moore JR, Achanchi SS, Panneton JM. Chapter 17: Techniques of open and hybrid mesenteric revascularization of acute mesenteric ischemia. In: Oderich GS, ed. *Mesenteric Vascular Disease*. New York: Springer Science & Business Media; 2015; used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

In addition to open surgery and the hybrid approach, similar to the developments in acute stroke care, the role and timing of endovascular treatments alone in the management of AMI also continues to evolve and appears to offer an additional treatment modality, especially in those patients deemed to be a poor surgical candidate due to underlying medical issues or patient goals of care. Numerous reports have detailed the use of thrombolytic agents, angioplasty, embolectomy, or vascular stenting to restore mesenteric blood flow. Although randomized control trials are needed, several retrospective studies have demonstrated favorable success and complication rates of endovascular revascularization of AMI. Patient vascular anatomy is a factor, as an angular or tortuous SMA can lower technical success of intervention.

The treatment of mesenteric venous thrombosis is unique in that in the absence of peritoneal findings, initial treatment with heparin infusion and then transition to long-term anticoagulation with warfarin. A targeted international normalized ration (INR) of 2.0 to 3.0 is adequate in 95% of cases. To date, non-vitamin K antagonist oral anticoagulants (NOACs) have not been studied for the treatment of MVT. A treatment duration of 6 months for patients diagnosed with a provoked and reversible cause is suggested, although life-long anticoagulation may be needed if a hypercoagulable condition is uncovered. If the case is refractory to anticoagulation or the condition of the patient worsens, catheter-directed fibrinolysis or thrombectomy may be considered.[23] If peritonitis is present or develops later in the patient's hospital course, bowel necrosis is likely, and prompt laparotomy is still indicated. Similar to mesenteric arterial occlusion, if bowel viability is unclear, a second-look laparotomy may also be needed. A suggestive outline of the management of occlusive mesenteric arterial and venous ischemia is presented in Fig. 78.12.

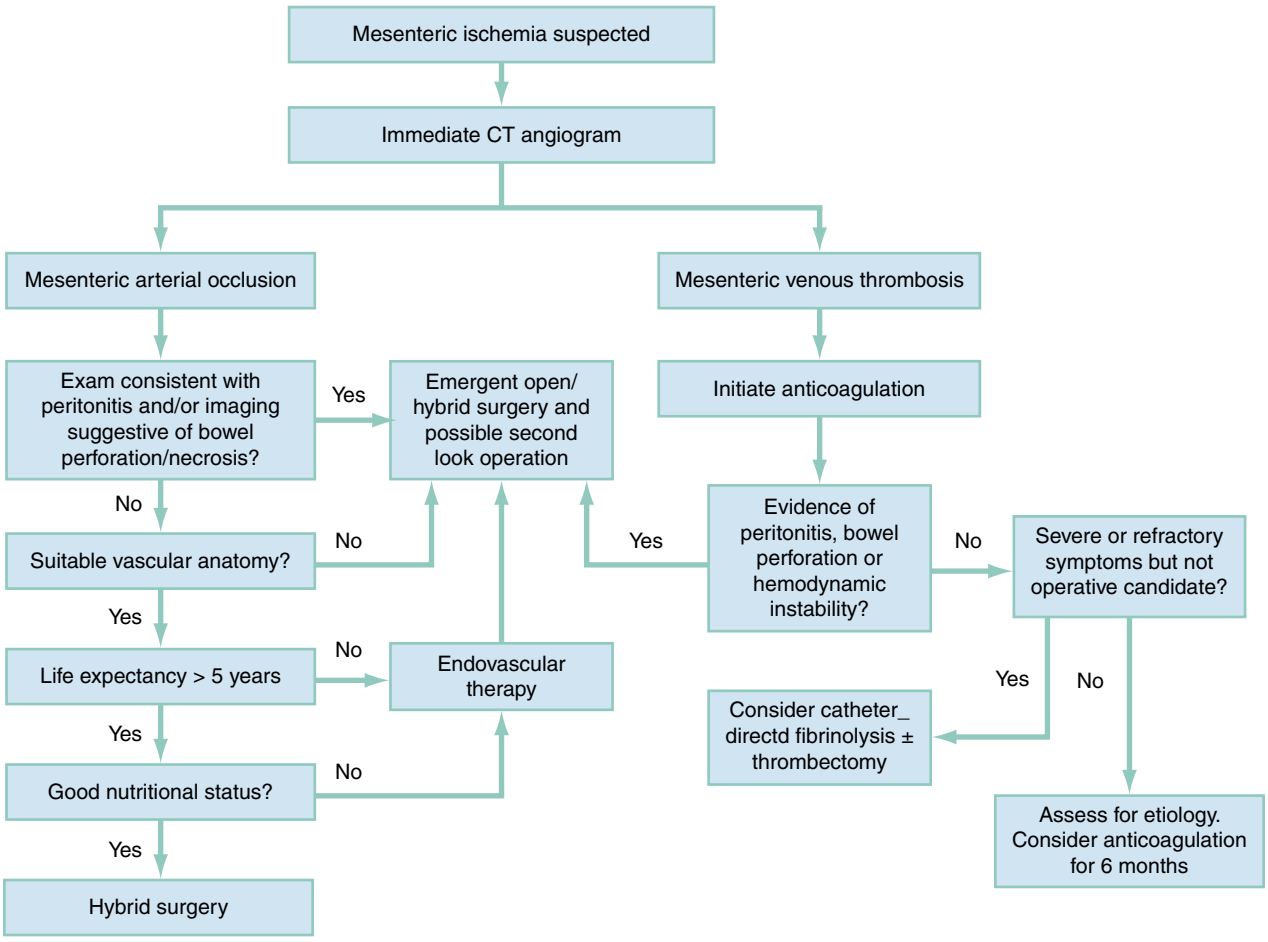

Fig. 78.12 Management Algorithm of Occlusive Arterial and Venous Mesenteric Ischemia.

Primary treatment of nonocclusive mesenteric ischemia involves interventions to reverse the underlying cause and consideration for papaverine infusion via angiographic catheter, as well as IV heparin to prevent thrombosis in the vasospastic vessel. Papaverine infusion is often maintained for 24 hours, at which time angiography may be repeated to evaluate for the resolution of vasospasm. If peritoneal signs develop, laparotomy is indicated. If the underlying medical condition persists, the mortality of nonocclusive mesenteric ischemia remains high.

Complications

Even with prompt recognition and treatment of acute mesenteric ischemia, a complicated course is expected. Secondary reperfusion injury is common, and bowel initially identified as viable may progress to necrosis requiring additional resection. Other complications include wound infections, sepsis, or pneumonia. Given the population in which AMI tends to occur, the physiologic stress of this disease process also places patients at high risk for myocardial infarction, renal failure, or pulmonary embolism while hospitalized.

Disposition

Patients with acute mesenteric ischemia routinely require hospital admission, with the majority requiring intensive care.

CHAPTER 78: QUESTIONS AND ANSWERS

1. What is the most common cause of small bowel obstruction in the developed world?

a. Gallstone ileus
b. Hernias
c. Intussusception
d. Postoperative adhesions
e. Tumors

Answer: d. In the developed world, postoperative adhesions account for approximately 60% of cases of small bowel obstruction. Patients with a history of intestinal or pelvic surgery are at the highest risk.

2. Which of the following patients is at the highest risk of developing an obturator hernia?

a. 2-year-old boy with no known medical problems
b. 45-year-old woman with a 1-year history of hysterectomy
c. 67-year-old man with a history of metastatic prostate cancer
d. 80-year-old woman with a 3-month history of rapid weight loss

Answer: d. This type of hernia is especially common in older women who have recently lost a significant amount of weight. The female pelvis is wider, and the obturator canal is more oblique in women. This, in combination with a loss of preperitoneal fat, predisposes to its development. Because an external mass is absent, diagnosis is especially challenging and explains why it carries the highest mortality of any abdominal hernia – nearly 70% when incarcerated.

3. A 55-year-old woman with a history of Roux-en-Y gastric bypass surgery presents with one day of worsening colicky abdominal pain and vomiting. A CT scan reveals an internal hernia. What is the most appropriate disposition?

a. Administer broad-spectrum antibiotics and admit to the medicine floor.
b. Arrange for barium swallow with small bowel follow-through.
c. Insert nasogastric tube and admit to the medicine floor.
d. Prompt surgical consultation and preparation for surgery.

Answer: d. Although rare in the general population, internal hernias are a recognized complication of bariatric surgery, especially when a Roux-en-Y type procedure has been performed. Because of the closed loop nature of an internal hernia, they are not suitable for conservative management and require surgical intervention.

4. What is the length of time from acute ischemia of the intestines to completion of transmural necrosis?

a. 15 minutes
b. 60 minutes
c. 2 hours
d. 6 hours
e. 24 hours

Answer: d. Although the mesenteric circulation is able to adapt to variations in circulation, the small bowel is quickly injured after acute ischemia. Within 15 minutes, structural damage to the intestinal villi can be seen histologically. If blood flow is not restored, mucosal sloughing can start to occur within 3 hours and, by 6 hours, transmural necrosis is complete.

CHAPTER 78: QUESTIONS AND ANSWERS—Cont'd

5. A 35-year-old woman taking oral contraceptive pills presents with 2 days of progressively worsening diffuse abdominal pain without peritoneal findings on examination. A CT scan reveals mesenteric venous thrombosis. What is the next most appropriate step?

a. Arrange for formal mesenteric venous angiography to confirm and treat.

b. Arrange for immediate exploratory laparotomy regardless of current clinical status, given the high risk of severe complications.

c. Discharge home because this will resolve without intervention.

d. Institute pain control and admit to the floor.

e. Start anticoagulation with therapeutic dosing of heparin.

Answer: e. The treatment of mesenteric venous thrombosis is unique in that in the absence of peritoneal findings, initial treatment with heparin alone may be adequate. In the vast majority of cases (>75%) an underlying inherited or acquired hypercoagulable state can be identified. Oral contraceptive use accounts for 9% to 18% of cases in young women.

Acute Appendicitis

David J. Carlberg and Nadine T. Himelfarb

KEY CONCEPT

- Appendicitis is a progressive illness caused by appendiceal luminal distention followed by appendiceal wall ischemia, transmural inflammation, and eventual perforation, with resulting peritonitis.
- Clinical history, physical examination, and laboratory findings need to be combined to formulate a comprehensive assessment. No one finding can definitively diagnose or exclude appendicitis.
- The most useful historical features in evaluating appendicitis are right lower quadrant (RLQ) pain, pain preceding vomiting, and migration of pain to the RLQ.
- The most useful physical findings in evaluating appendicitis are RLQ tenderness or rigidity.
- Cervical motion tenderness is not specific for pelvic pathology and is found in up to 28% of females with appendicitis.
- A rectal examination contributes little and should not be routinely performed in the evaluation of appendicitis.
- The white blood cell count alone is neither sensitive nor specific for appendicitis and offers little in the evaluation.
- When clinicians have a low pretest probability for appendicitis, the combination of a WBC count < 10,000/mm^3 and CRP < 8 mg/L support the exclusion of appendicitis as a likely diagnosis.
- A young, healthy adult patient with classic symptoms and signs of appendicitis should receive graded compression ultrasound as the initial imaging of choice, if available. If the ultrasound is negative or inconclusive and concern for appendicitis persists, the patient should receive a CT of the abdomen and pelvis with IV contrast, which is the most sensitive test for appendicitis. There is no need for oral or rectal contrast when ordering a CT for appendicitis.
- When there is a concern for acute appendicitis, pregnant women should first have graded compression ultrasound followed by MRI if the ultrasound is negative or nondiagnostic.
- Nonoperative management of acute appendicitis (IV antibiotics, admission) is gaining support. The patient should not have high-risk features on imaging (e.g., presence of a fecalith, abscess, tumor, fluid collection, or appendiceal diameter > 1.1 cm) and should be made aware of the risks of treatment failure and recurrent appendicitis, both of which generally require surgical removal of the appendix.
- Because of the risk of malignancy, guidelines recommend follow-up colonoscopy for patients > 40 years old treated with nonoperative management.
- Delays of 12 to 24 hours between appendicitis diagnosis and operative management are not associated with adverse outcomes. Many surgeons will perform an appendectomy the following morning if a patient presents in the evening or overnight hours. Early appendectomy should be considered in elderly patients, because up to 41% of patients 65 years or older develop perforation between diagnosis of appendicitis and surgery.

PRINCIPLES

Background

Appendicitis is the most common cause of acute abdominal pain requiring operative intervention in patients younger than 50 years, with a lifetime risk of 8.6% in males and 6.9% in females.[1] Approximately 69% of appendicitis cases occur in patients younger than 30 years, with the highest rates of presentation during the summer months. It is the most common nonobstetric abdominal emergency in pregnancy, with an incidence of 101 cases per 100,000 live births, occurring most often in the second trimester. Although appendicitis is less frequent in nonwhite individuals, these patients are at higher risk of perforation or experiencing complications of appendicitis, possibly due to health care access inequities.[2]

Formerly considered a vestigial organ, new research has revealed that the appendix likely performs an important immunologic function. It is postulated that a biofilm with bacteria-bacteriophage complexes contained within the appendix can reinnoculate the terminal ileum and proximal colon with intestinal flora when the intestinal microbiome becomes unbalanced in the setting of life stressors, dietary choices, or antibiotics.[3]

Anatomy and Physiology

The appendix is a blind-ended tube that originates from the cecum, approximately 3 cm from the ileocecal valve. It is considered part of the cecum and has the same histologic arrangement as the large intestine, although comparatively it has a larger amount of lymphoid tissue in the mucosa and submucosa. Although the appendix classically originates from the McBurney point (≈4 to 5 cm from the right anterior superior iliac spine on a straight line drawn to the umbilicus), anatomic variants may originate as distant as 10 cm from this site. Additionally, although it has an average length of 8 to 10 cm, the appendix may be more than 20 cm long. Therefore, an atypical origin and length may allow it to traverse into nearly any quadrant of the abdomen. The average appendix has a diameter ranging from 6 to 11 mm, and has an average wall thickness of 1.5 mm.

The appendix maintains afferent sensory fibers that follow the sympathetic innervation and enter the spinal cord at the 10th thoracic level (T10). This neurosensory pathway results in the periumbilical (visceral) pain of early appendicitis.

Pathophysiology

Appendicitis progresses in a stepwise fashion. First, the appendiceal lumen becomes obstructed, preventing egress of mucus and bacteria from the appendix. Continued mucus production and bacterial proliferation result in luminal distention, which stimulates the T10 visceral sensory nerves of the appendix. The resulting periumbilical pain classically lasts 4 to 6 hours. Intraluminal pressure eventually exceeds local capillary pressure in the appendiceal wall, preventing perfusion

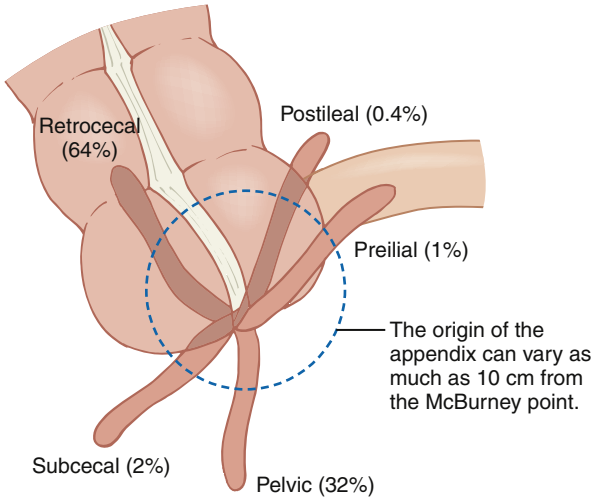

Fig. 79.1 This figure shows the variation in location of the base of the appendix and its course within the peritoneum. The McBurney point classically represents the point of maximal tenderness in appendicitis; however, depending on the path, length, and degree of inflammation of the appendix, the true point of maximal tenderness is highly variable.

and resulting in tissue ischemia and inflammation. The integrity of the appendiceal wall becomes compromised, allowing bacteria to invade the wall. This produces transmural inflammation, which extends into the surrounding tissues and causes localized somatic pain, typically focused in the right lower quadrant. If this process continues, the appendix becomes necrotic and perforates, releasing enteric contents into the peritoneum. The subsequent peritonitis typically causes diffuse abdominal pain. The length of time from the onset of symptoms to perforation is highly variable. Although rare, spontaneous resolution of appendicitis may occur.

Although the somatic pain from appendicitis classically occurs in the right lower quadrant, three important anatomic features determine the site of pain and tenderness: (1) the location of the origin of the appendix; (2) the course the appendix takes from its origin; and (3) the length of the appendix (Fig. 79.1). All these features are variable and result in a wide range of potential signs and symptoms: an appendix that courses into the left lower or right upper abdomen may cause pain in these areas; a retrocecal appendix may cause flank pain, psoas irritation, or obturator irritation; and an appendix that courses into the pelvis may cause pelvic pain, testicular or adnexal pain, diarrhea (as the inflamed appendix irritates the rectum), or even pyuria or dysuria (as the inflamed appendix irritates the urinary tract). Finally, when the inflamed appendix does not touch the parietal peritoneum, as sometimes occurs with pre-ileal and post-ileal appendicitis (see Fig. 79.1), patients may only exhibit vague abdominal discomfort or gastrointestinal symptoms until perforation occurs and inflammation becomes more diffuse.

Though it is commonly understood that obstruction of the appendiceal lumen triggers acute appendicitis, the causes of obstruction are variable and often go undetermined, even after imaging and pathologic evaluation. Fecaliths (hard stools) are the most common cause of obstruction in nonperforated appendicitis (65%), followed by appendicoliths (calcified deposits) and lymphoid hyperplasia (primary or secondary to an enteric infection). Other less common causes of obstruction are fecal stasis, foreign bodies (e.g., vegetable matter, inspissated barium), tumors, or intestinal parasites.

There are two additional pathologic processes associated with appendicitis: tip appendicitis and stump appendicitis. Tip appendicitis is inflammation localized to the distal end of the appendix, which carries a higher risk of missed diagnosis on imaging because of more subtle findings. Stump appendicitis results from inflammation of the appendiceal remnant that may persist after appendectomy. This phenomenon is rare, and its timing varies; it has been diagnosed between 4 days and 50 years after initial appendectomy.[4]

CLINICAL FEATURES

Selected patients presenting with classic historical and examination features of appendicitis may be rapidly diagnosed without the need for further testing. Unfortunately, however, periumbilical abdominal pain radiating to the right lower quadrant with associated right lower quadrant tenderness occurs in fewer than 50% of patients.

No one element of the history or physical examination can reliably diagnose or exclude appendicitis. Therefore, a comprehensive evaluation of the overall clinical picture is necessary to risk stratify a patient's likelihood of having appendicitis. Laboratory testing and advanced imaging (ultrasound, computed tomography [CT], or magnetic resonance imaging [MRI]) are frequently utilized to aid in risk stratification and diagnosis.

History

The history and review of systems frequently provide valuable insights, either demonstrating features of acute appendicitis or suggesting a compelling alternative diagnosis. A prior history of similar symptoms suggests alternative diagnoses, because appendicitis is rarely a waxing and waning or recurrent condition. Because appendicitis is usually a progressive process, the patient's symptoms typically worsen until perforation of the appendix occurs. Upon perforation, the patient may have temporary relief due to a decrease in appendiceal intraluminal pressure, but subsequent peritonitis generally leads to more severe diffuse abdominal pain and potentially clinical decompensation. Table 79.1 lists the value of common symptoms in predicting the likelihood of appendicitis.[5] Duration of symptoms is variable and may not aid in risk stratification.

Physical Examination

Patients with abdominal pain should be appropriately disrobed, and ideally placed in a room where a genitourinary examination can be performed if clinically indicated. Cervical motion tenderness (CMT) is not specific for pelvic pathology and is noted in 28% of female patients with appendicitis. A rectal examination contributes little to the assessment of appendicitis and is not routinely recommended unless it is indicated for evaluation of other potential etiologies.[6]

Classic, eponymous examination maneuvers for appendicitis have overall poor sensitivity but, if present, have a modest predictive value (Table 79.2). Although not sensitive due to the potentially variable location of the appendix in the abdominal cavity, tenderness at the McBurney point has been shown to have a modest predictive value for appendicitis.

DIFFERENTIAL DIAGNOSIS

There are many diagnoses that mimic appendicitis; alternatively, appendicitis may present atypically and should be considered in patients presenting with a wide variety of abdominal complaints. Table 79.3 lists common differential considerations when evaluating for appendicitis.

DIAGNOSTIC TESTING

General Principles

Acute appendicitis, though one of the most common surgical causes of abdominal pain in the emergency department (ED), remains a

TABLE 79.1 Value of Common Symptoms in Predicting the Likelihood of Appendicitis[6]

	ADULT		CHILD	
Sign/Symptom	**LR+**	**LR–**	**LR+**	**LR–**
Right lower quadrant pain	7.3–8.5	0–0.28	1.4	NA
Rigidity	3.8	0.82	NA	NA

Inflammatory bowel disease		
Ileus or bowel obstruction		
Intestinal perforation		
Testicular torsion (males)		

diagnostic challenge. Delayed diagnosis carries significant morbidity and mortality, and, as a result, missed appendicitis remains a common cause of litigation in emergency medicine.[7] As such, the diagnosis of acute appendicitis remains largely clinical.

Laboratory Testing

No single laboratory test has been proven an accurate predictor of acute appendicitis. Rather, laboratory testing may contribute valuable information to the overall clinical picture, and may aid in the risk stratification of patients with potential acute appendicitis. Laboratory testing is best interpreted in conjunction with the patient's history and physical examination.

White Blood Cell Count

Although often part of the evaluation for acute appendicitis, the white blood cell (WBC) count alone does not have enough sensitivity, specificity, or predictive value to be clinically useful for diagnosing or excluding appendicitis.[8] An elevated WBC count (>10,000–12,000/mm^3) has a sensitivity of 71% to 93%, a specificity of 49% to 66%, a positive likelihood ratio (LR) of 1.73 to 2.37, and a negative LR of 0.14 to 0.44.[9] In one study of 1024 patients with suspected acute appendicitis, the highest positive predictive value (PPV) of an elevated WBC count peaked at 74.2%, and only when the WBC count was greater than 20,000/mm^3 and patients had symptoms for more than 48 hours.[10]

C-Reactive Protein

The C-reactive protein (CRP) level is a nonspecific systemic inflammatory marker synthesized by the liver. It has a poor predictive value in diagnosing or excluding acute appendicitis.[8] An elevated CRP (>3 mg/dL) has a sensitivity of 38% to 70%, a specificity of 65% to 85%, a positive LR of 1.98 to 2.63, and a negative LR of 0.47 to 0.72.[9]

Urinalysis

Pyuria may be present in 7% to 25% of patients with acute appendicitis.[11] When the inflamed appendix abuts a ureter or bladder, urinary tract inflammation may result. Despite this common occurrence, alternative causes of abdominal pain should be equally considered when urinalysis shows greater than 30 red blood cells (RBCs) per high-power field (HPF) or greater than 20 WBCs/HPF.

Other Laboratory Tests

A serum or urine pregnancy test is recommended for any female of childbearing age or reproductive capacity with abdominal pain. A basic metabolic panel should be considered for patients with suspected appendicitis to assess for electrolyte derangements. Liver function tests and a lipase level may help evaluate for alternative causes of abdominal pain. Procalcitonin, proportion of polymorphonuclear cells (WBC count differential), D-dimer, and bilirubin do not individually play any role in the diagnosis of appendicitis due to their poor predictive value.[1,2]

Combined Laboratory Tests

Combined laboratory findings offer the greatest impact in excluding appendicitis among patients with a low pretest probability of the disease. In one study, while normal WBC and CRP levels offered NPVs of 64% and 55% respectively, normal values of WBC and CRP combined resulted in a NPV of 88%.[10] Commercially available panels have been developed combining WBC, CRP, and myeloid-related protein in a mathematical algorithm that holds promise for excluding appendicitis in low-risk children and adults. Trials of these panels have shown sensitivities of 97%, and NPVs of 95% in children and

98% in adults.[12,13] Additional research is required prior to standard adoption of these tests in the ED setting.

Clinical Decision Instruments

Multiple clinical decision instruments combine clinical signs and laboratory test results to assist providers in risk stratifying patients into low, moderate, or high-risk categories. They may help determine whether a patient warrants outpatient follow-up, diagnostic imaging, or surgical consultation.

The best studied and most well-recognized clinical decision instrument is the Alvarado score, validated in both children and adults. Similar, though specific to children, is the Pediatric Appendicitis Score. Finally, the Appendicitis Inflammatory Response Score, validated in both children and adults, has been shown to have comparable predictability to the Alvarado score.[5] Table 79.4 lists the components of each scoring system.[14,15]

Imaging

General Principles

The decision to pursue imaging is based on the provider's clinical assessment, which combines the patient's history, examination, and potentially laboratory data to determine the likelihood of appendicitis. When the likelihood is sufficiently low, a patient may be discharged from the ED without imaging after an informed discussion of the risks and an explanation of return precautions. If there is a moderate to high likelihood of appendicitis, imaging should be pursued.

Patients in industrialized countries rarely undergo surgical removal of the appendix without receiving imaging first. The negative appendectomy rate—the number of normal appendices that are surgically removed—is far lower when imaging is utilized: the rate decreased from 13.5% to 3.7% in children and from 12% to 6% in adults with imaging.[16] Nevertheless, the decision to perform an appendectomy without imaging on a patient with a classic presentation may be pursued at the surgeon's discretion. This most frequently occurs in young healthy males.

Plain Radiographs

Due to their poor sensitivity and specificity, routine radiographs are of no clinical value in the evaluation of appendicitis. In a patient with peritonitis, an upright chest radiograph may be helpful if it reveals free air under the diaphragm resulting from perforation. In this circumstance, surgical consultation is necessary for likely operative exploration.

Graded Compression Ultrasound

Graded compression ultrasound (US) is an imaging tool commonly used to evaluate for appendicitis. Steady pressure is applied with the US probe to reduce bowel gas and collapse normal bowel to promote visualization of the appendix. Studies involving graded compression US for the diagnosis of appendicitis show sensitivities of 74% to 94%, specificities of 85% to 93%, positive LRs of 4.68 to 11.66, and negative LRs of 0.07 to 0.31.[9] Table 79.5 lists the US criteria for the diagnosis of appendicitis, and Figures 79.2 and 79.3 show appendicitis seen on US.

The cost of US is less compared to other imaging modalities, and it lacks ionizing radiation and frequently decreases time to diagnosis. However, US has decreased sensitivity compared to other imaging modalities and may be associated with increased pain due to the transducer pressure needed for graded compression. The biggest limitation with US is that the appendix is frequently not seen (i.e., a nondiagnostic examination). Potential contributing factors include operator experience, patient body habitus, patient cooperation, superimposed bowel gas, or an atypically located appendix.[16] In cases with nondiagnostic US findings, the patient typically requires further imaging with CT (or MRI in pregnancy), or admission for observation and serial examinations. US is generally most useful in children, for whom the long-term risks of ionizing radiation are greatest and in whom rates of obesity are lower than

TABLE 79.5 Diagnostic Criteria for Appendicitis on Imaging

Ultrasound	Computed Tomography	Magnetic Resonance Imaging
The first two criteria below must be fulfilled:	Not all criteria listed below need to be fulfilled, but the combination and severity of these findings contribute to a diagnosis:	Not all criteria listed need to be fulfilled but the combination and severity of these findings contribute to a diagnosis:
• Appendiceal diameter > 6–7 mm[a]	Appendiceal diameter (> 6 mm with surrounding inflammation or > 8 mm without such changes)	Appendiceal diameter > 7 mm
• Noncompressible appendix	Appendiceal circumferential wall thickening > 2 mm with mural enhancement (sign of inflammation)	Appendiceal circumferential wall thickening > 2 mm
Fat stranding (hyperechoic signals associated with periappendiceal inflammation) (secondary finding)	Calcified appendicolith	Signs of inflammation adjacent to the appendix, such as fat stranding or phlegmon formation
Peritoneal fluid surrounding the appendix (secondary finding)	Signs of periappendiceal inflammation (e.g., fat stranding, clouding of the adjacent mesentery)	Presence of an abscess or a fluid-filled appendix

[a]It is important to note that the diameter of a normal nondiseased appendix may be up to 11 mm, thus the other findings suggestive of appendicitis must also be factored in when evaluating for appendicitis on CT or MRI. Due to the graded compression technique employed during ultrasound examination for appendicitis, there is comparatively greater diagnostic certainty irrespective of appendiceal diameter because appendicitis is associated with noncompressibility regardless of size.

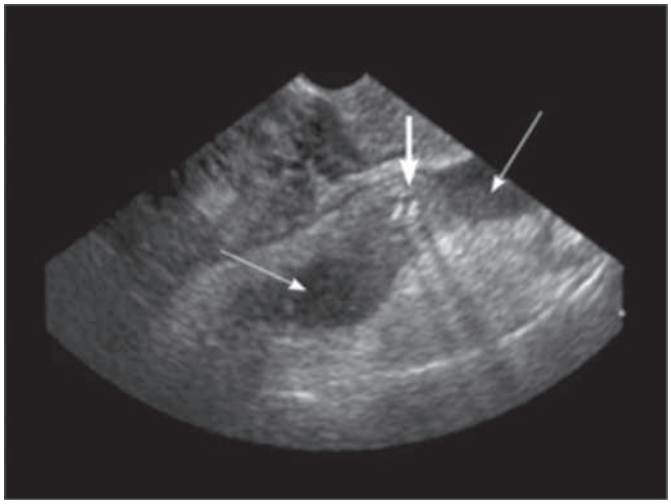

Fig. 79.2 Ultrasound image of appendicitis in an 8-year-old girl. Note the dilated noncompressible appendix *(thin arrows)* and the presence of a fecalith, with posterior acoustic shadowing *(thick arrow)*. (Courtesy Dr. Michael Cole, with permission.)

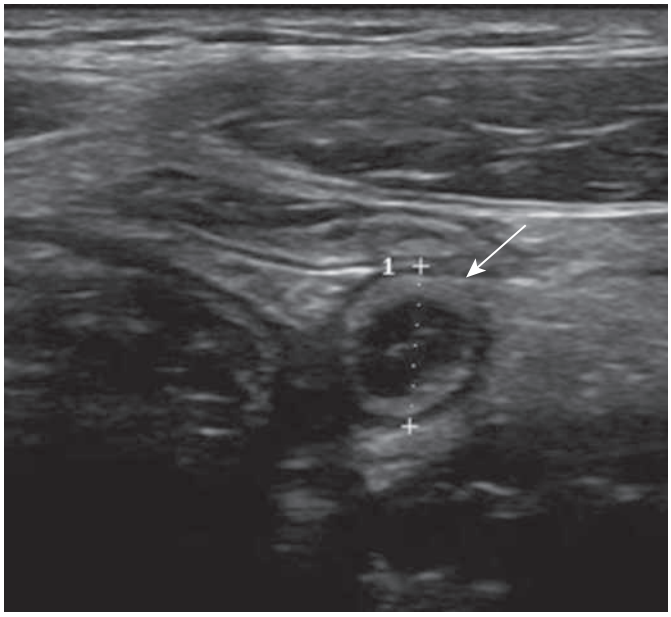

Fig. 79.3 Graded compression ultrasound scan demonstrating a dilated noncompressible appendix *(thin arrow)* representing appendicitis.

adults. US for appendicitis is also useful in pregnant females, but the rate of appendiceal visualization is lower in pregnancy.[5]

Previously, distinctions were made between radiology department US and nonradiologist physician point of care US (POCUS) examinations. A meta-analysis of POCUS studies on 6636 patients revealed a sensitivity of 91%, a specificity of 97%, a LR+ of 28.3, and a LR– of 0.09. Looking specifically at emergency physician performed POCUS, the sensitivity and specificity fell to 80% and 92%, respectively, with a LR+ of 10.2 and LR– of 0.22.[17] Ultimately, the diagnostic accuracy of US is dependent on the experience of the operator, and though helpful if it diagnoses appendicitis, given the variability of operator training and patient anatomy, US should not be utilized to exclude appendicitis in patients with high pretest probability.

Finally, in women with cervical motion tenderness, pelvic mass, or other suspected gynecologic pathology, pelvic US (which can be performed concurrently with US for appendicitis) evaluates for several alternative etiologies of pain. When a gynecologic source is suspected, performing pelvic US prior to CT may spare patients both cost and radiation, because pelvic US may provide a compelling alternative diagnosis and preclude further appendicitis workup.

Computed Tomography

CT of the abdomen and pelvis is considered the test of choice for definitive assessment for possible appendicitis in nonpregnant patients. It has a sensitivity of 95% to 100% and a specificity of 98% to 99.5%[1] CT is accurate and consistent in diagnosing appendicitis and decreases the negative appendectomy rate from 12% to 6%.[2] CT is readily available, can be performed rapidly, is not operator dependent, can be interpreted by most radiologists and surgeons, and has a greater likelihood of finding an alternative diagnosis than US. Figures 79.4 and 79.5 demonstrate appendicitis seen on CT.

The greatest disadvantage of CT is ionizing radiation. A CT of the abdomen exposes the patient to an average dose of 8 mSv of ionizing radiation. To place this in perspective, the average ionizing radiation dose associated with an abdominal x-ray is 0.7 mSv, and the average dose

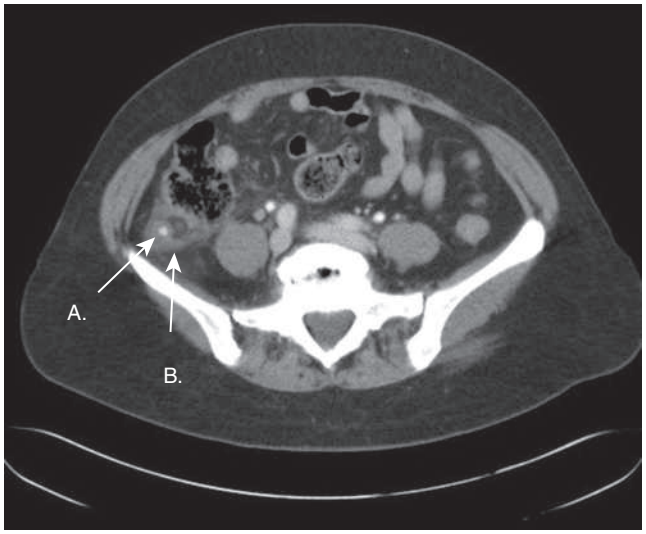

Fig. 79.4 CT scan of abdomen with typical findings of acute appendicitis (*Arrow A* = dilated appendix with wall thickening and central appendicolith, *Arrow B* = surrounding fat stranding indicating local inflammation).

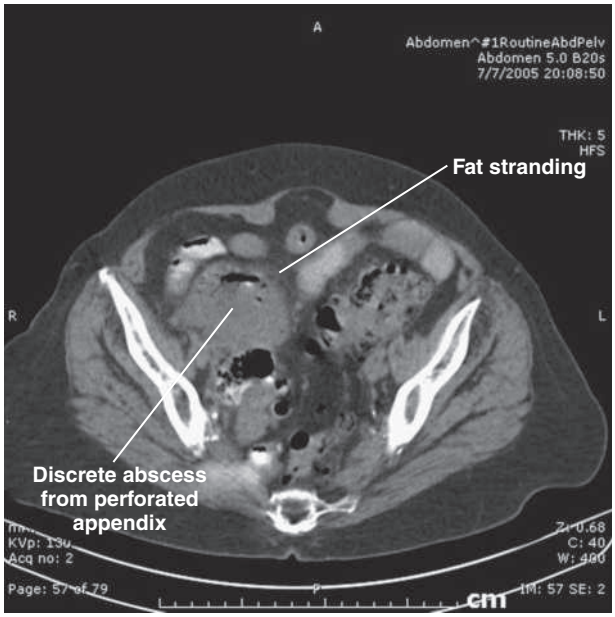

Fig. 79.5 CT scan showing discrete abscess from appendiceal perforation, with periappendiceal fat streaking. (Courtesy Jefferson Radiology, Avon, CT.)

associated with coronary angioplasty is 15 mSv. The risk of radiation-related cancers has led to the utilization of low-dose CT protocols for the diagnosis of appendicitis. Low-dose protocols decrease the average dose to approximately 2 mSv, with no detriment to the negative appendectomy rate. A diagnostic meta-analysis revealed no change in sensitivity and specificity between the standard and reduced-dose CT (96% and 94% respectively).[18]

CT findings of appendicitis include measurement of the highly variable appendiceal diameter (ranging 6–11 mm) and several others, as listed in Table 79.5. In some cases, the appendix cannot be visualized. In these cases, if CT demonstrates no findings of inflammation in the RLQ, appendicitis is unlikely. However, patients with a paucity of intra-abdominal fat may not display secondary signs of inflammation on CT, leading to false-negative results. The term *tip appendicitis* refers to obstruction and inflammation limited to the distal tip of the appendix and is a subtle finding on CT that frequently leads to a false-negative interpretation.

To assess for appendicitis, CT should be performed with IV contrast only. Enteric contrast of any type, oral or rectal, contributes little to the assessment of appendicitis. In addition, studies have demonstrated that non–contrast-enhanced CT has acceptable accuracy in diagnosing appendicitis. Furthermore, according to the American College of Radiology's appropriateness criteria for imaging suspected appendicitis, CT imaging with or without IV contrast are acceptable imaging modalities, with the use of enteric contrast deferred to institutional preference. Therefore, when IV contrast is contraindicated, non-contrast CT is generally sufficient to evaluate for appendicitis.[19]

Magnetic Resonance Imaging

Evidence supports the use of MRI to assess for appendicitis during pregnancy if US is nondiagnostic. MRI does not use ionizing radiation and is not operator dependent. However, its use is limited by cost, time required to acquire images, availability, and necessity for the radiologist or surgeon to be skilled in MRI interpretation.[20] A meta-analysis of MRI for acute appendicitis revealed a sensitivity of 94% and a specificity 97% for pregnant patients.[21] Table 79.5 lists the MRI criteria for the diagnosis of appendicitis.

In pregnant patients, IV gadolinium should not be used when evaluating for appendicitis due to potential harmful effects on the fetus. Enteric contrast may be used at the discretion of the interpreting radiologist or per institutional protocol.

Summary of Imaging Methods

Figure 79.6 illustrates a suggested imaging and management pathway for suspected acute appendicitis.

Nonpregnant Patients. Graded compression US may be considered first. In nonpregnant females, a pelvic US may also be considered to assess for pelvic pathology. The ability to visualize the appendix on US is operator dependent, and the provider's decision to use US may depend on the sonographer's level of experience with this examination.

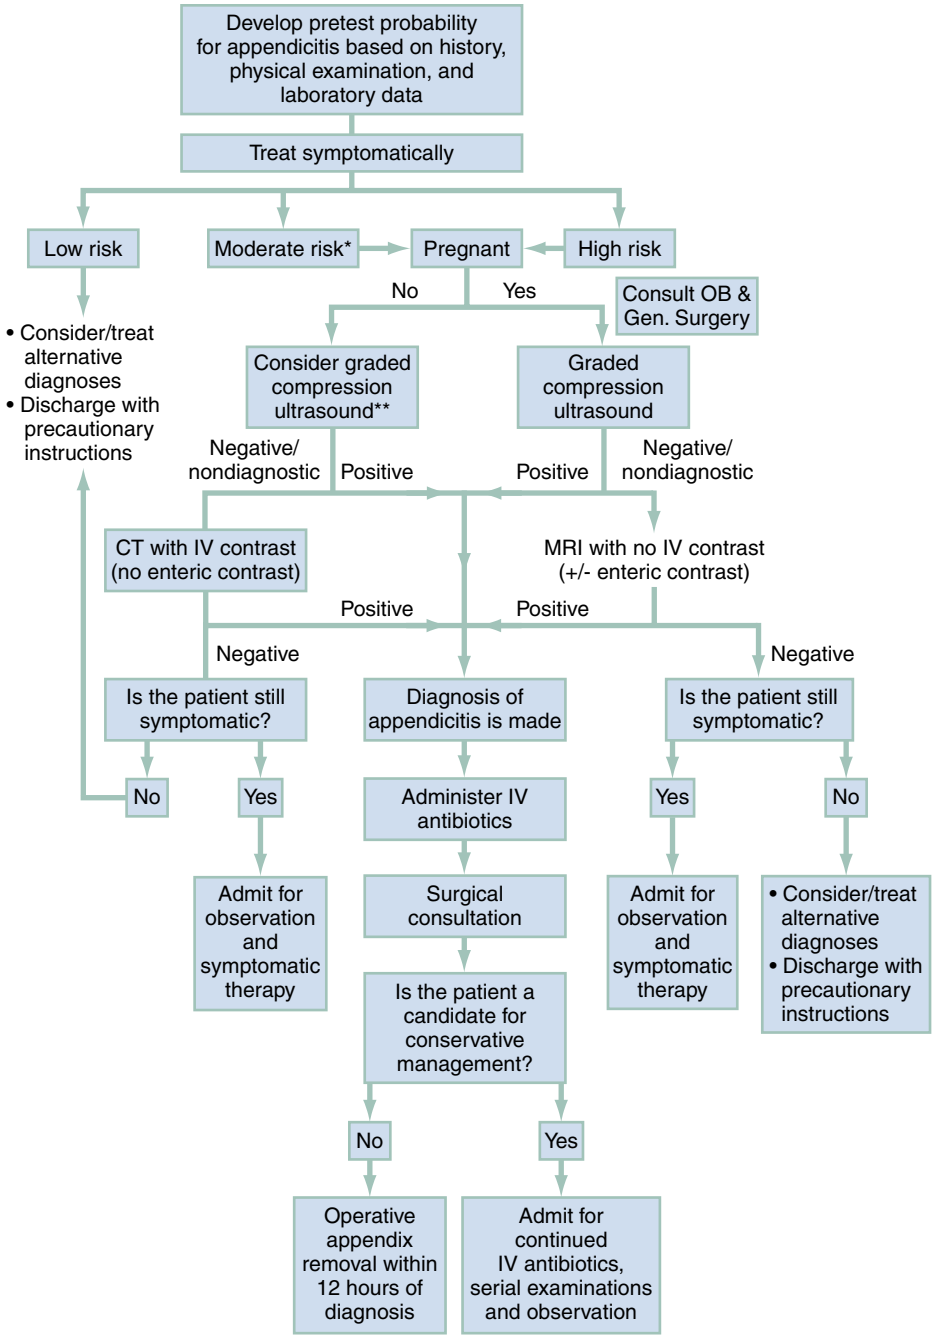
When US is negative or nondiagnostic (i.e., no appendix is visualized and no alternative pathology is noted) and clinical suspicion remains, the patient should undergo CT imaging of the abdomen and pelvis with IV contrast. An alternative to CT in low-risk cases with nondiagnostic US is admission for observation and serial examinations. Potential alternatives to CT in appropriately selected low-risk patients with a negative US include either continued ED observation or discharge with a planned reevaluation (e.g., in 6–12 hours).

Pregnant Patients. US should be the initial study of choice, followed by MRI of the abdomen without gadolinium in cases of nondiagnostic or negative US. If MRI is not available and transfer to a facility with MRI capabilities is not feasible, then, after consultation with appropriate specialists, including a radiologist, general surgeon, or obstetrician, abdominal CT with IV contrast may be indicated. However, in low-risk cases, admission for observation and serial examinations is an acceptable alternative with consultant support.

MANAGEMENT

Supportive Care

Once appendicitis is suspected, patients should be made NPO and supportive care should be initiated. Intravenous (IV) fluids, either normal saline or lactated Ringers, may be administered to maintain hydration. If necessary, pain should be treated with parenteral opiate analgesia (e.g., morphine sulfate 0.1 mg/kg IV), and nausea should be treated with parenteral antiemetics. Opiate analgesia does not limit abdominal examination for a potential surgical condition. Systemic signs of infection, which



*In moderate pretest probability patients, the provider may consider admission for serial examinations or discharge in select cases.

**In pediatric patients, graded compression ultrasound should always be the first imaging test performed.

Fig. 79.6 Suggested clinical management pathway for emergency department patients with possible appendicitis. *Gen.,* General; *OB,* obstetrician.

are more common in perforated appendicitis, should be treated with antipyretics and antibiotics as necessary. Acute uncomplicated appendicitis rarely causes severe sepsis or septic shock, however, such complications can arise with delayed presentation or diagnosis.

Antibiotic Therapy

Antibiotics should be administered upon diagnosis of appendicitis, or early in the management of septic patients with suspected appendicitis. Antibiotics should cover gram-negative aerobes, enteric gram-positive streptococci, and anaerobes. Pseudomonal coverage is not necessary for patients with mild to moderate disease severity and lack of health care–associated risk factors.

Acceptable antibiotic regimens for acute uncomplicated appendicitis include:

- Ertapenem 1g (adult) IV daily or 15 mg/kg (child, to max of 1g/day) IV twice daily,
- Piperacillin-tazobactam 3.375 g (adult) or 60–75 mg/kg of piperacillin (child, to max 3 g dose) IV every 6 hours, OR

- Ceftriaxone 1 g (adult) or 50–75 mg/kg (child, to max of 1 g) IV daily PLUS metronidazole 500 mg (adult) IV or 10 mg/kg (child, to max of 500 mg/dose) IV every 8 hours.

Patients with significant systemic illness, immunosuppression, or advanced age should receive imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, or metronidazole PLUS cefepime. Quinolone antibiotics were previously a mainstay in the management of acute appendicitis, but their side effects now make other comparatively lower-risk agents more appealing.

Definitive Treatment

Although management options for acute appendicitis have diversified significantly, surgical consultation remains vital. Although the final decision regarding operative management (OM) versus nonoperative management (NOM) is made between the patient and the surgeon, patients often ask emergency providers for insight and guidance; thus emergency providers should be educated on the indications for both treatment pathways.

Uncomplicated Appendicitis

Classically, the management of uncomplicated appendicitis (appendicitis without gangrene, phlegmon, abscess, or perforation) has involved either open or laparoscopic appendectomy. More recently, the possibility of in-hospital or outpatient antibiotic management has been explored.

Surgical appendectomy generally yields permanent resolution of appendicitis with little chance for recurrence. Multiple studies have demonstrated that delays of 12 to 24 hours between appendicitis diagnosis and OM are not associated with adverse outcomes.[22-25] Therefore, many surgeons will perform an appendectomy the following morning if a patient presents in the evening or overnight hours. Early appendectomy should be considered for elders, who are at high risk for developing appendiceal perforation after CT and before OM, with as many as 41% of patients 65 years or older developing perforation during this period.[22] Hospitalization for appendectomy is usually brief, with 87% of patients discharged on the day of, or day after, surgery.[26]

Despite its benefits, appendectomy puts patients at risk for intraoperative and postoperative complications. The overall complication rate of appendectomy ranges from 3% to 8%, with one study reporting serious complications (organ space infection, deep incisional infection, wound disruption, urinary tract infection, pneumonia, unplanned intubation, venous thromboembolism, acute renal insufficiency, septic shock, myocardial infarction, or cardiac arrest) in 2.2% of patients.[26-28] These complication rates markedly increase with age, reported as frequently as 13.7% in individuals 75 years or older.[28]

Although NOM spares patients the risks associated with surgery, there are other associated risks that need to be considered. Treatment failure and recurrent appendicitis, both of which are generally managed operatively, are realistic considerations for patients contemplating NOM. Treatment failure occurs in 2% to 6% of patients undergoing a trial of NOM.[29-32] The best known risk factor for treatment failure is the presence of a fecalith/appendicolith. Other risk factors for treatment failure and recurrence have been harder to elucidate. When NOM is successful, patients continue to remain at risk for recurrence. Approximately 25% of NOM patients require appendectomy during the first year after presentation, and approximately 40% receive appendectomy during the first five years.[29,30,33] Patients with recurrent appendicitis after initial NOM are not, however, at higher risk of developing complicated appendicitis.[30,34] Finally, when considering NOM, patients should be informed that 1% to 2% of appendicitis cases are associated with malignancy.[26,32,35-38] For this reason, guidelines recommend follow-up colonoscopy for patients over 40 years old treated with NOM.[39]

NOM may have both cost and quality-of-life benefits. Even when the costs of treatment failure and appendicitis recurrence after NOM are accounted for, the overall cost of OM is higher.[28,40,41] Additionally, NOM is associated with reduced pain and reduced disability when compared to OM.[40]

Once a patient is deemed appropriate for NOM and educated on the risks and benefits of this approach, many patients ultimately prefer a trial NOM over OM. In one study, 55 of 60 patients offered a choice between NOM and OM chose NOM.[34]

NOM has also been explored in children. As with adults, NOM in children has risks of treatment failure and recurrence, but the frequency of these events is not as well defined.[42-46] As in adult populations, presence of fecalith/appendicolith puts children at higher risk for failed NOM.[43] Children undergoing NOM have fewer days of disability but it is unclear whether overall costs are reduced with NOM, because these children are more likely to undergo advanced imaging, have more ED visits, and have more hospitalizations than children treated initially with OM.[45,47,48] One study showed that approximately 40% of caregivers would select NOM for their child after an explanation of the risks and benefits of OM and NOM.[49]

Previously, NOM required multiday hospitalization, however, recent research has demonstrated the potential for outpatient management. A small study determined that discharge from the ED was possible for patients meeting the following criteria:

- Age 14 years or older
- Systolic blood pressure > 90 mm Hg
- Heart rate < 100 beats per minute
- Temperature < 38.5°C
- Pain controlled by oral analgesics
- Tolerating oral fluids and medication
- Able to return for further evaluation
- Treating physician comfortable with discharge
- Patient comfortable with discharge

In this study, 14 out of 15 patients receiving NOM were eligible for outpatient management. Per protocol, enrolled patients were given 1 g of ertapenem IV in the ED and discharged with a planned next-day ED reevaluation. Patients who continued to do well at reevaluation were given an additional 1 g ertapenem IV and discharged with eight days of oral antibiotics (cefdinir 300 mg twice daily and metronidazole 500 mg every 8 hr). No NOM patients had treatment failure. Two of the 15 NOM patients later developed recurrent appendicitis, one having uncomplicated appendicitis and one having appendicitis with phlegmon.[40] Although these initial results are promising, outpatient treatment of appendicitis is not yet widely utilized and further data are needed. Studies have not evaluated outpatient NOM in children.

Finally, the evaluation and management of suspected appendicitis in pregnancy warrants special consideration. Because progression to complicated appendicitis is more common in pregnancy, diagnosis and management should be expedited as much as possible. Establishing a definitive diagnosis of appendicitis is crucial given that the risk of fetal loss with a negative appendectomy is 4% and the risk of premature labor is 11%.[50]

OM remains the generally preferred approach to appendicitis during pregnancy due to the risks associated with disease progression and the inability to predict which patients will fail NOM. When pregnant patients develop peritonitis from appendicitis, the risk of fetal loss increases from 2% to 6%, and the risk of premature labor increases from 4% to 11%.[50] One-third of pregnant appendicitis patients will develop perforation, with reported fetal loss rates of 24% to 36%.[50] Because of the increased risks associated with appendicitis

in pregnancy, emergency providers should strongly consider obstetrical consultation.

Complicated Appendicitis

Management of complicated appendicitis in both adults and children is rife with challenges. Surgical management may be high risk, but an antibiotics-only approach is often insufficient and is associated with longer hospitalization.[51,52] Interventional radiology may play an important role in the management of associated abscess. Complicated appendicitis generally requires hospitalization with surgical consultation and, when indicated, interventional radiology consultation.

DISPOSITION

There are three likely disposition pathways when a diagnosis of uncomplicated appendicitis is considered.

1. When a diagnosis of appendicitis is made based on imaging or, rarely, clinical assessment alone, IV antibiotics should be initiated, surgical consultation should be obtained, and the patient should be admitted for operative intervention or IV antibiotics and serial exams. In select cases, after surgical evaluation and a risk-benefit discussion, a reliable patient who (1) prefers outpatient management, (2) has a benign examination, (3) has no fecalith/appendicolith on imaging, and (4) has planned follow-up within 24 hours, can be discharged with oral antibiotics and strict return precautions.
2. When a diagnosis of appendicitis is considered, but the pretest probability is low based on clinical and laboratory assessment, a reliable patient may be discharged home if he or she has clinically improved, understands the concept of diagnostic uncertainty, and can follow strict return precautions. If these criteria are not met, advanced imaging or continued observation may be warranted. Alternative diagnoses should be considered as indicated.
3. When imaging results are inconclusive, or when imaging results are negative but posttest probability remains high (e.g., the patient is still symptomatic or has a concerning exam), the patient may be admitted for observation, symptomatic treatment, and serial examinations. If imaging is inconclusive but the overall suspicion for appendicitis is low and the patient is reliable, a reasonable approach includes discharge with close follow-up and strict return precautions after a shared decision-making discussion. Alternative diagnoses should also be considered.

CHAPTER 79: QUESTIONS AND ANSWERS

1. What percentage of women with acute appendicitis have accompanying cervical motion tenderness (CMT)?

a. <5%
b. 15%
c. 25%
d. 50%
e. 75%

Answer: c. Prior to the advent of routine imaging of the appendix, as many as 25% of women with acute appendicitis were initially misdiagnosed because of the presence of CMT.

2. Which of the following statements regarding ultrasonographic visualization of the appendix is true?

a. A compressible appendix is a positive finding.
b. An appendiceal diameter greater than 6 or 7 mm is a positive finding.
c. The sensitivity of ultrasound for appendicitis is 94% to 98%.
d. Ultrasonography has good reliability for detecting a retrocecal appendix.
e. Ultrasonography compares favorably with computed tomography (CT) scanning for the detection of appendicitis.

Answer: b. A noncompressible appendix with a diameter greater than 6 or 7 mm in a setting of clinical features of appendicitis is considered a positive finding. Ultrasound sensitivities are 75% to 90%. It is a less useful modality in the obese, those with peritoneal adhesions, or those with a retrocecal appendix. The sensitivity of CT is much higher than ultrasonography.

3. A 27-year-old G3P2 woman at 22 weeks of gestation presents with 2 days of right lower quadrant (RLQ) abdominal pain. It began midline and later became more pronounced in the RLQ. The physical examination is remarkable for RLQ tenderness without rebound. The gynecologic examination is negative except for a nontender gravid uterus, with good fetal movement by transabdominal ultrasound. Urinalysis shows 8 to 10 white blood cells (WBCs)/high-power field (HPF) and occasional bacteria. Complete blood count (CBC) shows a WBC count of 12,700/mm^3 with 77% neutrophils. Hemoglobin level is 11 g/dL. RLQ ultrasound examination is limited, without visualization of the appendix or secondary signs of appendicitis. Transvaginal ultrasound does not show a gynecologic or obstetric problem. Repeat examination shows continued RLQ tenderness. What is the most appropriate intervention at this point?

a. Administer cephalexin for urinary tract infection and schedule a 48-hour clinic recheck
b. Admit for observation and serial examination
c. Obtain surgical consultation for laparotomy
d. Order a CT scan of the abdomen.
e. Order a magnetic resonance imaging (MRI) scan

Answer: e. MRI for appendicitis is helpful in pregnant women, and radiation exposure should be minimized. Exploratory surgery carries significant risk of premature labor and fetal loss.

4. In young patients with classic symptoms and signs of appendicitis, what is the most appropriate initial intervention?

a. Antibiotics and serial abdominal examinations
b. CT scan of the abdomen
c. MRI scan of the abdomen
d. Surgery
e. Ultrasonography

Answer: e. Ultrasound is the most appropriate initial intervention because it uses no radiation and can often visualize and diagnose appendicitis without significant delay. It has become less common for a patient with a history and examination concerning for appendicitis to undergo surgery without imaging, and the use of advanced imaging has dramatically decreased the negative appendectomy rate. Graded compression ultrasound for appendicitis is specific but lacks the sensitivity of CT, so if clinical suspicion persists after a negative or nondiagnostic ultrasound, CT (or MRI in pregnant patients) is often the best next step.

Gastroenteritis

Thomas Nguyen and Saadia Akhtar

KEY CONCEPTS

- Gastroenteritis is usually self-limited and requires supportive care only. Routine laboratory testing or stool cultures are not indicated for most patients.
- Patients with gastroenteritis associated with fever, dysentery, bloody stools, severe dehydration, sepsis, a suspicion for *Clostridium difficile,* or an immunocompromised state should generally have a complete blood count, electrolytes, and stool cultures evaluated.
- Caution should be used in the care of the very young and elders with gastroenteritis, because these populations have the highest morbidity and mortality.
- Evaluate all individuals with gastroenteritis for dehydration. Use of oral rehydration therapy (ORT) with hypotonic oral rehydration solution (e.g., World Health Organization [WHO]-modified 245 mOsm ORT solution) is recommended.
- The use of antiemetic medications in patients with gastroenteritis may help with ORT. Ondansetron 0.15 mg/kg up to 8 mg given orally (PO) or intravenously is safe and cost effective.
- Early continuation of normal feeding is advised, and continuation of breastfeeding in mothers with gastroenteritis is suggested, if possible.
- *Campylobacter* and *Salmonella* are the top two causes of culture-proven bacterial enteritis in developed countries. Consult health authorities for local or regional outbreaks and pathogen prevalence.
- Norovirus, previously referred to as the Norwalk-like virus, is the most common cause of acute gastroenteritis in children and adults.
- Bacterial pathogens are responsible for approximately 80% of all cases of traveler's diarrhea, which is usually self-limited. Enterotoxigenic *Escherichia coli* (ETEC) is the most common etiology.
- Antibiotic treatments can prolong the shedding of *Salmonella* non-*typhi* organisms and therefore are not indicated in most gastrointestinal infections.
- Avoid antibiotic treatment in patients with gastroenteritis caused by *E. coli* O157:H7 or Shiga toxin 2–producing organisms as treatment increases the incidence of hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP).
- In patients with fever or bloody stools, if antimotility agents are to be given, they should be administered in combination with an antibiotic as these agents may increase the contact time of the toxin or invasive infectious organism within the intestinal mucosa.
- Classic food poisoning usually manifests 1–6 h post ingestion of preformed toxins from bacterial organisms such as *Staphylococcus, Bacillus cereus*, or *Clostridium perfringens*. Food poisoning is generally short-lived (24 h), and the treatment is typically supportive care only.
- Risk factors for *C. difficile* colitis include recent antibiotic use (1–4 weeks), recent hospitalization, living in a long-term care facility, solid organ transplant recipients, or the use of antacids.
- Evaluation with abdominal computerized tomography (CT) for toxic megacolon and pseudomembranous colitis is recommended for patients with *C. difficile* colitis who are older, appear septic, have a tender distended abdomen, or have a high leukocytosis. Consider empirical antibiotic treatment with vancomycin 125 mg PO every 8 h for 10 days for suspected *C. difficile.*
- Scombroid poisoning results from eating spoiled dark meat fish; scombroid poisoning is not an allergic reaction but results from ingestion of histamine.
- In addition to the regular enteropathic bacterial pathogens, human immunodeficiency virus (HIV)-positive patients, particularly those with a CD4+ count less than 200/mm^3, have increased susceptibility to certain viruses and parasites, such as *Cytomegalovirus, Cyclospora, Cryptosporidium, Isospora, Mycobacterium avium-intracellulare* complex, and *Giardia.*
- Consider *Giardia* for diarrhea lasting more than 2 weeks, with foul-smelling stools and symptoms of flatulence, abdominal bloating, cramping, and recent exposure to contaminated river water.
- Hand hygiene with soap and water or hand sanitizers will contain the spread of most infectious agents in gastroenteritis.

OVERVIEW

Foundations

Background and Importance

Gastroenteritis is an acute diarrheal infection of the gastrointestinal (GI) tract and is generally a self-limited illness. Most patients have nausea, vomiting, and diarrhea, often with diarrhea being the predominant symptom. Diarrhea is defined as the passage of three or more unformed liquid stools a day, stools of more than 250 g/day, or stool that takes the form of the container into which it is placed.[1] Dysentery refers to an inflammation of the intestine, particularly the colon, causing diarrhea associated with blood and mucus; it is generally associated with fever, abdominal pain, and rectal tenesmus (the sensation of incomplete defecation).

Gastroenteritis is one of the leading causes of morbidity and mortality worldwide, especially in children. Approximately 180 million cases of acute diarrhea occur each year in the United States, most of which are self-limited and without consequence. The incidence has been increasing due to heightened international travel, mass production of foods, and the increased consumption of raw produce, such as spinach or fresh fruits. Viruses account for most of the infectious causes.[2]

Diarrhea-related deaths in developed countries occur most often in elders or debilitated patients; *Clostridium difficile* and norovirus are most frequently implicated. Patients with *C. difficile*, human immunodeficiency virus (HIV) infection, immunocompromised-related enteritis, or fever and bloody stools require early diagnosis and treatment to maximize optimal outcomes. Diagnostic testing should be reserved for cases with a high suspicion for specific pathogens that cause more

severe clinical illness or cases occurring during an outbreak. Clinicians may play an important role in the surveillance and mitigate the spread of infection.

Diarrheal illnesses can be classified as being acute (<7 days), prolonged (7 to 13 days), persistent (14 to 29 days), or chronic (>30 days). Acute and prolonged gastroenteritis (13 or fewer days) are usually due to viral or bacterial causes. Persistent and chronic gastroenteritis (>13 days) is often caused by protozoans, parasites, or noninfectious conditions.[3,4]

Pathophysiology

The pathophysiology of an infection related to gastroenteritis involves one of four mechanisms—ingestion of preformed toxins, adherence of the infectious pathogens to the intestinal cell walls, invasion of mucosal cell walls, and production of enterotoxins and cytotoxins. Each mechanism leads to an increase in fluid secretion or a decrease in fluid absorption in the GI tract, resulting in diarrhea.

CLINICAL FEATURES

Patient History

The history of present illness should take into account epidemiologic factors that may help to identify the likely organism (Table 80.1). For example, travel outside of the United States to resource-poor countries raises suspicion for traveler's diarrhea, contact with persons on a cruise ship with a large GI outbreak is suspicious for norovirus, a recent camping trip with exposure to river water suggests giardiasis, and recent hospitalization or antibiotic use and patients in long-term care facilities are risk factors for *C. difficile* infection.

Associated factors are helpful in narrowing the list of possible causative organisms and in initiating treatments. For example, GI symptoms after a short exposure period (1 to 6 hours) may imply preformed toxins from Staphylococcal or *Bacillus* organisms. Diarrhea lasting more than 2 weeks may indicate the presence of *Giardia* or other protozoa, although noninfectious causes should be considered, such as inflammatory bowel disease (IBD). Norovirus classically causes a sudden onset of severe vomiting and only moderate diarrhea. Large-volume diarrhea usually indicates small bowel involvement, such as viral gastroenteritis or illness due to *Vibrio cholerae*. Colonic involvement causes smaller volume loss and more likely will be bloody or have fecal leukocytes from invasive organisms. A history of fever, abdominal pain, tenesmus, and bloody stools are signs of dysentery and may imply invasive organisms such as *Campylobacter* or *Shigella*. *Yersinia enterocolitica* GI infection may mimic acute appendicitis or regional enterocolitis due to its invasion of the local mesenteric lymph nodes. Vomiting without diarrhea generally should not be referred to as gastroenteritis. Alternative abdominal pathology such as appendicitis, cholecystitis, pancreatitis, or bowel obstruction should also be considered. Patients with lightheadedness or hypotension are likely to be dehydrated from diarrhea and vomiting. Muscle cramping may imply hypokalemia or hyponatremia from lack of oral intake or loss of electrolytes in diarrhea.

TABLE 80.1 Gastroenteritis: Epidemiologic Factors

Factor	Implications
Foreign travel	Traveler's diarrhea—enterotoxigenic *Escherichia coli* Southeast Asia—*Vibrio, Campylobacter* species South America, Asia, Africa—Rotavirus
Recent camping	*Giardia, Aeromonas, Cryptosporidium*
Recent antibiotics	Increase in *Clostridium difficile* infection
Daycare exposure	Rotavirus, Norovirus
Exposure to raw seafood	Noncholera *Vibrio*
Anal-receptive sex—men who have sex with men	*Shigella, Campylobacter, Salmonella, Entamoeba*
Human immunodeficiency virus (HIV)-positive status	*Mycobacterium avium-intracellulare* complex, microsporidia. cytomegalovirus, *Giardia, Salmonella, C. difficile, Shigella*
Outbreaks	Cruise ships—norovirus Contaminated local water, food, products, restaurants; organism usually identified by local health department (e.g., *Campylobacter, Salmonella, E. coli*)

Physical Examination

The physical examination focuses on the patient's general hydration status and assesses for life-threatening conditions. In the clinical setting of gastroenteritis, hypotension, and tachycardia likely indicate dehydration. Fever, altered mental status, or a toxic appearance may signify severe illness and possibly sepsis. Other disease states may mimic gastroenteritis, and a thorough examination is warranted.

Evaluation of the skin for the presence of petechiae or purpura, especially in the extremities, can suggest possible sepsis or disseminated intravascular coagulation (DIC). Dry mucous membranes, decreased skin turgor, or decreased urine output may also help to gauge hydration status. In children, weak pulses or sunken eyes are also good predictors of dehydration.[5] The abdominal examination focuses on conditions that may mimic gastroenteritis, such as small bowel obstruction (SBO), bowel ischemia, appendicitis, or colitis. In general, bowel sounds are hyperactive in acute gastroenteritis, although this may also be seen with intestinal obstruction. Abdominal findings such as focal tenderness, rebound, guarding, distention, or rigidity suggest a surgical process. A digital rectal examination can be performed to assess for gross blood, mucus, rectal lesions in the setting of blood or mucus in the stool, or complaints of rectal pain.

Differential Diagnoses

Other diagnoses to consider in patients with apparent gastroenteritis include SBO, diverticulitis, IBD, ischemic bowel disease, appendicitis, pancreatitis, hepatobiliary pathology, malabsorption, celiac disease, or irritable bowel syndrome.

An SBO is likely in the setting of recent abdominal surgery, crampy abdominal pain and vomiting, a distended and tender abdomen, and lack of passage of gas or stools. In diverticulitis, pain is generally localized to the left lower abdomen. IBD usually first presents in the young adult as recurrent diarrhea, with cramping. The stool may contain mucus or blood. Risk factors include obesity, smoking, and a family history of IBD, with the highest risk in females and Jewish persons of European ancestry. Patients with ischemic bowel may present with abdominal pain and tenderness, ranging from mild to severe with associated peritoneal signs. Risk factors include older age, low-flow states such as dehydration, recent congestive heart failure exacerbation, sepsis, smoking, atherosclerotic disease, or being at risk for thromboembolic events such as atrial fibrillation. Patients with gastroenteritis are generally not critically ill, and deterioration is not as rapid as seen in those with ischemic bowel disease.

Viruses account for up to 70% of cases of infectious gastroenteritis, bacteria 15% to 20%, and parasite approximately 10% to 15%. On initial presentation, it is often difficult to identify the exact organism causing the GI illness. The predominance of vomiting, along with upper respiratory symptoms, is more likely associated with a viral cause. Rapid onset of vomiting as the predominant symptom may suggest the presence of preformed bacterial toxins. The presence of high fever, fecal blood, abdominal pain, or colitis likely indicates an invasive bacterial organism.[3]

Diagnostic Testing

Diagnostic testing is guided by the clinical assessment. Routine laboratory tests are not needed in many cases. However, further evaluation may be required for patients presenting with severe illness or severe dehydration. A complete blood count (CBC) and serum metabolic profile should be considered for patients with high fevers, severe abdominal pain, bloody stools, or persistent diarrhea. Particular attention should be given to elders with abdominal pain as well as immunocompromised patients. For most cases of gastroenteritis, if the patient appears well and is likely to have a self-limited illness, stool cultures are not required. Stool cultures for *Salmonella, Shigella, Campylobacter, Yersinia,* Shiga toxin–producing *Escherichia coli* (STEC), and *C. difficile* may be considered for patients with severe illness, fever of 38.5°C (101°F) or higher, dysentery, immunocompromised state, recent hospitalization, or recent antibiotic use. With preliminary culture results, targeted antimicrobial treatment may be initiated to prevent the spread of infection (e.g., in an outbreak of daycare workers) and reduce the duration of symptoms. If diarrhea is persistent, stools for ova and parasite should be sent.[4] Stools sent for fecal leukocytes, lactoferrin, or hemoccult testing may help identify colonic inflammation with an invasive organism. Blood cultures should be considered in infants younger than 3 months of age, people of any age with signs of septicemia, those with suspicion for enteric fever, individuals with systemic manifestations of infection, immunocompromised states, high-risk conditions such as hemolytic anemia, or individuals who have traveled to or have had contact with travelers from enteric fever–endemic areas with a febrile illness of unknown etiology.[3] Tables 80.2, 80.3, and 80.4 summarize specific diagnostic testing and treatment for bacterial, viral, and parasitic infections, respectively.

Management

Patients who are severely dehydrated should receive an intravenous (IV) fluid bolus of an isotonic solution, such as lactated Ringers (LR). Electrolytes should be repleted, with particular attention to the sodium and potassium levels. Antiemetics can prevent ongoing loss of fluids and help with the initiation of oral rehydration therapy (ORT).

The exact cause of vomiting in gastroenteritis is not known, although it is thought to be due to peripheral stimuli arising from the GI tract primarily via the vagus nerve or by serotonin stimulation of the 5-hydroxytryptamine 3 (5-HT_3) receptors in the intestinal tract. These signals are transmitted to the emetic center in the brainstem that stimulates the muscles in the diaphragm, abdominal wall, and intestinal tract to produce vomiting.[6] Ondansetron 0.15 mg/kg up to 8 mg orally (PO) or IV is safe and potentially cost-effective due to its impact in decreasing IV fluid therapy needs and hospitalization rates in the pediatric population. Side effects of ondansetron include headache or diarrhea.[7]

The American Academy of Pediatrics (AAP), Centers for Disease Control and Prevention (CDC), European Society for Pediatric Gastroenterology and Nutrition (ESPGHAN), and World Health Organization (WHO) all strongly support the use of ORT as first line treatment for

TABLE 80.2 Bacterial Gastroenteritis: Diagnosis and Treatment

Organism	Diagnosis	Treatment
Shigella	Stool culture (conventional)	Ciprofloxacin 500 mg PO bid for 3 days; or azithromycin 500 mg PO daily for 3 days
Salmonella enteritidis Nontyphoid	Stool culture (conventional); PCR	No treatment in nonsevere cases. For severe cases (fever, bloody diarrhea, bacteremia)—levofloxacin 500 mg IV or PO daily for 7–10 days
Salmonella typhi Typhoid	Stool culture (conventional)	Ciprofloxacin 500 mg PO bid for 7 days; or azithromycin 500 mg PO daily for 7 days; IV ceftriaxone, 1–2 g daily for 7 days
Campylobacter jejuni	Stool culture (conventional)	Azithromycin 500 mg PO daily for 3 days; or erythromycin 500 PO mg bid for 5 days
Vibrio cholerae	Stool culture with salt-containing media- TCBS	Doxycycline PO, 4 to 6 mg/kg, up to 300 mg, once daily for 3 days
Vibrio—noncholera *(Vibrio parahaemolyticus)*	Stool culture with TCBS	Ciprofloxacin 500 mg PO bid for 3 days; or azithromycin 500 mg PO daily for 3 days
Enterotoxigenic *Escherichia coli* (ETEC)	Stool culture; assay for toxin	Ciprofloxacin 750 mg PO once or 500 mg PO bid for 3 days, rifaximin 200 mg PO tid for 3 days; azithromycin 1 g PO once
Shiga toxin–producing *E. coli; E. coli* O157:H7	Sorbitol MacConkey and serotyping for O157:H7; PCR	No treatment, supportive care only; antibiotics increase risk for HUS
Yersinia enterocolitica	Cefsulodin-irgasan-novobiocin (CIN) agar	Supportive care; in severe cases, TMP-SMX (160 mg/800 mg) 1 Tab PO bid for 3 days, ciprofloxacin 500 mg PO bid for 3 days
Clostridium difficile	Stool for *C. difficile* toxin; PCR	Vancomycin 125 mg PO qid for 10 days or fidaxomicin 200 mg PO bid for 10 days. Alternative: metronidazole 500 mg PO tid for 10 days
Staphylococcus aureus	Food may be cultured for *Staphylococcus*, though not routine	Supportive care
Clostridium perfringens	Detection of spores in stool; PCR	Supportive care
Bacillus cereus	Food may be cultured, though not routine	Supportive care; for severe cases—vancomycin 125 mg PO qid; or clindamycin 500 mg PO tid for 7–10 days

HUS, Hemolytic uremic syndrome; *PCR,* polymerase chain reaction; *TCBS,* thiosulfate, citrate, bile salts, and sucrose; *TMP-SMX,* trimethoprim-sulfamethoxazole.

TABLE 80.3 Viral Gastroenteritis: Diagnosis and Treatment

Organism	Diagnosis	Treatment
Norovirus	Stool sample—real-time reverse transcription–polymerase chain reaction (RT-PCR) assay	Supportive care
Sapovirus	PCR, immunoassay	Supportive care
Rotavirus	Rotavirus antigen in stool sample	Supportive care; vaccine or natural infection do not uniformly provide immunity; vaccine alternatives include RotaTeq (RV5), given in three PO doses at ages 2, 4, and 6 months; *or* Rotarix (RV1), given in two PO doses at ages 2 and 4 months; *or* Rotavac, given in three PO doses 4 weeks apart, beginning at 6 weeks of age; *or* Rotasil, given in three PO doses 4 weeks apart, beginning at 6 weeks of age
Adenovirus	Antigen detection, PCR, virus isolation, serology	Supportive care
Astrovirus	PCR, electron microscopy, immunoassay	Supportive care

TABLE 80.4 Parasitic Intestinal Infections: Diagnosis and Treatment

Organism	Diagnosis	Treatment
Giardia lamblia	Stool microscopy for ova and parasite; immunoassay	Tinidazole 2 g PO single dose Metronidazole 500 mg PO bid or 250 mg tid for 5–7 days Nitazoxanide 500 mg PO bid for 3 days *Alternative agents* Albendazole 400 mg PO once daily for 5 days Mebendazole 200 mg PO tid for 5 days Quinacrine 100 mg PO tid for 5 days Paromomycin 10 mg/kg PO tid day for 5–10 days
Entamoeba histolytica	Stool microscopy, culture, immunoassay	Metronidazole 500–750 mg PO tid for 7–10 days; Tinidazole 2 g PO once a day for 3–5 days; Nitazoxanide 500 mg PO bid for 3 days *Intraluminal infection* Paromomycin 25–35 mg/kg PO divided tid for 7 days. Iodoquinol 650 mg PO tid for 20 days for adults Diloxanide furoate 500 mg PO tid for 10 days for adults
Cryptosporidium	Stool microscopy, culture, immunoassay	Nitazoxanide 500 mg PO bid for 3 days
Cyclospora cayetanensis	Stool microscopy, stool culture, acid-fast stain, fluorescence microscopy	Trimethoprim-sulfamethoxazole (TMP-SMX), one double-strength 160/800 mg tablet PO bid for 7–10 days

acute gastroenteritis, except in cases of severe dehydration. Although ORT has been extensively studied in children, the results can generally be applied to adults. It is known to be safe and effective as the treatment of choice for mild and moderate dehydration. Morbidity and mortality can be greatly reduced with the use of ORT. It is also associated with fewer major adverse events and results in shorter hospital stays.

Fluids containing glucose and electrolytes provide optimal rehydration due to the cotransport of the water across the intestinal lumen. Choices of oral rehydration solution (ORS) include the standard WHO ORS (331 mOsm/kg), reduced osmolarity WHO ORS (245 mOsm/kg), and Pedialyte (oral electrolyte solution for children; 250 mOsm/kg). Reduced osmolarity rehydration solution is associated with a reduced need for unscheduled IV infusions, lower stool volume, and less vomiting compared with a standard WHO rehydration solution. Simple home remedies, such as diluted fruit drinks and chicken broth, or commercial solutions such as Gatorade will also suffice.[1]

The official recommendation by ESPGHAN is to hydrate orally with reduced osmolarity or hypotonic fluids. Oral intake of food, if tolerated, should be continued during the illness, as fasting may worsen the capacity of the bowel to absorb fluid. The presence of food in the bowel lumen also promotes mucosal recovery and improves fluid absorption.[8]

Zinc 20 mg PO given to moderately to severely malnourished children older than 6 months has been shown to decrease the duration of diarrhea by approximately a day. The side effects of zinc are vomiting and a metallic taste.[3,9]

Antimotility drugs such as loperamide (Imodium) and diphenoxylate hydrochloride (Lomotil) can help to limit the number of watery stools and prevent dehydration. The initial dose of loperamide is 4 mg PO, followed by 2 mg after each unformed stool, up to a maximum of 16 mg/day for 48 hours. Loperamide is generally not recommended for patients younger than 18 years of age due to a high incidence of abdominal distension, ileus, lethargy, or death (in children younger than 3 years old). In patients with suspected bacterial dysentery, it is recommended that if antimotility agents are to be administered, it should be done in conjunction with antibiotics, as antimotility agents may serve to increase the contact time with the toxins or invasive organisms.[1,3]

In general, antibiotics are not indicated for the treatment of the vast majority of cases of acute gastroenteritis. However, empirical antibiotic therapy can be considered in patients who appear toxic, have a fever, or have dysentery (see discussion later); in patients with severe traveler's diarrhea; patients with suspected *C. difficile* colitis; in patients who are

immunocompromised; or when a known organism has been isolated from a community outbreak. The recommendation for empiric antibiotic treatment is azithromycin 500 mg daily PO for up to 3 days or ciprofloxacin 500 mg PO bid for up to 3–5 days, pending culture results. Tables 80.2 and 80.4 summarize recommended antibiotics for treating various bacterial and parasitic infections, respectively.

Disposition

Most patients with gastroenteritis can be managed on an outpatient basis. Written instructions should be given with recommendations for oral fluid intake, diet, and follow-up care. Hospitalization should be considered for patients with a toxic appearance, severe or persistent symptoms, inability to tolerate oral liquids, significant electrolyte abnormalities, or severe dehydration. Special consideration should be given to patients at the extremes of age or who are immunocompromised. These patients may require more extensive evaluation and further care.

BACTERIAL GASTROENTERITIS

In the United States, foodborne diarrheal illness caused by bacteria has increased over the past decades. The four most commonly reported bacterial pathogens are nontyphoid *Salmonella, Campylobacter*, STEC, and *Shigella*.[10] The cause of most diarrheal illness is rarely identified. Most laboratories are equipped to culture only the common pathogens, and routine stool cultures for diagnostic testing often miss organisms such as enterotoxigenic *E. coli* (ETEC), enteroaggregative *E. coli* (EAEC), enteroinvasive *E. coli,* and noncholera *Vibrio* spp.

There are several risk factors that influence the development of bacterial gastroenteritis. Very young patients have low immunity, and passive maternal immunity is lost after weaning from breastfeeding. Elders are at risk due to the age-related intestinal mucosal alteration of mucosa production, gut flora, and cell surface receptor affinity for toxins. The use of antacids, such as proton pump inhibitors, decreases the bactericidal effect of gastric acid. Antibiotic use reduces healthy intestinal flora and therefore increases the colonization of pathogens such as *C. difficile*. Immunosuppressed patients such as those with HIV disease or undergoing treatment with chemotherapeutic agents are predisposed to nontyphoid *Salmonella*. Poor sanitation and overcrowded conditions also enhance the spread of infectious organisms.

Bacterial organisms are broadly categorized as invasive or noninvasive. Invasive gastroenteritis is a clinical diagnosis made in the presence of signs or symptoms of intestinal mucosal invasion, such as fever, gross or occult blood in the stool, tenesmus (feeling of constantly needing to pass stool), or severe abdominal pain (Table 80.5). Patients with noninvasive gastroenteritis generally do not exhibit fever, produce bloody stools, or experience significant abdominal pain. Noninvasive gastroenteritis likely suggests the presence of a viral pathogen or toxin-producing bacteria. This illness typically is brief and self-limited, and diagnostic testing is unlikely to be of benefit (Table 80.6).

INVASIVE BACTERIA

Campylobacter Enteritis

Epidemiology

Campylobacter is the most commonly diagnosed cause of bacterial enteritis in developed countries. It is more common during the summer months. *Campylobacter* species are a common cause of so-called backpacker's diarrhea, along with *Giardia*, both of which are frequently acquired by drinking water from wilderness sources.

TABLE 80.5 Invasive Bacteria Gastroenteritis: Causes and Clinical Features

Organism	Clinical Features	Incubation Period (I), Duration (D), Source (S)
Campylobacter jejuni	Most common bacteria; organism identified in stool cultures; acute watery diarrhea, fevers, dysenteric characteristics	I, 2–5 days D, 5–14 days S, food, water, chickens
Salmonella Nontyphoid	Usually foodborne (e.g., poultry); acute watery diarrhea, often with fever; common in sickle cell and immunocompromised patients	I, 12–24 h D, 2–7 days S, eggs, poultry, unpasteurized milk, pets
Salmonella Typhoid	Fever, abdominal pain, ileus, systemic effects; most infections acquired during international travel	I, 12–24 h D, 2–7 days S, food, person to person
Shigella	Common worldwide; acute watery diarrhea, fever, dysenteric characteristics; toxigenic; high incidence in men who have sex with men	I, 1–2 days D,2–7 days S, water, person to person
Yersinia enterocolitica	Acute diarrhea, dehydration; rare in the United States but common with travel to Asia; can mimic appendicitis	I, 12–48 h D, 5–14 days S, food, water, milk, cats, dogs, pigs
Vibrio, noncholera *(V. parahaemolyticus)*	Associated with seafood, shellfish; watery diarrhea, dysentery	I, 8–24 h D, 5–14 days S, raw, undercooked seafood
Escherichia coli Shiga toxin-producing; *E. coli* O157:H7	Watery, bloody diarrhea; foodborne—contaminated beef or produce; toxigenic; associated with HUS and TTP	I, 3–8 days D, 5–10 days S, uncooked beef, water, person to person, raw milk

HUS, Hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura.

Pathophysiology

Campylobacter organisms are small, spiral-shaped, gram-negative bacteria. The most common species isolated is *Campylobacter jejuni. Campylobacter* species produce disease primarily by direct invasion of the colonic epithelium. Most infections are acquired by ingesting tainted drinking water, dairy products, meats, or produce. The primary reservoirs for *Campylobacter* organisms are chickens.[11]

Clinical Features

The incubation period for *Campylobacter* is approximately 2 to 5 days. Disease onset usually is rapid, with signs and symptoms of fever, cramping abdominal pain, and diarrhea 24 to 48 hours later. Constitutional symptoms of anorexia, malaise, myalgias, or headache are common.

TABLE 80.6 Noninvasive Toxigenic Bacterial Gastroenteritis: Causes and Clinical Features

Organism	Clinical Features	Incubation Period (I), Duration (D), Source (S)
Staphylococcus aureus	Short incubation period, 2–7 h; preformed toxin; vomiting; lasts <24 h	I, 1–6 h D, 6–12 h S, mayonnaise, potato salad, food handlers
Clostridium perfringens	Watery diarrhea, seen in large foodborne outbreaks	I, 6–24 h D, 1 day S, Steam table meat, poultry, gravy
Bacillus cereus	Vomiting or diarrhea, typically from contaminated rice	I, 1–12 h D, 1–2 days S, contaminated foods, rice
Vibrio cholerae	Enterotoxin; acute "rice water" diarrhea, dehydrating. Rare in the United States but common with travel to Asia	I, 1–2 days D, 6–8 days S, raw shellfish, oysters
Noncholera *Vibrio* (e.g., *V. vulnificus*)	Enterotoxin. Acute diarrhea, occasional dysentery. Seen in Gulf coast in the United States. Can cause septic shock, wound infection	I, 1–2 days D, 6–8 days S, raw shellfish, oysters
Marine bacteria flora (scombroid fish poisoning)	Histamine toxin; tachycardia, itching, flushing, cramping, dizziness, metallic taste	I, 5–60 min D, 6 h S, mahi mahi, tuna, other dark meat fish
Marine dinoflagellate *Gambierdiscus toxicus* (ciguatera fish poisoning)	Ciguatoxin-heat stable; pain, paresthesias, dysesthesias, vomiting, diarrhea	I, 2–6 h D, 7–14 days S, coral reef fish
Enterotoxigenic *Escherichia coli* (ETEC)	Acute watery diarrhea. Common cause of traveler's diarrhea, but in the United States increasing cause of foodborne disease	I, 1–3 days D, 1–7 days S, unsanitary water or food
Clostridioides difficile	Colitis, diarrhea, fever, toxic megacolon. Recent antibiotic or proton pump inhibitor use. High mortality in elderly and immunocompromised.	I, 5–14 days D, variable S, person to person, contaminated surfaces

Typically, the stools are loose and bile colored but then become watery and grossly bloody approximately 40% of the time. At the height of the illness, patients usually pass 8 to 10 stools or more per day.

Most patients recover within a week, although diarrhea can persist for an extended period. Relapses are common, although generally milder than the original episode, and fatalities are rare.

Diagnostic Testing

Because the clinical presentation is similar to that of other invasive bacterial pathogens, the identification of the *Campylobacter* pathogen requires stool culture or real-time polymerase chain reaction (PCR) assay. Specimens should be obtained from patients with acute enteritis associated with fever, abdominal pain, occult blood, or hematochezia. Blood culture results are rarely positive and therefore not routinely indicated.

Management

Empirical antibiotic therapy is not usually recommended for otherwise healthy patients without severe illness, except in the setting of travel-related diarrhea. Initial treatment of invasive diarrhea should focus on rehydration. The decision to initiate antibiotic therapy should be deferred pending identification of a specific organism via stool studies.

For patients who are not improving, antibiotic therapy shortens the duration of campylobacteriosis by approximately 1.3 days. Erythromycin, 500 mg bid PO for 5 days, or azithromycin, 500 mg daily PO for 3 days, is the recommended first line therapeutic regimens. Ciprofloxacin, 500 mg bid PO for 7 days, can be used as the second choice of treatment, but alarming resistance to the fluoroquinolones has emerged. Approximately 20% of *Campylobacter* strains in the United States are now resistant to fluoroquinolones, and resistance of more than 80% has been documented in Southeast Asia. Because *Campylobacter* infection causes an invasive enteritis, antimotility agents are not recommended unless treatment with antibiotics is also given.

Complications of *Campylobacter* infection are rare. Cholecystitis, pancreatitis, and massive GI bleeding all have been reported, as have meningitis, endocarditis, and osteomyelitis. There is an association between *Campylobacter* infection with reactive arthritis and Guillain-Barré syndrome, with an incidence of approximately 1/1000 cases.

Salmonellosis

Epidemiology

Salmonella is the most common cause of bacterial enteritis in the United States. Enteritis caused by this organism affects people of all age groups but particularly children, with those younger than 5 years accounting for 20% of cases. Almost all *Salmonella* infections are acquired from the ingestion of contaminated food or drink. Poultry products and beef are the most common sources; other sources include unpasteurized milk, eggs, fish, or domestic pets. Approximately 10% of household dogs and cats excrete salmonellae, and pet reptiles, such as turtles, snakes, and iguanas, have been responsible for outbreaks. In the United States, the most common isolates are the *S. enterica* serovars *typhimurium*, *enteritidis*, and *Newport*, which together account for approximately half of culture-confirmed serotypes. *S. enterica* serovar

typhi is associated with enteric fever (typhoid fever) and is most prevalent in the late fall.[12]

Pathophysiology

Relatively large numbers of salmonellae must be ingested for illness to be produced. However, a carrier state can be induced with ingestion of 10 to 100 times fewer bacteria that needed to cause illness. In infants or adults with certain underlying diseases, a much smaller inoculum may produce illness. Decreased gastric acidity or alteration of intestinal flora resulting from the administration of antibiotics can impressively reduce the size of the required inoculum. Rates of invasive infection and disease severity are increased in infants, elders, or those with hemoglobinopathies such as sickle cell anemia, malignant neoplasms, or acquired immunodeficiency syndrome (AIDS).

Clinical Features

Family outbreaks and sporadic cases are more common than large epidemics. Ingested salmonellae penetrate the intestinal mucosal cells and lodge in the lamina propria. After an incubation period of 8 to 48 hours, the typical patient with *Salmonella* gastroenteritis develops a fever, colicky abdominal pain, and loose, watery stools, occasionally containing mucus and blood. Nausea and vomiting are common but rarely are severe or protracted. Mild to moderate diffuse abdominal tenderness can be elicited in most patients, but severe tenderness and even rebound tenderness may occasionally be noted. Symptoms usually abate within 2 to 5 days, and recovery typically is uneventful. Sustained or intermittent bacteremia may occur, especially in those with sickle cell anemia, malignancy, or AIDS.

Diagnostic Testing

The diagnosis of salmonellosis is confirmed with stool cultures or a real-time PCR assay. Blood culture results occasionally are positive, and blood samples should be obtained from severely ill or immunocompromised patients. The possibility of an underlying disease or immunodeficiency state should be considered in patients with a severe *Salmonella* infection.

Management

Empirical antibiotic therapy is not recommended for otherwise healthy patients with suspected *Salmonella* enteritis. Antibiotic therapy does not shorten the duration of the disease and may prolong the duration of the carrier state. Although its effectiveness is unproven, antibiotic therapy is recommended for patients with severe colitis and infants younger than 3 months, adults older than 50 years, and those at risk for severe disease, including those who are immunocompromised, with sickle cell disease, or with prosthetic grafts. Persons who represent a public health risk also should be treated in an attempt to eradicate the carrier state and prevent the spread of the organism. Any of the following antibiotic regimens are generally useful for the outpatient management of *Salmonella* gastroenteritis: ciprofloxacin, 500 mg PO bid for 5 to 7 days or azithromycin 1 g PO followed by 500 mg/day for the next 6 days. Treatment with fluoroquinolones PO for 28 days is effective in the treatment of chronic *S. typhi* carriers; however, this can prolong shedding of non–*S. typhi* organisms. Patients requiring hospitalization are best treated with IV ceftriaxone until the results of sensitivity studies become available.[13]

Follow-up with the patient's primary care physician should be arranged. Food handlers and health care personnel should not return to work until their carrier state has been eradicated. Repeated stool studies help guide further decision-making regarding return to job or school. Personal hygiene should be emphasized as untreated patients may continue to shed infective organisms in the stool for weeks or even months. As with other invasive pathogens, the use of antimotility drugs alone should be avoided. These drugs prolong fever and diarrhea, increase the incidence of bacteremia, and promote the development of a carrier state in patients with *Salmonella* enteritis. However, the administration of loperamide is safe when given concomitantly with an antibiotic.

Prevention of salmonellosis depends on cooking meat to an internal temperature of greater than 160°F (71°C) and minimizing how long foods are allowed to remain at room temperature, to reduce the chance of bacterial growth to an infectious inoculum. Careful personal hygiene, including handwashing, also is essential.

Shigellosis

Epidemiology

Shigellosis, or bacillary dysentery, is worldwide in distribution and is particularly common in countries lacking adequate sanitation. *Shigella sonnei* is responsible for approximately 75% of the infections occurring in the United States. *Shigella flexneri* causes most of the remaining cases, with *Shigella boydii* and *Shigella dysenteriae* responsible for less than 4% of cases.

Shigella infections are common in confined populations, such as those in mental or penal institutions, nursing homes, or daycare centers. Children younger than 5 years of age account for 30% of cases. An increased incidence has been documented among men who have sex with men and in the setting of AIDS. It is spread by the fecal-oral route, and humans are the only natural hosts. Outbreaks have been associated with recreational water venues such as swimming pools, water parks, fountains, hot tubs, or spas.

Pathophysiology

Shigella requires a very small inoculum to produce disease; as few as 50 to 100 *Shigella* bacilli are capable of causing infection. No other enteric pathogen is so efficient at producing overt disease in humans. Infection generally is superficial, localized to the epithelial lining of the colonic mucosa; therefore bowel perforation or invasion into the bloodstream is extremely rare. Bleeding occurs from superficial ulcerations of the mucosa.

Clinical Features

Clinical presentation varies among *Shigella* species. *S. sonnei* typically causes high-volume, watery diarrhea, with relatively few systemic signs. Infection with *S. flexneri, S. dysenteriae,* or *S. boydii* typically causes low-volume bloody diarrhea and more severe systemic symptoms.

The usual incubation period is 24 to 48 hours, and clinical manifestations vary considerably. When true dysentery develops, it ordinarily is preceded by a recognizable period of watery diarrhea lasting a few hours to a few days. Patients with dysentery have grossly bloody diarrhea, tenesmus, and constitutional symptoms and signs, such as fever, nausea, vomiting, headache, or myalgias. If symptoms are severe enough, profound dehydration and even circulatory collapse can occur. Children younger than 2 years of age may have associated neurologic manifestations, usually seizures; lethargy or frank coma develops in a small percentage of patients. *S. dysenteriae* type 2 (Shiga toxin–producing strains) infections are associated with hemolytic uremic syndrome (HUS).[14]

Diagnostic Testing

A definitive diagnosis of shigellosis is made with stool culture or real-time PCR assay. Stool culture results are positive in more than 90% of cases when samples are obtained during the first 3 days of illness, or 75% of cases when received more than 1 week after the onset of diarrhea.

Management

Treatment primarily involves the correction of fluid and electrolyte abnormalities. If *S. sonnei* or *S. flexneri* is cultured from the stool, the decision to administer antibiotics is based on the patient's clinical condition and feasibility of sanitary control. Asymptomatic or recovering patients do not require antibiotics, unless treatment is necessary for public health considerations. Patients whose condition is not improving or those who are immunocompromised should be treated with antibiotics.

Antibiotics shorten the clinical course and eradicate the pathogen from the stool, often within 48 hours. Whenever *S. dysenteriae* is isolated, the patient should be treated to prevent outbreaks of dysentery, even if the patient is asymptomatic when the culture result returns from the laboratory.

In the United States, *Shigella* organisms are highly resistant to ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX). Therefore ciprofloxacin 500 mg PO bid or azithromycin 500 mg PO daily is the drug of choice. Treatment is required for only 3 days in immunocompetent patients but should be extended to 7 to 10 days in those who are immunocompromised.[14]

Yersinia enterocolitica Gastroenteritis

Epidemiology

Yersinia enterocolitica, a gram-negative facultative anaerobic bacterium, is a member of the family Enterobacteriaceae. *Y. enterocolitica* is a relatively infrequent cause of enteritis in the United States. Yersiniosis is more prevalent among the pediatric population where infections are evenly distributed throughout the calendar year. The consumption of contaminated milk or raw pork has accounted for sporadic cases and several large outbreaks. Fecal-oral transmission to humans from a variety of animals (particularly dogs, cats, or pigs) and direct person-to-person spread probably occur, but communicability appears to be low.

Pathophysiology

After oral ingestion, the bacterium invades the intestinal epithelium and localizes to lymphoid tissue of the intestinal mucosa, particularly Peyer patches. It then invades the regional mesenteric lymph nodes. Invasive enteritis is the clinical presentation in approximately two-thirds of patients. Pseudoappendicitis and mesenteric adenitis account for the remainder of presentations.

Clinical Features

The clinical picture with *Y. enterocolitica* often resembles that with infection by other invasive intestinal organisms, including fever and colicky abdominal pain. The diarrhea may be watery, greenish, and sometimes bloody. The constitutional symptoms include anorexia, vomiting, or malaise. In cases of *Y. enterocolitica* gastroenteritis, abdominal pain, and diarrhea can often persist for 10 to 14 days or longer.

In a substantial number of patients with yersiniosis, particularly adolescents or young adults, an ileocecitis may develop. In these cases, lower abdominal pain with little or no diarrhea is the predominant symptom, and the clinical presentation may mimic that of acute appendicitis. Postinfection manifestations may occur, such as erythema nodosum, persistent polyarthritis, sacroiliitis, ankylosing spondylitis, Reiter syndrome, exudative pharyngitis, pneumonia, empyema, or lung abscess.

Diagnostic Testing

The diagnosis of yersiniosis can be confirmed with stool cultures or real-time PCR assay; however, most laboratories do not routinely include *Y. enterocolitica* in standard stool testing. *Yersinia* identification can be performed if clinically indicated, such as a history of *Yersinia* exposure, prolonged invasive enteritis despite a negative result on standard stool culture, or right lower quadrant pain with signs of invasive diarrhea.

Management

In general, *Y. enterocolitica* infection is self-limited at the diarrheal stage and resolves without treatment. As with other invasive GI pathogens, antiperistaltic drugs are not recommended unless the patient is simultaneously treated with antibiotics.

Treatment with antibiotics is not essential or efficacious in the management of uncomplicated *Y. enterocolitis*. *Yersinia* organisms usually are susceptible to TMP-SMX DS, one tablet PO bid, which is the agent of choice when antibiotic therapy is indicated. Doxycycline, 100 mg PO bid, is an alternative regimen, as is single-agent treatment with a quinolone. In immunocompetent adults, a 3-day course is sufficient; the course is extended to 7 to 10 days if the patient is immunocompromised. Treatment should be considered for patients who are still significantly ill at the time stool results return, particularly if they are immunocompromised or have an underlying medical illness, or in cases in which the fecal shedding could represent a public health hazard. Patients with *Y. enterocolitica* often continue to shed organisms in the stool well into convalescence, long after diarrhea subsides. The mean duration of fecal shedding is approximately 6 weeks. In patients who interact with potentially susceptible persons, appropriate steps should be taken to ensure that they do not spread their infection.

Vibrio parahaemolyticus Gastroenteritis

Epidemiology

Vibrio parahaemolyticus is a halophilic (salt-requiring) gram-negative bacillus found naturally in warm marine environments such as the coastal seawaters of Japan, the United States, and other temperate zone regions. In Japan, *V. parahaemolyticus* is the most common cause of bacterial enteritis, being responsible for approximately 70% of cases. The typical source is raw fish. In the United States, *V. parahaemolyticus* disease is much less common, although its incidence has been increasing. US cases are typically related to the consumption of raw or undercooked shellfish, especially oysters. Many cases occur as outbreaks on cruise ships or in persons who have patronized a common restaurant or seafood market. *V. parahaemolyticus* enteritis is much more common in the summer months when warm seawater temperatures favor proliferation of the organism.

Pathophysiology

The mechanism whereby *V. parahaemolyticus* causes human enteritis is thought to be related to the production of two thermostable direct hemolysin (TDH) virulence factors. Serotypes that produce one or both virulence factors attach to the colonic epithelium and induce secretory diarrhea, as well as local cell lysis. An infectious dose of *V. parahaemolyticus* is considered to be 100,000 colony-forming units (CFUs) or more. Although enteritis is the most common clinical presentation, accounting for 60% to 80% of cases, *V. parahaemolyticus* infections also manifest as wound infections (34%) or septicemia (5%). Serious wound infections and septicemia occur primarily in persons with underlying liver disease, alcoholism, or diabetes mellitus.

Clinical Features

Signs and symptoms usually appear 8 to 12 hours after the ingestion of contaminated food, but the incubation period can range from 4 to 48 hours. The predominant manifestation is acute diarrhea, although the volume of fluid lost generally is not significant. Moderately severe abdominal cramping is common, and vomiting is typically not prominent. The illness is almost invariably self-limited

and seldom lasts longer than 24 to 48 hours. *V. parahaemolyticus* infection should be suspected when a common-source outbreak of acute diarrheal disease occurs in persons exposed to fresh or frozen seafood.

Diagnostic Testing

The diagnosis of *Vibrio* gastroenteritis is made by stool culture or real-time PCR assay. Although blood agar and other nonselective media support the growth of this species, isolation from the stool usually requires the use of a selective medium containing thiosulfate, citrate, bile salts, and sucrose (TCBS) agar.

Management

Because the disease is self-limited, most patients require no therapy. Although data on the efficacy of antibiotic therapy are lacking, patients who still have diarrhea when culture results become available may benefit from treatment with tetracycline, fluoroquinolones, ceftriaxone, or another antibiotic, as guided by susceptibility testing. Ciprofloxacin 500 mg PO bid for 3 days *or* azithromycin 500 mg PO daily for 3 days, if susceptible, is recommended. Antimotility agents are not indicated. Because *V. parahaemolyticus* is widely present in coastal waters, the only effective preventive measures are adequate cooking, refrigeration, and hygienic practices in the preparation of seafood for human consumption.

Shiga Toxin–Producing *Escherichia coli*

Epidemiology

STEC was first recognized as a human pathogen in 1982 after two outbreaks of hemorrhagic colitis were traced to undercooked ground beef contaminated with *E. coli* serotype O157:H7 and distributed at a fast-food restaurant chain. It is now recognized that *E. coli* O157:H7 is one of more than 30 serotypes of *E. coli* known to produce *Shigella*-like toxins that, as a group, constitute a major cause of hemorrhagic colitis, HUS, or thrombotic thrombocytopenic purpura (TTP) in humans. Children younger than 10 years are at the highest risk for severe STEC infection. Approximately 15% of children with STEC diarrhea develop HUS.[3,15]

Inadequately cooked ground beef has caused many large outbreaks. STEC, present in the intestines of healthy cattle, contaminates the meat during slaughter, and the grinding process then transfers the organisms from the surface of the meat to the interior. The infectious dose is low, approximately 100 bacteria. The US Department of Agriculture food safety regulations now require that cooking of ground beef to an internal temperature of 70°C (160°F) to kill *E. coli* organisms effectively. Outbreaks also have occurred from consumption of fruits or vegetables, contamination of municipal water supplies, animal contact in petting zoos, and person-to-person spread in daycare centers. Food handlers with STEC-related diarrhea may lead to contaminated meals, causing institutional outbreaks. STEC enteritis is more common in the summer months.

Pathophysiology

Ingested STEC multiplies in competition with healthy bacterial enteric flora, adheres to the intestinal epithelial cells, and produces Shiga toxin. Toxins bind to absorptive enterocytes on the luminal surface of the small and large intestines, enter the cell, and irreversibly inhibit protein synthesis, resulting in enterocyte death. Shiga toxins can then enter the bloodstream via damaged intestinal epithelium and cause the death of vascular endothelial cells by the same mechanism. Endothelial cell lysis is accompanied by platelet activation and aggregation, cytokine secretion, vascular constriction contributing to fibrin deposition, and clot formation within the capillary lumen. Microangiopathy propagates distally as the toxins are carried to the kidneys, causing the clinical syndrome of hemolysis and renal dysfunction (HUS). The development of HUS is associated primarily with serotypes that produce Shiga toxin 2. The CDC has estimated that 90% of US cases of HUS are caused by *E. coli* O157:H7.

Clinical Features

After an incubation period of 3 to 4 days, patients initially produce watery diarrhea that becomes bloody hours to days later. Approximately 90% of patients report bloody stools. The amount of blood varies, but stools passed may appear to consist wholly of blood, and the infection may masquerade as GI bleeding from noninfectious causes. Bloody diarrhea typically is accompanied by severe abdominal cramps, pain, and often vomiting. Fever is a feature in fewer than one-third of cases and, if present, usually is low grade. Uncomplicated infection resolves spontaneously over 7 to 10 days. A carrier state may last another 1 to 2 weeks and resolves spontaneously.

STEC colitis has been associated with two serious complications, HUS and TTP (discussed in Chapters 168 and 111, respectively). These clinically similar disorders share the features of microangiopathic hemolytic anemia, thrombocytopenia, fever, neurologic deficits, and renal dysfunction. In TTP, neurologic findings predominate, and renal dysfunction is unusual. Renal dysfunction predominates in HUS, which is more common in children, especially those younger than 4 years, occurring in up to 15% of cases. Of these, 5% are fatal. Older adults, such as occurs in nursing home outbreaks, can also acquire HUS, with a high mortality rate. TTP is rare but is most often seen in immunosuppressed patients. HUS and TTP typically appear 5 to 20 days after the onset of infection. Death from STEC colitis alone or resulting from complications occurs primarily among elders.

Diagnostic Testing

The CDC recommends that if stools are submitted for routine testing in the setting of acute community-acquired diarrhea, *E. coli* O157:H7 should be simultaneously cultured for—regardless of age, season, or presence or absence of blood in the stool. An assay that detects non–O157 Shiga toxin should also be performed. In addition to the routine battery of media, specimens should be plated on the sorbitol MacConkey (SMAC) medium.

Management

Treatment is symptomatic. Antibiotic treatment is of no clinical benefit and may serve to increase the risk of HUS by eliminating competing bowel flora; thus it is not recommended for patients with known infection with *E. coli* O157:H7. Empirical antibiotic treatment for bloody diarrhea should be approached with caution. It is not recommended in children because of the risk of HUS. In adults, if general empirical treatment is initiated in patients with diarrhea, it is generally recommended for patients with a temperature greater than 38.5°C (101°F), because the presence of significant fever suggests a pathogen other than *E. coli* O157:H7.

NONINVASIVE TOXIN-FORMING BACTERIA

Pathogens associated with toxin-induced bacterial enteritis are summarized in see Table 80.3. In general, gastroenteritis caused by toxin-forming bacteria (classically known as food poisoning) will manifest as acute noninvasive enteritis, with watery diarrhea, minimal fever, little or no abdominal cramping, and absence of fecal leukocytes and erythrocytes. Treatment is primarily supportive, and diagnostic testing generally is not indicated for otherwise healthy patients. A specific

diagnosis may be of help in attempting to identify a common source during large outbreaks.

Staphylococcus spp.

Epidemiology

Staphylococcus-related food poisoning occurs after the multiplication of an enterotoxin-forming strain of *Staphylococcus* that is present in the food before ingestion. Food contamination with *Staphylococcus* is extremely common because the organism is ubiquitous in the environment. Most protein-rich foods support the growth of staphylococci, especially ham, eggs (even hard-boiled), custard-filled pastries, mayonnaise, milk, or salads such as egg, tuna, chicken, potato, and macaroni. Foods that require considerable handling during preparation and are then kept slightly warm after preparation are frequent offenders. Temperatures of 45°F to 140°F (7°C to 60°C) for only a few hours will allow the proliferation of the organism and production of sufficient enterotoxin to cause disease. Foods containing sufficient enterotoxin to produce violent illness usually are normal in appearance, odor, and taste. Large outbreaks are common worldwide, particularly in institutions such as school or hospital cafeterias, military bases, airlines, or restaurants.

Pathophysiology

Although the bacterium itself is killed by cooking at temperatures greater than 140°F (60°C), *Staphylococcus* enterotoxin is heat-stable. Thus, once it is present in food, reheating or even boiling will not prevent illness. The toxin has no local effect on the digestive tract. It is a potent stimulator of T lymphocytes in the host, resulting in their proliferation and the release of cytokines. The GI effects are believed to be mediated by the release of interleukin-2, tumor necrosis factor beta, and interferon from mast cells. Stool, vomitus, or blood can be tested for the presence of the enterotoxin, but this is typically performed by local health departments or the CDC during large outbreaks and is rarely done in routine clinical laboratories.

Clinical Features

The illness has an explosive onset, beginning 1 to 6 hours after ingestion of contaminated food. Cramping and abdominal pain, with violent and often-repeated retching and vomiting, are the predominant symptoms. Diarrhea is a variable feature; it usually is mild, occasionally absent entirely, and infrequently profuse. Fever occasionally is present. Staphylococcal food poisoning is short lived, usually subsiding in 6 to 8 hours and rarely lasting as long as 24 hours. Patients often are recovering by the time they seek medical attention. The short incubation period and multiple cases among persons eating the same meal are highly suggestive of this disease. Examination of the stool is noncontributory, and no practical laboratory test is clinically available to confirm the diagnosis.

Management

Rapid, uncomplicated, spontaneous recovery is the rule. Parenteral antiemetic agents help to control vomiting. IV fluids should be given to patients who are dehydrated or who have ongoing vomiting, particularly the very young, elders, or debilitated patients. Antibiotics are of no value because staphylococcal food poisoning is caused by preformed enterotoxins. Adherence to strict personal hygiene practices by food handlers and prompt refrigeration of foods not intended for immediate consumption are the most important preventive measures. Ordinary refrigerator temperatures prevent the production of the enterotoxin. Food should not be allowed to stand at room temperature for long periods before being served.

Clostridium perfringens

Epidemiology

Clostridium perfringens food poisoning is one of the most commonly reported foodborne illnesses in the United States. Most cases occur in large groups, with dozens or even hundreds of persons affected. The illness is caused by the ingestion of meat or poultry heavily contaminated with *C. perfringens* type A heat-resistant spores. The organism also is ubiquitous in the environment and in human or animal feces. Typically, poisoning results from ingesting food that is cooked more than 24 hours before consumption, allowed to cool slowly at room temperature, and then served cool or rewarmed. During this period of incubation, spores that survived cooking germinate, and clostridia multiply to reach sufficient numbers to constitute an infectious inoculum.

Pathophysiology

Ingestion of live organisms is required to produce disease, but illness is not caused by infection; rather, it is caused by an enterotoxin produced by sporulation of the organism in the GI tract. The enterotoxin is responsible for the symptoms of *C. perfringens* food poisoning.

Clinical Features

Symptoms usually appear within 6 to 12 hours but can occur up to 24 hours after ingestion of the contaminated food. Frequent passage of watery diarrheal stools and moderately severe abdominal cramping are the major symptoms. Fever, nausea, and vomiting are rare. The illness is self-limited and rarely lasts for more than 24 hours. *C. perfringens* food poisoning should be considered in a patient who experiences an acute onset of abdominal cramps and watery diarrhea shortly after eating a suspect meat or poultry dish, and when others who have eaten the same meal are similarly ill. Leukocytes and erythrocytes are not present on stool examination.

Management

Occasionally, a patient will need IV fluid replacement. Antibiotics are of no value because of the toxigenic nature and brief duration of the disease. Food poisoning from *C. perfringens* can be prevented by avoiding long periods of warming or cooling of foods that have already been cooked.

Bacillus cereus

Epidemiology

Bacillus cereus is an aerobic, spore-forming, gram-positive rod that is a common cause of foodborne illness. The organism is one of the most frequently isolated soil bacteria. Because of its abundance and the hardiness of its spores, *B. cereus* contaminates nearly all agricultural products and plays a major role in the spoilage of food items, including pasteurized milk and milk products. It is commonly isolated from pasta, rice, dairy, and dried milk products, spices, dried foods, meat, chicken, vegetables, seafood, fruits, and grains. Because it is ubiquitous and tolerates extremes of temperature, control of this bacterium in the food-processing environment is challenging to achieve.

B. cereus causes two distinct clinical syndromes: An emetic form produced by a heat-stable, *Staphylococcus*-like enterotoxin known as cereulide, and a diarrheal form resulting from a heat-labile enterotoxin known as HBL (a hemolysin consisting of three proteins, B, L_1, and L_2), which is similar to that of *E. coli*. The emetic form usually is caused by the ingestion of contaminated rice, although beef, poultry, vanilla sauce, pasteurized cream, milk pudding, pasta, potato, cheese, and infant formula also have been implicated. The diarrheal syndrome usually is associated with the ingestion of HBL in meats or vegetables.

Pathophysiology

The heat-resistant spores of *B. cereus* survive boiling and then germinate when boiled foods such as rice are left unrefrigerated. The vegetative forms multiply and produce toxin. Flash frying or brief rewarming of the food before serving often is not sufficient to destroy the preformed, heat-stable, emetic toxin. Improper holding temperatures for cooked food are the most common feature of *B. cereus* foodborne illness.

Clinical Features

The emetic syndrome is clinically indistinguishable from that caused by staphylococcal enterotoxin. After an incubation period of 1 to 5 hours, profound vomiting and abdominal cramping occurs. Diarrhea is present in approximately 25% to 30% of persons affected. The duration is short, usually less than 10 hours, and patients recover uneventfully.

The diarrheal syndrome begins after an incubation period of 6 to 14 hours and is characterized by diarrhea and abdominal cramps. Vomiting is less common. The duration of illness ranges from 12 to 36 hours. Symptoms are essentially the same as for food poisoning produced by *C. perfringens*. *B. cereus* food poisoning should be suspected when an illness localized predominantly to the upper GI tract develops less than 6 hours after eating, or when a predominantly lower intestinal tract illness occurs 6 to 24 hours after a suspect meal, usually of meats or vegetables.

Diagnostic Testing

Because of the brief and noninvasive nature of the illness, diagnostic testing typically is not performed. In response to large outbreaks, public health authorities may elect to test common food sources. Isolation of 10^5 CFU/g from incriminated foods confirms the diagnosis. *B. cereus* enteric infection can also be confirmed via detection of the emetic or diarrheal toxin in stool, emesis, or food, but this is done only in reference laboratories typically during the investigation of large outbreaks.

Management

Both syndromes generally are mild and self-limited. Antibiotics are not indicated as symptoms are mediated by enterotoxins. Parenteral antiemetic agents provide effective relief in patients with violent vomiting. *B. cereus* food poisoning is preventable if boiled rice or cooked foods are promptly eaten or refrigerated and not left to sit at room temperature.

Cholera and Noncholera *Vibrio* Species

Epidemiology

In addition to *V. parahaemolyticus*, other halophilic marine *Vibrio* species (e.g., *V. cholera* and *V. vulnificus*) have increasingly been implicated in acute gastroenteritis associated with seafood. Their epidemiology is similar to that of *V. parahaemolyticus*—presence in coastal seawater, outbreaks associated with eating raw or inadequately cooked shellfish, and an incidence largely limited to the warmer months of the year. Outbreaks of true *V. cholera* continue to occur sporadically along the US Gulf Coast from inadequately cooked crabs or oysters. Other identified foods include imported seafood, cooked rice, frozen or fresh coconut milk, and commercially prepared cut cantaloupe. Cholera outbreaks in the developing world have led to an increasing number of cases of cholera imported into the United States.

Pathophysiology

Cholera and noncholera Vibrio strains produce an enterotoxin in vivo that stimulates enterocyte adenylate cyclase, disrupting mucosal fluid absorption and leading to secretory diarrhea. Therefore symptoms resemble those of other forms of enterotoxin-induced gastroenteritis. The enterotoxin of the noncholera *Vibrio* species is antigenically similar to *V. cholerae* enterotoxin and produces similar secretory diarrhea, although it is much less severe.

Clinical Features

Patients with classic epidemic cholera experience copious so-called rice water diarrhea, abdominal cramps, and often nausea and vomiting within 24 to 48 hours after ingesting contaminated seafood. A low-grade fever may be present. In severe cases (cholera gravis), rates of diarrheal fluid loss can reach 1 L/h; fatality rates can reach 25% to 50% in untreated populations. The median duration of illness is approximately 7 days. Despite the notoriety of the classic form of cholera, the CDC estimates that only 1 in 20 cases is associated with cholera gravis. Most affected patients experience a relatively mild diarrheal illness that may go undocumented.

The other species, *Vibrio vulnificus,* is also associated with eating raw seafood, especially oysters. *V. vulnificus* can cause self-limited gastroenteritis, with onset approximately 16 hours after ingestion of contaminated food by healthy persons. In the compromised host, this organism may cause serious wound infections when contaminated seawater comes into contact with open wounds. It may also result in a syndrome of primary septicemia characterized by hemorrhagic bullae of the skin and rapidly progressive septic shock.

V. vulnificus infection is the leading cause of death in the United States associated with the consumption of seafood. Septicemia carries a mortality rate of approximately 50% in patients with significant underlying disease, particularly chronic liver disease. All patients with chronic liver disease, alcoholism, AIDS, or other immunodeficiency states should be advised to avoid all raw shellfish.

Diagnostic Testing

Because these are noninvasive *Vibrio* species, unlike *V. parahaemolyticus*, stained fecal smears will not show leukocytes or erythrocytes. Stool cultures will quickly identify *V. cholerae* if plated on TCBS medium. *V. vulnificus* infection can be diagnosed with stool, blood, or wound cultures. The clinical laboratory should be notified when this infection is suspected so that specific culture media can be used.

Management

Patients with cholera often will lose enough fluids to require rehydration therapy. The WHO oral rehydration formula has been used successfully to treat cholera worldwide. The use of oral or IV fluid hydration is dictated by the clinical picture. The role of antibiotics in the treatment of intestinal infections caused by noncholera *Vibrio* spp. has not been clearly established. However, antibiotics will decrease the severity and duration of cholera and may have the same effect on the other diarrheal diseases caused by these marine *Vibrio* spp.

Antibiotics should be guided by strain-specific sensitivities, if available. Typical choices include a single oral dose of doxycycline 300 mg PO, or a 3-day regimen of ciprofloxacin 500 mg PO bid or azithromycin 500 mg PO daily, or double-strength TMP-SMX PO bid, tetracycline 500 mg PO qid, or erythromycin 500 mg PO qid. Preventive measures include the use of bottled water, meticulous attention to handwashing before eating and after using the bathroom, avoidance of fecal soiled water sources, thorough cooking of food, peeling of fruits and vegetables, and bathing and toileting at least 30 yards away from drinking water sources. Cholera is a nationally reportable infection.

An oral cholera vaccine is available and appears to provide better immunity, with fewer adverse effects than the previously available parenteral vaccine. The CDC strongly recommends the cvd 103-hgr oral cholera vaccine for travelers to cholera-endemic areas.[16]

If *V. vulnificus* infection is known or suspected, antibiotics should be initiated immediately because this has been shown to improve survival. Wounds should be débrided because they may progress rapidly, sometimes necessitating fasciotomy or amputation. Single-agent antibiotic regimens include levofloxacin or ciprofloxacin. The combination of doxycycline 100 mg PO bid or IV, plus a third-generation cephalosporin, such as ceftazidime 1 to 2 g IV or intramuscularly (IM) tid, is also recommended. Children can be treated with TMP-SMX plus an aminoglycoside.

Enterotoxigenic *Escherichia coli*

Epidemiology

Enterotoxin-producing *E. coli*, or ETEC, is recognized as a major cause of acute diarrheal disease throughout most of the world. It is a major cause of diarrhea in persons traveling to underdeveloped areas, especially South Asia, sub-Saharan Africa, or Latin America. ETEC is increasingly being recognized as a cause of foodborne illness in developed countries, including the United States. Infection is acquired from fecally contaminated food or drink. Unpeeled fruits, leafy vegetables, unsanitary drinking water, and ice are the most common sources. Most tourists are careful about their food and drink, but there seems to be a poor correlation between individual eating habits and the incidence of traveler's diarrhea. It is likely that the quality of hygiene at a particular food source is the major determinant of risk; travelers should choose locations that have a reputation for excellence in hygiene.

Pathophysiology

For an *E. coli* strain to cause diarrhea, it must possess a surface factor that allows colonization (although not invasion) of the small intestine and the ability to secrete an enterotoxin that causes the outpouring of fluids and electrolytes into the small bowel lumen. The enterotoxin-induced secretion occurs in the absence of any demonstrable histologic damage to intestinal epithelial cells or the capillary endothelial cells. *E. coli* produces heat-labile and heat-stable toxins. The intestinal fluid losses are qualitatively identical to those seen in cholera and other toxigenic diarrheas.

Clinical Features

After an incubation period of 24 to 72 hours, an abrupt onset of watery diarrhea occurs. Severity varies, with the illness ranging from a fulminant, cholera-like disease to the much more common and milder turista, in which the symptoms of mild, watery diarrhea and abdominal cramps are more troublesome than life threatening. Fever is unusual. Vomiting occurs in less than one-half of affected adults and is seldom responsible for significant fluid losses. Even in severe cases, diarrhea rarely lasts longer than 48 to 72 hours, and the response to oral or IV fluids is uniformly good. Milder disease generally subsides more gradually, occasionally persisting for 1 week or longer. Virtually all persons recover entirely, without long-term sequelae.

ETEC disease should be suspected when a child or adult has frequent watery diarrhea and few other symptoms. It often is mild, nonspecific gastroenteritis that resolves spontaneously. ETEC is the most common cause of traveler's diarrhea, so most people who acquire toxigenic diarrhea while visiting a developing nation probably have this disease.

Diagnostic Testing

There are no easy or rapid means for laboratory diagnosis of ETEC infection. Methods that rely on the identification of specific *E. coli* serotypes are unreliable because *E. coli* is part of the healthy colonic flora and its ability to produce enterotoxin is not restricted to any specific serotype. Methods based on detection of the heat-stable and heat-labile toxins through the use of the real-time PCR assay have been developed but are generally available only in reference laboratories. Stool preparations demonstrate no erythrocytes or leukocytes.

Management

Because ETEC infections are almost always a self-limited disease process, no treatment other than maintenance of hydration is required. However, if the organism is identified while symptoms are still active or if the patient is traveling in an endemic area, antibiotics can afford clinical relief. For milder symptoms, a single oral dose of ciprofloxacin 750 mg PO, in addition to loperamide, is usually effective. For more severe symptoms, TMP-SMX 160 mg/800 mg PO bid or ciprofloxacin 500 mg PO bid for 3 days should eradicate the organism.

Clostridium difficile Colitis

Epidemiology

C. difficile is an anaerobic, spore-forming, gram-positive bacillus that is one of the leading causes of healthcare-associated infectious diarrhea. It has been associated with a range of illnesses, from asymptomatic colonization to severe diarrhea, pseudomembranous colitis, toxic megacolon, intestinal perforation, and death. It is the leading cause of morbidity and mortality among hospitalized elders and nursing home patients. The annual incidence of *C. difficile* infection has recently plateaued at historic highs, with approximately 450,000 cases annually in the United States.[17] The continued high incidence of *C. difficile* cases underscores the need for contact isolation procedures when there is a suspected case in the emergency department (ED).

Pathophysiology

C. difficile infections are usually related to antibiotic use that alters the gut flora and allows the *C. difficile* bacteria to colonize and proliferate. *C. difficile* colitis can manifest concomitantly with current antibiotic use or up to 4 weeks afterward, although most *C. difficile* infections will occur within 2 weeks of antibiotic use. Other risk factors include recent hospitalization, living in a long-term care facility, solid organ transplant recipients,[18] or use of antacids.[19] *C. difficile* spores are highly resistant to heat, acid, and antibiotics, making them highly contagious for person-to-person or surface-to-person infections. *C. difficile* bacteria secrete toxins A and B that cause inflammation, mucosal injury, and secretory diarrhea.

Clinical Features

Manifestations of *C. difficile* colitis include watery diarrhea up to 10 to 15 times daily, with lower abdominal pain, cramping, low-grade fever, or leukocytosis. Fever is associated with *C. difficile* colitis in approximately 15% of cases. Examination initially focuses on the patient's fluid status, including assessment for dry mucosa, tachycardia, hypotension, or lightheadedness. The abdomen is assessed for evidence of an acute surgical process. A rigid or distended abdomen may represent bowel perforation. A stool sample is taken for *C. difficile* toxins. The examiner should wear gloves and a protective gown. Vigorous handwashing with soap and warm water after each patient encounter is performed to decrease person-to-person infections because hand sanitizers do not kill *C. difficile* sufficiently.[20]

Diagnostic Testing

The stool of infected persons is assayed for *C. difficile* toxins A and B using enzyme immunoassays (EIAs). Nucleic acid amplification tests (NAATs) for *C. difficile* toxin genes (e.g., PCR assays) are superior to EIA for toxins A and B and are therefore recommended for definitive diagnostic testing. Glutamate dehydrogenase (GDH) screening with subsequent toxin A and B EIA testing has a lower sensitivity but is an

alternative diagnostic approach when NAAT testing is not available. In addition, a CBC, metabolic panel, and lactate level determination are considered based on the patient's fluid status and severity of symptoms. Leukocytosis in the setting of *C. difficile* colitis is common, with the white blood cell (WBC) count often greater than 15,000 cells/mm^3.

Persons at extremes of age tend to have more severe infections. The past decade has seen the emergence of a fulminant form of *C. difficile* in patients older than 65 years. Elders with a leukocyte count greater than 20,000 cells/mm^3, nosocomial infection, renal failure, or immunosuppression are at increased risk for complications such as toxic megacolon, shock, need for colectomy, and death. If a person has any of these risk factors, appears septic, or has a tender and distended abdomen, an emergent computed tomography (CT) scan abdomen with a surgical or GI consultation is recommended to evaluate for toxic megacolon.[20] A colonoscopy may provide direct visualization of the colon for the presence of pseudomembranous colitis and should be performed with caution in patients with toxic megacolon, because it may cause a bowel perforation.

Management

The management of *C. difficile* colitis includes discontinuation of any inciting antibiotic and rapid initiation of treatment. Vancomycin 125 mg PO qid for 10 days, is the first drug of choice or fidaxomicin 200 mg PO bid for 10 days. A third alternative is metronidazole 500 mg PO tid for 10 days.[20] Patients generally become afebrile and show clinical improvement within 36 to 72 hours of treatment. Diarrhea usually resolves over 5 to 7 days, even though the results of toxin assays and stool cultures may remain positive for weeks. Up to 30% of patients experience a relapse regardless of the antibiotic chosen, its dosage, or duration of treatment. Risk factors for recurrent disease include new exposure to antibiotics, age older than 65 years, severe underlying disease, low serum albumin level, need for admission to an intensive care unit, or extended hospital stay of 16 to 30 days. Most of these patients will respond to another course of antibiotic therapy.

Hospitalization is indicated for elders, nursing home patients, those with comorbid conditions such as renal failure, an immunocompromised state, or severe dehydration. Patients are placed in contact isolation, and hospital protocols should be followed for *C. difficile* infections. Outpatient therapy is appropriate for individuals without comorbid conditions who are non–toxic appearing, with mild disease, and who can tolerate oral hydration.

VIRAL GASTROENTERITIS

Most cases of gastroenteritis are caused by viruses, which include norovirus, rotavirus, *Sapovirus*, adenovirus, and astrovirus. Clinical features suggestive of a viral cause consist of an intermediate incubation period (24 to 60 hours) and short infectious duration (12 to 60 hours). The rate of rotavirus-associated gastroenteritis has significantly decreased with the increasing use of the rotavirus vaccine in children. Patients with viral gastroenteritis can present with nausea, vomiting, abdominal cramping, or diarrhea. Physical findings may include fever and abdominal tenderness. Symptoms and signs of dehydration can occur in severe cases. Norovirus and rotavirus are among the two most prevalent viral causes of gastroenteritis. Table 80.3 and Table 80.7 contain summaries of common causes, clinical features, diagnostic studies, and treatment of viral gastroenteritis.

Norovirus

Epidemiology

The norovirus, previously referred to as the Norwalk-like virus, is the most common cause of acute gastroenteritis in children and adults in the United States and usually occurs in the winter months. It is also the most common cause of foodborne disease and person to person outbreaks in the United States. Norovirus causes approximately 20 million illnesses/year, with approximately 400,000 ED visits. Patients who are immunocompromised or at extremes of age (adults >65 years and children <5 years) are at greatest risk of complications or death.[21]

Pathophysiology

Transmission of norovirus occurs via the fecal-oral route, including ingestion of contaminated food or water, or exposure to airborne droplets of vomitus-containing viral particles and fomites. It has an incubation period of 1 to 2 days, with symptoms typically lasting for 48 to 72 hours. Norovirus is highly infectious for all age groups, and only a small inoculum (≈100 virions) is needed for virus transmission. Shedding of the virus in the stool can occur up to 2 to 3 weeks after onset of symptoms.[22]

Clinical Features

The onset of symptoms is commonly abrupt and vomiting is a prominent feature. Patients develop diarrhea that is usually moderate in amount, defined as four to eight stools over a 24-hour period. The diarrhea is characterized as a non-bloody stool with a loose to watery consistency that lacks mucus. Associated symptoms include generalized malaise, myalgias, headache, or fever, which occur in approximately 50% of cases. Recovery is typically rapid, but the infection may be protracted, and symptoms may be present for a longer period due to prolonged viral shedding, especially in the immunocompromised. Advanced age is a risk factor for a fatal outcome from the disease. In rare circumstances, patients may present with central nervous system (CNS) complications, such as seizures or encephalopathy.

TABLE 80.7 Viral Gastroenteritis: Causes and Clinical Features

Organism	Mode of Transmission	Clinical Features
Norovirus	Ingestion of contaminated food and water; touching contaminated surfaces; highly contagious	Most common cause of gastroenteritis in the United States, and most common cause of US foodborne-disease outbreaks; fever, headache, myalgias, nausea, vomiting, abdominal pain, diarrhea; incubation period, 12–48 h
Sapovirus	Ingestion of contaminated food or water; fecal-oral route	Fever, nausea, vomiting, diarrhea; usually causes mild illness
Rotavirus	Ingestion of contaminated food or water; touching contaminated surfaces	Fever, nausea, vomiting, abdominal pain and watery diarrhea; incubation period ≅ 2 days
Adenovirus	Close personal contact; touching contaminated surfaces	Rare cause of serious illness; fever, diarrhea; can cause nongastrointestinal illness (e.g., bronchitis, pneumonia, conjunctivitis)
Astrovirus	Fecal-oral route	Malaise, headache, abdominal pain, diarrhea; vomiting less common

Diagnostic Testing

The diagnosis of viral gastroenteritis is commonly based on clinical features. A norovirus outbreak in the community is suspected when these criteria are met: A greater proportion of cases with vomiting than with fever, bloody diarrhea in less than 10% of cases, and vomiting in greater than 25% of cases.[23]

The identification of the exact causative viral agent is not usually necessary. However, in the setting of an outbreak, it is important to isolate the causative organism so that successful mechanisms that disrupt viral transmission can be recognized. The preferred specimen used to detect norovirus is a stool sample, which contains a higher quantity of virus as compared with vomitus or rectal swabs. The diagnosis of norovirus infection involves the detection of viral antigen or viral RNA. Quantitative reverse transcription-polymerase chain reaction (RT-qPCR) assays are used to detect norovirus in stool, vomitus, food, water, or in environmental specimens.[24] Norovirus antigen can also be detected in stool samples by the use of commercial EIAs. However, these kits have poor sensitivity (50% to 75%) and hence have limited use in the diagnosis of sporadic cases of gastroenteritis.[21]

Management

Viral gastroenteritis due to norovirus has no specific treatment. Management is based on the clinical condition of the patient. Supportive care, including oral hydration or IV fluid replacement, may be required. Implementation of proper hand hygiene is key to prevent the disease from occurring. During outbreaks, patients should be placed on contact precautions in a cohort setting. Routine disinfection and cleaning of environmental surfaces and equipment should also take place.[25]

Rotavirus

Epidemiology

Rotavirus predominantly infects infants and young children, with a milder disease occurring in adults. Prior to the development of the rotavirus vaccine, it was the leading cause of diarrhea in the US among infants and children. Rotavirus is a stable virus and primarily transmitted via the fecal-oral route or direct contact with contaminated surfaces. US epidemics occur typically in the winter and spring, from December to June.

Pathophysiology

Pathogenesis of the illness is associated with diarrhea, which occurs as a result of three main mechanisms: The direct effect of the rotavirus enterotoxin NSP4, loss of brush border enzymes, and activation of the enteric nervous system.

Clinical Features

Clinical features of rotavirus infection in children include fever, nausea, vomiting, and non-bloody watery diarrhea. Rotavirus causes severe acute gastroenteritis in a higher proportion of cases compared with norovirus.[26] Rotavirus has an incubation period of approximately 2 days, and symptoms can last from 3 to 8 days. Patients may also present with loss of appetite and signs of dehydration, including dry mucous membranes or decreased urinary output. Children with rotavirus can also have concurrent respiratory symptoms or CNS complications, including seizures, encephalopathy, and encephalitis. A milder form of rotavirus infection occurs in adults, especially in household members of infected children. Elders and immunocompromised patients are at increased risk for more severe disease with protracted illness, thus remain important factors in determining the duration of isolation and repeat testing to ensure eradication of the virus.

Diagnostic Testing

Rotavirus infection is best diagnosed with antigen-detection immunoassays or RT-PCR based nucleic amplification tests on stool specimens. Oral swabs have a lower sensitivity to detect enteric viruses.[27,28]

Management

Rotavirus is a self-limited illness that lasts for a few days in healthy individuals. Treatment involves supportive care and managing fluid status. Prevention of rotavirus infection occurs with the use of live, attenuated oral vaccines.[29] Neither natural infection nor vaccine ensures protection from future infections, so vaccinated and unvaccinated children may develop multiple episodes of rotavirus gastroenteritis. Hospitalizations from rotavirus and all-cause acute gastroenteritis have substantially decreased with the use of the rotavirus vaccines.[30]

PARASITES

Table 80.8 lists the clinical features of common parasites causing gastroenteritis, and Table 80.4 summarizes appropriate diagnostic tests and treatment.

Giardia

Epidemiology

Giardia lamblia enteritis is caused by the flagellated protozoan pathogen, *G. lamblia (G. duodenalis, G. intestinalis)*. The disease is one of the most common protozoan infections in the United States; it can also cause sporadic or epidemic gastroenteritis worldwide.[31] The disease is spread via the fecal-oral route or ingestion of contaminated food or water. It is easily transmittable between close contacts because the ingestion of as few as 10 cysts can result in illness. The illness occurs more commonly in developing countries that have poor sanitary conditions. Infants, young children, travelers, immunocompromised individuals, or patients with cystic fibrosis or hypochlorhydria (low stomach acid) are at most significant risk for developing the disease.

TABLE 80.8 Parasitic Gastrointestinal Infections: Causes and Clinical Features

Organism	Mode of Transmission	Clinical Features
Giardia lamblia	Ingestion of contaminated food or water; fecal-oral route	Nausea, vomiting, abdominal cramping, flatulence, greasy stool that may float
Entamoeba histolytica	Ingestion of contaminated food or water; touching contaminated surfaces; fecal-oral route	Fever, anorexia, abdominal cramping, watery or bloody diarrhea; illness ranges from asymptomatic infection to fulminant colitis, peritonitis to extraintestinal amebiasis
Cryptosporidium	One of the most frequent causes of waterborne disease in the US population	Abdominal cramping, diarrhea
Cyclospora cayetanensis	Ingestion of contaminated food or water; fecal-oral route	Nausea, vomiting, loss of appetite, weight loss, bloating, abdominal cramping, diarrhea

Pathophysiology

G. lamblia exists in two forms, trophozoite (active form) and cyst (inactive form). Trophozoites attach to the mucosal lining of the small intestine and cause symptoms. This active form of the parasite is unable to survive outside the body for an extended period of time and hence cannot spread infection to others. However, the cystic form is viable outside of the body for prolonged periods and, once ingested, changes into the trophozoite form. Trophozoites generate the cysts that exit the body via the feces. Giardiasis is a common cause of diarrhea in hikers exposed to contaminated water. Infection can also be transmitted via anal intercourse.

Clinical Features

Clinical features of acute giardiasis consist of sudden onset of diarrhea associated with malaise, weight loss, nausea, abdominal cramping, or bloating. Stools are characterized as being foul-smelling and greasy. Most cases of giardiasis are self-limiting. A small percentage can develop chronic symptoms, including abdominal pain, functional dyspepsia, intermittent chronic diarrhea, malnutrition, or weight loss.

Diagnostic Testing

Immunoassays have higher diagnostic sensitivities than stool microscopy and are the preferred diagnostic modality, when available. Several immunoassay tests are available, including direct immunofluorescent assays, immunochromatographic assays, and enzyme-linked immunosorbent assays (ELISAs).

Stool microscopy can identify ova and parasites, especially in the acute phase, when cysts and trophozoites appear in the stool. In subacute, chronic, or asymptomatic cases, trophozoites may be present in the stool in small numbers or on an intermittent basis. Collection of multiple stool samples (e.g., three stool samples collected on separate days) can increase the sensitivity of the test.

Biopsy of duodenal-jejunal tissue or aspiration of the duodenal-jejunal area by endoscopy may be required to make the diagnosis when repeated stool samples tested for ova and parasites do not yield any organisms.[3]

Management

Treatment of symptomatic cases consists of a single PO dose of tinidazole 2 g PO. Metronidazole 500 mg PO bid or 250 mg PO tid daily for 5 to 7 days, or nitazoxanide 500 mg PO bid for 3 days, may also be given. Alternative agents include albendazole, paromomycin, mebendazole, or quinacrine.[32,33] Treatment of asymptomatic giardiasis is controversial. Asymptomatic carriers, especially children or food handlers, may need to be treated to reduce the risk of spread and decrease the risk of developing chronic intermittent diarrhea. Prevention of the disease is promoted by the use of strict handwashing and the avoidance of ingesting contaminated water. Patients diagnosed with giardiasis and who are incontinent or wearing diapers should be placed on contact precautions.

Amebiasis

Epidemiology

Amebiasis is caused by the protozoan *Entamoeba histolytica*, which is found worldwide. The genus *Entamoeba* is composed of many species, but *E. histolytica* is the only one linked to disease.

Amebiasis is more common in developing countries with poor sanitary conditions. Most *E. histolytica* infections are asymptomatic, with only 10% of carriers presenting with symptoms. Specific groups of individuals are more predisposed to amebic colitis, such as those at the extremes of age, pregnant females, or malnourished individuals. Travelers to endemic areas are also at risk for infection.

Pathophysiology

E. histolytica exists in two forms, the trophozoite and cystic forms. The parasite is transmitted by the ingestion of the cystic form, which is the infective stage of the disease. Cysts can survive in the environment for weeks to months and can be found on the contaminated hands of food handlers or in fecally contaminated food and water. The infection can also spread through the ingestion of cysts via anal-oral sexual practices. Trophozoites are formed when excystation occurs in the terminal ileum or colon, resulting in the invasive stage of the disease. Trophozoites can cause tissue destruction by penetrating the colonic mucosal barrier, leading to secretory bloody diarrhea and colitis. Extraintestinal disease can also occur by the hematogenous spread of trophozoites via the portal circulation to the liver or other organs.

Clinical Features

Intestinal amebiasis includes asymptomatic colonization. However, the infection can progress to a symptomatic intestinal illness. Acute amebic dysentery has an incubation period that ranges from 1 week to 1 year. Patients present with acute onset of severe abdominal cramps associated with fever, profuse, bloody diarrhea, and tenesmus. Gradual onset of symptoms can result in chronic amebic colitis. Individuals present with intermittent diarrhea, with two to four foul-smelling stools daily, usually containing blood-streaked mucus. Associated symptoms of fever, weight loss, abdominal cramping, or flatulence can be present. The clinical condition may have alternating symptomatic and asymptomatic periods, which last over months to years. The most common serious complication of amebic colitis is amebic liver abscess.

Diagnostic Testing

The diagnosis of amebic colitis in the past was based on microscopic identification of cysts and trophozoites in stool samples. Trophozoites can also be identified in biopsy samples obtained during colonoscopy. The development of stool antigen assays has enhanced the diagnostic process for amebic colitis. EIA kits for *E. histolytica* antibody and antigen detection are available. However, they require fresh, not fixative-preserved stool for analysis. Molecular analysis by PCR-based assays is the gold standard with very high sensitivity and specificity.[34]

Management

For asymptomatic carriers, treatment consists of paromomycin 25 to 35 mg/kg/day PO divided tid for 7 days. Oral iodoquinol 650 mg tid for 20 days, or diloxanide furoate 500 mg PO tid for 10 days, can also be given. For mild to moderate intestinal amebiasis, metronidazole 500 mg to 750 mg PO tid for 7 to 10 days can be prescribed, followed by paromomycin treatment. Paromomycin can cause diarrhea as a side effect, thus making it difficult to assess the patient's response to metronidazole if both drugs are given together. Alternate therapies include tinidazole 2 g PO each day for 3 to 5 days or nitazoxanide 500 mg PO bid for 3 days. For amebic liver abscess, metronidazole 750 mg PO tid for 10 days or tinidazole 2 g PO each day for 5 days or nitazoxanide 500 mg PO bid for 3 days can be given.[34]

FOOD POISONING

Foundations

Foodborne gastroenteritis is an illness caused by the ingestion of food contaminated by viruses, bacteria, or bacteria toxins. *Food poisoning* is the term typically used for gastroenteritis caused by the ingestion of preformed toxins, such as staphylococcal toxins, *B. cereus* toxins, histamine-like substances from scombroid fish poisoning, ciguatoxins from ciguatera fish poisoning, or *Clostridium botulinum* toxins.

The enterotoxins can also be produced in vivo after the ingestion of the bacterium and subsequent production of the enterotoxin in the intestinal lumen. Examples include *C. perfringens, B. cereus, C. botulinum,* ETEC, *V. cholerae*, and noncholera *Vibrio* spp. such as *V. enterocolitica*.

Clinical Features

Food poisoning usually manifests 1 to 6 hours after the ingestion of preformed toxins from *Staphylococcus, B. cereus* (short incubation form), and scombroid fish or ciguatera fish poisoning. Moderate incubation periods of 8 to 16 hours are seen after the ingestion of toxin-forming bacteria such as *C. perfringens* or *B. cereus* (long incubation form). Longer incubation periods of more than 16 hours are associated with ETEC, STEC, and *Shigella* and *Vibrio* spp.

The clinical presentation usually involves an abrupt onset of nausea, vomiting, or abdominal cramping, followed by watery diarrhea. Fever is usually absent, and symptoms typically resolve within 24 hours. In some cases, *B. cereus* predominantly causes diarrhea and cramping. Often, there is a clear food exposure, such as at a picnic with many people who have the same illness at the same time.

Diagnostic Testing

Diagnostic testing is usually not indicated in cases of food poisoning, and most individuals will recover within 24 hours. A detailed history of the timing, types, and places of recent sources of food ingestion should be obtained. Similar patterns of GI illness involving others who may have ingested the same foods may assist in identifying the cause. If identification for outbreak surveillance is needed, stool samples can be sent to test for specific organisms.

Most state health departments encourage consumers to report food poisoning incidents to their local health department. Physicians and laboratories must report each singular diagnosed infection that is included in a notifiable disease list maintained by local, state, or federal agencies (www.cdc.gov/foodsafety). Foodborne illnesses are included in the notifiable disease lists. Examples include: Salmonellosis, shigellosis, cholera, STEC, norovirus, and hepatitis A. Physicians should suspect an outbreak when they detect a larger than normal number of people exhibiting the same symptoms.

Management

In general, oral hydration is the mainstay of treatment. Antiemetics such as ondansetron 0.15 mg/kg up to 8 mg PO, or metoclopramide 10 mg PO, may be used to enhance oral hydration. Antibiotic therapy is rarely required, and most patients will have a self-limited illness.

Scombroid Fish Poisoning

Epidemiology

Scombroid fish poisoning remains one of the most common forms of fish poisoning in the United States. The disease takes its name from the family Scombridae (e.g., tuna, mackerel, skipjack, bonito, and related species) but results from the ingestion of a wide variety of dark meat fish, including nonscombroid species such as herring, bluefish, anchovy, sardine, amberjack, black marlin, and mahi mahi. The fish species most commonly implicated include mahi mahi, tuna, and bluefish.

Most US cases occur in Hawaii and Florida, followed in frequency by California, New York, Washington, and Connecticut. However, scombroid poisoning can occur in any location where fresh fish is available.

Pathophysiology

The meat of implicated species naturally contains unusually high levels of histidine. Scombroid fish poisoning results from the ingestion of heat-stable toxins produced by bacterial action on the histidine present in the dark meat of the fish. The bacteria responsible are normal constituents of the surface marine flora, rather than contaminants. The histidine decarboxylase activity of these organisms produces histamine and histamine-like substances, which cause the symptoms of scombroid fish poisoning. High levels of histamine in the fish correlate directly with the occurrence of the illness.

Formation of the scombrotoxins is directly related to improper preservation and refrigeration of the fish from the time they are caught until when they are cooked. In general, the problem is caused by improper refrigeration by the supplier rather than being the fault of the restaurant serving the fish. Other foods, notably Swiss cheese, contain sufficient amounts of histidine and have also been implicated.

Clinical Features

The symptoms of scombroid fish poisoning resemble those of histamine intoxication. While eating the fish, the patient may note a metallic, bitter, or peppery taste, although many affected fish do not have an abnormal odor or taste. Symptoms usually develop abruptly within 20 to 30 minutes and consist of facial flushing, diarrhea, severe and throbbing headache, palpitations, or abdominal cramping. Other manifestations may include dizziness, dry mouth, nausea, and vomiting, or urticaria. The facial flushing resembles a sunburn and can extend over the entire skin surface. The conjunctivae usually are injected. The duration of the major symptom complex generally is less than 6 hours, and, although weakness and fatigue persist longer, the clinical course usually is benign. The attack rate is high; most persons sharing the same toxic fish will become ill.

Management

Parenteral antihistamine therapy, such as diphenhydramine 25–50 mg IM or IV, or cimetidine 300 mg IM or IV, usually relieve symptoms promptly. This is not an allergic reaction, so patients should not be told that they are allergic to these fish, nor should they be prohibited from eating them again in the future. Suspected cases of scombroid should be immediately reported to the health department.

Ciguatera Fish Poisoning

Epidemiology

Ciguatera fish poisoning is a common public health problem, with appreciable economic significance. It is endemic in tropical regions but is found worldwide. Fish caught around Hawaii and Florida cause most US cases but, because the responsible ocean fish are now commonly transported inland, cases can be seen virtually anywhere. More than 400 fish species that frequent coral reefs have been implicated as ciguatoxin carriers, but fewer than 50 are commercially important, including amberjack, barracuda, grouper, king mackerel, parrotfish, sea bass, snapper, sturgeon, surgeonfish, and ulua.

Pathophysiology

Ciguatera fish poisoning results from the ingestion of the ciguatoxin neurotoxin. Ciguatoxin is produced by the marine dinoflagellate *Gambierdiscus toxicus*, which attaches itself to marine algae and is passed up the food chain. The lipid-soluble toxin accumulates in the tissues of the larger predacious coral reef fish, with the highest concentrations in the liver, intestines, head, and roe. It does not affect the fish in any way. Only humans suffer its ill effects when the toxin is ingested.

Ciguatoxin is heat- and acid-stable, odorless, and tasteless. It is not deactivated by cooking or freezing, nor is the toxin eliminated by drying, salting, smoking, marinating, or pickling. It is not possible to predict whether a fish contains sufficient amounts of the toxin to produce illness.

Ciguatoxin has anticholinesterase and cholinergic properties, although its neurotoxicity is mediated by its effect on sodium channels. Ciguatoxins cause a hyperpolarizing shift of the voltage dependence of channel activation so that sodium channels are open at the resting membrane potential. Spontaneous firing of neurons occurs as tetrodotoxin-sensitive sodium channels are activated, giving rise to the typical neurologic signs and symptoms.

Clinical Features

Ciguatera fish poisoning is usually seen in the spring and summer months. The incubation period is approximately 2 to 6 hours, but a delay of 12 to 24 hours is not unusual. Attack rates are very high, with 80% to 90% of persons exposed becoming ill. Symptoms tend to be related to the amount of toxin ingested and vary considerably in their severity. If not fully recovered from an initial ingestion of ciguatoxin, affected persons are likely to have much more serious symptoms from a second ingestion.

Classically, patients exhibit GI and neurologic symptoms. The GI symptoms (e.g., nausea, vomiting, profuse watery diarrhea, crampy abdominal pain) tend to appear first and resolve over the first 24 hours. The constellation of neurologic symptoms consists largely of dysesthesias and paresthesias around the throat or perioral area. The sensation of burning feet, which may resemble alcoholic peripheral neuropathy, loose, painful teeth, and sometimes CNS changes, such as ataxia, weakness, vertigo, visual hallucinations, or even confusion and coma, may also occur.

Distortion of temperature perception is vividly described by patients with ciguatera poisoning. Cold allodynia, defined as dysesthesia experienced on contact with cold water or cold objects, is almost pathognomonic of ciguatera poisoning and often is incorrectly referred to as cold-hot temperature reversal. Another classic feature is a return or a worsening of associated symptoms after the ingestion of alcohol.

Ciguatera poisoning lasts an average of 1 to 2 weeks, but at least 50% of victims are still symptomatic at 9 weeks. The neurologic symptoms, particularly the paresthesias and dysesthesias, tend to persist longer than the GI symptoms and have been reported up to years later.

Management

Treatment is primarily supportive. IV fluids are given to replace volume losses from vomiting and diarrhea, and analgesics are used as needed. In severe cases, the toxin may exhibit some anticholinesterase activity, manifested as bradycardia and hypotension, which can be treated with atropine, 0.5 mg IV, or dopamine 5 to 20 μg/kg/min via IV infusion. Patients should be told to abstain from alcohol in any amount until symptoms have completely resolved. Pruritus may be managed with a histamine H1 receptor antagonist, such as diphenhydramine 25 mg PO qid, or cetirizine 10 mg PO once daily. Amitriptyline 25 mg PO bid can bring about a dramatic reduction in the pruritus and dysesthesias, two of the most disturbing and protracted symptoms.

SPECIFIC GROUPS WITH GASTROENTERITIS

Traveler's Diarrhea

Epidemiology

Traveler's diarrhea is the most common illness afflicting people traveling from resource-rich regions to the developing world. The traveler's destination is the most important factor in assessing the risk of developing disease. Ingestion of contaminated food and water is the primary mode of transmission of traveler's diarrhea.

Pathophysiology

The ingestion of fecally contaminated food or beverages causes traveler's diarrhea. Most cases are caused by bacterial pathogens. ETEC is the most common bacterial cause for traveler's diarrhea. A variety of viruses and parasites also causes the disease. Bacterial and viral pathogens have an incubation period ranging from 6 to 48 hours. Parasitic causes have a longer incubation period, up to 2 weeks in duration. Causative agents are listed in Table 80.9.

Clinical Features

Traveler's diarrhea is the sudden onset of abnormally loose or liquid, frequent stools resulting in an illness that is tolerable (mild), distressing (moderate), or incapacitating (severe) for the individual.

The classification is now based on functional impact on the traveler rather than the number of stools.[35] Patients commonly present with low-grade fever, abdominal cramping, or watery diarrhea. Traveler's diarrhea is typically a self-limited illness. Dysentery presents with fever, nausea, vomiting, abdominal pain, tenesmus, or blood in the stools.

Diagnostic Testing

Typically, traveler's diarrhea is self-diagnosed. Determination of the pathogen is generally unnecessary in the uncomplicated case. Diagnostic testing should be reserved for patients with severe or persistent symptoms. Routine stool cultures are rarely necessary, because EAEC and ETEC cannot be differentiated from nonpathogenic *E. coli* on stool culture. The cultures are mainly reserved to confirm outbreaks. If stool cultures are sent, testing should specifically look for ETEC, *Shigella*, *Campylobacter,* and norovirus. If the enteritis is chronic (>2 weeks in duration), associated with foul-smelling and excessive flatulence, the stool should be examined for *Giardia*.[35]

TABLE 80.9 Traveler's Diarrhea: Causative Organisms and Treatment

Severity	Definition
Mild	Diarrhea that is tolerable, not distressing, and does not interfere with planned activities. Antibiotics are not recommended.
Moderate	Diarrhea that is distressing or interferes with planned activities. Antibiotics may be indicated (e.g., immunosuppressed, solid organ transplant, elderly)
Severe	Diarrhea that is incapacitating or prevents planned activities; all dysentery (passage of grossly bloody stools) is considered severe. Antibiotics are indicated for severe traveler's diarrhea.[35]
Organism	**Treatment**
Enterotoxigenic *Escherichia coli* (ETEC)	Ciprofloxacin 500 mg PO bid or 750 mg PO once daily for 1–3 days
Enteroaggregate *E. coli* (EAEC)	Ciprofloxacin 500 mg PO bid or 750 mg PO once daily for 1–3 days
Campylobacter	Azithromycin 500 mg PO daily for 3 days
Salmonella	Levaquin 500 mg PO daily for 7 days
Shigella	Ciprofloxacin 750 mg PO daily for 3 days
Norovirus	Supportive care
Rotavirus	Supportive care
Giardia	Metronidazole 500 mg PO bid or 250 mg PO tid for 5–7 days

Management

The best strategy regarding traveler's diarrhea is prevention. Travelers should avoid eating dairy products, raw fruits, and vegetables, or undercooked meat and seafood. Individuals should use water that has been boiled, which is the most reliable method to make the water safe for consumption. Travelers should avoid ice or food served at room temperature. The risk of developing traveler's diarrhea is also reduced by the use of alcohol-based hand sanitizers (containing >60% alcohol) and meticulous hand hygiene. Table 80.10 lists preventive medications and treatment of traveler's diarrhea.

Management of traveler's diarrhea depends on the clinical scenario and the severity of illness. The mainstay of treatment is hydration. Commercially available oral rehydration packets can be used by travelers to maintain their fluid status. For mild or moderate diarrhea, symptomatic therapy, including antimotility agents such as loperamide or diphenoxylate can be used by travelers to reduce the rate of stooling. In severe cases, antimotility agents should be taken in conjunction with an antibiotic, as the antimotility agent may increase the contact time of the toxin or invasive infectious agents with the intestinal mucosa. Antimotility agents do not treat the cause of diarrhea and should be avoided in cases of dysentery.

The antacid bismuth subsalicylate decreases the incidence of traveler's diarrhea by 65% due to its antibacterial and antisecretory effects. The recommended dose is two tablets PO qid or one fluid ounce PO qid. Bismuth subsalicylate should be avoided in those who are allergic to aspirin because it contains salicylate. Potential side effects include blackening of the tongue or stool. It should not be taken for more than 3 weeks.

The risk of traveler's diarrhea can be reduced by more than 90% with the use of prophylactic antibiotics. However, due to the development of adverse side effects and resistance, prophylaxis is recommended only for individuals with comorbidities that place them at high risk for complications of diarrhea (e.g., transplant patients, patients with renal failure, or IBD, or patients who are immunosuppressed).[36] Prophylactic antibiotics should not be given for more than 2 to 3 weeks.

Antibiotics such as quinolones, azithromycin, and rifaximin can be prescribed when indicated (see Table 80.8). The decision to initiate treatment for traveler's diarrhea is based on the functional impact of the diarrhea, the associated signs and symptoms, and need for resolution of the diarrhea in regard to the patients' travel plans. In patients with moderate to severe traveler's diarrhea, antibiotics can shorten the duration of disease by 1.5 days. The choice of antibiotic is based on the location of the traveler. Single-dose azithromycin, levofloxacin, and rifaximin with loperamide have been shown to be comparable for the treatment of acute watery diarrhea.

Azithromycin 500 mg PO daily for 3 days is the drug of choice. Rifaximin 200 mg PO tid for 3 days is an alternate antibiotic that can be prescribed for patients with noninvasive illness. It is not effective against invasive pathogens such as *Campylobacter*, *Salmonella,* and *Shigella* spp.[35] Fluoroquinolones are no longer the first line antibiotic choice for treatment of traveler's diarrhea due to the widespread resistance and evidence for the increased risk of multidrug-resistant organisms. In November 2018, the US Food and Drug Administration approved rifamycin for the treatment of traveler's diarrhea. It is an enteric antibiotic that is similar to rifaximin and poorly absorbed with a low rate of adverse events. Rifamycin can also be used as an alternative for treatment of moderate to severe cases of traveler's diarrhea. The dose of rifamycin is 388 mg PO bid for 3 days.[37]

GASTROENTERITIS IN THE IMMUNOCOMPROMISED HOST WITH HIV/AIDS

Epidemiology and Pathophysiology

The evaluation of gastroenteritis in HIV-positive patients deserves special attention because these patients are at risk for opportunistic enteric infections and are more likely to develop chronic gastroenteritis. Rates of regular gram-negative bacterial enteric infections are at least 10-fold higher among HIV-infected adults than in the general population, but these rates decline when patients are treated with highly active antiretroviral therapy (HAART). The risk of bacterial diarrhea varies according to CD4 T lymphocyte (CD4) count. Those with a CD4+ count of less than 200/mm^3 are more susceptible to certain viruses and parasites, such cytomegalovirus (CMV), *Cyclospora, Cryptosporidium, Isospora, Mycobacterium avium-intracellulare* (MAI) complex, or *Giardia*. HIV itself may also cause diarrheal illness. Although not precisely clear, it is thought that HIV may cause direct infection of the enterocytes and invasion of the lymphoid tissues of the GI tract. Patients with an extremely low CD4+ count, less than 100/mm^3, tend to develop opportunistic infections that are chronic in nature.[38]

Clinical Features

The history should ascertain treatment with HAART, the CD4+ count, and viral load. A history of previous enteric pathogen-related diarrheal

TABLE 80.10 Traveler's Diarrhea in Adults: Preventive Medications and Treatment

Pharmacologic Agent	Recommended Dose	Adverse Effects/ Notes
Prevention		
Rifaximin	200 mg PO daily or bid for duration of trip, not to exceed 2 weeks	Considered safe as it is not absorbed
Bismuth subsalicylate	524 mg PO qid (1 oz liquid or two tablets) for duration of trip, not to exceed 2 weeks	Contains hydrogen sulfide, which turns stool or tongue black in color
Treatment		
Bismuth subsalicylate	524 mg PO qid (1 oz liquid or two tablets)	Contains hydrogen sulfide, which turns stool or tongue black in color
Loperamide	4 mg PO initially, then 2 mg PO after each unformed stool; not to exceed 16 mg/day.	Lowest effective dose should be taken to limit rebound constipation
Azithromycin	500 mg PO daily for 3 days or 1000 mg PO in single dose	First treatment of choice. Nausea is common adverse effect
Rifaximin	200 mg tid PO for 3 days	Considered safe because it is not absorbed. Alternative agent.
Rifamycin	388 mg PO bid for 3 days	Alternative for moderate to severe diarrhea.
Ciprofloxacin	500 mg PO bid for 3 days or 750 mg PO single dose	Achilles tendon damage; *C. difficile* infection. High resistance

illness is important as recurrence rates are common. Anal receptive intercourse may predispose to colonic pathogens, such as *Giardia, Entamoeba,* CMV, *Shigella,* and *Campylobacter*.

Antiviral therapy-induced diarrhea has also been known to cause watery diarrhea in HIV-infected patients. In HAART-naïve populations, *Cryptosporidium* and CMV infections are the two most common causes. Chronic high-volume watery diarrhea often is indicative of small bowel disease from one of the coccidia, *Cryptosporidium,* or *Cystoisospora belli*. Although self-limited in the healthy host, coccidial disease often is persistent in patients with CD4+ counts less than 200/mm^3. CMV and MAI also produce a chronic illness in those with CD4+ counts less than 100/mm^3.

Fever, weight loss, or abdominal pain are prominent; diarrhea is mild to moderate and sometimes bloody, typical of colonic disease. Microsporidia have emerged as a common cause of diarrhea in patients with AIDS in whom the CD4+ count is less than 100/mm^3. *Salmonella* infections, especially with *S. typhimurium,* are common in immunocompromised hosts. Patients with AIDS who acquire *Salmonella* enteritis are at increased risk for bacteremia and metastatic focal infection compared with normal hosts. *C. difficile* enteritis occurs more commonly in patients with AIDS owing to the common use of prophylactic antibiotic therapy and frequent hospitalizations. It is the most common bacterial enteritis in the AIDS population.

Diagnostic Testing

In patients with AIDS, the presenting signs and symptoms generally do not allow consistent classification of diarrheal illness, given the prevalence of multiple, concomitant enteric pathogens among this population. However, some clinical syndromes are typical. Patients with a fulminating clinical course usually have a disseminated infection, such as infection with CMV or MAI complex. Massive weight loss is also associated with diarrhea caused by infection with these two organisms, as well as the coccidia *Cryptosporidium* and *Cystoisospora*. Voluminous watery diarrhea usually is a result of one of the coccidial organisms, including *Cyclospora* or *Isospora*. Patients with a proctocolitis-like picture most often have herpes simplex virus or CMV infection.[39]

Laboratory testing should initially focus on testing stool samples for *C. difficile* toxins and other bacteria, specifically *Salmonella*. If the stool is bloody and the CD4+ count is less than 200/mm^3, stool should be sent for CMV and MAI testing. If the diarrhea is present for more than 14 days, three stool samples for stool ova and parasites should also be sent. An acid-fast smear should be requested to look for *Cryptosporidium, Cystoisospora, Isospora,* and *Cyclospora* if suspected as described.

If the patient has suspected infectious colitis but recent stool analyses have been negative for any organism, a flexible sigmoidoscopy may be performed by a specialist to enhance the yield of a pathogen. Small bowel biopsy and duodenal aspiration may be indicated when stool examination, cultures, and sigmoidoscopy fail to yield a definitive diagnosis. Small bowel studies are most helpful for detecting infection with *Cryptosporidium,* CMV, MAI, *Giardia*, or *C. belli.* Small bowel enterocolitis generally presents with watery diarrhea without fever or fecal leukocytes.[3]

Management

Treatment should be directed toward the presumptive causative organism. As for immunocompetent patients, a cautious approach to initiating any antibiotic is suggested. Empirical antibiotic treatment should be initiated if the patient has a fever, bloody stool, appears ill, or has a low CD4+ count. Ciprofloxacin 500 mg PO bid or IV ceftriaxone 1–2 g daily may be empirically initiated while the evaluation is in progress. If *Giardia* or *C. difficile* is suspected, metronidazole 500 mg PO tid or vancomycin 125 mg PO qid should be added, respectively. If CMV colitis is suspected, foscarnet 90 mg/kg IV bid should be given. See Tables 80.3, 80.4, and 80.5 for the treatment of specific organisms.[38]

Treatment failure is common and is often due to incorrect initial therapy. For example, CMV colitis can also mimic invasive bacterial pathogens because it can also cause severe colitis with bloody stool, fever, and abdominal cramps. Treatment failures are also due to the propensity for infections to recur or become chronic. Parasitic infections in immunocompromised patients may be difficult to eradicate, even with the correct treatment.

Gastroenteritis in the HIV-positive patient is often complex, prolonged in duration, and difficult to treat. It is recommended that an infectious disease specialist be involved in the care of these patients. Patients who have AIDS or are immunocompromised should generally be considered for admission for further management.

CHAPTER 80: QUESTIONS AND ANSWERS

1. After eating undercooked ground beef, a patient develops fever, abdominal pain, bloody diarrhea, and rectal tenesmus. Local health authorities are investigating a common source from a local diner, as 10 other patrons have presented with the same symptoms. Which of the following organism is likely to produce this dysentery outbreak?

a. Giardia
b. Norovirus
c. Shiga toxin–producing *Escherichia coli* (O157:H17)
d. *Staphylococcus aureus*

Answer: c. This patient is most likely infected with Shiga toxin–producing *E. coli* (ETEC) which often results from eating undercooked ground beef. Watery diarrhea that becomes bloody with significant abdominal pain is typical. The diarrhea may be grossly bloody and mimic inflammatory bowel disease or intestinal ischemia. Toxin assays are recommended. Endoscopic findings would be identical to those of any other severe colitis. Antibiotics are not effective and may increase the risk of hemolytic uremic syndrome (HUS) in children. Thrombotic thrombocytopenic purpura (TTP) is a risk in older children and adults. Norovirus

typically causes watery non-bloody diarrhea without severe abdominal pain. *S. aureus* causes the classic food poisoning with abdominal cramping and vomiting 1 to 6 hours after ingestion the preformed toxin.

2. A patient from a resource-rich country has traveled to a resource-poor developing country. He develops diarrhea, up to four times a day, with yellow watery stools. There is no fever or abdominal pain. Which of the following organism is most commonly the etiology of Traveler's Diarrhea?
   - **a.** Enterotoxigenic *Escherichia coli* (ETEC)
   - **b.** *Giardia*
   - **c.** *Shigella*
   - **d.** *Vibrio* noncholera

Answer: a. ETEC is the most common cause of traveler's diarrhea, especially with travel to resource poor countries. It is usually self-limited, requiring antibiotic treatment only in severe cases. *Giardia* causes persistent diarrhea for more than 14 days. Giardiasis is commonly acquired from the ingestion of contaminated water, classically a camper who has ingested river water. The symptoms include diarrhea, abdominal cramping, and bloating, with foul-smelling stools. Shigellosis usually causes a more severe illness with dysentery.

3. A 5-year-old patient with a likely viral gastroenteritis for 3 days is determined to be dehydrated. What is optimum mode of rehydration therapy in this patient?
   - **a.** High-glucose solution (e.g., apple juice)
   - **b.** IV normal saline (0.9%)
   - **c.** Oral hydration with clean water
   - **d.** Reduced osmolarity (245 mOsmol/kg) oral rehydration solution

Answer: d. Fluids containing glucose and electrolytes provide optimal rehydration due to the cotransport of water across the intestinal lumen. Reduced osmolarity rehydration solution (e.g., WHO ORS 245 mOsm/kg) is associated with a reduced need for unscheduled IV infusions, lower stool volume, and less vomiting. High-glucose solutions have high osmolarity, and pure water has a low osmolarity; thus neither are optimal for water resorption. IV hydration is generally not indicated or cost effective in patients with mild or moderate dehydration.

4. A patient comes to the emergency department (ED) with a complaint of abdominal cramping and vomiting twice; the first time was the food ingested from a buffet 8 hours ago and the second time yellowish vomitus. There is no diarrhea or fever. There is continued retching intermittently in the ED. What is the likely causative organism?
   - **a.** *Clostridium perfringens*
   - **b.** *Escherichia coli* O157:H7—Shiga-producing toxin
   - **c.** Norovirus
   - **d.** *Salmonella enteritidus*

Answer: a. *Clostridium perfringens* is a common source of foodborne illness. Food cooked in advance, cooled, and rewarmed is the typical culprit. This is a toxin-mediated, diarrhea-predominant syndrome that is almost always self-limited. Ingestion of live organisms or spores is required, and antibiotics are not indicated. Symptoms usually appear within 6 to 12 hours, slightly longer than for staphylococcal food poisoning.

5. A patient presents with non-bloody diarrhea for 5 days, crampy abdominal pain, and bloating. The white blood cell (WBC) is 16,000/mL. Which of the following types of patient and scenario is most likely to put the patient at high risk for *Clostridium difficile*?
   - **a.** A 3-year-old toddler in daycare
   - **b.** Elderly nursing home patient
   - **c.** Nurse who works in the emergency department
   - **d.** Traveler on vacation returning from Mexico

Answer: b. Elderly nursing home patients have the highest risk for acquiring *C. difficile*. These patients are in close quarters and have multiple daily contacts with staff members, making person to person transmission more likely. Antibiotics and antacids are frequently utilized in these patients, which are risk factors for *C. difficile*. The *C. difficile* spores are highly resistant to heat, acid, and antibiotics, making them highly contagious for person to person or surface to person infections. The WBC is generally greater than 15,000/mL.

Large Intestine

Natasha Thomas and Andrea W. Wu

KEY CONCEPTS

Irritable Bowel Syndrome

- Irritable bowel syndrome (IBS) is a chronic disorder that includes both abdominal pain and bloating and is either diarrhea-predominant, constipation-predominant, or a mixed picture.
- Treatment of IBS is challenging and commonly involves a combination of diet, pharmacological, and behavioral therapy, along with reassurance.

Diverticular Disease

- Diverticular disease can consist of diverticulosis, which can cause bleeding but is often asymptomatic, or inflammation of the involved diverticula, termed diverticulitis.
- Uncomplicated diverticulitis can typically be managed on an outpatient basis, with oral antibiotics if indicated. Complicated diverticulitis may require admission and intravenous antibiotics, often with surgery consultation.

Large Bowel Obstruction

- The most common cause of large bowel obstruction in the United States is colorectal malignancy. Treatment consists of endoscopic placement of an intraluminal stent with surgical resection at a later date.
- Acute colonic pseudo-obstruction commonly occurs in hospitalized elders. Treatment involves medical management, with endoscopic decompression if refractory.

Volvulus

- Sigmoid volvulus often affects elders or those that are in long-term care facilities and can usually be treated by endoscopic decompression.
- Cecal volvulus often affects younger patients and requires surgical management.

Intussusception

- Intussusception is the second most common cause of an acute abdomen in the pediatric population after appendicitis, is usually idiopathic, and may be successfully treated with hydrostatic or pneumatic reduction.
- In adults, intussusception is often associated with neoplasm or malignancy, typically requiring surgical management.

Inflammatory Bowel Disease

- Inflammatory bowel disease (IBD) is characterized by chronic, relapsing, and remitting inflammatory disease. Crohn disease's (CD) transmural inflammation can affect any area of the gastrointestinal (GI) tract, whereas ulcerative colitis (UC) inflammation is more superficial and is limited to the colon and rectum.
- Effective management of IBD requires prompt recognition and treatment of acute relapses, and appropriate choice and monitoring of medications for maintenance of remission. Most patients with CD respond to ileal-release budesonide or systemic steroids; aminosalicylates are less effective. In contrast, aminosalicylates are first-line therapies for UC, with steroids reserved for use only when necessary. Refractory exacerbations for both CD and UC may be treated with immunomodulators or biologic agents.
- Common complications of IBD include the formation of fistulae, strictures, or abscesses; less common yet more severe complications include fulminant colitis, toxic megacolon, or intestinal perforation.
- Chronic inflammation can have extraintestinal effects. Thromboembolic events affecting the venous and arterial systems in IBD patients may be underdiagnosed.

Colonic Ischemia

- Colonic ischemia (CI) typically presents in elders and is the most common ischemia disorder of the GI tract. Local hypoperfusion and reperfusion injury cause crampy abdominal pain over the segment of the colon involved, followed by a short course of bloody diarrhea.
- Although abdominal computed tomography (CT) is not diagnostic for CI, it is useful in supporting the clinical suspicion, assessing the extent of colon involvement, diagnosing complications, and excluding other disorders. Colonoscopy within 48 hours of symptom onset is the most accurate diagnostic study.
- CI is usually self-limited, and most patients experience resolution of symptoms with supportive medical management with bowel rest, hydration, and pain management. Those with more severe disease, especially those with right-sided colonic involvement, may develop peritoneal signs from transmural ischemia requiring antimicrobials and possible surgical intervention.

Stercoral Colitis

- Stercoral colitis is a rare complication of chronic constipation that is typically diagnosed on CT and is associated with high mortality. The condition primarily affects the elderly, individuals living in nursing homes, young patients with neurological impairment, and those with chronic opioid use.
- Fecal impaction leads to increased intraluminal and colonic wall pressure, which then causes inflammatory changes and pressure wall necrosis of the colon. It can be complicated by CI, stercoral ulcer formation, and subsequent perforation.

Radiation Proctocolitis

- Radiation proctocolitis occurs commonly in those that have received pelvic radiation. Acute radiation proctocolitis occurs during the course of treatment and is often self-limited. Chronic radiation proctocolitis can occur months after completion of treatment. Management typically varies based on severity and can range from stool softeners to hyperbaric therapy.

Neutropenic Enterocolitis

- Neutropenic enterocolitis, or typhlitis, occurs in those that have hematologic malignancies, are undergoing chemotherapeutic regimens, or are immunosuppressed for other reasons. It is characterized by neutropenia, fever, and abdominal pain. Treatment involves broad-spectrum antibiotics, bowel rest, and interventions to stimulate leukocyte count recovery.

IRRITABLE BOWEL SYNDROME

Foundations

Background

IBS is a chronic condition that affects approximately 7% to 21% of the general population. It is a disabling disease that can lead to a significant reduction in the quality of life. It is more commonly found in women and is characterized by abdominal pain, bloating, and altered bowel habits. IBS was previously considered a diagnosis of exclusion when no specific anatomical or biochemical abnormalities were found on workup, but new research shows that specific pathophysiological findings are associated with IBS.

There are numerous comorbidities associated with IBS, including functional pain syndromes, psychiatric disorders, as well as other intestinal disorders. This can result in frequent relapses and varying symptoms between relapses. These variable symptoms make both diagnosis and treatment of IBS challenging in the emergency department (ED). This is compounded by the fact that lab and imaging findings are often unrevealing. Patients tend to be discharged from the ED without a specific diagnosis.

Anatomy, Physiology, and Pathophysiology

The pathophysiology of IBS remains unclear, though there are many factors that are thought to contribute to its development. These include intestinal permeability, immune function, alterations in the gut microbiome, motility, and psychosocial status. For example, increased gas production by bacteria in an altered microbiome may result in intestinal reflex responses that create bowel distention. Other theories suggest the possibility of a brain-gut association in certain patients, especially in those with an underlying psychiatric disorder; there is also a potential converse gut-brain association, evidenced by the effect of probiotics in improving symptoms for some patients.

Clinical Features

The diagnosis of IBS is made with a detailed history as well as the exclusion of certain disorders. The Rome IV criteria are generally used to confirm the diagnosis of IBS (Box 81.1). These criteria account for the frequency of episodes, alterations in bowel habits, and the lack of any traditional "warning signs" such as the onset of symptoms over the age of 50 with the lack of age-appropriate colorectal cancer screening, gastrointestinal bleeding, or family history of colorectal cancer.

There are four distinct subtypes of IBS, and identification is important in determining treatment options. The subtypes include IBS with diarrhea (IBS-D), IBS with constipation (IBS-C), IBS with mixed symptoms of constipation and diarrhea (IBS-M), and unsubtyped-IBS. There is also a postinfectious IBS that can cause persistent symptoms in approximately 10% to 30% of patients with gastroenteritis.

Common symptoms include recurrent abdominal pain, abdominal bloating, and changes in bowel habits. The following symptoms would be concerning for more sinister pathology: age at onset greater than 50 years, no previous colon cancer screening, evidence of gastrointestinal bleeding, unintentional weight loss, or a positive fecal occult blood test, among others. Of note, it is unusual for IBS to be diagnosed for the first time in the ED, so attention should be paid to ensure more sinister diagnoses are considered, as they may warrant further evaluation.

Differential Diagnoses

The differential diagnosis for IBS depends on the particular subtype in question and can be rather broad (Box 81.2). Other gastrointestinal disorders such as colitis, gastroenteritis, pancreatitis, hepatitis, or biliary pathology should be considered, along with possible urological or gynecological disorders, based on the clinical history.

BOX 81.1 Rome IV Criteria for Irritable Bowel Syndrome

Patient has recurrent abdominal pain (>1 day/week in the previous 3 months), with an onset >6 months before diagnosis.

Abdominal pain is associated with at least two of the following three symptoms:

Pain related to defecation
Change in frequency of stool
Change in form (appearance) of stool

Patient has none of the following warning signs:

Age >50 years, no previous colon cancer screening, and presence of symptoms
Recent change in bowel habits
Evidence of overt gastrointestinal bleeding
Nocturnal pain or passage of stools
Unintentional weight loss
Family history of colorectal cancer or inflammatory bowel disease
Palpable abdominal mass or lymphadenopathy
Evidence of iron-deficiency anemia on blood testing
Positive test for fecal occult blood

From Lacy BE, Mearin F, Chang L, et al. Bowel disorders. *Gastroenterology*. 2016;150:1393–1407.

BOX 81.2 Differential Diagnosis in Irritable Bowel Syndrome

IBS With Constipation

Bowel obstruction
Malignancy
Adult-onset Hirschsprung disease
Rectocele
Paradoxical closure of the anus during defecation

IBS With Diarrhea

Bacterial or parasitic intestinal infection
Inflammatory bowel disease
Lactose intolerance
Malabsorption
Radiation proctocolitis
Celiac disease

IBS With Mixed Symptoms

Inflammatory bowel disease
Ureteral colic
Bowel obstruction
Diverticular disease
Gastroesophageal reflux of ulcer
Liver or pancreatic disease
Lead toxicity
Porphyria

IBS, Irritable bowel syndrome.

Diagnostic Testing

There are no specific tests to assess for IBS in the ED setting. A complete blood count (CBC) may be performed to assess for anemia in patients where malignancy is on the differential. Fecal calprotectin is a

test typically performed in an outpatient setting that may help differentiate IBS from IBD, as it may be increased in the latter.

Management

The management of IBS is largely based on the subtype. Typically, treatment involves a combination of diet, behavioral, and pharmacological therapies. Traditionally, small dietary changes such as increasing soluble fiber can improve IBS-C. Low-FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diets have been shown to improve abdominal pain and bloating associated with IBS. FODMAPs are a group of fermentable carbohydrates that can potentially aggravate symptoms. Fermentable oligosaccharides include wheat, rye, and certain legumes such as garlic and onions. Disaccharides are lactose-containing foods. Monosaccharides are found in some fruit such as mangoes and figs and also include honey and agave nectar. Certain fruits and vegetables such as blackberries and lychee contain polyols, as well as some low-calorie sweeteners that might be in sugar-free gum. Ondansetron (4 mg by mouth [PO] three times daily) and loperamide (4 mg PO as an initial dose, followed by 2 mg PO for subsequent doses, up to a maximum of 16 mg daily) may improve stool consistency for those with IBS-D. Probiotics have been associated with improvement in symptoms. Cognitive-behavioral therapy (CBT) and hypnotherapy may be useful. Evidence points toward using an individualized approach, with a focus on affirming the diagnosis of IBS, in order to help reduce symptoms. Unfortunately, management is typically not curative but may help improve quality of life.

Disposition

IBS is typically a non-emergent condition that can be managed on an outpatient basis. Emphasis should be placed on maintaining close follow-up in order to optimize therapy. Strict return precautions should be provided, and patients should be educated on monitoring for any of the warning symptoms that may point to a more concerning alternative diagnosis.

DIVERTICULAR DISEASE

Foundations

Background

Diverticular disease is one of the most common gastrointestinal diagnoses in the Western hemisphere, affecting 5% of patients younger than 40 years, and up to 60% of patients over the age of 80.[1] There are multiple theories regarding the increasing incidence of diverticular disease including diet, obesity, and bacterial colonization. There was once thought to be a link between fiber intake and the development of diverticular disease, but that theory is now questioned.

Risk factors for diverticular disease include smoking, use of NSAIDs, physical inactivity, obesity, red meat, and a diet high in refined carbohydrates.[2] Diverticular disease involves the development of false diverticula, which is the herniation of the inner mucosal and submucosal layers of the intestinal wall through the muscular layers. Diverticulosis refers to the presence of multiple diverticula. While the sigmoid colon is most often involved, interestingly, in the Japanese population, the right colon tends to be affected. The sigmoid colon is thought to be affected more commonly because of specific anatomic features including noncircumferential muscle layers, along with the location of insertion of the vasa recta (intestinal arteries) (Box 81.3).

Anatomy, Physiology, and Pathophysiology

Diverticulosis refers to the asymptomatic condition of having multiple diverticula. Diverticulitis results from inflammation of the diverticula. Diverticulitis can be uncomplicated, which can most often be managed in the outpatient setting. Complicated diverticulitis can include abscess formation, fistula formation, strictures, along with perforation or acute peritonitis. The pathophysiology of this inflammation is thought to involve changes in gut motility as well as increases in intraluminal pressure in the colon, which can lead to localized perforation. If the perforation occurs into the abdominal cavity, this may result in peritonitis, whereas if the diverticulum is covered by mesentery, perforation can create a phlegmon or abscess.[2]

Diverticulosis is also the cause of 40% of lower gastrointestinal hemorrhages. Severe hemorrhage occurs in 3% to 5% of all patients with diverticulosis. The bleeding is typically painless, as there is no associated inflammation.

BOX 81.3 Factors That Contribute to the Development of Colonic Diverticula

Weakness of the Bowel Wall
Noncircumferential muscular layers
Insertion of the vasa recta
Localized ischemia
Connective tissue disorders
Ehlers-Danlos syndrome

High Intraluminal Pressure
Increased collagen crosslinking with ageê more distensible, more contractile bowelê segmentation
Obstruction of diverticula
Colonic stasis, chronic constipation
Low fiber intake

Other Associated Factors
Seasonal variation (summer months)
Smoking
Age

Obesity
Alcohol use
Immunocompromised state
Composition of intestinal flora

From Meara MP, Alexander CM. Emergency presentations of diverticulitis. *Surg. Clin. North Am.* 2018;98:1025–1046.

Clinical Features

Diverticulosis

Most patients with diverticulosis are asymptomatic. It can result in bleeding, and it can also occasionally result in vague abdominal complaints, such as abdominal bloating. Diverticulosis progresses to acute diverticulitis in up to 25% of individuals and results in recurrent episodes of diverticulitis in up to 40%.

Diverticulitis

As the majority of patients develop diverticula in the sigmoid colon, diverticulitis tends to present with persistent left lower quadrant pain. Many patients will present with persistent pain over 24 hours, possibly with a low-grade fever. Other associated symptoms may include nausea, vomiting, or alterations in bowel movements. Physical examination may reveal tenderness in the left lower quadrant and possibly abdominal distention. Patients with more complicated cases may present with high fever or other vital sign abnormalities concerning sepsis.

Patients that are predisposed to developing diverticula in the right colon will present with right lower quadrant abdominal pain and tenderness on examination, which may be difficult to distinguish from

appendicitis. There may also be referred pain to the suprapubic region. Additional findings suggest various complications—diffuse tenderness with rebound or guarding may be associated with gross perforation or abscess rupture; dysuria can be present with a colovesical fistula; a palpable mass may be associated with localized abscess formation; vomiting with abdominal distention may suggest proximal obstruction; and feculent vaginal discharge may suggest a colovaginal fistula. Almost any organ adjacent to the colon can be involved in the inflammatory process. Elders and immunocompromised patients may present more subtly despite the potential for having an even more severe disease. Perforation is seen more frequently in this population and is associated with a high mortality rate.

Differential Diagnoses

Other diagnoses to consider include colitis (either inflammatory or ischemic), ureteral stones, inguinal hernia, or pelvic or ovarian pathology, including an ectopic pregnancy or pelvic inflammatory disease. Appendicitis should be considered when symptoms are predominantly right-sided. Diffuse abdominal pain and tenderness should prompt an evaluation for other causes of peritonitis. An underlying colonic malignancy should be considered, but it is typically safe to wait until the resolution of the acute presentation before further investigation.

Diagnostic Testing

Patients with prior history of diverticulitis that present with similar symptoms may not need further testing. As long as symptoms are relatively mild, without concerning findings on physical examination, the patient may be started on empirical treatment for diverticulitis without the need for bloodwork or imaging. When other diagnoses are being considered, or the clinical severity of diverticulitis is concerning, further testing is indicated. A CBC is not necessary to make the diagnosis, but many patients will have varying degrees of leukocytosis. A urinalysis is suggested when there is concern for a colovesical fistula.

Abdominal CT has become the standard of care for diagnosing diverticulitis. A CT without contrast can identify the presence of diverticular disease. CT with intravenous (IV) contrast is commonly used to assess for diverticulitis. However, CT with both IV and enteric (either oral or rectal) contrast is the ideal method to assess for diverticulitis and any associated complications, with 98% sensitivity and 99% specificity. CT findings may include colonic wall thickening, pericolonic fat stranding, localized perforation (also known as micro-perforation), abscesses, as well as free air or fluid (Figs. 81.1–81.3).[2] While generally outside the scope of ED practice, the Hinchey staging system can be used to stratify diverticulitis based on the level of abscess formation or perforation (Box 81.4).

There are other imaging methodologies that were once used or suggested for the evaluation of diverticulitis that are no longer recommended, such as barium enemas, water-soluble contrast enemas, ultrasonography, and plain radiography. Colonoscopy was previously indicated after resolution of the acute episode to assess for underlying malignancy; however, it is now recommended to follow age-appropriate screening guidelines for colonic malignancy.

Management

Diverticulosis

Patients with diverticulosis are recommended to initiate a high-fiber diet in order to reduce abdominal symptoms. Physical activity has been associated with a decreased risk for developing acute diverticulitis, although the mechanism behind this benefit is unclear. Patients were previously instructed to avoid foods that may obstruct diverticula, such as nuts, small seeds, and popcorn, but this has been largely discredited due to the lack of evidence.

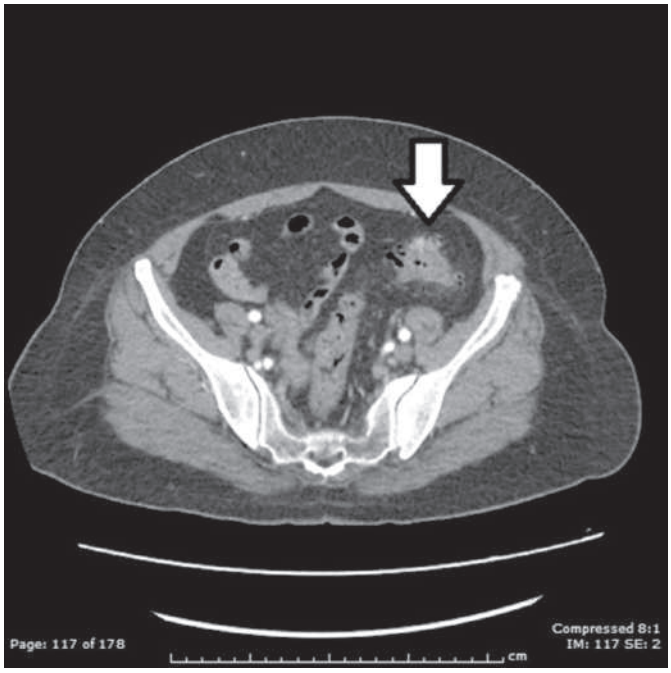

Fig. 81.1 Uncomplicated diverticulitis *(arrow)* showing multiple air-filled structures lining the edge of the left colon (diverticuli), and hazy outer border of bowel segment (fat stranding) indicative of inflammation.

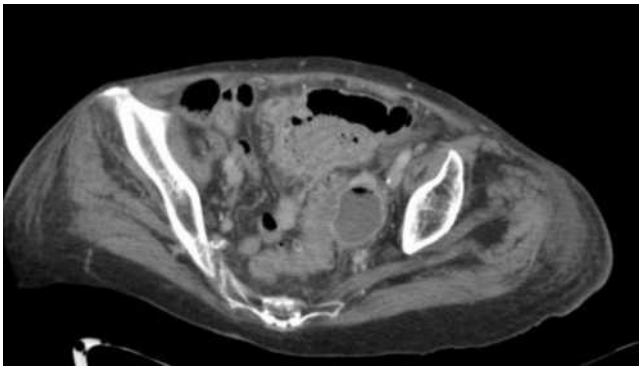

Fig. 81.2 Computed Tomography Imaging Demonstrating Diverticulitis With Abscess Formation. (From Sartelli M, Moore FA, et al. A proposal for a CT driven classification of left colon acute diverticulitis. *World J. Emerg. Surg.* 2015;10(3):1–11, Fig. 4.)

Uncomplicated Diverticulitis

There is more evidence to suggest that acute diverticulitis is an inflammatory process and not an infectious process. In fact, guidelines published by the American Gastrointestinal Association in 2015[1] advocate for the selective (as opposed to routine) use of antibiotics in treating uncomplicated diverticulitis. If antibiotics are utilized, oral antibiotics should cover both Gram-negative aerobic and anaerobic bacteria (Box 81.5). The vast majority of patients with uncomplicated diverticulitis can be managed on an outpatient basis. Studies have shown no benefit in the use of IV antibiotics when compared with oral antibiotics for uncomplicated diverticulitis. Liquid diets with instructions to advance as tolerated should be recommended for patients that are managed as outpatients.

Hospitalization for IV antibiotics and bowel rest is often required for elders, patients who are immunocompromised or have multiple

  or
- Amoxicillin-clavulanate, 875 mg–125 mg PO BID

comorbidities, and individuals who cannot tolerate oral liquids or have poor social support in the outpatient setting.

Complicated Diverticulitis

Patients with complicated diverticulitis should generally be admitted for IV antibiotics (Box 81.6) and bowel rest. Surgical consultation is indicated when there is concern for peritonitis or perforation, continuing clinical decline, or sepsis resistant to medical management. Small abscesses (4 cm or less) may resolve with IV antibiotics alone, whereas larger abscesses are often treated with percutaneous drainage, with possible surgical management if unsuccessful. Fistulae are usually repaired surgically on an elective basis. Surgical resection may be considered in patients with recurrent episodes of diverticulitis.

Disposition

Younger patients and those who are immunocompetent with uncomplicated diverticulitis may be discharged from the ED. If antibiotics are prescribed, a 7- to 10-day course is recommended. Follow-up evaluation is advised within a few days to determine the efficacy of treatment. Approximately 95% of patients will have a resolution of symptoms with this approach. If not improving, further diagnostic imaging to look for possible complications,

such as abscess formation, is prudent. Patients with complicated diverticulitis should be hospitalized for IV antibiotic therapy and bowel rest. Most patients (65% to 85%) recover with medical management alone, though some may require surgical intervention. Mortality rates range from 1% to 6% but increase to 12% to 18% for those requiring surgery.

LARGE BOWEL OBSTRUCTION

Foundations

Background

Large bowel obstruction (LBO) is not as common as small bowel obstruction but is a more ominous condition frequently associated with malignancy. Most cases of LBO are due to a progressive narrowing of the intestinal lumen from intrinsic lesions within the lumen. Approximately 50% of all cases of LBO are eventually found to be secondary to underlying colorectal malignancy. Diverticular disease and volvulus are the next most common causes of LBO. Other less common intrinsic causes of LBO include IBD, ischemia, adhesions, endometriosis, or radiation. Extrinsic lesions can also cause LBO from an impingement of the intestinal lumen. The most common causes of extrinsic lesions causing LBO include ovarian cancer, followed by hernias.[3]

Anatomy, Physiology, and Pathophysiology

The most common location for LBO is the sigmoid colon. Anatomically, it is important to note if the obstruction is proximal or distal to the splenic flexure for management purposes. Approximately 75% of colonic tumors are located distal to the splenic flexure.[4] LBO along the left side of the colon may manifest sooner than obstruction along the right side of the colon due to the smaller lumen of the sigmoid and descending colon.[5]

When mechanical obstruction is caused by an obstructing lesion, either intrinsic or extrinsic, the bowel proximal to the lesion becomes increasingly dilated. As the distention progresses, intraluminal pressure increases. When intraluminal pressure approaches systolic blood pressure, blood flow to the bowel wall is compromised, causing edema and subsequent transudation of fluid into the lumen. Transudation, along with decreased reabsorption of intraluminal fluid, further increases intraluminal pressure and decreases arterial flow to the bowel

wall, which can lead to ischemia and gangrene. The translocation of bacteria from compromised bowel can lead to sepsis. Perforation of the bowel wall follows if the process is left uninterrupted.

Acute colonic pseudo-obstruction (ACPO), also known as Ogilvie syndrome, may mimic LBO. It refers to acute colonic dilation without evidence of mechanical obstruction. ACPO tends to affect the cecum and right hemicolon, although dilation can extend all the way to the rectum.[6] It is thought to be a functional obstruction that results from either increased sympathetic tone or decreased parasympathetic tone. ACPO is often associated with other conditions that can affect autonomic intestinal innervation.[6] ACPO tends to affect elders, chronic opioid users, postoperative patients, and those with severe electrolyte disturbances or other significant acute comorbid conditions.

Clinical Features

The typical presenting complaints in LBO are abdominal pain, abdominal distention, obstipation, or vomiting. Vomiting tends to occur in patients with an incompetent ileocecal valve, as it causes backflow into the small intestine. Patients with a competent ileocecal valve less frequently present with emesis and instead will exhibit both significant distention and pain.[4] The time frame of symptom development varies in accordance with the etiology of the obstruction. LBO associated with a volvulus can develop rapidly, whereas obstruction from cancer tends to be gradual. The degree of stenosis is often associated with the acuity of presentation.[4]

Patients seen later in the course of obstruction may be significantly dehydrated. Fever or tachycardia should prompt an investigation for gangrene or perforation. A palpable abdominal mass may represent a tumor, abscess, or simply distended bowel. A rectal examination is helpful to look for an obstructing rectal mass or large volume of hard stool in the rectal vault consistent with fecal impaction.

Differential Diagnoses

The most common causes of LBO are colorectal cancer (53%), volvulus (17%), diverticulitis (12%), and compression from other malignancies or metastatic disease (6%). Other less common causes are strictures, incarcerated hernia, fecal impaction, adhesions, or pseudo-obstruction.

Diagnostic Testing

Laboratory Tests

A chemistry panel is important to identify electrolyte derangements, as fluid and electrolyte replacement therapy tend to be the mainstay of ED treatment for LBO. An elevated white blood cell (WBC) count should raise suspicion for gangrenous bowel. Anemia may suggest the possibility of colorectal cancer. An elevated serum lactate level may point toward ischemic bowel as a complication.

Imaging Studies

Plain Radiography. Both supine and upright plain films are advised for the workup of LBO and ACPO (Fig. 81.4). A distended colon (>6 cm diameter) is the hallmark of LBO, although the small bowel may be distended as well (>3 cm diameter) if the ileocecal valve is incompetent. A cecal diameter >6 cm is abnormal and when >12 cm is associated with a higher risk of perforation, although perforation has been known to occur at smaller diameters. The actual location and cause of the LBO are usually not evident on plain films.

Computed Tomography. CT is a valuable tool for determining the cause of the obstruction, especially if it is a diverticular abscess or intussusception. CT has the ability to locate the obstructing lesion in 96% of cases, especially if performed with both oral and rectal contrast.[4] CT can also help determine if the cause of obstruction is either intraluminal or extraluminal. Diagnosis of ACPO is suggested with increased colonic diameter without evidence of an obstructive lesion.

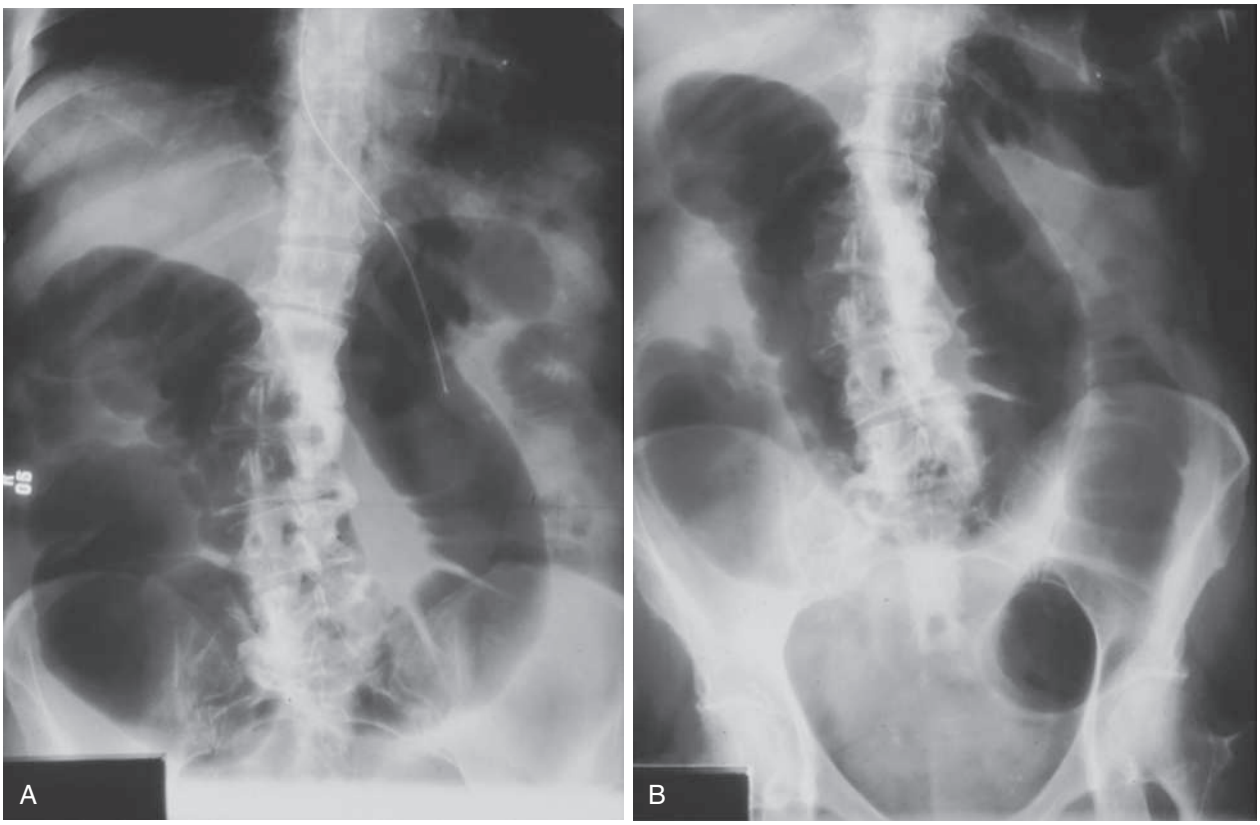

Fig. 81.4 Plain Radiographs Showing Large Bowel Obstruction at the Sigmoid Colon Caused by Carcinoma. (A) Upright view. (B) Supine view.

Colonoscopy and Water-Soluble Contrast Enema. Water-soluble contrast enemas are no longer advised, given that CTs are now more accurate in making the diagnosis of LBO. Colonoscopy can be used to identify the location of the lesion; however, it is more commonly used now in the management of LBO.

Management

Management of LBO and ACPO in the ED is directed at symptomatic relief and supportive care. Many of these patients will require large volume fluid resuscitation and electrolyte replacement. Intravenous (IV) pain control is often required. Gastric decompression with a nasogastric tube may be helpful in cases in which vomiting is prominent. The patient should be kept no food by mouth (NPO). Antibiotics are indicated if gangrene or perforation are suspected (see Box 81.6).

Definitive management depends on the cause of obstruction. Endoscopically placed self-expanding stents are now the mainstay of treatment for obstructing lesions.[4] These can either be placed as a bridge to surgery or can be used definitively for palliative management. Diverticular abscesses can be managed either with percutaneous or surgical drainage. Volvulus can be managed with endoscopic decompression or surgery (depending on whether it is sigmoid or cecal, respectively). Other less common causes of LBO, such as strictures, adhesions, or hernias, are typically managed surgically.

For ACPO, focus should be directed toward identifying and treating reversible factors such as electrolyte disturbances, or pharmacologic or metabolic factors. If conservative management is unsuccessful for up to 3 days, neostigmine (2 mg IV) or colonic decompression may be considered.[3] Neostigmine theoretically increases acetylcholine, which promotes colonic motility. Endoscopic decompression is used to treat ACPO refractory to medical management.[6]

Disposition

Most cases of LBO require procedural intervention to achieve resolution. Patients typically require hospitalization and consultation with a specialist capable of performing the appropriate procedure. Emergent surgical consultation is warranted for patients with evidence of gangrenous bowel or perforation. Oftentimes, ACPO develops in patients already hospitalized for other conditions associated with high morbidity,[5] but it can also develop in the long-term care facility setting, prompting ED evaluation. Patients should be admitted for both conservative medical management and for decompression if necessary.

VOLVULUS

Foundations

Background

Volvulus occurs in all age groups, but older adults (mean age 60 to 70 years) are affected most often. Mortality rates with sigmoid volvulus exceed 50% in patients when associated with gangrenous bowel. Cecal volvulus tends to occur in younger patients and is more commonly seen in women.

Anatomy, Physiology, and Pathophysiology

Volvulus is defined as a loop of bowel that twists around itself and its associated mesentery, resulting in obstructive pathology. If the mesentery is twisted enough such that blood supply to the intestine is affected, ischemia may arise. Colonic volvulus typically occurs in a redundant colonic segment with an elongated mesentery along a narrow base.[7] This most commonly occurs in the sigmoid and cecum, followed by transverse colon, or at the splenic flexure. Volvulus can result in ischemia, gangrene, perforation, and death. It is the third most common cause of colonic obstruction, following colorectal malignancy and diverticular disease.

Sigmoid Volvulus. Residents of long-term care facilities and patients with neurologic or psychiatric disease are predisposed to sigmoid volvulus, possibly as a result of alterations in colonic motility. There is an association of chronic constipation with the development of sigmoid volvulus, though this association is unclear. The mesentery of the sigmoid colon can withstand up to 180 degrees of twisting, and anything beyond this may result in colonic obstruction, ischemia, or necrosis. This occurs as a result of proximal colon forcing gas and liquid into the obstructed segment of the colon, causing a sometimes massive dilation of the distal colon. Electrolyte disturbances can occur secondary to third spacing, and respiratory compromise occasionally results from massive abdominal distention. Vascular supply can become compromised if left untreated.

Cecal Volvulus. The mobility of the colonic segment involving the cecum is likely a result of a congenital incomplete fusion of the cecal mesentery to the posterior abdominal wall.[8] Risk factors for cecal volvulus also include chronic constipation, as well as a high-fiber diet, frequent laxative use, and a history of laparotomy, pregnancy, pelvic surgery, or colonoscopy. Long-distance running is also considered a risk factor.[8]

Clinical Features

Sigmoid Volvulus

The hallmark of sigmoid volvulus is the triad of crampy lower abdominal pain, distention, and constipation. The extent to which the sigmoid colon can twist on itself varies, so the presentation can vary from subtle to dramatic. The clinical picture may range from one of minor discomfort that has been present for several days to an acute onset of severe abdominal pain associated with gross abdominal distention and unstable vital signs.

Physical examination may reveal a distended tympanic abdomen, often with most of the distention in the upper abdomen. Significant tenderness, fever, lack of bowel sounds, peritonitis, or cardiovascular instability suggests gangrenous or ischemic bowel and should prompt immediate surgical consultation. The absence of these findings does not exclude gangrene, and the duration of symptoms alone is not predictive of gangrene.

Cecal Volvulus

While up to 90% of patients with cecal volvulus present with acute abdominal pain, constipation, and abdominal distention are rarely seen. Vomiting is only seen in 50% of patients. Some patients with "mobile cecum syndrome" may have episodes that spontaneously resolve.

Differential Diagnoses

Any underlying pathology that may cause LBO can mimic volvulus, including neoplastic disease, paralytic ileus, toxic megacolon, or ACPO.

Diagnostic Testing

There are no specific laboratory tests that are essential for the diagnosis of volvulus. With this said, patients may have electrolyte derangements or coagulopathies that are important to identify.

Sigmoid Volvulus

The diagnosis of sigmoid volvulus is most often made with plain radiographs. Imaging findings include a large dilated loop of the colon (Fig. 81.5), absence of rectal gas, along with a "coffee bean sign" (where the bowel may have the appearance of a bent inner tube). Free air may be

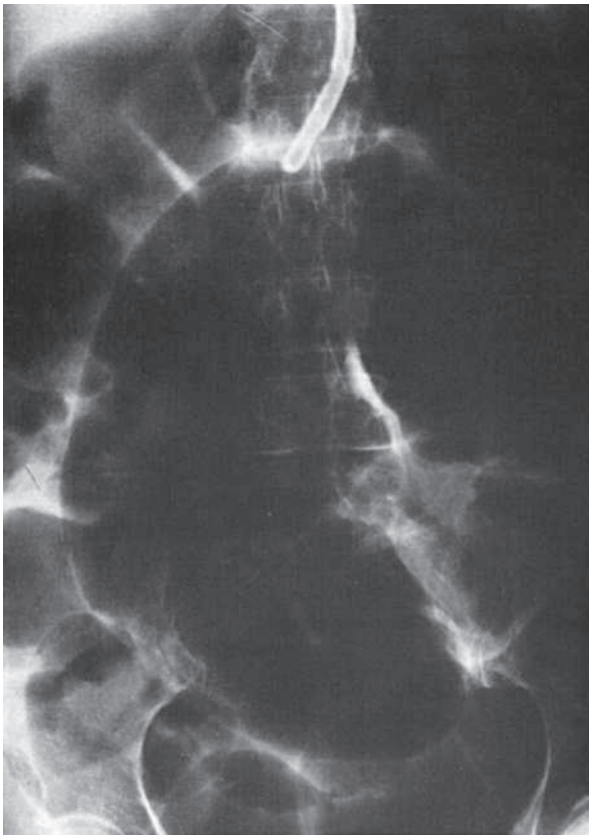

Fig. 81.5 Plain Film of the Abdomen Shows a Large Dilated Loop Characteristic of Sigmoid Volvulus.

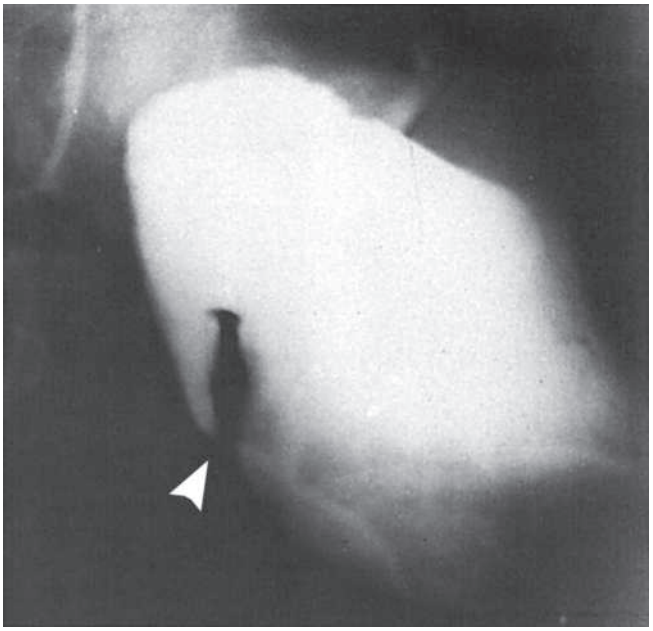

Fig. 81.6 Characteristic Bird's Beak Sign of Volvulus *(arrowhead)* Shown on This Image From a Barium Enema Study.

seen on an upright chest radiograph or lateral decubitus radiograph in patients with perforation. Gas backing up into the rest of the colon may obscure the typical appearance of sigmoid volvulus on plain radiographs, resulting in a number of nondiagnostic study results. When the diagnosis is in doubt, contrast enema may be helpful. Contrast material fills up the colon to the tapering point of torsion, causing a bird's beak appearance to the column of contrast material (Fig. 81.6). Sigmoidoscopy is diagnostic in many cases, as there is direct visualization of a spiral sphincter-like twist in the colonic mucosa. CT imaging is associated with a 100% sensitivity and over 90% specificity, but the diagnosis can often be made with plain radiographs alone. CT findings include a "whirl sign" (twisting of the mesentery and mesenteric vessels) along with a bird's beak sign.

Cecal Volvulus

Plain radiographs are often helpful in establishing a diagnosis of cecal volvulus. The cecum appears markedly dilated and may contain an air-fluid level. The small bowel is often distended as well. In contrast with sigmoid volvulus, the distal colon should have a paucity of gas. Free air suggests perforation and necessitates emergent surgical consultation (Fig. 81.7). If the differentiation of sigmoid from cecal volvulus is unclear, a contrast enema may be helpful in showing the site of torsion. On CT, the aforementioned "whirl sign" may be present (Fig. 81.8).

Management

Sigmoid Volvulus

Patients with any type of volvulus should undergo fluid resuscitation, especially if a shock state has developed. Electrolyte derangement should be corrected, and coagulopathy addressed. Antibiotics are indicated if gangrene or perforation are suspected (see Box 81.6). Endoscopic detorsion with flexible sigmoidoscopy can be attempted by an experienced operator, during which a lubricated flexible tube

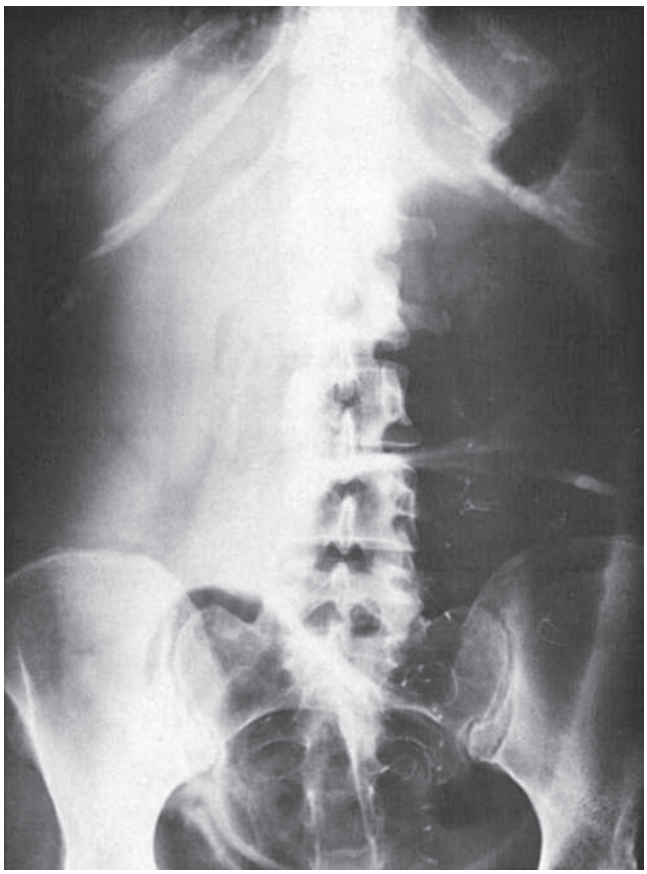

Fig. 81.7 Plain Radiograph Shows Distended Colon Characteristic of Cecal Volvulus. Note presentation in the left lower quadrant and absence of right-sided gas shadows.

is inserted through the obstruction. With decompression of gas and liquid stool, the bowel is able to undergo self-detorsion. Endoscopic decompression is successful in 70% to 95% of cases. If the patient has gangrenous bowel or if the volvulus does not respond to endoscopic decompression, surgical intervention is indicated.

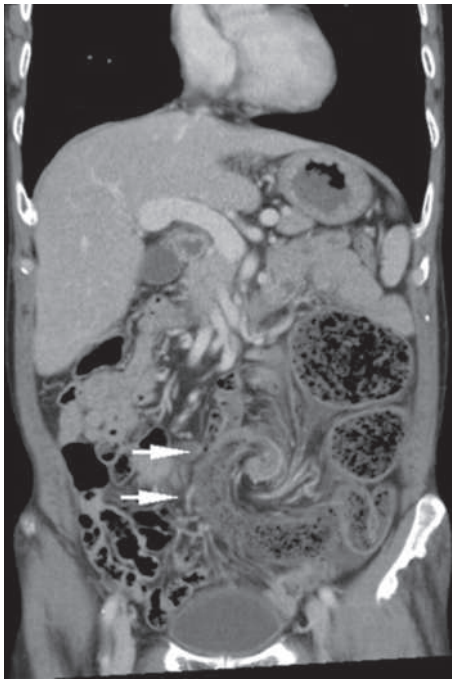

Fig. 81.8 CT scan of mesentery and intestine twisted into whirl pattern *(arrows)*, in this case from a sigmoid volvulus. (From Shaw W, Huang C, Hung T, Yeh Y. Typical whirl sign in sigmoid volvulus. *J Emerg Med.* 2014;46:383–384.)

Percutaneous endoscopic colopexy may be indicated for high-risk surgical patients.[9] Elective resection of the redundant sigmoid is recommended, given recurrence rates that are estimated at 60%. The mortality rate for sigmoid volvulus is 20% overall and exceeds 50% in those with gangrene.

Cecal Volvulus

Endoscopic evaluation and decompression are not options for cecal volvulus given its proximal location.[7] Cecal volvulus should be managed surgically, typically via resection of the cecum. Recurrence after resection is rare.

Disposition

Patients with volvulus require admission for procedural intervention.

INTUSSUSCEPTION

Foundation

Background

Intussusception is considered the primary cause of bowel obstruction in children and the second most common cause of an acute abdomen in children after appendicitis. The peak incidence is between 4 and 10 months of age, and the etiology is usually idiopathic. In contrast, adult intussusception is a rare cause of obstruction and is more often associated with a coexisting neoplasm or malignancy, particularly when occurring in the large bowel. In adults, the condition occurs over a wide range of ages, with a mean age at presentation of 50 years (Table 81.1).[10]

There is a small increased risk following rotavirus vaccination; however, the well-documented benefits of rotavirus vaccine have been found to outweigh the possible small risks of intussusception.[11]

Anatomy, Physiology, and Pathophysiology

The exact mechanism of intussusception is unknown, but it is believed that a lead point lesion changes the motility properties of the intestine, allowing a proximal segment to invaginate into a more distal segment. As peristaltic activity pushes the invaginated segment along with its mesentery and mesenteric blood vessels distally down the bowel, the blood supply to the segment can be compromised, and ischemia may occur. Edema associated with the intussusception can lead to a mechanical obstruction of the bowel. If not treated promptly, reduced blood supply can lead to bowel necrosis or perforation. The most common locations are at the junctions between freely moving segments, retroperitoneally, or adhesionally fixed segments.

In most infants, the intussusception involves the ileum invaginating through the ileocecal valve into the cecum and is typically idiopathic. In the pediatric population, there is an association with hyperplasia of lymphoid tissue in the small intestine (Peyer patches) secondary to viral infections. Adult intussusceptions that occur in the small bowel are caused by benign lesions 60% of the time; the remainder of small bowel intussusceptions are caused by malignancy (30%), which are generally metastatic tumors, or are idiopathic (10%). In contrast, most colonic intussusceptions (60% to 65%) are caused by malignancy.[10]

TABLE 81.1 Comparison of Pediatric Versus Adult Intussusception

	Pediatric Intussusception	Adult Intussusception
Typical age	Infants to toddlers	>50 years
Etiology	Idiopathic	Neoplasm, malignancy
Symptoms	Acute onset, intermittent, colicky abdominal pain with crying with pulling up knees, vomiting	Acute onset abdominal pain, vomiting, rectal bleeding
Diagnosis	Ultrasound	CT
Management	Reduction—either hydrostatic or pneumatic	Surgery

Clinical Features

Intussusception manifests in one of two patterns, acute or subacute. In pediatric intussusception, the classic presentation is acute, with abrupt onset of intermittent, colicky, abdominal pain, which can cause episodes of crying and pulling the knees up. The typical features of crying, abdominal pain, vomiting, pallor, abdominal mass, or lethargy are clinical indicators of pediatric intussusception. Individually, each variable is not helpful, but when multiple are present concurrently, there is a high probability of the disease.

In adults, the most common presentation is that of acute, partial intestinal obstruction, since only a small proportion of intussusceptions cause complete obstruction. The typical presenting complaints include abdominal pain, with vomiting and rectal bleeding. Constipation may also be present. The abdomen may be distended, and bowel sounds often are decreased. A mass is seldom palpated, especially if symptoms have been present for over 24 hours, as the overlying bowel distention will obscure it. The classic triad of abdominal pain, mass, and heme-positive stools noted in children is found in only 20% of pediatric intussusceptions and is rarely found in adults. Similarly, currant jelly stools or altered mental status are infrequent presentations and often occur late in the disease progression.

The subacute presentation is subtler, with intermittent abdominal pain for months. The diagnosis usually is made only when the pain becomes unrelenting or has been recurrent enough to prompt imaging.

Differential Diagnoses

The differential diagnosis includes other causes of bowel obstruction, including strangulated inguinal hernia; therefore, a genitourinary exam is an important component of the assessment. Gastroenteritis is a consideration, but the diarrhea in intussusception is of small volume and short duration. In pediatric patients, Hirschsprung disease is a differential consideration but typically involves a later age of onset with severe constipation history. Acute appendicitis is rare before the age of 2 years but can present similarly, and ultrasound may be helpful in distinguishing between the two conditions.

Diagnostic Testing

Ultrasound Examination

Ultrasonography is helpful in detecting intussusception, though is not as useful as CT in excluding other conditions. For facilities that have skilled ultrasound technicians available, ultrasound is the primary diagnostic test recommended in the pediatric population. A transverse view of the intussusception has a doughnut or target shape, with multiple concentric rings. A longitudinal view has an ultrasound appearance similar to that of a kidney (so-called pseudo–kidney sign), with a bright central area often surrounded by a darker outer layer (Fig. 81.9A and B).

Plain Radiography

Plain radiography is a reasonable screening test in a patient suspected of having bowel obstruction but usually shows only nonspecific large bowel dilation.

Computed Tomography

CT is the most useful test for adult patients with suspected intussusception but may not always detect the actual intussusception. The characteristic findings on CT include a target- or sausage-shaped soft tissue mass with a layering effect, with mesenteric vessels within the intestinal lumen (see Fig. 81.10A and B).

Colonoscopy

Colonoscopy is helpful in defining the lesion causing intussusception but does not usually detect the intussusception itself.

Management

The management of intussusception in the ED is supportive and aimed at optimizing fluid status, managing the patient's pain, decompressing the stomach with a nasogastric tube, recognizing perforation, administering antibiotics if compromised bowel is suspected, and securing appropriate surgical consultation when necessary. Occasionally, intussusception may resolve spontaneously, but an evaluation to exclude a pathologic lead point should still be pursued.

In pediatric intussusception, the treatment of choice for the stable child is a trial of pneumatic reduction with x-ray guidance, or hydrostatic reduction with ultrasound guidance when appropriate radiologic facilities are available.[12] The choice of hydrostatic or pneumatic reduction is largely dependent on institutional preference. Both have higher reduction rates when compared to barium. The reduction procedure is typically performed by a radiologist and may prevent the need for surgery. Reduction of pediatric intussusception is sufficient treatment in 80% of patients. One advantage of hydrostatic reduction with ultrasound guidance is the avoidance of radiation in children. A delayed repeat enema has been a recent advancement in the management of intussusception, as there is a 50% chance of successful reduction each time the enema is repeated. as the bowel edema subsides with each partial reduction. These advances have reduced operative rates, and surgical cases tend to occur when resection is required due to ischemic bowel necrosis or pathological lead point. Indications for surgery have been restricted to those with peritonitis, suggestive of bowel necrosis. Pediatric patients who improve rapidly after fluid resuscitation may still be candidates for reduction.

Surgery is required in most cases of adult intussusception. Because of the high incidence of malignancy and the concerns of spreading malignant cells from potentially malignant lead points, reduction often is not attempted in adults prior to surgical exploration. Surgical treatment is recommended for patients who are acutely ill, who have evidence of perforation, for whom non-operative reduction is unsuccessful, who need evaluation or resection of a pathologic lead point, or who are treated in a setting where radiologic facilities are unavailable.

Disposition

Recent literature suggests that discharge from the ED following reduction of intussusception is safe for carefully selected pediatric patients. Practice guidelines state that discharge can be considered if (1) there

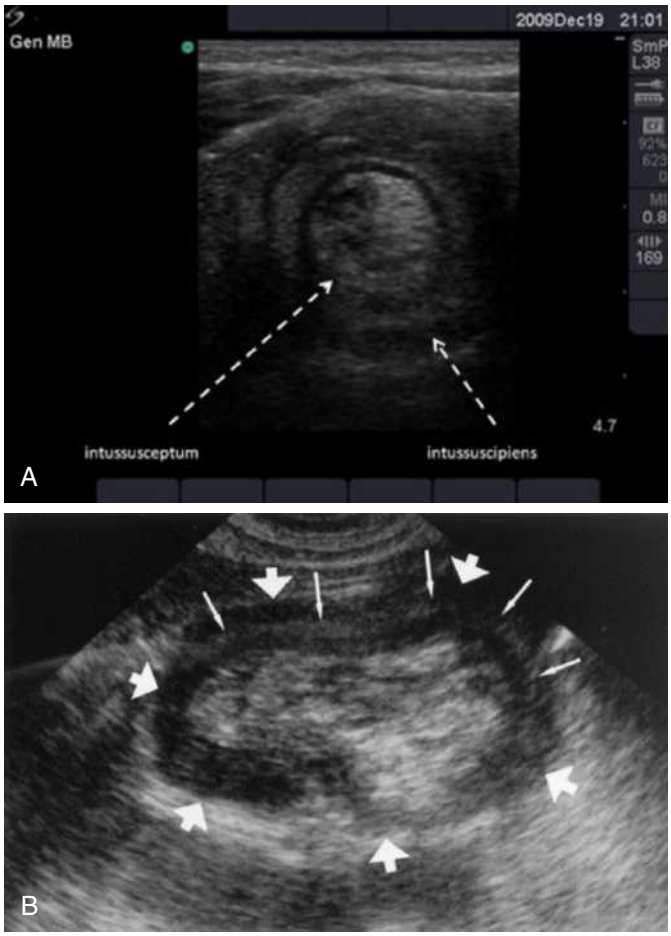

Fig. 81.9 Ultrasound of Intussusception. (A) Transverse view showing donut or target shape, with multiple concentric rings. (B) Oblique-transverse view on ultrasound showing a kidney-shaped mass (pseudo–kidney sign). *Large arrows* indicate the outer margin of the bowel; *small arrows* indicate the contiguous surfaces of the telescoping bowel. (A, From Riera A, Hsiao AL, Langhan ML, et al. Diagnosis of intussusception by physician novice sonographers in the emergency department. *Ann Emerg Med.* 2012;60:264–268. B, From Dean AJ, Lafferty K, Villanueva TC. Emergency medicine bedside ultrasound diagnosis of intussusception in a patient with chronic abdominal pain and unrecognized Peutz-Jeghers syndrome. *J Emerg Med.* 2003;24:203–210.)

are no signs of peritonitis on examination; (2) the patient is able to tolerate oral fluids 2 hours after reduction without nausea, vomiting, or abdominal pain; and (3) the patient remains symptom-free for 2 hours following the PO trial. Clinical studies evaluating this approach have not encountered adverse outcomes or significant recurrence rates.[13,14] Exclusions for discharge include failed reduction, sustained abdominal pain following reduction, history of prior abdominal surgery or neuromuscular disease, developmental delay, preterm birth <37 weeks, or revisit due to recurrence.

Adult patients diagnosed with intussusception typically require hospitalization. Operative mortality tends to be minimal.

INFLAMMATORY BOWEL DISEASE

Foundations

Background

IBD includes two clinically similar but distinct diseases, CD and UC. Table 81.2 summarizes important differences between CD and UC. Both diseases are characterized by chronic and unpredictable relapsing inflammation of the GI tract. The prevalence is more common in industrialized societies in North America and Europe, with increasing incidence in newly industrialized countries. The globalization appears to be associated with the Westernization of diets and environments, which affects the intestinal microbiome and increases the risk of IBD in genetically susceptible individuals.[15] IBD can occur at all ages, with a peak incidence in the second to fourth decade with no significant gender prevalence. Up to 25% of IBD cases develop during childhood or adolescence, whereas 10% to 15% of patients with IBD will receive their diagnosis when older than 60 years. Stable patients more often remain well controlled, whereas those with flares more frequently relapse. The long-term management of IBD is a complex stepwise process that involves multiple medications as well as surgical options.

The goals of ED evaluation are to (1) recognize potential new cases of IBD, (2) consider and exclude serious complications in patients with IBD, and (3) identify patients with IBD who require hospitalization. Treatment plans are best developed in collaboration with a physician experienced in the long-term management of IBD.

Anatomy, Physiology, and Pathophysiology

IBD is thought to develop as a result of dysregulation of the immune system driven by an immune response to normal intestinal flora in a genetically susceptible host. In essence, it is the loss of the normal tolerance to normal intestinal bacteria. In normal gut epithelium, the mucosal layer is relatively devoid of bacteria. In UC, a thinned mucosal layer is seen, and in CD, a defective mucosal layer is present. Both conditions lead to bacterial contamination and chronic inflammatory changes. The resulting defective mucosal barrier against bowel flora plays a major role in pathogenesis. The concentration of normal gut flora is highest in the terminal ileum and colon, where manifestations of both CD and UC are most commonly found. IBD is no longer thought of as an autoimmune disease, but rather a complex mucosal barrier disorder. Increased familial prevalence is found in patients diagnosed early in life, whereas environmental modifiers are thought to influence later onset. Chronic inflammation of the gut results, as well as extraintestinal manifestations.

TABLE 81.2 Comparison of Crohn Disease and Ulcerative Colitis

	Crohn Disease	Ulcerative Colitis
Inflammation type and location	Transmural inflammation, skip lesions, anywhere in gastrointestinal tract	Superficial, continuous involvement of colon or rectum
Most common extraintestinal symptoms	Arthritis, aphthous stomatitis, uveitis, erythema nodosum, and ankylosing spondyloarthropathy	Inflammatory arthropathies and primary sclerosing cholangitis
Diagnosis	Endoscopy, elevated fecal calprotectin, stool lacterferrin, ASCA	Endoscopy, elevated fecal calprotectin, stool lacterferrin, P-ANCA
Treatment	Ileal-release budesonide, systemic steroids, immunomodulators, biologics, may require multiple surgeries	Rectal or oral aminosalicylates, steroids, immunomodulators, biologics, surgery (colectomy) could be curative

ASCA, Anti-Saccharomyces cerevisiae antibodies; *P-ANCA*, perinuclear anti-neutrophil cytoplasmic antibodies.

Crohn Disease

CD may affect any part of the gastrointestinal tract, usually impacting the distal small intestine and proximal colon and, less commonly the esophagus, duodenum, or stomach. Because of the transmural inflammation, potential complications include the development of intestinal strictures, abscesses, or fistulae with adjacent organs. Although the onset of the disease can occur at any time of life, CD affects primarily younger patients, with an age of onset typically in the teens or 20s. Pediatric-onset disease is more often severe and extensive, with a higher likelihood of upper gastrointestinal tract disease when compared to adult-onset. Despite remission therapy, CD is often progressive, with half of the patients requiring surgery within 10 years of diagnosis and 80% within 20 years, due to stricture or fistula-related complications. Many patients will require multiple surgeries over their lifetime, as surgery is not curative.

Extraintestinal manifestations, such as arthritis, aphthous stomatitis, uveitis, erythema nodosum, or ankylosing spondyloarthropathy, occur more often in CD than UC.

Ulcerative Colitis

UC causes inflammation and ulceration throughout the colon and rectum but spares the small intestine. Inflammation is more superficial than in CD. Typically, the inflammation exists as one continuous lesion originating in the rectum and extending a variable distance into the colon, although cases of discontinuous disease (so-called skip lesions, similar to CD) have also been reported in UC.

Inflammatory arthropathies and primary sclerosing cholangitis are the most common extraintestinal manifestations of UC. Other extraintestinal manifestations include involvement of the skin, eyes, or bones.

Clinical Features

Typical presenting complaints in patients with IBD include abdominal pain or tenesmus, bloody diarrhea, and weight loss.[16] Patients with CD may have a history of nocturnal diarrhea and more non-gastrointestinal symptoms such as fatigue, fever, or weight loss, which helps differentiate CD from IBS. The physical examination may reveal significant abdominal tenderness, or an abdominal mass representing an abscess. Patients with CD may have fissures, ulcerated hemorrhoids, strictures, or cutaneous abscesses around the anus. Onset of symptoms usually occurs before the age of 30 years, although the diagnosis can be difficult to make in the early stages. The most useful clues of possible IBD in children or adolescents with abdominal pain include diarrhea, growth or pubertal delay, weight loss, rectal bleeding, anemia, pallor, fatigue, perianal skin tags, fistulae or abscesses, erythema nodusum or pyoderma gangrenosum, seronegative rheumatic joint pain, or family history of IBD.[16]

Patients often come to the ED with a known diagnosis of IBD and worsening abdominal symptoms. A common reason for relapse is the interruption of medications that have kept the disease in remission. Patients may become complacent during quiescent periods and stop taking IBD medications. Adherence to continuous, lifelong, maintenance therapy has been shown to reduce the risk of acute attacks and cancer. Common complications of IBD include the formation of fistulae, strictures, or abscesses; less common but life-threatening complications include fulminant colitis, toxic megacolon, or intestinal perforation.

Toxic Megacolon

Toxic megacolon is a pathologic dilation of the colon resulting from inflammation of the smooth muscle layers of the intestine, leading to muscle paralysis, dilation, and eventually perforation if left untreated. The hallmark of toxic megacolon is colonic dilation in a systemically toxic patient with a known inflammatory condition of the colon.

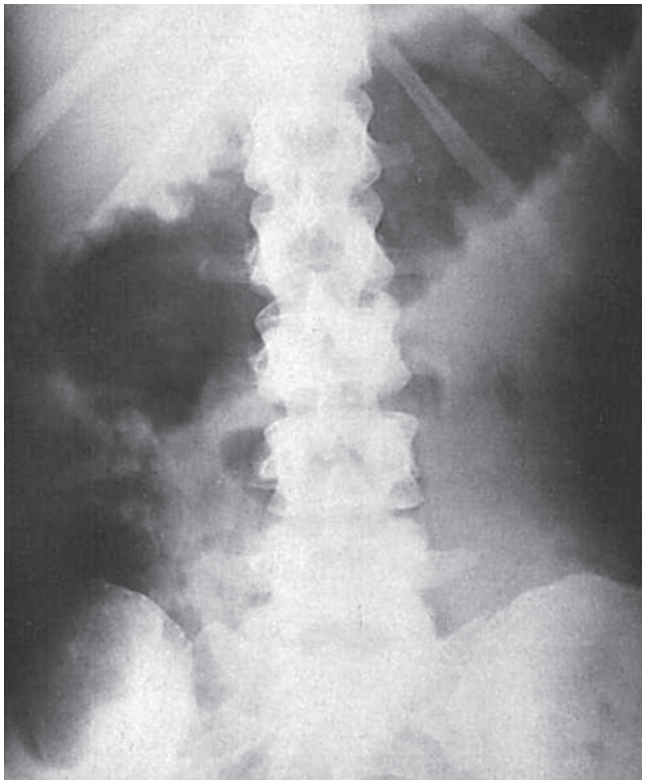

Fig. 81.11 Toxic Megacolon Secondary to Ulcerative Colitis. The smooth indentations seen along the margin of the colon represent pseudopolyps.

Systemic toxicity differentiates toxic megacolon from other disorders that cause colonic dilation, including mechanical obstruction, pseudo-obstruction, and congenital or acquired megacolon (Fig. 81.11).

The triggering event may be the recent ingestion of anticholinergics, antimotility agents, narcotics, or antidepressants. Patients usually have experienced severe symptoms of colitis for several days before the onset of toxic megacolon. Patients may have more than 10 stools daily, continuous bleeding, abdominal pain, distention, and acute, severe toxic symptoms, including fever or anorexia.

Extraintestinal Manifestations

About a third of IBD patients will have extraintestinal manifestations, where almost every organ system can be affected. Extraintestinal manifestations include inflammatory conditions of the skin (e.g., erythema nodosum, pyoderma gangrenosum), eyes (e.g., episcleritis, scleritis, uveitis), joints (e.g., arthritis, sacroiliitis), bone (e.g., osteoporosis), spine (e.g., ankylosing spondylitis), or liver (e.g., primary sclerosing cholangitis). Having one extraintestinal manifestation increases the risk of developing another, and the symptoms often parallel the underlying intestinal inflammation, and many will respond to treatment. Thromboembolic events in IBD patients are often overlooked and underdiagnosed, affecting the venous or arterial systems. The inflammatory process initiates clotting and decreases the activity of intrinsic anticoagulation mechanisms. There is a 60% increase in thromboembolic disease (including deep venous thrombosis [DVT] or pulmonary embolism [PE]) compared to the general population. Cerebrovascular complications, including cerebral sinus thrombosis, are more frequent during bouts of inflammation. There is also an increased risk of ischemic heart disease or mesenteric ischemia. Peripheral neuropathy is the most common neurologic complication of IBD, thought to be due to immune-mediated changes, metronidazole toxicity, or vitamin

deficiency. Chronic inflammation may be the most important driver of these complications in IBD.

Differential Diagnoses

History should include detailed questioning about the onset of symptoms, recent travel, food intolerances, medication (including antibiotics and non-steroidal anti-inflammatory drugs), and history of appendectomy. Particular attention should be paid to proven risk factors including smoking, family history, or recent infectious gastroenteritis. Careful questioning about nocturnal symptoms, features of extraintestinal manifestations involving the mouth, skin, eye, or joints, episodes of perianal abscess, or anal fissure is needed. General examination should include perineal and oral inspection, digital rectal examination, and measurement of body mass index.[16] Symptoms and signs overlap with those of many common abdominal conditions, including appendicitis, IBS, pancreatitis, infectious colitis, ischemic colitis, radiation colitis, diverticular disease, cancer, or bowel obstruction. In children, the differential diagnosis can also include Henoch-Schönlein purpura, celiac disease, or functional abdominal pain. Intestinal infections commonly mimic the symptoms of IBD, including those caused by *Escherichia coli* O157:H7, *Clostridium difficile,* or amebiasis.

Diagnosis

Endoscopic evaluation with biopsy confirms the diagnosis of IBD. Diffuse, continuous mucosal inflammation involving the rectum and extending to a point more proximal in the colon are suggestive of UC, whereas a complex or fistulizing lesion, involvement of the upper gastrointestinal tract, skip lesions, or granulomata are suggestive of CD.

Stool studies may be helpful in diagnosing IBD. Elevated fecal calprotectin is 89% to 98% sensitive and 81% to 91% specific for IBD and is now standard. Stool lacterferrin levels are 80% sensitive and 82% specific for IBD. Both fecal calprotectin and stool lacterferrin can predict clinical relapse are used to guide therapy as well as short-term follow-up.[16] As intestinal infections commonly mimic the symptoms of IBD, it is suggested that new patients should have microbiologic studies for bacterial or other infection.[16] Stool studies contain fecal leukocytes secondary to inflammation, but cultures and microbiologic studies should otherwise remain normal in IBD. Established patients who have recently been hospitalized or utilized antibiotics should be considered for *C. difficile* testing.

Biomarkers are commonly used to assess disease activity and predict relapse. Both an elevated C-reactive protein level or erythrocyte sedimentation rate can be useful for categorizing the severity of the disease and in differentiating it from IBS. Tests targeting antibodies to *Saccharomyces cerevisiae* (ASCA) or antineutrophil cytoplasm (P-ANCA) help differentiate between CD and UC. An elevated ASCA value is more suggestive of CD, whereas an elevated P-ANCA level is more suggestive of UC. Electrolyte abnormalities may result from severe diarrhea, and anemia may occur from gastrointestinal blood loss.

Plain radiographs should be limited to patients suspected of complications such as bowel obstruction, toxic megacolon, or perforation. For diagnosing toxic megacolon, plain radiographs are diagnostic and show a colon with a diameter of 6 cm or larger, although this feature may not be present in the early stages (see Fig. 81.11). CT of the abdomen and pelvis with at least IV contrast, and preferably with oral contrast if tolerated, is the preferred study to evaluate for extraluminal complications. Magnetic resonance imaging (MRI) enterography (with oral contrast) can locate affected bowel segments and identify fistulae, stenoses, or abscesses. It also has the advantage of limiting radiation exposure, which is preferable in children as well as individuals likely to undergo multiple imaging studies over time. Small bowel capsule endoscopy has a high negative predictive value for CD and is typically reserved for patients with a negative evaluation but high clinical suspicion for CD.[16,17]

Management

Since IBD is not curable, treatment goals are to minimize symptoms, improve quality of life, and minimize progression or complications of disease. Medical management is the mainstay of therapy for most patients. Treatment is typically driven by the severity of symptoms. The potential negative consequences of potentially toxic immunosuppressive or anti-inflammatory agents remain an important consideration. Newer treatment models have recommended symptom remission and endoscopic remission to prevent complications from disease progression due to chronic inflammation. Treatment regimens should be discussed with a gastroenterologist catered to consider the patient's preference, compliance, cost, safety, and response to selected agents.

Treatment of CD and UC differ significantly.[17] The choice of agents depends on the classification of the disease as mild, moderate, or severe (Box 81.7). Extraintestinal manifestations usually respond to therapy for intestinal disease. The dosages described are suggested induction doses. DVT and PE prophylaxis is important for admitted IBD

BOX 81.7 Disease Severity Criteria in Inflammatory Bowel Disease

Ulcerative Colitis

Mild Disease

- Fewer than four stools/day
- Stools may contain some blood
- No systemic signs of toxicity (e.g., fever, tachycardia, anemia, elevated erythrocyte sedimentation rate)

Moderate Disease

- More than four stools/day
- Minimal signs of toxicity

Severe Disease

- More than six bloody stools/day
- Signs of systemic toxicity

Crohn Disease

Mild to Moderate Disease

- Patient ambulatory and able to eat
- No dehydration
- No toxicity
- No significant abdominal pain or mass
- Weight loss of 10%

Moderate to Severe Disease—Any of the Following

- Mild disease that has failed to respond to treatment
- Patient may have some systemic toxicity, significant weight loss, anemia
- Fever, some abdominal pain or tenderness, intermittent nausea or vomiting

Severe Disease

- Persistence of symptoms during corticosteroid or biologic (e.g., infliximab) therapy
- High fever, persistent vomiting
- Intestinal obstruction
- Rebound tenderness
- Cachexia
- Abscess

Adapted from Hanauer SB, Present DH. The state of the art in the management of inflammatory bowel disease. *Rev Gastroenterol Disord.* 2003;3:81–92; and Lichtenstein GR, Hanauer SB, Sandborn WJ. Management of Crohn's disease in adults. *Am J Gastroenterol.* 2009;104:465–483.

patients.[18] For patients in remission, ongoing endoscopic monitoring is required given the increased risk for the development of colorectal cancer.

Crohn Disease

Mild to Moderate Disease. Since CD can affect any area of the GI tract, location of disease and severity of symptoms are important factors in treatment decisions. In general, mild disease can be treated by budesonide or oral steroids, whereas more severe disease often requires systemic IV corticosteroids, immunomodulators, or an anti-tumor necrosis factor (TNF) biologic strategy.

For remission-induction treatment for mild to moderate ileocecal CD, the recommended therapy is ileal-release budesonide at 9 mg PO once daily for 8 weeks.[16,17] Budesonide has unique delivery to the ileum and proximal colon, is degraded on its first pass through the bloodstream, and thus has fewer systemic side effects. For disease more widespread than isolated ileocecal, including mild to moderate CD colitis or ileocolonic CD, an 8-week course of systemic corticosteroid is recommended.

For mild esophageal or gastroduodenal CD, only a proton pump inhibitor is recommended. Patients with extensive small bowel CD should be initially treated with systemic corticosteroids, and with a biologic agent, such as an anti-TNF strategy. Prednisone is often initiated and then tapered, with induction dosing of 0.5 to 0.75 mg/kg/day PO, with higher dosage for more severe disease, typically 40 to 60 PO mg daily. Methylprednisolone 1 mg/kg/day IV is also used.[16] IV steroids are often reserved for hospitalized patients with severe disease. Steroids are avoided for maintenance treatment, as prolonged use of steroids can lead to gastrointestinal mucosal injury, problems with wound healing, osteopenia with fractures, or frank osteonecrosis.

Moderate to Severe Disease. For moderate to severe CD that is responsive to systemic steroids, early introduction to an immunomodulator, such as thiopurines or methotrexate, can be considered to reduce the risk of flare when steroids are withdrawn. Immunomodulators have a relatively slow onset, so are used adjunctively, and have limited use as monotherapy. Azathioprine 1.5 to 2.5 mg/kg/day PO or mercaptopurine 0.75 to 1.5 mg/kg/day PO may be used as an adjunctive therapy or steroid sparing agent. Methotrexate 25 mg/week subcutaneously or intramuscularly is the standard induction dose, with measurement of CBC and liver function tests prior to the initiation of therapy. Patients taking these medications should be assessed for bone marrow suppression or pancreatitis.

Aminosalicylates, such as mesalazine and sulfasalazine, are no longer routinely recommended for induction or maintenance of CD. Earlier trials showed oral aminosalicylates to be an effective treatment for CD, and they gained popularity due to comparatively limited toxicity. However, systemic reviews and meta-analyses of clinical trial data have not shown any clinically relevant improvement in CD with aminosalicylates over placebo.[16]

Biologic therapy with a US Food and Drug Administration (FDA) approved anti-TNF agent, such as infliximab, adalimumab, or certolizumab pegol, is recommended in patients with disease refractory to immunomodulatory therapy. Infliximab is given intravenously, and adalimumab subcutaneously; they are of equivalent efficacy and result in remission in roughly half of all patients treated. Vedolizumab, an IV anti-integrin inhibitor, is a newer alternative to anti-TNF agents, or for patients who are refractory to other medications.[16] Vedolizumab inhibits T-lymphocyte migration into inflamed GI parenchyma. All biologic agents have an increased risk of certain cancers or infections, including reactivation of tuberculosis. A step-up approach of adding therapies is commonly employed; however, a top-down approach at an early stage may also be tried.[16]

Antibiotics should be limited to treating complications such as abscess or fistula formation. Ciprofloxacin 500 mg PO twice daily and metronidazole 500 mg PO three times daily for 7 to 10 days are most commonly used. See Box 81.6 for recommended intravenous antibiotics. Bowel rest is not beneficial, except as preparation for surgical intervention. There is insufficient evidence to support the use of enteral nutritional supplementation.[16]

Severe to Fulminant Disease. Severe to fulminant disease requires aggressive therapy, gastroenterology consultation, and often hospitalization. For patients with symptoms suggestive of obstruction, mass, or abscess, surgical consultation is prudent. Evaluation includes CBC, complete metabolic panel, blood cultures, stool culture, C difficile toxin antigen, urinalysis, and abdominal CT or MRI. Treatment begins with intravenous steroids, bowel rest, fluid resuscitation, intravenous antibiotics, and often parenteral nutrition. Biologic therapy is an alternative in patients' refractory to high-dose intravenous steroids. Surgery is often indicated for patients who fail to improve after 1 to 2 weeks of intensive medical therapy.

Surgery is typically reserved for patients with severe disease who do not respond to medical therapy, or for those with serious complications. Percutaneous or surgical drainage may be necessary in the treatment of an abdominal abscess. Strictureplasty is a safe alternative to resection for those with shorter strictures <10 cm.[19] Perianal fistulization is managed with surgical drainage and antibiotic therapy. Complex disease often first requires surgical drainage followed by an anti-TNF agent.

Ulcerative Colitis

Mild to Moderate Disease. For mild to moderate UC, aminosalicylates (5-ASA) including mesalazine and sulfasalazine are mainstays of treatment.[18] Combined topical (suppository or enema) and oral 5-ASA has been shown to be superior to oral therapy alone.[17] Mild to moderate proctitis can be treated with either topical 5-ASA, such as mesalazine suppositories (at least 500 mg/day per rectum [PR]). For ulcerative proctosigmoiditis, mesalazine enemas may be effective, as enema formulations are capable of reaching the splenic flexure. For disease of the transverse or ascending colon, oral formulations are necessary. 5-ASA therapy is associated with renal toxicity and complications; thus, it is important to obtain baseline renal function and trend.[17]

For patients who do not respond to 5-ASA, steroid treatment is initiated. Budesonide may be used in mild-moderate UC to limit use of systemic corticosteroids, as there are colonic release formulations, rectal enemas, and rectal foams.[17] Topical budesonide rectal formulations can be used to induce remission in mild-moderate ulcerative proctitis and proctosigmoiditis. If unsuccessful in controlling symptoms, then topical steroids, such as hydrocortisone, can be given, which is available in suppository, enema, or foam preparations. Tacrolimus suppositories are a possible option for refractory UC proctitis, though there is limited data.

Mild to moderate active left-sided colitis or pancolitis is treated with topical rectal mesalazine foam or enemas combined with oral mesalazine (at least 3 g/day PO). If symptoms fail to improve, then corticosteroids should be given systemically with 0.5 to 1 mg/kg PO prednisone, or alternative equivalent steroid. Once symptoms improve, a steroid taper can be initiated. However, if symptoms persist, an immunomodulator such as azathioprine 2 mg/kg/day PO can be given. Infliximab can be effective in refractory disease.

Moderate to Severe Disease. Vedolizumab was approved to treat moderate to severe UC resistant to immunomodulators, steroids, or anti-TNF therapy. While some centers still utilize cyclosporine 2 to 4 mg/kg IV daily, rescue therapy with infliximab is used more

commonly in hospitalized patients given its ease of use and fewer side effects. Although most patients tolerate it well, cyclosporine has significant potential toxicity, including myelosuppression, electrolyte disturbances, and hepatic toxicity or nephrotoxicity. Opportunistic infections, including *Pneumocystis* pneumonia, have also been known to occur.

Symptoms typically requiring inpatient treatment include severe pain, abdominal distention, bleeding, or severe systemic symptoms.[18] Severe flares generally necessitate hospitalization for IV steroid treatment. Antibiotics should be considered in severe disease or with immunosuppressive drug use. Avoidance of drugs (anticholinergics, antidiarrheals) or procedures (colonoscopy, barium enema) that increase the risk of toxic megacolon is recommended. Early surgical consultation is recommended for most hospitalized UC patients, or for those that do not respond to aggressive medical management.

Surgery is reserved for patients with severe disease refractory to medical management or for patients with complications such as intestinal obstruction, significant bleeding, abscess, or fistula. Up to 25% of patients with UC will eventually require colectomy for uncontrolled disease. A colectomy can be curative for UC and improves the quality of life.

For most patients, remission can be maintained with 5-ASA agents. Azathioprine can also be used for patients who do not stay in remission with 5-ASA. Similarly, infliximab can be used for maintenance therapy if a patient is unresponsive to other drugs.

Managing Special Populations With Irritable Bowel Syndrome

Pregnancy can exacerbate active disease and is associated with a high risk of spontaneous abortion, low birth weight, premature birth, ischemic placental disease, stillbirth, or cesarean delivery. Concern for fetal effects may lead to discontinuation of medications; however, many treatments are safe during pregnancy. Selected antibiotics or steroids are relatively low risk during pregnancy. Ciprofloxacin and metronidazole should generally be avoided in the first trimester. Steroid use may increase the risk of gestational diabetes or low birth weight. 5-ASA agents, immunomodulators, and anti-TNF mediations are generally safe to use in pregnancy. Less is known about the newer anti-integrin inhibitors, such as vedolizumab. It is important to employ a multidisciplinary approach with an obstetrician as well as a gastroenterologist when treating pregnant IBD patients.

Elders often have delayed or misdiagnosis due to the wide differential for IBD symptoms. A new diagnosis of IBD in an older adult should be made only after the exclusion of CI. Due to polypharmacy and complex medication interactions, elderly patients may be more difficult to manage. Decreased glomerular filtration in the elderly may necessitate renal dosing for medications, including methotrexate and azathioprine. Since elderly patients are more likely to be taking multiple medications, such as warfarin, care must be taken to check for medication interactions. Several medications used to treat IBD interact with warfarin, including azathioprine and metronidazole. This patient population is also more prone to the negative side effects of steroids, including altered mental status, or exacerbation of diabetes and hypertension, as well as osteoporotic-related fractures and osteonecrosis.

Toxic Megacolon

Treatment for toxic megacolon includes fluid hydration, IV corticosteroids, antibiotics covering bowel flora (see Box 81.6), and evaluation for potential intestinal infection, especially in immunocompromised patients. Hypokalemia or hypomagnesemia should be corrected if present because it can exacerbate colonic dilation. The mortality rate has decreased to less than 2% as a result of early recognition and treatment.

Disposition

Consultation with a gastroenterologist is recommended. Most patients with an uncomplicated mild to moderate exacerbation of IBD need only to restart their maintenance therapy if it was interrupted, or add oral steroids to their regimen. Patients with severe disease or those in whom oral steroids have failed to effect improvement may need hospitalization for administration of parenteral steroids. Some patients with steroid refractory disease may need immunomodulators or biologic medications to control symptoms. Emergent surgical consultation should be sought for life-threatening hemorrhage, perforation, or toxic megacolon. Urgent surgical intervention is indicated if the bowel is obstructed. Abscesses may be treated percutaneously with imaging guidance or surgically. Chronic fistulae initially are treated medically. After hospital discharge, close follow-up by the physician monitoring the patient's disease is important to ensure that remission is achieved in a timely fashion and that the patient complies with suppressive therapy after the acute event.

COLONIC ISCHEMIA

Foundations

Background

CI is the most common intestinal ischemic disorder and a common cause of lower GI bleed.[20] It is also commonly referred to as ischemic colitis. Its presentation overlaps with that of many other abdominal diseases and is difficult to diagnose without endoscopic visualization of the colonic mucosa. Although 90% of CI cases occur in patients older than 60 years, it can occur in all age groups. There is a female predominance. Mortality rates range from 4% to 12%,[20] and in isolated right-sided colonic ischemia (IRCI), mortality rates are higher, around 20%.[21]

Anatomy, Physiology, and Pathophysiology

Nonocclusive CI due to hypoperfusion and reperfusion injury is the predominant mechanism,[2] usually affecting watershed areas with limited collateralization, such as the splenic flexure and rectosigmoid junction.[20,21] CI represents a spectrum of disease whose manifestations vary with the extent of the ischemic insult. Reversible disease is characterized by bowel wall edema and subepithelial hemorrhage, leading to ulceration of mucosa visible as acute colitis. In most cases, the ischemic episode is self-limited, and the condition resolves completely with conservative therapy; however, in one-third of patients, a prolonged or severe insult results in transmural ischemia, gangrene, intestinal perforation, scarring, or stricture formation of the colon. Disruption of the colonic epithelial barrier function leads to bacterial translocation. Reperfusion injury results in inflammatory changes that can lead to cell death.[20,21] The greater frequency in elders suggests a relationship to degenerative vascular changes.

The primary insult is a low blood flow state associated with a variety of factors. These causes include cardiac (arrhythmias, heart failure, shock), vascular (atherosclerosis, embolic, thrombotic, vasculitis), infectious (*E. coli* 0157:H7, Hepatitis B, cytomegalovirus), iatrogenic (surgical interventions on the aorta), physiologic (long-distance running), or illicit drugs (cocaine or methamphetamine abuse). Chronic obstructive pulmonary disease (COPD) is associated with a 4-fold increased risk of CI and predicts a more severe disease course.[20] CI is diagnosed about 3.5-fold more frequently in patients with IBS. Chronic kidney disease also is associated with increased risk and mortality from CI.[21] Younger patients may develop CI in the setting of collagen vascular disease, hematologic disorders, or long-distance running. Medications associated with CI include vasoactive drugs (antihypertensives or vasoconstrictors), antipsychotics, oral contraceptives, antidiarrheal

agents, pseudoephedrine, and immunosuppressive agents. Although less common, it is important to consider that distally obstructing lesions of the colon can also theoretically raise intracolonic pressure and cause CI by reducing colonic blood flow.

CI can occur in any part of the colon, including the rectum. The colon is particularly susceptible to vascular hypoperfusion as it has the lowest flow state of all splanchnic organs, with limited collaterals. CI is usually left-sided correlating with the inferior mesenteric artery distribution. IRCI occurs in only 10% to 25% of cases and is associated with a worse outcome than CI, affecting any other region on the colon. As the superior mesenteric artery (SMA) supplies the right side of the colon as well as the small intestine, it is thought that IRCI could be the heralding presentation of an acute SMA occlusion.

Clinical Features

The presentation of CI typically involves the acute onset of mild crampy abdominal pain over the involved segment of the bowel. Most patients will have pain in the left lower quadrant, with abdominal distention and blood in the stool. IRCI presents with more right-sided pain and less frequently with bloody stools.[20] The typical patient has had recent surgery or significant medical illness. Nausea and vomiting can occur with obstruction secondary to a stricture or ileus. Tenderness over the affected colon may be present but often is not dramatic. Peritoneal findings, fever, and an elevated WBC count are suggestive of gangrenous bowel or perforation. Toxic megacolon is a recognized complication. Without surgical intervention, fulminant gangrenous CI can lead to perforation, multiorgan failure, and death.

Differential Diagnoses

The symptoms of CI are nonspecific and overlap with those of numerous alternative disorders, including IBD, diverticulitis, infectious colitis, and other causes of non-profuse, lower gastrointestinal bleeding. If strictures are present, the possibility of diverticulitis or colon cancer should also be considered.

Diagnostic Testing

Laboratory Tests

There are no sensitive or specific biochemical markers for CI. Decreases in hemoglobin and bicarbonate or increases in lactate, WBC, or LDH are the most frequently seen abnormalities in severe CI. Decreased albumin or the presence of metabolic acidosis can be used to predict severity.[21] Serum electrolyte levels should be checked if diarrhea or vomiting has been severe or prolonged. Stool studies such as *C. diff* toxin, ova and parasite, or culture can help to exclude infectious etiologies.[21] Blood and WBCs in the stool are common findings in several of the entities that present similarly to CI, including IBD and infectious colitis. Unfortunately, the definitive diagnosis of CI is rarely made in the ED setting.

Imaging Studies

Plain Radiography. Plain radiographs often show only nonspecific dilated bowel. Findings specific for CI occur in approximately 20% of patients. Classic findings include (1) intraluminal prominences, known as thumbprinting, which represent submucosal hemorrhage and swelling, and (2) wall thickening and ahaustral segments. Air in the portal venous system or bowel wall suggests significant ischemia and imminent intestinal infarction.

Computed Tomography. Although CT does not allow the definitive diagnosis of CI, it is useful to support the clinical suspicion, assess the extent of colonic involvement, diagnose potential complications, and exclude other disorders. CT features suggestive of CI include mesenteric fat stranding, abnormal colon wall enhancement, thumbprinting, wall thickening, or luminal narrowing and inner wall hypoperfusion, the so-called double halo sign (Fig. 81.12).[22] Pneumatosis linearis, bowel dilation, and peri-colonic free fluid are associated with severe ischemia.

Colonoscopy. Emergent colonoscopy should be performed after the colon is prepped with an enema. It is the most useful within 48 hours of symptom onset when it is more likely to reveal subepithelial hemorrhage and ulcerations typical of CI. Biopsy specimens help differentiate between cancer and other nonischemic causes of colitis. Colonoscopy can also detect necrotic bowel by its distinct cyanotic or black appearance. If colonoscopy is delayed, pathologic changes consistent with CI may have already resolved. The diagnosis may be missed on colonoscopy in up to one-third of cases.

Angiography. Angiography is usually not helpful in the diagnosis or management of CI. In most cases, the blood flow defect is at the microvascular level and has resolved by the time the patient seeks evaluation. The exception is IRCI, in which case only the ascending colon is affected, suggesting an SMA thrombosis.

Management

In the absence of surgical complications, the treatment of CI is supportive and includes bowel rest, hydration, and pain management. Broad-spectrum antibiotics covering bowel flora are indicated for patients with more significant symptoms (see Box 81.6).[21] If CI is precipitated by an episode of hypotension, the underlying cause must be sought and treated, and cardiac output should be optimized. A cardiac evaluation should be considered, and if congestive heart failure or cardiac arrhythmia is identified, medical treatment should be initiated. Vasopressors, steroids, nonsteroidal antiinflammatory drugs (NSAIDs), and oral cathartics should be avoided. Serial imaging or endoscopic evaluations of the colon and continued monitoring of the hemoglobin and electrolyte levels are indicated until the patient's condition stabilizes. Colonic distention should prompt surgical consultation and decompression with a rectal tube to lower the transmural pressure and improve colonic perfusion. Patients not recovering with medical management should

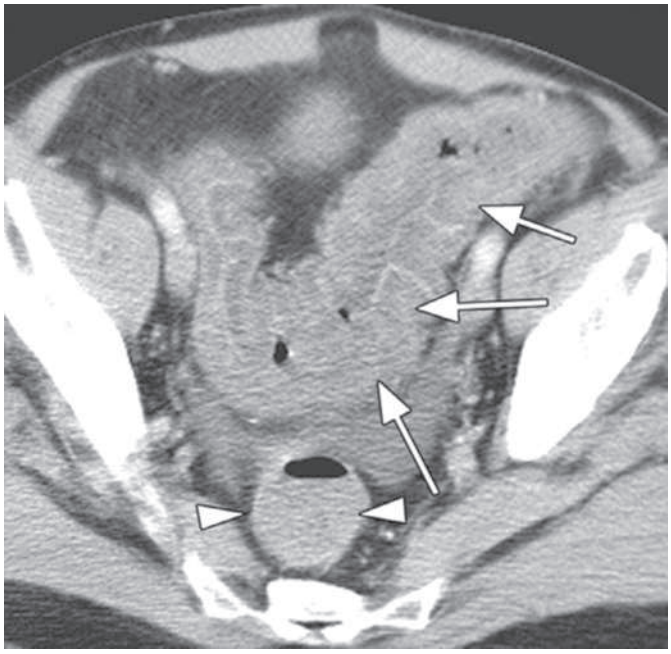

Fig. 81.12 CT scan of a patient with colonic ischemia showing thumbprinting *(arrows)* with thickening of the sigmoid colon associated with multiple nodular defects. Note that the rectal wall *(arrowheads)* is normal. (From Thoeni RF, Cello JP. CT Imaging of colitis. *Radiology*. 2006;240:623–638.)

receive surgical evaluation. Prompt surgical consultation should be considered in the setting of sepsis, peritoneal changes, free abdominal air, significant fever, massive bleeding, or a significant leukocytosis suggesting colon infarction or perforation.[21]

Disposition

Patients with mild symptoms and minimal abdominal tenderness or bleeding can be managed on an outpatient basis if they have reliable ability to obtain follow-up and are referred for urgent colonoscopy after discussion with gastroenterology. Patients with more significant findings, especially if the diagnosis of gangrenous bowel cannot be excluded, require hospitalization and surgical consultation. A high mortality rate (60%) is expected for patients undergoing emergent surgery, although deaths before the age of 50 years are rare. Most patients improve without surgical intervention, and only 5% have a recurrence of CI. In those with continuing significant symptoms, colectomy is usually curative.

STERCORAL COLITIS

Foundations

Background

Stercoral colitis (SC) most frequently occurs in the elderly, bedbound patients or young patients with neurologic disorders due to physical inactivity, comorbid chronic neurologic or psychiatric disorders, metabolic, or colonic function disorders, pharmacotherapy (especially narcotics), or inappropriate diet and fluid intake.[23–25] There have also been case reports of SC in the pediatric population.[26]

Anatomy, Physiology, and Pathophysiology

SC is a rare complication of chronic constipation and fecal impaction that can lead to increased intraluminal pressure wall necrosis, ischemic colitis, stercoral ulcer formation and ultimately perforation if left untreated.[25] Common locations for SC include the anterior rectum, rectosigmoid junction, and apex of the sigmoid colon. Overall mortality is around 30%.

Clinical Features

Patients typically present with lower abdominal pain in the setting of chronic constipation. Abdominal distention or vomiting may also be present. Some patients may have minimal to no abdominal pain in the initial stages.

Differential Diagnoses

The differential for constipation is wide but includes bowel obstruction, medication-related effects, diverticulitis, and behavior or diet-related causes.

Diagnosis

Given the neurologic and psychiatric comorbidities that are common in patients with SC, imaging with a CT scan is usually needed to make the diagnosis. CT findings include fecal impaction with a hard calcified fecal mass (fecaloma), colon dilation, colon wall thickening, mucosal discontinuity, pericolonic fat stranding, or extraluminal free air.[25]

Management

Treatment is focused on relieving constipation with bowel regimen, enemas, and manual fecal disimpaction, provided there is no evidence of peritonitis on examination or perforation on CT. Some cases may require endoscopic guided disimpaction. Antibiotic therapy or surgery may be indicated in the setting of perforation.

Disposition

Patients are typically admitted for serial abdominal examinations and surgical consultation given the high associated mortality. If the patient has no signs concerning for perforation, and symptoms have improved after relieving fecal impaction, then discharge for selected patients is reasonable. If the patient's symptoms persist or there is a concern for perforation, then IV antibiotics (see Box 81.6), admission, and surgical consultation are indicated.

RADIATION PROCTOCOLITIS

Foundations

Background

Radiation proctocolitis (RP) is a common and unfortunate side effect of radiation therapy that can occur in 50% to75% of patients receiving radiation to the pelvis. The dose of radiation determines the severity and duration of symptoms in RP. Presentations can be acute or chronic. Acute RP begins during or shortly after a course of radiation therapy, typically within 12 weeks, and is self-limited. Chronic RP occurs in 5% to 10% of patients who have undergone pelvic radiation therapy[27] and can begin any time following completion of radiation therapy, making the diagnosis challenging. Symptoms most often occur within 8 to 12 months. Recent advances in radiation techniques have resulted in a more targeted external radiation beam, which helps minimize the development of chronic RP.

Anatomy, Physiology, and Pathophysiology

Radiation is an important and effective treatment modality for neoplastic disease, but it also damages rapidly growing intestinal epithelium. The mucosal injury results in loss of normal barrier function, and luminal microbes trigger an acute inflammatory response leading to further mucosal damage. Impaired recognition of bacterial translocation worsens the inflammatory response and can lead to chronic inflammatory changes, such as strictures, fibrosis, or ischemia. The fixed portions of the colon, cecum, and rectum are at greater risk of receiving high doses of radiation.

Acute Radiation Proctocolitis. Intestinal epithelium normally sloughs off and is replaced at a rapid rate. After the initiation of radiation therapy, growth of replacement epithelium is slowed, but sloughing continues at the pre-exposure rate. This mismatch leads to gaps in the epithelium, which over time coalesce into ulcerations. In addition, edema and inflammatory changes of the submucosa cause excessive mucus secretion and bleeding. When radiation therapy has ended, the cycle of damage stops, and healing occurs over the next few weeks.

Chronic Radiation Proctocolitis. The pathologic mechanism in chronic RP is entirely different and results from a progressive endarteritis, with abnormal tissue collagen deposition. The affected intestine has a decreased microvascular density, with subsequent decreased perfusion. Over time, the affected bowel gradually becomes more ischemic, leading to ulceration, scarring, and ultimately narrowing of the bowel lumen.

Clinical Features

Acute RP presents with abdominal and rectal pain, along with diarrhea, hematochezia, and tenesmus.[27] Onset occurs during the course of radiation therapy. Symptoms can be severe and result in interruption of therapy or alterations in the treatment plan in 5% to 15% of cases.

Chronic RP has a more insidious onset with a number of possible presentations including ulcerative disease, stricture formation, obstruction, fistulae, or bowel perforation. Bleeding is common but is usually not significant. Decreased caliber of stool, along with increased

straining or constipation, suggests a stricture. Fistulae can develop between the affected bowel and any adjacent organ, but the most common site is rectovaginal.

Some patients with either acute or chronic RP may exhibit anal sphincter dysfunction. Fecal incontinence has been reported in up to 20% of patients, which can be devastating to quality of life.

As the most common indication for pelvic radiation therapy is malignancy, it is important to assess for any recurrence of the primary cancer in patients with chronic radiation proctitis. A digital rectal examination should be performed to evaluate sphincter tone, especially if the patient presents with fecal incontinence.

Differential Diagnosis

Recurrence of the primary malignancy should be considered in patients with chronic RP. Symptoms are generally indistinguishable from other causes of bowel inflammation, including IBD, infectious colitis, or ischemic colitis.

Diagnostic Testing

Acute RP is a clinical diagnosis based on history. Further evaluation in the ED is typically not necessary.

Chronic RP is a diagnosis of exclusion. Endoscopy may reveal pale, thickened, and friable mucosa with prominent telangiectasias. Biopsies may show chronic inflammation; however, biopsies are often contraindicated due to the friability of intestinal mucosa.

Management

Acute Radiation Proctocolitis

Management of acute RP largely involves supportive care. Treatment plans should be discussed with the patient's radiation oncologist. Measures to improve nutritional status should be considered. Possible interventions include steroid enemas (i.e., hydrocortisone enema, 100 mg bid) to reduce inflammation, sucralfate enemas (2 g of a 10% suspension in water bid) to stimulate epithelial healing, and water-absorbing stool softeners (e.g., docusate sodium) to reduce mucus-containing diarrhea. Reduction of the daily radiation dose may also help reduce symptoms. Butyrate enemas (short-chain fatty acids) may accelerate healing given that these short-chain fatty acids are an important nutrient for colonocytes.

Chronic Radiation Proctocolitis

Chronic RP treatment also involves supportive care. If rectal involvement is significant, stool softeners, analgesics, anti-inflammatory agents (i.e., sulfasalazine, mesalazine), and sucralfate enemas may be helpful. Metronidazole, 500 mg orally tid, for 4 weeks was previously suggested, but current guidelines advocate against its use due to a lack of adequate evaluation in the management of RP.[27] Continued rectal bleeding may be managed with topical formalin or laser photocoagulation. Other interventional treatments include hyperbaric therapy or radiofrequency ablation.[27] Hyperbaric therapy has shown significant improvement in patients with refractory colitis. Minimally symptomatic strictures can be managed with stool softeners or enemas in order to reduce the extent of luminal narrowing. Fistulae and significant stricture typically require surgical repair. Approximately 20% of all patients with chronic radiation injury to the intestinal tract require some form of surgical intervention.

Disposition

Unless symptoms are severe, patients with acute or chronic RP can usually be managed on an outpatient basis, under the care of their radiation oncologist. Suspected perforation necessitates surgical consultation; likewise, signs of bowel obstruction should prompt consideration of surgical consultation. Stricture or fistula formation can usually be managed on an outpatient basis, with surgical referral in the case of worsening symptoms.

NEUTROPENIC ENTEROCOLITIS

Foundations

Background

Neutropenic enterocolitis (NE), also known as typhlitis, is a rare but important condition to consider in all immunosuppressed individuals who present with acute abdominal pain. Initially, NE was only described in pediatric leukemia patients. It is now seen in children and adults with hematologic malignancies such as leukemia, lymphoma, multiple myeloma, aplastic anemia, and myelodysplastic syndrome. It can also be seen in individuals that are immunosuppressed from AIDS, therapy for solid tumors, or organ transplantation. The incidence in hospitalized adults is reported to be approximately 5.6%.[28] The associated mortality of NE can be as high as 50%.[28] Mortality has been shown to decrease with early recognition and management, making this an important diagnosis to consider in the ED.[29]

Anatomy, Pathology, and Pathophysiology

The pathogenesis of NE is not completely understood.[28] The main factors include intestinal mucosal injury, neutropenia, and an immunocompromised state. Anatomically, NE most commonly affects the cecum and terminal ileum. The cecum is thought to be most commonly implicated given its distensibility and limited vascular supply.[28] Pathogenesis tends to involve intestinal damage stemming from neutropenia and intensive chemotherapeutic regimens, followed by microbial and sometimes fungal invasion. This can cause bowel inflammation, ulceration, and eventually necrosis and perforation.[30] Neutropenia can result in intestinal edema, causing a disrupted mucosal surface, making it more vulnerable to bacterial intramural invasion. Chemotherapeutic agents can cause mucosal injury or can alter intestinal motility, thereby causing bowel distention and necrosis.[28] Some of the chemotherapeutic agents associated with the development of NE include cytarabine, gemcitabine, vincristine, doxorubicin, and cyclophosphamide.[28] Another consideration in the pathogenesis of NE is the infiltration by neoplastic cells. This infiltration can cause bowel ulceration and perforation, which is why some cases of NE are seen prior to the initiation of chemotherapy.[30]

Clinical Features

Patients with NE will often present with abdominal pain, diarrhea, and fever. Abdominal pain is typically localized in the right lower quadrant. Other symptoms include nausea, vomiting, abdominal distention, and rectal bleeding. Symptoms most commonly begin in the second week after chemotherapy.[28] Patients with bowel necrosis or perforation may present with peritoneal signs or hemodynamic instability.

Differential Diagnoses

Other diagnoses to consider when NE is clinically suspected include pseudomembranous colitis, appendicitis, ischemic colitis, and IBD.

Diagnostic Testing

Laboratory Tests

Neutropenia is the most important factor in establishing the diagnosis of NE. An absolute neutrophil count (ANC) less than 500 cells/μL is associated with the development of NE.[28] In addition to calculating an ANC, a CBC also screens for anemia or thrombocytopenia. Other helpful laboratory tests include a chemistry panel to assess for electrolyte abnormalities and coagulation studies. Blood cultures for aerobic

and anaerobic bacteria, as well as fungi, should be obtained. Blood cultures may show enteric organisms such as *E. coli*, *Clostridium septicum*, and enterococci.[28] Importantly, bacteremia from enteric organisms in febrile neutropenic patients with no other source should prompt evaluation for NE.[31] Fungal cultures are important given invasive fungal disease can occur in approximately 20% of NE cases.[32] Stool cultures and assays to assess for *C. difficile* toxin are important to rule out other potential causes of abdominal pain in neutropenic or immunosuppressed patients.

Radiologic Tests

Abdominal x-rays are generally unhelpful in the diagnosis of NE; however, if obtained may show pneumatosis intestinalis or pneumoperitoneum, which would respectively suggest necrosis and perforation. Abdominal ultrasound is an important diagnostic tool, especially in the pediatric population, that may help limit radiation exposure. Ultrasound imaging may show bowel wall thickening, and any thickness greater than 0.5 cm is considered to be diagnostic for NE.[30] CT is the most accurate imaging modality for NE.[28] Findings suggestive of NE on CT include bowel wall thickening, cecum dilation, pericolonic inflammation, pericecal fluid, and pneumatosis intestinalis or perforation in more severe cases. Barium enema should be avoided in neutropenic patients, as it can cause colonic perforation and bacteremia.[28] Colonoscopy is also contraindicated in these patients given the risk of perforation.[28]

Management

Patients that are thought to have NE should undergo fluid resuscitation (at 20 mg/kg IV), correction of any electrolyte imbalances, bowel rest, and expedient IV antibiotic administration. Antibiotic coverage includes gram positive, gram negative, and anaerobic pathogens. Common monotherapy options include piperacillin-tazobactam (3.375 g IV, every 6 hours for adult patients, or 100 mg piperacillin/12.5 mg tazobactam per kilogram every 8 hours in pediatric patients), imipenem-cilastatin (500 mg IV every 6 hours or 1 g IV every 6 to 8 hours for adults, or 15–25 mg/kg every 6 hours in pediatric patients). Dual therapy can be used with cefepime (1g IV every 8 hours in adults, or 50 mg/kg every 8 hours) with metronidazole (1 g IV every 6 hours in adults or 30 mg/kg/day divided every 6 hours in pediatric patients). Antifungal treatment targeting *candida albicans* should be used in severe cases or in patients not showing any improvement after 72 hours of antibiotic treatment.[28] Intravenous fluconazole can be used (800 mg on day 1, followed by 400 mg daily until 2 weeks after neutropenia resolves in adults, or 6 to 12 mg/kg daily until 2 weeks after neutropenia resolves).

Leukocyte count recovery has been shown to be associated with favorable outcomes in patients with NE. Granulocyte colony-stimulating factor can be considered in patients with severe neutropenia (ANC < 100 cells/μL), hemodynamic instability, or concern for invasive fungal infection.[28] Severe anemia and thrombocytopenia should be corrected if lower gastrointestinal bleeding occurs. Surgery is indicated when there is bowel perforation. Interventional radiology may be consulted along with surgery with severe rectal bleeding for embolization, if necessary.

Disposition

Patients with NE are often critically ill. Hospitalization is indicated, and most patients will require an intensive care unit. Surgical consultation is indicated in cases complicated by bowel necrosis, perforation, or severe bleeding, or when the diagnosis is uncertain.

CHAPTER 81: QUESTIONS AND ANSWERS

1. A 59-year-old man with a past history of diverticular disease presents with his second episode of left lower quadrant (LLQ) abdominal pain. He is afebrile, and laboratory examination is remarkable for a leukocytosis of 13,800/mm^3. Physical examination reveals moderate LLQ tenderness without masses or rebound. A computed tomography (CT) scan of the abdomen reveals a small (4 cm) abscess adjacent to the sigmoid colon, with moderate diverticulitis. Which of the following would be the most appropriate treatment?

a. Admission for intravenous antibiotics
b. Confirmation with double-contrast barium enema
c. Discharge on oral antibiotics with 2-day follow-up
d. Radiology consultation for percutaneous drainage
e. Surgical consultation for laparotomy

Answer: a. Abscesses smaller than 5 cm are typically treated with intravenous antibiotics followed by an outpatient oral regimen. Larger abscesses may be drained surgically or percutaneously.

2. What is the most common cause of large bowel obstruction in the US.?

a. Adhesions
b. Colon cancer
c. Diverticulitis
d. Intussusception
e. Volvulus

Answer: b. Colon cancer accounts for 53% of cases. Volvulus and diverticulitis account for 17% and 12% of cases, respectively. Extrinsic compression from malignancy accounts for 6% of cases. Adhesions, unlike for small bowel obstructions, are a rare cause of large bowel obstructions.

3. Which of the following statements regarding intussusception is true?
   - **a.** Bowel obstruction typically occurs.
   - **b.** CT scans have a high sensitivity for detection of intussusception.
   - **c.** Most adult cases involve the large bowel.
   - **d.** Most adult cases require surgery.
   - **e.** Most children have a causative lesion.

Answer: d. In contrast to children, most adult cases have a causative pathologic lesion, usually located within the small bowel. Complete obstruction occurs in less than 20% of cases. CT scans may miss as many as 50% of cases of intussusception. Surgery is usually required for adults with intussusception.

4. A 29-year-old woman presents with a 4-month history of intermittent abdominal pain with bloating and diarrhea. The diarrhea has been watery, nonbloody, and often nocturnal. Physical examination is remarkable for mild diffuse abdominal tenderness and brown, guaiac-positive stool. Rectal examination also demonstrates a small anal fissure at the 3-o'clock position. Laboratory evaluation is remarkable only for a normocytic anemia with a hemoglobin level of 11.5 g/dL. The diagnosis would most likely be confirmed by which of the following?
   - **a.** Colonoscopy
   - **b.** CT scan of the abdomen
   - **c.** Erythrocyte sedimentation rate
   - **d.** Mesenteric angiography
   - **e.** Response to a high-fiber diet

Answer: a. This presentation is typical for inflammatory bowel disease. Nocturnal diarrhea, blood in the stool, and presence of an eccentric (nonposterior midline) anal fissure argue against IBS or benign diarrhea. Ischemic colitis is unlikely in this age group. Endoscopy with biopsy is the diagnostic intervention of choice.

5. Which of the following statements regarding colonic ischemia is true?
   - **a.** CT scanning of the abdomen is diagnostic
   - **b.** It is rarely associated with bloody stool.
   - **c.** It is typically due to nonocclusive disease.
   - **d.** Isolated right-sided ischemic colitis is associated with comparatively lower mortality.
   - **e.** Specific serum biomarkers may be helpful.

Answer: c. Colonic ischemia is typically due to nonocclusive microvascular disease. It occurs due to low-flow conditions related to congestive heart failure (CHF), renal failure, hypovolemia, or recent illness or surgery. Bloody stools are predictable. It may also occur in younger patients with collagen vascular disease, hematologic abnormalities, or cocaine abuse. Isolated right-sided ischemic colitis is associated with comparatively higher mortality. There are no sensitive or specific laboratory tests, and although sometimes suggestive, CT scanning primarily rules out alternative processes.

82

Anorectum

Wendy C. Coates

KEY CONCEPTS

- Anorectal conditions can be approached using an algorithm that addresses the presence or absence of pain, bleeding, swelling, and pruritus, in combination with an assessment of the patient's overall health (see Fig. 82.2).
- Patients who seek treatment for nonspecific anorectal complaints should be evaluated for the presence of underlying systemic disease (e.g., cancer, diabetes mellitus, immunodeficiency) because disorders of the anorectum may be the initial presentation of associated conditions.
- Patients with a sexually transmitted disease (STD) should be evaluated for HIV infection, use of the anus for sexual purposes, and the possibility of domestic violence or abuse.
- Most anorectal conditions can be symptomatically improved by adherence to the WASH regimen (***w***arm water, ***a***nalgesics, ***s***tool softeners, ***h***igh-fiber diet).
- Thrombosed external hemorrhoids are covered by modified anoderm and may be excised and drained within 48 hours of formation. After 48 hours, the clot begins to dissolve, and conservative management with the WASH regimen is indicated.
- Internal hemorrhoids are covered with mucosa and should be referred to a colorectal surgeon for definitive management.
- Acutely thrombosed, gangrenous fourth-degree internal hemorrhoids require urgent surgical consultation.
- Fistulous tracts should not be probed.
- Pilonidal abscesses should be drained with needle aspiration or with a longitudinal incision off the midline.
- Pruritis ani is caused by a variety of conditions, including infection, hemorrhoids, topical irritants, cutaneous conditions, cancer, and hypersensitivity to foods and drugs (see Box 82.5).
- Sensitivity is required when managing patients with anorectal foreign bodies. Health care provider safety is imperative when evaluating foreign bodies with sharp edges.
- Distal anorectal foreign bodies often can often be removed in the ED, whereas proximal or sharp ones should be removed in the operating room.

FOUNDATIONS

Patients visit the emergency department (ED) with a variety of anorectal complaints. Particular focus on sensitivity and a professional demeanor is important in these interactions, because patients may find it challenging to discuss historical details openly and to describe physical complaints related to this area of the body and its function.

The anorectum begins at the rectosigmoid junction at the level of the third sacral vertebra (S3). The rectum follows the sacral curvature for 12 to 15 cm and then sharply turns posteriorly and inferiorly at the puborectalis muscle (Fig. 82.1). Here the anal canal begins its 4-cm course to the anus, which is supported by three muscle groups—levator ani and the internal and external anal sphincters. Anal valves and crypts with mucous glands for lubrication are located 2 cm proximal to the anal verge at the dentate line. Proximal to the crypts are the columns of Morgagni, where the epithelium of the anal canal changes from pink columnar (as in the rectum) to squamous.

The superior, middle, and inferior hemorrhoidal arteries provide blood supply to the anorectum. They arise from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. The superior hemorrhoidal veins drain into the portal system, and the inferior hemorrhoidal veins drain into the caval system. Lymphatic drainage is to the inferior mesenteric nodes above the dentate line and to the inguinal nodes from all areas of the anorectum.

Sympathetic and parasympathetic nervous systems function together to retain the contents of the rectum until evacuation is desired. Sympathetic fibers from L1 to L3 (upper rectum) and presacral nerves (lower rectum) inhibit the contraction of rectal smooth muscle, and L5 fibers cause the internal sphincter to contract. Elimination occurs when parasympathetic fibers from the anterior roots of S2 to S4 cause the rectal wall to contract and the internal sphincter to relax. Voluntary external sphincter control is mediated by motor branches of the pudendal nerve (S2, S3) and the perineal branch of S4. The levator ani is supplied by the pudendal nerve and pelvic branches of S3 to S4 fibers. Sensory perception of rectal distention relies on parasympathetic fibers from S2 to S4. The abundant sensory nerve endings of the distal anal epithelium transmit via the pudendal nerve.

Defecation begins as the rectum becomes distended, the internal sphincter relaxes, and stool enters the anal canal. At an appropriate time and place, the external sphincter relaxes to complete the process of elimination. When voluntary straining is required, abdominal muscles contract, the rectal angle straightens, and the pelvic floor descends. To postpone defecation, the external sphincter contracts voluntarily, relaxing the rectal wall and quelling the urge to defecate unless there is an underlying sphincter disorder or an overwhelming volume of stool.

CLINICAL FEATURES

A history of anorectal and gastrointestinal (GI) symptoms, as well as underlying systemic conditions, elucidate the diagnosis of most anorectal disorders (Box 82.1; Fig. 82.2). Common complaints include bleeding, swelling, pain, itching, and discharge. History includes questions about onset, duration, and quality of symptoms, and details of bowel habits (changes in color, frequency, or consistency of the stool and the presence of straining, flatus, or incontinence of solid or liquid stool). Sexual practices or history of radiation exposure are also relevant in most cases. Underlying GI disorders (e.g., Crohn's disease, cancer, polyps) often produce atypical presentations and patients with an underlying systemic disease such as AIDS, cancer, diabetes mellitus,

or coagulopathy may develop more severe complications of standard anorectal conditions.

In patients presenting with rectal bleeding, the color, amount, and relationship to defecation are essential factors. Pain and bright red blood are consistent with anal fissures or hemorrhoids. Fissure pain is sharp, sudden in onset, and is not associated with swelling, whereas pain from a prolapsed or thrombosed hemorrhoid is gnawing, continuous, and more gradual in onset. Painless rectal bleeding may occur with internal hemorrhoids, cancer, or precancerous lesions. Red blood on the toilet paper usually is caused by anal fissures or external hemorrhoids, though minute quantities can result from any irritating condition.

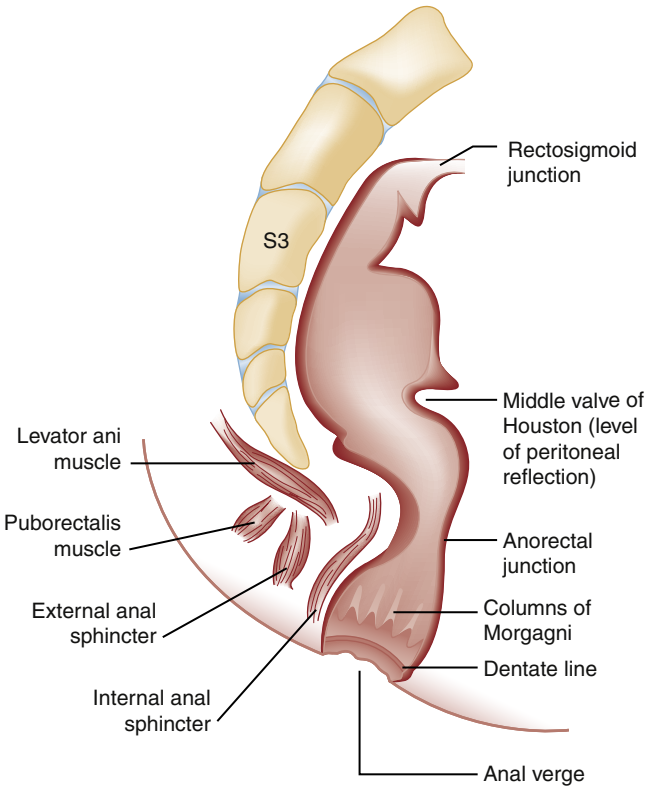

Fig. 82.1 Anorectal anatomy.

BOX 82.1 Medical History in Diagnosis of Anorectal Disorders

Anorectal History
Pain
Bleeding
Swelling
Itching
Discharge
Urgency

Gastrointestinal History
Change in bowel habits (straining, flatus, color, consistency, frequency)
Nausea or vomiting
Incontinence of stool
Underlying GI disease (Crohn's disease, cancer, polyps)

Systemic Disease History
Diabetes mellitus
Coagulopathy
Cancer
HIV infection

Sexual History of the Anus
Penetration
Known STDs
Assault

GI, Gastrointestinal; *HIV,* human immunodeficiency virus; *STD,* sexually transmitted disease.

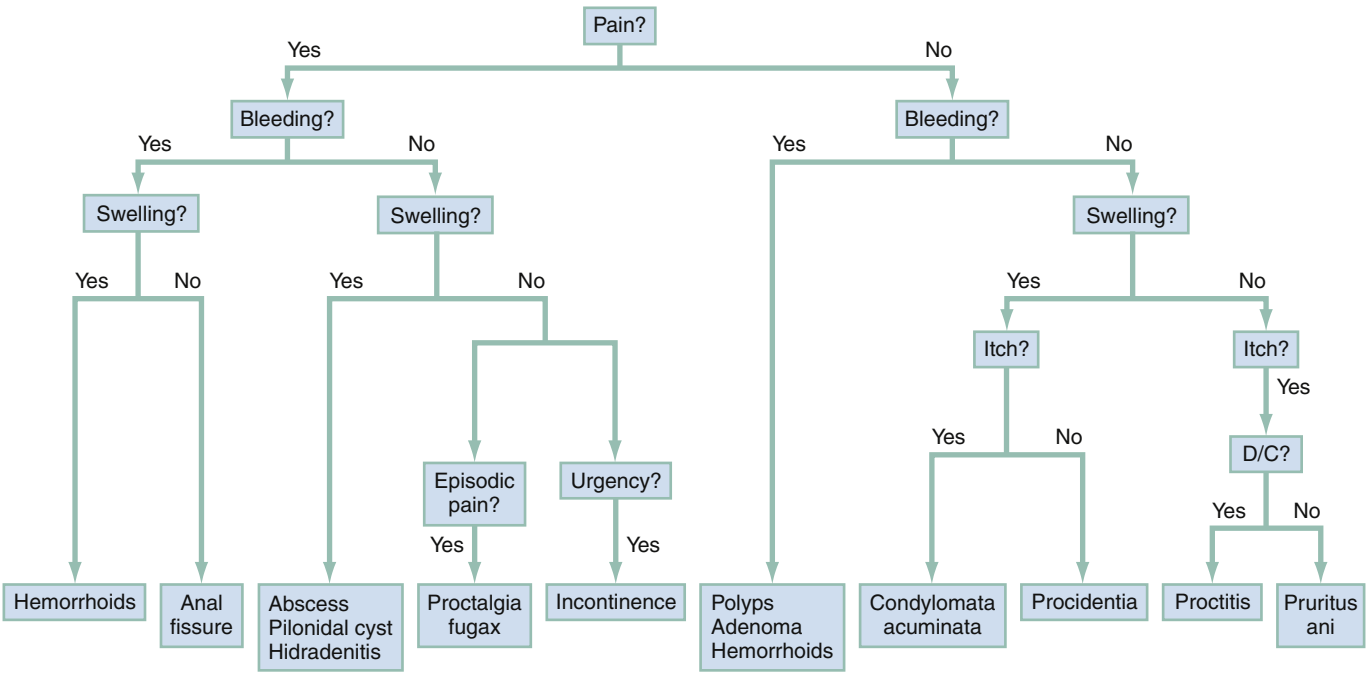

Fig. 82.2 Algorithm for anorectal complaints. *D/C,* Discharge.

Bright red blood that drips into the toilet bowl or streaks around the stool is frequently caused by internal hemorrhoids. Blood mixed with stool typically originates above the rectum, whereas melena indicates an upper GI source, proximal to the ligament of Treitz. Bloody mucus is associated with cancer, inflammatory bowel disease, and proctitis.[1]

Patients who experience perianal swelling or have the sensation of rectal fullness often list hemorrhoids as their chief complaint. Painful swelling that bleeds is usually a thrombosed hemorrhoid, but abscesses, pilonidal disease, and hidradenitis suppurativa should be considered. Painless, itchy swelling may be caused by condylomata acuminata or secondary syphilis. A mass protruding through the anal orifice may signal rectal prolapse or cancer (Fig. 82.3).

Severe, episodic anorectal pain that is not associated with bleeding or swelling may represent proctalgia fugax or levator ani syndrome. Perianal itching (pruritus ani) is caused by poor hygiene or any lesion that makes it difficult to clean the perineum, or may result from exposure to certain foods or medications.

The physical examination should ensure the patient's comfort and privacy. With the patient in the lateral decubitus position and partially covered with a sheet, inspect the buttocks and anal orifice. Note elements of personal hygiene and anatomic disruptions, such as fissures, skin tags, protruding hemorrhoids, abscesses, or other lesions. Ask the patient to strain and note the integrity of the pelvic floor, prolapse of hemorrhoids, or rectal mucosa. Placing the fingertips of both hands along either side of the anus, as close to the anal verge as possible, and applying gentle outward traction allows the anus to be slowly everted, which often reveals anal abnormalities. If the area is slippery, placing 4-by-4-inch gauze pads under the fingers will facilitate sufficient traction. A digital rectal examination begins by placing a well-lubricated gloved finger flat against the anal opening and exerting gentle pressure until the external sphincter relaxes, allowing the finger to enter the anus. Assess anal sphincter tone by asking the patient to squeeze the anal muscles against the examining finger. Accessible areas of the anorectum are examined for masses and areas of tenderness with a circumferential sweep. The cervix or prostate is palpated through the rectal wall. On withdrawal, the contents on the glove are assessed for frank or occult blood, mucus, or pus.

If desired, direct visualization of the anus may be accomplished by anoscopy. A lubricated anoscope is inserted into the anus, with the obturator in place. When the obturator is removed, the area can be viewed for sites of bleeding, hemorrhoids, masses, or abnormal tissue, as well as the dentate line and anal epithelium.

SPECIFIC ANORECTAL PROBLEMS

Hemorrhoids

Foundations

Hemorrhoids occur when the three anal vascular submucosal cushions become engorged. Blood supply arises from the arterial system, causing hemorrhoidal bleeding that is bright red. The muscularis submucosa cushions the anal canal during defecation and aids fecal continence. As the supportive tissue deteriorates, the veins draining the area become distended and prolapse through the anal orifice, which may result in bleeding and/or thrombosis. Some controversy exists about whether straining and constipation cause these changes by producing venous backflow when intra-abdominal pressure increases.[2] A familial predisposition is recognized, but whether this is a result of genetics or acquired factors such as diet is unknown. Direct pressure on a hemorrhoidal vein can produce symptomatic hemorrhoids in pregnant women, and thrombosed hemorrhoids are associated with prolonged labor or deliveries that result in traumatic tears.

Hemorrhoids are not varicose veins; rather, they are normal structures that manifest symptoms when the muscularis submucosa weakens and the anal cushions are displaced distally. Conditions that increase sphincter tone correlate with a higher prevalence of hemorrhoids. Portal hypertension does not typically cause hemorrhoids in adults, although it appears to be a cause in children.[3] Bleeding in patients with portal hypertension may be caused by rectal varices, which are vascular communications between the superior and middle hemorrhoidal veins.

Clinical Features

Patients often refer to any perianal condition as "hemorrhoids." Bleeding with defecation is the most common complaint and, unless the hemorrhoids are thrombosed, is typically painless. Patients report variable amounts of bright red blood on toilet paper when wiping or in the toilet bowl. Many complain of swelling, itching, mucoid discharge, or a moist perianal area. History should address recent stool patterns such as diarrhea or constipation, chronic medical problems such as portal hypertension or bleeding disorders, and a dietary and family history. Frequent bowel movements, prolonged sitting, heavy lifting, and straining while defecating exacerbate symptoms.

Physical examination should ascertain the type and degree of hemorrhoids by visual inspection at rest and during straining. Nonprolapsing hemorrhoids can be visualized on anoscopy as a focus of bleeding or as they bulge when the patient is asked to strain. Anoscopy is painful and not useful in cases of prolapsed or thrombosed hemorrhoids

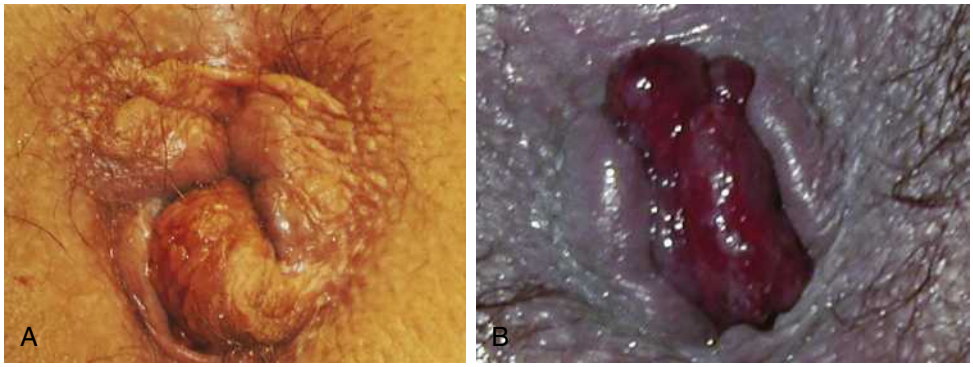

Fig. 82.3 Thrombosed hemorrhoids. (A) External. (B) Internal. Note the engorged external hemorrhoids surrounding the thrombosed internal hemorrhoids. BOX 82.2 WASH Regimen for Management of Hemorrhoids

Warm water
Analgesic agents
Stool softeners
High-fiber diet

(Table 82.1). Table 82.2 shows the classification of hemorrhoids based on history, physical findings, and reducibility.

Management

The symptoms of nonthrombosed external and nonprolapsing internal hemorrhoids can be ameliorated by a standard regimen, WASH (***w***arm water, ***a***nalgesics, ***s***tool softeners, and ***h***igh-fiber diet) aimed at combating the problems that led to their formation (Box 82.2). Anal canal pressures decrease in very warm water (40°C [104°F]—about the temperature of a well-heated "hot tub" or spa).[4] Patients can direct a shower stream at the area for several minutes or take sitz baths. This can facilitate spontaneous reduction of prolapsed hemorrhoids or other tissue and can ease the discomfort arising from tightly constricted musculature. Drinking water helps produce a softer stool. Mild oral analgesic agents such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) reduce pain. Passage of stool is more comfortable with stool softeners and fiber supplementation with psyllium (e.g., Metamucil©), one to two rounded teaspoons in eight ounces of water once a day, or a high-fiber diet (20–30 g of dietary fiber/day). Several over-the-counter preparations are available for the treatment of hemorrhoidal symptoms; their use improves hygiene and provides temporary symptom relief rather than correction of the condition. Topical anesthetics, corticosteroids, astringents (e.g., witch hazel), mineral oils, and cocoa butter are often applied as temporary soothing agents, although there is no evidence to support their use or the relative benefits of one over the other.[4] Astringents may promote better hygiene and reduce discomfort by preventing residual stool from further irritating the hemorrhoids. Lipophilic agents provide a smooth and greasy coating that can prevent the adherence of stool to the irritated areas and can promote a slippery pathway during defecation. We do not recommend use of topical corticosteroids beyond a few days because of risk of atrophic skin changes.

Patients with second- or third-degree internal hemorrhoids benefit from the WASH regimen and may be discharged from the ED. Permanent resolution of symptoms may require surgical banding, sclerotherapy, or elective hemorrhoidectomy (Table 82.3). Patients with acute, gangrenous, thrombosed fourth-degree internal hemorrhoids may require emergent hemorrhoidectomy.[5]

Acutely thrombosed external hemorrhoids can be excised (*not* incised and drained) to provide relief within the first 72 hours after the onset of symptoms (Fig. 82.4). Although incision may help to relieve pain in the short term, it results in incomplete evacuation of

TABLE 82.3 Surgical Management of Hemorrhoids

Classification	Management
Thrombosed external hemorrhoids	Excision in emergency department
Second- and third-degree internal hemorrhoids	Elective surgical repair Banding Sclerotherapy Hemorrhoidectomy
Fourth-degree hemorrhoids (nonthrombosed)	Nonemergent hemorrhoidectomy
Thrombosed or gangrenous fourth-degree internal hemorrhoids	Emergent hemorrhoidectomy

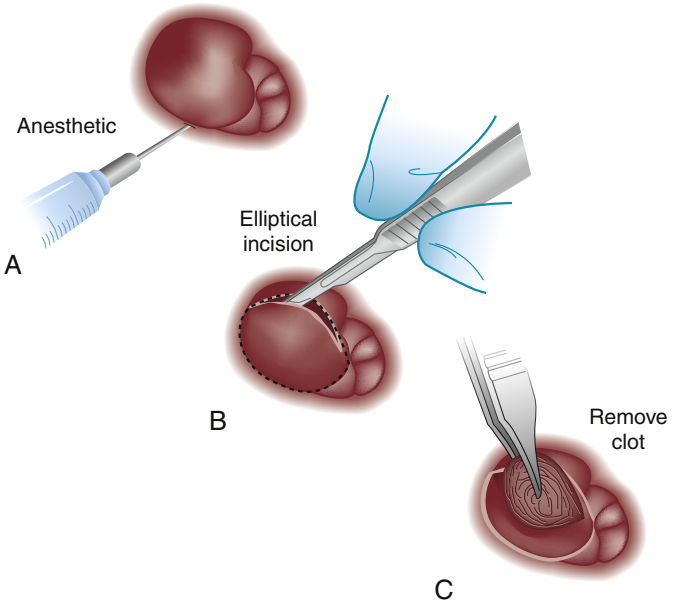

Fig. 82.4 Excision of thrombosed external hemorrhoid. (A) Field block with local anesthetic. (B) An elliptical incision is made around the hemorrhoid. (C) The thrombosed hemorrhoid is removed. (From Larson S, et al, eds. *Atlas of Emergency Procedures.* St. Louis: Mosby; 2001.)

Fig. 82.5 Lateral anal fissure. (Courtesy Dr. Gershon Effron, Sinai Hospital of Baltimore; from: Seidel HM, et al, eds. *Mosby's Guide to Physical Examination,* ed 4. St. Louis: Mosby; 1999.)

the clot, subsequent rebleeding, swelling, and formation of a skin tag. If not excised, a thrombosed external hemorrhoid resolves spontaneously after several days when it ulcerates and leaks the dark accumulated blood. Residual skin tags may persist, making anal hygiene more challenging. In the ED setting, this procedure is not commonly performed in pediatric patients, pregnant women, or immunocompromised patients.

Nonsurgical therapy with topical nifedipine (0.2%) and lidocaine (1.5%) gel applied twice daily for a few days may alleviate symptoms in some patients. Although not widely used, the purported effectiveness of this regimen is related to the ability of nifedipine to modulate resting sphincter tone and thereby reduce the associated pain and inflammation.[6]

Anal Fissures

Foundations

The development of an anal fissure is the most common cause of intensely painful rectal bleeding of sudden onset. A superficial tear in the anoderm results when a hard piece of feces is forced through the anus, usually in patients who are constipated, or may occur during sexually related anal instrumentation. It is the most commonly encountered anorectal problem in pediatric patients, especially infants.[7] Most fissures occur along the posterior midline, where the skeletal muscle fibers that encircle the anus are weakest. Anterior midline fissures are more common in women than in men. Fissures that occur elsewhere may be associated with systemic diseases such as leukemia, Crohn's disease, human immunodeficiency virus (HIV) infection, tuberculosis (TB), or syphilis. If the fissure does not resolve promptly, the classical so-called fissure triad of deep ulcer, sentinel pile, and enlarged anal papillae may develop (Fig. 82.5). A sentinel pile forms when the skin at the base of the fissure becomes edematous and hypertrophic; it can form a permanent skin tag and underlying fistulous tract.

Clinical Features

The patient with an anal fissure reports sudden, searing pain during defecation that may be accompanied by a small amount of bright red blood on the stool or toilet paper. This is followed by a nagging, intermittent or constant burning sensation caused by internal sphincter spasm. Subsequent bowel movements are often quite painful and the external sphincter may exhibit a reflex spasm. A physical examination must be performed cautiously to avoid perpetuating the cycle of spasm and pain. If the patient can tolerate it, gentle anal eversion, as described above, often reveals the culprit fissure. The depth of the fissure, its orientation to the midline, and the presence of a coexisting sentinel pile should be noted. A digital rectal examination during an acute exacerbation often is challenging because of pain and sphincter spasm.

BOX 82.3 Treatment of Anal Fissures

- WASH regimen[a]
- Nitroglycerin ointment (0.4%) bid or tid
- Nifedipine gel (0.2%) bid with lidocaine (1.5%)
- Botulinum toxin (surgical consultation)
- Anal dilation performed with the patient under general anesthesia
- Surgical excision

[a] See Box 86.2

Management

We recommend a trial of conservative treatment with the WASH regimen (see Box 82.2), which focuses on eliminating constipation with a bulking agent, stool softener, and high-fiber diet. For severe discomfort, one to three days of topical anesthetic gel may be helpful. Specific measures for the treatment of anal fissures that do not resolve with conservative therapy are summarized in Box 82.3 and are often employed during follow-up visits with the patient's primary care provider or specialist. Parental encouragement of pediatric patients helps prevent encopresis, which can result from a fear of painful bowel movements. Most acute uncomplicated fissures resolve in 2 to 4 weeks.

For adult patients with recurring anal fissures, application of various topical agents aimed at reducing sphincter pressures and local pain may be effective. There is not uniform consensus for any of these treatments, however, some gastroenterologists and colorectal surgeons report that some individuals may benefit. It would be prudent to consult with the patient's ongoing provider to determine if one of these drug therapies is favored. Nitroglycerin ointment applied topically to the anoderm 2 or 3 times daily may relieve the pain but may cause a vasodilatory headache. Nifedipine gel (0.2%) in combination with lidocaine (1.5%) applied to the anal area twice daily is effective in promoting healing and reducing discomfort in the management of anal fissures by reducing anal canal pressures through local calcium channel blockade. Referral to a colorectal surgeon for definitive management may include injection of botulinum toxin, anal dilation, or sphincterotomy in patients who do not respond to conservative therapy.[8,9]

Abscesses and Fistulae

Foundations

Anorectal abscesses and subsequent fistulae occur in otherwise healthy adults when the mucus-producing glands at the base of the anal crypts occlude. In most cases, this is simply a functional collection of excess thick mucus, however, sometimes abscesses may result from intrarectal or penetrating trauma, or herald the presence of inflammatory bowel disease, cancer, radiation injury, or infection (TB, lymphogranuloma venereum, actinomycosis). Common causative bacteria are *Staphylococcus aureus, Escherichia coli, Streptococcus, Proteus,* and *Bacteroides.*

Anorectal abscess is an acute disease that naturally progresses to fistula formation in the body's attempt to drain the infection spontaneously. Symptoms vary depending on the site of infection, but incision and drainage constitute curative treatment (Table 82.4). Delays may allow extension of the infection and eventual compromise of the sphincter mechanism. Adjunctive antimicrobial therapy is indicated

TABLE 82.4 Types of Abscesses of the Anorectum

Feature	Perianal	Ischiorectal	Intersphincteric	Supralevator	Postanal
Incidence	40%–45%	20%–25%	20%–25%	<5%	5%–10%
Location	Outside and verge	Buttocks	Lower rectum	Above levator ani	Deep to external sphincter
Symptoms	Painful perianal mass	Buttock pain	Rectal fullness	Perianal and buttock pain	Rectal fullness, pain near coccyx

Associated fistula	++	+	+++	+++	–
ED incision and drainage	+	±	–	–	–

ED, Emergency department; *WBCs,* white blood cells; –, does not occur; ±, occurs sometimes; ++, occurs often; +++, usually occurs.

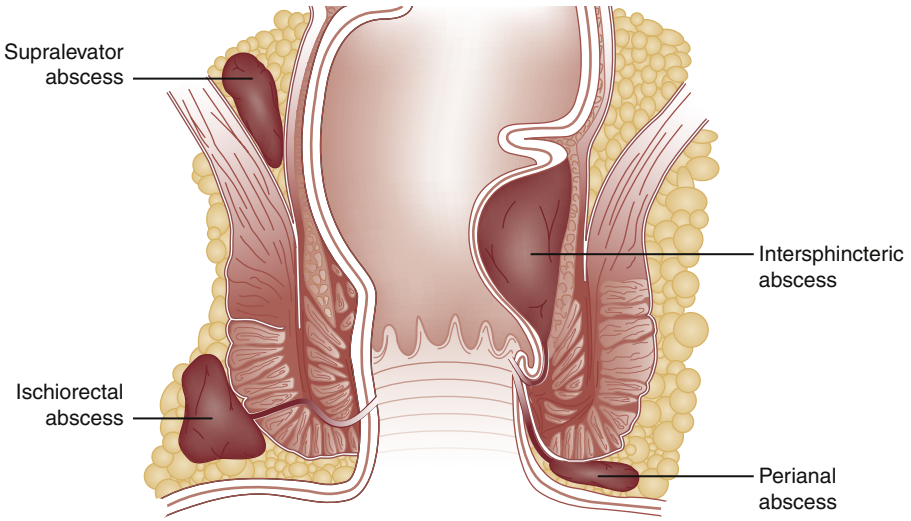

Fig. 82.6 Location of common anorectal abscesses. (Adapted from Gordon PH, Nivatvongs S. *Principles and Practice of Surgery for the Colon, Rectum, and Anus.* St. Louis: Quality Medical Publishing; 1992.)

in patients who are immunocompromised, diabetic, or have valvular heart disease. One-third of patients with AIDS develop anorectal abscesses and fistula. In these patients, antibiotic therapy choices should be guided by the patient's immune status in consultation with infectious disease specialists who are familiar with local antibiograms. HIV-infected patients are prone to having incomplete fistulous tracts, which impedes spontaneous drainage, highlighting the urgency of treating these patients promptly.[10]

Sites of anorectal abscess formation are depicted in Fig. 82.6. Early diagnosis may be difficult because pain often precedes physical findings of a mass or fluctuance.

Management

Perirectal and Perianal Abscesses. Perirectal and perianal abscesses account for about half of anorectal abscesses. They produce painful swelling at the anal verge that is worsened by defecating or sitting. Most patients are afebrile and have localized tenderness, erythema, swelling, and fluctuance that is particularly obvious on examination with palpation between the index finger (from within the rectum) and the thumb (through the outside skin). ED management by incision and drainage may be possible in patients without comorbidities (e.g., diabetes mellitus, extremes of age, compromised immune status), but the procedure can be very painful and often requires procedural sedation and/or field block with local anesthesia. The WASH regimen (see Box 82.2) may alleviate postprocedure discomfort. Antibiotics generally are unnecessary following incision and drainage of uncomplicated superficial abscesses in healthy adult patients, except in cases involving associated cellulitis. There is emerging evidence that adjuvant antibiotics may help reduce the likelihood of subsequent fistula formation, even in patients without cellulitis.[10-12] In consultation with infectious disease specialists at individual institutions to address local antibiograms and the prevalence of methicillin-resistant *Staphylococcus* aureus (MRSA), one could consider administering one or more of the following: cephalexin 500 mg PO bid-qid; sulfamethoxazole/trimethoprim (800 mg/160 mg PO Q12 hours; doxycycline 100 mg PO bid.

Ischiorectal Abscess. Ischiorectal abscesses account for one-fifth to one-quarter of anorectal abscesses. They form outside the sphincter muscles in the buttocks, and patients generally present complaining of severe pain. The diagnosis is evident if an indurated mass is seen on the buttocks but sometimes the abscess is deep in the tissue and not externally identifiable. Patients may have fever and/or leukocytosis. Ultrasound may be useful to localize fluid collections and guide aspiration, particularly if there is no significant induration. Although most of these abscesses will require drainage performed with the patient under general anesthesia, superficial abscesses can be treated in the ED. If the patient is febrile, we recommend a short course of antibiotics, such as cefazolin 1 g IM or IV administered before drainage, followed by cephalexin 500 mg orally qid for 5 to 7 days.[12]

Intersphincteric Abscess. One-fourth of abscesses form in the intersphincteric space, located deep to the external sphincter and inferior to the levator ani. The infection tracks cephalad and may appear to be a mass in the rectum and can be confused with a thrombosed internal hemorrhoid. Patients report continuous rectal pressure and

a throbbing pain exacerbated by defecation or sitting. These patients also may have fever and/or leukocytosis which are neither sensitive nor specific signs. External evidence of inflammation may be lacking, but a rectal examination reveals an indurated, and sometimes draining mass. Associated fistulae and inguinal lymphadenopathy are common. Surgical consultation and advanced imaging, such as CT scan or fistulogram, are necessary to evaluate and treat the entire abscess and fistula network.

Supralevator Abscess. Supralevator abscesses, which cause less than 5% of anorectal abscesses, present as perianal and buttock pain associated with fever and frequently, an associated leukocytosis. External evidence is usually absent, which often leads to a delay in accurate diagnosis. Patients are often obese or have diabetes, Crohn disease, pelvic inflammatory disease, or diverticulitis. A tender mass may be palpated on rectal or pelvic examination, but the abscess is often discovered on CT scan performed to evaluate the patient with significant symptoms but no identified cause. Emergent surgical treatment is indicated to drain the abscess and excise the fistulous network.

Postanal Abscess. Postanal abscesses are uncommon and occur posterior to the rectum, deep to the external sphincter and inferior to the levator ani. Patients experience severe rectal discomfort and coccygeal pain. They usually are febrile and have continuous pain that does not change with position. A rectal examination is painful, and anal drainage is rare. Many of these abscesses are missed on initial presentation, unless a CT scan is performed. These abscesses require surgical consultation and management.

Horseshoe Abscess. A large, communicating, horseshoe-shaped abscess may form in the ischiorectal, intersphincteric, or supralevator spaces. The extent of these abscesses is identified by CT scan and surgical management is necessary.

Necrotizing Infection. A delay in the management of an anorectal abscess may lead to the destruction of surrounding tissue, especially in diabetic or immunocompromised patients. Extensive cellulitis, necrotic tissue, or identification of gas on radiography suggest the possibility of necrotizing fasciitis, Fournier gangrene, or tetanus. Treatment is described in Chapter 126, and includes timely, wide surgical débridement, administration of intravenous antibiotics with anaerobic coverage such as a combination of piperacillin (4.5 gm IV q8h), vancomycin (15 to 20 mg/kg q8h to q12h), and clindamycin (900 mg IV q8h), and tetanus prophylaxis.

Fistulae. A fistula is a connection between two epithelium-lined surfaces and commonly develops in patients with abscesses. Other causes include Crohn's disease, trauma, foreign body reactions, TB, and cancer. The anorectal complaint may be the presenting symptom of the underlying disease. Patients notice a recurrent or persistent perianal discharge that becomes painful when one of the openings becomes occluded. A digital rectal examination may reveal a tract in the perineum or canal. Probing of fistulous tracts is not recommended because the danger of creating a new tract outweighs the benefit of identifying the path of the existing fistula. Spontaneous resolution of fistula-in-ano is rare.

Although symptoms may resolve when antibiotics are administered, they commonly return when therapy is discontinued. Definitive treatment of the fistulous network at the time of incision and drainage of the abscess prevents the ongoing progression of the disease. Fistulectomy or application of fibrin glue are commonly accepted practices of adult and pediatric colorectal surgeons.[13] New treatments that are underway include the use of biomaterials (e.g., platelet rich plasma) and laser closure techniques.[11]

Pilonidal Disease

Foundations

Abscesses containing hair and pus in the midline of the sacrococcygeal area afflict young adults with a 4:1 male predominance and are more common in obese and hirsute persons. Many of those who develop this disease have evidence of midline hair growth in other areas of the body, such as eyebrows that connect with each other. Pilonidal disease occurs more commonly in people who sit for long periods, and was first identified as "Jeep driver's disease" during World War II. The disease is rare after 40 years of age, even for those who were affected in their youth, and should not be confused with anal fistulae, perirectal abscesses, hidradenitis suppurativa, or granulomatous diseases (e.g., syphilis, TB). Pilonidal disease is believed to arise when bacteria enter the usually sterile hair follicle and produce inflammation and edema, thereby occluding the opening to the skin surface. The contents expand until the hair follicle ruptures, and the material spreads into the surrounding subcutaneous fatty tissue, where a foreign body reaction leads to abscess formation. The purulent material subsequently spreads to the presacral skin through an epithelialized tract. In those with chronic or recurrent disease, visible or palpable tracts containing hair and cellular debris may be identified.

Management

Treatment options vary, ranging from aspiration to extensive surgical excision. Supplementary antibiotics, such as cephalexin 500 mg qid for 7 days, are indicated in cases accompanied by cellulitis, but are not effective as the sole treatment for the long term. ED management of pilonidal disease involves aspiration or incision and drainage of the acute abscess for the immediate relief of symptoms. Aspiration of pus plus antibiotics and referral to a surgeon for follow-up may be effective for small pus collections.[14] If incision and drainage are performed, a longitudinal incision lateral to the midline prevents reaccumulation of debris and minimizes the inflammatory response in the midline. Fibrin glue application has shown promise in the early treatment of pilonidal disease and is usually applied by a specialist. Recalcitrant disease may require surgical unroofing, marsupialization, or wide excision.[15]

Hidradenitis Suppurativa

Foundations

Perianal hidradenitis suppurativa is an infection of the apocrine glands. It is most common in young adults and is associated with poor skin hygiene, hyperhidrosis, obesity, acne, diabetes mellitus, and smoking. Occluded apocrine ducts may be infected with strains of *Staphylococcus, Streptococcus, E. coli,* or *Proteus.* Extension through the dermis spreads the infection to neighboring ducts and forms a network of sinus tracts, leading to extensive scarring.[16]

Clinical Findings

Patients report one or more tender, draining pustules or abscesses in the perianal area, which may be associated with fever, malaise, or leukocytosis. Local lymphadenopathy and surrounding cellulitis are common.

Differential Diagnosis

This condition is often misdiagnosed as pilonidal disease or fistula-in-ano. Other considerations in the differential diagnosis include sebaceous cysts, furuncles, granulomas (from TB or syphilis), or Crohn disease.

Management

Treatment begins with careful attention to perianal hygiene, warm compresses, antibiotics (e.g., cephalexin, 500 mg PO qid for 7 days), and dietary modifications (avoidance of dairy products and foods with a high glycemic index). Drainage of isolated lesions by aspiration or incision and drainage may provide symptomatic relief, but the recurrence rate approaches 40%. Referral to a surgeon for wide excision of tissue involved in advanced chronic disease may be necessary.[17]

Proctalgia

Anorectal pain (proctalgia) that does not arise from an identified organic disorder can be severe and difficult to treat. Two common causes of this functional proctalgia are levator ani syndrome and proctalgia fugax. Their patterns of affliction can distinguish these disorders. Other causes of pelvic pain, such as tumors, cauda equina syndrome, or endometriosis, should also be considered.

Levator Ani Syndrome

Constant dull pressure in the sacrococcygeal region precipitated by defecation or prolonged periods of sitting suggests levator ani syndrome. The patient usually has tenderness of the levator muscles, which may be firmly contracted on examination. No standard treatment regimen has been studied, but anecdotal reports indicate that sitz baths, levator ani muscle massage, and benzodiazepines, such as diazepam (beginning with 2 mg PO bid to qid) can provide relief.[18]

Proctalgia Fugax

Proctalgia fugax is an intensely painful spasm in the rectal area that begins abruptly and lasts up to 30 minutes, resulting from a sudden spasm of the levator muscle complex or sigmoid colon. Professionals, managers, perfectionists, and people who frequent the toilet are more likely to be affected. Symptoms begin abruptly during sleep, defecation, urination, or intercourse. The pain has been compared to that of a charley horse (painful spasms in the leg muscles) and may radiate to the coccyx or perineum. Each patient has a unique but recurrent constellation of symptoms. Treatment includes a bowel-cleansing regimen, manual upward pressure on the anus, diazepam (beginning with 2 mg PO bid to qid).

Fecal Incontinence

Foundations

Fecal incontinence is a condition that affects parous women, elders, young children, and patients with a variety of neurologic or traumatic disorders in which the delicate balance among the pelvic floor muscles, sphincters, and anorectal sensation is disrupted. Complete incontinence is the inability to control the passage of solid feces. Partial incontinence is the loss of control of the passage of flatus or liquid feces.

Multiple causes of fecal incontinence have been described (Box 82.4). Liquid feces may seep around tumors or foreign bodies of the rectum or anal canal. Laxative abuse, inflammation, or infection can temporarily overwhelm a normal sphincter mechanism and cause explosive diarrhea. Encopresis may develop in young children experiencing emotional stress. In otherwise healthy children, sexual abuse involving the anus should be considered.

Clinical Features

The anorectum should be assessed for masses, hemorrhoids, evidence of previous surgery, and neuromuscular function. Careful neurologic examination, particularly if back or sacral pain is present, will identify sensory changes caused by neurologic disease, such as cauda equina syndrome, spinal epidural abscess, or mass. Neuromuscular causes of fecal incontinence are diagnosed by anorectal physiologic testing.

Management

Acute fecal incontinence caused by a neurologic condition requires urgent treatment, usually through consultation with a spine surgeon. If CT scan is obtained and confirms a colorectal mass, outpatient surgical referral is necessary for definitive treatment, unless bowel obstruction is present, requiring acute surgical consultation in the ED. The management of subacute or chronic fecal incontinence depends on the cause, and is best managed by an outpatient longitudinal care provider, such as a primary care physician. Depending on the cause, Kegel exercises, which contract the perineal muscles, biofeedback training, or surgical repair may be indicated. In cases of transient incontinence caused by diarrhea, a high-fiber diet and brief therapy with loperamide, 2 mg, after each bowel movement, up to a maximum of 16 mg a day, can solidify stool and enhance rectal compliance.

BOX 82.4 Causes of Fecal Incontinence

Traumatic Causes
Iatrogenic (surgical) nerve injury
Spinal cord injury
Obstetric trauma
Sphincter injury

Neurologic Causes
Spinal cord lesions
Dementia
Autonomic neuropathy (e.g., diabetes mellitus)
Obstetric—pudendal nerve damage from stretching during surgery, Hirschsprung disease

Mass Effect
Carcinoma of anal canal
Carcinoma of rectum
Foreign body
Fecal impaction
Hemorrhoids

Medical Causes
Procidentia
Inflammatory disease
Diarrhea
Laxative abuse

Pediatric Patients
Congenital
Meningocele
Myelomeningocele
Spina bifida

Other Causes
After corrective surgery for imperforate anus
Sexual abuse
Encopresis

Pruritis Ani

Foundations

Patients with pruritus ani complain of uncontrollable itching of the perianal area. The condition is more common in the summer and is more noticeable at night. The sensation of itching arises when the richly innervated perianal skin becomes irritated. Vigorous scratching may result in excoriation (which leads to more intense symptoms). The most common cause is the presence of feces on the perianal skin. Conditions ranging from poor personal hygiene to anatomic disorders allow feces to accumulate. Obesity, deep perianal clefts, hair, hemorrhoids, skin tags, rectal prolapse, anal fissures, and fistulae make the area difficult to clean effectively. Decreased air circulation from wearing tight pants or undergarments of synthetic, nonbreathable fabric may exacerbate symptoms. The causes of pruritus ani are summarized in Box 82.5. The acronym "ITCH" categorizes typical causes—***i***nfection, ***t***opical irritants; ***c***utaneous conditions and cancer; and ***h***ypersensitivity to foods and drugs.[19]

BOX 82.5 Causes of Pruritus Ani

Dermatitis

Fecal Irritation

Poor hygiene

Anorectal conditions—fissure, fistula, hemorrhoids, skin tags, perianal clefts

Systemic—caffeine, tea, beer, spicy foods, citrus fruits, quinidine, intravenous hydrocortisone, colchicine, tetracycline

Contact Dermatitis

Anesthetic agents, topical corticosteroids, perfumed soap

Systemic Diseases

Dermatologic

Psoriasis, seborrhea

Lichen simplex or lichen sclerosus

Nondermatologic

Chronic renal failure, myxedema, diabetes mellitus, thyrotoxicosis, polycythemia vera

Vitamin A or D deficiency, iron deficiency

Cancer—Bowen, Paget, Hodgkin disease

Infections

STDs

Syphilis

HSV infection

HPV infection

Other Infectious Processes

Scabies

Pinworm

Bacterial infection

Fungal infection

HPV, Human papillomavirus; *HSV,* herpes simplex virus; *STD,* sexually transmitted disease.

Diagnostic Testing

Pinworms are most commonly found in young children and their close contacts, as well as in institutionalized patients. The organisms can be identified by applying transparent tape to the perianal area and attaching it to a glass slide or simply inspecting the tape. The visualization of eggs under microscopy confirms the diagnosis, but is not necessary because the worms have a characteristic size and shape and are often identifiable.

Management

A careful history and physical examination will generally identify the cause of pruritus ani. Important considerations include hygienic care of the anus, coexisting anorectal or systemic conditions, diet, and sexual practices.

The first-line agent for pinworms is mebendazole (Vermox), 100 mg orally (over age 2) as a single dose. An alternative agent is pyrantel pamoate (Antiminth), 1 g orally (11 mg/kg, to a maximum of 1 g for pediatric patients over 7 months of age) as a single dose.[20] Repeat doses may be needed in 2 and 4 weeks, and one may consider treating family members. Scabies and pediculosis pubis should be treated with 5% permethrin cream application that can be repeated in 7 days. An alternative regimen for those over the age of 10 years is ivermectin 200 micrograms/kg orally as a single dose (repeated in 2 weeks).[21]

Fungal dermatitis causes a rash with sharply demarcated borders and is treated with clotrimazole 1% or nystatin cream, accompanied by meticulous hygiene and thorough drying of the area before application. Definitive treatment of concomitant anorectal conditions (e.g., fissures, fistulae, hemorrhoids, skin tags, rectal prolapse) can prevent recurrence of pruritus ani.

Underlying systemic diseases should be treated. Patients should be instructed to clean the area thoroughly with lukewarm water after each bowel movement and pat (rather than rub) dry with tissue that is free of chemical irritants. Loose-fitting underwear and exposure to fresh air may alleviate symptoms. The treatment of acute dermatitis includes a short course of topical corticosteroids, such as hydrocortisone 2.5%, calamine lotion, or systemic antihistamines. Some success with topical application of capsaicin cream has been reported, although there is insufficient evidence to support a recommendation.

Sexually Transmitted Disease and Proctitis

Foundations

Anorectal transmission of sexually transmitted disease (STD) is a concern in all sexually active patients with anorectal complaints, but especially in those with HIV. The history should ascertain whether sexual practices involve oral-anal contact or anal penetration and whether condoms are used. Education regarding the transmission of STDs and the efficacy of barrier methods is an essential means of public health prevention of disease.[21,22] Semen has a concentrated viral load, and the damaged epithelium of ulcerated anoderm provides a portal for entry. Syphilis, gonorrhea, and chlamydial infection have been documented in men who have sex with men.

Gonorrhea. The gram-negative diplococcus *Neisseria gonorrhoeae* causes gonorrhea. Proctitis (inflammation of the rectum) results from anal intercourse or autoinoculation from vaginal secretions and becomes symptomatic after a 5- to 7-day incubation period. Symptomatic patients report pruritus ani, tenesmus, and bloody or thick, purulent yellow drainage. Anoscopy reveals proctitis and mucus in the anal crypts. Recovery of the organism from the crypts increases the likelihood of identification. Water should be used to lubricate the anoscope because lubricants contain an antibacterial agent. Disseminated gonococcal infection may include arthritis, skin lesions, perihepatitis, endocarditis, and meningitis.

Chlamydial Infection and Lymphogranuloma Venereum. Infection with *Chlamydia trachomatis,* an intracellular organism that is endemic to the tropics, is a common STD in the United States. Signs and symptoms include mucoid or bloody rectal discharge and tenesmus. Some people are asymptomatic carriers of the organism. Lymphogranuloma venereum is a more serious manifestation caused by specific strains of *C. trachomatis.* It starts as a painful anal or perianal ulceration with an erythematous friable rectal mucosa, fever, and malaise. Prominent unilateral lymph nodes coalesce to form a bubo, which must be distinguished from the granuloma of secondary syphilis. Rectal cultures are unreliable because the organism is intracellular. In the final stage, rectal strictures and rectovaginal fistulae may form.

Herpes Simplex Virus Infection. Herpes proctitis is caused by herpes simplex virus type 1 (HSV-1) and HSV-2. Symptoms appear 1 to 3 weeks after exposure. Those with proctitis may have rectal pain, bloody mucoid discharge, tenesmus, constipation, sacral paresthesias, or urinary difficulties. An examination may be challenging without anesthesia. Single or coalesced vesicles and ulcerations occur in the perianal area and rectum, and the rectal mucosa is erythematous, friable, and ulcerated. Chronic mucocutaneous HSV infection is considered diagnostic for AIDS. Definitive diagnosis with viral or immunofluorescent staining relies on the collection of fluid and scrapings from the base of the vesicle.

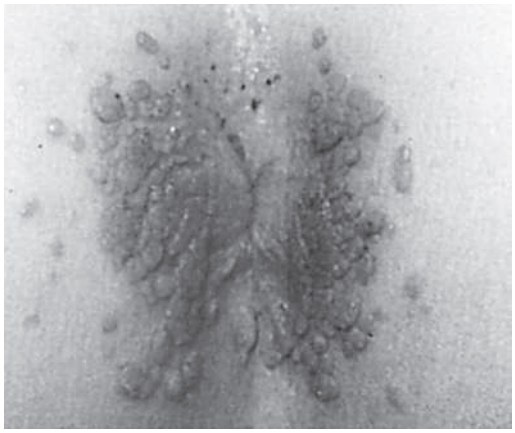

Fig. 82.7 Condylomata acuminata in a child.

Syphilis. Syphilis is caused by *Treponema pallidum,* a motile spirochete. During anal intercourse, the organism enters the rectal mucosa or anoderm and forms an ulcer (chancre) within 2 to 6 weeks. The chancre heralds the primary phase of syphilis and may resemble an anal fissure. Patients may experience discomfort during defecation, tenesmus, mucoid discharge, and inguinal adenopathy. Primary syphilis can be confused with lymphoma, but the diagnosis can be made by visualizing spirochetes on darkfield microscopy from scrapings taken from the base of the ulcer.

Serologic testing is useful several weeks after the appearance of the chancre. Treponemal tests such as the fluorescent treponemal antibody (FTA) yield a positive result earlier than the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests. If the chancre goes unnoticed, the patient may present with secondary syphilis, marked by a maculopapular rash that characteristically involves the palms and soles, and condyloma latum, a spirochete-laden, weeping, verrucous lesion in the perianal area that emits a foul odor. It is easily distinguishable from condyloma acuminatum, which has a drier, more keratinized appearance. Serologic testing results usually are positive. Tertiary syphilis is rare but may manifest as a rectal gumma with perianal pain and paralysis of the sphincters and may be mistaken for anal cancer.

Chancroid. Chancroid is caused by the gram-negative bacillus *Haemophilus ducreyi*, and begins as an inflammatory pustule or macule that ruptures to form an irregularly shaped ulcer. In several days, painful inguinal adenitis develops. Chancroid often is a diagnosis of exclusion.

Condyloma Acuminatum. Condyloma acuminatum (genital warts), the most commonly encountered anorectal STD, is caused by the human papillomavirus. The mode of transmission is primarily through sexual intercourse, but transmission can occur through close personal contact, as often happens in pediatric cases when an infected person changes a diaper and transmits the virus due to poor handwashing techniques. It is incumbent on the evaluating physician to consider sexual abuse in pediatric cases. Because half of HIV-positive patients have anal warts, HIV testing is recommended in patients with this diagnosis.

The pink to gray papilliform growths are a result of hyperplastic epithelial growth (Fig. 82.7). They may coalesce to form a massive patch that obscures the anal verge. Patients may be asymptomatic or report pruritus ani, hemorrhoids, or bleeding. Evaluation can include anoscopy because warts often grow within the anal canal. Failure to treat the internal lesions results in recurrence. The differential diagnosis includes condyloma latum (secondary syphilis) and squamous cell carcinoma. The preferred treatment is cryotherapy, but outpatient treatment with 0.5% podofilox solution or gel can be successful in limited cases.

BOX 82.6 Anorectal Lesions in the Patient With HIV Infection

Common Conditions

Anal fissure
- Abscess and fistula
- Hemorrhoids
- Pruritus ani
- Pilonidal disease

Common STDs

Gonorrhea
- Chlamydial infection
- Herpes
- Chancroid
- Syphilis
- Condyloma acuminatum

Atypical Conditions

Infectious

TB, CMV infection, actinomycosis, cryptococcosis

Neoplastic

Lymphoma, Kaposi sarcoma, squamous cell carcinoma

Other

Idiopathic anal ulcer

CMV, Cytomegalovirus; *HIV,* human immunodeficiency virus; *STD,* sexually transmitted disease; *TB,* tuberculosis.

Ulcerative Lesions in HIV-Infected Patients. There is significant comorbidity between patients who are HIV seropositive and other STDs. Anorectal complaints in HIV-positive patients fall into three categories: (1) routine proctologic conditions, as seen in the general population, (2) STDs, and (3) opportunistic infections (Box 82.6). The treatment of routine conditions and common STDs is similar to that in other patients except that wound healing may be delayed.

Management

A summary of common infections and treatment guidelines is presented in Table 82.5. Empirical therapy is indicated for patients who have recently practiced anal-receptive intercourse and have a rectal discharge. The recommended regimen is a single dose of ceftriaxone, 250 mg intramuscularly, plus doxycycline, 100 mg bid orally for 7 days. Patients with anorectal infections and their partners should be referred for HIV testing. The possibility of sexual assault should be considered. The health care provider should report STDs and new diagnoses of HIV infection per state and local health department regulations.

In immunocompromised patients, the differential diagnosis of ulcerative anorectal lesions should include opportunistic infections, lymphoma, and Kaposi sarcoma. Patients with AIDS often exhibit idiopathic anal ulcerations with pain and bleeding. Before this diagnosis is made, other possible causes of the lesions must be considered (see Box 82.6). Symptomatic relief can often be achieved with the WASH regimen (see Box 82.2), but recalcitrant lesions may require surgical excision.

Radiation Proctitis

Radiation-induced injury of the rectum is often caused by the treatment of gynecologic, urologic, or GI malignancies. Immediate radiation proctitis usually is self-limited and responds to symptomatic treatment. Late radiation proctitis can manifest up to 2 years after exposure.

TABLE 82.5 Sexually Transmitted Diseases of the Anorectum[21]

Disease or Condition (With Specific Pathogen When Known)	Findings	Treatment
Ulcerative Conditions		
LGV	Unilateral inguinal adenopathy Fever, malaise Mucoid or bloody discharge	Doxycycline, 100 mg PO bid, for 21 days Azithromycin 1 g PO weekly × 3 weeks *For pregnant patients or those allergic to tetracyclines*—erythromycin, 500 mg PO qid, × 21 days
HSV infection	Rectal pain, tenesmus, constipation Bloody mucoid discharge Vesicles and ulcerations Fever, malaise, myalgias, paresthesias	*First episode*—Acyclovir, 400 mg PO tid, 7–10 days *or* Acyclovir, 200 mg PO, 5×/day, for 7–10 days *or* Famciclovir, 250 mg PO tid, for 7–10 days *or* Valacyclovir, 1 g PO bid, for 7–10 days
Early (primary) syphilis (*Treponema pallidum*)	Chancre Tenesmus, pain, mucoid drainage Inguinal lymphadenopathy	Benzathine penicillin G, 2.4 million units IM, once
Chancroid (*Haemophilus ducreyi*)	Inflammatory lesion progresses to ulcer Inguinal adenitis—bubo	Azithromycin, 1 g PO once, or Ceftriaxone, 250 mg IM once, or Ciprofloxacin, 500 mg PO bid, for 3 days or Erythromycin base, 500 mg PO tid, for 7 days
Idiopathic (usually HIV-positive)	Eccentric, deep, poor-healing, multiple lesions	Symptomatic relief or surgical referral
Nonulcerative Conditions		
Condylomata acuminata (HPV)	Keratinized vegetative growths in anus or skin Asymptomatic, pruritus ani, or bleeding	Podofilox, 0.5% topically, or Imiquimod 3.75 or 5% cream or provider-administered cryotherapy, excision, or trichloroacetic acid
Gonorrhea (*Neisseria gonorrhoeae*)	Pruritus ani Tenesmus Purulent yellow discharge	Ceftriaxone, 500 mg IM once, PLUS Doxycycline 100 mg PO BID × 7 d or Cefixime, 800 mg PO, once PLUS Doxycycline 100 mg PO BID × 7d
Chlamydial infection (*Chlamydia trachomatis*)	Mucoid or bloody discharge Tenesmus	Azithromycin, 1 g PO once, or Doxycycline 100 mg PO bid, for 7 days
Syphilis (secondary)	Maculopapular rash Condyloma latum	Benzathine penicillin G, 2.4 million units IM, once

HIV, Human immunodeficiency virus; *HPV,* human papillomavirus; *HSV,* herpes simplex virus; *IM,* intramuscularly; *LGV,* lymphogranuloma venereum; *PO,* orally.

Signs and symptoms of radiation proctitis include bleeding ranging in severity from spotting to hemorrhage, tenesmus, diarrhea, pain, fistula-in-ano, and rectal strictures. Diagnosis is often presumptive, based on the patient's history of radiation therapy, but can be confirmed by rectal mucosal biopsy.

Treatment regimens include supportive therapy and the use of antiinflammatory agents, formalin application, oral sucralfate therapy combined with sucralfate retention enemas, hyperbaric oxygen therapy, and sclerosing therapy.[23] When a patient with suspected radiation proctitis presents to the ED, the first measures should focus on pain management while coordinating a care plan with the primary physician, a gastroenterologist, or surgical specialist as needed.

Rectal Prolapse

Rectal prolapse, or procidentia, is a disease of persons at the extremes of age. Prolapse is complete if all bowel layers protrude and incomplete if only the mucosal layer is involved. In adults, complete procidentia is most common among older women and is caused by a laxity of attachment structures. It often is accompanied by uterine prolapse or cystocele. Patients report an anal mass that protrudes during defecation, coughing, or sneezing.

Findings may include fecal incontinence, bloody or mucoid discharge, or a foul odor. In some cases, the patient can reduce the prolapse manually, whereas in others, the tissue becomes edematous, and a red, ulcerated mass protrudes from the anus (Fig. 82.8). A reduction may be attempted by placing the patient prone and applying an osmotically active solution, such as sucrose-soaked gauze that can be applied to the mass. After several minutes, gentle diffusely applied pressure is used to guide the tissue back into the rectal vault. Care should be taken not to poke at the tissue, because this could cause penetrating trauma. When reduction is successful, the patient may be discharged with agents to relieve constipation. Surgical repair often is necessary.[24]

Fig. 82.8 Prolapse of the rectum. (Courtesy Dr. Gershon Effron, Sinai Hospital of Baltimore; from: Seidel HM, et al, eds. *Mosby's Guide to Physical Examination*, ed 4. St. Louis: Mosby; 1999.)

In children up to 4 years of age, procidentia often is associated with chronic constipation or diarrheal disease. However, it may herald the presence of malnutrition, parasitic infection, or cystic fibrosis. Children usually have mucosal prolapse. The parent reports protrusion during defecation, with small amounts of mucus or blood. This condition must be distinguished from a protruding juvenile polyp and intussusception. A gentle reduction may be attempted. Increasing the dietary fiber and fluid intake frequently is successful as first-line therapy.

Rectal Foreign Bodies

Foundations

Anorectal foreign bodies may result from the use of the anus for sexual gratification, although they also are found in children, psychiatric patients, and victims of assault or iatrogenic injury. Most objects are introduced directly into the anus, but some become lodged there after oral ingestion. Foreign bodies that are unlikely to pass on their own or that have dangerous features must be removed to prevent mucosal lacerations, intestinal perforation and obstruction, sepsis, and peritonitis.[25]

Some foreign bodies that are ingested pass through the GI tract and subsequently become lodged in the rectum or anal crypts. Patients at the highest risk for ingested foreign bodies are children, psychiatric patients, and body packers.

Clinical Features

Rarely, a foreign body such as an enema tip or broken rectal thermometer is introduced iatrogenically. In most cases, the foreign body is placed deliberately by the patient or a partner for medicinal or sexual purposes. Objects that are commonly retrieved include fruits and vegetables, household items, especially those whose morphology and dimensions resemble the penis. and items purchased specifically with an anal erotic intent. By the time patients arrive at the ED, sometimes days after the introduction of the foreign body, they have likely tried to remove it at home. The history often is reluctantly given or is vague and inconsistent. The initial ED evaluation, conducted in a nonjudgmental manner, should ascertain the type of foreign body involved, how long it has been there, what attempts have been made to remove it, and whether the patient has a fever, abdominal pain or rectal bleeding. The possibility of an assault should be considered.

Physical examination begins with an external examination for signs of trauma. If no sharp objects are suspected, a digital rectal examination and anoscopy may reveal the foreign body, lax sphincter, or mucosal injury. An abdominal examination may demonstrate signs of perforation or obstruction.

Diagnostic Testing

The foreign body may be visible on abdominal radiographs, or its presence may be inferred by a nonspecific gas pattern, free air, or signs of intestinal obstruction. If a perforation is suspected, water-soluble contrast material can be introduced to delineate the outline of radiolucent foreign bodies and may identify perforation with extravasation.

Management

Treatment depends on the location and type of object found. In general, objects that are soft and low-lying (<10 cm from the anal verge) can be removed safely in the ED. The awake patient can assist in expulsion by performing the Valsalva maneuver. Premedication with a benzodiazepine, such as lorazepam, 1 mg, is helpful to relax the sphincter and patient. With the patient in the lithotomy position, suprapubic pressure can assist in removal (Fig. 82.9).

Several methods are useful for removal. The easiest is to grasp an edge of the foreign body with forceps and apply traction while the patient bears down. If the foreign body does not have a convenient place to grasp, other methods are needed. A Foley catheter can be placed beside the foreign body and the balloon inflated proximally to it (Fig. 82.10). This maneuver breaks the suction of the rectal wall mucosa and provides a way to guide the object out of the rectal vault. Hollow objects may be filled with plaster of Paris, with an inset inflated Foley catheter to be used as a handle. If the foreign body is large, difficult to grip, or fragile (a light bulb meets all three criteria), patients often require removal under general anesthesia in an operating room.

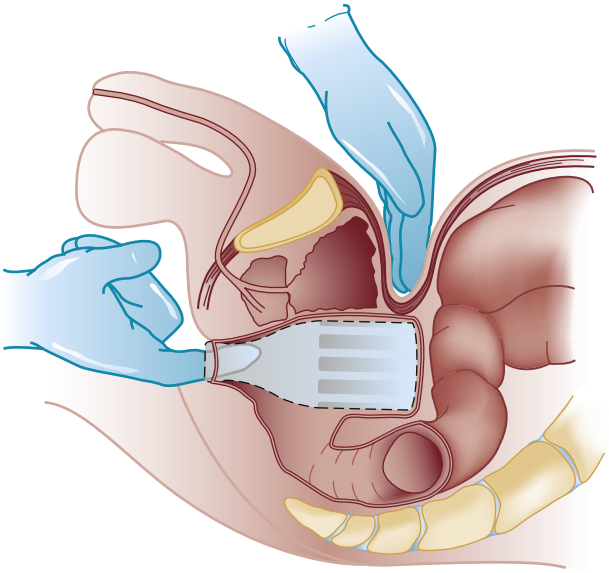

Fig. 82.9 Removal of a foreign body from the rectum.

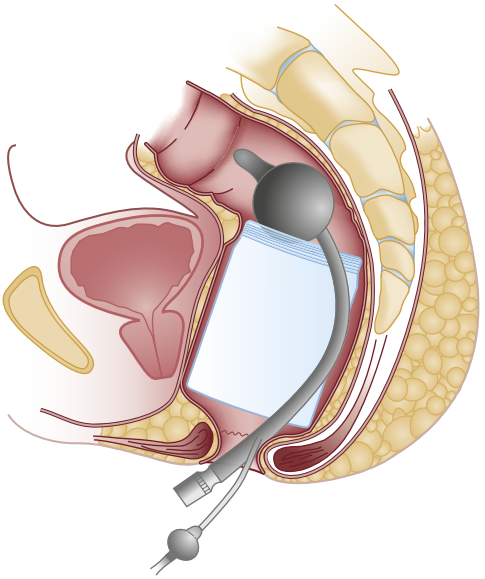

Fig. 82.10 Foley catheter–assisted removal of a rectal foreign body.

Large, hard, fragile objects and those that have migrated proximally are difficult to remove without anal dilation and instrumentation to assist in the passage through the sacral curve and sphincters. These are best performed with the patient under general anesthesia. After the removal of the foreign body, one should consider the possibility of mucosal tears or perforations. Discharge instructions should warn the patient about the signs and symptoms of perforation, peritonitis, and sepsis.

CHAPTER 82: QUESTIONS AND ANSWERS

1. Which of the following modifying factors is most likely to lead to the development of hemorrhoids as a result of portal hypertension?
- **a.** Alcoholism
- **b.** Obesity
- **c.** Pediatric age group
- **d.** Pregnancy
- **e.** HIV infection

Answer: c. Portal hypertension does not predispose to hemorrhoids, except in children. Bleeding in adults is likely from rectal varices. Most hemorrhoidal bleeding is from the superior rectal artery and thus is bright red. Approximately one-third of pregnant patients experience hemorrhoids in the third trimester or postpartum period. Traumatic deliveries can result in hemorrhoid development. Painless bleeding with defecation is the most common symptom (pain usually occurs if hemorrhoids are thrombosed).

2. What is the most common cause of sudden-onset rectal pain?
- **a.** Anal fissure
- **b.** Proctalgia fugax
- **c.** Sacral radiculopathy
- **d.** Thrombosed external hemorrhoid
- **e.** Thrombosed internal hemorrhoid

Answer: a. Anal fissures typically result from superficial tears in the anoderm, usually occurring in the posterior midline. The pain is heightened by secondary spasm of the anal sphincter.

3. Which of the following approaches to performing incision and drainage of a pilonidal cyst is most appropriate?
- **a.** Elliptic incision
- **b.** Horizontal incision at the center of the affected area
- **c.** Horizontal incision at the lower portion of the affected area
- **d.** Longitudinal incision along the midline
- **e.** Longitudinal incision lateral to the midline

Answer: e. Making a longitudinal incision lateral to the midline spares the area that is most vulnerable to reaccumulation of debris and the inflammatory response. Removal of pus, inflammatory tissue, and ingrown hairs relieves the pain of the abscess and promotes healing.

4. A 68-year-old woman presents with hemorrhoids. On examination, you note three protruding masses that are maroon in color and may be reduced manually into the anorectal opening. What is the most appropriate curative therapy?
- **a.** Application of a concentrated sucrose solution to the affected area
- **b.** Emergent surgical intervention (e.g., banding, sclerosing, hemorrhoidectomy)
- **c.** Prescription of a 7-day course of topical corticosteroid cream
- **d.** Referral to a surgeon for an outpatient procedure
- **e.** Removal of the hemorrhoid with an elliptic incision, including overlying tissue

Answer: d. Third-degree internal hemorrhoids may be manually reduced in the emergency department (ED) but are unlikely to heal spontaneously. Referral for operative therapy is curative. Excision of internal hemorrhoids is contraindicated. Acutely thrombosed external hemorrhoids may be excised in the ED. Temporizing measures include using the WASH regimen—using *w*arm water to encourage reduction of the protruded hemorrhoids, maintaining hygiene, *a*nalgesics, *s*tool softeners to ease passage of stool, and a *h*igh-fiber diet. Topical corticosteroids may be used for 1 or 2 days during an acute exacerbation, but their continued use promotes skin breakdown and itching. A sucrose solution may prove helpful in reducing procidentia (rectal prolapse). A thorough history should be obtained and a physical examination performed to learn if an underlying medical condition may be associated with the hemorrhoids.

83

Renal Failure

Allan B. Wolfson

KEY CONCEPTS

- The causes of acute kidney injury (AKI) can be classified as prerenal, postrenal, and intrinsic renal disorders. Abrupt cessation of glomerular filtration typically results in a rise of the serum creatinine level of 1 to 2 mg/dL per day.
- Management of AKI is directed first at potentially lethal complications such as hyperkalemia or volume overload and then at reversal of the underlying cause of renal dysfunction. It is important to avoid any further hemodynamic or toxic insults to the kidneys.
- Patients with acute or chronic kidney disease have a limited ability to handle fluid and solute loads and have altered metabolism of many drugs. Therefore, the patient's impaired renal function must be considered when fluid is administered or drugs are prescribed.
- The most rapidly lethal complication of acute and chronic kidney disease is hyperkalemia.
- The most common problems with vascular access devices used for hemodialysis are thrombosis, hemorrhage, and infection. Access infection often presents as fever without an obvious source and, if suspected, appropriate IV antibiotics should be administered presumptively while awaiting blood culture results.
- Peritoneal dialysis–associated peritonitis typically presents with cloudiness of the peritoneal dialysis effluent. The diagnosis is made by a positive Gram stain or finding of more than 100 WBC/mm^3 in the effluent, with at least 50% polys. It is generally treated on an outpatient basis with intraperitoneal antibiotics self-administered by the patient.
- Chest pain in the dialysis patient should be presumed initially to be due to acute coronary syndrome, although other potentially serious causes may also be responsible. Serum troponin levels tend to be elevated in patients with poor renal function, but patients with myocardial infarction show the typical temporal pattern of rise and fall of troponin levels.
- Hypotension in patients with chronic kidney disease (CKD) may be caused by infection but may also be the result of rapid fluid removal during dialysis. This often responds readily to fluid administration. Pericardial tamponade is another cause of hypotension that should be considered for these patients.
- Altered mental status is most commonly due to causes similar to those seen in patients without renal disease but is sometimes the result of overrapid shifts in intravascular fluid and solutes during dialysis, termed *disequilibrium syndrome.*

RENAL FAILURE

The evaluation of renal disease in the emergency department (ED) requires an approach that incorporates the urinalysis, serum and urine chemical determinations, and renal imaging studies. This approach assesses the degree of renal dysfunction and establishes the foundation for distinguishing acute kidney injury (AKI) from chronic kidney disease (CKD).

ACUTE KIDNEY INJURY

Foundations

The hallmark of AKI (formerly termed *acute renal failure* [ARF]) is progressive azotemia, which commonly is accompanied by a wide range of other disturbances, depending on the severity and duration of renal dysfunction. These include metabolic derangements (e.g., metabolic acidosis, hyperkalemia), disturbances of body fluid balance (particularly volume overload), and a variety of effects on almost every organ system (Box 83.1).

The causes of AKI are divided into those that decrease renal blood flow (prerenal), produce a renal parenchymal insult (intrarenal), or obstruct urine flow (obstructive, or postrenal). Identification of a prerenal or postrenal cause of AKI generally makes it possible to initiate specific corrective therapy; if these two broad categories of AKI can be excluded, an intrarenal cause is implicated. The renal parenchymal causes of AKI can be usefully subdivided into those primarily affecting the glomeruli, intrarenal vasculature, or renal interstitium. The term *acute tubular necrosis* denotes another broad category of intrinsic renal failure that cannot be attributed to a specific glomerular, vascular, or interstitial cause (Fig. 83.1).

Renal failure can lead to numerous other systemic and organ-specific effects. Uremia impairs host defenses, particularly leukocyte function, and infection is a significant cause of morbidity and mortality in AKI. Pericarditis, which has a prevalence of 10% to 20% in dialyzed patients with CKD, also may occur in patients with AKI. Urgent dialysis is indicated when there is associated pericardial effusion and tamponade. Neurologic abnormalities in AKI may be precipitated by electrolyte abnormalities, medications, or uremia. Anorexia, nausea, vomiting, gastritis, and pancreatitis also are associated with AKI and significant gastrointestinal (GI) hemorrhage is seen in about 10% of patients.

Impaired erythropoiesis, shortened red blood cell (RBC) survival, hemolysis, hemodilution, and GI blood loss all play a role in the normocytic normochromic anemia that usually accompanies AKI. Although mild thrombocytopenia may be present, it is the qualitative defect in platelet function thought to be caused by the effect of circulating uremic toxins that contributes to these patients' bleeding tendencies.

Clinical Features

When the presence of azotemia or renal failure has been discovered, the first consideration in the ED evaluation should be the possibility of potentially life-threatening complications (e.g., hyperkalemia, pulmonary edema). Assuming that these have been satisfactorily ruled out, the next step is to determine whether the condition represents AKI or is the result of preexisting renal disease. The clinical distinction between AKI and CKD often is difficult, especially if prior records and laboratory results are not available. The finding of small kidneys on abdominal imaging or bone changes of secondary hyperparathyroidism on hand films demonstrating abnormal calcifications suggests that the renal failure is chronic. Anemia, hypocalcemia, and hyperphosphatemia, however, should not be relied on to identify patients who have CKD because these abnormalities can develop rapidly in AKI.

In evaluating the patient with azotemia, the emergency clinician uses history, physical examination, and laboratory studies to seek clues to the cause and to identify signs and symptoms of uremia, volume overload, or other complications of renal failure. In attempting to identify the cause, the general strategy is to rule out prerenal and postrenal causes before considering the many intrinsic renal causes. First, potential sources of volume loss and causes of decreased cardiac output are sought in the history, and the patient should be questioned about lightheadedness, bleeding, GI fluid loss, abnormal polyuria, or symptoms of congestive heart failure (CHF). In men, a history of nocturia, frequency, hesitancy, or decreased urinary stream suggests prostatic obstruction. A history of lower tract symptoms or of abdominal or pelvic tumor in either gender is sought, as is a history of kidney stones or chronic urinary tract infection (UTI). A history of acute anuria, defined as the production of less than 100 mL of urine/day, is most often the result of high-grade urinary tract obstruction, although it also may accompany severe volume depletion, severe acute glomerulonephritis, cortical necrosis, or bilateral renal vascular occlusion. Intermittent anuria, on the other hand, is characteristic of obstructive disease. Medication use and possible exposure to radiographic contrast agents or other exogenous toxins are other key components of the history. A history of hypertension, dark-colored urine, rash, fever, or arthritis suggests intrinsic renal disease or a multisystem disorder.

The physical examination focuses on signs of volume depletion, such as tachycardia and decreased skin turgor. Documented short-term changes in body weight also offer a valuable clue in assessing volume status, particularly in patients who are chronically ill. Volume overload

BOX 83.1 Clinical Features of Acute Kidney Injury

Cardiovascular
Pulmonary edema

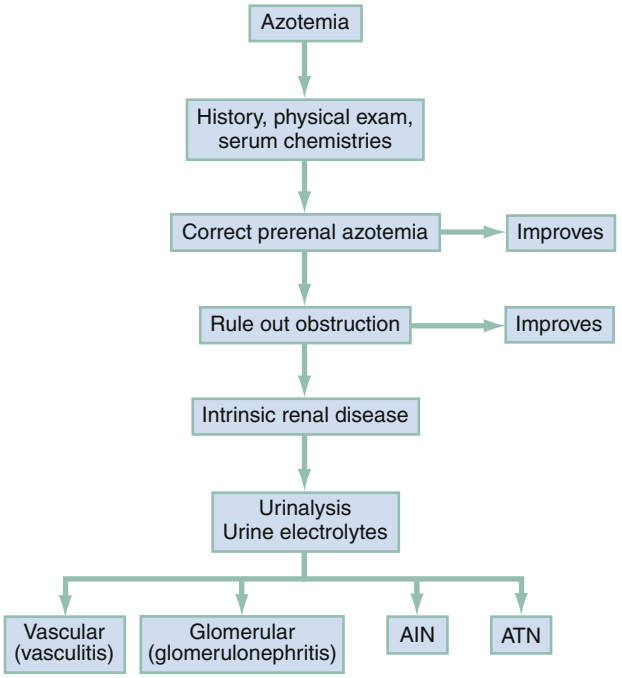

Fig. 83.1 Evaluation of azotemia. *AIN,* Acute interstitial nephritis; *ATN,* acute tubular necrosis.

is suggested by findings of jugular vein distention and the presence of rales or peripheral edema.

A distended bladder is percussible when it contains at least 150 mL of urine, and the dome is palpable abdominally when the bladder contains 500 mL. Ultrasonography can be used to detect bladder distention or postvoid residual volume if there is a question of urinary retention. A prostate examination in men and pelvic examination in women are also necessary components of the examination. The presence of rash, purpura, pallor, or petechiae on skin examination may be noted, as is arthritis, musculoskeletal tenderness, and findings suggestive of infection or malignancy.

Differential Diagnosis

The management of AKI requires a systematic approach to the potential underlying causes. Once prerenal and postrenal causes are considered, the diagnostic and management strategies focus on the intrarenal pathologies.

Prerenal Azotemia

Decreased renal perfusion that is sufficient to cause a decrease in the glomerular filtration rate (GFR) results in azotemia. The possible causes are grouped into entities causing intravascular volume depletion, volume redistribution, or decreased cardiac output (Box 83.2). Patients who have preexisting renal disease are particularly sensitive to the effects of diminished renal perfusion.

Prerenal azotemia is characterized by increased urine specific gravity, a blood urea nitrogen (BUN) to creatinine ratio generally between 10:1 and 20:1, urine sodium concentration less than 20 mEq/dL, and fractional excretion of sodium (FENa) less than 1%. The condition generally can be corrected readily by expanding extracellular fluid volume, augmenting cardiac output, or discontinuing vasodilating antihypertensive drugs. However, severe prolonged prerenal azotemia can result in acute tubular necrosis (ATN).

BOX 83.2 Causes of Prerenal Azotemia

Volume Loss
Gastrointestinal—vomiting, diarrhea, nasogastric drainage
Renal—diuresis
Blood loss
Insensible losses
Third-space sequestration
Pancreatitis
Peritonitis
Trauma
Burns

Cardiac Causes

Patients who have CHF or cirrhosis form an important subset of those with prerenal azotemia. These patients often are sodium-overloaded and water-overloaded, yet the effective intra-arterial volume is decreased. Administration of diuretics has the potential to decrease intravascular volume further, resulting in decreased glomerular filtration and prerenal azotemia. For some patients with advanced CHF or hepatic disease, a state of chronic, stable, prerenal azotemia may be the best achievable compromise between symptomatic volume overload and severe renal hypoperfusion.

Glomerular perfusion also may be decreased in patients with normal intravascular volume and normal renal blood flow who take angiotensin-converting enzyme (ACE) inhibitors or, more commonly, prostaglandin inhibitors. All nonsteroidal antiinflammatory drugs (NSAIDs), including aspirin, inhibit prostaglandin synthesis. Renal vasodilator prostaglandins are critical in maintaining glomerular perfusion in patients with conditions such as CHF, chronic renal insufficiency, and cirrhosis, in which elevated circulating levels of renin and angiotensin II decrease renal blood flow and GFR. In this setting, a decrease in the production of vasodilator prostaglandins may result in acute intrarenal hemodynamic changes and a reversible decrease in renal function. This phenomenon also is seen with the selective cyclooxygenase-2 inhibitor class of NSAIDs. Other risk factors include advanced age, diuretic use, renovascular disease, and diabetes. This entity is distinct from other renal complications of NSAIDs such as interstitial nephritis and papillary necrosis.

Postrenal (Obstructive) Acute Kidney Injury

Obstruction is an eminently reversible cause of AKI and should be considered in every patient with newly discovered azotemia or worsening renal function. Obstruction may occur at any level of the urinary tract but usually is caused by prostatic hypertrophy or functional bladder neck obstruction (e.g., secondary to medication side effects or neurogenic bladder; Box 83.3). Intrarenal obstruction may result from the intratubular precipitation of uric acid crystals (e.g., with tumor lysis), oxalic acid (as in ethylene glycol ingestion), phosphates, myeloma proteins, methotrexate, sulfadiazine, acyclovir, or indinavir. Bilateral ureteral obstruction (or obstruction of the ureter of a solitary kidney) may be caused by retroperitoneal fibrosis, tumor, surgical complications (such as inadvertent ligation of the ureter), stones, or

blood clots. A sudden deterioration in renal function in the setting of diabetes mellitus, analgesic nephropathy, or sickle cell disease suggests papillary necrosis.

Intrinsic Acute Kidney Injury

Of the specific intrarenal disorders that cause AKI, glomerulonephritis, interstitial nephritis, and abnormalities of the intrarenal vasculature are amenable to specific therapy and are important to consider as possible causes. These entities are responsible for only 5% to 10% of cases of AKI in adult inpatients; most cases are caused by ATN. In adults in whom AKI develops outside the hospital, the incidence of glomerular, interstitial, and small vessel disease is much greater. In children, these entities account for approximately 50% of the cases of AKI (Box 83.4).

Acute Glomerulonephritis. This may represent a primary renal process or may be the manifestation of any of a wide range of other disease entities (see Box 83.4). Patients may have dark urine, hypertension, edema, or CHF (secondary to volume overload) or may be completely asymptomatic, in which case the diagnosis rests on an incidental finding on urinalysis. The hematuria associated with glomerular disease may be microscopic or gross and may be persistent or intermittent. Proteinuria, although often in the range of 500 mg/day to 3 g/day, is not uncommonly in the nephrotic range, defined as 3.5 g/day or more. The presence of hematuria, proteinuria, or red cell casts is highly suggestive of glomerulonephritis. Conversely, the absence of red cell casts, proteinuria, and hematuria essentially excludes glomerulonephritis as the cause of AKI.

The specific diagnosis of acute glomerulonephritis caused by primary renal disease often is ultimately made by renal biopsy. However, when glomerulonephritis is secondary to a systemic disease such as systemic lupus erythematosus, the clinical signs and symptoms and results of laboratory assessment aid considerably in narrowing the scope of the differential diagnosis. As a rule, extensive laboratory testing to identify the cause of acute glomerulonephritis is not indicated in the ED setting and is more appropriately performed as part of an inpatient evaluation.

Acute Interstitial Nephritis. Acute interstitial nephritis (AIN) is usually precipitated by drug exposure or by infection. Drug-induced AIN is poorly understood, but the absence of a clear relationship to the dose, and recurrence of the syndrome on rechallenge with the offending agent, suggests that an immunologic mechanism is responsible. The most commonly incriminated drugs are the penicillins, diuretics, and NSAIDs. AIN has been reported in association with bacterial, fungal, protozoan, and rickettsial infections.

Patients with AIN typically have rash, fever, eosinophilia, and eosinophiluria, but it is common for one or more of these cardinal signs to be absent. Pyuria, gross or microscopic hematuria, and mild proteinuria are observed in some cases. A definite diagnosis sometimes can be made only on renal biopsy. Treatment of AIN is directed at removing the presumed cause; infections should be treated and offending drugs discontinued. Renal function generally returns to baseline over several weeks, although chronic renal failure has been reported to occur.

Intrarenal Vascular Disease of the Kidney. This can be classified according to the size of the vessel that is affected. Disorders such as renal arterial thrombosis or embolism, which affect large blood vessels, must be bilateral—or affect a single functioning kidney—to produce AKI. Whether to attribute such cases of AKI to a prerenal or intrarenal vascular cause is a matter of semantics. The most common cause of thrombosis probably is trauma; thrombosis also may occur after angiography or may be secondary to aortic or renal arterial dissection. Renal atheroembolism is thought to occur commonly, at least on a microscopic level, after arteriography but it is an uncommon cause of AKI. Similarly, patients with chronic atrial fibrillation or infective endocarditis may experience embolization of the kidney but rarely develop AKI as a result. Renal arterial embolism can

cause acute renal infarction, generally manifested by sudden flank, back, chest, or upper abdominal pain. Urinary findings, including hematuria, are variable. The diagnosis usually is made by renal flow scanning or arteriography.

Several diseases that affect the smaller intrarenal vessels can cause AKI (see Box 83.4). Patients whose disease is severe enough to cause AKI also are generally found to have hypertension, microangiopathic hemolytic anemia, and other systemic and organ-specific manifestations. Infection with *Escherichia coli* O157:H7 has emerged as a major cause of hemolytic uremic syndrome, an important cause of AKI in children.

Patients with scleroderma (systemic sclerosis) may have so-called scleroderma renal crisis, characterized by malignant hypertension and rapidly progressive renal failure. Whereas vasculitis associated with glomerular capillary inflammation typically causes gross or microscopic hematuria and the formation of red cell casts, vascular involvement of the medium-sized vessels, such as that produced by scleroderma, often spares the preglomerular vessels and tends not to produce an active urine sediment. Extrarenal manifestations (e.g., rash, fever, arthritis, pulmonary symptoms) are usually evident.

For malignant hypertension, both as a separate entity and as a part of scleroderma renal crisis, appropriate treatment can produce remission of AKI. Patients with malignant hypertension have been reported to recover renal function after aggressive antihypertensive therapy, with temporary maintenance on dialysis if necessary. In patients with scleroderma renal crisis, specific therapy with ACE inhibitors has been shown to result in improvement in renal function in a significant proportion of cases.

Acute Tubular Necrosis. ATN refers to a generally reversible deterioration of kidney function associated with a variety of renal insults. Oliguria may or may not be a feature. The diagnosis is made after prerenal and postrenal causes of ARF and disorders of glomeruli, interstitium, and intrarenal vasculature have been excluded. In a few disorders, these discrete categories overlap. For example, AKI associated with multiple myeloma or ethylene glycol toxicity is associated with intrarenal obstruction and interstitial disease, as well as a probable direct toxic effect on the renal tubule itself.

The most common precipitant of ATN is renal ischemia occurring during surgery or after trauma and sepsis. The remainder of cases occur in the setting of medical illness, usually as a result of the administration of a nephrotoxic aminoglycoside antibiotic or in association with rhabdomyolysis. Multiple causes can be identified in some cases; in others, a definitive cause cannot be established.

Decreased renal perfusion results in a continuum of renal dysfunction that ranges from transient prerenal azotemia at one extreme to ATN at the other. Early during the period of renal ischemia, renal function can be restored completely by restoring renal blood flow but, at some point, continued hypoperfusion results in renal dysfunction unresponsive to volume repletion, and ATN supervenes. ATN may occur in the absence of frank hypotension; even modest renal ischemia may result in ATN in susceptible persons. Individual susceptibility to ATN may be related to the balance of prostaglandin-mediated vasopressor and vasodilatory influences on the renal vasculature.

Postischemic ATN can occur in the setting of volume loss from the GI tract (upper or lower), skin, or kidneys or can result from severe hemorrhage or major burns. Heat stroke commonly is associated with the development of ATN, which is thought to result from a combination of volume loss, hyperpyrexia, and rhabdomyolysis. Another cause of ATN is hyperglycemic hyperosmolar syndrome, which can be associated with loss of as much as 25% of total body water. ATN also is seen in the setting of cardiogenic shock, sepsis, and third spacing of fluids in pancreatitis and peritonitis.

ATN is common in postoperative patients, although not all cases can be attributed to intraoperative hypotension or hemorrhage. Concomitant sepsis, increased age, preexisting renal disease, and other comorbid conditions are associated with a worse outcome.

Recently, it has been noted that patients hospitalized for coronavirus disease 2019 (COVID-19) may develop AKI during the course of their illness, particularly when intensive care is required. The mechanism is likely to be multifactorial, including hypovolemia, cardiac dysfunction, exposure to nephrotoxins, and direct renal endothelial damage related to viremia, immune dysfunction, or hypercoagulability. Patients may initially present with proteinuria early in the course; AKI is felt to be a marker of the severity of disease. Treatment is supportive, with careful management of fluid balance and optimization of renal perfusion. More severe cases require hemodialysis or other forms of renal replacement therapy.[14]

Nephrotoxins constitute the other major cause of ATN. Among the most prominent of these are the endogenous pigments myoglobin and hemoglobin, associated with rhabdomyolysis (Box 83.5). Hypotension secondary to fluid loss into damaged muscle is thought to worsen the effects of myoglobinuria on the renal tubule, as does acidemia. Hemolysis, resulting in the release of hemoglobin into the circulation and hemoglobinuria, can cause ATN but usually only in the presence of coexisting dehydration, acidosis, or other causes of decreased renal perfusion. ATN may be associated with the hemolysis of as little as 100 mL of blood.

ATN associated with rhabdomyolysis is often oliguric; it is characterized by rapid increases in the serum creatinine, potassium, phosphorus, and uric acid levels. Creatine released from muscle is metabolized to creatinine, which may result in serum creatinine level increases of more than 2 mg/dL/day, in contrast to the increase of 0.5 to 1.0 mg/dL/day typically seen in other forms of AKI. The BUN/creatinine ratio often is *less* than 10 : 1. Intracellular potassium released from damaged muscle may raise the serum potassium level by 1 to 2 mEq/L in several hours. Likewise, phosphate released from muscle may cause dramatic increases in the serum phosphate level. Uric acid, produced by the metabolism of purines released from damaged muscle, may accumulate to levels high enough to cause acute uric acid nephropathy.

G6PD, Glucose-6-phosphate dehydrogenase; *RBCs*, red blood cells.

Urine dipstick testing yields a positive result for heme in, at most, 50% of patients with rhabdomyolysis, because myoglobin is rapidly cleared from the serum and may therefore be undetectable in the urine at the time of presentation. Thus, a negative result on urine dipstick testing does not rule out the diagnosis. Serum creatine kinase (CK) is cleared much more slowly, so measurement of serum CK levels is a more sensitive test.

Antibiotics are commonly implicated in the development of ATN, with aminoglycosides being the most commonly associated. Higher doses and longer duration of therapy are associated with higher serum drug levels, leading to greater accumulation of drug in the renal parenchyma and a greater likelihood of nephrotoxicity. Increased age, impaired renal function, dehydration, and exposure to other nephrotoxins are additional risk factors. Once-daily administration of a somewhat higher dose is associated with less nephrotoxicity but has equal antimicrobial effectiveness.

Aminoglycoside-induced ATN typically has a gradual onset. Clinically significant renal dysfunction usually occurs only after several days and often after more than 1 week of therapy. However, renal failure can develop as late as 10 days after a drug has been discontinued, an observation that appears to be explained by the prolonged tissue half-life characteristic of these agents. Renal function returns to normal after an average of 6 weeks, but the condition occasionally progresses to permanent renal injury.

Radiographic contrast agents have long been considered a common cause of hospital-acquired renal insufficiency. AKI associated with these agents has been defined as an increase in serum creatinine level of 25% or an increase of 0.5 mg/dL over baseline, with a temporal relation to contrast medium administration and in the absence of other identifiable causes. Cases have been noted after any procedure involving intravascular administration of contrast material.

Radiocontrast-associated AKI presents on a spectrum ranging from asymptomatic nonoliguric renal insufficiency to severe renal failure requiring dialysis. Most cases are mild, however, likely due at least partially to the broad criteria by which the entity has been defined.[1-3] Typically, an increase in the serum creatinine level is noted within 3 days of exposure, with a return to normal levels within 10 to 14 days.

The most important risk factor for radiocontrast agent–induced AKI is preexisting renal insufficiency. Diabetes mellitus, multiple myeloma, age older than 60 years, and volume depletion are also associated with greater risk. Diabetic patients with a serum creatinine level less than 1.5 mg/dL appear to be at lower risk than those whose serum creatinine level is more than 1.5 mg/dL. Importantly, large doses and repeated doses of contrast material are associated with increased risk of ATN, particularly if a second study is performed within 72 hours of the first.

Volume depletion is an independent risk factor for contrast nephropathy, and aggressive volume expansion before contrast exposure appears to have a protective effect.[4] Modest volumes of intravenous normal saline (3 mL/kg over 1 hour, followed by 1.5 mL/kg/hr for 4 hours after contrast exposure) appear to be effective in decreasing the likelihood of nephrotoxicity. Sodium bicarbonate does not appear to offer an advantage over normal saline, and the weight of evidence does not favor a beneficial effect of administering oral *N*-acetylcysteine as part of the treatment regimen.[5]

Diagnostic Testing

Laboratory evaluation of renal dysfunction begins with a dipstick and microscopic urinalysis and measurement of urine output. BUN, serum creatinine, urine sodium, and FENa levels are determined to help evaluate renal function and provide clues about the cause of AKI. A complete blood count, serum electrolyte panel (expanded to include calcium, phosphorus, and magnesium determinations), electrocardiogram (ECG), and chest radiograph help establish the patient's baseline status and provide information about possible complications.

Urine Volume

Urine flow does not diminish until the GFR is sharply decreased; thus, urine volume is a poor indicator of renal dysfunction. Oliguria, defined as a urine volume of 100 to 400 mL/24 hr, may be seen with prerenal (blood flow–dependent), intrinsic (intrarenal), or postrenal (obstructive) causes of AKI. Although uncommon, alternating oliguria and anuria (the latter defined as less than 100 mL/24 hr), is a classic indicator of intermittent obstruction, which occurs as urine collects behind an obstructing stone or tumor and then is allowed to flow past as the obstructing material shifts position.

Urinalysis

The standard urinalysis consists of dipstick screening for heme pigment, protein, glucose, ketones, pH, leukocyte esterase, and nitrite and microscopic examination of a spun specimen of freshly voided urine and should be performed on all patients with AKI. Dipstick testing for heme and protein can provide important information related to renal function.

Heme. The dipstick detects free hemoglobin from lysed RBCs (or myoglobin) and the hemoglobin inside RBCs but is more sensitive to free hemoglobin. Although as few as three RBCs/high-power field (hpf) can be detected, on any given sample the dipstick may fail to identify 10% to 15% of patients who are otherwise found to have microscopic hematuria, typically defined as more than three RBCs/hpf. A positive result on dipstick testing should prompt microscopic examination of the urine. If red cells are seen, the diagnosis of hematuria is confirmed, though a level of two to three RBCs/hpf is commonly accepted as normal. If the dipstick result is positive but findings on microscopic examination are negative, pigmenturia (myoglobin or free hemoglobin) is suspected.

Protein. The dipstick test for protein, which uses the color change of tetrabromophenol blue, can detect protein at concentrations of 10 to 15 mg/dL but does not yield reliably positive results until the concentration is greater than 30 mg/dL. Moreover, the relation between color intensity and protein concentration is only approximate. The dipstick reagent is three to five times more sensitive to albumin than to globulins and immunoglobulin light chains (e.g., Bence Jones protein), an important limitation. False-positive results are caused by alkaline urine, hematuria, or prolonged immersion of the dipstick in the urine. False-negative results are seen with dilute urine. After dipstick testing has been completed, the sediment from a spun urine specimen is examined under the microscope.

Casts are formed from urinary Tamm-Horsfall protein—a product of the tubular epithelial cells that gels at low pH and high concentration and when mixed with albumin—or from red cells, tubular cells, or cellular debris in the urine. The composition of a cast reflects the contents of the tubule. Casts are classified according to their appearance or constituents (e.g., hyaline, red cell, white cell, granular, or fatty casts). Hyaline casts, those that are devoid of contents, are seen with dehydration, after exercise, or in association with glomerular proteinuria. Red cell casts indicate glomerular hematuria, as seen in glomerulonephritis; the presence of even a few red cell casts is significant. White cell casts imply the presence of renal parenchymal inflammation. Granular casts are composed of cellular remnants and debris. Fatty casts, like oval fat bodies, generally are associated with heavy proteinuria and nephrotic syndrome.

Microscopic examination of the urinary sediment can be helpful in establishing the cause of AKI. A sediment without formed elements

or with only hyaline casts is characteristic of prerenal azotemia or obstruction. Red cell casts suggest glomerulonephritis or vasculitis. Fatty casts also suggest glomerular disease. In ATN, the urinary sediment commonly shows granular casts and renal tubular epithelial cells. Large numbers of polymorphonuclear leukocytes are observed in interstitial nephritis, papillary necrosis, and pyelonephritis. Eosinophil-containing casts, appreciated only after staining of the sediment, are typical of allergic interstitial nephritis. Uric acid crystals suggest uric acid nephropathy but are extremely nonspecific; oxalic acid or hippuric acid crystals may be seen in cases of ethylene glycol ingestion.

Serum and Urine Chemical Analysis

Creatinine and Blood Urea Nitrogen. The normal range for the serum creatinine level extends from 0.5 mg/dL in thin people to 1.5 mg/dL in muscular persons. Spurious elevations (up to 2 mg/dL) can be caused by acetoacetate, which cross-reacts with creatinine in some commonly used assays, and by certain medications (such as trimethoprim and cimetidine) that reversibly inhibit tubular creatinine secretion, causing a modest elevation of the serum creatinine despite a normal GFR. Serum creatinine concentration is a function of the amount of creatinine entering the blood from muscle, its volume of distribution, and its rate of excretion. Because the first two are usually constant, changes in the serum creatinine concentration generally reflect changes in GFR. The creatinine clearance is commonly estimated by the Cockcroft-Gault equation:

$$\text{Creatinine clearance (mL/min)} = ([140 - \text{age}] \times \text{weight}) / (72 \times \text{serum creatinine}) \quad (\times 0.85 \text{ if female})$$

Under steady-state conditions, if the GFR is halved, the serum creatinine doubles. Abrupt cessation of glomerular filtration causes the serum creatinine level to rise by 1 to 2 mg/dL per day. Thus, a daily increment of less than 1 mg/dL suggests that at least some renal function has been preserved. Rhabdomyolysis releases creatine into the plasma and may cause the serum creatinine level to increase by more than 2 mg/dL per day. The BUN level also rises with renal dysfunction but is also influenced by many extrarenal factors. Increased protein intake, GI bleeding, and the catabolic effects of fever, trauma, infection, and drugs such as tetracycline and corticosteroids all increase protein turnover and result in increased hepatic urea production and increased BUN levels. Conversely, the BUN level tends to be decreased in patients with liver failure or protein malnutrition.

When glomerular filtrate has been formed, renal urea clearance is largely a function of flow rate. Urea clearance is thus decreased in patients with prerenal azotemia or acute obstruction, despite preservation of tubular function. In such cases, the BUN/creatinine ratio usually is greater than the normal value of 10:1, whereas this ratio usually is not markedly increased in cases of uncomplicated intrinsic AKI.

Urine Sodium and Fractional Excretion of Sodium. Normally, urine sodium concentration parallels sodium intake. A low urine sodium concentration thus indicates not only intact tubular reabsorptive function but also the presence of a stimulus to conserve sodium. The urine sodium concentration, as well as the FENa, an additional measure of tubular sodium handling, helps distinguish between the two most common causes of AKI, prerenal azotemia and ATN.

Measurement of urinary indices can be helpful in oliguric patients. An oliguric patient with a urine sodium concentration less than 20 mEq/L and FENa less than 1% is likely to have prerenal azotemia, whereas a urine sodium concentration more than 40 mEq/L and FENa more than 1% suggest ATN. Values in patients with prerenal azotemia overlap somewhat with those in patients with nonoliguric ATN, particularly if the renal injury is mild and some capability to retain sodium has been preserved. Thus, intermediate values for urine sodium concentration and FENa are of little help in differentiating between the two conditions. The administration of mannitol or a loop diuretic within the several hours preceding urine collection also may make interpretation of urine values difficult because the urinary sodium level will tend to be higher and the urine less concentrated, causing the results in prerenal azotemia to resemble those in intrinsic renal failure.

In glomerulonephritis, the urinary indices generally reflect intact tubular sodium handling, but the diagnosis is more accurately made by urine microscopy. In obstructive uropathy, the values of the urinary indices depend on the duration of obstruction and cannot be relied on to indicate the presence or absence of obstruction.

Renal Imaging

Renal imaging is often helpful in the evaluation of the patient with kidney dysfunction, particularly when obstruction is suspected. Computed tomography (CT) scanning provides an anatomic image of the urinary tract but does not provide an evaluation of renal function. The classic CT findings of obstruction are kidneys that are normal to large in size, and demonstration of hydronephrosis or hydroureter. Since contrast-enhanced CT subjects the kidneys of an already azotemic patient to the risk of an additional potential insult from the contrast agent, ultrasonography and noncontrast CT are much preferred for patients with preexisting renal insufficiency (Fig. 83.2).

Computed Tomography. Noncontrast CT may be useful in evaluating some azotemic patients. Hydronephrosis can be recognized without the use of contrast material. Often, dilated ureters can also be seen without contrast enhancement, and the level of obstruction can be determined. The cause of obstruction (e.g., bilateral stones, lymphoma, retroperitoneal hemorrhage, metastatic cancer, retroperitoneal fibrosis) often can also be delineated. Occasionally, bilateral ureteral obstruction produced by malignancy or retroperitoneal fibrosis may not cause detectable proximal dilation of the urinary tract. When noninvasive studies yield negative results, the diagnosis of obstruction can be made by retrograde pyelography or antegrade pyelography performed via a percutaneous nephrostomy.

Ultrasonography. Ultrasonography is a safe and reasonably reliable method for excluding obstruction as a cause of AKI. The normal kidney shows an echo-free renal parenchyma surrounding the echogenic central

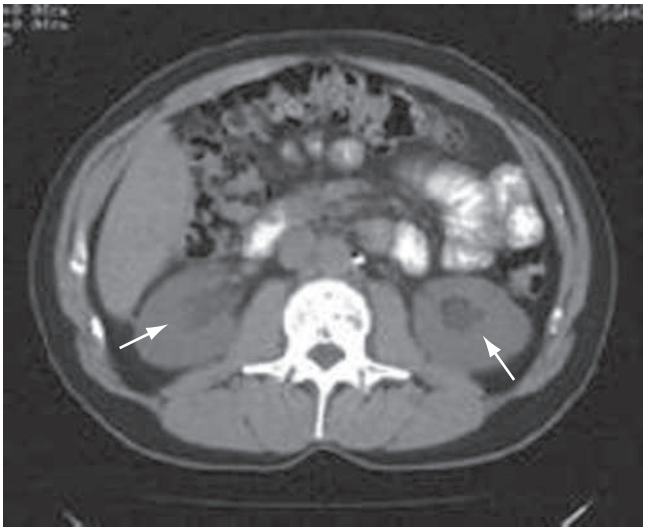

Fig. 83.2 CT scan of bilateral hydronephrotic kidneys without IV contrast medium.

urothelium of the renal pelvis and calices. The sonographic appearance of the kidney in obstruction is that of an enlarged, central, sonolucent area that spreads the normal central echo densities. A similar pattern may be produced by renal cysts, but without associated ureteral dilation. Dilation of the collecting system generally is apparent within 24 to 36 hours of the onset of obstruction, but obstruction may not be evident in patients who are evaluated early in the development of obstructive AKI.

Diagnosis

Prerenal azotemia is suspected in the setting of volume loss, volume redistribution, or decreased effective renal perfusion. It typically is associated with a normal urinalysis, high BUN/creatinine ratio, increased urine osmolality, urine sodium concentration less than 20 mEq/L, and FENa less than 1%. A rapid response to volume repletion also is characteristic.

Urethral or bladder neck obstruction is documented by the finding of significant amounts of residual urine in the bladder by catheterization or ultrasound examination after the patient has voided or attempted to void spontaneously. An important point is that the ability to void does not rule out obstruction. In fact, the urine volume in the presence of obstruction may range from zero to several liters per day. Flank pain is likewise an insensitive marker for obstruction. Urine indices and the BUN/creatinine ratio tend not to be helpful, although an increase in the latter is common in obstruction. A renal parenchymal disorder often can be diagnosed by its manifestations on microscopic urinalysis or by associated extrarenal manifestations (e.g., with multisystem disease) or clinical setting (e.g., recent exposure to a new medication). The absence of evidence of prerenal or postrenal causes in a patient with AKI may be taken as presumptive evidence of an intrarenal parenchymal process. Among these, the possibility of an acute or ongoing vascular insult should be kept in mind because timely intervention can be important in preserving ultimate renal function.

Management

ED management of AKI is directed at reversing decreases in GFR and urine output (if possible) while minimizing further hemodynamic and toxic insults, maintaining normal fluid and electrolyte balance, and managing other complications of AKI, as required. Because renal failure alters the metabolism and action of many drugs, often in ways that are not predictable, great care should be exercised in prescribing all medications. Easy access to online sources that provide guidelines for drug dosages in renal failure, and readily available consultation with a hospital pharmacist are of great help for this purpose.

After ensuring that the vital signs are adequate and the patient is in no immediate danger from volume or metabolic derangements, the next step is to correct prerenal and postrenal factors, if any are identified. Intravascular volume is repleted in hypovolemic patients and maintained in euvolemic patients by matching input to measured and insensible output. Inadequate cardiac output is augmented when possible. Postrenal or obstructive AKI is treated by restoration of normal urine outflow. Bladder outlet obstruction may be relieved by passage of a Foley catheter, whereas upper tract obstruction may require percutaneous nephrostomy.

Renal insufficiency secondary to NSAIDs generally is reversible after withdrawal of the causative agent. For patients who are at increased risk but require treatment with NSAIDs, a short-acting preparation (e.g., ibuprofen) should be prescribed and follow-up monitoring of renal function and the serum potassium level should begin within days rather than weeks. If renal function is unchanged after a short course of treatment, adverse effects from continuing therapy are unlikely, although other potential mechanisms for the development of renal dysfunction (e.g., interstitial nephritis) should be kept in mind.

Treatment of postrenal AKI consists of relief of the obstruction. In the absence of infection, full renal recovery is possible, even after 1 to 2 weeks of total obstruction, although the serum creatinine level may not return to baseline for several weeks. Because the onset of irreversible loss of renal function with obstruction appears to be gradual, a few days' delay in diagnosis generally is considered acceptable. Still, common sense dictates that obstructions should be detected and relieved promptly.

When prerenal and postrenal factors have been ruled out, the challenge is to identify the cause of intrinsic renal AKI, keeping in mind the multitude of known possible causes (see Box 83.4). The differential diagnosis can often be significantly narrowed by considering the clinical setting and physical and laboratory findings. The clinical picture is often most consistent with the broad category of ATN.

Patients who have oliguric AKI have a significantly higher mortality rate and much greater risk of complications than those who are not oliguric. The difference in prognosis may simply reflect a more severe renal insult in patients who are oliguric, however, and it is not clear that interventions aimed at converting oliguric to nonoliguric AKI have a beneficial effect on renal function or mortality. Nevertheless, because nonoliguric patients are easier to manage, an attempt to increase urine flow is warranted.

The use of loop diuretics or mannitol often is effective in increasing urine flow when intravascular volume deficits have been corrected. Furosemide has not been shown to shorten the clinical course or affect mortality. Mannitol appears to be most useful when given at the time of, or shortly after, the renal insult; the recommended adult dose is 12.5 to 25 g, intravenous (IV). If urine output does not increase, further doses may cause hyperosmolality and clinically significant intravascular volume overload in patients with impaired renal function. Dopamine also has been used in an effort to increase urine output, but it has not been proven effective.

Certain specific considerations apply to toxin-induced ATN. Pigment-induced ATN may be prevented by avoidance of hemolysis and muscle injury and correction of the factors (e.g., dehydration, acidemia) known to predispose patients with pigmenturia to the development of renal failure. When hemolysis or rhabdomyolysis has occurred, treatment is directed at eliminating the cause and preventing the development of renal failure.

Mannitol has been shown to prevent AKI in experimental models of myoglobinuria, presumably by inducing osmotic diuresis and decreasing intratubular deposition of pigment. Furosemide, on the other hand, has not consistently shown a beneficial effect. Other studies have suggested that myoglobin precipitates in an acidic urine but not in an alkaline urine. Thus, aggressive volume repletion, alkalinization, and mannitol infusion have traditionally been recommended after crush injuries to reduce the likelihood or severity of AKI. However, there is good evidence that aggressive volume resuscitation alone is equally effective. When AKI has occurred, management is similar to that for other forms of AKI, but early dialysis may be required to control rapidly developing hyperkalemia, hyperphosphatemia, and hyperuricemia.

Patients who have radiocontrast agent–induced ATN usually require only supportive therapy. A more significant aspect of ED management is identifying patients who are at risk when contrast studies are being considered. BUN and serum creatinine levels should be checked before contrast exposure in patient with risk factors, such as older age, diabetes, volume depletion, and underlying renal disease. Patients at risk should be volume-repleted (if not contraindicated) before undergoing the study, the administered dose of contrast agent should be kept as low as possible, and multiple exposures to contrast should be avoided, as should concomitant use of other nephrotoxins.[4]

In addition to general measures aimed at minimizing decreases in GFR and increasing urine output, an important component of the management of AKI is the prevention or control of systemic complications. Of particular significance in this regard are metabolic derangements (e.g., hyperkalemia, hypocalcemia, hyperphosphatemia, metabolic acidosis) and complications of volume overload (e.g., hypertension, CHF).

Hyperkalemia and Other Metabolic Derangements

Hyperkalemia. The most common metabolic cause of death in patients with AKI results from an inability to excrete endogenous and exogenous potassium loads. In oliguric patients, the serum potassium level typically increases by 0.3 to 0.5 mEq/L per day, but greater increases occur in catabolic, septic, or traumatized patients and in the presence of acidosis or exogenous potassium loads from diet or medication. This is of particular concern in patients with rhabdomyolysis and associated AKI.

Hyperkalemia results in serious disturbances in cardiac electrophysiology that may culminate in cardiac arrest. Calcium chloride is considered the second choice agent given its irritating effect when administered parentally. Hyperkalemia is essentially asymptomatic until major manifestations of cardiotoxicity appear. Accordingly, detection of hyperkalemia is a primary consideration in these patients. Electrocardiographic changes correlate only roughly with the serum potassium level. Mild hyperkalemia (serum potassium < 6.0 mEq/L) may be cautiously observed without specific treatment while all exogenous sources of potassium are eliminated. If the serum potassium level is greater than 6.5 mEq/L, and particularly if electrocardiographic changes are present, urgent intervention is necessary.

When cardiotoxicity must be reversed immediately (e.g., when there is hemodynamic compromise), IV calcium (10 mL of 10% calcium gluconate infused over 2 minutes, repeated after 5 minutes if necessary) is the treatment of choice. Calcium directly antagonizes the membrane effects of hyperkalemia. IV insulin, given with glucose to prevent hypoglycemia, temporarily shifts potassium to the intracellular space. The safety and efficacy of β-agonists in hyperkalemic patients have been well documented; like insulin, inhaled albuterol (in a dose of 10–20 mg for adult patients; for pediatric patients, a fixed dose should be given based on patient weight [<25 kg: 2.5 mg, 25 to 50 kg: 5 mg, >50 kg: 10 mg]) causes potassium to move into cells, thereby controlling hyperkalemia for 2 hours or more. Bicarbonate appears to be less effective in shifting potassium into cells than once thought. It should be used with caution in patients with renal failure because of its potential to cause volume overload and provoke hypocalcemic tetany or seizures. Sodium polystyrene sulfonate (Kayexalate), a potassium-binding ion exchange resin, has long been administered with sorbitol to promote elimination of potassium from the body, but it is no longer considered to be effective or free of adverse effects.[6] More recently, other nonabsorbable cation exchangers such as patiromer and sodium zirconium cyclosilicate have been used to control hyperkalemia in patients with renal failure, but they have not been evaluated in patients who present with acute hyperkalemia.[7]

Hypocalcemia. Hypocalcemia is a common feature of AKI that can develop rapidly after its onset. Vitamin D–dependent intestinal absorption of calcium is decreased in AKI because of decreased renal synthesis of 1,25-dihydroxyvitamin D. Another factor promoting hypocalcemia is the complexing of calcium with retained phosphate. Rhabdomyolysis-associated AKI, in particular, is often associated with the deposition of complexed calcium in muscle and other tissues. Asymptomatic hypocalcemia requires no immediate treatment, but subtle or frank tetany should be treated with IV calcium (10–20 mL of 10% calcium gluconate infused over several minutes).

Hyperphosphatemia. Hyperphosphatemia resulting from decreased renal elimination of phosphate is another common feature. The serum phosphorus level usually ranges from 6 to 8 mg/dL but may be much higher with rhabdomyolysis or in catabolic states. A calcium-phosphate product greater than 70 mg^2/dL^2 may result in metastatic soft tissue calcification. Hyperphosphatemia often is treated with oral calcium-based antacids that bind ingested phosphate in the gut.

Acids produced in normal metabolic processes accumulate in AKI and are buffered in part by serum bicarbonate, resulting in a decrease in the serum bicarbonate level and a high anion gap metabolic acidosis. Compensatory hyperventilation may be mistakenly attributed to primary cardiac failure or volume overload. The metabolic acidosis associated with AKI usually is mild, and treatment generally is not necessary if the serum bicarbonate level is greater than 10 mEq/L. Overzealous correction may result in hypokalemia, hypocalcemia, or volume overload.

Hypermagnesemia. This may complicate AKI when patients are given magnesium-containing antacids or laxatives. Thus, these products, as well as magnesium itself (e.g., when given for preeclampsia or for treatment of arrhythmia or wheezing), should be avoided in the setting of AKI.

Disturbances of Volume Regulation. These can be expected to occur in most patients with AKI. Some nonoliguric patients excrete enough salt and water to produce intravascular volume depletion if adequate fluid replacement is not provided. Volume depletion prolongs recovery from AKI. Much more commonly, AKI is complicated by volume overload because sodium and water excretion may be inadequate to match even modest intakes. Volume overload is largely responsible for the hypertension often seen in those with AKI and commonly leads to CHF and pulmonary edema. Iatrogenic volume overload is particularly common and can be prevented only by careful attention to fluid intake and output, with prudent estimates of insensible loss. Volume overload can be treated with diuretics or intravenous nitroglycerin while preparations are being made to initiate dialysis.

Disposition

Patients with new-onset severe AKI should be hospitalized. If nephrology consultation and dialysis facilities are not available, transfer to another institution is advisable once volume and metabolic abnormalities have been controlled and the patient is hemodynamically stable.

Decisions regarding dialysis generally are made by the nephrology consultant and take into account many factors, including laboratory test abnormalities and the presence or absence of signs and symptoms of uremia (e.g., nausea, vomiting, change in mental status). Many nephrologists choose to initiate dialysis when the BUN level exceeds 100 mg/dL or the serum creatinine level exceeds 10 mg/dL. Intractable volume overload and life-threatening hyperkalemia are the two most common indications for emergency dialysis.

CHRONIC KIDNEY DISEASE

Foundations

CKD denotes kidney damage or decreased renal function for 3 months or longer and is characterized by irreversible nephron loss and scarring. Chronic renal insufficiency, which denotes a condition in which the GFR has been moderately reduced but not to a degree sufficient to cause clear-cut clinical symptoms, has been replaced by an indication of the degree to which the GFR is reduced. End-stage renal disease, now termed *kidney failure,* describes a condition in which renal function has diminished to a low level and in which serious, life-threatening manifestations can be expected to occur without dialysis or transplantation. At this stage, the kidneys often are shrunken and diffusely scarred to such a degree that it may be impossible to make an etiologic diagnosis, even on pathologic examination.

The causes of CKD are numerous; their relative frequency depends primarily on the population studied. As with AKI, they can be conveniently classified as prerenal (vascular), intrinsic renal (glomerular and tubulointerstitial), or postrenal (obstructive; Box 83.6). Glomerular disease accounts for approximately one-third to half of the cases of CKD; in the United States, diabetic nephropathy forms the largest group of these. Hypertensive nephrosclerosis is another important cause, particularly among blacks, in whom it may be the cause of 25% or more of cases of CKD. Among children and adolescents, reflux nephropathy is the most common cause of CKD. Renal failure related to IV drug use or human immunodeficiency virus disease is a major consideration in some populations. Clues to other specific causes may be gained from elements of the history, physical examination, and laboratory and imaging studies. Although determining the underlying cause of CKD can permit the underlying disease to be treated and can lead to some improvement in renal function in some cases, this is the exception rather than the rule.

BOX 83.6 Major Causes of Chronic Kidney Disease

Vascular Causes
- Renal arterial disease
- Hypertensive nephrosclerosis

Glomerular Causes

Primary Glomerulopathies
- Focal sclerosing glomerulonephritis (GN)
- Membranoproliferative GN
- Membranous GN
- Crescentic GN
- IgA nephropathy

Secondary Glomerulopathies
- Diabetic nephropathy
- Collagen vascular disease
- Amyloidosis
- Postinfectious
- HIV nephropathy

Tubulointerstitial Causes
- Nephrotoxins
- Analgesic nephropathy
- Hypercalcemia or nephrocalcinosis
- Multiple myeloma
- Reflux nephropathy
- Sickle nephropathy
- Chronic pyelonephritis
- Tuberculosis

Obstructive Causes
- Nephrolithiasis
- Ureteral tuberculosis
- Retroperitoneal fibrosis
- Retroperitoneal tumor
- Prostatic obstruction
- Congenital abnormalities

Hereditary Causes
- Polycystic kidney disease
- Alport syndrome
- Medullary cystic disease

HIV, Human immunodeficiency virus; *IgA*, immunoglobulin A.

Barring renal transplantation, CKD is an essentially irreversible condition generally characterized by a relentless decrease in renal function. The most common problems requiring emergent intervention are severe hyperkalemia and symptomatic volume overload. In the patient with CKD who has an acute problem, the focus should be on the identification and treatment of an intercurrent illness that has caused clinical decompensation, with the goal of returning the patient to a stable, chronically compensated status.

Pathophysiology

Progressive loss of renal function eventually results in a recognizable syndrome termed *uremia*. Clinical manifestations do not generally appear, however, until the GFR has been reduced to approximately 15% to 20% of normal. As the patient becomes unable to excrete an ingested salt or water load promptly, the external balance of sodium and water is affected; volume overload or hypernatremia or hyponatremia may result. Inability to concentrate the urine is an early manifestation of renal insufficiency and may be manifested as nocturia. Potassium homeostasis is likewise disrupted, and a relatively small potassium load may lead to dangerous hyperkalemia. The acid-base balance is affected because the kidney fails to clear the daily metabolic acid load owing to a decreased ability to excrete ammonium and phosphate; the result is a non–anion gap acidosis in the earlier stages of CKD and a superimposed anion gap acidosis as the GFR decreases further. Calcium and phosphate metabolism is affected as well; retention of phosphate and progressive loss of the kidney's capacity to synthesize 1,25-dihydroxycholecalciferol, the active form of vitamin D, lead to hypocalcemia, secondary hyperparathyroidism, and eventually the development of renal osteodystrophy.

Nitrogenous byproducts of protein catabolism retained in the blood are the presumed cause of many of the diverse abnormalities of organ function in renal failure. Most patients with CKD show decreased glucose tolerance, although it is rarely severe enough to require treatment unless the medical history includes established diabetes. In the latter case, insulin or other hypoglycemic therapy may need to be continued, but generally at a lower dosage than required before the onset of renal failure because the normal kidney has a major role in insulin degradation. Alterations in lipid metabolism result in elevated low-density lipoprotein levels and hypertriglyceridemia in many patients with CKD.

Clinical Features

Uremia has specific effects on a variety of organ systems. Many of these manifestations are relieved by dialysis, but others are not. A number have been attributed in some degree to the retention of nitrogenous wastes and to derangements in vitamin D and parathyroid hormone metabolism.

Cardiovascular System

The cardiovascular system is perhaps most dramatically affected in CKD. Many of the manifestations can be attributed to the effects of chronic volume overload, anemia, hyperlipidemia, alterations in calcium and phosphorus metabolism, and volume- and hormone-mediated hypertension. Pericarditis, with or without pericardial fluid accumulation, also is common in CKD, particularly among patients who have not undergone dialysis.[8]

Pulmonary Effects

Uremic pleuritis, with or without associated pleural fluid collections, may develop in some patients. So-called "uremic lung," often manifested radiographically by bat wing perihilar infiltrates, represents pulmonary edema and is almost always caused by volume overload

or myocardial dysfunction. Noninflammatory pleural effusion caused by volume overload also is fairly common. Of special importance in the ED evaluation is that the radiographic appearance in pulmonary edema may at times be misleading, simulating an infectious lobar infiltrate or even assuming a nodular appearance in some cases.

Neurologic Features

Neurologic dysfunction is common in those with advanced uremia and may manifest as lethargy, somnolence, difficulty concentrating, or frank alteration in mental status. Seizures may occur, although causes other than uremia alone must be ruled out. Uremic encephalopathy commonly manifests with hiccups, asterixis, or myoclonic twitching. The latter should not be confused with tetany caused by hypocalcemia, which also is common in untreated CKD patients. In the peripheral nervous system, uremia often causes cramps and a distal sensorimotor neuropathy.

Gastrointestinal System

Anorexia and nausea are nearly constant features of uremia. These GI manifestations are caused by the accumulation of nitrogenous wastes that correlate roughly with the BUN level and may be relieved even in the undialyzed patient by introduction of a low-protein diet.

Dermatologic Features

The skin of patients with CKD has a characteristic yellowish tinge. Uremic frost, the result of the deposition of urea from evaporated sweat on the skin, is a classic finding that, like so-called uremic fetor, is seen only rarely now with the widespread use of dialysis (Fig. 83.3). Diffuse pruritus is often a major source of discomfort for the patient with CKD; in some cases, it may be caused by calcium deposition in the skin secondary to derangements in calcium metabolism.

The use of gadolinium-based contrast agents for magnetic resonance imaging has been associated with the development of nephrogenic systemic fibrosis, a potentially fatal disorder that occurs in patients with moderate-to-severe chronic kidney failure.

Musculoskeletal System

The complex disturbances of calcium and phosphate metabolism in CKD result in renal osteodystrophy, a clinical entity encompassing several overlapping varieties of bone disease that can cause bone pain or frank fractures. Patients with CKD generally are treated with long-term oral calcium and vitamin D in an effort to prevent secondary hyperparathyroidism and uremic osteodystrophy. Occasional patients will have a poor response to therapy and require parathyroidectomy. A specific type of arthritis caused by the deposition of calcium hydroxyapatite or calcium oxalate crystals in joints is seen in some patients, as are periarticular calcium deposition, spontaneous tendon rupture, myopathy, and carpal tunnel syndrome.

Fig. 83.3 Uremic frost. Note the fine white powder on the skin of this patient with kidney failure.

Immunologic Considerations

Uremic patients have long been noted to have an increased susceptibility to infection due to alteration of both humoral and cellular immunity. The relative importance of each in the pathogenesis of infection in renal failure is not completely clear, but defects in cellular immunity appear to be more significant clinically. Although patients with renal failure should be considered to be immunocompromised, most infections in patients with CKD are caused by common pathogens rather than opportunistic organisms.

Hematologic Effects

A pronounced normochromic normocytic anemia, with a hematocrit value commonly in the range of 18% to 25%, is nearly universal in those with untreated CKD, except among patients with polycystic disease. It is caused primarily by the kidneys' decreased production of erythropoietin, a hormone that stimulates red cell production by the bone marrow. Other contributing factors are increased red cell hemolysis, nutritional deficiencies, and increased bleeding secondary to platelet dysfunction.

Although the platelet number generally is normal in uremia, the bleeding time is prolonged because of defective platelet adhesiveness and activation. Numerous ecchymoses, seen in many patients with CKD, are a common manifestation.

Differential Diagnosis

Patients with CKD commonly present with nonspecific complaints that are often of insidious onset, such as generalized weakness, poor appetite, or deterioration of mental functioning. However, because CKD can affect all organ systems, a number of life-threatening conditions, including hyperkalemia and myocardial infarction, are in the differential, and a comprehensive evaluation is generally indicated.

In patients without an established diagnosis of CKD, the first consideration is to determine that the renal failure is chronic rather than acute. An explicit history to that effect, obtained from previous medical records or from the patient or family, provides the most straightforward and reliable confirmation, as does the presence of a dialysis access device on physical examination. If such a history is unavailable, the finding of bilaterally small kidneys, readily detected by plain abdominal radiography or ultrasonography, constitutes equally good evidence. However, the converse is not necessarily true—a finding of normal-sized or large kidneys does not rule out CKD. In such cases, additional diagnostic steps are required to establish the diagnosis. A convincing history of the long-standing presence of the presenting symptoms or of symptoms, such as nocturia, may be helpful in suggesting chronicity, as may a history of familial kidney disease, such as polycystic kidney disease or Alport syndrome.

Laboratory abnormalities such as anemia, acidosis, hyperuricemia, hypocalcemia, and hyperphosphatemia can occur in patients with acute kidney failure as early as 10 days after onset. Although urinary findings likewise tend not to be helpful, the presence of broad waxy casts on microscopic examination is suggestive of chronic disease, whereas the finding of an active sediment (e.g., red cell casts) is good evidence for an acute process.

Although as a rule chronic kidney failure is irreversible and slowly progressive, an essential component of the ED evaluation is to exclude the possibility of potentially reversible factors (in effect, ruling out "acute on chronic" renal failure) and to ensure that treatable causes of CKD—disorders that if treated might allow for some return of renal function—have not been overlooked. These potentially reversible factors and treatable causes of CKD are important to keep in mind because they represent the only potential opportunity to reverse the patient's disease rather than simply to manage its results (Box 83.7).

Primary among superimposed reversible factors are those that lead to decreased renal perfusion. Of these, the most common is volume depletion. Regardless of the initiating cause, the process is exacerbated by the diseased kidney's impaired ability to conserve sodium and concentrate the urine appropriately. Decreased renal perfusion caused by cardiac dysfunction of any cause is another extremely common and potentially reversible factor. An uncommonly encountered but important vascular cause of reversible deterioration of renal function is scleroderma renal crisis, a syndrome of accelerated hypertension and severe vasoconstriction in patients with underlying scleroderma that can be reversed by timely treatment with ACE inhibitors. Increased catabolism caused by infection, trauma, surgery, corticosteroids, or GI bleeding is another reversible factor that often is responsible for worsening azotemia and the development of uremic symptoms.

Drugs and toxins constitute another important group of reversible factors. Not only may these agents exacerbate renal insufficiency by causing intravascular volume depletion (diuretics), decreased renal perfusion (antihypertensive agents), or increased catabolism (tetracycline), they also can cause ATN (aminoglycosides, rhabdomyolysis), AIN (many drugs), or inhibition of renal prostaglandin synthesis (NSAIDs). Particularly noteworthy is the dramatic decrease in renal function produced when an ACE inhibitor is administered to a patient with renal insufficiency caused by bilateral renal artery stenosis or renal artery stenosis in a solitary kidney.

Postrenal reversible factors also are important because of their frequency, particularly obstructive disease in the older male patient and reflux nephropathy in the child. Papillary necrosis should remain a consideration in the diabetic patient and the patient with sickle cell disease. Stone disease, retroperitoneal fibrosis, and even rarer entities such as ureteral tuberculosis also should not be overlooked.

Finally, treatment of the underlying disorder that has caused the CKD can occasionally result in the return of some renal function, most notably in cases of myeloma kidney, some forms of secondary glomerulonephritis, and severe hypertensive disease. Although this consideration relates to long-term care and follow-up, it is appropriate that ED management address this issue to ensure that appropriate evaluation and disposition are arranged.

BOX 83.7 Reversible Factors and Treatable Causes of Chronic Kidney Disease

Reversible Factors
Hypovolemia
Congestive heart failure
Pericardial tamponade
Severe hypertension
Catabolic state, protein loads
Nephrotoxic agents
Obstructive disease
Reflux disease

Treatable Causes
Renal artery stenosis
Malignant hypertension
Acute interstitial nephritis
Hypercalcemic nephropathy
Multiple myeloma
Vasculitis (e.g., systemic lupus erythematosus, Wegener granulomatosis, polyarteritis nodosa)
Obstructive nephropathy
Reflux nephropathy

Diagnostic Testing

Diagnostic testing for CKD generally follows the principles outlined for AKI (see earlier section "Acute Kidney Injury: Diagnostic Testing"), though prerenal causes are of concern mostly as exacerbating factors in patients with CKD.

Management

CKD patients are susceptible to infection, bleeding, and the numerous other complications associated with renal failure, as well as those that may be associated with the underlying causative disorder. Moreover, these patients are more vulnerable to the effects of any intercurrent illness or trauma. Those who are maintained with chronic hemodialysis or peritoneal dialysis are subject to potential complications from the dialysis therapy itself.

Patients with CKD also are uniquely susceptible to iatrogenic illness. First, they are less able to handle fluid and solute loads than normal persons. Just as important, the presence of renal failure significantly alters the metabolism and action of many drugs, often in ways that are not predictable (Box 83.8). Thus, the dose and schedule of every agent administered, even those that are apparently innocuous, such as antacids, laxatives, antiemetics, or multivitamin preparations, should be carefully considered, and the hospital pharmacist or other dependable resource consulted. In general, consultation with the patient's nephrologist is recommended on completion of the initial ED evaluation because management and follow-up monitoring after the patient has left the ED are often complex.

In the United States, most patients with advancing CKD eventually will require dialysis, but several true emergencies may develop in the patient with CKD before chronic dialysis has been instituted. Specific diagnostic and therapeutic considerations apply to the management of these conditions, regardless of whether they occur in dialyzed or undialyzed patients.

Hyperkalemia

Potentially the most rapidly lethal complication of CKD is severe hyperkalemia. As a rule, this condition is clinically silent until it causes

BOX 83.8 Mechanisms of Drug Toxicity in Renal Failure

Excessive drug level
Impaired renal excretion of drug
Impaired renal excretion of active metabolite
Impaired hepatic metabolism
Increased sensitivity to drug
Changes in protein binding
Changes in volume of distribution
Changes in target organ sensitivity
Metabolic loads administered with drug
Misinterpretation of measured serum drug level (i.e., change in therapeutic range)

potentially life-threatening manifestations. Accordingly, hyperkalemia must be looked for in every patient with CKD. These patients can become severely hyperkalemic when required to handle even modest exogenous and endogenous potassium loads; moreover, even drugs that have only minimal effects on the serum potassium level in normal persons, such as β-blockers and ACE inhibitors, can cause hyperkalemia in these patients. There is concern that the use of succinylcholine in patients with CKD has the potential to cause rapid deterioration in patients who are already hyperkalemic, although this appears to be rare.

An ECG should be obtained whenever hyperkalemia is a possibility and, if signs of hyperkalemia are noted, appropriate therapy should be started immediately, even before laboratory confirmation of a high serum potassium level. Electrocardiographic changes may be completely absent, even when hyperkalemia is severe; thus, a normal ECG does not preclude the need for laboratory confirmation of a normal serum potassium level. A potassium level of 6 mEq/L should be considered potentially dangerous, even though many patients with CKD chronically tolerate levels somewhat above this threshold, without electrocardiographic changes. A patient with CKD who is in cardiac arrest should be assumed to be hyperkalemic and treated accordingly while the usual resuscitative measures are taken. See earlier ("Acute Kidney Injury: Management") and Table 83.1.

In patients who still retain some renal function, the most effective way to treat hyperkalemia in patients with CKI may be to administer an IV diuretic such as furosemide (if the patient is not hypovolemic) and to provide volume, if necessary. Large doses of diuretic may be necessary for a satisfactory diuresis to be induced. In light of the potential for ototoxicity with the use of loop-active diuretics, these drugs should be administered by slow infusion rather than by bolus and may be contraindicated in patients who also are receiving other potentially ototoxic agents. During the course of any of these therapeutic interventions, the electrocardiographic and serum potassium levels must be monitored frequently.

Pulmonary Edema

Perhaps the most common ED problem in patients with CKD is pulmonary edema secondary to volume overload. Surprisingly, the diagnosis is not always straightforward. A history of increasing dyspnea on exertion or paroxysmal nocturnal dyspnea may be suggestive, but the physical examination may not reveal the expected signs of CHF, and even chest radiography may be deceptive. Recent weight gain or a body weight considerably over dry weight (typically >5 pounds) is the most reliable clue and, in the absence of convincing evidence of another cause for dyspnea, volume overload should be assumed to be the cause.

Treatment of pulmonary edema in the patient with CKD is of necessity somewhat different from that in other patients. Arrangements for initiation of dialysis should be made as soon as possible because it is the most rapidly effective means to decrease intravascular volume in the absence of renal function. Other immediate measures should be instituted in the meantime. Although such measures may occasionally prove to be effective enough to avoid dialysis temporarily in patients who possess some residual renal function, it should nevertheless be anticipated that the response to even extremely aggressive medical therapy, short of dialysis, will be inadequate.

The CKD patient with pulmonary edema is placed in the sitting position, and high-flow oxygen is administered by mask. The use of continuous or bilevel positive airway pressure (CPAP or BiPAP) is a useful adjunct for patients with CKD, as it is for patients without renal failure. Sublingual nitroglycerin can be administered immediately and functions rapidly to reduce preload and afterload; an IV infusion beginning at 10 to 20 μg/min can be initiated promptly and titrated to effect. Diuretics are not expected to be helpful unless the patient has retained a significant level of renal function.

Infection

Because infection is a major contributor to morbidity and mortality among patients with CKD, the possibility of serious infection should be entertained, even when the expected classic findings are not all present. For example, bacteremia may manifest with fever alone, just as in other patients with impaired immunity. Patients with pneumonia may have only vague dyspnea or malaise, symptoms that may be attributed to volume overload or uremia. Thus, all diagnostic possibilities should

TABLE 83.1 Treatment of Hyperkalemia

Agent or Modality	Dose and Regimen	Onset/Duration of Action	Mechanism of Action	Comments
Calcium gluconate (10%)	10 mL IV (may repeat × 2 prn every 5–10 min)	1–5 min/≈1 hr	Antagonizes membrane effects of K	Monitoring of ECG required; do not mix with HCO_3^- *Beware*—hypercalcemia
Albuterol	10–20 mg (nebulized) by inhalation	30 min/2 hr or more	Intracellular movement of K	Relatively free of significant side effects; tachycardia
Glucose and insulin	10–20 units regular insulin/100 g glucose	30 min/while infusion continued	Intracellular movement of K	*Beware*—hyperglycemia, hypoglycemia Infused volume may be decreased by giving $D_{10}W$, $D_{20}W$, or $D_{50}W$
Sodium bicarbonate	150 mEq/L IV infusion (rate variable)	Approximately 10–15 min/1–2 hr	Possible intracellular movement of K	Most effective with organic acidosis
Dialysis	HD, PD	Minutes/while continued	Removal of K from blood	HD may remove 50 mEq/hr *Beware*—K rebound PD may remove 15 mEq/hr
IV diuretics (IV fluid if patient is hypovolemic)	Furosemide 40–80 mg IV	15 minutes/while diuresis continued (depending on renal function)	Urinary K excretion	Only in patients with some residual renal function

$D_{10}W$, 10% dextrose in water; *$D_{20}W$*, 20% dextrose in water; *$D_{50}W$*, 50% dextrose in water; *ECG*, electrocardiogram; *HD*, hemodialysis; *IV*, intravenous; *PD*, peritoneal dialysis; *PO*, orally.

be pursued, and empirical broad-spectrum antibiotic coverage often is advisable until infection has been ruled out in the hospital. Bacteremia resulting from vascular access infection is common in patients undergoing hemodialysis, as is peritonitis in patients undergoing peritoneal dialysis.

A UTI can occur even in patients with minimal urine output or those with long-standing renal failure. Urinary stasis is undoubtedly a predisposing factor. However, asymptomatic pyuria is common in these patients and is not necessarily indicative of infection. For patients with symptoms, urine culture is helpful in guiding treatment decisions. An upper UTI associated with a clinical picture typical of pyelonephritis or renal colic is unusual, but when seen it is often in patients with polycystic kidney disease and requires parenteral treatment. A clinical diagnosis can be made presumptively in the ED, but invasive measures sometimes are necessary to document infection and guide therapy. For infected cysts, lipid-soluble antibiotics (e.g., ciprofloxacin, trimethoprim-sulfamethoxazole) offer the best antibiotic penetration, although surgical intervention for these infections sometimes becomes necessary.

Dialysis

Dialysis can normalize fluid balance, correct electrolyte and other solute abnormalities, and remove uremic toxins or drugs from the circulation when the patient's kidneys are unable to do so. Dialysis also can reverse some uremic symptoms, but generally to a lesser degree, and permit better long-term control of hypertension, anemia, and renal osteodystrophy.

The two major dialysis modalities are hemodialysis and peritoneal dialysis. Each is based on a technique whereby the patient's blood comes into contact with a semipermeable membrane, on the other side of which is a specially constituted balanced physiologic solution. Water and solutes diffuse across the membrane by moving along concentration and osmotic gradients, effectively normalizing the blood's composition.

Hemodialysis. This requires special access to the patient's circulation, generally through a surgically created arteriovenous fistula or an implanted artificial graft or through a surgically placed tunneled catheter. The vascular access site must be treated with care because hemodialysis cannot be performed without it. Careless manipulation or puncture can cause bleeding, infection, or thrombosis, which may result in loss of the access. The involved arm should not be used for blood pressure determinations and a tourniquet should not be applied.

In general, blood is drawn and IV lines are established in other locations. In exceptional circumstances, if no other site is available and it is essential to obtain blood samples quickly, the fistula or graft may be used, but with precautions. A tourniquet is not applied, the area is cleansed scrupulously before the puncture, and extreme care is taken not to puncture the back wall of the access. After the puncture, firm but nonocclusive pressure is applied for at least 10 minutes. The presence of a thrill before and after the procedure is documented. Similar precautions are taken in the exceptional cases in which the fistula or graft must be used for IV access. If this is done, an automated infusion pump is essential to control the infusion rate into these relatively high-pressure blood vessels.

Peritoneal Dialysis. In peritoneal dialysis, the patient's peritoneum functions as the dialysis membrane. Dialysate is infused through a surgically implanted Silastic catheter (Tenckhoff catheter) that penetrates the lower abdominal wall. Fluid exchanges are generally performed several times daily, typically by the patient at home. As compared with hemodialysis, peritoneal dialysis offers the theoretical advantages of greater patient independence, avoidance of anticoagulation, and smoother control of volume and hypertension, without the intermittent rapid shifts of solute typical of hemodialysis. Medications such as insulin and antibiotics can be administered via the intraperitoneal (IP) route, allowing smoother absorption and more stable blood levels. The main disadvantage of peritoneal dialysis is a significant incidence of bacterial peritonitis, which is usually readily treatable.

Indications for Dialysis. The decision to initiate chronic dialysis in the patient with CKD generally is made by the patient's nephrologist in the setting of a gradually decreasing GFR and progressive manifestations of renal failure. The absolute value of the BUN or serum creatinine level generally is used only as a rough guide to determine when chronic dialysis should be instituted. The provision of vascular or peritoneal access usually has been arranged weeks to months before the anticipated initiation of dialysis to allow the access site to mature and to minimize any mechanical complications of the procedure.

For patients who come to the ED with AKI, however, as well as for patients with CKD in whom acute problems have developed, the emergency clinician must be prepared to make the decision to arrange for emergent dialysis (Box 83.9). How urgently dialysis must be initiated depends not only on the severity and acuteness of the presenting problem, but also on the availability of technical facilities and trained dialysis personnel and the effectiveness of available temporizing measures for the problem at hand.

The most common problem requiring emergent dialysis, particularly in the patient with CKD, is pulmonary edema secondary to volume overload. In general, the inciting cause is over-ingestion of fluid and salt in excess of the patient's greatly diminished renal excretory capacity. Despite the effectiveness of temporizing measures, many of these patients require immediate dialysis—emergency hemodialysis or, in the case of the patient maintained on peritoneal dialysis, intensification of the usual dialysis regimen.

A related problem that may require emergent, or at least urgent, dialysis is malignant hypertension, particularly when associated with hypertensive encephalopathy or cardiovascular decompensation. Because hypertension in patients with renal failure is commonly volume-dependent, correction of volume overload, even if not apparent clinically, is a central component of therapy. Temporizing measures such as the administration of IV nitroglycerin often permit hypertension to be controlled sufficiently for dialysis to be delayed for several hours. However, in many cases, hypertension and associated symptoms are difficult to control until dialysis permits the volume overload to be corrected. Because blood pressure often is dramatically responsive to reduction of circulating volume, other antihypertensive agents with more prolonged effects should be withheld until after dialysis to avoid hypotension after circulating volume has been acutely reduced.

Severe hyperkalemia is another common indication for emergent or urgent dialysis, particularly in the patient with AKI who is hypercatabolic. In the patient with CKD, hyperkalemia usually is caused by excessive potassium intake, but endogenous causes such as hemolysis or rhabdomyolysis should also be kept in mind. The available temporizing measures can be used to control the serum potassium level, but dialysis remains the most effective means of removing potassium from

BOX 83.9 Indications for Emergency Dialysis

- Pulmonary edema
- Severe uncontrollable hypertension
- Hyperkalemia
- Other severe electrolyte or acid-base disturbances
- Some overdoses
- Pericarditis (possibly)

the body. For rapid control of the serum potassium level, hemodialysis leads to high clearance rates and is preferred to peritoneal dialysis.

Other severe electrolyte and acid-base disturbances, including diabetic ketoacidosis, may sometimes necessitate emergent dialysis. Occasional patients with renal failure and severe hypercalcemia uncontrollable by other modalities (e.g., patients with multiple myeloma causing both renal failure and hypercalcemia) may require dialysis. The occasional patient with renal failure in whom severe hypermagnesemia develops after inappropriate therapy or magnesium ingestion may require immediate dialysis to reverse life-threatening paralysis or cardiac dysrhythmia. Severe metabolic acidosis in the setting of renal failure is another indication for emergent dialysis, particularly if volume overload or hypocalcemia (with the risk of tetany and convulsions) precludes the administration of bicarbonate.

A related situation is one in which a patient with renal failure has taken an overdose or inadvertently been administered medication that is ordinarily cleared by the kidneys. If the agent is adequately dialyzable and its continued presence in the circulation poses a significant risk to the patient, immediate dialysis can be lifesaving. An example is the ingestion of methanol or ethylene glycol by a dialysis patient. Similarly, ill-advised use of magnesium-containing cathartics or phosphate-containing enemas by patients with CKD can lead to dangerous hypermagnesemia and hyperphosphatemia and may necessitate urgent dialysis.

The serum creatinine and BUN levels themselves are not considered definitive indications for dialysis. A creatinine level of 10 mg/dL or BUN level of 100 mg/dL often is used as a guideline for beginning chronic dialysis in the patient with progressive renal failure. In dialyzed patients, however, the serum creatinine level often is considerably greater than 10 mg/dL but is a reflection of total body muscle mass more than of the adequacy of dialysis. The BUN level is a somewhat better indicator; in well-dialyzed persons, it generally is in the range of 50 to 80 mg/dL and is more than 100 mg/dL in less well-dialyzed patients. Neither blood level, however, correlates more than roughly with uremic symptoms, even in undialyzed patients, or has any direct bearing on how urgently dialysis should be initiated.

The occurrence of uremic symptoms or signs such as nausea, vomiting, lethargy, or twitching indicates a need for dialysis but does not necessitate immediate initiation of dialysis unless symptoms are severe. Pericarditis, even in the absence of cardiac tamponade, often is considered an indication for urgent dialysis, but pericarditis can also occur in well-dialyzed CKD patients. In a previously undialyzed patient with progressive renal insufficiency, the appearance of pericarditis indicates that it is time to initiate dialysis, although not necessarily on an emergency basis.

COMPLICATIONS OF DIALYSIS

A number of complications can be manifested after dialysis has been initiated.

Hemodialysis

Vascular Access–Related Complications

The performance of hemodialysis depends on reliable vascular access, and it is the vascular access device that is responsible for the complications of dialysis that most often require evaluation in the ED setting. These problems must be attended to promptly to minimize the risk of losing the patient's dialysis lifeline.

Bleeding from the dialysis puncture site can occur hours after a hemodialysis treatment, either spontaneously or after inadvertent minor trauma to the site. Such bleeding can usually be stopped by applying firm pressure to the access site. Care should be taken not to occlude and possibly cause thrombosis of the vessel by compressing it too vigorously, and the presence of a thrill immediately after the procedure should be documented in the chart. It may be necessary to keep the patient in the ED for a time to ensure that bleeding does not recur. Recurrent bleeding, especially from an aneurysm or a pseudoaneurysm, is best evaluated by a vascular surgeon.

Similarly, if the patient reports that the thrill in the access has been lost, a vascular surgeon is consulted immediately. Although thrombolytic agents are generally used, definitive treatment is usually surgical revision. The access device should not be forcefully manipulated or irrigated because rupture of the vessel or venous embolization may result.

Infection of the vascular access can result in persistent or recurrent bacteremia, as well as loss of the access. Infection appears to be a consequence of contamination at the time of puncture for dialysis, and most infections are caused by staphylococci typical of skin flora. Infections are more likely to occur in grafts than in native fistulas. The signs and symptoms of an access infection—redness, warmth, and tenderness over the site—often are obvious, but in many cases localizing findings are absent and the patient has only a fever or a history of recurrent episodes of fever and documented bacteremia. For this reason, it is common practice to obtain blood cultures for all patients on hemodialysis who have a fever without an obvious source of infection and to treat them presumptively for an abscess infection. A careful search for other sources of infection should be performed before an abscess infection is assumed to be the cause. Infections such as odontogenic abscess, extremity cellulitis (particularly in diabetics), and perirectal abscess can easily be missed.

Although some nephrologists prefer to admit all dialysis patients with fever to the hospital, management of these patients on an outpatient basis often is possible, provided that they otherwise feel well and do not appear to be septic and provided that they can care for themselves at home and return promptly if their condition worsens. This course is made possible by the fact that they can be loaded with IV antibiotics that dependably maintain adequate blood levels until the next scheduled dialysis treatment, at which time the culture and sensitivity test results can be checked and therapy adjusted accordingly. IV vancomycin, 1 to 1.5 g, given as a single loading dose, is the drug of choice in this case because most abscess infections are staphylococcal and because this drug is only minimally hemodialyzable and needs to be given only every 4 to 7 days in the chronic dialysis patient. If a gram-negative infection also is thought to be likely, as in a patient who has had recent episodes of gram-negative bacteremia, a loading dose of a second drug (e.g., a third-generation cephalosporin or aminoglycoside) also can be administered. Patients can be reloaded with these drugs at the end of their next hemodialysis session if culture results prove to be positive.

Non–Vascular Access–Related Complications of Dialysis

The hemodialysis procedure itself, which entails invasion of the vasculature, anticoagulation, and significant shifts of fluid and solutes, often is associated with acute complications such as hypotension, shortness of breath, chest pain, and neurologic abnormalities.

Hypotension. Hypotension that occurs after dialysis is usually the result of an acute reduction in circulating intravascular volume and failure of the patient's homeostatic mechanisms to compensate for it. Because hemodialysis is episodic, each treatment must remove the excess fluid that has accumulated over the period since the last dialysis (generally, 2–3 days), and patients often are relatively volume-overloaded at the beginning of each treatment. With rapid removal of extracellular fluid, there is inadequate time for transcellular fluid shifts to replace intravascular volume. Antihypertensive medications that are

BOX 83.10 Differential Diagnosis of Hypotension in Hemodialysis Patients

Pericardial tamponade
Myocardial infarction
Myocardial or valvular dysfunction
Electrolyte disorders
Hyperkalemia or hypokalemia
Hypercalcemia or hypocalcemia
Hypermagnesemia
Vascular instability
Drug-related
Dialysate-related
Autonomic neuropathy
Excessive access arteriovenous flow
Anaphylactoid reaction
Air embolism

required when the patient is in a volume-expanded state, particularly β-blockers, can contribute to the hypotension when intravascular volume is normalized.

Most episodes of hypotension that occur during hemodialysis resolve spontaneously or can be readily managed by a decrease in blood flow rate or by infusion of small volumes of saline (to cause transient volume expansion) or hypertonic solutions (to reverse transient acute hypo-osmolality). Patients with significant hypotension who do not respond to these maneuvers often are brought to the ED for further evaluation. Patients on dialysis with persistent hypotension should be considered to be at risk for acute myocardial infarction, acute dysrhythmias, and sepsis (Box 83.10).

Acute blood loss is another consideration when a hemodialysis patient presents with hypotension, symptomatic angina, or CHF. Dialysis patients are commonly treated with epoetin or darbepoetin to prevent severe anemia; untreated patients typically have low baseline hemoglobin levels. Serum levels of clotting factors are normal in CKD, but patients are routinely anticoagulated for each hemodialysis treatment and, although transient thrombocytopenia may occur during the dialysis procedure, the qualitative platelet defect characteristic of renal failure is an important factor in bleeding that continues beyond the peridialytic period. This abnormality is only partially reversed by dialysis but can be corrected by the administration of desmopressin (DDAVP), which increases the release of factor VIII–von Willebrand factor polymers from vascular endothelium. DDAVP has been used successfully to normalize the bleeding time in preparation for surgery in patients with CKD.[9] Cryoprecipitate and conjugated estrogen both have been shown to produce similar effects for a longer period.

Overt bleeding from the GI tract, often caused by angiodysplasia or peptic ulcer disease, is common and can be dramatic. Occult hemorrhage in other locations, however, can present a diagnostic challenge because symptoms and signs of volume loss tend to be overshadowed by local manifestations of bleeding into a closed space. Spontaneous retroperitoneal or pleural hemorrhage may manifest with flank pain or with chest pain and shortness of breath, respectively.

Acute pulmonary embolism and acute air embolism are two less likely possibilities. The former, although it does occur occasionally in dialysis patients, is unusual. The latter, although reported occasionally in the past, has been all but eliminated by improved dialysis monitoring equipment and safety mechanisms.

Two additional entities in the differential diagnosis for hypotension are of particular importance in the patient with CKD—acute pericardial tamponade and severe, life-threatening hyperkalemia. Acute pericardial tamponade may be the result of sudden pericardial hemorrhage or sudden worsening of a formerly compensated pericardial effusion after acute correction of elevated preload. The clinical features of tamponade in the dialysis patient are similar to those in other populations, but the common preexistence of cardiomegaly may make the chest film difficult to interpret unless it shows the typical water bottle shape and a definite increase in heart size from previous examinations.

Similarly, an elevated central venous pressure is of little use in differentiating tamponade from underlying right-sided heart failure. Even the finding of pericardial fluid on bedside ultrasonographic examination, although suggestive, is not proof that tamponade is present, because many dialysis patients chronically have pericardial effusions that do not cause hemodynamic compromise. The ultrasonographic demonstration of right ventricular diastolic collapse is more specific. A definitive diagnosis of tamponade depends on the direct demonstration of equal pressures in the right and left atria on cardiac catheterization.

Emergency pericardiocentesis must occasionally be performed in the ED to relieve acute tamponade, but there often is enough time for the patient to be transported to the catheterization suite or operating room for safer and more definitive therapy in a controlled setting. If immediate pericardiocentesis is believed to be necessary, the emergency clinician should not hesitate to perform this potentially lifesaving procedure, despite the many potential complications and increased risk of bleeding in patients with CKD. Similarly, in the case of a dialysis patient who is in cardiac arrest, pericardiocentesis generally should be attempted if initial resuscitative efforts have not been successful.

Severe life-threatening hyperkalemia, although unusual in a dialyzed patient, can occur in the presence of underlying catabolic illness or with a prolonged period of hypotension and low flow. Patients who are hyperkalemic can have profoundly slow heart rates, particularly if they have been treated with β-blockers or calcium channel blockers. If a dialysis patient is in cardiac arrest, it should be assumed that hyperkalemia is present, and IV calcium should be given immediately.

Shortness of Breath. Shortness of breath in dialysis patients generally is caused by volume overload. In the patient who becomes short of breath while being dialyzed, however, other causes must be sought—primarily sudden cardiac failure, pericardial tamponade, pleural effusion, or pleural hemorrhage. Air embolism and anaphylactoid reactions are unusual causes. Pneumonia or underlying reactive airway disease may be responsible.

Chest Pain. Cardiovascular disease is a leading cause of death in patients with CKD, and most episodes of chest pain occurring during dialysis are likely to be ischemic in origin. Most dialysis patients have risk factors for coronary artery disease, related to CKD itself or to the underlying condition that led to renal failure, and many have well-documented coronary artery disease. CKD is commonly associated with hypertension, hyperlipidemia, carbohydrate intolerance, and disturbances of calcium and phosphorus metabolism. In addition, dialysis patients may be anemic, and many are chronically volume-overloaded. During hemodialysis, these underlying factors may be added to acute physiologic stresses such as transient hypotension and hypoxemia, which often are associated with the dialysis procedure, thereby increasing myocardial oxygen demand while decreasing oxygen delivery.

In evaluating presumed ischemic chest pain in a patient with CKD, reversible precipitants should be considered. It should be determined whether increasing anemia, poorly controlled hypertension, or uncorrected volume overload are factors, particularly when a patient whose angina has been stable begins to experience more frequent or more severe anginal episodes. Patients who repeatedly experience chest pain during dialysis are candidates for a complete cardiac evaluation. Dialysis patients who have repeated ED visits for chest pain should have a coordinated strategy developed by their nephrologist and cardiologist to set guidelines regarding further admissions.

The presence of renal failure and its associated electrolyte and acid-base disturbances does not obscure the usual electrocardiographic changes of angina or acute myocardial infarction. The pattern of change of serum cardiac enzyme levels with acute infarction also is not altered by CKD, although the baseline level of these enzymes may be higher than in the general population.[10-12] Troponin appears to perform best as a marker of infarction in patients with CKD.[10-12] Treatment of ischemic chest pain is the same as for other populations.

Among nonischemic causes of chest pain, pericarditis should always be a consideration, even in the well-dialyzed patient. The presentation is essentially the same as in nonrenal patients; fever, a friction rub, or atrial dysrhythmias may be associated findings. Signs of pericardial effusion or early tamponade should be sought by bedside ultrasonography. Indomethacin often is effective in relieving pain, but some patients eventually require further measures, such as pericardiocentesis with corticosteroid instillation or pericardial stripping. Patients with pericarditis may require more frequent or intensified dialysis because pericarditis is thought to be a marker for inadequate dialysis.[8]

Neurologic Dysfunction. Neurologic symptoms during or immediately after hemodialysis may be caused by disequilibrium syndrome, a constellation of symptoms and signs thought to result from rapid changes in body fluid composition and osmolality during hemodialysis. It usually occurs only in patients with high BUN levels who are just starting hemodialysis and does not occur with peritoneal dialysis. Typically, patients have headache, dizziness, nausea, vomiting, and muscle cramps, but in more severe cases features may include altered mental status, seizures, or coma. Symptoms resolve over several hours as fluid and solutes are redistributed across cell membranes.

Altered mental status in the CKD patient should not be attributed to disequilibrium syndrome unless other causes have been ruled out (Box 83.11), particularly when symptoms persist, fluctuate, or worsen during a reasonable period of observation. Likewise, when seizures occur during dialysis, they should not be attributed to disequilibrium syndrome without considering other potentially serious causes, even in patients who have had seizures in the past. Any new focal neurologic abnormality requires an immediate head CT scan to detect intracranial hemorrhage. Similarly, if fever or other evidence of infection is present, meningitis should be a serious consideration. Other considerations include hyperglycemia and hypoglycemia, especially in the diabetic patient, as well as electrolyte abnormalities, hypoxic states, hypotension, and other toxic or metabolic causes. The acute treatment of seizures in patients with CKD is essentially the same as for other populations.

Peritoneal Dialysis

As with hemodialysis, most of the complications of peritoneal dialysis are related to the dialysis access device, in this case the peritoneal catheter. In contrast to hemodialysis, however, the dialytic process in peritoneal dialysis occasions few immediate difficulties.

Peritonitis is the most common complication of peritoneal dialysis. Fortunately, it is generally much less severe than other types of peritonitis and can be treated readily on an outpatient basis, despite the continued presence of a foreign body—the Tenckhoff catheter—in the peritoneal cavity. Occasionally, when an episode of peritonitis responds poorly to antimicrobial therapy or when a patient has repeated episodes of peritonitis caused by the same organism, the catheter must be removed and the patient sustained with hemodialysis until the infection is completely cleared and a new catheter can be placed. Repeated infections carry the risk of permanently altering peritoneal permeability or effective surface area and necessitating a permanent switch to hemodialysis.

Peritonitis in patients who are on peritoneal dialysis is presumably caused by inadvertent bacterial contamination of the dialysate or tubing during an exchange or by extension of an infection of the exit site or subcutaneous tunnel into the peritoneal cavity. Most cases of peritonitis are caused by *Staphylococcus aureus* or *Staphylococcus epidermidis,* and most of the remainder (≈30%) by gram-negative enteric organisms.[13] Fungal infections are uncommon but generally are refractory to medical therapy and are often considered as an indication for catheter removal. Polymicrobial infection suggests direct contamination from the GI tract and mandates a search for the site of perforation or fistula, although such a source is identified in only a minority of cases. No organism is identified in approximately 10% to 20% of cases of peritoneal dialysis–associated peritonitis.

The diagnosis of peritonitis usually is made by the patient when a cloudy dialysis effluent is noted, corresponding with the appearance of white blood cells (WBCs) in the dialysate. Peritonitis is often accompanied by nonspecific abdominal pain, malaise, or fever. When a patient has fever or abdominal symptoms, even in the absence of cloudy fluid, it is advisable to consider peritonitis and check the fluid, because early peritonitis may manifest in an atypical manner. In more severe cases, peritonitis is accompanied by nausea, vomiting, severe pain, and hypotension, necessitating hospitalization and consideration of the possibility of acute surgical disease.

In the ED setting, the diagnosis of peritonitis is confirmed by the finding of more than 100 WBCs/mm^3 in the peritoneal fluid, with more than 50% neutrophils, or by a positive result on Gram stain. A sample of fluid is obtained for analysis. If a specialized dialysis nurse

is available to obtain the fluid, this may be preferable. If not, the fluid is obtained through the use of sterile technique. Fluid is sent for cell count and differential, Gram staining, and culture, with the use of blood culture bottles.

Peritoneal dialysis–associated peritonitis is treated with an initial intraperitoneal (IP) loading dose of antibiotic, followed by a 10- to 14-day course of IP antibiotics self-administered by the patient on an outpatient basis. After the diagnosis has been confirmed, consultation with the patient's nephrologist or dialysis nurse specialist is indicated to determine antibiotic therapy and to plan for outpatient management and follow-up evaluation or, occasionally, if peritonitis is severe or outpatient management is precluded by psychosocial considerations, for hospitalization. A common treatment regimen is a loading dose of vancomycin, 15 to 30 mg/kg IP, followed by further IP doses every 4 to 7 days, plus ceftazidime or cefepime, 1 g IP, or gentamicin, 0.6 mg/kg IP. The last two regimens are given as a loading dose followed by maintenance doses administered IP once daily at the time of an exchange.[13] Heparin, 500 to 1000 units, may also be added to each liter of dialysate for the first few days of treatment to help reduce the formation of fibrin strands that may obstruct the catheter. Patients should be seen by the dialysis nurse in 24 to 48 hours for assessment of the response to therapy and adjustment of antibiotic therapy as necessary after review of the results of culture and sensitivity testing.

Catheter contamination or leaks from the catheter, tubing, or dialysate bag should be managed in the same fashion as for frank peritonitis. The site and cause of leakage are identified, and damaged elements are promptly replaced. Occasionally, with leakage of peritoneal fluid from around the catheter, surgical correction of the underlying problem will be necessary.

Patients who have severe abdominal pain, vomiting, ileus, chills or high fever, or hypotension require hospital admission and management. Likewise, patients with severe underlying illness and those who cannot reliably perform exchanges or administer antibiotics at home also require inpatient management. Dialysis exchanges are continued on the same schedule. The inpatient antibiotic regimen is essentially the same as for outpatients.

Perhaps the most serious potential pitfall in caring for the patient maintained on peritoneal dialysis with abdominal pain or other signs of peritonitis is to overlook other serious intra-abdominal conditions whose presentation may mimic that of peritonitis. Patients on peritoneal dialysis are at increased risk for abdominal wall or inguinal hernia because of chronically increased intra-abdominal pressures; previous abdominal surgery also places them at risk for hernia, as well as for obstruction secondary to adhesions. The manifestations of serious disorders unrelated to dialysis (e.g., acute appendicitis, diverticulitis, cholecystitis, acute pancreatitis, ischemic bowel, perforated viscus, or spontaneous bacterial peritonitis in patients with chronic liver disease) also may be attributed to ordinary peritoneal dialysis–associated peritonitis, with the potential for disastrous consequences. The accessibility of the peritoneal fluid for examination may prove to be helpful in documenting the presence of an inflammatory process, but it also has the potential to mislead ED investigation of its cause. A finding of brownish or fecal material in the peritoneal drainage should suggest a ruptured viscus until proven otherwise and immediate surgical consultation should be sought. Detection of a localized tenderness, palpable mass, or incarcerated hernia on physical examination can be extremely helpful in making the diagnosis. Plain abdominal radiography or abdominal CT may be useful for demonstrating the presence of ileus, but pneumoperitoneum may reflect only the introduction of air during a recent fluid exchange rather than a perforated viscus.

Infection of the catheter exit site or tunnel is another relatively common problem for which the patient on chronic peritoneal dialysis may seek care in the ED. These infections tend to be caused by typical skin flora and manifest with local signs of infection. Although not serious in themselves, exit site infections may lead to infection of the subcutaneous tunnel, which can cause repeated episodes of peritonitis and may ultimately necessitate removal of the catheter. Any visible exudate is cultured and Gram-stained and therapy with an oral antibiotic such as cephalexin or dicloxacillin is started, pending the results of culture and sensitivity testing. The patient is instructed to cleanse the site meticulously several times a day using povidone-iodine or peroxide solution.

Tunnel infections can be difficult to detect on physical examination and may be suspected only after the patient has several bouts of peritonitis caused by the same organism. As with other closed space infections, tunnel infections tend to be difficult to eradicate unless the tunnel is partially unroofed and drained.

Patients maintained on peritoneal dialysis also may come to the ED with positional or mechanical problems with the site, of which the most common is failure of the dialysate to drain completely at the time of an exchange. Occasionally this problem is caused simply by kinking or inadvertent clamping of the external catheter or tubing. More often, however, it is the result of catheter obstruction by fibrinous debris or kinking or migration of the catheter within the peritoneal cavity, often associated with constipation. Catheter position is best assessed by a CT scan of the abdomen. Specific intervention may be guided by a contrast catheterogram. Fibrinolytic agents have been used successfully to open occluded catheters, but surgical intervention for catheter replacement often is required. Severe metabolic disturbances are much less common among patients on peritoneal dialysis than patients on hemodialysis, because in the former group dialysis is being performed essentially continuously and the blood remains in near-equilibrium with the dialysate. However, significant disturbances do occasionally occur, usually in association with hypercatabolic states, major dietary indiscretions, or significant GI fluid loss. One derangement that occurs occasionally in diabetic patients undergoing peritoneal dialysis is a syndrome of severe hyperglycemia—sometimes even despite continuation of the usual insulin dose—that results from absorption of glucose from the hyperosmolar dialysate, with associated nonspecific symptoms of malaise, weakness, and headache. Although glucose levels may be as high as 1500 mg/dL in these patients, they cannot undergo an osmotic diuresis and remain clinically euvolemic. Correction of hyperglycemia must be undertaken carefully to avoid causing rapid osmolar and volume shifts.

CHAPTER 83: QUESTIONS AND ANSWERS

1. Of the following choices, which is the correct match between type of urine cast and pathologic condition?
- **a.** Fatty casts—glomerulonephritis
- **b.** Granular casts—renal parenchymal infection
- **c.** Hyaline casts—dehydration, exercise
- **d.** Red cell casts—nephrotic syndrome
- **e.** White cell casts—acute tubular necrosis (ATN)

Answer: c. Hyaline casts are associated with dehydration, exercise, and glomerular proteinuria. The following are the other correct associations:
- Fatty casts—nephrotic syndrome
- Red cell casts—glomerulonephritis
- White cell casts—renal parenchymal infection
- Granular casts—ATN

2. A 34-year-old man with chronic kidney disease has missed his last two hemodialysis treatments and presents with generalized fatigue and dyspnea on exertion. Vital signs include a blood pressure of 165/94 mm Hg but are otherwise normal. Room air Sao_2 is 94% at rest. A portable chest x-ray shows vascular congestion. Which of the following is an indication for immediate dialysis?
- **a.** Blood urea nitrogen (BUN) level of 87 mg/dL and serum creatinine level of 10.6 mg/dL
- **b.** Serum calcium level of 6.8 mg/dL and serum albumin level of 3.0 g/dL
- **c.** Serum potassium level of 7.6 mEq/L (not hemolyzed)
- **d.** Serum sodium level of 124 mEq/L
- **e.** Serum troponin level of 0.08 ng/mL

Answer: c. Severe hyperkalemia is an indication for immediate dialysis in this patient. An ECG should be obtained stat to determine the degree of cardiotoxicity, and immediate medical treatment for hyperkalemia should be given while awaiting initiation of dialysis. Abnormalities of the serum sodium or calcium level can generally be treated without hemodialysis. A minimal troponin level elevation may be seen in patients with chronic kidney disease, but does not generally require specific treatment without other signs of cardiac ischemia; dialysis is not required.

3. What is the most common cause of nontraumatic hematuria?
- **a.** Carcinoma of the kidney or bladder
- **b.** Cystitis
- **c.** Kidney stones
- **d.** Prostatic hyperplasia
- **e.** Transfusion reaction

Answer: c. In descending frequency, the most common causes are kidney stones, lower urinary tract infection (UTI), benign prostatic hypertrophy (BPH), carcinoma of the kidney or bladder, urethritis, and glomerulonephritis.

4. A 53-year-old man presents with painless gross hematuria. His only past medical history is an aortic valve replacement for which he takes warfarin. The physical examination is nonfocal. Laboratory evaluation is remarkable for a normal chemistry panel and blood count, too numerous to count (TNTC) red blood cells (RBCs) on urinalysis, and international normalized ratio (INR) of 1.8. What is the next indicated step?
- **a.** Admission and observation
- **b.** Parenteral vitamin K
- **c.** Reassurance
- **d.** Renal imaging
- **e.** Withholding warfarin (Coumadin) for 3 days

Answer: d. When hematuria is associated with anticoagulant use, underlying disease can be identified in a significant proportion of patients.

5. A 33-year-old woman presents with mild nonfocal abdominal pain and subjective fever. Her past medical history is significant for hypertension-induced renal failure, for which she is on peritoneal dialysis (PD). The physical examination is remarkable for a temperature of 38°C (100.4°F), blood pressure 190/110 mm Hg, and mild nonfocal abdominal pain. Slightly cloudy peritoneal fluid is aspirated from the PD catheter and sent for analysis. Which of the following statements regarding this patient's condition is correct?
- **a.** A peritoneal fluid white blood cell (WBC) count >50/mm^3 is diagnostic.
- **b.** Intravenous antibiotics should be started empirically.

CHAPTER 83: QUESTIONS AND ANSWERS—cont'd

c. Most cases are due to *Staphylococcus*.
d. No organism is identified in 50% of cases.
e. Polymicrobial infections suggest sample contamination.

Answer: c. Most PD-associated cases of peritonitis are due to *Staphylococcus aureus* or *Staphylococcus epidermidis*. No organism is identified in 20% of cases. A polymicrobial infection warrants GI evaluation for possible perforation or intra-abdominal abscess. A PD fluid count >100 cells/mm^3, with a neutrophil count >50% or positive Gram stain, is considered confirmatory. Treatment is typically with intraperitoneal antibiotics given for a 10- to 14-day course.

Sexually Transmitted Infections

Jeffry McKinzie

KEY CONCEPTS

- The emergency department (ED) diagnosis of sexually transmitted infections (STIs) is often based on clinical findings. Empirical antibiotic treatment is warranted to cover the most likely infecting organisms based upon history and physical examination findings. Rapidly available diagnostic tests (Gram stain, darkfield microscopy, wet mount microscopy, and other point-of-care tests) increase diagnostic sensitivity and specificity.
- Confirmatory diagnostic studies (PCR, culture, serology, and others) should be considered even when results are not immediately available. A mechanism for follow-up of test results should be established and appropriate patient contact information obtained.
- STIs frequently coexist. Diagnosis of one STI should prompt consideration and screening for others, including HIV.
- Genital herpes, the most common ulcerating STI, is often transmitted by persons who are unaware that they are infected or are asymptomatic at the time of transmission.
- In a patient with a genital ulcer, visualization of spirochetes on darkfield microscopy is highly specific for the diagnosis of syphilis and provides rapid confirmatory results.
- Single-dose antibiotic therapy should be used for treatment of STIs when possible. Directly observed therapy administered in the ED enhances treatment compliance. Single-dose antibiotic therapy is recommended for treatment of uncomplicated gonorrhea, primary and secondary syphilis, chancroid, and trichomoniasis in men.
- HIV, syphilis, gonorrhea, chlamydia, and chancroid are reportable diseases in all 50 of the United States (US).

FOUNDATIONS

Sexually transmitted infections ((STIs) are a diverse group of conditions caused by more than 30 viral, bacterial, and parasitic organisms that are transmitted through sexual contact. Four of the pathogens that contribute most to the global incidence of STIs (chlamydia, gonorrhea, syphilis, and trichomoniasis) are curable, often with a single dose of an antibiotic.[1,2] More than 1 million newly acquired cases of these curable STIs occur worldwide each year.[3] Viral pathogens responsible for common STIs (herpes simplex virus, human papillomavirus, and HIV) cause chronic infection in which symptoms and progression of disease can be modified with appropriate antiviral therapy.

STIs are seen across all demographic, cultural, and socioeconomic strata, and all sexually active persons are at risk for acquiring them. Factors associated with higher risk for STIs reflect the importance of individual sexual practices and risk-taking behaviors (i.e., multiple sex partners, substance abuse, commercial sex workers, men who have sex with men, and unsafe sex practices), as well as various demographic and social determinants that influence health status (i.e., adolescents and young adults, minorities, and low socioeconomic status).

STIs are among the most common urogenital conditions encountered in the ED. The management of patients with STIs is particularly challenging for multiple reasons: (1) the clinical presentation is highly variable; (2) available diagnostic tests have limited sensitivity and results are usually delayed; (3) compliance with treatment, follow-up, and partner notification is often poor; and (4) misdiagnosis and suboptimal treatment can result in serious sequelae. In addition to the morbidity associated with individual STIs, many of these infections also increase the risk of human immunodeficiency virus (HIV) transmission and acquisition in both the infected person and their sexual partners. Thus, STIs have a significant impact on both individual and public health.

Patients with STIs frequently present with complaints related to the genitalia but may also present with a variety of nonspecific dermatologic, gastrointestinal, musculoskeletal, and systemic complaints. Because the signs and symptoms of many common STIs are often nonspecific, one must maintain a high level of awareness for these conditions and their associated complications. A thorough history, including sexual history, and focused physical examination facilitate appropriate diagnosis and treatment. The sexual history should include number and gender of sexual partners, types of sexual practices, use of barrier contraception (condoms), and past history of STIs. Obtaining an accurate sexual history may be difficult due to the sensitive nature of the subject, lack of established physician-patient rapport, and other constraints of the ED setting. Evaluation is facilitated by the use of a nonjudgmental approach, maintenance of patient privacy, and assurance of confidentiality.

The differential diagnosis for STIs is extensive, including many other infectious and noninfectious conditions (Table 84.1). Most STIs can be broadly categorized as conditions characterized by one of the following manifestations: genital ulcers, genital discharge, epithelial cell infections, and infestation by ectoparasites. Some STIs, such as syphilis, frequently have associated systemic symptoms in addition to their genitourinary manifestations. Other STIs, such as HIV, may have systemic manifestations in the absence of genitourinary signs and symptoms.

STIs frequently coexist. Diagnosis of one STI should prompt consideration of other coexisting infections, which may not be clinically apparent. Screening for other STIs, including HIV, should be considered, because early diagnosis and treatment benefits both the individual patient and the public health. Despite current recommendations from the Centers for Disease Control and Prevention (CDC) for routine HIV screening among patients age 13 to 64 years in all health care settings, systematic HIV testing is not routinely performed in most EDs. When available, rapid HIV testing should be considered. Patients should be counseled regarding the need for HIV testing if it is not performed in the ED.

Empirical antibiotic treatment designed to cover the most likely infecting organisms is recommended for patients with suspected STIs

TABLE 84.1 Differential Diagnosis of Common Sexually Transmitted Infection Syndromes

Genital Ulcers	Genital Discharge	Epithelial Cell Lesions	Ectoparasites
Genital herpes	Gonorrhea	Genital warts	Pubic lice
Primary syphilis	Chlamydia	Secondary syphilis	Scabies
Chancroid	Nongonococcal urethritis (NGU)	Molluscum contagiosum	Other lice (body, head)
Lymphogranuloma venereum	Pelvic inflammatory disease	Neoplasm	Other mites (chiggers)
Granuloma inguinale	Trichomoniasis	Nevi	Ticks
Trauma	Bacterial vaginosis	Skin tags	
Neoplasm	*Candida* vaginitis		
Behçet disease	Foreign body		
Abscess (draining)	Irritants/allergens		

to maximize eradication of disease in the individual patient and reduce the spread of infection to other susceptible persons. Empirical therapy is particularly important when there are concerns about the patient's ability to obtain appropriate follow-up care. Confirmatory diagnostic studies should still be considered, even when empirical therapy is provided. Microbiologic diagnosis confirms the appropriate choice of empirical therapy, provides guidance for potential changes in treatment, and facilitates reporting of specific STIs to public health authorities. Point-of-care rapid diagnostic testing may minimize the need for empirical antibiotic treatment by providing confirmatory test results before treatment decisions are made and prior to patient discharge from the ED. This reduces the unnecessary use of antibiotics with associated costs, side effects, and development of antimicrobial resistance.

The diagnosis of an STIs provides the physician with a "teachable moment" to educate the patient regarding important factors, including (1) nature of the infection and how it is transmitted; (2) compliance with prescribed therapy and recommended follow-up; (3) importance of preventive measures, including condom use and other safe sex practices; and (4) partner notification and treatment. Patients diagnosed with STIs should be counseled to abstain from sexual intercourse for at least 7 days after the patient and partner(s) complete treatment. Proper counseling helps to ensure the success of initial treatment and reduce the incidence of reinfection. When the diagnosis of an STI is suspected but not confirmed, the patient should be informed of the uncertainty of the diagnosis and the rationale for empirical treatment. The physician should be sensitive to the stress and anxiety that may ensue when discussing the diagnosis of an STI, particularly with a patient who assumes he or she is in a monogamous relationship. A respectful, nonjudgmental, and compassionate approach should be maintained.

The CDC recommends the use of expedited partner therapy (EPT) to ensure treatment in sexual partners of selected patients diagnosed with gonorrhea or chlamydia. With EPT, the clinician provides patient-delivered medication or prescriptions for sexual partners without personally evaluating them. The use of EPT in the ED is potentially problematic due to lack of knowledge regarding the partner's medical history, allergies, pregnancy status, and other factors. In addition, some states prohibit the prescribing or dispensing of medications to patients who have not been seen and are unknown to the provider. Updated information regarding the use of EPT and applicable state regulations is available online from the CDC website.[4] All patients diagnosed with an STI in the ED should be advised to notify their sexual partners to seek prompt evaluation and treatment.

An organized mechanism for follow-up of positive diagnostic test results is recommended when these results are not available until after the patient and physician have left the ED. Obtaining accurate contact information at the time of the initial visit is important in ensuring timely patient notification. Reporting requirements vary by state, but the following STIs must be reported in all 50 states: gonorrhea, chlamydia, syphilis, chancroid, and HIV. Reporting may be laboratory-based or provider-based, or both. The clinician should be familiar with applicable state reporting requirements and the reporting mechanism used at their hospital.

This chapter reviews the clinical features, diagnosis, and treatment of selected common STIs encountered in the ED setting. Readers are referred to the "Sexually Transmitted Infections Treatment Guidelines" published by the CDC for additional information regarding the diagnosis and treatment of these conditions, as well as other less common STIs.[5] Updates regarding changes in treatment guidelines are provided by the CDC in the *Morbidity and Mortality Weekly Report,* available at www.cdc.gov/mmwr.

DISORDERS CHARACTERIZED BY GENITAL ULCERS

Genital ulcers may be caused by several different STIs, as well as various other infectious and noninfectious conditions. Genital herpes is the most common ulcerating STI seen in the United States, followed by syphilis. Chancroid is an uncommon cause of genital ulcers in the United States, and other STIs that may be manifested by genital ulcers (lymphogranuloma venereum, granuloma inguinale) are rare. Although the history, clinical appearance of the ulcers, and other associated findings provide helpful clues in differentiating the various causes of genital ulcers, these features are not specific enough to provide a definitive diagnosis. Diagnostic studies such as darkfield microscopy, serology for syphilis, polymerase chain reaction (PCR), and viral culture should be considered to discriminate between the various etiologies and facilitate a definitive diagnosis, even when empirical therapy is initiated. Diagnostic testing is particularly important in patients that are unresponsive to previous empirical antibiotic therapy. Ulcerating STIs play an important role in facilitating the transmission and acquisition of HIV.

Herpes

Background and Importance

Genital herpes is a lifelong viral infection caused by one of two types of herpes simplex virus (HSV): HSV-1 or HSV-2. Sexual transmission occurs more commonly with HSV-2, but both types of HSV can be transmitted through sexual or nonsexual contact. Many cases of HSV are undiagnosed. HSV is often transmitted by persons who are unaware that they are infected, or who are asymptomatic at the time of transmission. HSV transmission occurs through viral contact with a break in the skin or intact mucous membranes. The average incubation

Fig. 84.1 Genital herpes lesions on the penile shaft.

period is 4 days but may range from 2 to 12 days. The virus ascends via sensory nerves to the dorsal root ganglia, where it becomes latent but may reactivate periodically. Herpes, like other ulcerating STIs, facilitates the transmission and acquisition of HIV. Herpes infection in pregnant women may result in transmission to the infant at the time of delivery, with devastating associated neonatal morbidity and mortality.

Clinical Features

Typical herpetic lesions begin as a cluster of small erythematous painful vesicles, which quickly ulcerate (Fig. 84.1). Lesions may occur anywhere the organism is inoculated, but they are typically seen on the skin of the external genitalia, perineum, and buttocks and on the mucous membranes of the vagina, rectum, and oropharynx. Primary infection occurs when a patient is infected with HSV-1 or HSV-2 with no preexisting antibodies to either type. The primary infection is usually more painful and symptomatic, with associated tender regional lymphadenopathy, fever, malaise, headache, and other systemic symptoms. Dysuria is common due to the proximity of the lesions to the urethra. The symptoms of untreated primary infection typically last from 2 to 4 weeks before resolving spontaneously.

Recurrent episodes of genital herpes tend to be less symptomatic and shorter in duration, with lesions occurring in the same distribution due to reactivation of latent HSV infection in the affected nerve roots. Recurrences are more frequent with infection caused by HSV-2 than with HSV-1. Recurrent outbreaks are often heralded by prodromal symptoms of itching, burning, and paresthesias prior to the development of skin or mucous membrane lesions. Reactivation of latent HSV may occur in response to a variety of stressors, including acute illness or injury, immunosuppression, psychological stress, and menses. Recurrences typically become less frequent and less severe over time. Extragenital complications of HSV infection include meningoencephalitis, transverse myelitis, hepatitis, pneumonitis, and disseminated infection. Asymptomatic viral shedding and transmission occurs even in the absence of visible lesions on the skin or mucous membranes.

Diagnostic Testing

The diagnosis of genital herpes is frequently made based upon clinical findings. Although the presence of typical skin or mucous membrane lesions is suggestive of herpes, the clinical diagnosis is both insensitive and nonspecific. A history of similar lesions in the same anatomic distribution supports the clinical diagnosis. HSV type-specific nucleic acid amplification tests (NAATs) are the diagnostic tests of choice, with the highest sensitivity and specificity in the presence of active lesions. Viral culture is also specific but less sensitive than NAATs. Darkfield microscopy and serologic testing for syphilis should be considered to help differentiate cases of syphilis. The utility of these diagnostic studies is limited in the ED because test results are delayed, but results may be helpful at the time of follow-up. Direct fluorescent antibody (DFA) and serology for HSV are available, but less commonly used in the ED setting. Cytologic testing (Tzanck preparation) is nonspecific and insensitive and should not be relied upon to make the diagnosis of HSV.

Management

Genital herpes is treated with the antiviral medications acyclovir, famciclovir, or valacyclovir. Antiviral therapy is not curative but has been shown to decrease the duration and severity of symptoms and the development of complicated HSV infection, particularly when started early during the primary infection. Prompt initiation of antiviral treatment is key to obtaining optimal clinical benefit. Although most studies have evaluated drug initiation within 72 hours of symptom onset, antiviral therapy may still be offered after this time frame in the presence of ongoing symptoms and the development of new lesions. Multiple regimens are available for treatment of primary and recurrent episodes of genital herpes with oral antiviral medications (Table 84.2). Oral antiviral therapy is generally well tolerated with few side effects. Suppressive therapy with daily antiviral use has been shown to decrease the frequency of recurrences while the medication is being taken, but it does not affect the frequency or severity of recurrences after the drug is discontinued. Topical antiviral therapy provides minimal clinical benefit and is not recommended.

Disposition

Most patients with genital herpes are managed as outpatients. Hospitalization for parenteral therapy with acyclovir is indicated for systemic complications of HSV infection, including meningoencephalitis, hepatitis, pneumonitis, and disseminated infection. Patients with genital herpes should be counseled that transmission may occur even in the absence of clinical symptoms. Condom use has been shown to reduce but not eliminate the incidence of HSV transmission. Discordant couples (i.e., those in which one partner is HSV+) should be advised to avoid sexual contact during active outbreaks, which is when viral transmission is highest. Condoms should be used during asymptomatic periods. Patients with genital herpes should also be counseled regarding the increased risk of acquisition and transmission of HIV in the presence of genital ulcers.

Syphilis

Background and Importance

Humans are the only known host for *Treponema pallidum,* the spirochete that causes syphilis. The incidence of syphilis has declined significantly since penicillin became widely available in 1945, but outbreaks still occur intermittently. After a progressive decline in the incidence of syphilis from 1990 to 2000, there has been an increase in recent years. More than 35,000 cases of primary and secondary syphilis were reported to the CDC in 2018.[6] The rates of primary and secondary syphilis are higher among those between 20 to 34 years old, minority groups, and men who have sex with men (MSM). It is more common in

TABLE 84.2 Treatment of Common Ulcerating Sexually Transmitted Infections[a]

Disease	Recommended Treatments
Herpes simplex	
Primary episode	Acyclovir 400 mg PO tid for 7 to 10 days *or* Valacyclovir 1000 mg PO bid for 7 to 10 days *or* Famciclovir 250 mg PO tid for 7 to 10 days
Recurrent episodes	Acyclovir 800 mg PO bid for 5 days *or* Acyclovir 800 mg PO tid for 2 days *or* Valacyclovir 500 mg PO bid for 3 days *or* Valacyclovir 1000 mg PO daily for 5 days *or* Famciclovir 125 mg PO bid for 5 days *or* Famciclovir 1000 mg PO bid for 1 day *or* Famciclovir 500 mg PO once, then 250 mg bid for 2 days
Syphilis[b]	
Primary, secondary, and early latent syphilis	Benzathine penicillin G 2.4 million units IM single dose
Neurosyphilis	Aqueous penicillin G 3 to 4 million units IV every 4 hours for 10 to 14 days
Chancroid	Ceftriaxone 250 mg IM single dose *or* Azithromycin 1000 mg PO single dose *or* Ciprofloxacin 500 mg PO bid for 3 days Erythromycin 500 mg by mouth TID × 7 days

[a]Alternative treatment regimens for selected patients (including pregnancy, drug allergies) can be found at www.cdc.gov/std/treatment.
[b]Pregnant women with syphilis who are allergic to penicillin should be admitted for desensitization and treatment with penicillin.
IM, Intramuscular; *PO,* per os (by mouth).

the western and southeastern United States compared to other regions of the country.

Clinical Features

Syphilis has been called "the great imitator," because its clinical manifestations are protean. The classification and staging of syphilis based upon clinical and serologic findings was updated in 2017.[7] The primary and secondary stages of syphilis are most commonly seen in the ED setting. Transmission occurs when the spirochetes gain access through disrupted epithelium of the skin or mucous membranes. The average incubation period is approximately 21 days but may range from 3 to 90 days.

Primary syphilis is initially manifested by the development of a painless papule at the site of inoculation. The lesion ulcerates, forming the chancre of primary syphilis (Fig. 84.2). The chancre is classically described as a relatively painless clean-based ulcer with well demarcated indurated edges, measuring approximately 1 to 2 cm in size. Nontender regional lymphadenopathy may be seen. Although the chancre often occurs in the genital or perianal area, it may occur at any site of inoculation, including the oropharynx, breasts, hands, and other sites. The chancre will heal spontaneously over the course of 3 to 6 weeks. Because the chancre is relatively painless, it may go unnoticed by the patient.

Secondary syphilis will develop in approximately 25% of patients with primary syphilis over a period of several weeks to months. Manifestations of secondary syphilis include rash, generalized lymphadenopathy, mucous membrane lesions, and systemic symptoms. The rash is diffuse, involving the face, trunk, and extremities, including the palms and soles.

Fig. 84.2 Chancre of primary syphilis. (From: Morse S, Ballard RC, Holmes KK, et al, eds. *Atlas of Sexually Transmitted Diseases and AIDS*, ed 4. London: Saunders/Elsevier; 2010: Fig. 7.9, p 185.)

Fig. 84.3 Rash of secondary syphilis on palms and soles. (From: Morse S, Ballard RC, Holmes KK, et al, eds. *Atlas of Sexually Transmitted Diseases and AIDS*, ed 4. London: Saunders/Elsevier; 2010: Fig. 7.24, p 188.)

The appearance of the rash is highly variable. Lesions may be macular, papular, scaly, or pustular in appearance (Fig. 84.3). Mucous patches are multiple shallow erosions of the oropharyngeal mucosa that are usually accompanied by other dermatologic and systemic manifestations of secondary syphilis. Condyloma lata, which resemble genital warts, are broad-based papular lesions that occur on the genitalia and perineum and typically have a moist surface appearance (Fig. 84.4). Lymphadenopathy is typically diffuse, rubbery, and nontender. Epitrochlear adenopathy is particularly suggestive of secondary syphilis. A nonspecific "moth-eaten" alopecia may be seen. Systemic manifestations include low-grade fever, anorexia, headache, malaise, myalgias, and weight loss. Symptoms of secondary syphilis will resolve without treatment, with subsequent progression to latent syphilis.

Patients infected with syphilis who exhibit no clinical manifestations of primary or secondary syphilis are classified as *early nonprimary, nonsecondary syphilis* if infection occurred within the past 12 months. *Unknown duration or late syphilis* includes those patients infected more than 12 months previously and those in whom time

Fig. 84.4 Condyloma lata of secondary syphilis.

of infection is unknown.[8] Neurologic, ophthalmologic, and otologic manifestations can occur at any stage of syphilis. *Neurosyphilis* may be manifested by meningitis, dementia, tabes dorsalis, and general paresis. Patients with *ocular syphilis* may exhibit uveitis, optic neuropathy, and retinal vasculitis. Otic syphilis may cause sensorineural hearing loss, vertigo, and tinnitus.

Tertiary syphilis, which includes cardiovascular manifestations and gummatous disease, is uncommon in the United States. Aortitis, aortic aneurysm, and gummatous lesions of the skin, bones, and other organs may be seen. In patients with untreated syphilis, the estimated risk of eventual progression to tertiary syphilis ranges from 25% to 40%.

Congenital syphilis is transmitted perinatally to the fetus and has significant associated morbidity in infected children. Although relatively uncommon in the United States, congenital syphilis has increased in prevalence in recent years.

Diagnostic Testing

T. pallidum is fastidious and cannot be cultured in the laboratory. The diagnosis of syphilis can be confirmed with darkfield microscopy or by serologic testing. Visualization of the spirochete on darkfield examination of specimens obtained from a chancre or from the moist lesions of secondary syphilis provides an immediate diagnosis. Darkfield microscopy is particularly useful in primary syphilis when false-negative serology is common. The utility of darkfield microscopy is limited by the need for specialized laboratory equipment and appropriately trained personnel, which are lacking at many hospitals.

Serologic tests for syphilis include nonspecific nontreponemal tests and specific treponemal tests. Nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). The VDRL and RPR provide quantitative measurements of nonspecific antibodies that are produced in response to *T. pallidum* infection. The titers correlate with disease activity, typically rising with active syphilis infection and declining after successful treatment. The sensitivity of nontreponemal tests is approximately 70% to 80% in primary syphilis but rises to nearly 100% in secondary syphilis. False-positive nontreponemal tests may be seen in a variety of conditions, including pregnancy, endocarditis, autoimmune disease, and other acute or chronic illnesses. A positive nontreponemal test should always be confirmed with a specific treponemal test. Specific treponemal tests include the *T. pallidum* enzyme immunoassay (TP-EIA), the fluorescent treponemal antibody absorption (FTA-ABS) and the microhemagglutination test for antibodies to *T. pallidum* (MHA-TP). These treponemal tests provide qualitative measurements of specific antitreponemal antibodies. Although these treponemal tests are highly specific for syphilis, they may remain positive for life even after successful treatment and cure.

The traditional testing algorithm begins with a nontreponemal test for screening purposes, because the quantitative titers serve as a better marker for acute infection. A specific treponemal test is used to confirm the diagnosis when the nontreponemal test is positive. An acceptable alternative testing algorithm begins with the specific treponemal test, which is then confirmed with the quantitative titers of the nontreponemal test. Both types of serologic testing are necessary for the proper diagnosis of syphilis.

Management

Penicillin is the cornerstone of treatment for syphilis, with *T. pallidum* remaining highly sensitive to penicillin. The dosage and preparation of penicillin and the length of treatment vary depending upon the stage of the disease and the associated clinical manifestations (see Table 84.2). A single dose of long-acting benzathine penicillin G (2.4 million units intramuscularly [IM]) is curative in the majority of cases of primary and secondary syphilis. Patients with significant penicillin allergy can be treated with doxycycline or tetracycline (preferred in late latent syphilis) for 2 weeks if no contraindication to these drugs exists. Ceftriaxone has antitreponemal activity, but the optimal dosage and duration of therapy have not been established. Azithromycin has some efficacy but is not recommended as a first-line therapy due to documented resistance and treatment failures. Penicillin remains the drug of choice for patients with neurosyphilis, congenital syphilis, and syphilis during pregnancy even in the presence of penicillin allergy, due to the known efficacy of penicillin and the absence of proven alternative therapies. Patients with these conditions should be admitted for desensitization and treatment with penicillin.

The Jarisch-Herxheimer reaction is an acute worsening of symptoms that may develop after antibiotic therapy is initiated for syphilis. The patient typically reports worsening malaise, myalgias, and fever within 24 hours of antibiotic treatment. The condition has traditionally been thought to be caused by the sudden lysis of spirochetes, but the mechanism is poorly understood. Treatment is supportive, including rest, hydration, and antipyretics. The symptoms resolve spontaneously. Anticipatory guidance regarding the appropriate management of this common self-limited reaction may prevent a return visit to the ED.

Disposition

Most cases of syphilis are treated on an outpatient basis. Hospitalization is recommended for patients with penicillin allergy who require desensitization prior to penicillin therapy, including pregnant women with syphilis and patients with neurosyphilis or congenital syphilis.

Chancroid

Background and Importance

Chancroid is an ulcerating STI caused by the gram-negative organism *Haemophilus ducreyi.* Chancroid is common in parts of the developing world but is rare in the United States, with only 3 cases reported in 2018. Like other ulcerating STIs, chancroid is a cofactor for the transmission and acquisition of HIV.

Clinical Features

After an incubation period of less than 1 week, a tender erythematous papule develops at the site of inoculation. The initial lesion rapidly ulcerates, and multiple painful ulcers subsequently develop (Fig. 84.5). The ulcers typically have an irregular, inflamed, and "dirty" appearance compared to the well circumscribed clean-based chancre of syphilis, and the smaller punched-out appearance of herpetic ulcers. Painful inguinal lymphadenopathy is common and may progress to bubo formation. A *bubo* is a large, painful, fluctuant unilateral inguinal lymph node, which may spontaneously rupture and drain purulent material.

Fig. 84.5 Multiple vulvar ulcers due to chancroid. (From: Morse S, Ballard RC, Holmes KK, et al, eds. *Atlas of Sexually Transmitted Diseases and AIDS*, ed 4. London: Saunders/Elsevier; 2010: Fig. 8.14, p 219.)

Diagnostic Testing

Differential diagnosis of genital ulcers includes herpes and syphilis, both of which are more common than chancroid in the United States. Although the appearance of the ulcers may suggest the diagnosis of chancroid, the clinical diagnosis may be inaccurate. Darkfield microscopy and serologic testing are useful in identifying syphilis, whereas NAAT and viral culture can confirm HSV infection. Chancroid is usually a clinical diagnosis based upon the presence of typical painful genital ulcers and associated tender adenopathy. Culture provides definitive diagnosis but is difficult due to the fastidious nature of *H. ducreyi,* which requires special culture media. No FDA-approved NAAT is available in the U.S., but some clinical laboratories have developed their own NAAT and have performed the necessary Clinical Laboratory Improvement Amendment (CLIA) studies to allow for their use in the diagnosis of chancroid.

Management

Patients with chancroid are treated as outpatients. Single-dose therapy with azithromycin or ceftriaxone is recommended for suspected chancroid (see Table 84.2). Alternative treatment regimens include oral ciprofloxacin or erythromycin.

DISORDERS CHARACTERIZED BY GENITAL DISCHARGE

Foundations

Some STIs, including gonorrhea, chlamydia, trichomoniasis, and pelvic inflammatory disease (PID), are frequently characterized by the presence of genital discharge in absence of genital ulcers and lymphadenopathy. The differential diagnosis of genital discharge is broad, including infections that are not sexually transmitted and noninfectious conditions (see Table 84.1). For example, bacterial vaginosis and candidiasis are common conditions that are not considered to be sexually transmitted but are frequently found during the evaluation of a woman with vaginal discharge. Urethritis, cervicitis, and vaginitis caused by various organisms can present with associated genital discharge.

Infectious causes of urethritis are generally divided into two categories: gonococcal urethritis and nongonococcal urethritis (NGU). Urethritis occurs in men and women and may be asymptomatic, particularly in persons with NGU. When present, symptoms include dysuria, urethral pruritus, and urethral discharge. The absence of visible discharge does not exclude the diagnosis. A clinical diagnosis of urethritis can be made on the basis of any of the following findings in the setting of compatible symptoms: (1) mucoid, mucopurulent or purulent urethral discharge, (2) Gram stain of urethral discharge containing two or more white blood cells (WBCs) per oil immersion field, (3) first-void urine sediment containing 10 or more WBCs per high-power field, and (4) positive leukocyte esterase test on first-void urine. Diagnosis and management of specific causes of urethritis are discussed later.

Cervicitis is characterized by the presence of purulent or mucopurulent discharge from the endocervix and the presence of cervical friability. Many women with cervicitis are asymptomatic. The discharge may be visible in the endocervical canal or noted on an endocervical swab specimen. Cervical friability is demonstrated when endocervical bleeding is easily induced with gentle passage of a swab through the cervical os. Gonorrhea and chlamydia are common causes, but trichomonas and HSV may also cause cervicitis. Frequently, no organism is isolated despite the presence of clinical findings consistent with cervicitis. Women with cervicitis may complain of abnormal vaginal discharge, dyspareunia, and postcoital vaginal bleeding. Pelvic examination may demonstrate endocervical discharge and friability. These findings are insensitive, and the absence of these findings on history and examination do not exclude the diagnosis of cervicitis. Specific causes of cervicitis and their management are discussed later.

Gonorrhea

Background and Importance

Gonorrhea is the second most commonly reported STI in the United States, with more than 500,000 cases reported to the CDC annually. Humans are the only reservoir for the causative organism, *Neisseria gonorrhoeae,* a gram-negative intracellular diplococcus. The prevalence of gonorrhea varies widely, with higher rates of gonorrhea seen among adolescents and young adults, minorities, people with low socioeconomic status, those with a history of substance abuse, and those who engage in high-risk sexual behaviors.

Clinical Features

The signs and symptoms of gonorrhea vary depending upon the sex of the patient, the site of inoculation, and the local or systemic spread of the infection. The incubation period for gonorrhea typically ranges from 3 to 7 days. Most men with gonococcal urethritis become symptomatic within 1 to 2 weeks, prompting them to seek curative treatment. Patients complain of urethral discharge and dysuria. The discharge is usually copious and purulent, although the clinical appearance alone cannot differentiate gonococcal urethritis from NGU (see Fig. 84.6). Women with gonococcal cervicitis are often asymptomatic until ascending infection develops. Because many women remain asymptomatic for prolonged periods, a larger reservoir of untreated women exists. When present, symptoms of gonococcal cervicitis may include abnormal vaginal discharge, dyspareunia, and intermenstrual bleeding. Women with gonococcal cervicitis may also complain of dysuria due to associated urethritis.

Gonococcal proctitis may occur in men and women who engage in receptive anal intercourse and in women who are inoculated by infected vaginal secretions. Patients with gonococcal proctitis are often asymptomatic but may complain of rectal pain, tenesmus, rectal discharge, or bleeding. Anoscopy may reveal abnormal discharge and inflamed friable rectal mucosa.

Gonococcal pharyngitis is usually acquired from oral sexual exposure. Patients with pharyngitis are usually asymptomatic but may complain of sore throat. Tonsillar erythema and cervical lymphadenopathy may be present. Differentiating gonococcal pharyngitis from common

Fig. 84.6 Purulent urethral discharge due to gonococcal urethritis.

viral or bacterial forms of pharyngitis requires a careful history in patients presenting with symptoms of pharyngitis.

Gonococcal conjunctivitis was historically seen most often in infants born to infected mothers. Because infants are now routinely prophylaxed at birth, gonococcal conjunctivitis is now more common in adults who self-inoculate by rubbing the eye with contaminated fingers. Severe conjunctival injection with copious purulent discharge is typically seen. The infection can progress rapidly to corneal ulceration, perforation, and blindness if untreated.

Disseminated gonococcal infection (DGI) results from hematogenous spread of *N. gonorrhoeae.* DGI may occur in the absence of any signs or symptoms of the initial local infection. Characteristic clinical findings include rash, polyarthralgias, tenosynovitis, and septic arthritis. The rash usually consists of petechial or pustular lesions in an acral distribution on the distal extremities. The rash is sparse, with 2 to 10 skin lesions being typical and more than 40 lesions uncommon. Septic arthritis presents as a swollen, red, warm, and painful joint. One or more joints may be involved. The knees, wrists, and ankles are the most common sites. Rarer complications of DGI include hepatitis, meningitis, and myocarditis.

Diagnostic Testing

Nucleic acid amplification tests (NAATs) have replaced culture as the gold standard for the diagnosis of gonorrhea. These tests are widely available and have a higher sensitivity compared to culture. A wide variety of specimens can be used for NAATs, including first-void urine and swabs from the urethra, cervix, vagina, oropharynx, and rectum. Suitable specimens can be obtained by the examining clinician or provided by the patient.

Culture with selective Thayer Martin media is still useful in selected patients and has the advantage of allowing antimicrobial susceptibility testing. Isolation of *N. gonorrhoeae* from the blood, synovial fluid, or skin lesions establishes a definitive diagnosis of DGI, but sensitivity of these cultures is poor. The organism may be more readily identified from other sites (urethra, cervix, rectum, or pharynx) even in the absence of localized symptoms at these sites. When accompanied by the appropriate clinical presentation, identification of gonorrhea by NAATs or culture from any site is sufficient for a presumptive diagnosis of DGI. In symptomatic men, a Gram stain of urethral discharge that reveals gram-negative intracellular diplococci has a sensitivity and specificity approaching 100% for the diagnosis of gonorrhea. A positive Gram stain does not exclude coinfection with chlamydia or other organisms. Gram stain of genitourinary specimens in female patients is not recommended due to potential false-positive results caused by nonpathogenic *Neisseria* organisms that may be normal flora in the female reproductive tract.

Treatment

Recommended treatment options for gonorrhea have changed in recent years due to the increasing antimicrobial resistance of *N. gonorrhoeae.* Ceftriaxone remains the drug of choice for the treatment of gonorrhea. Single-dose therapy with an intramuscular injection of ceftriaxone 500 mg is recommended for gonococcal urethritis, cervicitis, proctitis, and pharyngitis in patients weighing <150 kg. The recommended single dose of ceftriaxone is increased to 1 g IM for patients weighing ≥150 kg (see Table 84.2). Concomitant single-dose therapy with azithromycin is no longer recommended for treatment of gonorrhea due to increasing antimicrobial resistance patterns. When chlamydial infection has not been excluded, antichlamydial therapy should also be administered (discussed later in this chapter). The use of oral cephalosporins or fluoroquinolones is also no longer recommended. DGI and gonococcal arthritis are treated with parenteral ceftriaxone 1 g daily. Several parenteral antibiotic regimens are available for treatment of severe or complicated PID (discussed later in this chapter).

Disposition

Uncomplicated gonococcal infections are treated on an outpatient basis. Hospitalization may be warranted for more severe cases of upper tract infection, such as PID or epididymo-orchitis. Admission and treatment with parenteral ceftriaxone is recommended for DGI, septic arthritis, and conjunctivitis.

Chlamydia

Background and Importance

Chlamydia is the most commonly reported STI in the United States, with more than 1.7 million cases reported to the CDC in 2018. *Chlamydia trachomatis,* an obligate intracellular organism, is the causative pathogen. Approximately 50% of men and 70% of women who are infected with chlamydia are asymptomatic. Adolescents and young adults 15 to 24 years old have the highest rate of chlamydia infection. The reported rate of chlamydia is twice as high among women compared to men, reflecting the higher number of women screened for this infection.

Clinical Features

Chlamydia infection is a common cause of NGU. When present, the urethral discharge associated with chlamydia is typically scant, mucoid, and less purulent than the discharge seen with gonorrhea. Dysuria is less pronounced and presentation is often delayed. Chlamydia cervicitis may present with mucopurulent cervical discharge or postcoital bleeding but is often asymptomatic. When untreated, chlamydia can progress to upper tract infection, including epididymitis and orchitis in men and PID in women. Patients with epididymitis and orchitis complain of unilateral scrotal pain and swelling, and they may also report symptoms of urethritis. Swelling and tenderness of the epididymis and testicle are usually present. Epididymitis is more common with chlamydia infection alone or combined gonorrhea and chlamydia infections, rather than with gonorrhea alone. Chlamydia frequently

TABLE 84.3 Treatment of Sexually Transmitted Infections Associated With Genital Discharge[a]

Disease	Recommended Treatments
Gonorrhea	
Urethritis, cervicitis, proctitis, pharyngitis	Ceftriaxone 500 mg[b] IM single dose
Chlamydia	
Urethritis, cervicitis, proctitis, pharyngitis	Doxycycline 100 mg PO bid for 7 days
Nongonococcal urethritis (NGU)	Doxycycline 100 mg PO bid for 7 days
Trichomoniasis	Men: Metronidazole 2 g PO single dose Women: Metronidazole 500 mg PO bid for 7 days

[a]Alternative treatment regimens for selected patients (including pregnancy, drug allergies) can be found at www.cdc.gov/std/treatment.
[b]For weight ≥150 kg, ceftriaxone 1 g IM single dose.
IM, Intramuscular; *PO,* per os (by mouth).

contributes to the development of PID, which may be indolent or clinically silent, but results in significant chronic sequelae.

Diagnostic Testing

Differentiation between chlamydial and gonococcal infection based solely upon history and physical examination is unreliable, and these infections frequently coexist. NAATs are the diagnostic test of choice, with sensitivity greater than 90% and specificity of 99% for the diagnosis of chlamydia. Concurrent testing for gonorrhea can be performed on the same NAATs specimen obtained from either genital or extragenital sites.

Management

The recommended treatment for chlamydia urethritis, cervicitis, pharyngitis or proctitis is doxycycline 100 mg PO bid for 7 days (Table 84.3). Single-dose azithromycin 1 g PO is no longer the preferred treatment for uncomplicated chlamydia infection, but remains an alternative treatment for use during pregnancy or when doxycycline is otherwise contraindicated. Levofloxacin may also be used in the nonpregant patient. Suspected upper genitourinary tract infection with chlamydia (i.e., epididymitis, PID) requires a longer course of antibiotic therapy ranging from 10 to 14 days (Table 84.4).

Empirical treatment for both gonorrhea and chlamydia is recommended when confirmatory test results are unavailable, because history and physical examination cannot reliably differentiate these conditions and coinfections often occur. Weight-based single-dose ceftriaxone IM plus doxycycline 100 mg PO bid for 7 days treats uncomplicated gonorrhea in addition to lower tract chlamydia infection.

Disposition

Most chlamydia infections are treated on an outpatient basis. Patients with severe upper tract infection and those with associated complications may require hospitalization for parenteral antibiotics. Indications for admission include suspected tubo-ovarian abscess, Fitz-Hugh-Curtis syndrome, patients with intractable vomiting, septic patients, those with peritonitis, prepubertal children, and women with an indwelling intrauterine device (IUD).

Nongonococcal Urethritis

NGU is most often caused by *Chlamydia trachomatis,* but may also be caused by *Trichomonas vaginalis, Mycoplasma genitalium,*

TABLE 84.4 Treatment of Complicated or Upper Genitourinary Tract Sexually Transmitted Infections[a]

Disease	Recommended Treatments
Disseminated gonorrhea	Ceftriaxone 1 g IV or IM every 24 hours *Hospitalization and infectious disease (ID) consult recommended*
Gonococcal conjunctivitis	Ceftriaxone 1 g IV or IM single dose[b] *Consider hospitalization & ID consult*
Epididymitis/orchitis	Ceftriaxone 500 mg[b] IM single dose *plus* Doxycycline 100 mg PO bid for 10 days[c] *Or* Ceftriaxone 500 mg[b] IM single dose *plus* Levofloxacin 500 mg PO every day for 10 days[d] *Or* Levofloxacin 500 mg PO every day for 10 days[e]
Pelvic inflammatory disease (PID)	
Inpatient	Cefotetan 2 g IV every 12 hours *plus* Doxycycline 100 mg PO or IV every 12 hours *Or* Cefoxitin 2 g IV every 6 hours *plus* Doxycycline 100 mg PO or IV every 12 hours *Or* Ceftriaxone 1 g IV every 24 hours *plus* Doxycycline 100 mg PO or IV every 12 hours *plus* Metronidazole 500 mg PO or IV every 12 hours
Outpatient	Ceftriaxone 500 mg[b] IM single dose *plus* Doxycycline 100 mg PO bid for 14 days ± Metronidazole 500 mg PO bid for 14 days

[a]Alternative treatment regimens for selected patients (including pregnancy, drug allergies) can be found at www.cdc.gov/std/treatment.
[b]For weight ≥150 kg, ceftriaxone 1 g IM single dose.
[c]For suspected gonorrhea and/or chlamydia.
[d]For suspected gonorrhea and/or chlamydia *and* enteric organisms (i.e., men who practice insertive anal intercourse).
[e]For suspected enteric organisms.
IM, Intramuscular; *IV,* intravenous; *PO,* per os (by mouth).

other *Mycoplasma* species, *Ureaplasma* species, and other organisms. Patients with NGU are often asymptomatic. Symptoms, when present, are usually less prominent than those seen with gonococcal urethritis. Clinical features are not sufficiently specific to distinguish between gonococcal urethritis and NGU, and coinfection is common. NAATs have high sensitivity and specificity for chlamydia, gonorrhea, trichomoniasis and *M. genitalium* infection. Wet mount microscopy can identify cases of trichomoniasis, but is less sensitive than NAATs, which are now the gold standard. Diagnostic testing is not routinely performed for other causes of NGU. Recommended treatment for NGU is doxycycline 100 mg PO bid for 7 days. Additional empirical treatment with weight-based single-dose ceftriaxone IM is recommended when gonorrhea has not been ruled out with negative NAATs. Treatment of trichomoniasis is discussed separately.

Persistent or recurrent NGU may be caused by treatment failure or reinfection following successful treatment. Management of these patients should be guided by results of diagnostic testing for causative organisms, when possible. *M. genitalium* is increasingly recognized

Fig. 84.7 Frothy vaginal discharge due to trichomoniasis. (From: Morse S, Ballard RC, Holmes KK, et al, eds. *Atlas of Sexually Transmitted Diseases and AIDS*, ed 4. London: Saunders/Elsevier; 2010: Fig. 5.23, p 140.)

as a cause of NGU that may be resistant to treatment with doxycycline alone. NAATs for *M. genitalium* should be obtained. The recommended two-stage treatment for confirmed *M. genitalium* infection is doxycycline 100 mg PO bid for 7 days, followed by moxifloxacin 400 mg PO once daily for 7 days. If antimicrobial resistance testing confirms sensitivity to macrolides, then azithromycin 1 g PO initial dose, followed by 500 mg PO once daily for 3 additional days may be considered as an alternative to moxifloxacin following the recommended 7 day course of doxycycline.

Trichomoniasis

Background and Importance

Trichomonas vaginalis is the flagellated protozoan organism responsible for trichomoniasis, the most common curable STI worldwide. Women are typically more symptomatic than men, but asymptomatic infection occurs in both sexes. Trichomoniasis usually causes mild disease, but significant morbidity can occur. Trichomoniasis has been associated with PID, preterm birth among pregnant women, prostatitis, epididymitis, and increased susceptibility to HIV acquisition.

Clinical Features

Trichomoniasis causes vaginitis in women. Common symptoms include vaginal discharge, pruritus, dysuria, urinary frequency, dyspareunia, and postcoital bleeding. The discharge is classically described as malodorous, frothy, and greenish yellow in color (Fig. 84.7). Pelvic examination may reveal erythema of the vaginal mucosa and vulva, in addition to the discharge. Punctate hemorrhages of the cervix ("strawberry cervix") are seen in up to 10% of cases. Trichomoniasis is often asymptomatic in men but may cause urethritis with associated dysuria and urethral discharge.

Diagnostic Testing

The diagnosis of trichomoniasis is often confirmed with microscopic examination of a saline wet mount slide, which reveals motile flagellated trichomonads and leukocytes (Fig. 84.8). The sensitivity of the wet mount slide is approximately 50% to 65%. Trichomonas may be seen incidentally on microscopic analysis of the urine sediment. NAATs are superior to microscopic examination, with reported sensitivity and specificity greater than 95% for some assays. Point-of-care antigen detection kits are now available. Culture is also confirmatory, but seldom used in the ED.

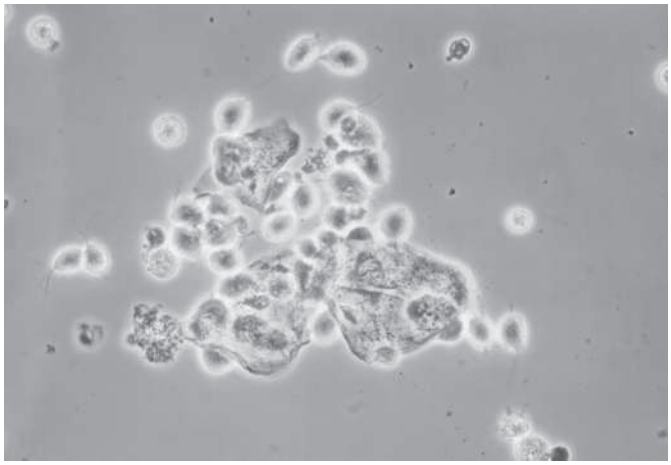

Fig. 84.8 *T. vaginalis* on a wet mount slide prep. (From Centers for Disease Control and Prevention [CDC]: Public Health Image Library [PHIL]. Image #14500. Available at phil.cdc.gov/phil/.)

Management

Treatment of trichomoniasis is indicated in both symptomatic and asymptomatic men and nonpregnant women. Although single-dose metronidazole 2 g PO was previously recommended for treatment of trichomoniasis in men and women, studies have demonstrated increased efficacy using a multi-dose regimen of metronidazole in women. The recommended treatment in women is metronidazole 500 mg PO bid for 7 days. Metronidazole 2 g PO single dose is still recommended for treatment in men. (see Table 84.3). Tinidazole 2 g PO single dose is an acceptable treatment alternative in men and nonpregnant women, but should be avoided during pregnancy. Metronidazole is the recommended treatment for symptomatic trichomoniasis during pregnancy. The treatment of asymptomatic pregnant women with trichomoniasis is controversial, because there is conflicting data regarding the possible increased incidence of preterm labor in pregnant women treated with metronidazole.

Disposition

Trichomoniasis is treated on an outpatient basis. Patients should be counseled to avoid alcohol use for at least 24 hours after completion of metronidazole therapy and 72 hours after completion of tinidazole therapy, due to the occurrence of a disulfiram-like reaction following alcohol use.

Pelvic Inflammatory Disease

Background and Importance

PID is an ascending infection that begins at the level of the endocervix but progresses to the upper reproductive tract, causing endometritis, salpingitis, and peritonitis. *N. gonorrhoeae* and *Chlamydia trachomatis* have traditionally been implicated in the development of PID, but many women diagnosed with PID do not test positive for either of these organisms. Negative testing for gonorrhea and chlamydia from endocervical specimens does not reliably exclude them as a cause for upper tract infection. Polymicrobial involvement is common, with anaerobes, enteric organisms, vaginal flora, and other STIs often implicated in PID. An estimated 10% to 20% of women with gonorrhea or chlamydia may develop PID if they do not receive proper treatment. Other recognized complications of PID include chronic pelvic pain, infertility, and ectopic pregnancy.

Clinical Features

PID causes a spectrum of illness ranging from asymptomatic infection to severe illness with associated peritonitis and systemic toxicity. Lower abdominal pain is the most common presenting complaint. Other

TABLE 84.5 Diagnosis of Pelvic Inflammatory Disease[a]

Minimum Criteria	Additional Criteria[b]
Cervical motion tenderness *or*	Mucopurulent cervical discharge
Adnexal tenderness *or*	Cervical friability
Uterine tenderness	Oral temperature >101°F
	Elevated erythrocyte sedimentation rate
	Elevated C-reactive protein
	White blood cells (WBCs) on microscopy of vaginal secretions
	Laboratory confirmation of endocervical gonorrhea or chlamydia

[a]In a sexually active woman at risk for sexually transmitted infections (STIs) who presents with abdominal pain and no alternative diagnosis is identified, a presumptive diagnosis of pelvic inflammatory disease (PID) may be based upon the criteria listed in this table.
[b]Additional criteria increase specificity but decrease sensitivity for the diagnosis of PID.

symptoms include dyspareunia, abnormal vaginal discharge or bleeding, dysuria, and fever. Nausea, vomiting, diarrhea, and anorexia may be present, mimicking gastrointestinal conditions. Physical findings may include lower abdominal tenderness, cervical friability, mucopurulent discharge, cervical motion tenderness, and adnexal tenderness. Vital sign abnormalities, such as fever and tachycardia, may be seen.

Diagnostic Testing

PID is a clinical diagnosis. No single historical, physical, or laboratory finding or combination of findings is sufficiently sensitive or specific to make a definitive diagnosis of PID. Because PID causes significant morbidity, the CDC recommends a low threshold for the diagnosis and empirical treatment of PID. The diagnosis of PID should be considered and presumptive treatment initiated in any sexually active woman at risk for STIs who presents with lower abdominal or pelvic pain if no alternative diagnosis is identified and if one or more of the following findings are present on pelvic examination: (1) cervical motion tenderness, or (2) uterine tenderness, or (3) adnexal tenderness. These criteria have high sensitivity but low specificity for the diagnosis of PID. Because the use of these criteria will result in the over-diagnosis of PID, one should consider other possible diagnoses. The use of the additional criteria improves the specificity of the diagnosis of PID but decreases the diagnostic sensitivity (see Table 84.5).

NAATs for gonorrhea and chlamydia are recommended. A pregnancy test should always be obtained, because ectopic pregnancy and other pregnancy-related conditions may mimic PID. Computed tomography (CT) and pelvic ultrasonography may reveal findings supporting the diagnosis of PID, including evidence of swelling and inflammation within the endometrial cavity and fallopian tubes. Imaging studies are also helpful in ruling out other diagnoses, such as appendicitis, and for identifying complications of PID, such as tubo-ovarian abscess. Laparoscopy can confirm the diagnosis but is of limited utility due to its invasive nature, limited availability, and expense. In addition, laparoscopy may not identify mild cases of PID.

Management

Treatment should be initiated as soon as possible after the diagnosis is made and should not await the results of microbiologic testing or other delayed diagnostic studies. Delays in the initiation of antibiotic therapy contribute to the development of complications of PID. Multiple inpatient and outpatient antibiotic regimens are available for the treatment of PID (see Table 84.4). The total duration of antibiotic therapy is 14 days. Antibiotic selection should include empirical coverage of gonorrhea and chlamydia. Anaerobic coverage with metronidazole was previously considered optional, but is now recommended in the routine outpatient treatment of PID. Recommended inpatient parenteral treatment regimens also include anaerobic coverage with metronidazole or cephalosporins. Supportive care measures include analgesics, antipyretics, and hydration. Sexual intercourse should be deferred until symptoms have resolved and antibiotic therapy has been completed by the patient and her partner.

Disposition

Most women with PID are treated as outpatients. Current recommendations no longer mandate hospitalization for adolescents or for HIV-positive patients with PID. Follow-up within 72 hours is recommended to ensure appropriate response to initial treatment. Women who meet any of the following criteria should be considered for inpatient treatment of PID:

- Surgical emergencies cannot be excluded (i.e., appendicitis)
- Pregnancy
- Tubo-ovarian abscess
- Severe illness, nausea and vomiting, or high fever
- Inability to follow or tolerate outpatient oral regimens
- Failure to respond to oral antibiotic therapy

In addition, to chronic pelvic pain, ectopic pregnancy, and infertility, other complications of PID are common. Tubo-ovarian abscess or pyosalpinx may be identified on pelvic ultrasound or CT. Perihepatitis, known as *Fitz-Hugh-Curtis syndrome,* is occasionally seen and may result in associated right upper quadrant abdominal pain.

Bacterial Vaginosis

Background and Importance

Bacterial vaginosis (BV) is the most common cause of abnormal vaginal discharge in the United States. Although BV is not considered to be an STI, it is often encountered during the evaluation of patients with an abnormal vaginal discharge. BV is due to an alteration in the vaginal flora with replacement of normal *Lactobacillus* species by a polymicrobial group of organisms, including *Gardnerella vaginalis,* anaerobes, and others.

Clinical Features and Diagnostic Testing

Many women with bacterial vaginosis are asymptomatic. Symptomatic women complain of a malodorous thin whitish vaginal discharge. A fishy odor is often reported and can be accentuated with the addition of 10% potassium hydroxide (KOH) solution to a wet mount slide at the time of pelvic examination (the "whiff test"). The pH of vaginal fluid is greater than 4.5. Microscopic examination of the wet mount slide reveals clue cells, which are vaginal epithelial cells with indistinct borders due to a coating of bacteria. Multiple available NAATs have high sensitivity and specificity for BV. Bacterial vaginosis is associated with an increased risk of PID and complications of pregnancy (premature rupture of membranes and preterm delivery). Bacterial vaginosis may also be a cofactor in the acquisition and transmission of other STIs, including HIV.

Management

Treatment is recommended for all symptomatic women with bacterial vaginosis, regardless of pregnancy status. The established benefit of therapy is the relief of vaginal symptoms. There is conflicting data regarding the efficacy of treatment in reducing the incidence of associated illnesses in pregnant and nonpregnant women. Treatment of bacterial vaginosis in asymptomatic women is not recommended.

Treatment of male sexual partners is of no benefit. Recommended treatment regimens for bacterial vaginosis include: (1) metronidazole 500 mg PO twice a day for 7 days, (2) metronidazole gel 0.75% 5 g intravaginally once a day for 5 days, and (3) clindamycin cream 2% 5 g intravaginally at bedtime for 7 days. Symptomatic pregnant women can be treated with the same oral or topical regimens recommended for nonpregnant women. The use of intravaginal *Lactobacillus* preparations and other probiotics are of no proven benefit in the restoration of normal vaginal flora or in the treatment of bacterial vaginosis.

Vulvovaginal Candidiasis

Background and Importance

Vulvovaginal candidiasis is usually caused by the yeast species *Candida albicans.* An estimated 75% of women will have at least one episode of candidiasis during their lifetime, and recurrent episodes are common. Like bacterial vaginosis, candidiasis is not considered to be an STI but is frequently encountered in the evaluation of patients with abnormal vaginal discharge.

Clinical Features and Diagnostic Testing

Common nonspecific symptoms include pruritus, abnormal discharge, dyspareunia, and external dysuria. Pelvic examination may reveal vulvar erythema and edema with satellite lesions, erythema of the vaginal mucosa, and a thick curdy whitish vaginal discharge. Microscopic examination of a wet mount slide may reveal the presence of budding yeast or pseudohyphae. Diagnosis is facilitated with the use of 10% KOH, which disrupts other cellular structures and facilitates visualization of fungal elements. Fungal culture is the diagnostic gold standard but is rarely performed.

Management

Multiple topical antifungal azole drugs are recommended for the treatment of vulvovaginal candidiasis, including clotrimazole, miconazole, butoconazole, terconazole, and tioconazole. Several topical agents are available over the counter. Fluconazole is the only oral antifungal agent approved by the FDA for treatment of candidiasis. A single dose of fluconazole 150 mg PO is highly effective in nonpregnant women but is contraindicated during pregnancy. A 7-day course of topical azoles is recommended during pregnancy. Single-dose and short-course therapy with azoles is associated with a cure rate of 80% to 90% in uncomplicated *Candida* vulvovaginitis. Male sexual partners may develop *Candida balanitis,* which typically responds to topical antifungal therapy. Treatment of asymptomatic sexual partners is of no proven benefit.

EPITHELIAL CELL INFECTIONS

Condyloma Acuminata (Genital Warts)

Background and Importance

Genital warts are caused by human papillomavirus (HPV). More than 40 types of HPV can infect humans, with the majority of HPV infections remaining asymptomatic or unrecognized. Clinically apparent warts occur in approximately 1% of cases. HPV types 6 and 11 cause most cases of visible genital warts and are considered non-oncogenic. HPV types 16 and 18 are responsible for most cases of cervical cancer and are also associated with vaginal, vulvar, anal, penile, and oropharyngeal cancers. The 9-valent vaccine currently available in the United States provides protection against the most common HPV types that cause cancer and visible genital warts. This vaccine is approved for use in women and men from 9 to 45 years of age, with the optimal timing of vaccine initiation prior to an individual's sexual debut.

Fig. 84.9 Perianal condyloma acuminata. (From: Morse S, Ballard RC, Holmes KK, et al, eds. *Atlas of Sexually Transmitted Diseases and AIDS*, ed 4. London: Saunders/Elsevier; 2010: Fig. 11.10, p 294.)

Clinical Findings

Genital warts are typically manifested by small painless fleshy papular lesions on the skin or mucous membranes (Fig. 84.9). The slow-growing lesions gradually become more lobulated, pedunculated, or verrucous in appearance. Lesions may become friable and painful due to local irritation or secondary infection. Warts are typically found on the external genitalia, buttocks, and perineum, but they may occur anywhere the organism is inoculated.

Diagnostic Testing

A clinical diagnosis of genital warts is usually made by visual inspection. Differential diagnosis includes molluscum contagiosum, skin tags, nevi, neoplasm, and condyloma lata. Genital warts may have a moist appearance in intertriginous areas, but they do not usually have the denuded surface typically seen with condyloma lata in secondary syphilis. The duration of lesions and presence of associated symptoms are helpful features, because genital warts are often present for months or years but have no associated systemic symptoms. Darkfield microscopy and serology are useful in excluding a diagnosis of syphilis. Although not generally performed in the ED, biopsy can confirm the diagnosis and exclude neoplasm. The application of topical acetic acid to mucosal lesions to screen for HPV is nonspecific and is not recommended.

Management

All available treatments for HPV have significant failure rates. Treatment options include patient-applied regimens and provider-administered regimens. Patient-applied regimens include topical application of imiquimod cream, podofilox solution or gel, or sinecatechins ointment. The patient must be able to adequately visualize and reach the lesions to use these patient-applied agents. These modalities are preferable to some patients, because they can administer the treatment in the privacy of their own home. Provider-administered treatments include surgical excision, cryotherapy, or topical therapy with trichloroacetic acid (TCA) or bichloracetic acid (BCA). Podophyllin-based therapy is contraindicated during pregnancy due to possible teratogenic effects. The emergency clinician may

elect to defer initiation of treatment for genital warts and refer the patient to a primary care provider or STI clinic, because the condition is not emergent and a prolonged course of treatment is usually required.

Molluscum Contagiosum

Molluscum contagiosum is a localized skin infection caused by a member of the pox virus family. The condition is common in childhood when it is usually acquired via nonsexual contact. It may be sexually acquired in adolescents and adults. Clinical appearance consists of one or more small 2- to 5-mm papules. The lesions have a waxy appearance, and central umbilication is common. Spontaneous resolution typically occurs within 6 to 12 months. Differential diagnosis may include genital warts, skin cancers, nevi, skin tags, and other benign skin lesions. Clinical diagnosis is made based upon the typical appearance of the lesions. No specific diagnostic testing or treatment is necessary in the ED. The patient can be referred to a primary care provider or dermatologist for curettage, cryotherapy, or treatment with topical agents for lesions that persist.

ECTOPARASITES

Pediculosis Pubis

Pediculosis pubis is a parasitic infestation caused by *Phthirus pubis,* the pubic louse. Although pubic lice are usually sexually transmitted, they can be transmitted via nonsexual contact with infected individuals or contact with infested fomites, such as linen or clothing. Symptoms include pruritus and mild discomfort at the site of the bites. Small erythematous maculopapular lesions with associated punctate bleeding may be seen. The lice are visible in the pubic hair or attached to the skin while feeding. The eggs (nits) are attached to the shaft of the pubic hairs. Diagnosis is confirmed by visual inspection.

Treatment includes topical permethrin 1% creams and rinses which are available over the counter. Permethrin should be applied to the affected area and washed off after 10 minutes. Alternative topical agents include pyrethrin shampoo and malathion. The patient should attempt to remove any visible nits, because topical treatment is not always ovicidal. Potentially infested linen and clothing should be washed in hot water with detergent. Repeat topical treatment can be applied in 1 to 2 weeks to kill any newly hatched lice. Resistance to pediculicides has been widely reported. An alternative topical agent or oral ivermectin may be used for treatment failures.

Scabies

Sarcoptes scabiei is the mite responsible for scabies. The organism is transmitted via direct person-to-person contact or exposure to infested linens and clothing. Although sexual transmission is common, many cases occur from nonsexual contact. The mite creates superficial burrows in the skin where eggs and excrement are deposited. Intense pruritus is caused by a hypersensitivity reaction to the foreign material in the skin. Careful inspection often reveals characteristic burrows in the skin. Excoriations, papules, and nodules are frequently seen. Commonly affected areas include the groin, genitalia, axilla, and interdigital web spaces of the hands. Diagnosis can be confirmed by microscopic examination of scrapings from characteristic skin lesions, which reveals the mites. Recommended treatments for scabies includes topical permethrin 5% cream, topical ivermectin 1% lotion or oral ivermectin. Permethrin is nontoxic and can be used safely in pregnancy and in patients of all ages. Linen and clothing should be washed in hot water with detergent.

CHAPTER 84: QUESTIONS AND ANSWERS

1. A 30-year-old pregnant female presents for evaluation of a genital ulcer. Darkfield microscopy reveals spirochetes. She is allergic to penicillin. Which of the following statements is false?

- **a.** Azithromycin is an acceptable treatment alternative for primary syphilis during pregnancy in a patient with known penicillin allergy.
- **b.** Nontreponemal serologic tests for syphilis (rapid plasma reagin [RPR], Venereal Disease Research Laboratory [VDRL]) may yield false-negative results in primary syphilis.
- **c.** Primary syphilis facilitates the transmission and acquisition of human immunodeficiency virus (HIV) infection.
- **d.** Syphilis is a reportable disease in all 50 states.
- **e.** The chancre of primary syphilis will heal spontaneously without antibiotic therapy.

Answer: A. Penicillin remains the drug of choice for treatment of syphilis during pregnancy. A pregnant patient with syphilis and known penicillin allergy should be admitted for desensitization and treatment with penicillin. Nontreponemal serologic tests may yield false-negative results in primary syphilis when antibody titers have not yet risen. False-positive serology may be seen with a variety of other medical conditions. Visualization of spirochetes on darkfield microscopy confirms the diagnosis of syphilis. All sexually transmitted infections (STIs) facilitate the transmission and acquisition of HIV. Reportable STIs in all 50 states include gonorrhea, chlamydia, syphilis, HIV, and chancroid.

2. A 17-year-old female presents with complaints of pelvic pain. She reports multiple sexual partners and inconsistent condom use. Pelvic examination reveals yellow cervical discharge, cervical motion tenderness, and bilateral adnexal tenderness. Pregnancy test is negative. Which of the following statements regarding this scenario is true?

- **a.** All adolescents with pelvic inflammatory disease require hospital admission for intravenous antibiotics.
- **b.** A negative nucleic acid amplification test for gonorrhea and chlamydia reliably excludes the diagnosis of pelvic inflammatory disease.
- **c.** In the absence of an identifiable alternative diagnosis, the clinical diagnosis and empirical treatment of pelvic inflammatory disease is warranted.
- **d.** The clinical diagnosis of pelvic inflammatory disease requires the presence of lower abdominal tenderness *and* cervical motion tenderness *and* adnexal tenderness on physical examination.
- **e.** Women treated as outpatients for pelvic inflammatory disease should have a follow-up evaluation in 2 weeks.

Answer: C. The clinical diagnosis of pelvic inflammatory disease is warranted in a sexually active woman at risk for sexually transmitted infections (STIs) if no alternative diagnosis is identified and any one of the following findings is present on examination: (1) cervical motion tenderness, (2) uterine tenderness, and/or (3) adnexal tenderness. Additional diagnostic criteria (mucopurulent cervical discharge, fever, elevated white blood cell count, positive testing for gonorrhea or chlamydia, and others) improve specificity but decrease sensitivity in the diagnosis of pelvic inflammatory disease (PID). Adolescents with PID may be treated as outpatients using the same criteria as adult women. Women receiving outpatient treatment for PID should be advised to seek a follow-up evaluation within 48 to 72 hours.

3. Which of the following antibiotic regimens is acceptable for outpatient treatment of pelvic inflammatory disease in a 70-kg woman?

- **a.** Azithromycin 1 g *per os* (by mouth) (PO) (single dose) *and* metronidazole 500 mg bid for 14 days
- **b.** Ceftriaxone 125 mg IM (single dose) *and* doxycycline 100 mg bid for 7 days
- **c.** Ceftriaxone 250 mg IM (single dose) *and* azithromycin 1 g PO (single dose)
- **d.** Ceftriaxone 500 mg IM (single dose) *and* doxycycline 100 mg PO bid for 14 days *and* metronidazole 500 mg PO bid for 14 days
- **e.** Metronidazole 2 g PO (single dose) *and* doxycycline 100 mg PO bid for 14 days

Answer: D. Pelvic inflammatory disease is typically a polymicrobial infection. *Neisseria gonorrhoeae* and/or *Chlamydia trachomatis* are frequently implicated organisms, but anaerobes, enteric organisms, and normal vaginal flora may also be present. Empirical treatment of PID should include adequate coverage for gonorrhea and chlamydia. A single dose of ceftriaxone 500 mg IM is adequate treatment for upper tract gonococcal infection in a patient weighing <150 kg. A 14-day course of antibiotics is recommended for adequate coverage of chlamydia and anaerobes in PID.

4. A 24-year-old sexually active male presents with painful genital ulcers. Physical examination reveals a cluster of 2- to 3-mm tender superficial ulcers on the penile shaft. He reports a history of similar lesions in the same location sporadically in the past. Which statement regarding this clinical scenario is false?

- **a.** Both herpes simplex virus (HSV)-1 and HSV-2 can be transmitted through sexual contact.
- **b.** Genital herpes is a lifelong viral infection.
- **c.** Prompt initiation of antiviral medication reduces the duration and severity of symptoms.
- **d.** Topical antiviral therapy is not recommended.
- **e.** Use of condoms is not necessary to prevent transmission in the absence of clinically apparent lesions.

Answer: E. Genital herpes is a lifelong infection caused by herpes simplex virus. Sexual transmission is more common with HSV-2 but

may also occur with HSV-1. Condom use is recommended during asymptomatic periods, because viral shedding and transmission may occur even in the absence of clinically apparent lesions. Antiviral therapy is not curative. Prompt initiation of systemic antiviral medication within 72 hours (acyclovir, famciclovir, or valacyclovir) reduces the duration and severity of symptoms, particularly at the time of primary infection. Topical antiviral therapy is not recommended.

5. A 24-year-old female presents to the emergency department (ED) complaining of vaginal discharge. A copious frothy whitish discharge is noted on speculum examination. Microscopic examination of a saline wet mount reveals motile flagellated organisms. Which of the following statements regarding this patient's treatment is true?
   - **a.** Metronidazole is the drug of choice for treatment of symptomatic trichomoniasis during all stages of pregnancy.
   - **b.** Punctate hemorrhagic lesions are seen on the cervix in most cases of trichomonas vaginitis.
   - **c.** Tinidazole is a safe alternative for treatment of trichomoniasis during pregnancy.
   - **d.** Trichomoniasis is always symptomatic in men and women.
   - **e.** Wet mount microscopy approaches 100% sensitivity in the diagnosis of trichomonas vaginitis.

   Answer: A. Metronidazole is the drug of choice for treatment of symptomatic trichomoniasis during all stages of pregnancy. Tinidazole should be avoided in pregnant women due to limited data regarding safety for use in pregnancy. Visualization of flagellated protozoans on wet mount microscopy of vaginal discharge is highly specific, but only 50% to 65% sensitive for the diagnosis of trichomoniasis. Punctate hemorrhagic lesions on the cervix (so called "strawberry cervix") is seen in up to 10% of cases. Nucleic acid amplification tests for trichomonas are highly sensitive and specific. Trichomoniasis may be asymptomatic in men and women.

6. Single-dose antibiotic therapy is recommended for treatment of which of the following STIs?
   - **a.** Nongonococcal urethritis (NGU)
   - **b.** Vaginal trichomoniasis
   - **c.** Primary and secondary syphilis
   - **d.** Pelvic inflammatory disease
   - **e.** Chlamydia proctitis

   Answer: C. Primary and secondary syphilis are treated with a single dose of benzathine penicillin. Gonococcal urethritis, cervicitis, pharyngitis, and proctitis are treated with a single dose of ceftriaxone. Single-dose metronidazole is no longer recommended for vaginal trichomoniasis, but is still recommended for trichomoniasis in men. A 7-day course of doxycycline is now recommended for chlamydia urethritis, cervicitis, pharyngitis, and proctitis in men and nonpregnant women. Treatment of NGU should include chlamydia coverage. Treatment of upper genitourinary tract STIs, including pelvic inflammatory disease and epididymoorchits, requires a longer course of antibiotic therapy.

Urologic Disorders

Carl A. Germann

KEY CONCEPTS

- Urinary obstruction should be considered in patients with a urinary tract infection (UTI) with risk factors for obstruction. Urinary obstruction should be ruled out in patients presenting in septic shock.
- Patients presenting with acute ureteral obstruction require a urinalysis to rule out the presence of a superimposed UTI.
- Acute, uncomplicated UTIs should be treated with fosfomycin, nitrofurantoin, or trimethoprim-sulfamethoxazole. Fluoroquinolones are not recommended as first-line therapy for uncomplicated UTI.
- Acute bacterial prostatitis (ABP) generally affects men between the ages of 20 and 40 years old with a second peak in men older than 60 years old. A very tender and swollen prostate gland is present in more than 90% of patients with acute prostatitis.
- The three primary predictors of stone passage without the need for surgical intervention are calculus size, location, and degree of patient pain. The most important factor that relates to passage of a calculus though the genitourinary tract is its size (stone <5 mm has a 90% chance of passing spontaneously in 4 weeks).
- Imaging is not needed in all patients with renal colic. It should be performed when symptoms and signs are atypical and the diagnosis is uncertain, when high-grade obstruction is suspected, or when the patient appears toxic or has a solitary or transplanted kidney.
- Testicular torsion should be suspected in all patients presenting with acute scrotal pain. There is no historical factor or physical finding that reliably differentiates torsion from other causes of testicular pain.
- Approximately 10% of patients with testicular trauma have associated torsion and require prompt identification and detorsion.
- Sexually active males should receive ceftriaxone and doxycycline to treat epididymitis. Patients in whom enteric organisms are likely the cause of epididymitis should receive fluoroquinolones. Most cases of pediatric epididymitis are idiopathic, and antibiotics are not routinely recommended.
- Acute urinary retention (AUR) is usually caused by an obstructive lesion but also can be the presenting manifestation of other pathologic processes. Patients with AUR and concomitant infection, pelvic mass, or neurologic deficits warrant imaging in the emergency department.
- Although generally associated with a benign process, the presence of gross or microscopic hematuria requires consideration of life-threatening causes such as aortic abdominal aneurysms and malignancy.

URINARY TRACT INFECTION IN ADULTS

Background

Urinary tract infections (UTI) occur when bacteria, often from the skin or rectum, ascend the urethra and infect the urinary tract. In the United States, the urinary tract is the most common source of infection of patients presenting in septic shock, with an associated mortality of 10% to 20%.

UTI describes an inflammatory response of the urothelium to microorganisms in the urinary tract, resulting in clinical symptoms that include dysuria, frequency, urgency, hematuria, and suprapubic or costovertebral angle discomfort. The diagnosis of a UTI requires the presence of urinary-specific symptoms or signs in a patient who has bacteriuria and no other identified source of infection. Bacteriuria is the presence of bacteria in the urine but is not considered to represent a UTI in the absence of clinical manifestations. Bacteriuria accompanied by symptoms should be treated, whereas bacteriuria in the absence of symptoms should be treated only in select patients (e.g., pregnant women, immunosuppressed patients).

UTIs are classified as lower (confined to the bladder) or upper (involving the ureters or kidneys) and as uncomplicated or complicated. An uncomplicated infection occurs in a nonpregnant individual with a structurally and functionally normal urinary tract. A complicated UTI is a heterogeneous term that may be associated with an underlying functional or structural abnormality, history of urinary instrumentation or organ transplantation, or systemic disease, such as renal insufficiency, diabetes, and immunodeficiency. UTIs in men are generally categorized as complicated given the higher incidence of associated urologic abnormalities. However, men can experience a UTI without an underlying structural or functional abnormality. Complicated UTIs often require a prolonged course of antibiotic therapy and a more in-depth approach to testing and anatomic evaluation.

The term *urethritis* refers to the inflammation of the urethra secondary to an infection or trauma. Frequently, urethritis may be a manifestation of a sexually transmitted infection (STI), such as gonococcal urethritis in *Neisseria gonorrhoeae* infection, but may occur in other clinical scenarios as well. *Cystitis* generally refers to inflammation of the bladder resulting in increased urinary frequency, urgency, dysuria, and suprapubic pain. The causes of cystitis can be separated into bacterial and nonbacterial (e.g., radiation) categories. *Acute pyelonephritis* is a UTI involving the renal parenchyma and collecting system, manifesting with the clinical syndrome of fever, chills, and flank pain. Management and disposition of patients with acute pyelonephritis depend on whether the infection is simple or complicated.

Anatomy and Physiology

In women, the urethra is short and opens close to the vulvar and perirectal areas. This contributes to the much higher incidence of UTI in women. The route of infection in men is also usually ascending, from the urethra to the prostate to the bladder and then to the kidney. Risk factors for cystitis and pyelonephritis include sexual intercourse, use of spermicides, previous UTI, new sex partner, and history of UTI in a first-degree female relative suggestive of possible inherited urethral anatomic pathology.

Pathophysiology

UTIs arise when urinary pathogens from the bowel or vagina colonize the periurethral mucosa and ascend through the urethra and into the collecting system. Infrequently, bacterial infection of the urinary tract arises from hematogenous or lymphatic sources. This is frequently the pathologic mechanism in debilitated and chronically ill patients who are immunosuppressed. Obstruction from any cause, with resultant stasis of urine, is a common contributor to infection. Urinary calculi may cause obstruction and increased susceptibility to the development of a UTI. Likewise, numerous abnormalities of the urinary tract may interfere with its innate ability to resist infection.

Subgroups of patients who are more susceptible than the normal population to UTIs include diabetics, pregnant women, elders, patients who are unable to empty their bladder completely, patients with indwelling urinary catheters, and those with immunodeficiency disorders. Lower UTIs are more common in aging men in the setting of prostatic enlargement or obstruction.

Escherichia coli is responsible for approximately three-quarters of cases of UTI in men and women.[1] Other less common bacteria that may be responsible for infection include *Staphylococcus saprophyticus* and other members of the Enterobacteriaceae family (*Klebsiella pneumonia* and *Proteus mirabilis*). Unusual microorganisms may be found in institutionalized or hospitalized populations. Such settings and conditions predispose the patient to alterations in the normal gastrointestinal (GI) flora, leading to complex UTIs. The uropathogens in these patients include more resistant strains of *Escherichia, Klebsiella, Proteus,* and *Enterobacter,* as well as *Pseudomonas, Enterococcus, Staphylococcus, Providencia, Serratia, Morganella, Citrobacter, Salmonella, Shigella,* and *Haemophilus* spp., *Mycobacterium tuberculosis,* and fungi.

Clinical Features

UTI is usually manifested as dysuria, with or without frequency, urgency, hematuria, or suprapubic discomfort. Symptoms of dysuria, frequency, hematuria, nocturia, and urgency all increase the probability of UTI, whereas vaginal discharge decreases the likelihood of UTI. The probability of cystitis is greater than 90% in women who have dysuria and frequency without vaginal discharge or irritation.

Symptoms of UTI in men may also represent storage or voiding disturbances that are common in aging men (e.g., prostatic enlargement). Commonly, men with lower UTIs have symptoms of urinary urgency, frequency, dysuria, hematuria, and suprapubic pain. If fever and chills are present in association with irritative symptoms and difficulty voiding, acute bacterial prostatitis should be strongly considered. A digital rectal examination of the prostate gland with attention to size, shape, and consistency can identify prostatic enlargement, inflammation, or cancer.

Clinical signs and symptoms suggestive of pyelonephritis include fever, chills, flank pain, costovertebral angle tenderness, and nausea or vomiting, with or without symptoms of cystitis. The presentation of UTI and pyelonephritis can be particularly challenging in those who are debilitated and elders because they may not be able to verbalize their symptoms and can present without fever; these patients may present with nonspecific complaints such as altered mental status, lethargy, abdominal pain, or generalized weakness.

Differential Diagnosis

Bacterial UTI is the most common cause of dysuria. Differential considerations include acute urethritis or acute vaginitis from STI, as well as mechanical trauma or irritation (Table 85.1). In the ED setting, UTI is often overdiagnosed and associated with missed STI diagnoses.[2] In general, if historical information includes contact with multiple sexual partners, recent change in sexual partners, or sexual partner with dysuria or discharge, *Chlamydia trachomatis* and *N. gonorrhoeae* infection should be strongly considered. Because the diagnosis of UTI is rarer in men, a high suspicion for an STI such as gonococcal or nongonococcal urethritis should be maintained. Trauma, calculi, chemical irritation, candidal infections, psychogenic disorders, neoplasm, and malformations or space-occupying lesions compressing the distal genitourinary tract can also cause dysuria.

TABLE 85.1 Clinical Differentiation of Major Causes of Dysuria

Cause	Clinical Features
Urinary tract infection	Internal dysuria
	Frequency, urgency, voiding small volumes
	Abrupt onset
	Suprapubic pain
	Often associated with diaphragm use
	Presence of pyuria
	Presence of hematuria (50% of patients)
Sexually transmitted disease	Internal dysuria
	Occasional history of frequency, urgency, voiding small volumes
	Gradual onset
	History of new or multiple sexual partners
	Vaginal discharge
Vaginitis	External dysuria
	Gradual onset
	Vaginal discharge
	Vaginal odor
	Pruritus

Diagnostic Testing

Urinalysis and Urine Culture

A clean-catch, midstream specimen is the preferred type of urine sample for analysis. This is particularly important in woman in whom contamination from the perineum may result in a false-positive test result. However, even when the procedure is performed correctly, a specimen may be contaminated because the surrounding areas can be difficult to clean. A predominance of epithelial cells suggests that the specimen is contaminated. Sterile catheterization is the most accurate method of obtaining a urine specimen in women and may be the best solution for achieving a reliable urinalysis if the patient is unable to provide a clean-catch specimen or is actively menstruating. In men, the specimen is usually not affected by lack of cleansing or by the timing of specimen collection. Therefore, it is not appropriate to catheterize an adolescent or adult man for the purpose of collecting a urine specimen unless he is experiencing urinary retention.

Urine screening tests provide a quick and inexpensive diagnostic tool, with a goal of reliably predicting specimens that will provide positive or negative cultures. The most commonly used screening tests measure urinary leukocyte esterase and nitrite. Both can be detected by a color change on dipstick testing. Leukocyte esterase is an enzyme found in neutrophils, and nitrite is produced from nitrate reductase, present in gram-negative bacteria. Nitrite positivity is highly sensitive at 95% or greater. However, not all uropathogens, such as *S. saprophyticus* and *Enterococcus*, convert nitrate into nitrite. A urine dipstick test indicating the presence of nitrite and leukocyte esterase has a specificity of almost 100% for UTI. However, dipstick tests should be used

with caution because they can be less sensitive than the microscopic examination of urine (urinalysis). Given the limited negative predictive value of urine dipstick testing, a UTI may be difficult to rule out, even when all features are negative.[3] However, when there is a low pretest probability of UTI, a negative dipstick result for leukocyte esterase and nitrites excludes infection.[4] When the history is strongly suggestive of a UTI and the dipstick is negative, we recommend that a urine culture be sent.

Urine microscopy is an adjunct to the dipstick and helps reduce the number of urine cultures performed. Although no accepted level of pyuria is diagnostic of UTI, careful quantitation with a hemocytometer chamber will find pyuria in nearly all cases of acute UTI caused by coliforms. Pyuria is defined as 10 or more WBCs/mm^3. Microscopic examination of urine to identify bacteria remains the most reliable test for a diagnosis of UTI, but availability varies by institution.

The diagnosis of a UTI can be made only with clinical symptoms and the determination of bacteriuria; however, the diagnosis is confirmed with urine culture. A generally accepted definition of a positive culture is 10^5 or more colony-forming units (CFU)/mL. There is no absolute number of CFUs that is definitive for a UTI; the culture results alone are not diagnostic of infection and must be combined with symptoms suggestive of a UTI. The presence of 10^5 CFUs/mL of bacteria in a urine culture is associated with a 95% likelihood of infection, whereas 10^4 CFUs/mL is associated with a 50% likelihood of infection. The presence of bacteria on culture in the absence of clinical manifestations does not always indicate infection but may be due to patient colonization or contamination of the specimen.

The decision to perform a urine culture should be assessed for its relevance to patient care. Patients with frequency, dysuria, urgency, and suprapubic pain should be treated on the basis of symptoms, and a urine culture is not required to guide therapy. Patients with relapse or recurrent infections, complicated infection, or those in whom multidrug-resistant organisms are suspected based on previous microbiology or exposure to antibiotics should have a culture performed (Box 85.1).

An STI may mimic a UTI and, in sexually active patients, cultures for *C. trachomatis* and *N. gonorrhoeae* should be considered. Other causes of acute dysuria include infections with *Trichomonas vaginalis* and herpes simplex virus.

BOX 85.1 Patient Groups for Whom Urine Culture Is Indicated

- Children
- Adult men
- Immunocompromised patients
- Patients with treatment failure (i.e., with persistent urinary symptoms despite recently completed course of antibiotics)
- Patients with duration of symptoms more than 4–6 days
- Older patients at risk for bacteremia
- Ill-appearing patients with signs and symptoms suggestive of pyelonephritis or bacteremia
- Pregnant women
- Patients with known chronic or recurrent renal infection
- Patients with known anatomic urologic abnormalities
- Patients in whom urinary tract obstruction is suspected (e.g., stones, benign prostatic hypertrophy)
- Patients with serious medical diseases, including diabetes mellitus, sickle cell anemia, cancer, and other debilitating diseases
- Patients with alcoholism or drug dependence
- Recently hospitalized patients
- Patients taking antibiotics
- Patients who recently have undergone urinary tract instrumentation (e.g., cystoscopy, catheterization)

Imaging

Most patients with acute cystitis or pyelonephritis do not need emergency imaging of the urinary tract. Imaging is reserved for patients with a clinical suspicion for underlying structural abnormalities or complicating factors such as abscess, urolithiasis, or emphysematous pyelonephritis. Patients with pyelonephritis who have severe or worsening illness or persistent fever 48 to 72 hours after the initiation of appropriate antimicrobial treatment should undergo imaging to exclude renal stones, abscesses, or obstruction.

Ultrasonography is indicated to assess for potential urinary obstruction. Ultrasound is a sensitive tool for detecting postvoid residual bladder volume, intrarenal and perinephric abscess, and presence of hydroureter and hydronephrosis (Figs. 85.1 and 85.2). Ultrasound can also detect the presence of pyelonephritis and congenital anomalies. Regardless of patient age, this procedure is relatively inexpensive and avoids the hazards of contrast and radiation exposure. A suggestion of obstruction based on clinical suspicion or lack of response to medical therapy necessitates performance of an abdominal ultrasound or noncontrast CT scan.

A contrast CT scan of the abdomen is the most comprehensive test for assessing the kidneys, ureters, and bladder.[5] It has a high sensitivity for detecting abscess, obstruction, and acute inflammation. Imaging with an abdominal CT scan is recommended for those with pyelonephritis and known functional or anatomic abnormalities, recent instrumentation, immunosuppression, or concern for obstruction. Its disadvantages include radiation exposure, cost, and potential to induce contrast reactions.

Management

Simple Urinary Tract Infection

The options for treating uncomplicated lower UTI include single-dose therapy with fosfomycin, 5 days of nitrofurantoin, or 3 days of trimethoprim-sulfamethoxazole (Table 85.2). Fluoroquinolones such as ciprofloxacin or levofloxacin should not be used as first-line agents for empirical treatment of uncomplicated UTIs. Instead, they should be reserved for patients who have failed or have contraindications to first-line antibiotics. Fluoroquinolones achieve therapeutic levels in renal and prostate parenchyma and are indicated for complicated or more severe infections. However, they are not routinely used for

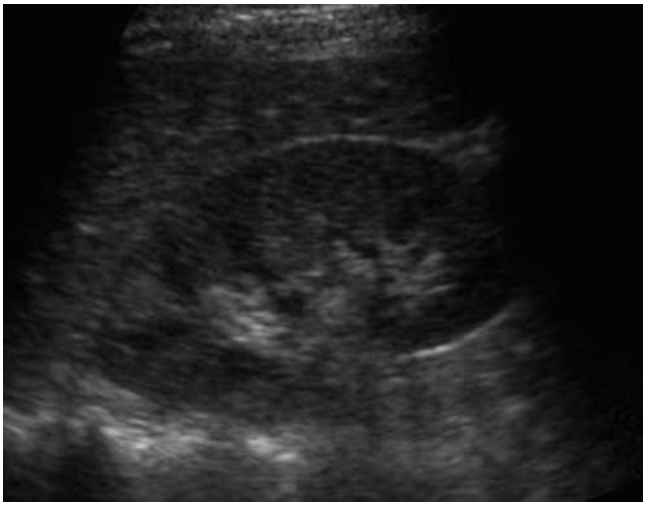

Fig. 85.2 Ultrasound Image Demonstrating a Normal Kidney. (Courtesy Dr. Peter Croft.)

TABLE 85.2 Antibiotic Options for Acute Uncomplicated Cystitis

Antimicrobial	Dose (Oral)	Duration	Common Side Effects
Trimethoprim-sulfamethoxazole	160/800 mg bid	3 days	Nausea, vomiting, anorexia, hypersensitivity reactions
Nitrofurantoin	100 mg bid	5 days	Gastrointestinal disturbance, headache, allergic reactions
Fosfomycin	3 g as a single dose		Diarrhea, nausea, headache, vaginitis, dizziness

uncomplicated cystitis due to adverse side-effect profiles and increasing resistance.

Antibiotics should be chosen with local resistance patterns in mind. The Infectious Disease Society of America (IDSA) recommends avoiding antimicrobial agents when local resistance exceeds 20%, emphasizing the need to be familiar with local outpatient resistance patterns. Although most hospitals monitor the resistance of organisms cultured in their microbiology laboratory, these data may reflect drug-exposed, hospital-acquired organisms more than community-acquired, outpatient-based illnesses. Thus, hospital antibiograms likely overestimate community resistance patterns.

Nitrofurantoin is a useful drug for the treatment of acute bacterial cystitis. It is inexpensive and maintains low serum and high urine levels. Nitrofurantoin is effective against *E. coli* but is inactive against other pathogens, such as *Proteus* and *Pseudomonas aeruginosa.* The rate of clearance is proportional to the creatinine clearance, and dose adjustments are necessary with renal impairment. The most common adverse effects of using nitrofurantoin are GI effects, including nausea, vomiting, and diarrhea.

Fosfomycin is an inhibitor of cell wall synthesis, structurally unrelated to any other antibiotic, and is active against most urinary tract pathogens, including multi-drug resistant gram-negative organisms. Fosfomycin is appealing for emergency department (ED) use because it can be given as a single dose for simple cystitis and does not require that a patient go to a pharmacy. However, we recommend the use of Fosfomycin only when other first-line therapies cannot be used because overuse might lead to an increased rate of resistance. Both nitrofurantoin and fosfomycin remain effective against extended-spectrum, β-lactamase–producing bacteria.[6]

A useful adjunctive therapy for UTIs in patients experiencing significant discomfort is phenazopyridine (Pyridium). It produces topical analgesia in the urinary tract and helps relieve dysuria. Patients should be cautioned that body secretions and excretions (e.g., tears, urine) will turn orange. This side effect can stain contact lenses and alarm unknowing patients.

The clinical presentations of UTIs and STIs can overlap. When coexisting vaginitis or pelvic inflammatory disease is suspected, empirical treatment should include the possibility of coinfection. In such cases, levofloxacin (500 mg/day for 7 days) has activity against common uropathogens as well as chlamydia and can be used with a single intramuscular dose of ceftriaxone (500 mg) for gonorrhea coverage.

Complex Urinary Tract Infection

Patients with mild to moderate pyelonephritis without complicating factors can be safely treated on an outpatient basis as long as the patient is able to eat and drink, has achieved adequate pain control, and has appropriate social support in the home. Given the risk for systemic illness, bacteremia, and progression to severe sepsis, medications must achieve therapeutic levels not only in the urine but also in the renal tissues and bloodstream. Therefore, fluoroquinolones are a first-line choice (Table 85.3). In areas in which the prevalence of resistance of fluoroquinolones is less than 10%, we recommend a 7-day course of ciprofloxacin for empirical outpatient treatment for uncomplicated pyelonephritis. In areas in which there is more than 10% fluoroquinolone resistance, the most recent IDSA guidelines recommend giving a long-acting parenteral antibiotic, such as 1 g ceftriaxone, followed by 10 to 14 days of an oral cephalosporin. Trimethoprim-sulfamethoxazole (TMP-SMX) for 10 to 14 days is an alternative treatment. Nitrofurantoin and fosfomycin do not achieve adequate blood and tissue levels and therefore are not effective for pyelonephritis.

A severe upper tract UTI necessitating hospitalization initially should be treated with parenteral antibiotics, such as cefepime, ceftriaxone, piperacillin-tazobactam, aztreonam, or a fluoroquinolone, with transition to oral therapy after the patient has been afebrile for 24 to 48 hours (Table 85.4). Oral therapy should be continued for 10 to 14 days. Follow-up urine cultures are recommended given the diverse flora and high rate of antimicrobial resistance.

In men, if there are no signs of toxicity, the patient can be treated on an outpatient basis with any of the urinary antibacterial agents (e.g., TMP-SMX, nitrofurantoin, fluoroquinolones) for 7 to 14 days. If concomitant prostatitis is suspected, TMP-SMX or a fluoroquinolone is recommended for 14 days. If evaluation demonstrates suspicion for prostate involvement, recurrent infection, or hematuria, the patient should be referred to a urologist for further evaluation. Patients with symptoms of prostatic enlargement can be treated with α-adrenergic receptor antagonists and/or 5-alpha-reductase inhibitor therapy (Table 85.5). Surgical treatment produces the most significant, long-term symptom improvement; it includes transurethral

TABLE 85.3 Antibiotic Options for Acute Uncomplicated Pyelonephritis

Antimicrobial	Dose (Oral)	Duration	Common Side Effects
Ciprofloxacin	500 mg bid	7 days	Gastrointestinal disturbance, headache, dizziness, tremors, restlessness, confusion, rash, *Candida* infections
Levofloxacin	750 mg once daily	5 days	Same as for ciprofloxacin
Trimethoprim-sulfamethoxazole	160/800 mg bid	10–14 days	Nausea, vomiting, anorexia, hypersensitivity reactions

TABLE 85.4 Antibiotic Options for Complicated Pyelonephritis

Antimicrobial	Dose (IV)	Common Side Effects
Cefepime	1–2 g every 8 h	Abdominal pain, muscle cramps, nausea, vomiting
Ceftriaxone	1 g every 24 h	Fever, cough, sore throat, fatigue
Piperacillin-tazobactam	3.375 g every 6 h	Diarrhea, nausea, vomiting, rash
Aztreonam	1 g every 8–12 h	Cough, abdominal pain, nausea, vomiting
Ciprofloxacin	400 mg every 12 h	GI disturbance, headache, dizziness, tremors, restlessness, confusion, rash, *Candida* infections
Levofloxacin	500 mg every 24 h	Same as for ciprofloxacin

TABLE 85.5 Medication Options for Prostatic Enlargement

Antimicrobial	Dose
Alpha-Adrenergic Receptor Antagonist	
Alfuzosin	10 mg once daily
Doxazosin	1 mg once daily
Tamsulosin	0.4 mg once daily
Terazosin	1 mg once daily or at bedtime
5-Alpha-Reductase Inhibitors	
Dutasteride	0.5 mg once daily
Finasteride	5 mg once daily

prostate resection, open prostatectomy, laser vaporization, transurethral microwave therapy, or needle ablation. Decisions regarding treatment options are based on the degree of obstruction and symptoms.

Disposition

Hospitalization is required in the presence of clinical toxicity (e.g., fever, tachycardia, hypotension, vomiting), inability to take oral medications, an immunocompromised state, third-trimester pregnancy, failure of oral outpatient therapy, urologic abnormalities, or patients with significant comorbid conditions, including heart failure and renal insufficiency. Patients who don't fall into these categories often benefit from short-term treatment in the ED or observation unit with IV hydration, pain and fever control, and the first dose of an IV fluoroquinolone. If these patients improve clinically, and can tolerate food and drink, they can be safely discharged home on a 10- to 14-day course of an oral fluoroquinolone, with close primary physician follow up. Urine culture with sensitivity testing and further diagnostic evaluation are not necessary in this patient population.

COMPLICATED URINARY TRACT INFECTION IN HIGH-RISK POPULATIONS

Pregnancy

UTI during pregnancy represents a special situation. Although the incidence of UTI in pregnancy is approximately the same as in nonpregnant women, pyelonephritis is more common during pregnancy. This is likely a result of the physiologic changes that occur within the urinary tract of pregnant women, which include ureteral and renal pelvis dilation. Factors associated with a higher risk of bacteriuria include a history of prior UTI, preexisting diabetes mellitus, increased parity, and low socioeconomic status.

Unlike bacteriuria in nonpregnant females, bacteriuria in pregnant women, even if they are asymptomatic, should be treated. Untreated bacteriuria in pregnancy is associated with premature labor, low birth weight, perinatal mortality, maternal anemia, and maternal pyelonephritis. Like nonpregnant women, *E. coli* is the most common uropathogen. The symptoms of UTI and pyelonephritis are also the same as in nonpregnant patients; however, urinary frequency and urgency may be symptoms of a normal pregnancy. Specimen collection and diagnostic strategies are also similar. A urine culture specimen should be obtained, along with a follow-up culture as a test of cure.

Options for empirical treatment for UTI include amoxicillin-clavulanate, cefpodoxime, nitrofurantoin, fosfomycin, and TMP-SMX (Table 85.6). The evidence regarding an association between the nitrofuran and sulfonamide classes of antibiotics and birth defects is mixed.[7] Previous American College of Obstetricians and Gynecologists (ACOG) recommendations were to avoid TMP-SMX and nitrofurantoin during the first trimester. Current recommendations state that it is appropriate to prescribing sulfonamides or nitrofurantoin in the first trimester when no other suitable alternative antibiotics are available.[7]

During the second and third trimesters, sulfonamides and nitrofurantoins may be used as first-line agents for the treatment of UTIs.[7] Fluoroquinolones should be avoided in pregnancy.

Hospital admission should be considered for patients in their last trimester, who appear ill, or who have evidence of pyelonephritis and would benefit from treatment with parenteral antibiotics and IV fluids. Parenteral regimens for the empirical treatment of pyelonephritis are similar to those for nonpregnant patients, except the use of fluoroquinolones, and include ceftriaxone, cefepime, aztreonam, and piperacillin-tazobactam (Table 85.7). Nitrofurantoin and fosfomycin do not achieve tissue levels adequate to treat pyelonephritis

TABLE 85.6 Antibiotic Options for Bacteriuria in Pregnancy

Antimicrobial	Dose (Oral)	Duration	Contraindications
Amoxicillin-clavulanate	500 mg tid	3–7 days	
Cefpodoxime	100 mg bid	5–7 days	
Nitrofurantoin	100 mg bid	5–7 days	First trimester and 38 weeks to delivery
Fosfomycin	3 g as a single dose		
Trimethoprim-sulfamethoxazole	160/800 mg bid	3 days	First trimester and term

TABLE 85.7 Parenteral Antibiotic Options for Pyelonephritis in Pregnancy

Antimicrobial	Dose (IV)
Ceftriaxone	1 g every 24 h
Cefepime	1 g every 8 h
Piperacillin-tazobactam	3.375 g every 6 h
Aztreonam	1 g every 8–12 hours

appropriately. Hospitalized pregnant patients who are afebrile for 48 hours can be discharged on oral antibiotics, directed by culture susceptibility results, to be completed in 10 to 14 days.

Indwelling and Temporary Urinary Catheters

Catheter-associated UTI (CAUTI) is defined as urine containing greater than 1000 CFU/ml of one or more bacterial species in a catheterized patient with suggestive symptoms, such as pelvic discomfort, flank pain, fever, rigors, malaise, altered mental status or lethargy with no other identified cause, costovertebral angle tenderness, or acute hematuria.

Screening for or treating asymptomatic bacteriuria in patients with indwelling catheters is not indicated. Antibiotic treatment results in the development of resistant microorganisms, whereas removal of the catheter leads to the spontaneous elimination of bacteria in many patients. Treatment of patients with a UTI in whom permanent removal of the catheter is contraindicated includes antibiotic therapy and urine culture and sensitivity. Replacement of the catheter and strong consideration for hospitalization is indicated in those who exhibit altered vital signs, systemic symptoms, or a toxic appearance.

Many patients with indwelling urinary catheters who present to the ED are older and not able to verbalize their symptoms or lack clinical signs of infection. Given that a catheter-associated UTI is a common cause of subsequent bacteremia and mortality, empirical antimicrobial therapy, in addition to replacement or removal of the catheter, is often appropriate in such patients. Urine culture with antibiotic sensitivity testing will help guide antibiotic therapy in this patient population. The most important risk factor for bacteriuria is the duration of catheterization. The most effective strategy for addressing CAUTIs is to prevent the infection from occurring by placing urinary catheters only when necessary and considering the use of intermittent catheterization and condom catheters, when appropriate.

PROSTATITIS

Background

Males with cystitis often have involvement of the prostate.[8] Prostatitis encompasses four distinct clinical processes—acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis–chronic pelvic pain syndrome, and asymptomatic inflammatory prostatitis.

Acute bacterial prostatitis generally affects men between the ages of 20 and 40 years, with a second peak in men older than 60 years. Acute prostatitis is caused by a bacterial infiltration that is usually precipitated by reflux of urine infected by *E. coli, Klebsiella, Enterobacter, Proteus,* or *Pseudomonas* spp.

Chronic bacterial prostatitis is a persistent bacterial infection of the prostate lasting more than 3 months. Approximately 10% of acute bacterial prostatitis cases develop into chronic bacterial prostatitis.[9] This can be caused by undertreated acute bacterial prostatitis or highly virulent strains. Like acute bacterial prostatitis, gram-negative bacteria are responsible for most cases of chronic prostatitis.

Whereas acute and chronic bacterial prostatitis have clear bacterial etiologies and are managed as infectious diseases, *chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS)* is characterized by chronic pelvic pain and voiding symptoms in the absence of a clear bacterial etiology.[10] CPPS is defined as urologic pain in the pelvic region associated with urinary symptoms or sexual dysfunction lasting for at least 3 of the previous 6 months. Symptoms of chronic bacterial prostatitis may not differ from those of CP/CPPS. It is a heterogeneous condition with broad diagnostic criteria and uncertain cause, making it difficult to determine an effective treatment regimen reliably.

Asymptomatic inflammatory prostatitis is a painless inflammation of the prostate gland in the absence of infection. It is a common finding in men with benign prostatic hyperplasia and a diagnosis of exclusion in the ED.

Clinical Features

Patients with acute prostatitis often report UTI symptoms such as fever, chills, dysuria, urinary frequency or urgency, and/or perineal and low back pain. A rectal examination will reveal an exquisitely tender and swollen prostate gland in more than 90% of patients. There is no evidence that performing a rectal examination induces clinically significant bacteremia.

Clinical manifestations of chronic prostatitis vary widely, making recognition difficult. Most patients report some degree of voiding symptoms (e.g., frequency, urgency, dysuria), low back and perineal pain and, occasionally, myalgias. Fever and chills are uncommon except during an acute exacerbation of the chronic infection. Findings on the physical examination, including examination of the prostate, often are unremarkable. The diagnosis is based on history, physical examination, and positive urine culture.

Diagnostic Testing

Acute bacterial prostatitis is a clinical diagnosis. A urine Gram stain and culture are recommended to identify causative organisms and guide treatment. Blood cultures are recommended for patients with acute prostatitis and fever who have not yet received antibiotics.[8] Although acute bacterial prostatitis is usually caused by typical urinary pathogens, an STI such as chlamydia and gonorrhea should be

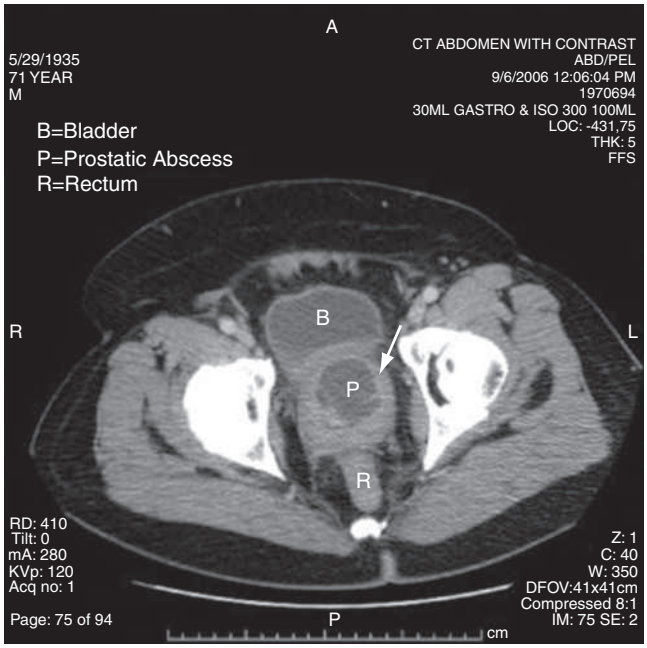

Fig. 85.3 Prostate Abscess. *B,* Bladder; *P,* prostate; *R,* rectum. (From Vandover JC, Patel N, Dalawari P. Prostatic abscess. *J Emerg Med.* 2011;40:e83–e85.)

considered, especially in sexually active patients. Urethral swabs or first-voided urine, with subsequent culture or DNA amplification, should be obtained if a STI is suspected.

The most common complications of acute prostatitis are acute urinary retention (AUR) and prostatic abscess. Approximately 10% of men with acute prostatitis will have some urinary retention, which can be diagnosed using bedside ultrasound. Transrectal ultrasound or CT can detect prostatic abscess and should be considered in patients who fail to improve with antibiotics (Fig. 85.3).

Management

Outpatient therapy can be used if the patient is not systemically ill, can tolerate oral medications, and does not have urinary retention. General support measures for outpatients should include bed rest, analgesics, nonsteroidal antiinflammatory drugs (NSAIDs), hydration, and stool softeners. Alpha blocker therapy is also recommended for obstructive voiding symptoms related to prostatitis (see Table 85.5).

There is no consensus regarding an optimal treatment regimen, so regional patterns of antibiotic resistance should be considered. Few antimicrobial agents are able to penetrate the prostrate and achieve sufficient concentrations to eradicate infection. Fluoroquinolones, such as ciprofloxacin or levofloxacin, achieve the highest concentrations in the prostate and are the first-line agents in the treatment of bacterial prostatitis. Empirical parenteral antibiotics such as ciprofloxacin, levofloxacin, or ceftriaxone are recommended until fever and other symptoms have subsided. After improvement, oral antibiotics are recommended for at least 4 weeks (Table 85.8). Hospitalization for parenteral antibiotics is recommended for patients who appear systemically ill, cannot tolerate oral medications, or have urinary retention as determined by ultrasound or catheterization. Antibiotic options include ciprofloxacin 400 mg IV every 12 hours, levofloxacin 500 mg IV every 24 hours, or ceftriaxone 2 g IV every 24 hours. Following clinical improvement, the patient may be transitioned to an oral regimen, such as a fluoroquinolone. The duration of treatment should be a minimum of 2 weeks, although 4 to 6 weeks may be necessary.

TABLE 85.8 Oral and Parenteral Antibiotic Options for Prostatitis (4 to 6 Weeks' Duration)

Antimicrobial	Dose
Ciprofloxacin	400 mg every 12 h (IV)
Levofloxacin	500 mg every 24 h (IV)
Ceftriaxone	2 g every 24 h (IV)
Ciprofloxacin	500 mg every 12 h (PO)
Levofloxacin	500 mg once daily (PO)
Trimethoprim-sulfamethoxazole	160/800 mg bid (PO)

The treatment of chronic bacterial prostatitis consists of antibiotics for 4 to 12 weeks. Of the researched treatments, α-adrenergic receptor blockers and antibiotics used alone or in combination result in the greatest improvement in symptoms (see Tables 85.5 and 85.8). Anti-inflammatories may also be beneficial. Patients thought to have chronic prostatitis or CPPS should be referred to a urologist.

Treatment of prostatic abscess consists of broad-spectrum intravenous antibiotics (e.g., ciprofloxacin, 400 mg IV every 12 hours) and urologic consultation for perineal drainage or surgical debridement.

RENAL CALCULI

Background

Urolithiasis affects about 12% of the world population and occurs approximately twice as much in men than women.[11] Multiple pathogenic factors interact to cause the formation of renal calculi. Risk factors include older age, male gender, obesity, and family history (Box 85.2). Its incidence depends on geographic, ethnic, dietary, and genetic factors. Approximately 50% of patients will have a recurrence within 5 years.

Pathophysiology

Most ureteral calculi originate in the kidney and then pass into the collecting system. The chemical composition of urinary tract stones is the key factor for determining optimal management. Stones are generally composed of calcium, struvite, or uric acid. Most stones (75%) are composed of calcium oxalate, alone or in combination with calcium phosphate. The hyperexcretion of calcium is a major contributor to stone formation; its most common identified cause is hyperparathyroidism. Other medical conditions that lead to increased calcium levels include hypercalcemia of malignancy, sarcoidosis, and excessive calcium ingestion or increased absorption from the gut. The other major component of calcium stones, oxalate, is influenced by diet. Hyperoxaluria occurs in the presence of small bowel disease, bariatric surgery, Crohn disease, ulcerative colitis, and radiation enteritis.

Magnesium ammonium phosphate (struvite) stones account for approximately 15% of all renal calculi. Struvite stones occur almost exclusively in patients with UTIs and are sometimes referred to as infection stones. They form as a result of the presence of urea-splitting organisms, such as *Proteus, Providencia, Klebsiella, Pseudomonas,* and *Staphylococcus.* Patients with anatomic abnormalities that predispose them to recurrent UTIs are at increased risk of developing struvite stones. Most staghorn calculi—stones that fill the greater part of the collecting system—are composed of struvite.

Uric acid stones account for 10% of all stones in the United States. Approximately 15% of patients with symptomatic gout have uric acid calculi, and the incidence of uric acid stones increases with the use of uricosuric agents. In addition to hyperuricosuria, aciduria is

BOX 85.2 Risk Factors for Urolithiasis

- Metabolic disease or disturbance

  - Previous kidney stone
  - Dehydration

UTI, urinary tract infection.

considered necessary because the precipitation of uric acid is unlikely at a higher urine pH. A distinctive feature of uric acid stones is their radiolucency.

Impaction along the genitourinary tract is a serious complication of renal calculi and can cause several physiologic changes. Once obstruction occurs, a rapid redistribution of renal blood flow results in a decrease in the glomerular filtration rate (GFR). As glomerular and tubular function decrease, renal excretion shifts to the unaffected kidney. Obstruction also causes a rapid decrease in ureteral peristaltic activity. In the presence of infection, renal and ureteral function may be impaired. Complete obstruction of the ureters may lead to loss of renal function with an increased incidence of irreversible damage after 1 to 2 weeks. Partial obstruction is associated with a lower likelihood of renal injury but may still result in irreversible damage.

Although calculus size and location are important determinants of the degree of disease, the major cause of progressive renal damage is associated infection. The stone behaves as a foreign body and leads to stasis and obstruction, decreasing host resistance and increasing the incidence of infection. Subsequent infectious complications include pyelonephritis, perinephric abscess, and gram-negative bacterial sepsis.

The three primary predictors of stone passage without the need for surgical intervention are calculus size, location, and degree of patient pain. The most important factor that relates to passage of a calculus though the genitourinary tract is its size. Approximately 90% of stones smaller than 5 mm pass spontaneously within 4 weeks. This percentage decreases to 15% for stones 5 to 8 mm in size. Up to 95% of stones larger than 8 mm become impacted along the genitourinary tract, and lithotripsy or surgical removal is usually required. Surgical intervention can be performed on an outpatient basis, provided the patient is able to tolerate oral intake and has adequate pain control unless the stone is infected, renal damage is considerable, there are bilateral obstructing stones, or there is obstruction of a solitary or transplanted kidney. Spontaneous passage is more frequent with stones located below the midureter than those located above the midureter.

Renal calculi seldom cause complete obstruction. There are five sites along the ureter at which calculi are likely to become impacted (Fig. 85.4). First, a stone may lodge in the calyx of the kidney or pass into the renal pelvis and become lodged at the ureteropelvic junction. Second, the relatively large renal pelvis (1 cm) narrows abruptly at its distal portion, where it is equal in diameter to its adjoining ureter (2 to 3 mm). The third region is near the pelvic brim, where the ureter arches over the iliac vessels posteriorly into the true pelvis. The most constricted area along the ureter, and a common location for impaction, is the ureterovesicular junction. This is the site at which the ureter enters the muscular coat of the bladder (intramural ureter). At the time of diagnosis, up to 75% of stones are located in the distal third of the ureter. Finally, calculi may become lodged in the vesical orifice.

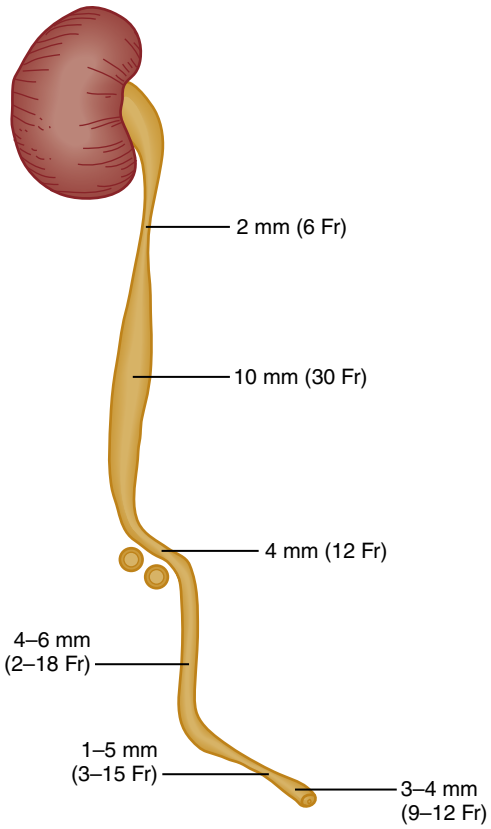

Fig. 85.4 Variations in Caliber of the Ureter. *Fr,* French catheter size. (Adapted from Eisendrath, Rolnick. Lich R Jr, et al. Childhood disorders and diseases. In: Harrison JH, Gittes RF., eds. *Campbell's Urology*. Vol. 1. 4th ed. Philadelphia: WB Saunders; 1978.)

Clinical Features

The onset of pain usually is abrupt, with a crescendo of extreme pain that begins in the flank, extends laterally around the abdomen, and radiates into the groin. Pain may radiate to the testicles in men and the labia majora in women. A constant, underlying dull ache in the flank is common between episodes of colic. The cause of colicky, severe flank pain is hyperperistalsis of the smooth muscle of the calyces, pelvis, and ureter, whereas the cause of a dull ache can be acute obstruction and renal capsular tension. GI symptoms of nausea and vomiting are common.

One-third of patients experience gross hematuria, with or without blood clots in the urine. Symptoms of urinary urgency and frequency often develop as the stone nears the bladder. A history of fever and chills strongly suggests superimposed infection; these cases should be regarded as true urologic emergencies.

BOX 85.3 Differential Diagnosis for Pain Associated With Urolithiasis

Urologic Disease

Upper Urinary Tract

Renal infarct
Renal parenchymal tumors
Urothelial tumors
Papillary necrosis
Pyelonephritis
Hemorrhage (blood clot)

Ureter

Urothelial tumors
Hemorrhage (blood clot)
Previous surgery (e.g., stricture)
Metastatic tumors

Lower Urinary Tract

Urothelial tumors
Urinary retention

Nonurologic Disease

Intra-abdominal

Peritonitis (especially appendicitis)
Biliary colic
Intestinal obstruction

Vascular

Abdominal aortic aneurysm
Superior mesenteric artery occlusion

Retroperitoneal

Retroperitoneal lymphadenopathy
Retroperitoneal fibrosis
Tumor

Gynecologic

Cervical cancer
Endometriosis
Ovarian vein syndrome

Musculoskeletal

Muscle strain or bony injury

A patient with renal colic often is in severe pain and paces or writhes in pain on the stretcher, unable to find a comfortable position. The abdomen should be auscultated and palpated in search of bruits and thrills over the abdominal aorta and iliac vessels because the clinical manifestations of aortic abdominal aneurysms (AAAs) may mimic those of renal colic. Patients commonly have intermittent pain that may nearly resolve between episodes of severe discomfort.

Differential Diagnosis

A number of clinical diseases can produce pain similar to that of renal colic (Box 85.3). Potentially serious or life-threatening alternate diagnoses include pulmonary embolism, ectopic pregnancy, biliary disease, bowel obstruction, incarcerated inguinal hernia, pancreatitis, appendicitis, AAA, renal vein thrombosis, and renal malignancies and infarction.

Diagnostic Testing

Urinalysis and Culture

Red blood cells (RBCs) generally are found in the urine of patients with urolithiasis. However, the absence of RBCs in the urine does not exclude the diagnosis. Up to 20% of patients with documented urolithiasis have no microscopic hematuria.[12] Furthermore, there is no correlation between the degree of obstruction and absence of hematuria.

Sterile pyuria can occur in the absence of infection as a result of ureteral inflammation, but the presence of a UTI should be investigated if other clinical signs of infection are present, such as fever and chills. A urinalysis with culture should be performed to look for pyuria and bacteriuria and to measure nitrite and leukocyte esterase levels when infection is suspected.

The kidney does not produce urine with a pH greater than 7.5 under normal conditions, so a urinary pH higher than 7.5 should raise suspicion for the presence of urea-splitting organisms such as *Proteus*. Renal tubular acidosis and ingestion of absorbable alkali also may increase the urinary pH and should be considered in the differential diagnosis. A pH less than 5 often is associated with the formation of uric acid calculi.

Other Laboratory Tests

Measurement of blood urea nitrogen (BUN) and serum creatinine levels is not routine but should be performed in patients who have a renal calculus with a solitary kidney, transplanted kidney, or history of renal insufficiency. On rare occasions, urolithiasis can present as acute renal failure resulting from obstruction of both ureters or the ureter of a solitary kidney. A slightly elevated white blood cell (WBC) count in patients with renal calculi may be the result of demargination from acute pain, but this is not a sensitive test and should be performed only in patients who are thought to be infected. A significantly elevated WBC count or left shift on the differential suggests active infection.

Imaging

Imaging is not needed in all patients with renal colic but should be performed when signs and symptoms are atypical and the diagnosis is in question, the patient has a solitary or transplanted kidney, or appears toxic, or high-grade obstruction is suspected.

Radiography of the Kidney, Ureter, and Bladder

As an initial imaging study, kidney, ureter, and bladder (KUB) radiography provides only presumptive evidence of calculi (<70% specificity), so it should be followed by a more definitive study or avoided altogether. It is of limited usefulness on its own except to monitor progression of a previously identified radiopaque stone in a stable patient.

Intravenous Pyelography

Intravenous pyelography is an accurate imaging modality to detect renal stones, but is seldom used now because CT scanning and ultrasonography have become first-line imaging modalities. It is very sensitive, capable of establishing the diagnosis of calculous disease in 96% of cases, and it can quantify the presence and severity of obstruction (Fig. 85.5A and B).

Computed Tomography

Non–contrast-enhanced helical (spiral) CT scanning is the standard imaging modality in the U.S. It is 95% sensitive and 98% specific for

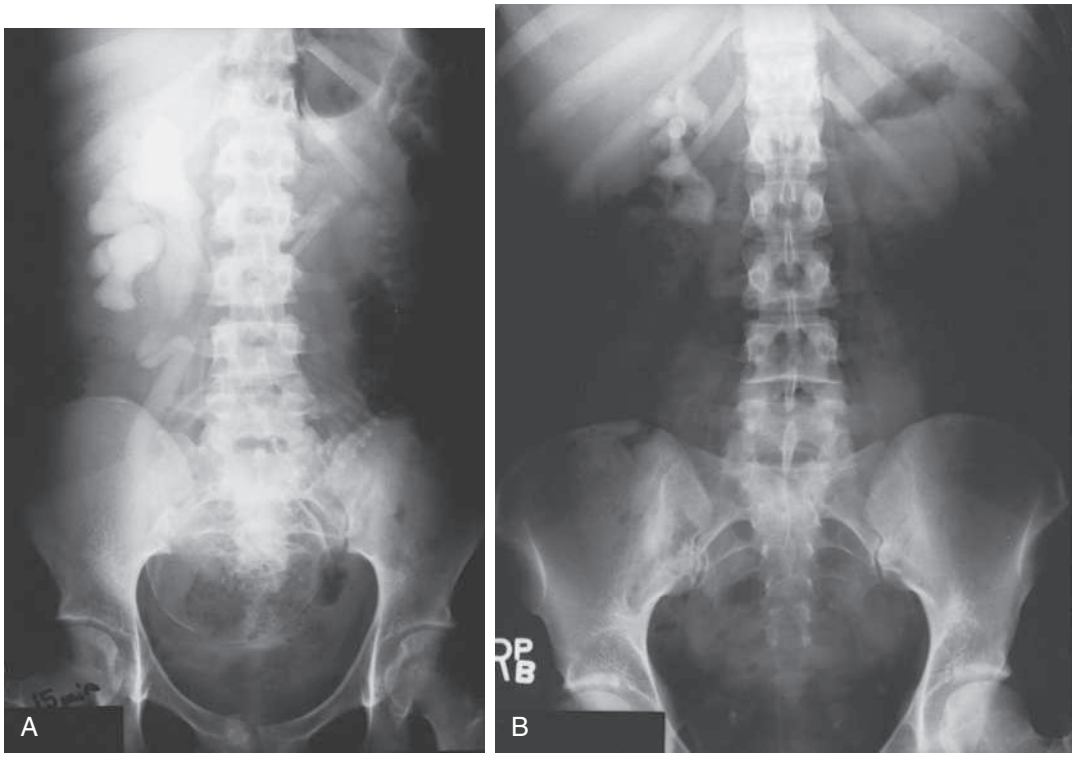

Fig. 85.5 (A) In a near-term pregnant woman with an obstructed left kidney, this intravenous pyelogram demonstrates a delayed nephrogram. (B) The right kidney has physiologic hydronephrosis from ureteral compression by the fetal head.

detecting ureteral calculi.[13] CT may detect calculi as small as 1 mm in diameter and provide direct visualization of complicating conditions such as hydroureter, hydronephrosis (Fig. 85.6), and ureteral edema. Some kidney stones, such as uric acid stones, may be radiolucent. CT is also superior to alternate imaging modalities in its ability to recognize other pathologies, such as malignancy, renal abscess, and AAA. Other advantages include lack of contrast exposure, short duration of testing, and ease of interpretation. For patients with a body mass index less than 30 kg/m^2, low radiation dose protocols can be used, with sensitivities and specificities still reported as more than 90%.[14] However, many patients with a history of nephrolithiasis and clinical picture consistent with renal colic do not require imaging. Patients with a history of nephrolithiasis who lack fever, a urinalysis showing infection, a solitary or transplanted kidney, suspicion for complicated urolithiasis, or diagnosis other than renal colic may forego CT imaging.[15]

Ultrasonography

Ultrasound, whether performed by a radiology technician or point of care in the ED, may provide diagnostic information to guide further evaluation and treatment. Performing an ultrasound as the initial imaging test often eliminates the need to obtain an abdominal and pelvic CT scan and decreases radiation exposure to the patient. Ultrasound has been found to be up to 100% sensitive and 90% specific for the diagnosis of ureteral obstruction in patients presenting with acute flank pain.[5] This has resulted in some guidelines to recommend it as the initial imaging modality for suspected obstructing ureterolithiasis and identification of hydronephrosis (Fig. 85.7).[16] Ultrasound may also guide clinical suspicion and need for further imaging in patients with less typical signs and symptoms of calculi. It is also the study of choice for ruling out hydronephrosis for pregnant and pediatric patients if obstructive urolithiasis is a concern.[17]

Ultrasound is less sensitive and specific than CT imaging for detecting stone size and location and has been found to be 54% sensitive and 91% specific for the diagnosis of urolithiasis.[18] For potential urological intervention, CT is generally performed given the accuracy for identification of stones and identification of other potential etiologies of flank pain.

Management

The first priority for a patient with a presumed diagnosis of kidney stone is adequate pain control. NSAIDs are first-line agents, but parenteral administration often is necessary because of nausea and vomiting. Ketorolac, 30 mg IV, or diclofenac, 75 mg intramuscularly (IM), provide rapid effective analgesia and decrease both ureteral spasm and renal capsular pressure by diminishing the GFR in the obstructed kidney. Accordingly, caution is advised with use of these agents in patients with underlying renal insufficiency or peptic ulcer disease. An IV narcotic such as fentanyl (1 to 2 µg/kg) is also very effective in providing rapid analgesia. The combination of NSAIDS and opiates may reduce length of stay in the ED. In the patient who is unable to tolerate oral fluids, IV fluids and an antiemetic such as ondansetron, 4 mg IV, should be given. There have been no definitive studies proving that high-volume fluid therapy in those with acute renal colic facilitates stone passage or improves outcomes.[19]

Concomitant infection with an obstructive stone and hydronephrosis constitutes a true urologic emergency and may warrant immediate urologic intervention for placement of ureteral stents or decompression of the renal pelvis by percutaneous nephrostomy.

Disposition

Indications for Admission

Hospitalization is recommended for patients who are severely dehydrated, are experiencing unrelenting pain or vomiting, or have an

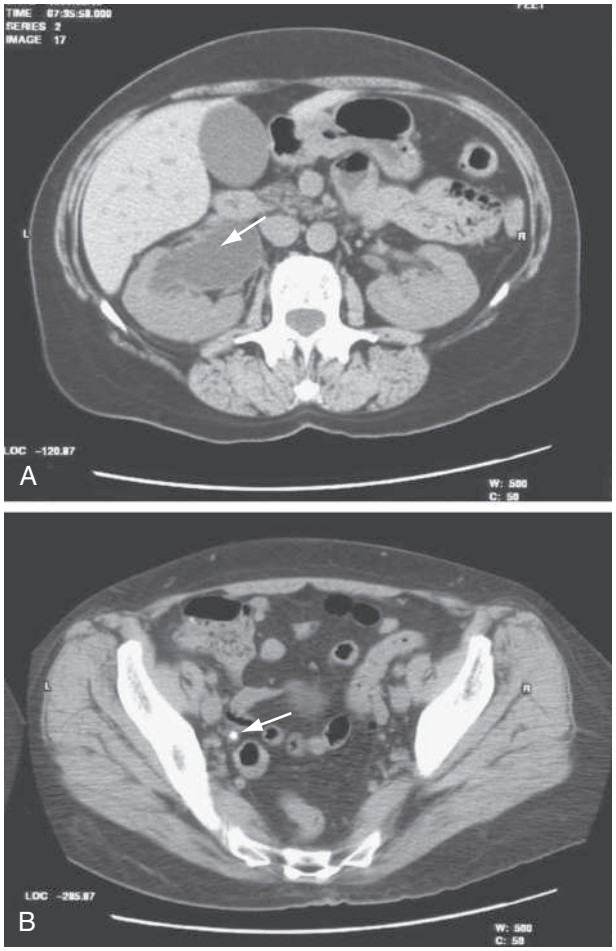

Fig. 85.6 CT Scans Obtained in a Patient With Renal Colic. (A) Right-sided hydronephrosis. (B) Right ureteral calculi.

underlying urinary infection (Box 85.4). Sepsis and renal damage are risks in the presence of obstruction and infection, so these patients require an emergent urologic consultation to evaluate the need for immediate operative intervention to provide drainage and relieve the obstruction. If signs of sepsis (e.g., tachycardia, fever, hypotension, shock) are present, parenteral antibiotics, such as ceftriaxone 1 g IV, should be given and fluid resuscitation carried out pending urologic evaluation.

Several interventional strategies are available to the urologist for the management of stones that do not pass spontaneously. Optimal therapy depends on the size, location, and composition of the stone. Ureteroscopy and extracorporeal shock wave lithotripsy (ESWL) are the two most commonly used techniques. Ureteroscopic removal of ureteral stones, compared to ESWL, achieves a greater stone-free state and lowers the need for retreatment.[20] Both treatment options have a low complication rate.[20] Percutaneous nephrolithotomy, which establishes a tract from the skin to the collecting system, is used for stones too large or hard for ECSWL or ureteroscopy by removing them directly from the renal pelvis.

Outpatient Management

Most patients with nephrolithiasis may be safely managed as outpatients. They should be instructed to return to the ED immediately for intractable or severe pain, persistent nausea and vomiting, fever or chills, or difficulty voiding. Spontaneous passage usually occurs within 4 weeks after the onset of symptoms. Patients with first-time stones or those who have not had chemical analysis of their stones should strain all urine or simply void into a glass jar; the calculus should be visible at the bottom. The stone can be submitted to the follow-up urologist for analysis. If a stone has not been passed within 4 weeks, intervention is indicated, because the risk of complications such as ureteral stricture and renal function deterioration increase. The patient should be instructed to drink a moderate amount of fluids, take analgesics as needed for pain, and engage in activity as tolerated.

Medical expulsive therapy is a potentially useful treatment modality for the management of ureteral stones. α_1-Antagonists (e.g., tamsulosin, 0.4 mg PO daily) may facilitate stone expulsion and decrease the time to spontaneous stone passage by blocking ureteral smooth muscle contraction and improving antegrade stone movement.[21–23] Some studies have questioned the effectiveness of tamulosin,[24–26] while others have suggested, and current guidelines acknowledge, a therapeutic benefit for patients with larger distal stones (5 to 10 mm).[22,25,27,28]

BLADDER (VESICAL) CALCULUS

Background

Approximately 5% of calculi originate in the bladder. Bladder stones occur almost exclusively in older men, often as a complication of an infection of residual bladder urine with urea-splitting organisms or an indwelling catheter. Other disorders predisposing to the formation of bladder stones include bladder neck obstruction (usually secondary to prostatic hyperplasia), neurogenic bladder, vesical diverticula, damage from irradiation, and schistosomiasis.

Clinical Features

Bladder stones cause pain on voiding and hematuria. The patient may report a sudden interruption of the urinary stream, which strongly suggests a vesical stone that intermittently obstructs the bladder outlet. Frequency, urgency, and dysuria are described by up to 50% of patients, and UTIs are common.

The physical examination is rarely helpful; the rectal examination may reveal an enlarged prostate or prostatic malignancy. Poor sphincter tone may suggest a neurogenic bladder.

Diagnostic Testing

Urinalysis generally reveals pyuria, bacteriuria, and hematuria. Plain radiographs of the pelvis reveal a bladder stone in 50% of cases. Contrast scans may demonstrate obstructive changes in the upper tracts or bladder diverticula. Ultrasonography also is useful in the diagnosis of bladder stones.

Management

Surgery is currently the gold standard of care. Depending on the size of the stone, an endoscopic or open approach is used.

ACUTE SCROTAL PAIN

Background

The most common causes of acute scrotal pain are epididymitis and torsions of the testicle and testicular appendage (Table 85.9). Some are emergent surgical conditions such as Fournier gangrene and incarcerated hernias. Others require less invasive and time-dependent therapies, such as antibiotics for epididymitis and observation for benign masses or torsion of the appendix of the testes. Box 85.5 lists a number of other disorders that can present as scrotal swelling.

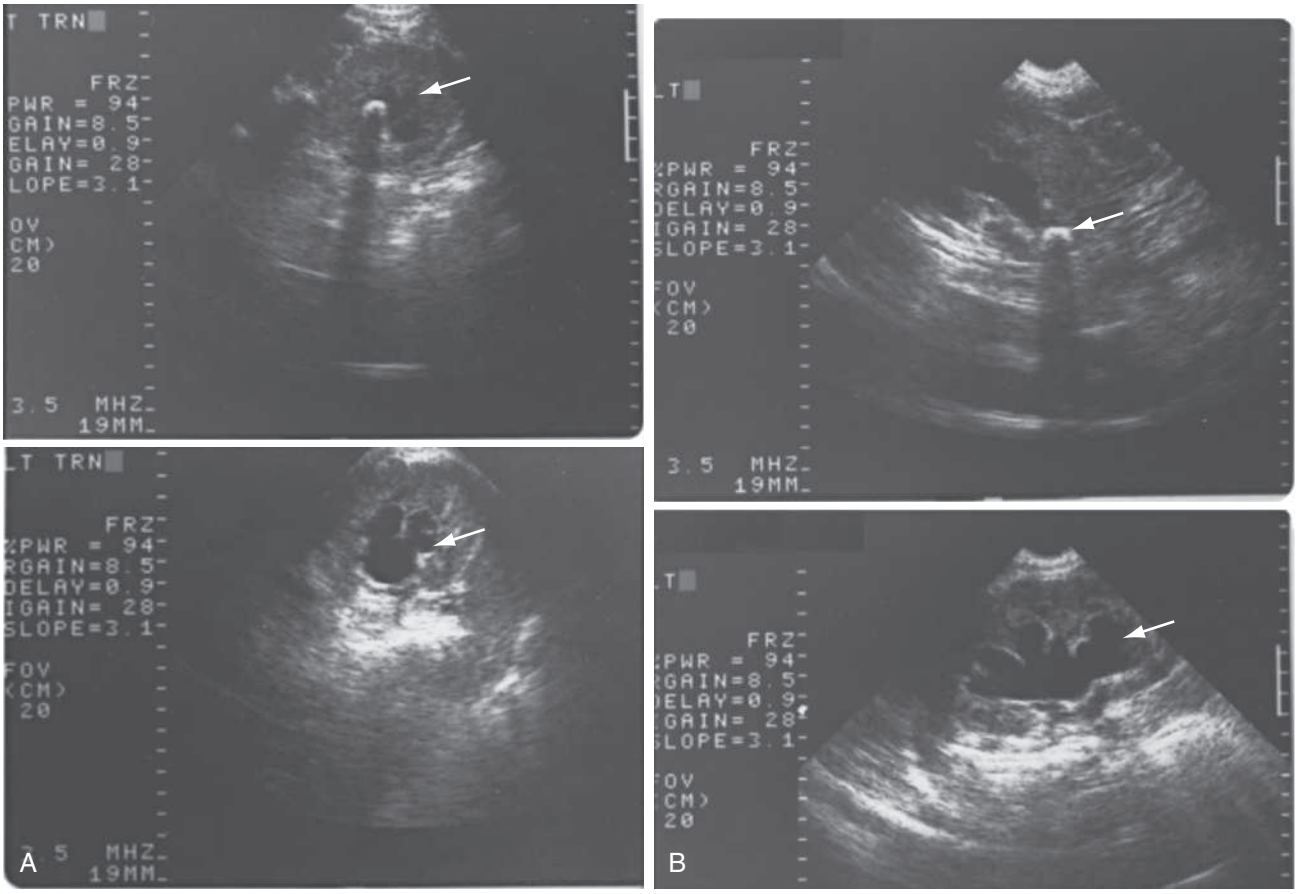

Fig. 85.7 (A) Ultrasound images of the kidney in a patient with renal colic. Hydronephrosis and a calcification with an acoustic shadow are visualized. (B) Ultrasound images of the kidney in a patient with renal colic. Short axis reveals a kidney stone and hydronephrosis.

BOX 85.4 Indications for Hospitalization of Patients With Urolithiasis

Absolute
Obstructing stone with signs of urinary infection
Intractable nausea or vomiting
Severe pain requiring parenteral analgesics
Urinary extravasation
Hypercalcemic crisis

Relative
Significant comorbid illness complicating outpatient management
High-grade obstruction
Leukocytosis
Solitary kidney or intrinsic renal disease
Psychosocial factors adversely affecting home management

Fig. 85.8 demonstrates the anatomy of the scrotum and testis. A normal scrotum is relatively symmetric, and both testicles are of equal mass and volume. The left testicle often is higher than the right because its blood flow empties into the large, low-pressure vena cava, whereas the right drains into the relatively smaller, high-pressure renal vein. A normal testis is found in the vertical axis with a slight forward tilt, and the epididymis is above the superior pole in the posterolateral position. The epididymis is located posterolateral to the testis and is normally nontender and soft. The cremasteric reflex is elicited by stroking or pinching the inner aspect of the thigh; more than 0.5 cm of elevation of the ipsilateral testicle is considered evidence of a normal reflex. This reflex normally is absent in 50% of male infants younger than 30 months.

SPECIFIC DISORDERS

Testicular Torsion

Background

The incidence of testicular torsion in males below 25 years old is approximately 1:4000.[29] Torsion can occur at any age, but has a bimodal age-incidence in the first year of life and at puberty during testicular growth (Fig 85.9). In neonatal torsion, extravaginal torsion usually occurs, with twisting of the entire cord including the tunica vaginalis. In older children and adults, intravaginal torsion (twisting of the cord within the tunica vaginalis) occurs and is commonly associated with a bell-clapper deformity.[30] A bell-clapper deformity is a congenitally abnormal fixation of the tunica vaginalis to the testicle that results in increased mobility of the testicle.

With torsion, abnormal testicular rotation of the spermatic cord results in obstruction of venous outflow, subsequent compromised arterial flow, and testicular ischemia. Testicular salvage hinges on the degree of torsion and duration of the ischemia. Testicular torsion in neonates has few known etiological factors, poor testicular viability, and rarely present to the ED.[31] Thus, the remainder of this discussion will focus on intravaginal torsion. Torsion that presents to the ED within 6 hours of the start of pain is associated with testicular salvage rates greater than 90%. After 6 hours of torsion, the rate of testicular

TABLE 85.9 Differentiation Among Common Causes of the Acute Scrotum

Parameter	Testicular Torsion	Appendix Torsion	Epididymitis
Age	<1 year, puberty	7–14 years	Adult
Onset	Hours	1–2 days	Days to weeks
Location of pain	Entire testicle	Upper pole	Epididymis
Testicle position	High-riding testicle Transverse alignment	Normal position Vertical alignment	Normal position Vertical alignment
Systemic symptoms	Nausea, vomiting	None	Possibly fever
Cremasteric reflex	No	Intact	Intact
Pyuria	Rare	No	Yes
Ultrasound findings	Diffusely hypoechoic Asymmetric testicles Normal or decreased flow Spermatic cord twist	Focally hypoechoic Symmetrical testicles Normal flow	Hypoechoic epididymis Symmetric testicles Increased flow
Treatment	Surgery	Supportive	Antibiotics; prepubescent—supportive only

Note: No single finding in patients with an acute scrotum can reliably differentiate torsion from other causative disorders. When torsion is a diagnostic possibility, prompt urology consultation and further testing are mandatory.

atrophy and orchiectomy increases rapidly. There is poor testicular viability if detorsion is delayed 24 hours or more.[29]

Clinical Features

Patients with testicular torsion typically report the sudden onset of rapidly escalating pain in the scrotum, lower abdomen, or inguinal area that awakens them from sleep or develops several hours after physical activity. While torsion can occur after trauma, it usually occurs without any specific preceding event. Patients with testicular torsion may describe similar pain in the past, caused by previous intermittent torsion in a predisposed testicle. Because torsion may present with abdominal pain and no scrotal pain, the scrotum should be examined in all patients presenting with abdominal pain.

The physical examination is more reliable than the history in determining the presence of testicular torsion. Patients with torsion frequently have a tender firm testicle that can be higher than the contralateral testicle owing to shortening of a twisted spermatic cord. Twisting also can leave the testicle in the transverse position and displace the epididymis from its usual location along the posterior aspect of the scrotum. Often, the patient's scrotum is so swollen and tender that a complete physical examination is impossible. The cremasteric reflex is usually absent in patients with torsion; however, its presence cannot be used to rule out torsion. The cremasteric reflex occurs when the ipsilateral testicle elevates after stroking the medial thigh. This reflex may be absent in normal patients as well as those with upper and lower motor neuron disorders or spinal cord trauma.[32]

Differential Diagnosis

There is no single historical or physical finding that reliably differentiates testicular torsion from other causes of acute scrotal pain (see Table 85.9).

Diagnostic Testing

Urinalysis

In patients in whom the history and physical findings strongly suggest torsion, emergent surgical consultation is warranted. If the diagnosis is equivocal, adjunctive tests should be performed to determine the cause of the pain. Although urinalysis results suggestive of infection are consistent with epididymitis, such findings also may be noted in patients with torsion and a concomitant UTI.

Imaging

Ultrasound is the diagnostic modality of choice for detecting torsion and has a sensitivity of 96% to 100% and specificity of 84% to 95%.[33] The torsed testicle is typically hypoechoic and enlarged (Fig. 85.10). False-negative findings occur when the testicle is examined early in the course of the disease, when blood flow is still present, and with intermittent torsion. Examination of the spermatic cord for twisting, instead of the testicle itself, has been shown to reduce the frequency of these false-negative results. Ultrasound is helpful when it demonstrates torsion in patients with equivocal findings on the history and physical examination, but it does not have sufficient sensitivity to rule out a diagnosis of torsion. A urologist should evaluate any patient in whom ultrasound findings are negative but history and physical

findings are suggestive of torsion. Moreover, an ultrasound examination should never delay evaluation by a urologist in a patient with probable torsion.

Ultrasound imaging for testicular torsion includes both grayscale and Doppler examination. Grayscale imaging can identify a spermatic cord twist, called a "whirlpool sign," above the testis. The parenchymal echotexture on ultrasound may help predict the viability of the testicle. Homogeneous echotexture portends extremely well for testicular viability. However, varying degrees of heterogeneous parenchymal echotexture may be seen in testicular torsion and significant heterogeneity indicates late torsion and testicular nonviability.[34–36] Grayscale imaging can also identify other diagnoses such as inflammation due to epididymitis and scrotal masses.

The Doppler ultrasound appearance of the testicle depends on the degree of twisting of the spermatic cord. With 180 degrees or less of twisting of the cord, venous flow from the testicle ceases but arterial flow persists. This leads to edema of the testicle on ultrasound that can be misinterpreted as inconsistent with torsion. In contrast, with more than 180 degrees of twisting of the cord, arterial flow also ceases, leading to a lack of Doppler signal on ultrasound.

Doppler studies can be more difficult to interpret in younger boys because blood flow is physiologically low in the testicles of prepubertal boys. As many as 50% of boys younger than 8 years do not show intratesticular flow. This hypovascularity can result in false-positive diagnoses, which could potentially lead to unnecessary surgical exploration. Comparison with the contralateral testicle can help avoid this misdiagnosis; as in normal patients, blood flow to the two testicles will be similar.

Magnetic resonance imaging (MRI) and radionuclide scanning of the scrotum have also been used to diagnose testicular torsion but are time-consuming. They have largely been replaced by ultrasound.

Management

The first step in the management of suspected testicular torsion is immediate consultation with a urologist. The longer the spermatic cord remains twisted, the lower the likelihood of testicular salvage. In addition, early consultation allows the urologist to accompany the patient to ultrasound—if imaging is obtained—where images can be reviewed in real time with the radiologist. Analgesia is provided systemically or with a spermatic cord block.

If the urologist is not readily available, manual detorsion may improve testicular salvage and should be attempted (Fig. 85.11).[37] Relief should be felt when the operator rotates the affected testicle away from the midline, as if turning the pages of a book. If this maneuver is successful, patients should report immediate improvement of symptoms. If only partial relief of pain is noticed, an attempt should be made to untwist past 360 degrees because a higher degree of rotation may be present. If pain increases or there is no relief, consider reversing the direction of reduction because over one-third of patients may be torsed laterally.[36] Unfortunately, no independent predictors of the direction of torsion have been identified to guide decision-making on manual detorsion.[36] If manual detorsion is attempted, a spermatic cord block or systemic analgesics should be administered (see Fig. 85.11).

Evaluation by a urologist should never be delayed to perform manual detorsion or any other maneuver. Likewise, regardless of the outcome with manual detorsion, patients require prompt urological evaluation. A surgeon can confirm the reduction and stabilize the testes with orchiopexy. Even for symptoms lasting beyond 24 hours, testicular salvage is possible for incomplete torsion, and orchiopexy can help prevent recurrence. Removal of a necrotic testicle speeds recovery.

Disposition

Rapid diagnosis of testicular torsion is essential and should be followed by emergent surgical scrotal exploration and bilateral orchiopexy, if necessary. Loss of the testicle is usually a result of delay in seeking medical attention. However, many cases of failed testicular salvage have been attributed to misdiagnosis, which almost always leads to orchiectomy and represents a common source of litigation.

TORSION OF APPENDAGES OF THE TESTIS

Background

A normal scrotum has several vestigial appendages that can also twist and become ischemic, with resultant scrotal pain. This process is most common between 7 and 14 years of age, with a mean age of 10 years. In retrospective analyses, torsion of an appendage rivals epididymo-orchitis as the most common cause of the acute scrotum.

The appendix testis, a remnant of the paramesonephric duct, is present in 92% of patients. It is located on the superior aspect of the testicle, between the testis and epididymis (Fig. 85.12). This appendage is prone to torsion owing to its pedunculated shape. After several days of ischemia from torsion, it will undergo necrosis, with eventual reabsorption. Its loss does not permanently affect fertility or have any impact on surrounding structures.

Clinical Features

As with testicular torsion, patients with torsion of an appendage complain of scrotal pain but report milder symptoms, with a more gradual onset. They report nausea, vomiting, urinary symptoms, or previous episodes of similar pain less commonly than patients with testicular torsion. They usually seek medical attention later than patients with testicular torsion, generally after 48 hours of symptoms.

On physical examination, twisting of the appendix testis leads to formation of a hard, tender, 2- to 3-mm nodule at the upper pole of the testicle. Unlike in testicular torsion, the entire testicle is not tender. The testicle also does not change in overall size, and the scrotum typically does not swell until late in the disease process. The cremasteric reflex typically is intact. On transillumination, the ischemic appendage may rarely be seen as a blue dot.

Diagnostic Testing

Urinalysis should not show evidence of infection. On ultrasound imaging, the appendix under torsion will appear hypoechoic. Color Doppler ultrasound can show decreased flow in normal and torsed appendages. With torsion of the appendix, a hypoechoic spherical nodule with a diameter more than 5 mm is present over the superior aspect of the testicle (Fig. 85.13).

Management and Disposition

If testicular torsion is ruled out, surgical excision of the appendix is rarely necessary. Treatment consists of scrotal support, ice packs, and NSAIDs. Resolution of symptoms can be expected within 7 to 10 days. Surgical excision is reserved for uncontrollable pain.

EPIDIDYMITIS

Background

Epididymitis is the most common intrascrotal inflammatory disease. Most cases occur in men between 18 and 35 years of age, but the disease can affect males at any age. It is uncommon in prepubertal males. If untreated, it can lead to orchitis, testicular abscess and, rarely, sepsis.

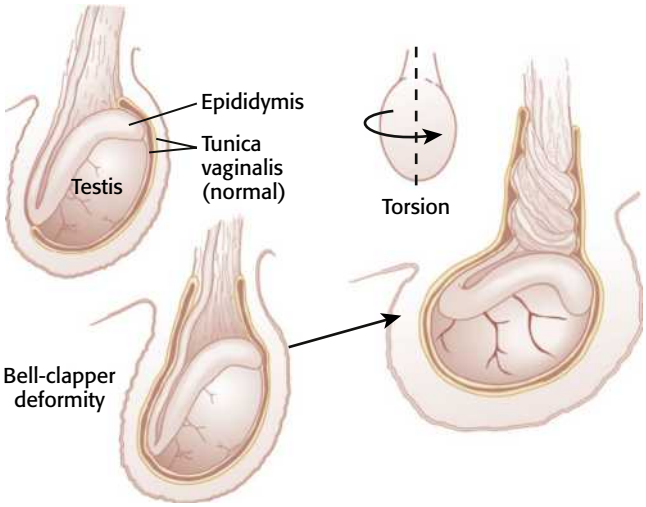
The epididymis is a tightly coiled tubular area along the posterior aspect of the testes, where sperm mature before their transit to the vas deferens. The epididymis becomes infected when organisms travel retrograde from the vas deferens. With infection, the ipsilateral testicle is also commonly involved, a condition referred to as epididymo-orchitis.

The common route of infection is local extension, mainly due to infections spreading from the urethra (sexually transmitted pathogens) or bladder (urinary pathogens). The particular organisms involved in the infection depend on the sexual activity of the patient. Although the literature classically describes men younger than 35 years who are prone to *C. trachomatis* and *N. gonorrhoeae* infections, all sexually active men, regardless of age, are at risk for epididymitis from these organisms. Acute epididymitis caused by sexually transmitted enteric organisms occurs in men who are the insertive partner during anal intercourse. Other rare causes of epididymitis include *M. tuberculosis, Treponema pallidum*, fungal infections, amiodarone use, and systemic inflammatory conditions such as Behçet syndrome.

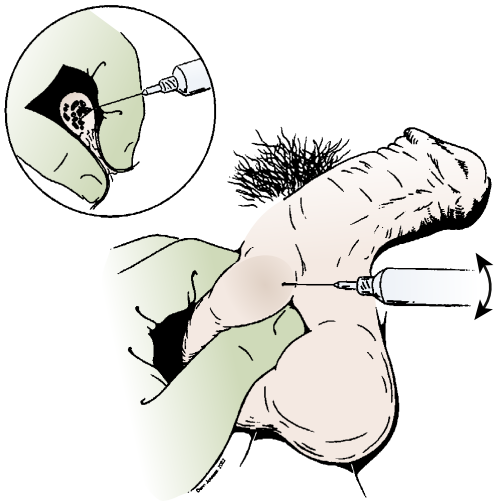
In men older than 35 years, urinary tract pathogens become the predominant cause of epididymitis. Unlike younger patients, older men with epididymitis tend to have urinary tract abnormalities that predispose them to these infections. Over 50% of men older than 60 years with epididymitis have lower urinary tract obstruction. Older men also are more likely to have concomitant prostatitis, benign prostatic hypertrophy (BPH), immunosuppression, or systemic disease or have undergone recent genitourinary instrumentation, surgery, or catheterization.

Epididymitis in children is usually idiopathic, although children can also have congenital genitourinary anomalies that predispose them to recurrent infection. The most commonly associated abnormality is neurogenic bladder, which produces increased pressure during urination and reflux into the ejaculatory ducts. In infants, bacterial causes are more common.

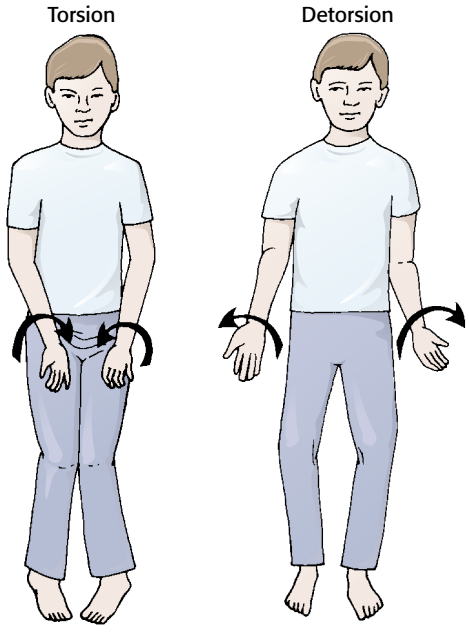
MANUAL TESTICULAR DETORSION



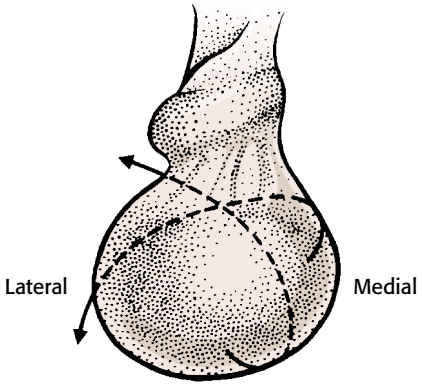
A. **Anatomy of testicular torsion**. Testicular torsion occurs when the testis twists within the tunica vaginalis. Patients with the bell clapper deformity (i.e. incomplete fusion of the tunica along the epididymis, which results in incomplete attachment of the testicle to the scrotum) are at higher risk.



B. **Spermatic cord block**. Grasp the spermatic cord between your thumb and index finger. Use a 30-gauge needle to infiltrate the entire cross section of the spermatic cord and its surrounding rim with anesthetic. This will cause visual ballooning of the grasped segment of the cord. Gently massage this bulge to disperse the anesthetic. Usually about 10 mL is required.



C. Testicular torsion more commonly occurs in a medial direction. Initially attempt detorsion by rotating the testis outward toward the thigh. This is most successful if attempted within the first few hours of torsion, before the onset of significant scrotal swelling. Intravenous narcotics (e.g. fentanyl) can be administered or a cord block performed before attempting detorsion.



D. **Detorsion maneuver**. Detorsion of the testicle may require testicular rotation through two planes. To release the cremasteric muscle, rotate the testis in a caudal-to-cranial direction simultaneously with medial-to-lateral rotation. The right testis is shown.

Fig. 85.11 Manual Testicular Detorsion. (Adapted from Roberts J, Custalow CB, Thomsen TW, eds. *Roberts and Hedges' clinical procedures in emergency medicine*. 6th ed. St. Louis: Elsevier Health Sciences; 2014.)

Clinical Features

Patients with epididymitis experience scrotal pain of gradual onset, prompting them to present later in the clinical course than patients with torsion. Initially, this pain may reside in the lower abdomen or flank, caused by inflammation of the vas deferens. Fever is uncommon. In the early stages of the disease, tenderness is localized to the epididymis but quickly spreads to the ipsilateral testicle. Later in the course, the scrotum can become edematous, erythematous, and extremely tender. The testis is located in the normal anatomic position, with an intact cremasteric reflex. Although Prehn sign—decrease in pain with

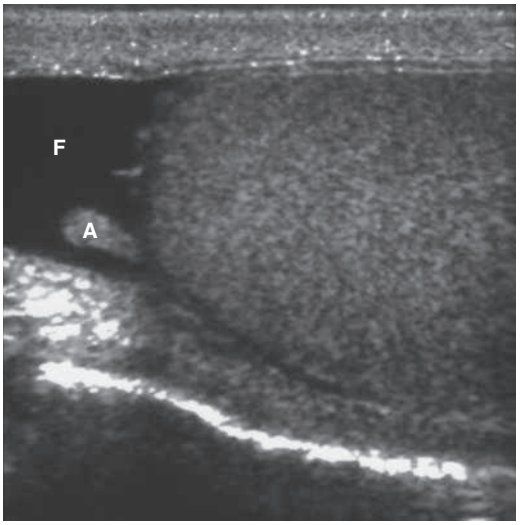


Fig. 85.12 Ultrasound image showing the testicular appendage *(A)* surrounded by a hydrocele *(F)*. (From Blaivas M, Brannam L. Testicular ultrasound. *Emerg Med Clin North Am.* 2004;22:723–748.)

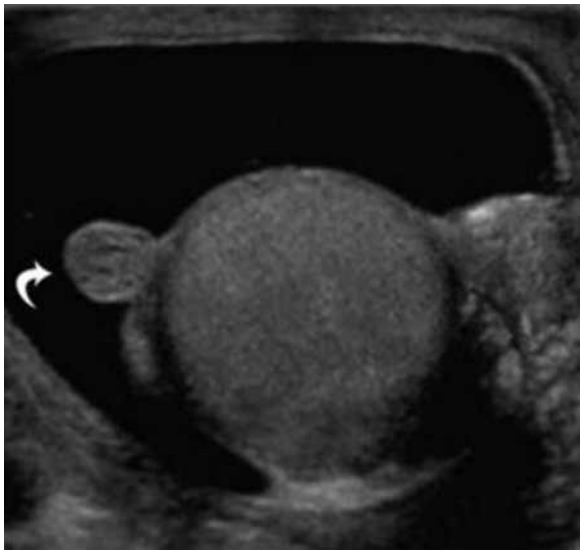

Fig. 85.13 Transverse ultrasound image shows a hyperechoic mass *(curved arrow)* with tiny central hypoechoic areas adjacent to the left testes and epididymis with a reactive hydrocele and mild scrotal wall thickening. (From Mirochnik B, Bhargava P, Dighe MK, Kanth N. Ultrasound evaluation of scrotal pathology. *Radiol Clin North Am.* 2012;50:317–332.)

elevation of the scrotum—has been touted as indicative of epididymitis, it has low sensitivity and specificity. Only 10% of patients with epididymitis from sexually transmitted organisms have symptoms of urethritis or a urethral discharge on examination. No single historical factor or physical finding has been shown to differentiate torsion from epididymitis reliably.

Diagnostic Testing

The diagnosis of epididymitis is typically made based on compatible physical examination findings and confirmed by laboratory testing. A urinalysis usually demonstrates evidence of pyuria. If patients are at risk for STI, a urethral swab or first-void urine sample should be tested for *C. trachomatis* and *N. gonorrhoeae;* a polymerase chain reaction (PCR) assay and other nucleic acid amplification tests have the greatest sensitivity and should be used, when available.

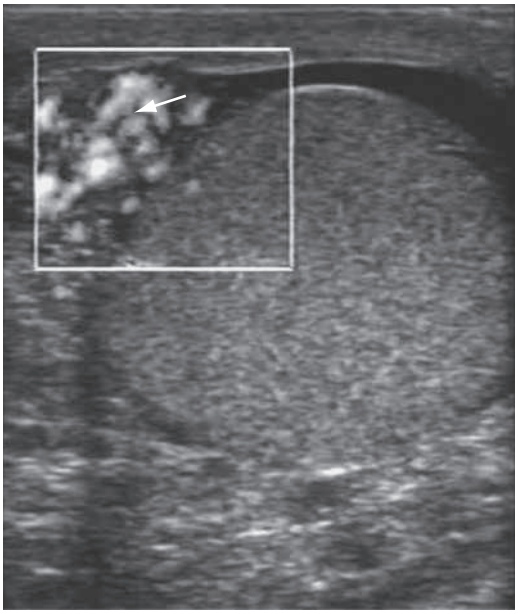

Fig. 85.14 Ultrasound of the testicle showing an enlarged epididymis and increased blood flow on Doppler ultrasound imaging *(white box).* (From Blaivas M, Brannam L. Testicular ultrasound. *Emerg Med Clin North Am.* 2004;22:723–748.)

Systemic leukocytosis may be present but is a nonspecific finding and does not differentiate epididymitis from torsion. In prepubertal children, urinalysis and urine culture rarely are positive. Nevertheless, in these patients, urine cultures should still be obtained to rule out bacterial infection because untreated bacterial infections may lead to long-term complications.

Because the history and physical examination features and laboratory results cannot reliably distinguish torsion from epididymitis or other diseases, equivocal presentation for epididymitis versus testicular torsion should be assessed using testicular ultrasound with Doppler. On ultrasound, an inflamed epididymis appears enlarged and hypoechoic (Fig. 85.14). However, a minority of patients with torsion have preserved flow that can appear similar to that of epididymitis; in these cases, the presence of a spermatic cord twist, indicative of torsion, should be sought.

Prepubertal children with recurrent epididymitis should undergo renal ultrasound and cystography to identify potential underlying urinary tract abnormalities. These are important to identify to reduce the risk of future inflammation.

Management

Empirical antibiotics are selected in accordance with the patient's risk for chlamydia and gonorrhea and/or enteric organisms (Table 85.10). Treatment goals include curing infection, preventing transmission, and reducing future complications such as infertility and chronic pain.

In patients with a suspected sexually acquired infection, ceftriaxone, 500 mg IM, should be given to treat possible *N. gonorrhoeae* infection. In conjunction, doxycycline, 100 mg PO twice a day for 10 to 14 days, should be started to treat *C. trachomatis* or *Ureaplasma urealyticum* infection.[38] Men with suspected or confirmed *N. gonorrhoeae* or *C. trachomatis* infection should be advised to abstain from sexual intercourse until they and their partners have been treated. Treatment of sexual partners should be arranged, even if the partner's culture demonstrates no growth.

In patients with infection by enteric organisms, levofloxacin, 500 mg PO once daily, or ofloxacin, 300 mg PO every 12 hours, is recommended. If the patient is high risk for STIs and enteric organisms,

TABLE 85.10 Treatment of Epididymitis

Drug of Choice	Dose and Route
Presumed Sexually Acquired Epididymitis	
Ceftriaxone *plus*	500 mg IM once
Doxycycline	100 mg PO twice a day for 10 days
Presumed Enteric Epididymitis[a]	
Levofloxacin	500 mg PO daily for 10 days
Potential Sexually Acquired or Enteric Epididymitis[a]	
Ceftriaxone *plus*	500 mg IM once
Levofloxacin	500 mg PO daily for 10 days

[a]Adjust antibacterial therapy according to results of urine culture.
IM, Intramuscularly; *PO,* orally.

treatment should include ceftriaxone and fluoroquinolones (see Table 85.10). Despite the absence of evidence to support benefit, we also recommend bed rest, scrotal elevation, ice packs, and NSAIDs. Discomfort may not completely resolve until weeks after completing an antibiotic regimen.

Most cases of pediatric epididymitis are idiopathic, and antibiotics are not routinely recommended. Urine culture specimens should be obtained and antibiotic therapy should be initiated only if cultures reveal bacteria. Despite the absence of evidence to support benefit, we recommend that boys limit activity, elevate the scrotum with ice packs, and reduce inflammation with NSAIDs. In contrast, infants often have bacterial epididymitis and should be treated empirically with antibiotics pending urine culture results.

Disposition

Patients with systemic signs of toxicity (fever, chills, nausea, vomiting) usually have extension of the infection to involve the testicle, termed epididymo-orchitis. These patients often require hospitalization and treatment with parenteral antibiotics. Most well-appearing patients with uncomplicated epididymitis can be managed as outpatients. Urology referral should be arranged for those likely infected with enteric organisms. Signs and symptoms of epididymitis that do not subside within 3 days require reevaluation of the diagnosis and therapy.

ORCHITIS

Background

Orchitis is a rare acute infection of the testis. With the exception of viral diseases, genitourinary tract infections seldom primarily involve the testis. Orchitis often presents as a progression of epididymitis and may be caused by bacterial or viral infection. Bacterial causes are usually associated with epididymo-orchitis. The most common viral cause of orchitis is mumps. Orchitis due to mumps tends to arise several days after the onset of parotitis. Although vaccination has significantly reduced the incidence of mumps infection, sporadic outbreaks have occurred. Infections in vaccinated individuals are increasingly common, presumably resulting from vaccine failure or antigenic differences between the infecting and vaccine strains.

Owing to the testes' relatively high threshold of resistance to infection, bacterial orchitis usually results from local bacterial spread from the epididymis, frequently referred to as epididymo-orchitis. The most frequent bacterial pathogens are *N. gonorrhoeae, C. trachomatis, E. coli, Klebsiella,* and *P. aeruginosa*. These organisms tend to infect postpubertal males and men older than 50 years with BPH.

Clinical Features

A patient with mumps orchitis has testicular pain and swelling that commonly begins 4 to 6 days after the onset of parotitis, although it can develop in the absence of parotitis. The clinical course varies, with adults having more severe symptoms. Clinical resolution generally occurs in 4 to 5 days.

Patients with bacterial orchitis typically have fever and scrotal pain. They often have constitutional signs and symptoms, including nausea, vomiting, myalgias, and malaise. The disease may be bilateral in up to 30% of patients. The affected testicle and scrotum are swollen, tender, and erythematous.

Diagnostic Testing

As with all causes of scrotal pain, the first priority is to exclude testicular torsion. If the patient clearly has mumps orchitis based on the clinical presentation and a history of preceding parotitis, no other tests are necessary. For all other patients, urinalysis, urine culture, and ultrasound should be performed. On ultrasound, orchitis shows hypervascularity, commonly described as a testicular inferno. Blood tests are typically not helpful, because false-negative results are common with serologic testing, particularly in vaccinated individuals.

Management

In sexually active patients, ceftriaxone and doxycycline should be used to cover *N. gonorrhoeae* and *C. trachomatis.* In older patients, fluoroquinolones provide the best coverage of gram-negative organisms (see Table 85.10). Treatment of viral orchitis is supportive only. Although steroids may improve symptoms, they can reduce testosterone levels. All patients should receive local scrotal care as described for epididymitis. Patients with marked pain, high fever, or constitutional symptoms merit hospitalization and parenteral antibiotics.

TESTICULAR TUMORS

Background

Tumor of the testis is the most common malignancy in young men but accounts for only 1% of all cancers in men. These tumors are more common in infertile patients and patients with cryptorchidism. Approximately 95% of testicular tumors are germ cell tumors, with 50% of these being seminomas and the other 50% being mixed types, including teratomas, choriocarcinomas, and yolk sac tumors. The other 5% of testicular tumors are sex cord stromal tumors. The disease course will depend on the type of tumor present, as well as the age of the patient.

Clinical Features

Testicular cancer usually presents as a painless, unilateral scrotal mass or as an incidental ultrasound finding. However, scrotal pain may be the first symptom in up to 20% of cases. Unlike other painless scrotal masses, such as hydroceles and varicoceles, tumors cannot be separated from the underlying testicle. Palpable tumors are more likely to be malignant compared with tumors identified only with imaging.

Diagnostic Testing

All patients with a scrotal enlargement or palpable scrotal lesions on physical examination should undergo a scrotal ultrasound examination. This study can reveal a concomitant hydrocele or homogeneous hypoechoic lesion. Intratesticular tumors are typically hypervascular, with irregular branching vessels. Leydig cell tumors are unique, because they show hypervascularity around the lesion but no internal color Doppler flow. Although helpful for staging purposes, CT scans of the chest and abdomen are necessary in the ED only if the patient has complaints related to these parts of the body. Most paratesticular masses are benign lesions such as epididymal cysts, epididymitis, spermatoceles, hydroceles, or hernias.

Management and Disposition

Urgent referral to a urologist is indicated for patients with intratesticular masses. The radiosensitive nature of seminomas renders the combined treatment of orchiectomy and radiation therapy highly successful for early-stage disease. Testicular cancer has become one of the most curable solid neoplasms, with an expected 5-year survival rate over 95%.[39]

TESTICULAR TRAUMA

The most concerning injury associated with trauma is rupture of the testicle. Testicular rupture is characterized by tear of the tunica albuginea and extrusion of the seminiferous tubules. The presentation can range from a tender, large, blood-filled scrotum to minimal swelling, with mild pain of the testicle. If there is any concern for rupture, scrotal ultrasound is indicated. Disruption in the echogenic tunica albuginea is 100% sensitive and 65% specific for rupture. Early surgical intervention is associated with higher rates of testicular salvage. Hematomas can be intratesticular or extratesticular, with or without testicular rupture. Similar to rupture, rapid evacuation of an intratesticular hematoma will reduce the risk of necrosis. Extratesticular hemorrhage into the tunica vaginalis is termed a *hematocele* and is the most common finding after blunt scrotal injury. Surgical exploration with hematoma extraction is recommended for patients with large hematoceles to prevent testicular atrophy. Approximately 10% of patients with testicular trauma have associated torsion and require prompt identification and detorsion.

INGUINAL HERNIA, ACUTE HYDROCELE, VARICOCELE, AND SPERMATOCELE

Inguinal hernias, hydroceles, varicoceles, and spermatoceles are considerations in the differential diagnosis of an acute scrotal mass. These clinical entities are typically painless and readily identifiable on physical examination.

Most children with inguinal hernias will not have a palpable mass on examination but will report a history of intermittent bulge in the groin that appears with straining or crying. Less commonly, an inguinal mass is palpable and may extend into the scrotum. If this mass becomes incarcerated, it will be tender, and often the overlying skin will be edematous and erythematous. Children typically will develop irritability, vomiting, or abdominal distention. Incarcerated hernias should be reduced promptly to prevent bowel infarction from strangulation. Reduction can be accomplished by placing the patient in a Trendelenburg position and applying gentle pressure to expel the gas and stool in the bowel from the hernia. Pressure is then applied over the distal aspect of the hernia to reduce the bowel. If this technique fails, surgery is consulted. After reduction of an incarcerated hernia, children typically require hospitalization and delayed surgical repair.

Acute hydroceles typically are benign. They are caused by the accumulation of fluid between the two layers of the tunica vaginalis. They are painless, localized to the scrotum, and will transilluminate.

Varicoceles are enlarged spermatic cord veins that typically are painless or cause only minimal discomfort. On examination, they are often described as feeling similar to a bag of worms, just superior to the testicle, and decrease in size when the patient is supine. In contrast, a spermatocele is a sperm-containing cyst that is palpated as a nontender mass posterior to the testicle. Ultrasound is diagnostic of these conditions. No emergent treatment is necessary, but patients require outpatient urologic evaluation.

Regardless of the cause of the scrotal swelling, concomitant pathology is always a consideration. A careful evaluation for torsion, epididymitis, and tumors should be performed.

ACUTE URINARY RETENTION

Background

AUR is the sudden inability to pass urine voluntarily from the bladder. The lifetime risk of AUR increases with age, occurring in 10% of men in their 70s and in 33% of men in their 80s. AUR is usually caused by an obstructive lesion but also can be the presenting manifestation of other pathologic processes. AUR in women is much less common than in men; common causes in women include an atonic bladder, inflammation occurring postpartum or secondary to herpes, Bartholin abscess, acute urethritis, or vulvovaginitis. Causes in younger patients include obstruction, cystitis, and neurologic disturbances.

Physiology and Pathophysiology

Holding urine requires relaxation of the bladder detrusor muscle, through parasympathetic inhibition and β-adrenergic stimulation, and contraction of the bladder neck and internal sphincter, through α-adrenergic stimulation. Conversely, micturition requires a coordinated contraction of detrusor muscle, with the simultaneous relaxation of the urethral sphincter muscle. AUR results from a disruption of this coordinated physiology caused by an increased resistance to flow via mechanical (e.g., urethral stricture, clot retention) or dynamic means (e.g., increased α-adrenergic activity, prostatic inflammation) or decreased neurogenic control of the detrusor muscle (e.g., drugs inhibiting bladder contractility, diabetes cystopathy).

The most common cause of AUR seen in the ED is obstruction of the urinary tract distal to the bladder. In men, BPH is the most common precipitant. Enlargement of the prostate coupled with constriction of the prostatic urethra from heightened α-adrenergic tone obstructs urinary output. Strictures of the urethra after prior procedural trauma, infection, or radiation therapy can also lead to AUR. Other less common obstructive causes of AUR include prostate cancer, phimosis (inability to retract the foreskin over the glans penis), and paraphimosis (inability to reduce the foreskin over an edematous glans). In women, the most frequent obstructive causes are pelvic masses and prolapse of pelvic organs such as the bladder, rectum, or uterus. These structures cause AUR by compressing the urethra and obstructing urine flow. Finally, congenital posterior urethral valves are the most common source of AUR in children.

Infectious and inflammatory conditions can also cause AUR from urethral edema and obstruction, particularly in the setting of underlying prostatic disease. The most common infectious causative disorder is acute prostatitis, followed by urethritis and vulvovaginitis. In pediatric patients. UTIs can induce sufficient dysuria that the child refuses to void, with consequent urinary retention.

Pharmacologic agents associated with AUR include the anticholinergic and sympathomimetic agents. Anticholinergic agents inhibit detrusor muscle contraction, whereas sympathomimetic agents increase α-adrenergic tone in the prostate. NSAIDs and calcium channel blockers have also been known to increase the rate of AUR by inhibiting prostaglandin and calcium-mediated detrusor muscle contraction.

Neurogenic causes of AUR result from a cortical, spinal cord, or peripheral nerve deficit in the sensory or motor nerve supply of the detrusor muscle. Most neurologic causes of AUR are chronic conditions such as multiple sclerosis, Parkinson disease, neoplasms, and diabetic peripheral neuropathy. Other more acute neurologic conditions that should be diagnosed emergently as causative factors in the ED include spinal trauma, stroke, epidural abscess, and intervertebral disk herniation.

Clinical Features

Although the potential causes of AUR are many, the history and physical examination can considerably narrow the scope of the differential diagnosis (Table 85.11). Most patients with AUR report sudden pain and have a distended tender bladder. Patients with dementia or limited verbal ability may only present with restlessness and agitation. With lesions proximal to the bladder, patients typically note pain in the flank, whereas lesions distal to the bladder can produce pain radiating to the scrotum or labia. With acute obstruction, pain is often quite severe. Patients with slowly developing or chronic obstructions are typically older and report overflow incontinence and little to no pain.

When obstruction is the cause of AUR, the patient often will recall multiple previous episodes of urinary retention. In addition to this history, patients with BPH report frequency, urgency, hesitancy, nocturia, difficulty initiating the urinary stream, decreased force of the stream, sensation of incomplete voiding, and terminal dribbling. The prostate is enlarged, firm, and nonnodular. Normal findings on the prostate examination do not exclude BPH. Patients with prostate cancer can have similar symptoms, but these are more often accompanied by weight loss, bone pain, and other constitutional signs and symptoms. These patients generally will have an enlarged nodular prostate. Examination of the penis is important to identify phimosis or paraphimosis. In women with obstruction, pelvic pain and pressure are symptoms commonly associated with AUR. A prolapsed bladder, rectum, or uterus and enlarged ovaries or uterus can be identified on pelvic examination.

Patients with an infectious cause for their symptoms may complain of dysuria, frequency, urgency, hematuria, fever, chills, and low back pain. In acute prostatitis, these symptoms can be associated with penile discharge and a tender boggy prostate. Despite the obstruction, the patient may nevertheless be able to void small amounts of urine. In vulvovaginitis and urethritis, presenting complaints also may include discharge, pruritus, and vulvar skin findings.

Patients with a neurogenic cause for AUR may already have a history of neurologic disease that contributes to AUR. The examination should focus on any findings suggestive of acute neurologic deficit. Strength, sensation, and reflexes in the lower extremities should be examined because they have similar innervation to that of the bladder. The status of the bulbocavernosus reflex, anal reflex, sphincter tone, and perineal sensation should also be assessed.

Differential Diagnosis

The differential diagnosis for AUR is very broad and dependent on the patient's symptoms (Box 85.6). AUR presenting as lower abdominal pain may present similarly to small bowel obstruction, UTI, or prostatitis. Flank and back pain secondary to hydronephrosis can be confused with nephrolithiasis, pyelonephritis, and spinal pathology. Urinary symptoms of overflow incontinence and urinary hesitancy can be confused with UTI or spinal cord compression. Genital pain may present similarly to trauma, testicular torsion, or inguinal hernia.

TABLE 85.11 Presentation and Diagnosis of Acute Urinary Retention

Cause	History	Physical Examination Findings	Diagnosis[a]
Benign prostatic hypertrophy	Frequency, urgency, hesitancy Prior retention	Enlarged, firm prostate	UA
Prostate cancer	Frequency, urgency, hesitancy Previous retention Constitutional symptoms	Enlarged, firm prostate Nodular prostate	UA
Phimosis, paraphimosis	Penile pain	Nonretractable foreskin Edematous penis	Clinical only
Prostatitis	Dysuria, frequency, urgency Fever, chills	Warm, tender, boggy prostate Penile discharge	UA Urine culture
Urethritis, vulvovaginitis	Dysuria, frequency, urgency Itching	Discharge	UA Urine culture Urethral or cervical culture
Pelvic mass	Pelvic pain pressure	Prolapse of rectum, bladder, uterus	UA Ultrasound imaging, CT
Neurogenic bladder	Other neurologic complaints	Neurologic deficits	UA CT, MRI

[a]In the emergency department setting, each of these diagnoses is made primarily by the history and findings on the physical examination. Additional tests are needed as described.

CT, Computed tomography; *MRI,* magnetic resonance imaging; *UA,* urinalysis.

Diagnostic Testing

A urinalysis is recommended for AUR as it can reveal infection or the presence of hematuria from infection, tumor, or calculi. A basic chemistry panel for the assessment of renal function should be performed only when renal damage or hydronephrosis is a concern. There is no history, physical examination, or ultrasound finding that can reliably correlate with an acutely elevated creatinine level. It should be considered for patients with prolonged obstruction or preexisting renal insufficiency.

Additional studies are selectively indicated based on the history and physical examination to identify potentially serious or reversible causes, or when the diagnosis of AUR is unclear. With an equivocal history or physical examination, bedside ultrasound can confirm AUR.

BOX 85.6 Causes of Acute Urinary Retention in Adults

Obstructive
Benign prostatic hypertrophy
Prostatitis
Phimosis
Paraphimosis
Meatal stenosis
Tumor
Foreign body
Calculus
Stricture
Hematoma
Carcinoma

Infectious, Inflammatory

Drugs
Antihistamines
Anticholinergic agents
Antispasmodic agents
Tricyclic antidepressants
α-Adrenergic stimulators
Cold tablets
Ephedrine derivatives
Amphetamines

Psychogenic Problems
Psychodynamic stressors (e.g., lazy bladder syndrome)

Renal and bladder ultrasound studies provide visualization of an elevated postvoid residual, obstruction, hydronephrosis, or other cause of upper urinary tract disease. Pelvic ultrasound examination and CT scan evaluate for masses or malignancy causing obstruction. MRI of the spine detects disk herniation, cord compression, and cauda equina syndrome. Cystoscopy and retrograde cystourethrography can identify problems in the lower urinary tract and usually are performed as outpatient procedures. A prostate-specific antigen assay is not helpful in diagnosing or differentiating prostate cancer from other causes of AUR and should not be routinely performed.

Management

Treatment focuses on bladder decompression and identification of the underlying cause. Immediate placement of a 14 to 18 Fr Foley catheter should provide decompression of the bladder. If this fails, placement of an elbowed catheter (coudé catheter) with a cephalad orientation should be attempted to assist bypassing by any obstruction. If both these techniques prove to be unsuccessful, urologic consultation is indicated. If obstruction is believed to be caused by retained blood clots, a three-way catheter should be placed to allow for bladder irrigation. When immediate bladder decompression is required and a urologist is not available, major urethral trauma is present, or the patient has recently undergone urethral surgery, suprapubic bladder drainage should be performed.

Placement of a catheter has been reported to cause post-obstructive diuresis, hypotension, and hematuria. Such problems are believed to be related to rapid bladder decompression so, historically, gradual decompression has been recommended to prevent these complications. Neither has been proven to have any clinical significance. We recommend that all patients with AUR undergo rapid and complete decompression of the bladder.

Although the catheter is an inconvenience for the patient, and chronic use has been associated with UTIs, trauma, stones, and urethral strictures, early removal of the catheter is also associated with heightened risk for recurrence of AUR, which has been reported in up to 70% of cases. Leaving the catheter in place for 3 to 7 days decreases the incidence of recurrent retention.

Studies have suggested that administration of an α-adrenergic blocker, such as tamsulosin, at the time of catheter insertion in patients with BPH improves the likelihood of spontaneous voiding after catheter removal and may also improve the likelihood that a patient will not require ongoing catheter placement (see Table 85.5). While we recommend this approach, these medications are associated with an increased risk of orthostatic hypotension, particularly in older adults, so initiation of treatment should be coordinated with the patient's primary care physician. 5-Alpha-reductase inhibitors, another agent typically used for BPH, have not been shown to reduce the recurrence of AUR.

Prophylactic antibiotic therapy is not recommended for patients with AUR. Although bacteriuria often develops in patients with indwelling catheters, it typically is not clinically significant, and the use of prophylactic antibiotics only promotes resistance.

Definitive therapy often requires surgical correction of any underlying obstruction. This should not be performed emergently because early surgery is associated with increased morbidity.

Disposition

After bladder drainage, healthy and reliable patients can be safely discharged from the ED with an indwelling catheter and urology follow-up. Patients with concomitant infection, significant comorbid illnesses, impaired renal function, neurologic deficits, or complications from catheterization require further diagnosis and treatment and probably admission.

HEMATURIA

Background

Blood in the urine can be microscopic or gross. Although generally associated with a benign process, microscopic hematuria can reflect serious underlying pathology, such as a urothelial malignancy. Therefore, following ED assessment, patients with any degree of hematuria require outpatient follow-up. Less commonly, patients come to the ED complaining of gross blood in their urine. Compared to microscopic hematuria, gross blood in the urine is more likely to be a presenting symptom of an underlying malignancy. Regardless of age or visibility of blood in the urine, patients with hematuria require evaluation in the ED to rule out life-threatening diagnoses, such as malignancy and AAA.

Gross and microscopic hematuria can arise from anywhere along or near the urinary tract. In the upper and lower portions of the urinary tract, infection, trauma, and renal calculi are the most common causative disorders. Patients also can have more serious causes of hematuria, such as malignancy or vascular lesions (e.g., AAA), and these diagnoses should be excluded. Up to 5% of patients with asymptomatic microscopic hematuria and 30% to 40% of patients with gross hematuria are found to have a urinary tract malignancy. The risk of urologic malignancy is increased in patients older than 35 years, male gender, and those with a history of smoking.

Occasionally, hematuria also has been attributed to warfarin use, BPH, and exercise. Supratherapeutic anticoagulant therapy can lead to blood in the urine, but therapeutic anticoagulation does not typically produce spontaneous hematuria. Similarly, BPH can lead to increased vascularity of the prostate but does not increase the risk of hematuria. High-intensity exercise also can produce hematuria. This bleeding typically is transient and clinically inconsequential. Because warfarin use, BPH, and exercise do not directly cause persistent hematuria, patients with ongoing bleeding require further urologic evaluation.

Clinical Features

A careful history will often identify a benign cause for hematuria, such as menstruation, recent heavy exercise or urologic procedure, sexual activity, or use of agents that can produce red urine without blood (Box 85.7). Repeated episodes of bleeding during and after menstruation in women suggest endometriosis of the urinary tract. Patients may report frequency, urgency, and dysuria in the setting of infection. They may note flank pain with urolithiasis or pyelonephritis. Microscopic hematuria in the setting of a UTI should resolve after appropriate antibiotic treatment.

The physical examination may point toward the underlying cause. For example, hypertension occurs with glomerulosclerosis and, in the setting of peripheral edema, suggests nephrotic syndrome. An abdominal bruit may be caused by an arteriovenous fistula, whereas a palpable abdominal mass may represent an AAA. Flank pain and tenderness can arise with pyelonephritis or nephrolithiasis. The external genital examination can show evidence of trauma or a tumor and may reveal a rectal or vaginal source for the bleeding. A pelvic examination should be performed in women to identify a vaginal or uterine source of bleeding.

Diagnostic Testing

Microscopic hematuria is defined as the presence of three or more RBCs/high-power field (hpf) of urinary sediment. A clean-catch or catheterized urine specimen should be obtained in all patients with hematuria. Catheterization itself induces hematuria in approximately 15% of patients, but the amount of bleeding is inconsequential, rarely exceeding three RBCs/hpf. If available, bedside urine dipstick testing should be performed. A negative urine dipstick rules out the presence of hematuria and obviates the need for urine microscopy. If positive for blood, urine microscopy should be performed.

BOX 85.7 Causes of Red-Colored Urine Without Hematuria

- Phenazopyridine
- Nitrofurantoin
- Rifampin
- Chloroquine
- Hydroxychloroquine
- Iodine
- Bromide
- Food coloring
- Beets
- Berries
- Rhubarb

As little as 1 mL of whole blood in 1 L of urine can produce gross hematuria, turning the urine red. A number of other substances and reactions can turn the urine red, and centrifugation of the urine and microscopic analysis differentiate these false-positive results from true hematuria. After centrifugation, the red color persists only in the urine sediment with hematuria. By contrast, a red supernatant that contains no RBCs on microscopic analysis typically represents a benign condition (see Box 85.7).

Microscopy will reveal WBCs in addition to RBCs in the presence of infection. Proteinuria, cellular casts, and dysmorphic RBCs are seen with glomerular disease. Patients with these findings may also have cola-colored urine and should be referred to a nephrologist.

Management and Disposition

The combination of a careful history, physical examination, and laboratory studies should identify benign causes of microhematuria such as infection, menstruation, vigorous exercise, and trauma. According to the American Urological Association (AUA) Guideline on Asymptomatic Microhematuria, once benign causes have been ruled out, a prompt outpatient urologic evaluation should occur.[40] This evaluation generally consists of an assessment of renal function (BUN and creatinine levels, calculated GFR) and multiphasic CT urography, including sufficient phases to evaluate the renal parenchyma and urothelium of the upper tracts.

CT urography identifies hydronephrosis, urinary calculi, and renal and ureteral lesions. For patients with contraindications to contrasted CT, MR urography is an acceptable alternative imaging approach. Finally, the AUA guidelines recommend that cystoscopy be performed on all patients aged 35 years or older or those with risk factors for urinary tract malignancy, such as tobacco use, exposure to carcinogenic chemicals (e.g., aniline dye, benzidine, petroleum products), or history of chronic UTIs.[40] Risk factors for urinary tract malignancy in patients with microscopic hematuria are listed in Box 85.8. For persistent microhematuria following a negative evaluation, yearly urinalyses are recommended, with consideration for a repeat urologic examination every 3 to 5 years.

By contrast, patients with gross hematuria require a thorough evaluation before discharge from the ED. Renal function should be assessed to rule out the development of renal insufficiency. The patient should also undergo appropriate imaging tests, although clear consensus is lacking on the appropriate radiographic study. If the initial assessment fails to identify a benign cause for the hematuria, a CT scan with contrast or renal ultrasound study should be performed. CT scanning is

BOX 85.8 Risk Factors for Urinary Tract Malignancy

- Age >35 years
- Past or current cigarette smoking
- Occupational exposure (chemicals or dyes)
- Analgesic abuse
- Chronic indwelling foreign body
- Chronic urinary tract infection
- Exposure to known carcinogenic or chemotherapeutic agent
- Gross hematuria
- Irritative voiding symptoms
- Pelvic irradiation
- Urologic disorder or disease

highly sensitive for stones, masses, and other diseases of the upper urinary tract. If contrast CT must be avoided owing to pregnancy, renal insufficiency, or history of anaphylaxis to contrast medium, ultrasound imaging is the modality of choice. Ultrasound is less sensitive than a CT scan for detecting stones, small masses, and traumatic causes of hematuria.

CT is the appropriate imaging modality for traumatic hematuria because its sensitivity and specificity exceed those of ultrasound. The exact level of hematuria that should trigger imaging is unclear, but it appears that patients without gross hematuria or evidence of coexisting abdominal or pelvic injuries are unlikely to have clinically significant injuries on CT.

CHAPTER 85: QUESTIONS AND ANSWERS

1. Which of the following medications is not an appropriate first-line choice for empirical treatment of uncomplicated urinary tract infections (UTIs)?

a. Fosfomycin
b. Nitrofurantoin
c. Trimethoprim-sulfamethoxazole
d. Ciprofloxacin

Answer: d. The options for treating uncomplicated lower UTI include single-dose therapy with fosfomycin, 5 days of nitrofurantoin, or 3 days of trimethoprim-sulfamethoxazole. Fluoroquinolones such as ciprofloxacin or levofloxacin should not be used as first-line agents for empirical treatment of uncomplicated UTIs. Instead, they should be reserved for patients who have failed or have contraindications to first-line antibiotics.

2. Which of the following drugs is not an appropriate first-line choice for treatment of an uncomplicated urinary tract infection (UTI) in women?
   a. Fosfomycin
   b. Ciprofloxacin
   c. Nitrofurantoin
   d. Trimethoprim-sulfamethoxazole
   e. All of the above

Answer: b. According to the Infectious Disease Society of America (IDSA) practice guidelines, fluoroquinolones should not be used as first-line agents for uncomplicated UTI because of increased resistance.

3. Computed tomography should be undertaken in the patient suspected of having renal colic if which of the following is present?
   a. The patient has a solitary or transplanted kidney.
   b. The patient has gross hematuria.
   c. The patient has had a prior history of nephrolithiasis.
   d. The patient presents in severe pain.

Answer: a. Imaging is appropriate for patients who have a history of nephrolithiasis who do not improve with treatment, have a urinalysis showing infection, have a solitary or transplanted kidney, or for whom a diagnosis other than renal colic is suspected.

4. What percentage of cases of acute bacterial prostatitis eventually develop into chronic bacterial prostatitis?
   a. 1%
   b. 5%
   c. 10%
   d. 20%

Answer: c. Chronic bacterial prostatitis will eventually develop in 10% of patients with acute bacterial prostatitis.

5. In testicular torsion, testicular salvage may be predicted by which of the following factors?
   a. Degree of torsion
   b. Duration of the ischemia
   c. Cremasteric reflex
   d. Age of the patient
   e. Both A and B

Answer: e. Testicular torsion results in obstruction of venous outflow, subsequent compromised arterial flow, and testicular ischemia. Testicular salvage hinges on the degree of torsion and duration of the ischemia.

6. To detorse a testicular torsion, you should first rotate the testis medially to laterally. If this does not produce immediate relief, you should do which of the following?
   a. Assume that the testicle is already necrotic and not amenable to further reduction attempts.
   b. Attempt untwisting past 360 degrees because a higher degree of rotation may be present.
   c. Both A and B.
   d. Reverse the direction of reduction.

Answer: d. Most testes torse laterally to medially, but some may torse medially to laterally. If no immediate relief is obtained by rotating medially to laterally, reverse the direction of the reduction attempt.

86

Gynecologic Disorders

Trevor R. Pour and Christina S. Hajicharalambous

KEY CONCEPTS

- Adnexal torsion is easily missed on initial presentation and should be considered in any patient with known risk factors, even if symptoms are subtle or atypical.
- Doppler ultrasound is the preferred initial imaging study for suspected adnexal torsion.
- An ultrasound examination may distinguish among the various types of ovarian cysts and identify associated complications, such as torsion, hemorrhage, and malignancy. Most ovarian cysts are simple follicular cysts that resolve without pharmacologic or surgical intervention.
- Abnormal uterine bleeding (AUB) has many structural, hormonal, and coagulopathic causes. Selected imaging and laboratory testing, based on a careful history and physical examination, can often lead to determination of the cause. Combined oral contraceptive pills can help to regulate the cycle and alleviate AUB.
- Emergency contraception is a safe, effective option to prevent an undesired pregnancy. Levonorgestrel and ulipristal are both effective oral medications and are associated with fewer side effects than the traditional combined contraceptive method. Intrauterine devices should also be considered for emergency contraception if a patient desires a long-term contraceptive option.

GYNECOLOGIC DISORDERS

Many women present to the emergency department (ED) with pelvic pain or vaginal bleeding. After the possibility of pregnancy-related diagnoses has been eliminated, the primary goal is to recognize the presence of conditions that warrant urgent intervention, such as adnexal torsion, versus those that can be managed as an outpatient, such as new postmenopausal uterine bleeding. Most patients also benefit from symptom relief and reassurance. This chapter specifically addresses the ED management of adnexal torsion, ovarian cysts, abnormal uterine bleeding (AUB), and emergency contraception. The general approach to vaginal bleeding is discussed in Chapter 30, complications of pregnancy are discussed in Chapter 173, and sexually transmitted disease is discussed in Chapter 84.

ADNEXAL TORSION

Foundations

The bilateral adnexal structures consist of the ovaries and fallopian tubes. Torsion accounts for approximately 3% of gynecologic emergencies and refers to the twisting of the ovary and/or fallopian tube on the axis between the utero-ovarian and infundibulopelvic ligaments. Although most commonly both structures are involved in this process, isolated ovarian torsion and, more rarely, isolated fallopian tube torsion may occur. In the early phases of torsion, venous and lymphatic obstruction initially occur, followed subsequent congestion and edema of the adnexal structures, which then progress to ischemia and necrosis.

In addition to loss of tubal or ovarian function, torsion left untreated can progress further to hemorrhage, peritonitis, and infection. Because of the dual blood supply of the ovary from the uterine and ovarian arteries, total arterial obstruction is rare but can develop (Fig. 86.1).

Ovarian torsion can occur at any age but is most common in the reproductive years due to the regular development of a corpus luteal cyst during the menstrual cycle. Torsion may be a complication of pregnancy, more likely to occur in the first and early second trimesters.[1] A history of tubal ligation is a risk factor for ovarian torsion.[2] A predominance of torsion on the right side has been noted in approximately a 2:1 ratio to cases on the left, likely related to the stabilizing effect of the fixed sigmoid colon.

In premenarchal patients, torsion frequently occurs despite normal ovarian size, thought to be secondary to the excessive mobility of the adnexa due to relatively longer supporting ligaments and the smaller size of the uterus.[3,4]

Most cases of torsion in the postmenarchal population are associated with an enlarged ovary with a diameter greater than 5.0 cm as the result of a benign neoplasm or cysts, which can be the result of ovulation induction, hyperstimulation syndrome, or polycystic ovarian syndrome. Masses prone to developing adhesions and therefore restricting mobility of adnexal structures, such as malignant tumors, endometriomas, or tubo-ovarian abscesses, are less likely to develop torsion than benign lesions.

Clinical Features

Despite advances in imaging modalities, the definitive preoperative diagnosis rate of ectopic pregnancy approaches only 40%, making clinical assessment the primary driver of management decisions. The classic symptoms of ovarian torsion are severe, sharp, unilateral lower abdominal pain accompanied by nausea and vomiting; however, these elements are not consistently present in all cases.[5] The presence of known risk factors, such as an ovarian mass or recent assisted reproductive treatments, may suggest the diagnosis in postmenarchal patients.

Patients typically report pain lasting from several hours to days, sometimes with intermittent resolution likely owing to spontaneous detorsion. Rarely, patients report pain for weeks to months in duration, most likely due to intermittent or chronic torsion.[6] Nausea and vomiting are present in approximately 60% to 70% of cases. Fever is a an uncommonly reported finding, typically seen late in the course of disease and likely secondary to ischemia and necrosis of adnexal tissue.

Most patients will have unilateral tenderness on abdominal palpation, but peritoneal signs are rare, especially in early presentations. Only 50% of patients will have a palpable adnexal mass on pelvic

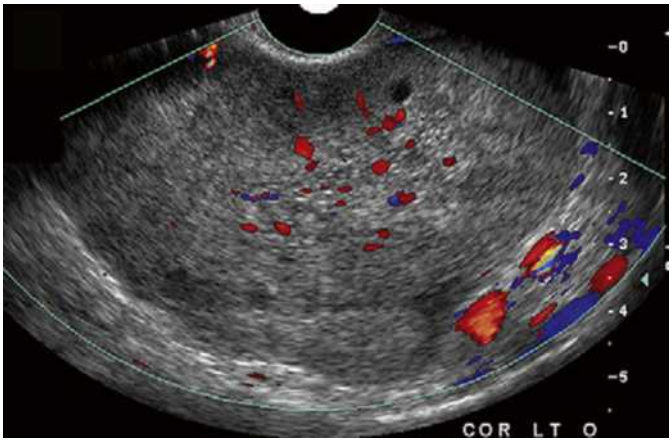

Fig. 86.3 Ovarian torsion with color Doppler image demonstrating venous and arterial flow. (From Cicchiello LA, Hamper UM, Scoutt LM. Ultrasound evaluation of gynecologic causes of pelvic pain. *Obstet Gynecol Clin North Am.* 2011;38:85–114.)

examination; a palpable mass is more common in adults than pediatric patients with torsion.[7] Predictive scoring systems for adnexal torsion—typically involving a combination of clinical elements and imaging or laboratory findings—have been developed but have not yet been shown to be generalizable to all populations and therefore cannot be recommended at this time.[8,9] Clinical signs of isolated tubal torsion are indistinguishable from those of ovarian or full adnexal torsion.[10]

Differential Diagnoses

The differential diagnosis of adnexal torsion includes appendicitis, ruptured ovarian cyst, cystitis or pyelonephritis, nephrolithiasis, pelvic inflammatory disease, uterine leiomyoma, diverticulitis, bowel obstruction, and ectopic pregnancy. A pregnancy test, physical examination, and imaging with ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), if necessary, can typically distinguish among these possibilities.

Diagnostic Testing

Laboratory Tests

No specific laboratory tests are routinely used in the diagnosis of adnexal torsion, although preoperative labs should be drawn on all patients suspected of torsion. A negative pregnancy test may exclude ectopic pregnancy from the differential, but importantly a positive test does not rule out adnexal torsion. Leukocytosis and elevated C-reactive protein (CRP) are occasionally associated with torsion but both are nonspecific and cannot be used as reliable predictors.

Small studies on serum interleukin-6 (IL-6) and D-dimer levels have revealed moderate sensitivity and specificity for detection of ovarian torsion, especially when coupled with findings suggestive of torsion on ultrasonography.[11,12] These tests in combination may eventually prove to be useful if early findings are confirmed by larger trials, but neither is considered a routine test at this time.

Imaging Tests

Ultrasonography. Ultrasound examination is the optimal initial imaging test in the evaluation of patients with pelvic pain highly suggestive of torsion, but findings can vary depending on timing and duration of symptoms. Asymmetric enlargement of the ovary is the most common finding. Enlargement of an ovary with a heterogeneous stroma secondary to edema along with small, peripherally displaced follicles is the classic ultrasound appearance of torsion but is often absent, particularly in the setting of prolonged ischemia.[13] Ultrasound may also reveal a discrete ovarian mass, evidence of hemorrhage, or free pelvic fluid (Fig. 86.2). Hemorrhagic cysts and other nonneoplastic masses frequently are associated with torsion; these may appear fluid filled, exhibit a complex pattern with debris and septations, or be visualized as a solid mass. The characteristic appearance of torsion may be difficult to appreciate if the ovary is obscured by an associated mass. In isolated tubal torsion, tubal lesions such as hydrosalpinx or a tuboovarian abscess may be seen.

Doppler ultrasound findings are inconsistent in the definitive diagnosis of adnexal torsion. Up to 60% of surgically proven cases have ovarian blood flow on the preceding Doppler examination (Fig. 86.3).[14] These findings may vary depending on the time of the examination because torsion may occur intermittently, and

clinical symptoms commonly precede arterial compromise. If a large adnexal mass is present, the examination may also be technically difficult to perform. Despite these limitations, the Doppler examination is still useful, as recognition of ovarian enlargement or masses, as well as detection of abnormal venous flow is particularly important in early cases of torsion (Fig. 86.4). Absence of arterial flow is highly specific for torsion, with a positive predictive value nearing 100%. Visualization of the twisting of the pedicle and coiled vessels is referred to as a "whirlpool sign" and has a 90% positive predictive value for torsion.[15]

Computed tomography. When alternative abdominal pathologies are strong considerations in the differential diagnosis of a patient's acute pelvic pain, abdominopelvic CT may be the best initial study, particularly in patients who have a presentation less typical for torsion. In ovarian torsion, CT findings include asymmetric ovarian enlargement or asymmetric adnexal enhancement following intravenous (IV) contrast, fallopian tube thickening, twisted vascular pedicle, fat stranding surrounding the affected adnexa, and uterine deviation to the affected side.[16] Pelvic free fluid can also be seen, especially in cases of hemorrhagic infarction.

Multiple studies show that patients with ultrasonographic or surgically confirmed torsion have evidence of at least one abnormal finding on CT. This suggests that a completely normal contrast-enhanced CT scan of the abdomen and pelvis—including the absence of ovarian enlargement or masses in addition to the aforementioned findings—may be sufficient to rule out ovarian torsion.[17] Negative CT imaging findings should be interpreted with caution when clinical suspicion is high, but with lower suspicion, normal-appearing pelvic structures on a CT scan is reassuring and potentially sufficient imaging.

Magnetic resonance imaging. MRI may also demonstrate findings consistent with torsion. It is particularly helpful when the diagnosis is unclear, such as in patients who present with intermittent pain over days, or for pregnant patients when the history is suggestive of torsion but ultrasound findings are inconclusive or equivocal and CT scans are not preferred. Findings on MRI suggestive of torsion are similar to those on CT (Box 86.1).

Laparoscopy. Given the frequency of equivocal findings on imaging studies, the lack of reliable clinical decision tools, the absence of a proven biomarker, and the variable clinical presentation, adnexal torsion is commonly a surgical diagnosis. Diagnostic laparoscopy is therefore indicated for patients in whom clinical suspicion is high despite negative imaging results. Laparoscopy also allows for the diagnosis of other unsuspected conditions, including appendicitis or tubo-ovarian abscess.[18]

Management and Disposition

Once the diagnosis of suspected torsion has been made, the patient should be taken to the operating room as soon as possible. The adnexal

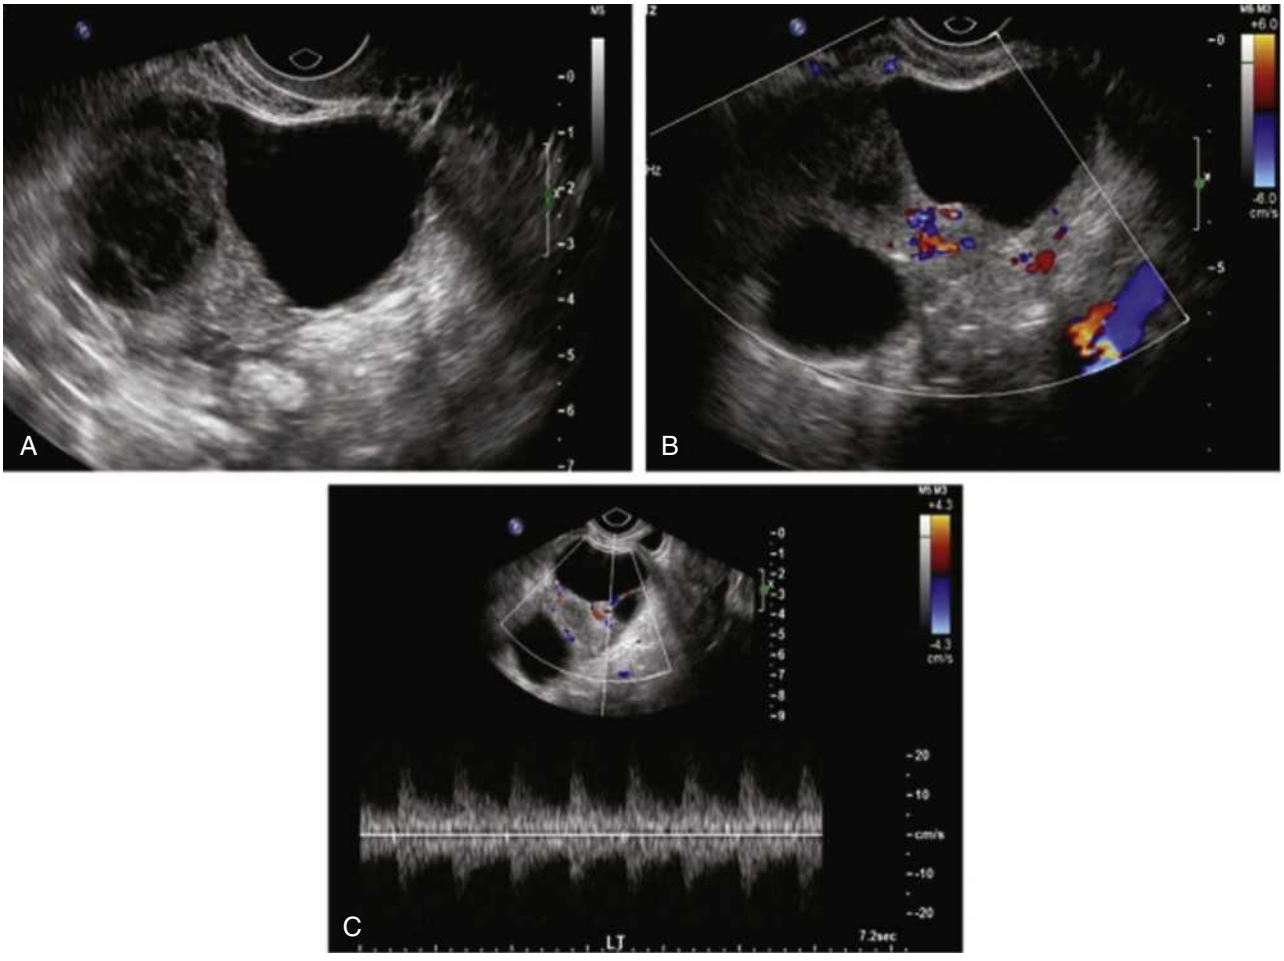

Fig. 86.4 (A) Ultrasound examination demonstrating a large associated hemorrhagic cyst. (B and C) Arterial Doppler signal without venous signal in a patient with surgically proven torsion. (From Andreotti RF, Shadinger L, Fleischer A. The sonographic diagnosis of ovarian torsion: pearls and pitfalls. *Ultrasound Clin.* 2007;2:155.)

structures often will recover, even if visibly ischemic or dusky in appearance at the time of surgery. Because of its dual blood supply and potential to recover function, attempts at ovarian salvage are warranted even if the diagnosis is delayed. This is particularly true in adolescent patients.

OVARIAN CYSTS AND MASSES

Foundations

Cysts are the most common cause of gynecologic masses. They occur at any stage of life but are most frequent in the reproductive years because of the cyclic changes of the ovary associated with menstruation (Fig. 86.5). Most ovarian cysts in premenopausal and postmenopausal women are benign and resolve without intervention, but on occasion they may be malignant or associated with complications such as hemorrhage or torsion.[19,20]

BOX 86.1 Imaging Characteristics of Adnexal Torsion

Ultrasonography
Enlargement of the ovary
Associated ovarian mass
Loss of enhancement
Edema
Free pelvic fluid
Loss of venous waveforms
Loss of arterial waveforms

Computed Tomography and Magnetic Resonance Imaging
Enlargement of the ovary
Associated ovarian mass
Thickening of the fallopian tube
Free pelvic fluid
Edema of the ovary
Deviation of the uterus to the affected side
Associated hemorrhage

The most common type of cyst is a simple follicular, or functional cyst, developing from a follicle that fails to rupture or regress, and is defined as pathologic when the diameter exceeds 3.0 cm. Follicular cysts are typically thin-walled and filled with clear fluid, whereas a corpus luteal cyst is often filled with hemorrhagic fluid. Several other types of cystic masses can occur in the ovary, including endometriomas (often called "chocolate cysts"), nonneoplastic lesions such as benign cystic teratoma or dermoid cyst, fibroma, cystadenoma, and various types of malignant neoplasms.[21]

Clinical Features

The most common presentation for patients with an ovarian cyst is pelvic pain. Rupture of a follicular cyst may produce transient pelvic pain, be associated with dyspareunia, or be asymptomatic. Because of the thin and fragile wall, a follicular cyst may rupture during sexual intercourse or during the pelvic examination. Follicular cysts are rarely associated with hemorrhage.

Presentation of a corpus luteal cyst may range from an asymptomatic mass to dull, chronic pelvic pain to severe pain associated with rupture. Rupture of a corpus luteal cyst is frequently associated with a significant degree of hemorrhage. As with a follicular cyst, rupture may follow a pelvic examination, sexual intercourse, exercise, or trauma. Rupture of a large or complex cyst may result in severe pain and peritoneal signs. Occasionally, a large cyst may be discovered on a routine pelvic examination as an asymptomatic mass, but this is uncommon.

Differential Diagnoses

Diagnostic considerations in the patient with symptomatic ovarian cysts and masses include other causes of pelvic pain that require urgent intervention, such as ectopic pregnancy, pelvic inflammatory disease, urinary tract infections, nephrolithiasis, appendicitis, and diverticulitis. Tumors or abscesses of the gastrointestinal tract may also mimic adnexal masses.

Diagnostic Testing

Laboratory Tests

The initial step in the evaluation of pelvic pain or a pelvic mass is to exclude pregnancy with a urine or serum β-human chorionic gonadotropin (β-hCG) test. A hematocrit may be valuable in the unstable

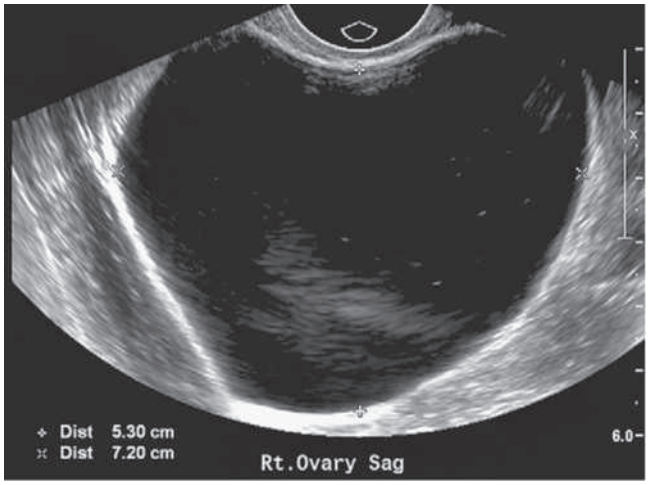

Fig. 86.7 Endovaginal ultrasound image of a follicular cyst, with smooth wall and posterior wall enhancement. (From Cicchiello LA, Hamper UM, Scoutt LM. Ultrasound evaluation of gynecologic causes of pelvic pain. *Obstet Gynecol Clin North Am*. 2011;38:85–114.)

patient as a marker of blood loss. The serum antigen CA-125 is elevated in 80% of women with epithelial ovarian cancer but can also be elevated by nonmalignant conditions such as endometriosis, pregnancy, and pelvic inflammatory disorder, limiting its usefulness in the emergency setting.

Imaging Tests

Ultrasonography. Ultrasonography is used to diagnose and characterize all ovarian pathologic processes and lesions, including cysts and masses. Approximately 90% of adnexal masses are adequately characterized by ultrasound imaging alone. Transabdominal and endovaginal examinations provide useful information. The transabdominal approach is performed with a full bladder as a sonographic window. It permits an overall view of the pelvis and will visualize large masses and pelvic free fluid. Use of the endovaginal probe, which should be performed with an empty bladder to reduce artifact, provides a detailed picture of the ovary. Follicles are part of the normal architecture of the ovary and are typically smaller than 1.0 cm in diameter, whereas the dominant follicle may measure up to 2.5 cm at the time of ovulation. Depending on the timing of the scan and degree of clot formation and lysis, hemorrhage may be seen; serial bedside abdominal ultrasound imaging can also serve as a rapid assessment tool to detect worsening hemoperitoneum in the setting of hemorrhagic cyst rupture. Fig. 86.6 demonstrates a normal ovary with a dominant follicle, Fig. 86.7 demonstrates a large cyst, and Fig. 86.8 demonstrates hemorrhage and free pelvic fluid. Ultrasound findings suggestive of malignancy include internal septations, solid elements within cystic structures, a thickened wall, and large amounts of ascites or free fluid.[22]

Computed tomography. When the differential diagnosis of unilateral pelvic pain is broad, particularly in the patient with symptoms or physical findings not solely confined to the pelvis, a CT scan may be a more appropriate initial imaging study. However, it is not recommended as the first line imaging study if an adnexal mass is of primary concern due to poor soft tissue discrimination.[23] However, once the diagnosis of potential malignancy has been made, ultrasound is insensitive for staging or follow-up imaging, and contrast-enhanced CT is indicated at that time. A CT scan can detect a cyst and associated complications, including torsion, as noted earlier in this chapter. CT findings suggestive of malignancy are a cystic solid mass, necrosis in a solid lesion, complex or cystic lesion with thick, irregular walls, and the presence of ascites, peritoneal metastases, and lymphadenopathy.

Magnetic resonance imaging. MRI provides better soft tissue contrast than CT and has been shown in multiple studies to differentiate benign from malignant adnexal masses better than ultrasound. Its use is often limited by availability, cost, and duration of examination. MRI should be considered for pregnant patients or those with equivocal findings on ultrasound or CT.

Management and Disposition

Patients with a simple cyst, no evidence of additional pathology, and improvement in symptoms may be safely discharged with referral for outpatient gynecologic follow-up to ensure resolution. Most uncomplicated simple cysts will resolve without further intervention. Pain should be controlled with nonsteroidal antiinflammatory drugs (NSAIDs) as a first line approach and with oral opioids reserved only for severe cases. Oral contraceptives are not recommended for the routine management of ovarian cysts; despite being theorized to accelerate the regression of ovarian cysts, multiple randomized controlled trials have shown no difference in cyst resolution when compared to expectant management.

A complex cyst concerning for malignancy requires more urgent gynecologic intervention. Such patients may benefit from gynecologic consultation in the ED, particularly if reliable follow-up is unlikely or if the patient is particularly symptomatic.

ABNORMAL UTERINE BLEEDING IN THE NONPREGNANT PATIENT

Foundations

An understanding of the normal menstrual cycle is necessary to understand the potential causes of AUB (Fig. 86.9). The menstrual cycle starts on the first day of menses. During the first part of the menstrual cycle, the endometrium thickens under the influence of estrogen, and a dominant follicle develops in the ovary, releasing an ovum at the midpoint of the cycle. After ovulation, the luteal phase begins and is characterized by the production of progesterone from the corpus luteum. Progesterone matures the lining of the uterus and, if implantation does

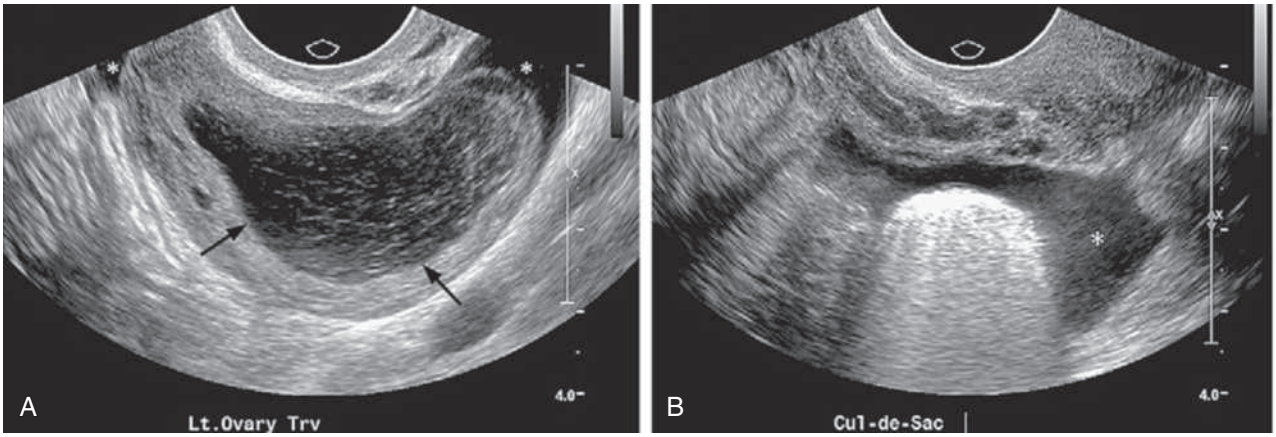

Fig. 86.8 Endovaginal ultrasound image of a hemorrhagic ovarian cyst with free fluid *(*)*. (From Cicchiello LA, Hamper UM, Scoutt LM. Ultrasound evaluation of gynecologic causes of pelvic pain. *Obstet Gynecol Clin North Am.* 2011;38:85–114.)

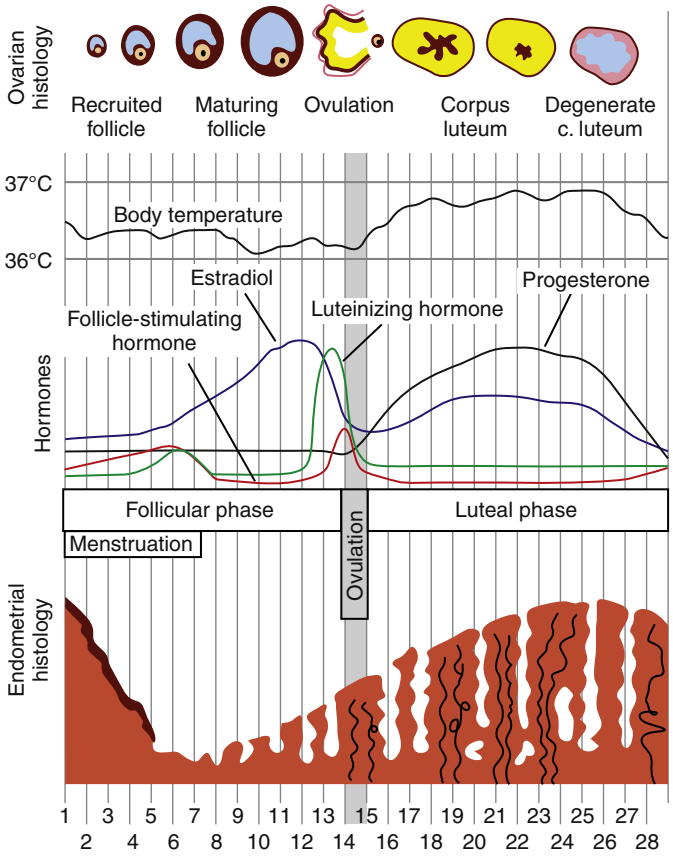

Fig. 86.9 Normal Menstrual Cycle.

not occur, the corpus luteum dies, accompanied by sharp drops in progesterone and estrogen levels. These changes typically are followed by menstruation. Menstrual bleeding is usually predictable, cyclic, and results from withdrawal of the effects of hormones on the endometrium, which occurs approximately 14 days after ovulation.

A revised system of terminology, PALM-COEIN, regarding AUB was created in 2011 by the International Federation of Gynecology and Obstetrics (FIGO) to standardize language and facilitate multiinstitutional investigation (Box 86.2).[24] The first four letters, PALM, represent structural causes for AUB—***p***olyp, ***a***denomyosis, ***l***eiomyoma, and ***m***alignancy or hyperplasia, whereas the latter, COEIN, represent nonstructural causes—***c***oagulopathy, ***o***vulatory dysfunction, ***e***ndometrial, ***i***atrogenic, and ***n***ot yet classified. The term *dysfunctional uterine bleeding* is obsolete and should not be used.

BOX 86.2 PALM-COEIN Classification for Abnormal Uterine Bleeding (AUB)

PALM—Structural Causes

Polyp (AUB-P)
Adenomyosis (AUB-A)
Leiomyoma (AUB-L)
- Submucosal leiomyoma (AUB-LSM)
- Other leiomyoma (AUB-LO)

Malignancy and hyperplasia (AUB-M)

COEIN—Nonstructural Causes

Coagulopathy (AUB-C)
Ovulatory Dysfunction (AUB-O)
Endometrial (AUB-E)
Iatrogenic (AUB-I)
Not yet classified (AUB-N)

Clinical Features

History

Many conditions cause AUB, defined as any change in the frequency, regularity, duration, or volume of bleeding. A systematic history and physical examination tailored to the patient's menstrual development will help narrow these possibilities. Vaginal bleeding in prepubertal patients can be concerning and may be the result of infection, trauma such as sexual abuse or a vaginal foreign body, or a structural lesion. Adolescents who develop heavy bleeding at the time of menarche may be presenting with their first sign of an inherited bleeding disorder. In the postmenopausal woman, any bleeding 12 months after the cessation of menses or unpredictable bleeding during hormone therapy is abnormal. The volume and frequency of bleeding, the duration of symptoms, and the relationship between bleeding and the patient's normal menstrual cycle should be established. A menstrual cycle shorter than 21 days in duration or more than 35 days apart, or flow for

less than 2 or more than 7 days, is classified as abnormal. A pattern of irregular bleeding between cycles or an abrupt change in the previous pattern of bleeding should also be determined.

Systemic conditions, such as liver or thyroid disease, may be associated with AUB. Endometrial cancer is associated with underlying diabetes mellitus, metabolic syndrome and obesity, anovulatory cycles, nulliparity, and age older than 55 years. Cervical dysplasia or other genital tract pathology may cause postcoital or irregular bleeding, and patients should routinely be questioned on risk factors for sexually transmitted infections. Prior history of cesarean section may contribute to iatrogenic AUB; studies have found that irregular scarring postoperatively leads to a higher prevalence of vaginal spotting.

Disruption along the hypothalamus-pituitary-ovarian pathway leading to anovulation is frequently the cause of AUB. Disruption of this pathway may be physiologic, such as during adolescence, perimenopause, or lactation. Pathologic causes include polycystic ovary syndrome (PCOS), hypothalamic dysfunction seen in anorexia nervosa, hyperprolactinemia, and primary pituitary disease.

Patients should be questioned about excessive bleeding or bruising or any family history of bleeding disorders because up to 20% of women presenting with heavy menstrual bleeding will have an underlying coagulopathy. Von Willebrand disease is the most common of these, seen in up to 13% of cases of AUB, and often first presents with heavy uterine bleeding since menarche.

Physical Examination

In the setting of acute, heavy bleeding, the initial physical examination should focus on signs of hypovolemia and anemia. PCOS is a common cause of AUB and suggested by the presence of obesity, acne, hirsutism, and acanthosis nigricans. The examination should include inspection of the thyroid, particularly for nodules, as well as a comprehensive skin examination for petechiae and ecchymosis. Other causes of bleeding include vaginal or cervical lesions, which may be visible on the vaginal speculum examination. A leiomyoma or fibroid uterus may be palpable on the bimanual examination.[25]

Differential Diagnoses

The differential diagnosis of AUB in the nonpregnant patient is extensive but may be narrowed by patient age. In adolescents, consider undiagnosed coagulopathy, pelvic infection, or hypothalamic-pituitary-ovarian axis dysregulation due to physiologic immaturity or PCOS. Young adults often have structural lesions such as polyps or leiomyomas, endometrial hyperplasia, or anovulation secondary to PCOS or the other conditions listed earlier. In patients older than 40 years but not yet postmenopausal, anovulatory bleeding due to perimenopause becomes more likely, as does endometrial carcinoma or hyperplasia and leiomyoma. Postmenopausal patients require an outpatient evaluation for malignancy.

Diagnostic Strategies

Laboratory Tests

A urine or serum pregnancy test is essential in evaluating a woman of reproductive age with vaginal bleeding. In a patient with excessive bleeding, hemodynamic instability, or clinical evidence of anemia (e.g., excessive fatigue, pale conjunctiva), a hemoglobin or hematocrit is indicated. If coagulopathy is suspected, platelet count, prothrombin and partial thromboplastin time should be measured. In the emergency setting, testing for von Willebrand disease and other specific coagulopathies can usually be deferred to outpatient follow-up. Sexually transmitted infections should be tested for in patients with risk factors or clinical signs of infection, particularly *Chlamydia trachomatis*. The presence of chlamydial antigens has been linked to AUB, likely due to endometrial inflammation. Thyroid dysfunction, particularly hypothyroidism, is associated with AUB, and therefore screening to determine the thyroid-stimulating hormone serum level is recommended.

Imaging Tests

The decision to perform ultrasound imaging to evaluate AUB in the ED depends on the urgency to determine the cause of bleeding and the reliability of outpatient follow-up. Transvaginal ultrasonography (TVUS) may reveal a fibroid uterus, endometrial thickening, or a focal mass (Fig. 86.10). In postmenopausal patients with AUB, an endometrium measuring less than 4 to 5 mm of thickness on TVUS reliably excludes endometrial cancer. A thickened endometrium may indicate an underlying lesion or excess estrogen. For most nonpregnant patients with AUB, ultrasound findings do not immediately affect ED decision making. In patients who have reliable access to outpatient gynecologic services, imaging may be deferred until follow-up evaluation.

Management

The likely causative disorder coupled with the volume of bleeding and overall stability of the patient will guide ED management. Patients with uncontrolled bleeding and hemodynamic instability on presentation should receive standard resuscitation IV fluids and blood products, and surgical options should be considered, including urgent dilation and curettage, uterine artery embolization, endometrial ablation, or hysterectomy. Alternatively, conjugated equine estrogen may be administered at a dose of 25 mg given IV every 4 to 6 hours for 24 hours or until the bleeding stops. In emergent situations, intrauterine tamponade with a 26-French foley catheter instilled with 30 mL of saline can also be attempted.

In less emergent situations, oral medications can be considered for the treatment of AUB. Disruption of the hypothalamic-pituitary-ovarian axis from a variety of causes can result in bleeding related to ovulatory dysfunction (AUB-O). Restoring the balance of estrogen and progesterone with oral contraceptives will help many patients regulate the cycle, with reduction in or cessation of AUB. Combination oral contraceptive pills can help regulate the cycle and counteract the long-term effects of unopposed estrogen on the endometrium. We recommend a combination oral contraceptive with 35 μg of ethinyl estradiol or 20 mg or medroxyprogesterone three times daily for 1 week. Contraindications must be reviewed with the patient prior to prescribing

Fig. 86.10 Longitudinal view of the uterus with thickened endometrium. (Courtesy Dr. Robert Reardon, Hennepin County Medical Center, Minneapolis; with permission.)

these medications, specifically to determine a history of thromboembolic events, cigarette smoking, breast cancer, or liver disease. However, patients with contraindications to estrogen-progesterone combination treatment can also consider progestin-only treatment, given as 5 mg norethindrone orally three times daily for 1 week.[23] The levonorgestrel intrauterine device (IUD) is also a nonemergent option to treat AUB in patients who are interested in long-term contraception.[26]

Nonhormonal medications also have been shown to be effective in AUB. Tranexamic acid, an antifibrinolytic agent, may also be used for either emergent or outpatient management of bleeding. It can be administered IV at 10 mg/kg with a maximum dose of 600 mg, or orally at a dose of 1.3 g every 8 hours for 5 days. NSAIDs are generally safe and well tolerated and are effective for relief of associated cramping pelvic pain. They have also been shown to be more effective than placebo to reduce heavy menstrual bleeding, although less effective than either tranexamic acid or a hormonal IUD, with limited data to compare efficacy to oral contraceptives.[27,28] In patients with suspected bleeding disorders, specifically those with platelet dysfunction, NSAIDs should be used with caution.

Disposition

Most patients with pelvic pain from ovarian cysts or AUB without hemodynamic compromise may be managed with specific therapies to minimize symptoms and should be referred to a gynecologist for definitive management on an outpatient basis. Patients with severe, acute AUB and hemodynamic instability require urgent gynecologic consultation and hospitalization.

EMERGENCY CONTRACEPTION

Emergency contraception, more commonly known as the "morning after pill," consists of medical therapy to prevent pregnancy immediately following unprotected or inadequately protected sexual intercourse. At present, there are three oral formulations available: ulipristal acetate (a progesterone receptor modulator), levonorgestrel (a progestin), and combined oral contraceptives consisting of progestin and estrogen taken together and often referred to as the Yuzpe regimen. In addition to oral options, the copper IUD is extremely effective as emergency contraception and works through inhibition of sperm function, inhibition of fertilized egg transport, and likely inhibition of implantation.[29]

The most commonly used regimen, and the only formulation available without a prescription in the United States, consists of a single dose of 1.5 mg or two doses of 0.75 mg levonorgestrel spaced 12 hours apart. The one-time dose of 1.5 mg is simpler to use and is at least as effective as the two-dose regimen and is therefore recommended.[30] It is labeled for use for up to 72 hours following intercourse. Studies have indicated an association between higher patient body mass index (BMI) and decreased effectiveness of levonorgestrel, suggesting that perhaps an increased dose may be indicated in obese individuals. However, further study is necessary before this can be definitively recommended.[31]

Another regimen, a single tablet of 30 mg of ulipristal acetate, is available only with a prescription but has demonstrated effectiveness for up to 120 hours from intercourse, making it a preferred choice over levonorgestrel beyond the 72-hour window. Both forms of contraception—levonorgestrel and ulipristal—are maximally effective when used within 24 hours. Combined oral contraceptives, consisting of 100 μg of ethinyl estradiol and 0.5 to 1.0 mg of levonorgestrel, have largely fallen out of favor due to the simplicity and success of levonorgestrel alone.

Adverse effects of oral emergency contraception include nausea and headache, with the combined oral contraceptive regimen producing significantly higher rates of nausea than levonorgestrel or ulipristal alone. Irregular menstrual bleeding, which can occur within 1 week to 1 month after treatment, resolves without intervention.

The copper IUD is highly effective when placed within 5 days of intercourse and appears to be effective for as long as 10 days. It carries a 1/1000 risk of uterine perforation and is associated with uterine cramping but also provides ongoing contraceptive benefit. The major barrier to utilization for emergency contraception is the requirement to make a clinic appointment or visit with a qualified provider within the timeframe outlined earlier.[32]

Both levonorgestrel and ulipristal act to delay or inhibit ovulation, whereas the copper IUD prevents fertilization. As such, a common misconception is that emergency contraception is equivalent to medical abortion. None of the methods discussed involve the termination of a preexisting pregnancy, and emergency contraception has not been shown to have adverse effects on a developing fetus when taken during an established pregnancy. It is still possible for a patient who uses emergency contraception to get pregnant in the same menstrual cycle, so patients should be advised to use an alternative form of contraception and to undergo a pregnancy test if menstruation is delayed for more than 3 weeks. Patients who receive emergency contraception should be counseled regarding birth control and have a follow-up pregnancy test should they miss their next period.

CHAPTER 86: QUESTIONS AND ANSWERS

1. Which of the following statements regarding ovarian torsion is true?

a. Abdominal tenderness is predictable
b. Complete arterial obstruction is common
c. Computed tomography (CT) has a higher sensitivity than ultrasound
d. Most cases are associated with an ovarian mass
e. There is a left-sided predominance

Answer: d. Most cases are associated with a benign ovarian tumor or cyst. There is a modest right-sided predominance. Due to the collateral uterine and ovarian arterial supply, complete arterial obstruction is rare. In cases of intermittent or chronic torsion particularly, abdominal tenderness may be absent. CT has a lower sensitivity than ultrasound, which is still only approximately 71%. Interpret negative studies carefully.

2. Which of the following patterns of menses should be considered abnormal?

a. A 23-day menstrual cycle
b. A 40-day menstrual cycle
c. Bleeding 6 months after menopause
d. Seven days of menstrual flow
e. Three days of menstrual flow

Answer: b. A menstrual cycle shorter than 21 days or more than 35 days apart, or flow that is less than 2 days or more than 7 days, is considered abnormal. In the postmenopausal woman, any bleeding 12 months after cessation of menses is considered abnormal.

continued

CHAPTER 86: QUESTIONS AND ANSWERS—cont'd.

3. A 33-year-old gravida 3 para 3 woman presents with 7 days of heavy, painless vaginal bleeding. Her only other complaint is dizziness. Urine pregnancy test is negative. Vital signs are blood pressure, 85/40 mm Hg, and heart rate, 130 beats/min. The pelvic examination reveals copious vaginal bleeding through a partially open cervical os. The hemoglobin level is 6.8 g/dL. Which of the following interventions is most appropriate?

a. 20 μg of ethinyl estradiol daily until the bleeding subsides
b. 35 μg ethinyl estradiol bid until the bleeding subsides
c. Blood transfusion and urgent gynecologic consultation for dilation and curettage
d. Premarin, 25 mg intravenously every 6 hours
e. Saline hydration followed by a 2-day recheck

Answer: c. This patient is symptomatic, hypovolemic, anemic, and exhibiting ongoing bleeding. Oral estrogens are indicated in cases of modest bleeding. Parenteral estrogen may be used as an adjunct to other therapies for patients requiring admission. The degree of anemia in the face of ongoing bleeding in this case warrants gynecologic intervention.

4. To be most effective, the emergency contraceptive ulipristal should be given as soon as possible but is approved to be given within how many hours of intercourse?

a. 12
b. 24
c. 48
d. 72
e. 120

Answer: e. The efficacy of all emergency contraceptive pills in preventing pregnancy is greatest when a contraceptive is taken soon after intercourse. Ulipristal is labeled for 120 hours post coitus. Because it is not as effective as preplanned contraception, women should still be aware of the possibility of pregnancy after its use.

87

Stroke

Linda Papa and William J. Meurer

KEY CONCEPTS

- Anterior circulation strokes result in contralateral hemiparesis of the face and body.
- Vertebrobasilar strokes result in ipsilateral cranial nerve (CN) deficits and contralateral hemiparesis.
- Posterior cerebral artery stroke causes ipsilateral CN III palsy and contralateral homonymous hemianopsia.
- *Wallenberg syndrome* (lateral medullary syndrome) causes vertigo, Horner syndrome, ipsilateral facial numbness, loss of corneal reflex, along with contralateral loss of pain and temperature.
- Cervical artery dissection is a common cause of stroke in young patients; trans ischemic attacks (TIAs) preceding stroke in these patients are often misdiagnosed.
- The goal for eligible patients is to receive thrombolytics within 90 min of symptoms onset; the dose of the tissue plasminogen activator Alteplase (t-PA) is 0.9 mg/kg with 10% given as a bolus and the remaining 90% given over 1 h.
- Overly aggressive blood pressure (BP) management should be avoided in patients with acute ischemic stroke. If thrombolytic therapy is indicated, stringent control of BP is indicated to reduce the potential for intracranial hemorrhage.
- Accurate identification noting the last time a patient was known to be at his or her neurologic baseline should be documented in all patients with stroke.
- Acute ischemic stroke patients receiving Alteplase are at risk of developing a spontaneous intracranial hemorrhage; the risk is lowest in patients with a low National Institutes of Health Stroke Scale (NIHSS) score, no hypertension, no diabetes, and age younger than 70 years.
- In acute ischemic stroke, the patient and/or their families should be informed of the risk and benefit of treatment with thrombolytic therapy.
- The incidence of symptomatic intracerebral hemorrhage after intravenous (IV) thrombolysis is 2%–7%. The incidence of asymptomatic intracranial hemorrhage is higher with 30%–45% of patients experiencing >10 cerebral microbleeds.
- Beyond 4.5 h, the benefit of IV thrombolysis is not clear and should be determined after consulting with the neurologist or stroke specialist.
- In patients with mild nondisabling stroke symptoms, IV thrombolysis is not recommended. However, for otherwise eligible patients with mild but disabling stroke symptoms, IV thrombolysis is recommended for patients within 4.5 h of ischemic stroke symptom onset.
- Patients with a hemorrhagic stroke on coumadin should *be reversed* using vitamin K and prothrombin complex concentrate (PCC). Fresh frozen plasma (FFP) can be used if PCC is not available. However, PCC is preferred over FFP due to more rapid correction of international normalized ratio (INR), lower risk of infection, and lower administered volume.
- Prognosis is worse in acute stroke in the setting of fever, hypotension, hypoxia, and hypo/hyperglycemia. Measures should be taken to rapidly correct these.
- Carotid Doppler, magnetic resonance angiography (MRA), or computed tomography angiography (CTA) studies are recommended before discharge of a patient with TIA from the emergency department (ED).
- TIA has moved from time-based to tissue-based definition (defined as a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without evidence of acute infarction).
- MRI with diffusion-weighted imaging (DWI) has a greater sensitivity than computed tomography (CT) for detecting small infarcts in patients with TIA.
- Patients with TIA or nondisabling strokes are at increased risk of recurrent stroke and should be evaluated and treated immediately in order to reduce the risk of subsequent stroke.
- CTA with CT pulmonary angiogram (CTPA) or MRA with DW-MRI is useful for selecting candidates for mechanical thrombectomy between 6 and 24 h after patient was last known to be well.
- Mechanical thrombectomy can be used in addition to treatment with intravenous thrombolytics. However, pretreatment with intravenous thrombolytics (within 4.5 h of symptom onset) is not required prior to thrombectomy.

FOUNDATIONS

Background and Importance

Stroke is the fifth leading cause of death in the United States and a leading cause of long-term disability. It affects nearly 800,000 people per year. On average, someone has a stroke every 40 seconds, and someone dies of a stroke every 4 minutes.[1] Stroke patients have an in-hospital mortality rate of 5% to 10% for ischemic stroke and 40% to 60% for intracerebral hemorrhage (ICH).[2] Only 10% of stroke survivors will recover completely, 25% will recover with minor impairments, and 40% will have moderate to severe impairments, making stroke a leading cause of adult disability.

Stroke is any vascular injury that reduces cerebral blood flow (CBF) to a specific region of the brain, retina, or spinal cord, causing

neurologic impairment. The onset of symptoms may be sudden or stuttering, often with transient or permanent loss of neurologic function. Approximately 87% of all strokes are ischemic in origin, caused by the occlusion of a cerebral vessel, and 13% are hemorrhagic strokes caused by the rupture of a blood vessel into the parenchyma of the brain (ICH) or into the subarachnoid space (subarachnoid hemorrhage [SAH]). Only ischemic stroke involving the brain and ICH are discussed in this chapter. SAH is discussed in Chapters 16 and 33.

Current acute interventional treatment regimens are designed to reverse or minimize brain damage. Strategies include blood pressure (BP) management, anticoagulation, thrombolytic therapy, catheter-based interventions, and surgery.[3]

Ischemic Stroke

About 600,000 "first-ever" ischemic strokes occur each year in the United States. These may result from either in situ thrombosis or embolic obstruction from a more proximal source, usually the heart. In more than one-third of these first-ever strokes, no clear cause is identified. Strokes of all subtypes are more common in Blacks and Hispanics versus non-Hispanic whites.[1]

Approximately one-third of all ischemic strokes are thrombotic in nature, caused by either large- or small-vessel occlusions. Common areas for large-vessel occlusions are cerebral vessel branch points, especially in the distribution of the internal carotid artery (ICA). Thrombosis usually results from clot formation in the area of an ulcerated atherosclerotic plaque that forms in the area of turbulent blood flow, such as a vessel bifurcation. A marked reduction in flow results when the stenosis occludes more than 90% of the blood vessel diameter. With further ulceration and thrombosis, platelets adhere to the region. A clot then either embolizes or occludes the artery.

Lacunae, or small-vessel strokes, involve small terminal sections of the vasculature and more commonly occur in patients with diabetes and hypertension. About 80% to 90% of patients experiencing lacunar strokes have hypertension. The subcortical areas of the cerebrum and brainstem often are involved. Infarcts here range in size from a few millimeters to 2 cm and are seen most commonly in the basal ganglia, thalamus, pons, and internal capsule. They may be caused by small emboli or by a process termed *lipohyalinosis,* which occurs in patients with hypertensive cerebral vasculopathy.

One-fourth of all ischemic strokes are cardioembolic in nature. Embolization of a mural thrombus in patients with atrial fibrillation is the most common mechanism, and patients with atrial fibrillation have an approximate fivefold increased risk for development of a stroke. Noncardiac sources of emboli most commonly include diseased portions of extracranial arteries, resulting in an artery-to-artery embolus. One common example is amaurosis fugax, in which emboli from a proximal carotid artery plaque embolizes to the ophthalmic artery, causing transient monocular blindness. Aortic atheromas represent another non-cardiac source of emboli.

Although stroke risk increases with age, approximately 3% to 4% of all strokes occur in patients 15 to 45 years old, and there have been trends observed showing the average age of first stroke is becoming younger.[1,4] Atherosclerosis is the most common cause in elders while causative disorders and conditions in younger patients often are uncommon and may be reversible. Pregnancy, the use of oral contraceptives, antiphospholipid antibodies (such as lupus anticoagulant and anticardiolipin antibodies), protein S and C deficiencies, sickle cell anemia, and polycythemia all predispose patients to sludging or thrombosis, thereby increasing the risk of stroke. Fibromuscular dysplasia of the cerebral vasculature also may lead to stroke, and in rare instances prolonged vasoconstriction from a migraine syndrome causes stroke. Recreational drugs such as cocaine and amphetamines are potent vasoconstrictors that have been associated with both ischemic and hemorrhagic stroke. Infectious processes, particularly varicella and recently fungal meningitis, can induce vasculopathies that lead to stroke as well or can induce longer-term inflammatory processes that ultimately cause a clinical stroke.

Carotid and vertebral dissections often are associated with trauma but may follow mild events such as sneezing. Dissections are the leading determined cause of stroke in the young and are slightly less common than idiopathic strokes. Carotid and vertebral dissections also are seen more frequently in people with underlying pathology of the vessel wall, such as in fibromuscular dysplasia and connective tissue disorders. Alteration in the vessel intima can lead to vessel stenosis, occlusion, or embolism. The patient may report a minor preceding event, such as spinal manipulation, strenuous exercise, yoga, coughing, or vomiting. Presenting manifestations may include headache, facial pain, visual changes, cranial nerve (CN) palsies, pain over the affected vessel, Horner syndrome, amaurosis fugax, SAH, or an ischemic stroke. The headache frequently is unilateral and may occur days before onset of the other neurologic symptoms. Dissections are typically diagnosed by noninvasive modalities, such as ultrasonography, magnetic resonance angiography (MRA), and computed tomography angiography (CTA).

Transient Ischemic Attack

A transient ischemic attack (TIA) was previously defined as a neurologic deficit that completely resolves within 24 hours; however, a portion of TIA cases have evidence of permanent brain ischemia on neuroimaging. Therefore, the American Heart Association (AHA) has adopted a tissue-based definition: "A transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction."

About 240,000 TIAs per year occur in the United States, with an incidence rate of 8 per 1000 person years. TIAs constitute an important warning sign for the future development of cerebral infarction. Approximately 10% of the patients who experience a TIA will sustain a stroke within 3 months of the sentinel event, and one-half of these occur within the first 2 days. High-grade carotid stenosis in the neck and cardioemboli are two key causes that contribute to early stroke following TIA. In addition, recurrence data is primarily derived from an era where MRI was much less commonly used; patients with DWI negative TIAs generally have a much lower risk of recurrence.[5,6]

Hemorrhagic Stroke

Spontaneous ICH causes 10% to 15% of all acute strokes, affecting approximately 65,000 patients per year. It carries a 30-day mortality rate of up to 50% with one-half of patients dying in the first 2 days. Among survivors, only one in five are living independently at 6 months.

The two major underlying causes of ICH are hypertensive vasculopathy (caused by long-standing hypertension) and cerebral amyloid~angiopathy (usually found in elder patients, which is the result of amyloid deposition in cerebral vessel walls). Hypertensive hemorrhage results from degenerative changes in the small penetrating arteries and arterioles, leading to lipohyalinosis of small, deep penetrating arteries. Such hemorrhages generally occur in the deep regions, including basal ganglia and thalamus. The most common sites for hypertensive hemorrhage are summarized in Box 87.1. ICH caused by amyloid angiopathy tends to be lobar in nature and to occur more commonly in older adults.

Other factors leading to ICH include underlying vascular malformations (i.e., arteriovenous malformations [AVMs] and aneurysms, drug intoxication [particularly sympathomimetics, such as cocaine], malignant hypertension, saccular aneurysms, blood dyscrasias, venous sinus thrombosis, hemorrhagic transformation of an ischemic stroke,

BOX 87.1 Most Common Sites for Hypertensive Intracranial Hemorrhage

Affected Area (Frequency)
Putamen (44%)
Thalamus (13%)
Cerebellum (9%)
Pons (9%)
Other cortical areas (25%)

Common Clinical Presentation
Contralateral motor/sensory loss
Limb pain, speech difficulty
Uncoordinated movements of trunk and limbs
Numbness, weakness, ataxia, dizziness
Numbness, weakness, language disturbances

moyamoya disease, and tumors). High-risk features for such secondary forms of ICH include lobar location, presence of intraventricular blood, and younger age.

Anatomy, Physiology, and Pathophysiology

The cerebral vasculature supplies the brain with a rich flow of blood that contains the critical supply of oxygen and glucose necessary for normal brain function. When a stroke occurs, there are immediate alterations in CBF and extensive changes in cellular homeostasis. The normal CBF is approximately 40 to 60 mL/100 g of brain per minute. When CBF drops below 15 to 18 mL/100 g of brain per minute, several physiologic changes occur. The brain loses electrical activity, becoming electrically "silent," although neuronal membrane integrity and function remain intact. Clinically, the areas of the brain maintaining electrical silence manifest a neurologic deficit, even though the brain cells are viable. When CBF is below 10 mL/100 g of brain per minute, membrane failure occurs, with a subsequent increase in the extracellular potassium and intracellular calcium and eventual cell death.

The ischemic penumbra is the area of the brain surrounding the primary injury, which is preserved by a tenuous supply of blood from collateral vessels. This border zone of neuronal tissue is the area of greatest interest to investigators for possible salvage in both ischemic and hemorrhagic stroke. In ischemic stroke, the duration of occlusion plays a critical role in neuronal survival.

In ICH, acute vessel rupture is most often caused by underlying small vessel disease and causes injury by several mechanisms. First, there is mass effect from the hematoma itself, followed by activation of the coagulation cascade, release of inflammatory cytokines, and blood-brain barrier (BBB) disruption. This leads to perihematomal edema formation and secondary brain injury. Finally, continued bleeding, or hematoma expansion, occurs in many patients—either continued bleeding from the primary source, or secondary bleeding at the periphery of the hemorrhage.

Blood is supplied to the brain by the anterior and posterior circulations. The anterior circulation originates from the carotid system and perfuses 80% of the brain, including the optic nerve, retina, and frontoparietal and anterior-temporal lobes. The first branch off the ICA is the ophthalmic artery, which supplies the optic nerve and retina. As a result, the sudden onset of painless monocular blindness *(amaurosis fugax)* identifies the stroke as involving the anterior circulation (specifically the ipsilateral carotid artery) at or below the level of the ophthalmic artery. The ICAs terminate by branching into the anterior and middle cerebral arteries (MCAs) at the circle of Willis.

The anterior cerebral artery supplies the basal and medial aspects of the cerebral hemispheres and extends to the anterior two-thirds of the parietal lobe. The MCA feeds the lenticulostriate branches that supply the putamen, part of the anterior limb of the internal capsule, the lentiform nucleus, and the external capsule. Main cortical branches of the MCA supply the lateral surfaces of the cerebral cortex from the anterior portion of the frontal lobe to the posterolateral occipital lobe.

Although the posterior circulation is smaller and usually supplies only 20% of the brain, it supplies the brainstem (which is critical for normal consciousness, movement, and sensation), cerebellum, thalamus, auditory and vestibular centers of the ear, medial temporal lobe, and visual occipital cortex. The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum and supply the cerebellum by the posterior inferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries. Some variants exist, importantly, the fetal origin posterior cerebral artery, which is where the posterior cerebral artery is actually fed by the anterior circulation.

The extent of injury in either an anterior or a posterior stroke depends on both the vessel involved and the presence of collateral blood flow distal to the vessel occlusion. A patient with adequate collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. By contrast, a patient with poor collateral flow may have hemiplegia with the same lesion.

CLINICAL FEATURES

Ischemic Stroke

The signs and symptoms of an ischemic stroke may appear suddenly and without warning or may have a stuttering, insidious onset. Disruption of the flow to one of the major vascular limbs of the cerebral circulation will result in physiologic disruption to the anatomic area of the brain supplied by that blood vessel. Ischemic strokes involve either the anterior or posterior circulation strokes and the neurologic deficits are highly dependent on amount of collateral blood flow. In addition to the vascular supply involved, ischemic strokes can be further described by the temporal presentation of their neurologic deficits.

A "stroke in evolution" is one in which focal neurologic deficits worsen over the course of minutes or hours. Approximately 20% of anterior circulation strokes and 40% of posterior circulation strokes will show evidence of progression. Since a single low score on the National Institutes of Health Stroke Scale (NIHSS) may not be sufficient to determine t-PA eligibility, repeating the NIHSS and reassessing these patients is recommended. Anterior circulation strokes may progress within the first 24 hours, whereas posterior strokes may progress for up to 3 days. Propagation of thrombus is postulated as a likely mechanism for progression. With anterior circulation strokes (involving primarily the carotid, anterior, and MCAs), the clinical presentation rarely includes complete loss of consciousness unless the lesion occurs in the previously unaffected hemisphere of a patient who has experienced a previous contralateral stroke.

Occlusions in the anterior cerebral artery mainly affect frontal lobe function. The patient has altered mentation coupled with impaired judgment and insight, as well as the presence of primitive grasp and suck reflexes on physical examination. Bowel and bladder incontinence may be features of anterior cerebral artery stroke. Paralysis and hypesthesia of the lower limb opposite the side of the lesion are characteristic. Leg weakness is more pronounced than arm weakness in anterior cerebral distribution stroke. Apraxia or clumsiness in the patient's gait is often observed.

Marked motor and sensory disturbances are the hallmarks of occlusion of the MCA. They occur on the side of the body contralateral to the side of the lesion and usually are more pronounced in the arm and face than the leg. Such disturbances may involve only part of an extremity or the face but almost always are accompanied by numbness in the same region as that of the motor loss. Hemianopsia, or blindness in one-half of the visual field, occurs contralateral to the lesion. Agnosia, or the inability to recognize previously known subjects, is common, and aphasia may be present if the lesion occurs in the dominant hemisphere. Patients often have a gaze preference toward the affected hemisphere because of disruption of the cortical lateral gaze centers.

Aphasia, a disorder of language in which the patient articulates clearly but uses language inappropriately or comprehends it poorly, also is common in dominant-hemisphere stroke. Aphasia may be expressive, receptive, or a combination of both. *Wernicke aphasia* occurs when the patient is unable to process sensory input, such as speech, and thus fails to understand verbal communication (receptive aphasia). *Broca aphasia* refers to the inability to communicate verbally in an effective way, even though understanding may be intact (expressive aphasia). Aphasia should be distinguished from dysarthria, which is a motor deficit of the mouth and speech muscles; the dysarthric patient articulates poorly but understands words and word choices. Aphasia is important to recognize because it usually localizes a lesion to the dominant cerebral cortex (typically the left side) in the MCA distribution. *Aphasia* and *dysphasia* are terms that are used interchangeably but must be distinguished from *dysphagia,* which is difficulty in swallowing.

Chemoreceptor Trigger Zone for Emesis

Pathology in the vertebrobasilar system (i.e., posterior circulation strokes) can cause the widest variety of symptoms and as a result may be the most challenging to diagnose. The symptoms reflect CN deficits, cerebellar involvement, and involvement of neurosensory tracts. The brainstem also contains the reticular activating system, which is responsible for mediating consciousness, and the chemoreceptor trigger zone (CTZ) for emesis (commonly referred to as the "vomiting center"). Unlike those with anterior circulation strokes, patients with posterior circulation stroke can have loss of consciousness and frequently have nausea and vomiting. The posterior cerebral artery supplies portions of the parietal and occipital lobes, so vision and thought processing are impaired. Visual agnosia, the inability to recognize seen objects, is a common feature, as is alexia, the inability to understand the written word. A third CN palsy may occur, and the patient may experience homonymous hemianopsia. One of the more unique facets of this syndrome is that the patient may be unaware of any visual problem (visual neglect). Vertigo, syncope, diplopia, visual field defects, weakness, paralysis, dysarthria, dysphagia, spasticity, ataxia, or nystagmus may be associated with vertebrobasilar artery insufficiency. Posterior circulation strokes also demonstrate crossed deficits, such as motor deficits on one side of the body and sensory loss on the other. In anterior circulation strokes, by contrast, abnormalities are limited to one side of the body.

A focused neurologic examination should assess level of consciousness, speech, CN function, motor and sensory function, and cerebellar function. Level of consciousness and fluency of speech can be rapidly assessed in a dialogue with the patient to determine the presence of dysarthria or aphasia. The head should be evaluated for signs of trauma. Pupillary size and reactivity and extraocular movements provide important information about brainstem function, particularly CN III through CN VI; an abnormal third nerve function may be the first sign of tentorial herniation. Gaze preference suggests brainstem or cortical involvement. Central facial nerve weakness from a stroke should be distinguished from the peripheral causes of CN VII weakness. With a peripheral lesion, the patient is unable to wrinkle the forehead. Assessment of facial sensation, eyebrow elevation and squinting, smiling symmetry, gross auditory acuity, gag reflex, shoulder elevation, sternocleidomastoid strength, and tongue protrusion complete the CN evaluation.

Motor and sensory testing is performed next. Muscle tone can be assessed by moving a relaxed limb. Proximal and distal muscle group strength is assessed against resistance. Pronator drift of the arm is a sensitive sign of motor weakness and can be tested simultaneously by having the patient sit with eyes closed and arms outstretched, with palms toward the ceiling for 10 seconds. Asymmetrical sensation to pain and light touch may be subtle and difficult to detect. Double simultaneous extinction evaluation tests for sensory neglect and can be performed by simultaneously touching the right and left limbs. The patient may feel both the right and left sides being touched individually but may not discern touch on one side when both are touched simultaneously. Similarly, the ability to discern a number gently scratched on a forearm, termed graphesthesia, is another readily performed test of cortical parietal lobe. These tests can help differentiate a pure motor deficit of a lacunar stroke from a sensorimotor MCA deficit.

Cerebellar testing and the assessment of reflexes and gait complete the neurological examination. Finger-to-nose and heel-to-shin evaluations are important tests of cerebellar functions. Asymmetry of the deep tendon reflexes or unilateral Babinski sign may be an early finding of corticospinal tract dysfunction. Gait testing is commonly omitted yet is a critical part of the neurologic examination when it can be safely performed. Observing routine ambulation and heel-to-toe walking can assess for subtle ataxia, weakness, or focal cerebellar lesions.

Several prehospital stroke scales have been created to assist emergency medical service (EMS) personnel with the rapid assessment of potential stroke patients. Many of these prehospital stroke scales have been prospectively validated for their accuracy in stroke detection. Two of the more commonly used scales include the Cincinnati Prehospital Stroke Scale (Fig. 87.1) and the Los Angeles Prehospital Stroke Screen (Fig. 87.2). Scales that can reliably identify patients with large vessel occlusion (LVO) who may benefit from preferential triage to a thrombectomy capable stroke center are being evaluated.[7] The Los Angeles Motor Score (LAMS) performed by paramedics in the field has potential for identifying individuals with LVOs.[8]

Cincinnati Prehospital Stroke Scale	
Facial Droop	
Normal:	Both sides of face move equally
Abnormal:	One side of face does not move at all
Arm Drift	
Normal:	Both arms move equally or not at all
Abnormal:	One arm drifts compared to the other
Speech	
Normal:	Patient uses correct words with no slurring
Abnormal:	Slurred or inappropriate words or mute

The NIHSS is a useful and rapid tool for quantifying neurologic deficit in patients with stroke and can be used in determining treatment options (Table 87.1). NIHSS scores have been shown to be reproducible, valid, and correlate well with the amount of infarcted tissue on computed tomography (CT) scan. The baseline NIHSS score can identify patients who are appropriate candidates for fibrinolytic therapy, as well as those at increased risk for hemorrhage. It is, however, possible for patients to have disabling strokes with an NIHSS of zero (severe truncal ataxia). In addition, it has been used as a prognostic tool to predict outcome and is currently being used by certain stroke centers to stratify patients for entry into treatment trials.

Hemorrhagic Stroke

The classic presentation of ICH is the sudden onset of headache, vomiting, severely elevated BP, and focal neurologic deficits that progress

Los Angeles Prehospital Stroke Scale (LAPSS)

Patient name: _____

Rater name: _____

Date: _____

Screening criteria	Yes	No
4. Age over 45 years	____	____
5. No prior history of seizure disorder	____	____
6. New onset of neurologic symptoms in last 24 hours	____	____
7. Patient was ambulatory at baseline (prior to event)	____	____
8. Blood glucose between 60 and 400	____	____

9. Exam: ***Look for obvious asymmetry***

	Normal	Right	Left
Facial smile / grimace:	☐	☐ Droop	☐ Droop
Grip:	☐	☐ Weak grip ☐ No grip	☐ Weak grip ☐ No grip
Arm weakness:	☐	☐ Drifts down ☐ Falls rapidly	☐ Drifts down ☐ Falls rapidly

Based on exam, patient has only unilateral (and not bilateral) weakness: Yes ☐ No ☐

10. If yes (or unknown) to all items above LAPSS screening criteria met: Yes ☐ No ☐

11. If LAPSS criteria for stroke met, call receiving hospital with "CODE STROKE," if not then return to the appropriate treatment protocol. (Note: The patient may still be experiencing a stroke if even if LAPSS criteria are not met.)

TABLE 87.1 National Institutes of Health Stroke Scale Scoring Form

Item	Scoring Definitions	Score
1a. Level of consciousness (LOC)	0 = Alert and responsive 1 = Arousable to minor stimulation 2 = Arousable only to painful stimulation 3 = Reflex responses or unarousable	
1b. LOC-related questions: Ask patient's age and month. Must be exact.	0 = Both correct 1 = One correct (or dysarthria, intubated, foreign language) 2 = Neither correct	
1c. Commands: Open and close eyes, grip and release nonparetic hand. (Other one-step commands or mimic also acceptable.)	0 = Both correct (acceptable if impaired by weakness) 1 = One correct 2 = Neither correct	
2. Best gaze: Horizontal EOM by voluntary or doll's eye maneuver.	0 = Normal 1 = Partial gaze palsy; abnormal gaze in one or both eyes 2 = Forced eye deviation or total paresis that cannot be overcome by doll's eye maneuver	
3. Visual field: Use visual threat if necessary. If monocular, score field of good eye.	0 = No visual loss 1 = Partial hemianopsia, quadrantanopia, extinction 2 = Complete hemianopsia 3 = Bilateral hemianopsia or blindness	
4. Facial palsy: If patient is stuporous, check symmetry of grimace to pain.	0 = Normal 1 = Minor paralysis, flat NLF, asymmetrical smile 2 = Partial paralysis (lower face = UMN lesion) 3 = Complete paralysis (upper and lower face)	
5. Motor arm: Arms outstretched 90 degrees (sitting) or 45 degrees (supine) for 10 seconds. Encourage best effort. Indicate paretic limb in score box.	0 = No drift for 10 seconds 1 = Drift but does not hit bed 2 = Some antigravity effort, but cannot sustain 3 = No antigravity effort, but even minimal movement counts 4 = No movement at all X = Unable to assess owing to amputation, fusion, fracture, and so on	L or R
6. Motor leg: Raise leg to 30 degrees (from supine) for 5 seconds. Indicate paretic limb in score box.	0 = No drift for 5 seconds 1 = Drift but does not hit bed 2 = Some antigravity effort, but cannot sustain 3 = No antigravity effort, but even minimal movement counts 4 = No movement at all X = Unable to assess owing to amputation, fusion, fracture, and so on	L or R
7. Limb ataxia: Check finger-nose-finger, heel-shin position sense; and score only if out of proportion to paralysis.	0 = No ataxia (or aphasic, hemiplegic) 1 = Ataxia in upper or lower extremity 2 = Ataxia in upper *and* lower extremity X = Unable to assess owing to amputation, fusion, fracture, and so on	L or R
8. Sensory: Use safety pin. Check grimace or withdrawal if patient is stuporous. Score only stroke-related losses.	0 = Normal 1 = Mild-moderate unilateral loss but patient aware of touch (or aphasic, confused) 2 = Total loss, patient unaware of touch; coma, bilateral loss	
9. Best language: Describe cookie jar picture, name objects, read sentences. May use repeating, writing, stereognosis.	0 = Normal 1 = Mild-moderate aphasia (speech difficult to understand but partly comprehensible) 2 = Severe aphasia (almost no information exchanged) 3 = Mute, global aphasia, coma; no one-step commands	
10. Dysarthria: Read list of words.	0 = Normal 1 = Mild-moderate; slurred but intelligible 2 = Severe; unintelligible or mute X = Intubation or mechanical barrier	
11. Extinction or neglect: Simultaneously check bilateral visual fields and auditory sensation, touch in both hands and recognition of body parts looking for extinction or neglect.	0 = Normal, none detected (visual loss alone) 1 = Neglects or extinguishes to double simultaneous stimulation in any modality (visual, auditory, sensation, spatial, body parts) 2 = Profound neglect in more than one modality

over minutes. Similar to ischemic stroke, ICH is often associated with a motor and sensory deficit contralateral to the brain lesion. Almost 40% of patients will demonstrate significant growth in hemorrhage volume within the first few hours.

Although headache, vomiting, and coma are common, many patients do not have these findings, and the clinical presentation can be identical to that of patients with ischemic stroke; the two cannot be reliably differentiated in the absence of neuroimaging.

Ongoing assessment of airway and mental status is part of a comprehensive care plan since patients with ICH can precipitously deteriorate. Emergency airway management requires careful judgment: On the one hand, airway control can prevent aspiration, hypoxia, and hypercarbia; on the other, sedation and paralysis can make it difficult to follow serial neurologic exams, which can help monitor for hemorrhage expansion, elevated intracranial pressure (ICP), seizure activity, and brainstem herniation.

As with ischemic stroke, the neurologic examination localizes the region and extent of injury. Baseline NIHSS and Glasgow Coma Scale scores can be used to assess stroke severity, although the Glasgow Coma Score (GCS) may be more practical to follow for neurologic or mental status deterioration (Table 87.2). In addition, serial examinations can detect early changes that may suggest ongoing bleeding during the acute phase. The ICH score can also predict mortality (Table 87.3).

Baseline characteristics associated with unfavorable outcome for patients with ICH include a decreased level of consciousness on arrival, intraventricular hemorrhage, and large ICH volume, all of which can be assessed in the emergency department (ED) (Fig. 87.3). Prognostic studies of ICH have been biased by early care limitation; newer research suggests a number of patients with early care limitations could have acceptable outcomes. Based on the uncertainty, emergency clinicians are best served in avoiding specific predictions regarding chances of recovery shortly after ICH.[9]

DIFFERENTIAL DIAGNOSES

Ischemic Stroke

Extra-axial collections of blood secondary to trauma can mimic stroke. An epidural or subdural hematoma can cause an altered mental status, focal neurologic signs, and rapid progression to coma. Elders, who represent the age group at highest risk for stroke, can be victims of recurrent falls that lead to chronic subdural hematomas (particularly those on anticoagulation therapy). Carotid dissection may occur after neck trauma or sudden hyperextension and may be associated with focal neurologic signs and symptoms, as with an aortic dissection that extends into the carotid arteries.

Other structural lesions that may cause focal neurological findings include brain tumors and abscesses. Air embolism should be suspected in the setting of marked atmospheric pressure changes, such as in scuba diving or during medical procedures or injuries that may allow air into the vascular system. Seizure activity, altered mental status, and focal neurologic findings also may be manifestations of air embolism.

Metabolic abnormalities also can mimic stroke syndromes. Hypoglycemia often is responsible for an altered mental status and is a common cause of sustained focal neurologic symptoms that can persist for several days. Wernicke encephalopathy from thiamine deficiency causes ophthalmoplegia, ataxia, and confusion that can be mistaken for signs of cerebellar infarction.

Complex migraines may present with focal neurologic findings, with or without headache. A seizure followed by Todd postictal paralysis may mimic stroke. Bell or peripheral facial nerve palsy, labyrinthitis, vestibular neuronitis, peripheral nerve palsy, and demyelinating diseases may all mimic stroke. Ménière disease may be difficult to distinguish from a posterior circulation stroke or TIA. Dizziness, vertigo, hearing loss, and tinnitus in Ménière disease are common, whereas difficulties with vision or speech or other focal symptoms are less common.

Similar to stroke, giant cell arteritis is a disease of elder adults. It may cause severe headache, visual disturbances, and, rarely, aphasia and hemiparesis. Other symptoms include intermittent fever, malaise,

TABLE 87.2 Glasgow Coma Scale Score[a]

Fig. 87.3 The computed tomography (CT) slice with the largest area of hemorrhage is identified. The largest diameter of the hemorrhage on this slice is measured in centimeters *(line A)*. The largest diameter 90 degrees to A on the same slice is measured *(line B)*. C is the approximate number of 10-mm slices on which the intracerebral hemorrhage (ICH) was seen. (Many centers use 5-mm slices, in which case an adjustment can be made by dividing by 2.) The volume of the hemorrhage = A × B × C ÷ 2 (ABC/2).

jaw claudication, morning stiffness, and myalgias. The diagnosis should be suspected in patients with an elevated erythrocyte sedimentation rate (ESR) and is confirmed by temporal artery biopsy. Collagen vascular diseases such as polyarteritis nodosa, systemic lupus erythematous (SLE), and other types of vasculitis may cause stroke syndromes.

Cerebral venous sinus thrombosis (CVST) is another cause of focal neurologic symptoms that most commonly affects the superior sagittal sinus and lateral sinuses (see Chapter 89).[10] The diagnosis of CVST can be difficult because of the nonspecific nature of symptoms, as well as the variable time frame of symptom onset (from hours to weeks). Patients may have generalized headaches, nausea, vomiting, paresis, visual disturbances, depressed level of consciousness, seizures, or symptoms generally ascribed to psychiatric disorders (such as depression). Depending on the location of the thrombus, physical examination of the patient may reveal papilledema, proptosis, or palsies of CNs III, IV, and VI, as well as other focal neurologic signs. Risk factors for CVST include trauma, infectious processes, hypercoagulable states, low-flow states, compression of the venous sinus, dehydration, pregnancy, postpartum state, and certain drugs (such as androgens, designer amphetamines, and oral contraceptives).

Hemorrhagic Stroke

Differential diagnoses for ICH is similar to that for ischemic stroke; considerations include migraine, seizure, brain tumor, abscess, hypertensive encephalopathy, and head trauma. Hypertensive encephalopathy and migraine also can manifest with headache, nausea, and vomiting, although focal neurologic signs are less common in these entities. With hypertensive encephalopathy, patients usually exhibit marked elevation in BP and other evidence of end-organ injury, such as proteinuria, cardiomegaly, papilledema, and malignant hypertensive retinopathy. These patients usually improve with treatment of their hypertension. The posterior reversible encephalopathy syndrome (PRES) is a subset of hypertensive encephalopathy presentations and has characteristic CT or magnetic resonance imaging (MRI) changes.

Once ICH is diagnosed on neuroimaging, it can be difficult to determine the underlying cause. Primary ICH typically manifests as a parenchymal hematoma with new onset neurologic symptoms. Patients with hemorrhagic transformation of an ischemic stroke may have recurrence or worsening of previously established neurological deficits. Patients with known underlying cancer, or perihematomal edema out of proportion to the hemorrhage, should be considered for hemorrhage into a metastatic lesion or primary tumor. Finally, patients with known underlying venous thromboembolic risk factors may have underlying CVST.

DIAGNOSTIC TESTING

Ischemic Stroke

Although clinical data can help establish the diagnosis and location of the stroke, confirmatory diagnostic tests are often required to establish the final cause or to eliminate other processes. The immediate evaluation includes cranial imaging, an electrocardiogram (ECG), and laboratory testing, particularly blood glucose determination.

An emergent noncontrast cranial CT of the head is the standard initial imaging technique for evaluating a patient with a potential stroke. However, it has limited sensitivity to assess strokes involving the posterior circulation, especially in the posterior fossa structures. It can quickly differentiate an ischemic stroke from ICH and other mass lesions. This information is crucial to the subsequent therapeutic decisions that need to be rapidly made. A CT scan can identify the vast majority of parenchymal hemorrhages larger than 1 cm in diameter and it has a high sensitivity for the detection of SAH. With most ischemic strokes, gross signs of infarction will not appear on routine CT scans for at least 6 to 12 hours, depending on the size of the infarct. However, subtle, early ischemic changes have been noted in up to 67% of noncontrast CT head scans within the first 3 hours. These early ischemic changes include the hyperdense artery sign (acute thrombus in a vessel), sulcal effacement, loss of the insular ribbon, loss of gray-white interface, mass effect, and acute hypodensity (Fig. 87.4).

In addition, CTA or MRA can be used to identify the presence of intravascular thrombosis, vasculature dissection, or stenosis. CTA can be used for the triage of patients who may be candidates for endovascular therapy to determine if there is an LVO. CTA can be obtained concurrently with head CT. Imaging with CTA can also be helpful to identify patients who might benefit from thrombectomy following t-PA administration. Vigilance should be taken to avoid delaying administration of thrombolytics as the thrombectomy trials with the largest treatment effects were predominantly populated with patients who had received t-PA promptly prior to thrombectomy.

Automated CT perfusion (CTP) has emerged as an additional methodology to identify patients who may benefit from reperfusion in extended time windows.[11–13] CTP is generally not helpful in the first 6 hours following stroke onset in that most of these patients will either qualify for t-PA on clinical grounds and for thrombectomy based on CTA findings. MRI has also been investigated to identify candidates for systemic thrombolysis with "wake up" strokes.[14] Advanced imaging should not delay the administration of t-PA.

The clinical importance of early ischemic CT findings with regard to fibrinolytic therapy within 3 hours of symptom onset is controversial, because the ability of treating clinicians to reproducibly identify these findings is poor and their clinical significance is questionable. Only acute hypodensity and mass effect have been shown to be associated with an increased risk of ICH after fibrinolysis (over that in treated patients without these findings). However, these findings do

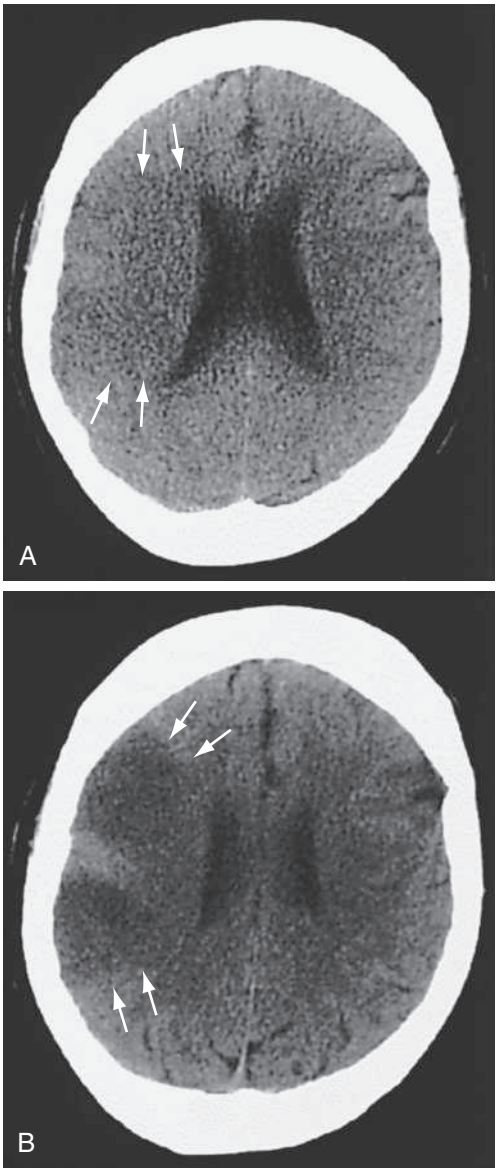

Fig. 87.4 (A) Computed tomography (CT) scan taken 2 hours and 50 minutes after a large right middle cerebral artery occlusion. There are subtle, ultra-early ischemic changes, including loss of the gray-white interface *(arrows)* and subtle evidence of sulcal effacement. (B) CT scan of same patient approximately 8 hours after symptom onset shows acute hypodensity *(arrows)* and more prominent sulcal effacement.

not exclude patients from fibrinolytic therapy, which is associated with an improved neurological outcome. Patients with a hyperdense artery sign and acute hypodensity of one-third of the MCA distribution tend to have a poorer prognosis. Their outcomes, however, are still better with t-PA treatment than without fibrinolytic therapy.

MRI can visualize ischemic brain infarcts earlier and identify acute posterior circulation strokes more accurately than CT, and it is as effective as CT in identifying ICH. However, availability, proximity to the ED, difficulty in accessing critically ill patients, and image time limit the use of MRI in acute stroke. Advances in MRA technology have allowed a noninvasive method of demonstrating large-vessel occlusions of the anterior and posterior circulation, although small intracranial vascular occlusions may not be readily apparent. With the improvements in MRI and MRA speed and resolution, some stroke centers are replacing CT protocols with limited "stroke protocol" MRI or MRA as the initial imaging modality of choice. The choice of initial cranial imaging modality is highly dependent on the speed with which these scans can be performed and interpreted at each individual center.

Diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI) are MRI techniques that take minutes to perform and may allow differentiation between reversible and irreversible neuronal injury. Other potential imaging modalities include CTA and perfusion scans. In CTA, CT imaging is enhanced by an intravenous (IV) contrast agent to better define the vasculature of the brain. Areas of vascular stenosis and occlusion can be visualized with this technique. This information can then be used by interventionalists to determine whether a lesion is amenable to endovascular thrombectomy. Also requiring IV contrast, perfusion CT scans can reveal perfusion deficits within different regions of the brain. In addition, CTA and perfusion CT can differentiate reversible from irreversible ischemic insults.

An ECG is indicated in all patients with acute ischemic stroke; atrial fibrillation and acute myocardial infarction are associated with up to 60% of all cardioembolic strokes. The hematologic evaluation includes a complete blood and platelet count, prothrombin time (including international normalized ratio [INR]), partial thromboplastin time, troponin levels, and serum glucose measurement. Elevated blood viscosity, even when hematocrit levels are not polycythemic, can affect blood flow and prognosis. A platelet count can identify thrombocytosis or thrombocytopenia, which may precipitate a thrombosis or hemorrhage. Coagulation studies are especially helpful to guide management for patients in whom anticoagulation is being considered or for patients with an acute hemorrhagic stroke.

Other ancillary diagnostic tests to consider include an echocardiogram, carotid duplex scan, and angiogram. Some stroke centers are performing these studies as part of a TIA observation unit protocol to exclude a patent foramen ovale or valvular vegetation in those patients in whom a cardioembolic stroke is suspected. An echocardiogram should also be performed in patients with no obvious cause for their stroke.[3] Finally, conventional angiography can demonstrate stenosis or occlusion of both large and small blood vessels of the head and neck. It can detect subtle abnormalities, such as with dissection, that may not be demonstrated with noninvasive imaging techniques.

Transient Ischemic Attack

Patients with new-onset TIAs should receive an expedited evaluation and treatment owing to the substantial short-term risk of stroke and other adverse events. In 2016, a multi-national study reported a 2% stroke recurrence rate in the week following a presentation for TIA or minor stroke.[15] Emergency neuroimaging, vascular imaging (such as with a carotid Doppler study, MRA, or CTA), electrocardiography, and basic blood tests should be performed. A medically or surgically treatable cause for TIAs (e.g., high-grade carotid stenosis, mural thrombus) should be considered, which would require in-hospital treatment such as anticoagulation, stenting, or carotid endarterectomy.

Hemorrhagic Stroke

The hematologic evaluation for the patient with hemorrhagic stroke should be performed in the same manner as for the patient with ischemic stroke. Particular attention should be directed to uncovering the presence of a coagulopathy. A drug screen should be obtained to evaluate for use of sympathomimetics (such as cocaine) if substance abuse is suspected. Increased sympathetic outflow secondary to the hemorrhage may lead to an increase in dysrhythmias. Dysrhythmias also may signal impending brainstem compression from an expanding hemorrhage.

As in ischemic stroke, the cranial CT scan is the diagnostic test of choice to evaluate for an ICH. The noncontrast CT scan will reliably

diagnose patients with clinically relevant acute ICH. Hemorrhages that are several days old may not be as apparent as acute hemorrhages and appear as isodense regions on CT imaging.

Also, as with ischemic stroke, advanced neuroimaging modalities are gaining favor in ICH. CTA produces high-quality images of the larger arterial vessels and can help exclude secondary causes, such as aneurysm, AVM, or fistula. Some patients with primary ICH show contrast extravasation on CTA, and such patients are at particularly high risk of ongoing bleeding and hematoma expansion. A venous phase can be added to this study (computed tomography venography [CTV]) to evaluate for CVST. An MRI can help detect underlying lesions (such as a brain tumor) and may offer better resolution for evaluating perihematomal edema. When available, MRA and magnetic resonance venography (MRV) can be used in place of CTA and CTV.

MANAGEMENT

Ischemic Stroke

With a focus on rapid recognition, evaluation, and treatment of stroke, many medical centers have streamlined care to meet recommended time goals (Table 87.4). This has led to the development of stroke protocols, critical pathways, and acute interventional stroke teams that may even be deployed in the field by EMS personnel before the patient arrives at the ED.

Prehospital Considerations: In the prehospital setting, the focus should be on ensuring central nervous system (CNS) oxygenation and perfusion, rapid identification, early hospital notification, and rapid transport. Although it is unusual for patients with ischemic stroke to be unresponsive on presentation, their ability to communicate may be altered by dysphasia. After an ischemic stroke, patients usually can maintain their airway unless the brainstem is affected or significant cerebral edema is compressing the opposite hemisphere. Patients with intact protective airway reflexes should receive oxygen if they are hypoxic (oxygen saturation less than 95%). Routine oxygen supplementation of normoxic stroke patients should be avoided.

A monitor and IV line should be established. Overhydration should be avoided to prevent cerebral edema. By contrast, dehydration may lead to decreased cerebral perfusion, and saline infusion should be given if dehydration is suspected. Dextrose-containing solutions should be avoided in normoglycemic patients suspected of having had a stroke because elevated blood glucose levels may worsen an ischemic deficit.

Prehospital personnel should rapidly ascertain the patient's blood sugar. Both hypo- and hyperglycemia can mimic acute stroke presentations. Electrocardiographic monitoring is recommended to identify life-threatening arrhythmias and atrial fibrillation.[3]

Prehospital providers should document the exact time the patient was last seen to be neurologically normal and the level of neurologic functioning using one of the validated prehospital stroke scores. The level of consciousness, gross focal motor deficits, difficulty with speech, clumsiness, facial asymmetry, and any other focal deficits should be noted. Prehospital stroke scales assist in identifying patients who have had a stroke and who are potential candidates for fibrinolytic therapy. Early recognition, notification, and transport by EMS are associated with expedited delivery of fibrinolytic treatment and improved patient outcomes.

In the ED setting, the vital signs should be reassessed on an ongoing basis because patients may rapidly deteriorate even with subacute stroke. Some stroke patients are found at home 1 or 2 days after the event has occurred and may have concomitant illnesses, such as aspiration pneumonia, dehydration, hypothermia, rhabdomyolysis, or myocardial ischemia. Fever necessitates an evaluation to identify sources of infection, followed by prompt institution of treatment, including appropriate antibiotics. Even minor degrees of hyperthermia have been associated with increased neurologic injury. Oral medications, liquids, and food should be withheld until some form of swallowing assessment has been performed, given the risk of aspiration in patients with an acute stroke.

TABLE 87.4 National Institute of Neurological Disorders and Stroke Recommended Stroke Evaluation Targets for Potential Thrombolytic Candidates

Management Component	Target Time Frame
Door to doctor	10 min
Door to CT completion	25 min
Door to CT scan reading	45 min
Door to treatment	60 min
Access to neurologic expertise[a]	15 min
Access to neurosurgical expertise [a]	2 h

CT, Computed tomography.

Blood Pressure Management

Current guidelines for the management of hypertension in patients with acute ischemic stroke recommend that antihypertensive treatment be reserved for those with markedly elevated BPs, unless fibrinolytic therapy is anticipated or specific medical indications are present. These medical indications include acute myocardial infarction, aortic dissection, hypertensive encephalopathy, and severe left ventricular heart failure. Oral or parenteral agents are withheld unless the patient's systolic pressure is greater than 220 mm Hg, diastolic pressure is greater than 120 mm Hg, or mean arterial pressure (MAP) is greater than 130 mm Hg (Box 87.2).

If thrombolytic therapy is indicated, stringent control of BP is indicated to reduce the potential for intracranial hemorrhage (see Box 87.2). Thrombolytic therapy is not recommended for patients whose systolic pressure is consistently higher than 185 mm Hg or whose diastolic pressure is 110 mm Hg at the time of treatment. Patients who have elevated BP and are otherwise eligible for treatment with IV thrombolytics should have their BP carefully lowered so that their systolic BP is less than 185 mm Hg and their diastolic BP is less than 110 mm Hg before IV fibrinolytic therapy is initiated. In patients for whom mechanical thrombectomy is planned and who have not received IV fibrinolytic therapy, it is reasonable to maintain BP ≤185/110 mm Hg before the procedure.[3] Simple measures can be used to lower the BP below this level: Recommended approaches include the use of IV labetalol 10 to 20 mg over 1 to 2 minutes; or continuous nicardipine 5 mg/h IV, titrate up by 2.5 mg/h every 5 to 15 minutes (maximum 15 mg/h); or clevidipine 1 to 2 mg/h IV, titrate by doubling the dose every 2 to 5 minutes (maximum 21 mg/h). Other agents such as hydralazine and enalaprilat can be used.[3] Once thrombolytic therapy has been initiated, hypertension should be treated aggressively and monitored closely for the first 24 hours after treatment.

Just as problematic as an elevated BP can be, low BP can be equally detrimental to patients with ischemic stroke. Hypotension and hypovolemia should be corrected to maintain systemic perfusion levels necessary to support organ function. Normally normotensive stroke patients with low BP or normally hypertensive stroke patients with low or even

low-normal BP are given a fluid bolus to try to increase cerebral perfusion. This is especially important in patients in a dehydrated state. If initial fluid challenge is ineffective, the patient may require vasopressor therapy to gradually increase MAP and improve cerebral perfusion.

Temperature

Sources of hyperthermia (temperature >38°C) should be identified and treated, and antipyretic medications should be administered to lower temperature in hyperthermic patients with stroke.[3] For patients with stroke peak temperature in the first 24 hours less than 37°C and greater than 39°C is associated with an increased risk of in-hospital death compared with normothermia.[16] The benefit of treatment with induced hypothermia remains unclear. To date, studies of hypothermia in acute ischemic stroke show no benefit in functional outcome and suggest that induction of hypothermia increases the risk of infection, including pneumonia.[3]

BOX 87.2 Emergency Antihypertensive Therapy for Acute Ischemic Stroke

Indication That Patient Is Eligible for Treatment With Intravenous Recombinant Tissue Plasminogen Activator or Other Acute Reperfusion Intervention

Blood Pressure Level

Systolic >185 mm Hg or diastolic >110 mm Hg

- Labetalol 10–20 mg IV over 1–2 min; may repeat 1 time
- *or*
- Nicardipine infusion, 5 mg/h; titrate up by 2.5 mg/h at 5- to 15-min intervals, maximum dose 15 mg/h; when desired BP attained, reduce to 3 mg/h
- *or*
- Clevidipine 1 to 2 mg/h IV, titrate by doubling dose every 2 to 5 minutes (maximum 21 mg/h)

Other agents (e.g., hydralazine, enalaprilat) may be considered when appropriate.

If BP does not decline and remains >185/110 mm Hg, do not administer rtPA.

Management of Blood Pressure During and After Treatment With Recombinant Tissue Plasminogen Activator or Other Acute Reperfusion Intervention

Monitor BP every 15 min during treatment and then for another 2 h, then every 30 min for 6 h, and then every hour for 16 h.

Blood Pressure Level

Systolic 180–230 mm Hg or diastolic 105–120 mm Hg

- Labetalol 10 mg IV over 1–2 min; may repeat every 10–20 min; maximum dose of 300 mg
- *or*
- Labetalol 10 mg IV followed by an infusion at 2–8 mg/min

Systolic >230 mm Hg or diastolic 121–140 mm Hg

- Labetalol 10 mg IV over 1–2 min; may repeat every 10–20 min; maximum dose of 300 mg
- *or*
- Labetalol 10 mg IV followed by an infusion at 2–8 mg/min
- *or*
- Nicardipine infusion, 5 mg/h; titrate up to desired effect by increasing 2.5 mg/h every 5 minutes to maximum of 15 mg/h

If BP not controlled, consider sodium nitroprusside.

BP, Blood pressure; *IV,* intravenous; *rtPA,* recombinant tissue plasminogen activator.

Adapted from Jauch EC, Saver JL, Adams HP Jr, et al. Guidelines for the early management of adults with ischemic stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke* 2013;44(3):870–947.

Blood Glucose

Evidence indicates that persistent in-hospital hyperglycemia during the first 24 hours after stroke is associated with worse outcomes than normoglycemia, and thus we recommend treating hyperglycemia to achieve blood glucose levels in a range of 140 to 180 mg/dL and to closely monitor to prevent hypoglycemia. Hypoglycemia (blood glucose <60 mg/dL) should be treated with IV dextrose solution.

Reperfusion Therapy

The ultimate goal of reperfusion therapy for acute ischemic stroke is to improve outcome by reducing stroke-related disability and mortality. Restoring perfusion to ischemic areas of the brain that are not yet infarcted is critical to achieving this goal and is time dependent. There are two reperfusion strategies that have been extensively studied and proven effective: (1) IV thrombolytic therapy and (2) mechanical thrombectomy.

Thrombolytic Therapy

Agent and Dosage

Options for thrombolytic therapy that are proven effective include two types of recombinant tissue plasminogen activators (t-PA): IV alteplase and IV tenecteplase. Alteplase is the primary IV thrombolytic agent approved by the U.S. Food and Drug Administration (FDA) for treatment of patients with acute ischemic stroke within 3 hours of clearly defined symptom onset to restore blood flow to the regions of brain that are ischemic. Approval was initially based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) trial. The dosage of alteplase is 0.9 mg/kg (maximum dose 90 mg) over 60 minutes with initial 10% of dose given as bolus over 1 minute. The ENCHANTED trial evaluated a low-dose alteplase (0.6 mg/kg IV) versus standard-dose alteplase (0.9 mg/kg IV) in 3300 patients (63% Asian) with acute ischemic stroke. Low-dose alteplase was noninferior to standard-dose alteplase with respect to death and disability at 90 days and there were significantly fewer symptomatic ICHs with low-dose alteplase.[17] Low-dose alteplase is the standard of care in Japan but current AHA/ASA guidelines still recommend 0.9 mg/Kg.

There is moderate- to high-quality evidence that IV tenecteplase 0.25 mg/kg (maximum 25 mg) given in a single bolus has similar rates of functional outcome, symptomatic ICH, and mortality at 90 days compared with alteplase.[18–20] The EXTEND-IA TNK trial (Tenecteplase Versus Alteplase Before Endovascular Therapy for Ischemic Stroke) randomized 202 patients with acute ischemic stroke within 4.5 hours of symptoms undergoing endovascular therapy to thrombolysis with tenecteplase versus alteplase.[21] Tenecteplase was associated with a higher incidence of reperfusion and better functional outcome compared with alteplase. Intracranial hemorrhage was similar between groups.[21] Tenecteplase can be used in place of alteplase in patients without contraindications for IV fibrinolysis who are also eligible to undergo mechanical thrombectomy.[3,21] From a practical standpoint, the bolus infusion of tenecteplase is easier to administer than a 1-hour infusion of alteplase.

The potential risks should be discussed with the patient when determining eligibility for thrombolysis and weighed against the anticipated benefits during decision making (Table 87.5).

Time Window

Within 3 hours of symptom onset: The safety and efficacy of alteplase treatment when administered within the first 3 hours after stroke onset are solidly supported by combined data from multiple RCTs[3,22] and confirmed by extensive community experience in many countries.[23] The eligibility criteria for IV thrombolytic therapy have evolved over time as its usefulness and true risks have become clearer (see eligibility criteria).

TABLE 87.5 2019 AHA/ASA Acute Stroke Management Guidelines for Alteplase Treatment in Acute Ischemic Stroke

A. Eligibility Recommendations for IV Alteplase in Patients With Acute Ischemic Stroke

Within 3 h	IV alteplase (0.9 mg/kg, maximum dose 90 mg over 60 min with initial 10% of dose given as bolus over 1 min) is recommended for selected patients who may be treated within 3 h of ischemic stroke symptom onset or patient last known well or at baseline state.
Within 3 h—Age	For otherwise medically eligible patients ≥18 years of age, IV alteplase administration within 3 h is equally recommended for patients ≤80 and >80 years of age.
Within 3 h—Severe stroke	For severe stroke, IV alteplase is indicated within 3 h from symptom onset of ischemic stroke. Despite increased risk of hemorrhagic transformation, there is still proven clinical benefit for patients with severe stroke symptoms.
Within 3 h—Mild disabling stroke	For otherwise eligible patients with mild but disabling stroke symptoms, IV alteplase is recommended for patients who can be treated within 3 hours of ischemic stroke symptom onset or patient last known well or at baseline state.
3–4.5 h	IV alteplase is also recommended for selected patients who can be treated within 3 and 4.5 h of ischemic stroke symptom onset or patient last known well.
3–4.5 h—Age	IV alteplase treatment in the 3- to 4.5-h time window is recommended for those patients ≤80 years of age, without a history of both diabetes mellitus and prior stroke, NIHSS score ≤25, not taking any oral anticoagulants, and without imaging evidence of ischemic injury involving more than one-third of the MCA territory.
Urgency	Treatment should be initiated as quickly as possible within the above-listed time frames because time to treatment is strongly associated with outcomes.
BP	IV alteplase is recommended in patients with BP <185/110 mm Hg and in those patients whose BP can be lowered safely to this level with antihypertensive agents, with the physician assessing the stability of the BP before starting IV alteplase.
Blood glucose	IV alteplase is recommended in otherwise eligible patients with initial glucose levels >50 mg/dL.
CT	IV alteplase administration is recommended in the setting of early ischemic changes on NCCT of mild to moderate extent (other than frank hypodensity).
Prior antiplatelet therapy	IV alteplase is recommended for patients taking antiplatelet drug monotherapy before stroke on the basis of evidence that the benefit of alteplase outweighs a possible small increased risk of sICH. IV alteplase is recommended for patients taking antiplatelet drug combination therapy (e.g., aspirin and clopidogrel) before stroke on the basis of evidence that the benefit of alteplase outweighs a probable increased risk of sICH.
End-stage renal disease	In patients with end-stage renal disease on hemodialysis and normal aPTT, IV alteplase is recommended. However, those with elevated aPTT may have elevated risk for hemorrhagic complications.

B. Exclusions for IV Alteplase in Patients With Acute Ischemic Stroke

0- to 3-h window–Mild nondisabling stroke	For otherwise eligible patients with mild nondisabling stroke (NIHSS score 0–5), IV alteplase is not recommended for patients who could be treated within 3 h of ischemic stroke symptom onset or patient last known well or at baseline state.
3- to 4.5-h window–Mild nondisabling stroke	For otherwise eligible patients with mild nondisabling stroke (NIHSS score 0–5), IV alteplase is not recommended for patients who could be treated within 3 and 4.5 h of ischemic stroke symptom onset or patient last known well or at baseline state.
CT	There remains insufficient evidence to identify a threshold of hypoattenuation severity or extent that affects treatment response to alteplase. However, administering IV alteplase to patients whose CT brain imaging exhibits extensive regions of clear hypoattenuation is not recommended. These patients have a poor prognosis despite IV alteplase, and severe hypoattenuation defined as obvious hypodensity represents irreversible injury.
ICH	IV alteplase should not be administered to a patient whose CT reveals an acute intracranial hemorrhage.
Ischemic stroke within 3 months	Use of IV alteplase in patients presenting with AIS who have had a prior ischemic stroke within 3 months may be harmful.
Severe head trauma within 3 months	In AIS patients with recent severe head trauma (within 3 months), IV alteplase is contraindicated.
Acute head trauma	Given the possibility of bleeding complications from the underlying severe head trauma, IV alteplase should not be administered in posttraumatic infarction that occurs during the acute in-hospital phase.
Intracranial/intraspinal surgery within 3 months	For patients with AIS and a history of intracranial/spinal surgery within the prior 3 months, IV alteplase is potentially harmful.
History of intracranial hemorrhage	IV alteplase administration in patients who have a history of intracranial hemorrhage is potentially harmful.
Subarachnoid hemorrhage	IV alteplase is contraindicated in patients presenting with symptoms and signs most consistent with an SAH.
GI malignancy or GI bleed within 21 days	Patients with a structural GI malignancy or recent bleeding event within 21 days of their stroke event should be considered high risk, and IV alteplase administration is potentially harmful.
Coagulopathy	The safety and efficacy of IV alteplase for acute stroke patients with platelets <100 000/mm3, INR >1.7, aPTT > 40 s, or PT >15 s are unknown, and IV alteplase should not be administered. (In patients without history of thrombocytopenia, treatment with IV alteplase can be initiated before availability of platelet count but should be discontinued if platelet count is <100,000/mm^3. In patients without recent use of OACs or heparin, treatment with IV alteplase can be initiated before availability of coagulation test results but should be discontinued if INR is >1.7 or PT is abnormally elevated by local laboratory standards.)

(continued)

TABLE 87.5 2019 AHA/ASA Acute Stroke Management Guidelines for Alteplase Treatment in Acute Ischemic Stroke—cont'd.

LMWH	IV alteplase should not be administered to patients who have received a full treatment dose of LMWH within the previous 24 h.
Thrombin inhibitors or factor Xa inhibitors	The use of IV alteplase in patients taking direct thrombin inhibitors or direct factor Xa inhibitors has not been firmly established but may be harmful. IV alteplase should not be administered to patients taking direct thrombin inhibitors or direct factor Xa inhibitors unless laboratory tests such as aPTT, INR, platelet count, ecarin clotting time, thrombin time, or appropriate direct factor Xa activity assays are normal or the patient has not received a dose of these agents for >48 h (assuming normal renal metabolizing function). (Alteplase could be considered when appropriate laboratory tests such as aPTT, INR, ecarin clotting time, thrombin time, or direct factor Xa activity assays are normal or when the patient has not taken a dose of these ACs for >48 h and renal function is normal.)
Concomitant Abciximab	Abciximab should not be administered concurrently with IV alteplase.
Concomitant IV aspirin	IV aspirin should not be administered within 90 min after the start of IV alteplase.
Infective endocarditis	For patients with AIS and symptoms consistent with infective endocarditis, treatment with IV alteplase should not be administered because of the increased risk of intracranial hemorrhage.
Aortic arch dissection	IV alteplase in AIS known or suspected to be associated with aortic arch dissection is potentially harmful and should not be administered.
Intra-axial intracranial neoplasm	IV alteplase treatment for patients with AIS who harbor an intra-axial intracranial neoplasm is potentially harmful.

AIS, Acute ischemic stroke; *aPPT*, activated partial thromboplatin time; *CT*, computed tomography; *GI*, gastrointestinal; *ICH*, intracerebral hemorrhage; *INR*, international normalized ratio; *IV*, intravenous; *LMWH*, low molecular weight heparin; *MCA*, middle cerebral artery; *NCCT*, noncontrast computed tomography; *SAH*, subarachnoid hemorrhage; *sICH*, spontaneous intracerebral hemorrhage.

The benefit of IV alteplase is well established for adult patients with disabling stroke symptoms regardless of age and stroke severity.[24] Patients should receive IV thrombolytics without delay, if eligible, even if mechanical thrombectomy is being considered.

Three to 4.5 hours of symptom onset: Subsequent studies have demonstrated the usefulness of IV thrombolytics at 3 to 4.5 hours of ischemic stroke symptom onset or patient last known well or at baseline state. Treatment with IV alteplase initiated within 4.5 hours of stroke onset improves functional outcome at 3 to 6 months for patients across the age spectrum and severities of stroke.[24,25] However, the earlier that treatment is initiated, the greater the benefit, as the benefit decreases continuously over time from symptom onset. Faster IV thrombolysis delivery is associated with less disability at 3 months especially for door-to-needle time less than 30 minutes.[26] IV tenecteplase has been compared with alteplase up to 6 hours after stroke and appears to be similarly safe, but it is unclear whether it is as effective as or more effective than alteplase.[3]

In patients with acute ischemic stroke known or suspected to be associated with extracranial cervical arterial dissection, who are otherwise eligible for thrombolysis, it is reasonably safe to administer thrombolytics within 4.5 hours of symptom onset.[3] However, the usefulness and hemorrhagic risk of thrombolytics in acute ischemic stroke known or suspected to be associated with intracranial arterial dissection remain unknown and thrombolysis is not recommended.[3]

4.5 to 9 hours of symptom onset or unwitnessed onset or "wake-up" stroke: In patients with acute ischemic stroke who awake with stroke symptoms or have unclear time of onset greater than 4.5 hours from last known well or at baseline state, MRI to identify DWI-positive (diffusion weighted imaging) and FLAIR-negative (fluid-attenuated inversion recovery) lesions can be useful for selecting those who can benefit from IV alteplase administration within 4.5 hours of stroke symptom recognition (Fig. 87.5).[3] The WAKE-UP trial (Efficacy and Safety of MRI-based Thrombolysis in Wake-Up Stroke) randomized 503 patients who awoke with stroke (90%) or had unclear time of onset greater than 4.5 hours from last known well (10%) and were otherwise eligible for IV alteplase. Favorable outcome (mRS score of 0 to 1) at 90 days was achieved in significantly more patients in the IV alteplase group versus the placebo group (53% vs. 42%). Mortality rate was not significantly higher in the alteplase group (4% vs. 1%) as was the rate of symptomatic intracranial hemorrhage (2% vs. 0.4%).[14]

The EXTEND trial (EXtending the time for Thrombolysis in Emergency Neurological Deficits) enrolled 225 adults who had hypoperfused but salvageable brain tissue on automated perfusion imaging (CT or MRI) and could be treated between 4.5 and 9 hours after the onset of ischemic stroke or awoke with stroke symptoms (9 hours from the midpoint of sleep) and randomly assigned them to IV alteplase or placebo. Favorable outcome (mRS score of 0 to 1) at 90 days was more likely for the IV alteplase group compared with the placebo group (35% vs. 30%); when adjusted for age and severity, there was no significant difference between alteplase and placebo in the unadjusted analysis. Symptomatic intracranial hemorrhage within 36 hours of treatment was higher with alteplase (6% vs. 1%) ($P = .053$) though mortality was not significantly higher with alteplase (12% vs. 9%).[11] Similarly, in the ECASS-4 trial, IV alteplase administered between 4.5 and 9 hours after the onset of symptoms in patients with salvageable tissue did not result in a significant benefit over placebo.[27]

Therefore, beyond 4.5 hours, the benefit of IV alteplase is not clear. The application of DWI-positive (diffusion-weighted imaging) and FLAIR-negative (fluid-attenuated inversion recovery) lesions on MRI to identify patients with a stroke onset time greater than 4.5 hours or an unknown stroke onset time who would benefit from IV alteplase, is promising.

Thrombolysis for Mild Disabling Versus Nondisabling Acute Ischemic Stroke

For otherwise eligible patients with *mild nondisabling* stroke symptoms (NIHSS score 0 to 5), IV alteplase is not recommended for patients who could be treated within 3 or 4.5 hours of ischemic stroke symptom onset or patient last known to be well or at baseline state.[3] The PRISMS trial (A Study of the Safety and Efficacy of Alteplase in Patients With Mild Stroke) evaluated IV alteplase in 313 patients with mild acute ischemic stroke within three hours of symptom onset (NIHSS score 0 to 5) whose acute neurological deficits were judged to not interfere with activities of daily living or prevent return to work (nondisabling).

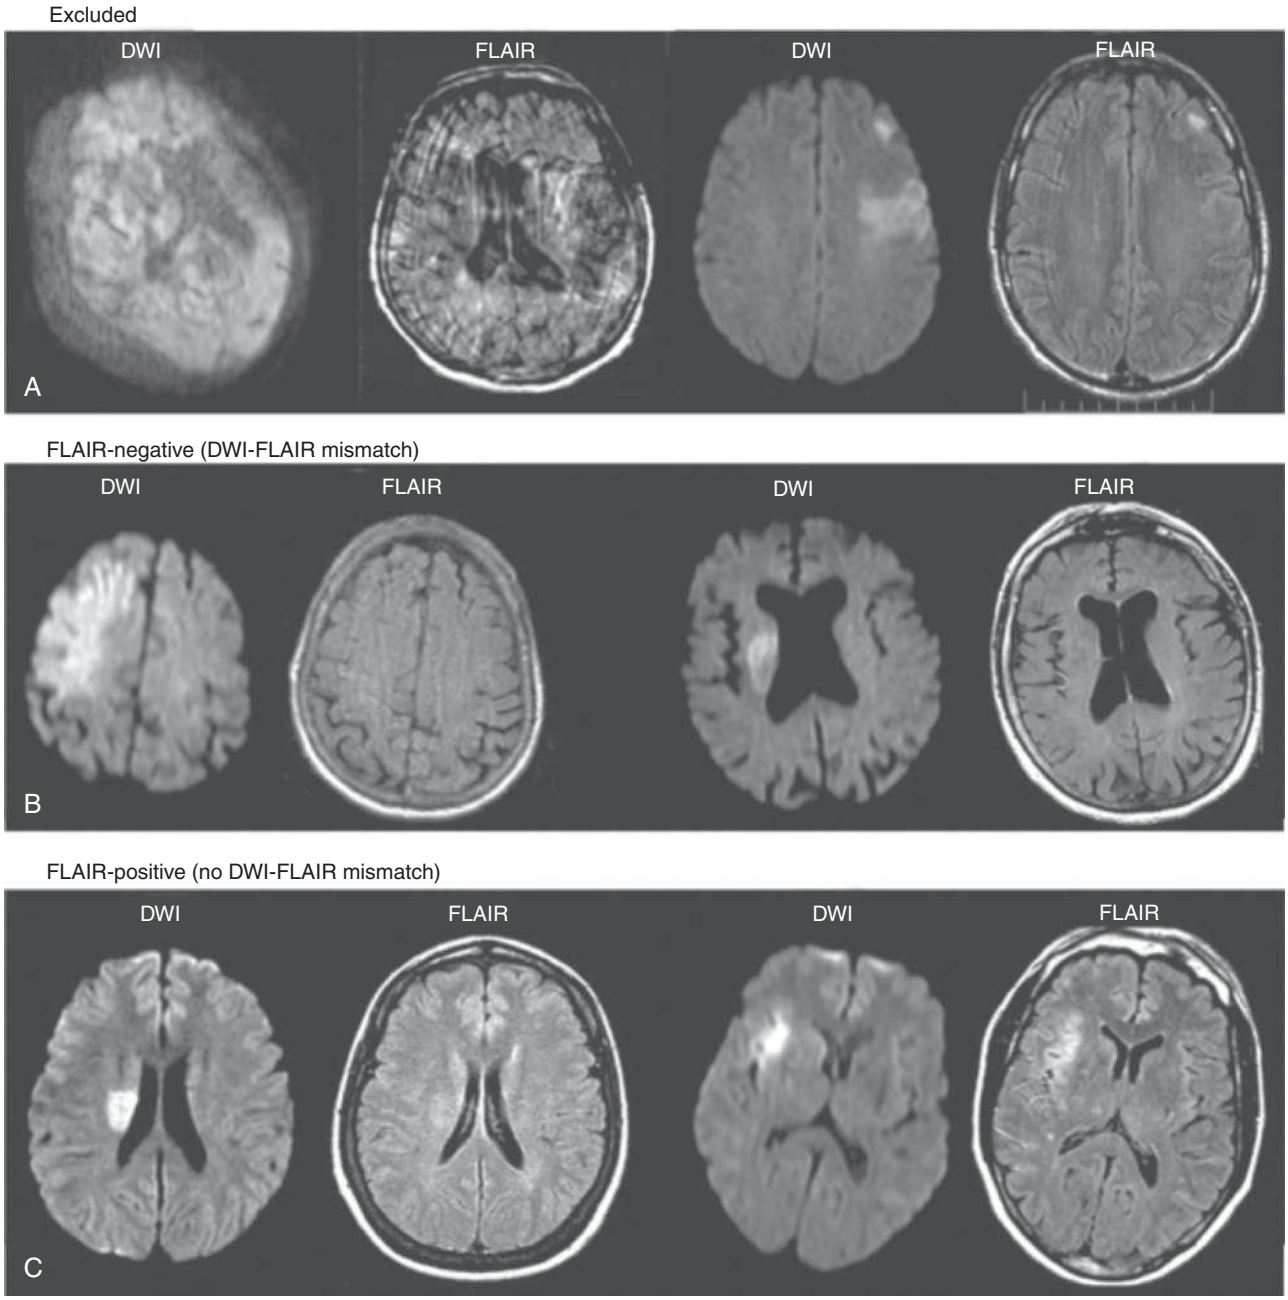

Fig. 87.5 Examples of DWI and FLAIR images. (A) Diffusion-weighted imaging (DWI) and fluid-attenuated inversion recovery (FLAIR) images excluded from the final analysis because of poor quality (left) or the presence of multiple acute and subacute ischemic lesions of different ages, precluding the attribution of symptom onset to one specific lesion (right). (B) Pairs of images showing acute ischemic lesions on DWI but not on FLAIR imaging (FLAIR-negative, DWI-FLAIR mismatch). (C) Pairs of images showing acute ischemic lesions on DWI together with a corresponding subtle (left) or obvious (right) parenchymal hyperintensity on FLAIR imaging (FLAIR-positive, no DWI-FLAIR mismatch). (Reprinted with permission from Elsevier. From Thomalla G, Cheng B, Ebinger M, et al. DWI-FLAIR mismatch for the identification of patients with acute ischaemic stroke within 4·5 h of symptom onset (PRE-FLAIR): a multicentre observational study. *Lancet Neurology*, 2011;10(11):981; Figure 2.)

There was no difference in the rate of a favorable functional outcome (mRS of 0 or 1) at 90 days for patients assigned to treatment with IV alteplase or to aspirin (78% vs. 82%).[28,29]

However, for otherwise eligible patients with *mild but disabling* stroke symptoms, IV alteplase is recommended for patients who can be treated within 3 hours and within 3 and 4.5 hours of ischemic stroke symptom onset or patient last known to be well or at baseline state (Powers et al., 2019).[30]

Thrombolysis in Patients on Anticoagulants Before the Stroke

Antiplatelet: IV alteplase is recommended for patients taking antiplatelet drug monotherapy before stroke on the basis of evidence that the benefit of alteplase outweighs a possible small increased risk of symptomatic ICH. Similarly, IV alteplase is recommended for patients taking antiplatelet drug combination therapy (e.g., aspirin and clopidogrel) before stroke on the basis of evidence that the benefit of alteplase outweighs a probable increased risk of ICH.

LMWH: IV alteplase should not be administered to patients who have received a full treatment dose of low molecular weight heparin (LMWH) within the previous 24 hours.

Factor IIa and Factor Xa Inhibitors: The use of IV alteplase in patients taking direct thrombin inhibitors or direct factor Xa inhibitors has not been firmly established but may be harmful. Therefore, IV alteplase should not be administered to patients taking direct thrombin inhibitors or direct factor Xa inhibitors unless laboratory tests such as activated partial thromboplastin time (aPTT), INR, platelet count, ecarin clotting time, thrombin time, or appropriate direct factor Xa activity assays are normal, or the patient has not received a dose of these agents for greater than 48 hours (assuming normal renal metabolizing function).[3]

Symptomatic Intracerebral Hemorrhage Following Thrombolysis

IV thrombolysis with tissue plasminogen activator after acute ischemic stroke carries a risk of symptomatic ICH with an incidence from 2% to 7%[31] with greatest risk in patients with the most severe strokes.[25] Asymptomatic ICH occurs more frequently and usually occurs within 36 hours after t-PA infusion and half of the events are diagnosed within 5 to 10 hours. Intracranial hemorrhage occurring after 36 hours is unlikely to be caused by thrombolysis. Classification of symptomatic ICH after thrombolytic therapy is based on two main factors: (1) radiographic appearance of the hemorrhage and (2) the presence of associated neurological deterioration.[31] Unfortunately, variability in the definition of clinical neurological deterioration has a dramatic impact on the reported incidence of ICH in different studies.

Radiographically, hemorrhage is graded as: (1) *petechial* hemorrhage along the infarcted tissue margin (HI1), (2) *confluent petechial* hemorrhage within the infarcted tissue (HI2), (3) *parenchymal* hematoma involving 30% or less of the infarcted tissue with slight mass effect (PH1), (4) *parenchymal* hematoma involving greater than 30% of the infarcted tissue with significant mass effect (PH2). Subtype PH2 is the most clinically significant as it carries a poor prognosis, approaching 50% mortality and significant morbidity in survivors. Subtypes HI1, HI2, and PH1 occur more frequently than PH2.[32]

In a systematic review and meta-analysis of 55 studies, older age, greater stroke severity, higher baseline glucose, hypertension, congestive heart failure, renal impairment, diabetes mellitus, ischemic heart disease, atrial fibrillation, baseline antiplatelet use, leukoaraiosis, and visible acute infarction on brain imaging were all associated with increased risk of symptomatic ICH (Box 87.3).[31] Several risk scores have been developed to predict the risk of ICH or prognosis for patients treated with IV thrombolysis.[33] They include the HAT score, DRAGON score, SEDAN score, Stroke-Thrombolytic Predictive Instrument, SPAN-100 index, and the SITS SICH risk score. The predictive ability of the risk scores varies with absolute risk for symptomatic ICH for SITS at 0.2% for a score of zero to 14% for a score of 10 or more. For SEDAN the risk has ranged from 1% for a score of zero to 28% for a score of five points. For HAT the symptomatic ICH rate has ranged from 3% to 14%. Validation studies are needed to confirm their utility before they can be instituted in clinical practice.

Current protocols include ICU monitoring for 24 hours with repeat neuroimaging if there is any neurological deterioration. Treatment of post-thrombolytic hemorrhage includes cardiovascular and respiratory support, BP management, neurological monitoring, prevention of hematoma expansion, control of elevated ICP, and seizure control. Treatment options for ICH related to IV thrombolytics include the administration of agents to reverse the effects of thrombolytic therapy and antithrombotic therapy but no specific agent has been shown to be most effective.[31] These include antifibrinolytic agents (epsilon-aminocaproic acid and tranexamic acid), cryoprecipitate, fresh frozen plasma, platelets, prothrombin complex concentrate, and vitamin K. It's preferable to withhold the use of activated Factor VIIa (rFVIIa) until more studies establish its safety in this setting, given that it is associated with relatively high thrombosis rates.[31] Of these treatment options, we recommend cryoprecipitate. Once symptomatic ICH is diagnosed, consider immediately sending a fibrinogen level and empirically transfusing with 10 U cryoprecipitate intravenously over 10 to 30 minutes.[3] Additional cryoprecipitate may be needed to achieve a fibrinogen level of ≥150 mg/dL. Neurosurgical intervention may also be considered if clinically indicated.[31]

BOX 87.3 Factors Associated With Increased Risk for Symptomatic Intracerebral Hemorrhage After Thrombolysis

- Older age
- Greater stroke severity
- Higher baseline glucose
- Hypertension
- Congestive heart failure
- Renal impairment
- Diabetes mellitus
- Ischemic heart disease
- Atrial fibrillation
- Baseline antiplatelet use
- Leukoaraiosis (periventricular white matter disease)
- Visible acute infarction on brain imaging
- Cerebral microbleeds

Cerebral Microbleeds

Cerebral microbleeds (CMBs) are small accumulations of blood products in brain tissue that are associated with cerebrovascular disease, dementia, and aging. They occur in the setting of impaired small vessel integrity due to hypertension or cerebral amyloid angiopathy.[34] In the setting of acute ischemic stroke, CMBs are considered markers of bleeding-prone cerebral vessel microangiopathies that increase the risk of ICH[35–37] along with poor 3- to 6-month functional outcome after administration of IV thrombolysis.[37–39] The risk of symptomatic ICH in patients with greater than 10 CMBs is significantly greater (30% to 47%) than in those without CMBs (1% to 4%).[35,36,38] Thus, the presence of CMBs increases the risk of ICH and the chances of poor outcomes after thrombolytics, but it is unclear whether these negative effects fully negate the benefit of thrombolytics.[37] Therefore, in patients who have previously had a high burden of CMBs (>10) demonstrated on MRI, the benefits of thrombolytic treatment are uncertain.[3]

Mechanical Thrombectomy

The recent trials demonstrating clear benefit of endovascular thrombectomy come after a decade of negative studies. The difference in results is due to a combination of improved devices, emphasis on early intervention, advanced imaging techniques and careful patient selection. These studies have conclusively demonstrated that patients with severe strokes and evidence of proximal LVOs have significantly better functional outcomes when treated with the new-generation devices. Mechanical thrombectomy is now indicated for patients with acute ischemic stroke with large artery occlusion in the anterior circulation who meet selected criteria and who present within 24 hours of last known to be well regardless of whether they receive IV alteplase for the same ischemic stroke event.

Timing

Shorter time to endovascular-reperfusion therapy is significantly associated with better outcomes.[40,41] In pooled patient-level data from five trials (MR CLEAN, ESCAPE, REVASCAT, SWIFT PRIME, and EXTEND-IA), shorter time from symptom onset to arterial puncture with mechanical thrombectomy was associated with lower degrees of disability at 3 months but the benefit became nonsignificant after 7 hours.[42] The majority of these patients also received thrombolytics. Among those who achieved substantial reperfusion each 1-hour delay to reperfusion was associated with a less favorable degree of disability and less functional independence, but no change in mortality.[42]

Zero to 6 hours of symptom onset: Guidelines from the AHA/American Stroke Association (ASA) recommend mechanical thrombectomy for adults with: (1) no significant prestroke disability (i.e., a mRS score of ≤1); (2) a causative occlusion of the ICA or the M1 segment of the MCA; (3) NIHSS score of ≥6; and (4) ASPECTS of ≥6 (associated with better functional outcome at 3 months). These guidelines are based on results from 6 recent randomized trials of mechanical thrombectomy using predominantly stent retriever devices (MR CLEAN, SWIFT PRIME, EXTEND-IA, ESCAPE, REVASCAT, THRACE).[3]

The benefits of thrombectomy are uncertain for patients with occlusion of the ICA or proximal MCA (M1), who have a prestroke mRS score greater than 1, or an NIHSS score less than 6, or a larger infarct core (i.e., ASPECTS score <6). Using pooled patient data, the direction of treatment effect for mechanical thrombectomy over standard care appears favorable in M2 occlusions but does not reach statistical significance.[43–45] Therefore, the benefits of thrombectomy for distal MCA occlusion, MCA segment 2 (M2) or MCA segment 3 (M3), are uncertain. Additionally, the benefits are uncertain in those with occlusion of the anterior cerebral arteries, vertebral arteries, basilar artery, or posterior cerebral arteries.

Pooled patient-level data showed that mechanical thrombectomy had a favorable effect over standard care in patients ≥70 years of age and ≥80 years of age.[43,44,46] However, the number of patients in these trials who were ≥90 years of age was very small. As with any treatment decision in an elderly patient, consideration of comorbidities and risks should factor into the decision-making for mechanical thrombectomy.

Six to 16 hours of symptom onset: In selected patients with acute ischemic stroke within 6 to 16 hours of last known normal who have LVO in the anterior circulation and meet other DAWN or DEFUSE 3 eligibility criteria, mechanical thrombectomy is recommended (without thrombolysis).[3]

The DAWN trial used clinical-core mismatch (a combination of NIHSS score and imaging findings on CT perfusion or diffusion-weighted MRI) as eligibility criteria to select patients with large anterior circulation vessel occlusion for treatment with mechanical thrombectomy between 6 and 24 hours from last known to be at their normal neurological baseline. This trial demonstrated an overall significant benefit in function outcome at 90 days in the treatment group (mRS score 0 to 2) of 49% versus 13%.[13] Only 12% with witnessed onset of symptoms. The DEFUSE 3 trial used perfusion-core mismatch and maximum core size as imaging criteria to select patients had large anterior circulation occlusion 6 to 16 hours from last seen well for mechanical thrombectomy (Fig. 87.6). This trial showed a significant benefit in functional outcome at 90 days in the treated group (mRS score 0 to 2) of 45% versus 17%.[12] Benefit was independently demonstrated for the subgroup of patients who met DAWN eligibility criteria and for the subgroup who did not. DAWN and DEFUSE 3 are the only RCTs showing benefit of mechanical thrombectomy greater than 6 hours from onset. Therefore, only the eligibility criteria from one or the other of these trials should be used for patient selection. Although future RCTs may demonstrate that additional eligibility criteria can be used to select patients who benefit from mechanical thrombectomy, at this time, the DAWN or DEFUSE 3 eligibility should be strictly adhered to in clinical practice.[3,12,13]

Sixteen to 24 hours of symptom onset: In selected patients with acute ischemia stroke within 16 to 24 hours of last known normal who have

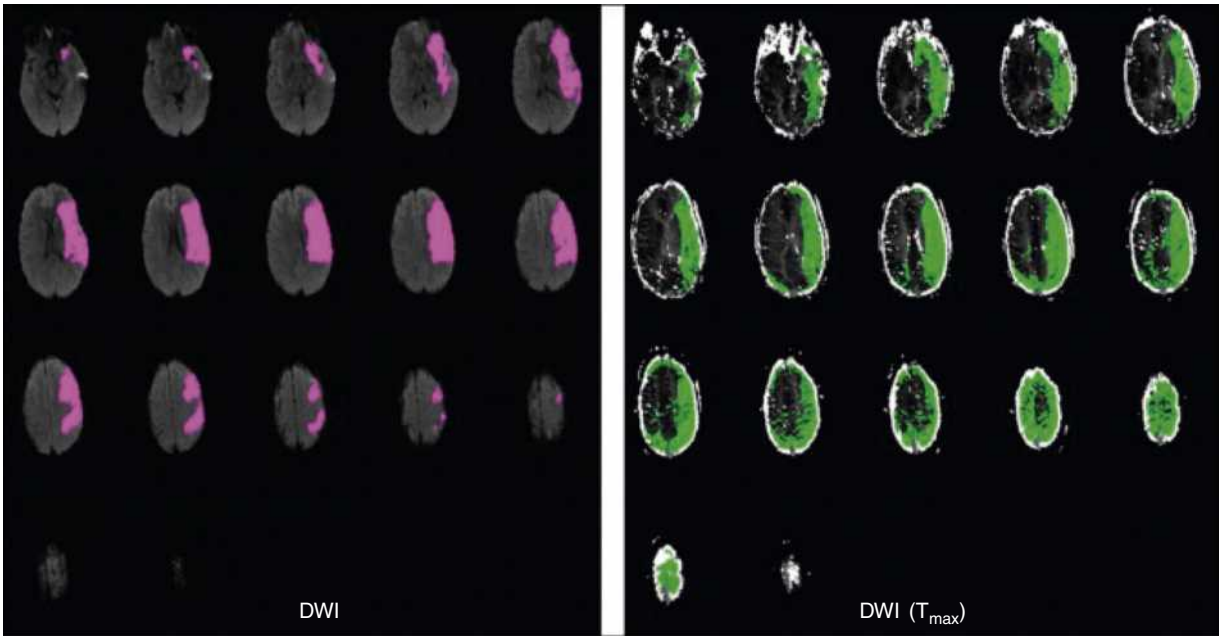

Fig. 87.6 Malignant penumbral profile unfavorable for treatment more than 3 h after stroke onset. MRI scan with DWI showing large established infarct core (*left*; 143 cm^3) and perfusion-weighted imaging showing extremely large region of tissue at risk (*right*; 255 cm^3). Although mismatch is present (ratio 1:8), and the patient presented within the treatment window, the large size of the already completed infarct in the dominant hemisphere shows reperfusion would probably be futile, because tissue loss sufficient to cause death or severe dependency has already occurred. DWI, diffusion-weighted imaging; Tmax, time-to-maximum of the residue function. (Images courtesy of Greg Albers, Stanford University, School of Medicine, CA, USA).

LVO in the anterior circulation and meet other DAWN eligibility criteria, mechanical thrombectomy is a reasonable approach.[3]

Mechanical Thrombectomy and Thrombolysis

Mechanical thrombectomy can be used in addition to treatment with IV thrombolytics. However, pretreatment with IV thrombolytics (if initiated within 4.5 hours of symptom onset) is not required prior to thrombectomy.[26] Mechanical thrombectomy treatment should be initiated as quickly as possible and should not be delayed to assess the response to IV alteplase.[3] A post hoc analyses of pooled data compared thrombectomy alone versus dual therapy (IV thrombolysis and thrombectomy) for LVO and concluded that dual therapy was associated with a higher likelihood of 3-month functional independence and lower odds of 3-month mortality. The two groups did not differ in functional improvement or symptomatic intracranial hemorrhage.[47] There are no randomized controlled trials of mechanical thrombectomy for posterior circulation LVOs.[48]

Intra-arterial fibrinolysis initiated within 6 hours of stroke onset in carefully selected patients who have contraindications to the use of IV alteplase might be considered, but the consequences are unknown and therefore not recommended. In this scenario, mechanical thrombectomy with stent retrievers is recommended over intraarterial fibrinolysis as first-line therapy.[3]

Spontaneous Intracerebral Hemorrhage (Hemorrhagic Stroke)

Evidence from clinical trials to guide management for spontaneous ICH has lagged behind that of ischemic stroke and aneurysmal SAH. Initial goals of treatment include preventing hemorrhage expansion (which occurs in about 20% to 30% of patients) and prevention of secondary brain injury via stabilization of airway, breathing, and circulation. Patients may require intubation and mechanical ventilation, anticoagulation reversal, BP control, interventions for elevated ICP, treatment for seizures, or neurosurgical hematoma evacuation.

Monitoring

Patients with spontaneous ICH are frequently medically and neurologically unstable, particularly within the first few days after onset and they can deteriorate from hematoma expansion (which most often occurs within the first few hours), elevations in ICP, hydrocephalus, seizures, and herniation. Admission to an intensive care unit or dedicated stroke unit is recommended as it is associated with a lower mortality rate.[2]

Blood Pressure Management

Two large phase III, multicenter, prospective randomized controlled trials (RCTs) have shown that early lowering of SBP to less than 140 mm Hg is safe without significant adversary effects. The INTERACT2 (Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial 2) trial evaluated the efficacy of intensive BP lowering within 6 hours of spontaneous ICH in 2839 patients with systolic BP between 150 and 220 mm Hg. Patients were randomized to intensive BP lowering (target systolic BP less than140 mm Hg within 1 hour) versus standard treatment (target systolic BP <180 mm Hg). Intensive lowering of BP did not result in a significant reduction in death or severe disability but did improve functional outcomes at 90 days. In the ATACH 2 trial (Antihypertensive Treatment of Acute Cerebral Hemorrhage), IV nicardipine was administered within 3 hours of ICH in 1000 patients and the rate of death or disability was not different between subjects randomized to a target SBP of 110 to 139 mm Hg compared to a target of 140 to 179 mm Hg. The rate of renal adverse events within 7 days was significantly higher in the intensive-treatment group than in the standard-treatment group (9.0% vs. 4.0%).[49] A pooled analysis of individual patient-level data from INTERACT2 and ATACH2 showed early and steady reduction in SBP (potentially down to 120 to 130 mm Hg) seemed to be safe and associated with favorable outcomes in patients with ICH that were mild to moderate in severity. However, a rapid and large reduction (≥60 mm Hg) within 1 hour of the initiation of treatment was associated with some harm.[50] Further analysis on the INTERACT2 data revealed that intensive BP lowering was beneficial across a wide range of baseline BPs (<160, 160 to 169, 170 to 179, 180 to 189, and ≥190 mm Hg) and that lowering SBP to 130 to 139 mm Hg was likely to be maximally beneficial.[51]

Therefore, for ICH patients presenting with SBP between 150 and 220 mm Hg and without contraindication to acute BP treatment, acute lowering of SBP to 140 mm Hg is safe and can be effective for improving functional outcome. For ICH patients presenting with SBP greater than 220 mm Hg, it may be reasonable to consider aggressive reduction of BP with a continuous IV infusion and frequent BP monitoring, but the target BP is less clear.[2] IV calcium channel blockers (e.g., nicardipine) and β-blockers (i.e., labetalol) are the treatments of choice for early BP reduction, given their short half-life and ease of titration. Nitrates should be avoided given their potential for cerebral vasodilation and elevated ICP.[52]

Reversal of Anticoagulation

All anticoagulants such as vitamin K antagonists (e.g., warfarin), antiplatelet medications (aspirin, clopidogrel, prasugrel, ticagrelor), and non–vitamin K antagonists known as direct oral anticoagulants (DOACs) such as Factor IIa (thrombin) inhibitors (e.g., dabigatran, argatroban and bivalirudin) or Factor Xa inhibitors (rivaroxaban, apixaban, edoxaban, betrixaban, darexaban) should be discontinued acutely and reversed immediately with appropriate agents.[53]

Patients taking vitamin K antagonists with INR ≥1.4 can be reversed with IV vitamin K and 3-factor or 4-factor prothrombin complex concentrate (PCC) or fresh frozen plasma administered intravenously.[53] Vitamin K 10 mg is administered slowly IV but its effects are delayed. 3-factor or 4-factor prothrombin complex concentrate is preferred over fresh-frozen plasma due to more rapid correction of INR, lower volume, and lower risk of infection and pulmonary edema.[53] PCC is an inactivated concentrate of factors II, IX, and X, with variable amounts of factor VII. Variation in factor VII concentrations in PCC has led to their classification as either 3- or 4-factor.[52]

Although direct thrombin inhibitors (Factor IIa inhibitors) have less risk of ICH than vitamin K antagonists, reversal is indicated if patients present within 3 to 5 half-lives of drug exposure.[52] Idarucizumab is a Fab fragment of a monoclonal antibody that binds to and inactivates dabigatran and 5 g is administered as two consecutive 2.5-g IV bolus injections.[54] If idarucizumab is not available or if other direct thrombin inhibitors have been ingested, clotting factor products such as prothrombin complex concentrates or fresh-frozen plasma can be used.[55] Dabigatran can also be reversed with hemodialysis. Idarucizumab should not be combined with other clotting factor products.

Patients requiring emergent reversal of Factor Xa inhibitors can be treated with Andexanet alfa or 4-factor prothrombin complex concentrates.[56] Andexanet alfa is a class-specific antidote targeted to competitively inhibit Factor Xa inhibitors.[57] The initial dose depends on the dose of the Factor Xa inhibitor and the interval since the last dose. Andexanet should not be combined with other clotting factor products.

There is inadequate evidence to support the routine use of platelet transfusion for ICH in patients taking preinjury antiplatelet medications.[58] Platelet transfusion should be considered for patients with aspirin- or adenosine diphosphate receptor (ADP) inhibitor-associated ICH who will undergo a neurosurgical procedure.[53] Desmopressin (ddAVP) (0.4 μg/kg IV single dose) can be considered in ICH associated with cyclooxygenase (COX) inhibitors or ADP receptor inhibitors.[53]

Hemostatic Agents

The TICH2 was an international double-blind randomized trial of 2325 patients with ICH comparing 2 g of tranexamic acid to placebo given within 8 hours of onset. Tranexamic acid did not affect functional status at 90 days compared to placebo, although potential benefits were seen with reductions in hematoma expansion, early death, and serious adverse events.[59]

Seizures

Patients with ICH have up to 16% risk of clinical seizures within 1 week, with the majority occurring at or near onset. There is no association between clinical seizures and neurological outcome or mortality.[52] Clinical seizures should be treated with anticonvulsants. Patients with a change in mental status who are found to have electrographic seizures on EEG should also be treated with anticonvulsants (e.g., levetiracetam 1000 to 1500 mg IV). Continuous EEG monitoring is probably indicated in ICH patients with depressed mental status that is out of proportion to the degree of brain injury. However, prophylactic antiseizure medication is not recommended.[2]

Prognosis

Factors that may affect outcome after ICH include hematoma volume and location, hematoma expansion, age, GCS score on presentation, intraventricular extension, and anticoagulant use. However, none of the existing ICH prediction models has proven reliable.[52] When health care providers initiate early do not resuscitate (DNR) orders, patients with otherwise equivalent prognoses are more likely to die. Therefore, current AHA/ASA guidelines recommend early and aggressive care for ICH patients and postponement of any new DNR orders until at least the second full day of treatment. Patients with pre-existing DNR orders are excluded from this recommendation.[2] However, DNR status should not limit appropriate medical and surgical interventions, unless explicitly indicated.

Increased Intracranial Pressure

In patients with supratentorial ICH with radiographic hydrocephalus, especially in patients with decreased level of consciousness, an external ventricular drain is advised. Patients with a GCS score of ≤8, those with clinical evidence of transtentorial herniation, or those with intraventricular hemorrhage or hydrocephalus should be considered for ICP monitoring and treatment. A CPP of 50 to 70 mm Hg is recommended.[2]

Mannitol and hypertonic saline (HTS 3% or 23.4%) are the first-line medical therapies for patients with symptomatic cerebral edema and elevated ICP. In an analysis of the INTERACT2 patients, there was no significant difference in outcome in mannitol and non–mannitol-treated patients so mannitol was safe, but did not improve outcome.[60] In a small retrospective study, treatment with 23.4% of HTS was associated with rapid reversal of transtentorial herniation and reduced ICP. Early continuous infusion of 3% of HTS for sodium goal of 145 to 155 mmol/L was associated with less cerebral edema and ICP elevations. A meta-analysis showed that HTS is slightly more effective than mannitol for the treatment of elevated ICP.[52]

Both hyperglycemia and hypoglycemia should be avoided. Corticosteroids should not be administered for treatment of elevated ICP. The risk of central fever is increased in patients with larger ICH and in those with IVH and negatively impacts outcome.[61] Sources of hyperthermia (temperature > 38°C) should be identified and treated, and antipyretic medications should be administered.[3]

Neurosurgical Intervention

Urgent neurosurgical consultation is recommended for assessment for hydrocephalus and the possible need for surgical decompression or hematoma evacuation.[62] Cerebellar ICH is considered a neurosurgical emergency. Patients with cerebellar hemorrhage who are deteriorating neurologically or who have brainstem compression or hydrocephalus from ventricular obstruction should undergo surgical removal of the hemorrhage as soon as possible.[2]

For most patients with supratentorial ICH the benefits of surgical evacuation of the hematoma are still under investigation. Open craniotomy hematoma evacuation has not been found to have any benefit in large randomized trials.[63] Current guidelines suggest that evacuation may be considered in patients with supratentorial ICH who exhibit neurological deterioration, coma, midline shift, or elevated ICP refractory to medical treatment.[2]

As an alternative to open surgical approaches, minimally invasive approaches to evacuate clots are being investigated. These approaches use small incisions and burr holes and insert either a catheter into the clot for drainage or a small tube into the clot for direct evacuation. A meta-analysis of five randomized trials and nine prospective studies in patients with supratentorial ICH found that minimally invasive approaches conferred a mortality benefit, as well as a lower rate of rebleeding and higher rate of good recovery.[64] The MISTIE III (Minimally Invasive Surgery Plus rt-PA for Intracerebral Hemorrhage Evacuation III) trial was an open-label blinded endpoint trial that randomized 506 patients to minimally invasive surgery (catheter evacuation followed by thrombolytic irrigation of the clot with alteplase) versus standard medical treatment. Eligible patients had a supratentorial ICH measuring ≥30 mL, NIHSS ≥6, good baseline status, a CT angiogram negative for an underlying lesion, and a repeat CT demonstrating clot volume stability for at least 6 hours. At one year, the number of patients with good functional outcome (mRS score of 0 to 3) was similar for the minimally invasive surgery group compared with the standard care group (45% vs. 41%). Mortality was lower in the minimally invasive surgery group (19% vs. 26%).[63]

The ENRICH (Early MiNimally-invasive Removal of ICH) is a multicenter randomized clinical trial of ICH patients aged 18 to 80 years with a GCS score of 5 to 14 and an intraparenchymal hemorrhage volume of 30 to 80 mL comparing standard medical management to early surgical hematoma evacuation within 24 hours using minimally invasive parafascicular surgery (MIPS). An initial single-arm surgical evaluation of this endoport system in 39 patients with primary IPH reported functional independence in 52% of patients at follow-up and no mortality.[65]

Intraventricular extension of the ICH (intraventricular hemorrhage or IVH) occurs in up to 45% of patients with ICH[52] and puts patients at risk for hydrocephalus, especially if the third and fourth ventricles are involved because the normal circulation of cerebrospinal fluid (CSF) can become interrupted. Such patients should be closely monitored with frequent neurological assessments. When neurologic deterioration occurs, an emergent CT scan should be done to exclude the development of hydrocephalus. Patients with neurologic deterioration in the setting of ventricular enlargement may be candidates for ventriculostomy and external ventricular drainage.[2] The CLEAR III trial (Clot Lysis: Evaluating Accelerated Resolution of Intraventricular Hemorrhage III) was a double-blinded, placebo-controlled trial conducted in 500 ICH patients with intraventricular hemorrhage obstructing the third or fourth ventricles. Patients were randomized to irrigation of the extraventricular drain with alteplase versus saline. Alteplase did not substantially improve functional outcomes at the mRS 3 cutoff compared with irrigation with saline.[66]

Decompressive craniectomy is a procedure that removes a portion of the skull bone enabling the brain to expand to decrease ICP. In small non-randomized studies decompressive craniectomy treatment for spontaneous supratentorial ICH showed lower rates of in-hospital mortality and better functional status compared with medically managed patients

in certain populations.[67,68] The SWITCH trial (Swiss trial of decompressive craniectomy versus best medical treatment of spontaneous supratentorial ICH) is currently enrolling ICH patients between 18 and 75 years with hemorrhage into the basal ganglia or thalamus with a GCS 8 to 13, NIHSS ≥10 and ≤30, and volume of hematoma 30 to 100 mL.

TRANSIENT ISCHEMIC ATTACK

TIA is no longer defined by an arbitrary time of 24 hours. Patients with symptoms less than 24 hours can have representative ischemic lesions on diffusion-weighted or perfusion-weighted MRI, so TIA has moved from time-based to tissue-based definition. Patients with TIA or nondisabling strokes are at increased risk of recurrent stroke and should be evaluated and treated immediately in order to reduce the risk of subsequent stroke and to identify patients who may benefit from preventive therapy or from revascularization of large vessels.

Some centers have developed rapid outpatient TIA clinics to ensure an expedited evaluation within 24 hours of presentation. However, patients at higher risk for subsequent stroke should be hospitalized. Previous guidelines have used the ABCD2 score (i.e., ABCDD, for Age, BP, Clinical features, Duration of symptoms, and Diabetes) as a prognostic assessment tool designed to identify TIA patients at high risk of ischemic stroke and thus requiring admission (Table 87.6). More recent studies have found the score does not provide an accurate estimate of stroke risk.[69,70] Others have combined the ABCD2 score with imaging such as MRI and MRA (ABCD2-I and ABCD3-I)[6,71,72] to improve the short-term prediction of cerebral infarction but have yet to be validated.

Most patients without a contraindication will be started on antithrombotic therapy in the ED after consultation with a neurologist. Dual antiplatelet therapy with clopidogrel and aspirin is effective for secondary prevention after minor ischemic stroke or TIA.[73] Pooled analysis of two RCTs, POINT and CHANCE, showed that early and short-term clopidogrel-aspirin treatment was associated with a reduction in the risk of major ischemic events compared to aspirin alone. The benefit of dual antiplatelet therapy appeared to be confined to the first 21 days after minor ischemic stroke or high-risk TIA.[74] The risk for major hemorrhages in patients receiving either clopidogrel plus aspirin or aspirin alone after TIA was low. Nevertheless, treatment with clopidogrel plus aspirin increased the risk of major hemorrhages over aspirin alone from 0.2% to 0.9%.[75] In patients presenting with minor noncardioembolic ischemic stroke (NIHSS score ≤3) who did not receive IV alteplase, treatment with dual antiplatelet therapy (aspirin and clopidogrel) started within 24 hours after symptom onset and continued for 21 days is effective in reducing recurrent ischemic stroke for a period of up to 90 days from symptom onset.[3]

In patients with new onset atrial fibrillation, immediate anticoagulation should be considered, except those for whom the risks of bleeding exceed the benefits or those with a CHA2DS2-VASc score of 0 in men or 1 in women who have short paroxysms of AF that self-terminate (see Chapter 65 for suggested anticoagulants).

TABLE 87.6 ABCD2 Score for Assessing Stroke Risk in Patients With a Transient Ischemic Attack

Risk Factor	Points
Age >60 years old	1
Initial BP >140/90 mm Hg	1
Unilateral weakness	2
Speech Impairment	
Without weakness	1
Symptoms 10–59 min	1
Symptoms ≥60 min	2
History of diabetes	1
Result	
0–3 = Low risk (1% risk of stroke in 48 h)	
4–5 = Moderate risk (4.1% risk of stroke in 48 h)	
≥6 = High risk (8% risk of stroke in 48 h)	

BP, Blood pressure.

DISPOSITION

"Stroke center" definitions have been established, and there is a national certification process for primary stroke centers (PSCs) and comprehensive stroke centers (CSCs) in the United States. In broad terms, institutional certification as a PSC requires the establishment of a stroke infrastructure (i.e., a dedicated stroke team, stroke unit, patient care protocols, and support services, including CT/MRI scanning and laboratory testing availability), as well as institutional administrative support and specialty-qualified leadership. CSCs offer advanced imaging modalities, perform surgical and endovascular interventions, and maintain a core infrastructure, such as a stroke unit and stroke registry. The establishment of PSCs and CSCs is intended to improve outcomes for stroke patients by ensuring a high level of coordinated care. Early identification and transfer of patients with acute stroke to a PSCs or CSCs results in more favorable outcomes.

The most recent level of stroke classification for hospitals is the acute stroke-ready hospital (ASRH). These hospitals are typically smaller facilities with lower stroke patient volumes. An ASRH is capable of establishing the initial stroke diagnosis, as well as providing acute stabilization and treatment. The use of tele-technologies between the ASRH and PSC/CSC will likely serve a pivotal role in support of clinical care. After initial stabilization and treatment, stroke patients will frequently be transferred to PSC or CSC institutions. A systematic review of retrospective studies evaluating the safety and efficacy of IV alteplase delivered within 3 hours of symptom onset through telestroke networks concluded that there was no difference in mortality or functional independence at 3 months between telestroke-guided and stroke center–managed patients.[76]

Reducing the time interval from ED presentation to initial brain imaging can help to reduce the time to treatment initiation. Studies have shown that median or mean door-to-imaging times of ≤20 minutes can be achieved in a variety of different hospital settings.[77–79] The benefit of bypassing the closest hospital that offers thrombolytic therapy to transporting the patient directly to an institution that offers a higher level of stroke care (including mechanical thrombectomy) has not been established. However, it is reasonable to introduce prehospital procedures to identify patients who have a strong probability of LVO stroke and are eligible for thrombectomy and facilitate rapid transport of these patients to centers that perform mechanical thrombectomy.[3] Telestroke networks may also be reasonable for triaging patients with acute ischemic stroke who may be eligible for interfacility transfer in order to be considered for emergency mechanical thrombectomy.[76]

Patients with acute ischemic stroke may deteriorate over the first 24 hours and require close in-hospital monitoring. There is evidence suggesting a benefit from admission to a stroke-specific unit. Patients with large acute hemispheric strokes (associated with increased risk of herniation) or with significant posterior circulation-related changes and those treated with a fibrinolytic agent should be monitored in an ICU for at least 24 hours.

CHAPTER 87: QUESTIONS AND ANSWERS

1. Which of the following statements concerning ischemic stroke is true?
   a. Anterior circulation strokes are more likely than posterior strokes to show evidence of progression at the time of presentation.
   b. Anterior circulation strokes rarely present with complete loss of consciousness.
   c. Posterior cerebral artery strokes are associated with incontinence, leg weakness greater than arm weakness, and gait clumsiness.
   d. The presence of aphasia suggests an anterior cerebral artery (ACA) distribution stroke, typically left sided.
   e. The presence of diplopia suggests an anterior circulation stroke.

Answer: b. Forty percent of posterior and 20% of anterior circulation strokes present with progressive symptoms. It is rare for anterior circulation (carotid, ACA, and middle cerebral artery [MCA]) strokes to significantly alter consciousness, unless there has been a previous contralateral stroke. ACA strokes primarily affect frontal lobe functions and may also present with primitive grasp and such reflexes. In addition to contralateral motor and sensory defects, MCA strokes may present with expressive aphasia, agnosia, and ipsilateral hemianopsia.

2. Which of the following is not associated with posterior circulation strokes?
   a. Diplopia
   b. Homonymous cranial nerve (CN) and extremity motor deficits
   c. Loss of consciousness
   d. Loss of visual object recognition
   e. Nausea, vomiting, and ataxia

Answer: b. Posterior circulation (vertebrobasilar) strokes involve the vertebral, basilar, and posterior cerebral arteries. Because this system supplies the reticular activating system, cerebellum, brainstem, occipital lobe, and brainstem vomiting centers, loss of consciousness with vomiting, visual changes, and cerebral ataxia may be seen. Ipsilateral CN deficits (because these nuclei largely reside in the brainstem) occur with contralateral "body" deficits resulting from motor/sensory fiber decussation.

3. Headache, vomiting, and a decreased level of consciousness are most commonly seen with which of the following disorders?
   a. Ischemic stroke
   b. Intracranial hemorrhage
   c. Migraine headache
   d. Subarachnoid hemorrhage (SAH)
   e. Tic douloureux

Answer: d. The incidence of headache is highest by far in patients with SAH. Vomiting and depressed loss of consciousness are also generally more common in this group. Pure migraine headache rarely, if ever, causes a depressed loss of consciousness. Tic headaches do not cause loss of consciousness.

4. What percentage of patients with hemorrhagic stroke experience clinical deterioration because of growth in hemorrhage volume within the first hours?
   a. 10%
   b. 20%
   c. 30%
   d. 50%
   e. 75%

Answer: c. Thirty percent of patients with intracerebral hemorrhage (ICH) experience early hemorrhage expansion. Progression of neurologic deficits and decreasing mental status suggest the diagnosis.

5. A 69-year-old male presents with headache, vomiting, aphasia, a right lower facial palsy, and right upper greater than right lower extremity weakness. The symptoms began approximately 4 hours before arrival. Vital signs are temperature 99°C, blood pressure (BP) 180/90 mm Hg, respiratory rate 18 breaths/min, heart rate 92 beats/min, and oxygen saturation 96% on room air. Emergent computed tomography (CT) scan shows a left temporal intracerebral hemorrhage (ICH). Soon after presentation, the patient experiences increased vomiting and a diminishing level of consciousness. What is the most likely explanation for this deterioration?
   a. Accompanying subarachnoid hemorrhage (SAH)
   b. Acute brainstem herniation
   c. Hypoxia from neurogenic pulmonary edema
   d. Increase in volume of the ICH
   e. Myocardial infarction with cardiogenic shock

Answer: d. Approximately one-third of patients with ICH experience early hemorrhage volume expansion. Although brainstem herniation is a possibility, this is typically a delayed sequela with a more gradual presentation. Acute myocardial infarction may be associated with intracranial emergencies but would not likely cause an abrupt mental status change. Neurogenic pulmonary edema may accompany any condition with elevated intracranial pressure (ICP) and would not likely cause an abrupt mental status change.

6. After complete occlusion of cerebral vessels, irreversible neurologic deficits are expected to reliably occur within how many hours?
   a. 2
   b. 3
   c. 4
   d. 5
   e. 6

Answer: e. As a result, ischemic stroke trials, using fibrinolytic or antiplatelet agents, have attempted to recanalize occluded arteries and reperfuse ischemic areas of the brain within a 2- to 6-hour therapeutic window.

7. Which of the following areas of the brain is perfused by the posterior circulation?
   a. Internal capsule
   b. Posterior aspect of the temporal lobe
   c. Putamen
   d. Speech areas of the temporal lobe
   e. Thalamus

Answer: e. The thalamus is perfused by the posterior circulation. The other areas are perfused by the anterior circulation.

8. Which of the following statements regarding stroke etiology is true?
   a. Lacunar strokes reliably cause a pure motor deficit.
   b. Less than 1% of strokes occur in the 15- to 45-year-old age group.
   c. One-third of ischemic strokes are thrombotic.
   d. Strokes resulting from atrial fibrillation likely involve small vessels.
   e. Two-thirds of ischemic strokes are cardioembolic.

Answer: c. One-third of ischemic strokes are thrombotic. Lacunar strokes may cause a pure motor, pure sensory, or ataxic/hemiparesis stroke. Vessel occlusion resulting from atrial fibrillation–induced emboli more likely involves the large vessels. Three percent to 4% of ischemic strokes occur in the 15- to 45-year-old age group.

9. A 29-year-old female presents with a left-sided headache after a moderate-speed motor vehicle collision (MVC). She suffered no loss of consciousness and has no other complaints or obvious injuries. Physical examination is remarkable only for drooping of the left eyelid and slight miosis of the left pupil compared with the right. Which of the following would be the diagnostic test of choice?
- **a.** Brain magnetic resonance imaging (MRI) with gadolinium
- **b.** Contrasted computed tomography (CT) scan of the brain
- **c.** CT angiogram of the carotid arteries
- **d.** Uncontrasted CT scan of the brain
- **e.** Urine drug screen

Answer: c. Carotid or vertebral artery dissection can occur after trauma or mild events, such as yoga, twisting, or prolonged static positions looking upward. The hallmark is unilateral neck pain, face pain, or headache, often with accompanying Horner syndrome. Acutely, cerebral ischemic changes would not be seen on brain imaging. Carotid and vertebral dissection is not a contraindication for thrombolytic therapy in the eligible patient.

10. A 28-year-old G3P3 woman who is 2-week postpartum after an uncomplicated vaginal delivery presents with acute onset of mild headache, lethargy, and double vision. Physical examination is remarkable for normal vital signs and a left eye lateral gaze palsy. The most appropriate intervention is likely to be which of the following?
- **a.** Computed tomography (CT) scan of the brain with possible lumbar puncture
- **b.** CT scan of the brain and intravenous (IV) heparin
- **c.** Erythrocyte sedimentation rate (ESR) and IV corticosteroids
- **d.** IV magnesium
- **e.** Lumbar puncture and IV antibiotics

Answer: b. Cerebral venous thrombosis may present with headache, lethargy, cranial nerve (CN) deficits, seizures, or even psychiatric complaints. CT scan and/or magnetic resonance imaging (MRI)/magnetic resonance angiography (MRA) are likely to reveal the diagnosis. Treatment includes heparin. Neurosurgical consultation is not useful. Subarachnoid hemorrhage (SAH) would not be expected to cause a focal neurologic deficit. Eclampsia and meningitis would be expected to give characteristic findings on history and examination.

11. An 82-year-old male presents with an apparent stroke. He is rapidly evaluated and determined to be within the 3- to 4.5-hour window for fibrinolytic therapy. Which of the following exclusion criteria applies only to the 3- to 4.5-hour criteria and not the 0- to 3-hour criteria?
- **a.** Administration of heparin within the 48 hours preceding the stroke onset
- **b.** Age older than 80 years
- **c.** High clinical suspicion for subarachnoid hemorrhage (SAH)
- **d.** Seizure at the onset of the stroke
- **e.** Symptoms rapidly improving

Answer: b. In the 3- to 4.5-hour window, patients cannot exceed 80 years of age. Heparin administration within the 48 hours preceding stroke onset is a contraindication in both the 0- to 3-hour window as well as the 3- to 4.5-hour window. Similarly, high clinical suspicion for SAH, seizure at the onset of the stroke symptoms, and rapidly improving symptoms are contraindications to fibrinolysis in both time windows.

12. A 66-year-old female presents with a possible transient ischemic attack (TIA). Approximately 1 hour before her arrival, she had a 15-minute episode of strictly right arm and right leg weakness, and her symptoms have now resolved. Her blood pressure (BP) is 165/92 mm Hg. Her prior medical history is significant for hypertension, high cholesterol, and diabetes mellitus. What is her ABCD2 score?
- **a.** 4
- **b.** 5
- **c.** 6
- **d.** 7
- **e.** 8

Answer: c. The patient's ABCD2 score is 6 (age >60 years, BP >140/90 mm Hg, unilateral weakness, symptoms lasting 10 to 59 minutes, and history of diabetes). No speech impairment is reported.

13. A 72-year-old male presents with an apparent stroke. Computed tomography (CT) imaging of the brain demonstrates only a hyperdense middle cerebral artery (MCA) sign and no other ischemic changes. He was last seen neurologically normal 4 hours earlier. Which of the following is a contraindication to fibrinolytic therapy in this patient?
- **a.** His blood glucose is 372 mg/dL.
- **b.** His National Institutes of Health (NIH) Stroke Scale score is 24.
- **c.** His platelet count is 110,000/mm^3.
- **d.** His systolic blood pressure (BP) is 180 mm Hg.
- **e.** He takes warfarin daily.

Answer: e. Any oral anticoagulant treatment (regardless of the patient's international normalized ratio [INR]) is a contraindication to fibrinolysis in the 3- to 4.5-hour treatment window. Other contraindications include an NIH stroke scale score greater than 25, platelet count less than 100,000/mm^3, blood glucose greater than 400 mg/dL, and systolic BP greater than 185 mm Hg.

14. A 75-year-old man is brought to the emergency department (ED) for altered mental status. After computed tomography (CT) imaging of the brain is performed, he is found to have a large intracerebral hemorrhage (ICH). Which of the following options is *not* an appropriate strategy for lowering intracranial pressure (ICP)?
- **a.** Barbiturate-induced coma
- **b.** Hyperthermia induction
- **c.** Hypertonic saline administration
- **d.** Hyperventilation
- **e.** Mannitol administration

Answer: b. Hypothermia is an experimental modality for lowering ICP. Hyperventilation can serve as a temporizing measure for reducing ICP. Mannitol and/or hypertonic saline can also be administered. Inducing a barbiturate coma is also an experimental modality.

88

Seizure

Carolina Barbosa Maciel and Marie-Carmelle Elie-Turenne

KEY CONCEPTS

- Epilepsy is a neurologic condition associated with an intrinsically lower seizure threshold and a higher risk of recurrent seizures without a clear trigger.
- The characterization of seizure semiology, duration, and etiology is important for accurate classification of seizures and status epilepticus; these impact definitive treatment choices.
- There is no single test to confirm that a patient seized, and several seizure mimics, including convulsive syncope, exist. A postictal alteration in mental status makes a seizure five times more likely than syncope.
- Key factors in the evaluation of epilepsy patients who present with breakthrough seizures include: changes in anti-seizure regimen, compliance, the addition of new medications that may lower the seizure threshold or levels of antiseizure drugs, presence of common infections or metabolic derangements, and recent sleep habits.
- Although most seizures are self-limited, the management of patients with seizures involves a targeted search for underlying pathology, treatment of complications associated with convulsions, and the prevention of future episodes.
- Serious systemic complications of seizures and status epilepticus include cardiac arrest, arrhythmias, apnea, hypoxia, acute kidney injury, rhabdomyolysis, acidosis, and death. The prognosis of status epilepticus is directly related to the etiology of seizures.
- Primary seizure prophylaxis should only be given for 7 days following traumatic brain injury. The period is shorter, although less well-defined, in unsecured aneurysmal subarachnoid hemorrhage. Prolonged primary prophylaxis is not recommended because it has not been demonstrated to reduce long-term seizure risk. The duration of secondary seizure prophylaxis and the antiseizure regimen in patients with acute brain injury who had a seizure during hospitalization should be individualized.
- Patients with a first-time seizure who have no known structural brain pathology, normal serum glucose and sodium levels, and normal neurologic examination can be discharged from the ED with appropriate outpatient follow-up.
- Emerging evidence supports the consideration of secondary seizure prophylaxis for first-time unprovoked seizures in selected patients. However, data are heterogeneous, and a thorough discussion with the patient and a specialist is advised before the initiation of anti-seizure drugs.
- Alcohol withdrawal syndrome can include seizures resulting from the cessation or reduction of alcohol consumption leading to an unopposed excitatory sympathomimetic response. Benzodiazepines are the drug of choice and should be supplemented by supportive measures, including electrolyte and thiamine supplementation. In pregnant patients, evaluations for new-onset seizures before 20 weeks should be the same as in nonpregnant patients. After 20 weeks, and up to 8 weeks postpartum, eclampsia is a major cause of seizures and should be included in the differential. IV magnesium remains first-line treatment for patients with eclamptic seizures and should not be delayed. Benzodiazepines and non-teratogenic antiseizure medications are reasonable alternatives in magnesium-refractory cases.
- Post-anoxic status epilepticus, including myoclonic status, frequently observed following cardiac arrest, was considered pathognomonic of poor neurologic outcome. However, in patients lacking factors with high predictive value for poor outcome post cardiac arrest, early antiseizure therapy can lead to improved outcomes.
- Therapeutic approaches to nonconvulsive status epilepticus are commonly extrapolated from convulsive generalized status epilepticus guidelines. However, the presumed etiology of seizures, extent of cortical area involved (focal versus diffuse or generalized), comorbidities, and response to therapy should be considered when selecting an antiseizure therapeutic algorithm.
- Immunomodulation remains the cornerstone of therapy for autoimmune epilepsies, in conjunction with antiseizure drugs. Transdisciplinary decision making is warranted before initiating immune-targeted therapy, which may include high-dose methylprednisolone, intravenous immunoglobulin, plasma exchange, rituximab, cyclophosphamide, and more recently, tocilizumab.

FOUNDATIONS

Background and Classification

Seizures are excessive excitatory neuronal activity associated with hypersynchrony of neighboring cells, resulting in sensory, motor, autonomic, or cognitive function alterations. *Convulsion* refers specifically to the motor manifestations of a seizure. The *ictal period* is the time during which a seizure or seizure-like activity occurs. A *postictal period* is an interval of transient neurologic dysfunction (commonly altered mental status or weakness) immediately following a seizure, generally lasting less than 1 hour. Longer ictal activity is associated with more prominent and prolonged postictal symptoms. When precipitating factors can be identified, provoked seizures are termed *acute symptomatic seizures.* Conversely, *primary seizures* are unprovoked and have no acute inciting pathology. Epilepsy refers to a condition of recurrent unprovoked seizures.

The International League Against Epilepsy defines epilepsy as a disease in which the threshold for seizures is lower than the normal population reflected by meeting at least one of the following: (A) diagnosis of epilepsy syndrome (e.g., juvenile myoclonic epilepsy, Lennox-Gastault syndrome, benign rolandic epilepsy, infantile spasms); (B) two or more seizures occurring more than 24 hours apart without an identified trigger; (C) one unprovoked seizure coupled with a higher likelihood of recurrent seizures over the subsequent decade

(similar to the recurrence risk for fulfilling criterion B, or ≥60% recurrence risk). For example, a patient who suffers head trauma might have a seizure in close proximity to the acute brain injury but would not be considered to have epilepsy unless unprovoked seizures recur remotely from the initial brain injury. Epilepsies are classified further according to seizure onset and semiology (focal with or without impairment of awareness, generalized or unknown onset; see Figure 14.1 in Chapter 14),[1] epilepsy syndrome (e.g., idiopathic generalized and self-limited focal epilepsies), and etiology (e.g., structural, genetic, infectious, metabolic, immune, or unknown).[2]

The majority of epilepsy syndromes have onset during childhood or adolescence. However, there have been reports of onset in early adulthood[2]; a thorough evaluation with a specialist is indicated in these cases. Breakthrough seizures in patients with epilepsy are commonly triggered by sleep deprivation, emotional or physical stress, and menses. Additionally, even slight adjustments in the antiseizure regimen or missing doses of medications may precipitate a recurrent seizure. A specific sensory stimulus, such as flashing lights or a specific smell, may also trigger seizures in epilepsies; these are still considered "unprovoked" when triggered by a process that would not cause a seizure in the patient that does not have epilepsy.

Medically refractory epilepsy (also known as "uncontrolled" or "drug-resistant") refers to patients who are unable to achieve or maintain seizure freedom despite 2 trials of adequately dosed antiseizure regimens. These patients continue to have seizures with a variable baseline frequency of occurrence. There are several definitions for seizure *clusters* reported in the literature: 3 or more seizures in 24 hours, 2 or more seizures in 24 hours, or 2 or more seizures in 6 hours.[3] The timely recognition of seizure clusters allows for prompt administration of seizure abortive measures (at home as instructed by the neurologist or epileptologist, in the pre-hospital, or in the hospital settings). Patients with medically refractory epilepsy presenting with seizure clusters are at a higher risk for status epilepticus.

Uncontrollable seizures, or status epilepticus, are seizures that have reached a prespecified duration according to specific seizure types (see Table 14.1 in Chapter 14) or recur with a frequency that does not allow a patient to return to the baseline neurologic status in between seizures.

Seizures may be provoked by a multitude of insults, such as acute brain injury (e.g., ischemic and hemorrhagic strokes, trauma, meningoencephalitis), toxins, and metabolic derangements. The main cause of status epilepticus and epilepsy in the elderly remains cerebrovascular disease. Patients with diabetes, higher stroke severity, cortical location of infarcts, and thromboembolic mechanisms are at the highest risk for experiencing seizures in the acute phase, with an incidence of up to 5% of all ischemic strokes in some series.[4,5] Nevertheless, the true incidence of seizures in the setting of stroke is difficult to ascertain because studies had variable methods of detection, use of primary seizure prophylaxis, and follow-up duration. Box 88.1 summarizes etiologies of seizures and status epilepticus according to the type of insult or neurologic process. Being familiar with common seizure triggers allows for identifying patients at higher risk for seizures and status epilepticus who may benefit from further diagnostic workup such as neuroimaging, EEG, or neurologic consultation.

When seizures are prolonged and the duration exceeds the respective threshold according to type (convulsive, nonconvulsive, or absence; see Table 14.1 in Chapter 14), they are termed *status epilepticus*. Overall, status epilepticus is associated with significant morbidity and mortality, particularly convulsive generalized status epilepticus. In the United States, reported status epilepticus incidence ranges from 10 to 40 persons per 100,000 annually. In a meta-analysis, the leading cause of status epilepticus globally was acute symptomatic (in close temporal relationship with a brain insult).[6] Overall case fatality rates were 15%; the highest case fatality rates were seen in low- and middle-income countries, refractory status epilepticus, and in the elderly population.

Several different scores exist to predict outcomes in status epilepticus. The Epidemiology based Mortality Score in Status Epilepticus (EMSE; Table 88.1) accounts for etiology of seizures, age, comorbidities, and EEG findings and performs well in predicting mortality and morbidity, but fails to predict responses to therapy satisfactorily.[7]

Anatomy, Physiology, and Pathophysiology

Neuronal cell membranes are stabilized by transmembrane electrochemical gradients and equilibrium among inhibitory neurotransmitters (e.g., GABA) and excitatory neurotransmitters (e.g., glutamate and acetylcholine). Seizures start when the equilibrium across the cell membrane is disrupted by an imbalance between these factors, leading to abnormal electrical discharge of cortical and subcortical neurons. The recruitment of neighboring neurons leads to spreading of this abnormal excitation. It may manifest clinically by propagating clonic activity in adjacent areas in the body following their corresponding topography in the brain (i.e., *Jacksonian March*, when focal motor seizure symptoms spread in a step-wise fashion). If there is involvement of large areas in both hemispheres, thalami, or deeper structures, and of the reticular activating system in the brainstem, impairment in consciousness ensues.

Physiologic mechanisms implicated in seizure termination involve reflex inhibition, hyperpolarization of neurons preventing their depolarization, and neuronal exhaustion, among others. Most drugs used to interrupt seizures act on $GABA_A$ subtype receptors, therefore enhancing inhibitory activity. However, with prolonged seizure activity, $GABA_A$ receptors are sequestered inside the cells and become unresponsive to GABA[8] (and GABA-ergic medications), whereas excitatory *N*-methyl-D-aspartate (NMDA) receptors may be upregulated. This perpetuates an excitatory state and leads to sustained seizure activity, explaining why timely treatment of seizures is of utmost importance.

CLINICAL FEATURES

In caring for patients who may have seized, the first step is to determine whether the event in question was truly a seizure. A common clinical scenario for the emergency clinician is the patient who presents with a history of having had a seizure-like episode, usually involving sudden loss of consciousness and some type of motor activity. Characterizing the episodes with particular attention to the predominant features at onset helps define the seizure type. In Chapter 14, Figure 14.1 depicts the revised expanded classification of seizure types according to their semiology at onset[1] and Table 14.1, the operational definition of status epilepticus according to time domains and seizure types.[9]

Once a seizure has met the criteria for status epilepticus, it can be further subdivided according to response to treatment: refractory status epilepticus when seizures persist despite 2 appropriately dosed antiseizure therapies, or super-refractory status epilepticus when seizures do not entirely resolve despite at least 24 hours of therapeutic coma with anesthetics (including propofol and benzodiazepines) or when seizures recur preventing tapering off anesthetics. Status epilepticus persisting for over 7 days despite appropriate management is termed prolonged and is associated with complications and longer hospital length-of-stay[10] (Table 88.2).

Recently revised definitions of clinical syndromes have been proposed for new-onset refractory status epilepticus (NORSE) and febrile infection-related epilepsy syndrome (FIRES).[10] NORSE includes patients without a known diagnosis of epilepsy or clear triggers (absent toxic exposure, metabolic derangements, or structural brain injury)

BOX 88.1 Etiologies of Seizures and Status Epilepticus According to Class of Insult/Pathology

Autoimmune
Acute disseminated encephalomyelitis
Antibody-mediated autoimmune and paraneuroplastic encephalitides
CREST, Goodpasture syndrome, and systemic lupus erythematosus
Multiple sclerosis
Rasmussen encephalitis
Thrombotic thrombocytopenic purpura

Cerebrovascular Disease
Acute ischemic stroke
Cavernous and arteriovenous malformations
Cerebral venous thrombosis
Intracerebral hemorrhage
Nontraumatic subarachnoid hemorrhage
Posterior reversible encephalopathy syndrome
Reversible cerebral vasoconstriction syndrome

Dementias
Alzheimer disease
Corticobasal degeneration
Frontotemporal dementia
Vascular dementia

Genetic Syndromes and Structural Anomalies
Focal cortical dysplasia
Hydrocephalus
Inherited metabolic diseases
Mitochondrial diseases
Polymicrogyria
Porphyria
Tuberous sclerosis complex
Wilson disease

Hypoxic-Ischemic Brain Injury
Cardiac arrest

Intracranial Tumor
Dysembryoplastic neuroepithelial tumor
Gangliogliomas
Gliomas
Lymphoma
Meningioma
Metastases
Primitive neuroectodermal tumor

Metabolic Derangements
Acidosis
Elevated blood urea nitrogen
Hyperammonemia
Hyperglycemia
Hypernatremia
Hypocalcemia
Hypoglycemia
Hypomagnesemia
Hyponatremia
Wernicke encephalopathy

Medications and Toxins
Alcohol intoxication and withdrawal
Alkylating agents
Baclofen intoxication and withdrawal
Benzodiazepine and barbiturate withdrawal
Beta-interferons
CAR-T (chimeric antigen receptor T cell therapy)
Carbapenems (imipenem in particular)
Cephalosporin (cefepime in particular)
Cyclosporine
Digoxin
Fentanyl
Heavy metals
Lidocaine
Metronidazole
Mexiletine
Theophylline
Tramadol
Tacrolimus
Subtherapeutic antiseizure drug levels

Systemic Disease
Acute and chronic renal failure
Cirrhosis

Trauma
Blunt or penetrating head injury (skull fracture)
Epidural hematoma
Subarachnoid hemorrhage
Subdural hematoma
Diffuse Axonal Injury

Although this list includes many recognized etiologies for epilepsy and acute symptomatic seizures, several entities were clustered into themes, and less common etiologies were omitted.

presenting with de novo refractory status epilepticus. FIRES is a subcategory of NORSE to specify the subset of patients with a clear prodrome of febrile illness for 24 hours up to 2 weeks prior to status epilepticus presentation; FIRES is common but not exclusive to the pediatric population. Box 88.2 summarizes other status epilepticus classifications according to their semiology, etiology, age, and EEG correlate.[9]

Classifications are important because they often dictate the aggressiveness of treatment. Not all types of status epilepticus warrant seizure suppression with third-tier therapy (therapeutic coma with anesthetics). An example is *epilepsia partialis continua* which, as the name implies, is characterized by continuous focal seizures that are notoriously refractory to antiseizure therapies. These patients learn how to live with ongoing focal clonic activity, and the therapeutic goal is shifted towards minimizing the side effects of medications. In this condition, seizures remain confined to a relatively small cortical region without spreading, which often leads to EEG recordings without epileptiform activity in most cases.

Seizures produce many secondary physiologic derangements that can result in poor outcomes. Epilepsy patients with poorly controlled generalized tonic-clonic seizures are at highest risk of sudden unexpected death in epilepsy (SUDEP), which exceeds the expected death rate in the general population by 24 times, primarily affecting young adults between 15 and 44 years of age.

The potential systemic complications of convulsive status are summarized in Table 88.3.[11,12] Sympathetic stimulation increases body temperature, heart rate, respiratory rate, serum glucose, and lactic acid.

The involvement of the insula, a highly epileptogenic area in which the cortical representation of the heart is also located, may be implicated in tachy- and bradyarrhythmias associated with ictal activity. Ictal asystole is a syndrome implicated in focal epilepsies, particularly of left temporal onset, female sex, and prior history of a heart condition. However, ictal asystole lasting longer than 30 seconds is associated with extra-temporal seizure focus and secondary generalized tonic-clonic seizures.[13]

Prominent autonomic dysregulation and apnea, possibly associated with spreading depolarization in the brainstem, and postictal diffuse suppression of cortical electrical activity have been implicated as potential mechanisms leading to SUDEP. With more prolonged convulsions, hypoglycemia, neurogenic pulmonary edema, skeletal muscle damage, and, rarely, frank rhabdomyolysis may ensue. A rise in the peripheral white blood cell count without an increase in bands is also often seen. Autonomic discharge and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting, tongue biting, and potential airway impairment. Rarely, the force generated by the muscle contractions in these seizures can be strong enough to cause posterior shoulder dislocations or fractures.

TABLE 88.1 Epidemiology-Based Mortality Score in Status Epilepticus (EMSE)[34]

Age	Points	Comorbidity (Score Each Disease)	Points
>80	10	AIDS, metastatic solid tumor	60
71–80	8	Moderate to severe liver disease	30
61–70	7	Moderate to severe renal disease, any tumor (includes lymphoma and leukemia), hemiplegia, diabetes with end-organ damage	20
51–60	5		
41–50	3		
31–40	2	Peripheral vascular disease, connective tissue disease, diabetes, myocardial infarction, cerebrovascular disease, congestive heart failure, dementia, mild liver disease, peptic ulcer disease, chronic pulmonary disease	10
21–30	1		
Score one	____	Score each disease	____
EEG	Points	Etiology	Points
Spontaneous burst suppression	60	Anoxia	65
		Acute central nervous system infection	33
		Acute cerebrovascular disease	26
After status epilepticus ictal discharges	40	Metabolic disorders	22
		Metabolic, sodium imbalance	17
		Brain tumor	16
Lateralized periodic discharges (LPDs)	40	Cryptogenic	12
		Head trauma	12
		Drug overdose	11
Generalized periodic discharges (GPDs)	40	Alcohol abuse	10
		Hydrocephalus	8
		Remote cerebrovascular event or brain injury	7
No LPDs, GPDs, or ictal discharges	0	Multiple sclerosis	5
		Drug withdrawal, reduction, or poor compliance	2
		Central nervous system anomalies	2
Score only worst	____	Score one	____
Total Score = Sum of above scores

TABLE 88.2 Status Epilepticus Nomenclature According to Refractoriness and Duration[10]

Subtype of Status Epilepticus	Refractoriness to Treatment
Refractory (RSE)	Ongoing seizures despite first-line (benzodiazepine) and at least one second-line (appropriately selected parenteral antiseizure drug) therapies. Both first- and second-line therapies must have been adequately dosed to meet this criterion; status epilepticus may have any duration.
Super-Refractory (SRSE)	Ongoing seizures lasting over 24 hours from initiation of third-line therapy (therapeutic coma with anesthetics, regardless of which drug); status epilepticus may have any duration. This includes those that had a partial response at any point, but not completely subsided (recurred after or during attempts to wean anesthetics).
± Prolonged (qualifier for either types: refractory or super-refractory)	Status epilepticus lasting over 7 days despite adequate step-wise escalation of therapy: it may be refractory (no anesthetic trial introduced) or super-refractory (therapeutic trial with anesthetics included).

Hirsch LJ, Gaspard N, van Baalen A, et al. Proposed consensus definitions for new-onset refractory status epilepticus (NORSE), febrile infection-related epilepsy syndrome (FIRES), and related conditions. *Epilepsia*. 2018;59(4):739-744.

BOX 88.2 Status Epilepticus Subclassifications According to Semiology, Etiology, Age Group, and Electroencephalographic Correlate[35]

Semiology

Predominant motor features: convulsive status epilepticus (generalized, focal onset evolving to bilateral convulsive, unknown), myoclonic status epilepticus (with coma, without coma), focal motor status epilepticus (repeated focal motor, epilepsia partialis continua, adversive status, oculoclonic status, ictal paresis), tonic status epilepticus, hyperkinetic status epilepticus

Without prominent motor features (nonconvulsive status epilepticus): with coma, without coma (generalized: typical absence status, atypical absence status, myoclonic absence status; focal: without impairment of consciousness, aphasic status, with impaired consciousness; unknown focal versus generalized: autonomic status)

Etiology

Known or symptomatic: acute, remote, progressive, or status epilepticus in defined electroclinical syndromes

Unknown or cryptogenic

Age

Neonatal (0–30 days)
Infancy (1–24 months)
Childhood (>2–12 years)
Adolescence and adulthood (>12–59 years)
Elderly (+60 years)

Electroencephalographic Characteristics

Location: generalized, lateralized, bilateral independent, or multifocal

Pattern: periodic discharges, rhythmic delta activity, or spike-and-wave/sharp-and-wave

Morphology characterization of discharges according to sharpness, number of phases, amplitude and polarity

Time-related features of patterns according to prevalence, frequency, duration, onset, dynamics, daily burden

Modulation: spontaneous or stimulus-induced

Response to therapy

Leitinger M, Beniczky S, Rohracher A, et al. Salzburg Consensus Criteria for Non-Convulsive Status Epilepticus: approach to clinical application. *Epilepsy & Behavior : E&B*. 2015;49:158-163.

Clinical History

Identifying the circumstances surrounding the event, such as possible inciting factors and progression and duration of symptoms, provides important clues regarding whether the episode was a seizure and the likely etiology (a framework of cardinal features of seizures is provided in Chapter 14). The clinician should obtain any history of trauma (either before or during the seizure), alcohol intoxication or abuse, and pregnancy. Although febrile seizures are common in children (see separate discussion of seizures in pediatric patients in Chapter 169), hyperthermia alone as seizure etiology of adults is uncommon, and seizures in the setting of fever are highly suggestive of meningoencephalitis. Immunocompromised patients and those with recent neurosurgical instrumentation with or without hardware (e.g., shunt, drug delivery devices, spinal cord stimulator) are at particularly high risk for infection. Other red flags suggesting acute brain injury is thunderclap and severe headache preceding seizures or sudden neurologic deficits. New or recent changes in medication regimen, and history of comorbidities are also important in both patients with new-onset seizures and epilepsy because they assist in unveiling potential triggers: medications lowering seizure threshold, interacting with antiseizure regimen, or even leading to severe metabolic derangements such as hypoglycemia or hypocalcemia (Table 88.4).

In epilepsy patients, characterizing typical seizure semiology, typical seizure frequency, last known seizure, common precipitating factors, and neurologic baseline provides a meaningful comparison with the current presentation. Noncompliance with the antiseizure regimen is the most common cause for the ED presentation of recurrent seizures. Certain recreational drugs (e.g., cocaine, phencyclidine, ecstasy, and synthetic marijuana) are known to decrease the seizure threshold. Common causes of adult-onset focal seizures in low- and middle-income countries include neurocysticercosis (especially Central and South America) and malaria, both of which should be considered in travelers and immigrants. Finally, investigating potential precipitants (such as sleep deprivation, infection, or new medications, especially those that can lower the seizure threshold or affect antiseizure drug metabolism) is key to managing the patient with a known seizure disorder who has a typical event while on medications. Further details on key historical features are provided in Chapter 14; a stepwise approach to evaluating a patient with suspected seizures in the emergency department is displayed in Figure 14.2.

TABLE 88.3 Potential Systemic Complications Related to Seizures and Status Epilepticus[11,12]

Cardiac and Others	Heme/Musculoskeletal and tegmentum/ Gastrointestinal	Pulmonary	Renal/Acid-Base/ Metabolic	Prolonged Course Complications
Arrhythmias and conduction abnormalities	Dislocation	Airway obstruction	Acute renal failure	Critical illness myopathy or neuropathy
Cardiac arrest	Fracture	Apnea/ hypoventilation	Acidosis: lactic, respiratory	Deep vein thrombosis or pulmonary embolism
Cardiomyopathy	Hepatotoxicity and pancreatitis	Aspiration	Hyperglycemia	Gastrostomy
Cardiac necrosis	Leukocytosis/leukopenia/ thrombocytopenia	Hypoxia	Hyperkalemia	Infection
Hypertension	Rhabdomyolysis	Mucous plugging	Myoglobinuria	Tracheostomy
Thermodysregulation	Life-threatening rash	Pulmonary edema		Skin breakdown and poor wound healing
	Ileus and bowel ischemia			

Sutter R, Dittrich T, Semmlack S, Ruegg S, Marsch S, Kaplan PW. Acute systemic complications of convulsive status epilepticus: a systematic review. *Crit Care Med*. 2018;46(1):138-145; Legriel S, Bresson E, Deye N, et al. TABLE 88.4 Management of "Special Situations" Seizures in the Emergency Department

Clinical Situation	Agent of Choice	Dosage/Comment
Hyponatremia	Hypertonic (3%) saline	Adults: 100 mL 3% NaCl over 10 min; children: 2 to 5 mL/kg, up to 150 mL/dose 3% NaCl over 20 min
Hypocalcemia	Calcium chloride or gluconate	Sequential ampules until seizures stop
Tricyclic antidepressant overdose	Sodium bicarbonate	Administer 1 to 2 mEq/kg IV bolus; repeat as needed to maintain ECG QRS complex ≤ 100 msec
Salicylate overdose	Sodium bicarbonate; hemodialysis for severe cases	Administer 1 to 2 mEq/kg IV bolus; repeat as needed to maintain a blood pH of 7.4 to 7.5
Isoniazid overdose	Pyridoxine	5 g IV (adult) or 70 mg/kg (pediatric)
Cocaine intoxication	Benzodiazepines	As per idiopathic seizures
Lithium toxicity	Hemodialysis	
Alcohol-associated seizure	Lorazepam	0.05 to 0.10 mg/kg, or fixed doses of 2 to 4 mg for adults
MDMA	Benzodiazepines	Be aware of possible hyperthermia or hyponatremia
Eclampsia	Magnesium sulfate	IV loading dose of 4 to 6 g over 15 to 20 minutes, then 1 to 2 g/h infusion; monitor patients for hyporeflexia; alternatively, lorazepam (Ativan) 4 mg IV over 2 to 5 minutes or diazepam (Valium) 5 to 10 mg IV slowly can be used to terminate the seizure, after which magnesium sulfate is administered

Physical Examination

An accurate set of vital signs is the foundation of any physical examination and may direct the clinician to potential etiologies (e.g., fever suggesting meningoencephalitis, tachycardia and hypertension suggesting sympathomimetic intoxication) and indicate the existence of an ominous intracranial diagnosis (e.g., hypertension and bradycardia suggest herniation syndromes).

If the patient presents actively seizing, observe the specifics of the motor activity and pay close attention to focal findings and asymmetries such as dystonic posturing, clonic or tonic activity, eye deviation, or nystagmus. Apply gentle manual pressure to the limb in an attempt to suppress clonic activity: if suppressible, this suggests nonepileptic spells or movement disorders. Anecdotally, pupils are often reported to be dilated during or after a seizure; persistent mydriasis may reflect anticholinergic or sympathomimetic toxicity. Subtle automatisms, facial myoclonus, and nystagmus following convulsive activity suggest nonconvulsive status epilepticus.

A systematic neurologic exam should be performed including mental status. Postictal patients may be hyperreflexic, have an extensor plantar response, or have a focal motor deficit (e.g., Todd paralysis), all of which generally resolve within one hour of a seizure. Todd paralysis is associated with a high likelihood of an underlying structural cause for the seizure. If it does not quickly resolve, a new structural lesion should be suspected.

Seizures are often associated with injury, and the patient must be evaluated for both soft tissue and skeletal trauma. Head trauma and tongue lacerations are common. Seizure activity can also produce dislocations and fractures. Posterior shoulder dislocations are extremely rare but, when present, should prompt suspicion that a seizure has occurred. Seizure-induced fractures are rare but frequently missed; the humerus, thoracic spine, and femur are most commonly involved. Extremities should be inspected for signs of intravenous drug use and signs of systemic embolism and endocarditis, which may raise suspicion for intoxication, septic strokes or cerebral abscesses. Dysmorphic features and stigmata of neurocutaneous diseases help diagnose epilepsy syndromes, particularly in the pediatric population.

DIFFERENTIAL DIAGNOSIS

Common differential diagnoses to consider when evaluating for seizure are summarized in Chapter 14 and listed in Box 14.2. The history surrounding the circumstances of the event and precipitating factors help distinguish seizures from their mimics. However, as a general rule, no single clinical feature or diagnostic modality is 100% confirmatory of the diagnosis of seizures.

Commonly regarded features suggestive of seizures include postictal disorientation and amnesia, lateral tongue biting, cyanosis during the event, auras (e.g., déjà vu or jamais vu, which are focal nonconvulsive seizures), non-suppressible rhythmic limb shaking, and dystonic posturing. Conversely, diaphoresis, palpitations, nausea, and dizziness preceding seizures may suggest arrhythmias and transient cerebral hypoperfusion.

Convulsive syncope is characterized by some component of motor activity, most commonly involving tonic extension of the trunk or myoclonic jerks of the extremities, at times associated with bradycardia. As cerebral perfusion is restored, abnormal muscle activity ceases, and there is no postictal period; these events are usually not associated with tongue biting, but urinary incontinence may occur.

Nonepileptic spells, or psychogenic seizures/attacks, are paroxysmal events that may be misdiagnosed as a seizure or as status epilepticus. Psychogenic seizures are rarely caused by malingering but are more commonly a psychiatric disorder (e.g., a conversion disorder). Avoidance of eye contact with the examiner, asynchronous, stop-and-go clonic activity, forward pelvic thrusting, horizontal head movements, maintaining eyes closed during the spell, and relative short postictal confusion are findings consistent with nonepileptic spells. Spells lasting 5 minutes or longer were 24 times more likely to be nonepileptic than ictal in a video EEG study.[14] Approximately 10% of subjects in clinical trials of convulsive status epilepticus are ultimately diagnosed with nonepileptic spells. Given the characteristically long duration and overt convulsions in nonepileptic spells, these patients are more likely to receive higher cumulative doses of benzodiazepines, and up to 15% result in intubation and mechanical ventilation in the emergency department.[15] Lack of leukocytosis and metabolic acidosis despite prolonged events may also help differentiate nonepileptic spells from seizures. Video EEG monitoring capturing the spell and documenting an absence of an associated electrographic ictal pattern is required to establish the diagnosis of nonepileptic spells.

DIAGNOSTIC TESTING

A thorough history and physical examination primarily directs the evaluation and management and may obviate the need for extensive

BOX 88.3 Proposed Seizure Triggering Thresholds for Metabolic Derangements

Serum Glucose: <36 mg/dl (2.0 mm); >450 mg/dl (25 mM) associated with ketoacidosis
Serum Sodium: <115 mg/dl (<5 mm)
Serum Calcium: <5.0 mg/dl (<1.2 mm)

Serum Creatinine: >10.0 mg/dl (>884 μM)

diagnostic testing. Due to the challenges of obtaining an accurate history in an actively seizing or postictal patient, vigilance in seeking collateral information is warranted from witnesses,[16] relatives, paramedics, medical alert bracelets, old medical records, and medication lists or containers. These data will often provide critical elements in the patient assessment.

Laboratory Studies

If a patient with a new-onset seizure has no significant comorbid disease and a normal examination (including mental status), the likelihood of an electrolyte disorder is extremely low; thus, extensive metabolic testing in patients who have returned to a normal baseline after a first-time seizure is not indicated.[17] Patients with persistent alteration of mental status, those in status epilepticus, and those who have fever or new neurologic deficit require extensive diagnostic testing, including serum glucose, electrolytes (i.e., sodium, magnesium, calcium), urea nitrogen, creatinine, complete blood count, pregnancy tests in women of childbearing age, antiseizure drug levels, AST, ALT, and drugs-of-abuse screening. Box 88.3 lists proposed cutoff values for metabolic derangements lowering the seizure threshold. Blood alcohol level and toxicology screening should be considered in patients with first-time seizures, although there is no evidence that such testing changes outcomes. A positive drug-of-abuse screen does not prove causation, and the patient may still require further evaluation with EEG and neuroimaging. Seizure due to alcohol intoxication or withdrawal is a diagnosis of exclusion because alcoholics are at increased risk for electrolyte abnormalities and traumatic injuries. Chapter 14 summarizes key laboratory diagnostics in patients presenting with seizures.

Radiology

Neuroimaging is recommended in patients with a first-time seizure, though in select patients who have a normal examination, have returned to baseline, do not have headaches, and have access to follow-up care, imaging can be obtained as an outpatient. Patients with a history of epilepsy and who have returned to baseline do not need neuroimaging in the emergency department. Urgent neuroimaging is indicated in cases with status epilepticus, focal neurologic deficits, prominent headache, known or suspected trauma, history of malignancy or immunocompromised state, and use of systemic anticoagulation. Additionally, elderly patients and those with neurocutaneous syndromes are at higher risk for structural brain abnormalities. Box 14.1 summarizes factors that should prompt consideration for neuroimaging.

Computed tomography (CT) has the advantages of being widely available and requiring shorter imaging acquisition times. However, other modalities such as magnetic resonance imaging (MRI) and CT perfusion may provide additional information (see Chapter 14). Figure 88.1 depicts the typical diffusion restriction corresponding to a seizure focus in an MRI of a patient with refractory focal status epilepticus.

Special Procedures and Tests

Lumbar puncture is indicated in patients with fever, severe headache, persistent altered mental status, or immunocompromise, unless a clear alternative diagnosis is present. Obtaining an EEG is often logistically challenging in the ED, but can be of high yield for patients whose diagnosis is unclear or who remain altered. EEG assists in the diagnosis of both epilepsy and nonepileptic spells, the detection of nonconvulsive seizures, and status epilepticus in those with altered mental status. Moreover, EEG guides management in monitoring the duration and depth of therapeutic coma management in refractory status epilepticus.

MANAGEMENT

Stabilization and Empirical Therapy

The initial approach to a patient with seizures centers on the characterization of the nature of events (seizures versus not seizures and underlying etiology), implementing supportive measures, and identifying critical and emergent diagnoses, listed in Box 14.3 in Chapter 14. The timely administration of adequate doses of first-line therapy (i.e., lorazepam 0.1 mg/kg [max 4 mg/dose] or midazolam 0.2 mg/kg [max 10 mg/dose]) remains the cornerstone of empirical abortive seizure therapy.[18,19] In status epilepticus, the use of benzodiazepines as the first line of treatment and a higher cumulative dose of antiseizure medications were associated with quicker cessation of status epilepticus.[20] Approximately 1 in 3 patients with status epilepticus require endotracheal intubation.[21] Proposed algorithms for the initial assessment, support, and implementation of empiric therapy of seizures and status epilepticus are displayed in Figure 14.2 and Figure 14.3, and most commonly used agents in first-, second- and third-line therapies are included in Table 14.2.

Definitive Management

While the empirical therapy centers on benzodiazepines as first-line therapy for most seizures that warrant abortive drugs, certain underlying pathologies warrant specific treatments; these are summarized in Table 88.3 which also provides specific dose considerations.

SPECIAL CASES

Alcohol-Related Seizures

Alcohol-withdrawal seizures account for a substantial portion of alcohol-related seizures. Alcohol suppresses glutamate-mediated excitatory tone while enhancing the inhibitory GABA-ergic receptors; in chronic use, there is upregulation of excitatory receptors. The interruption of alcohol use leads to excess excitation and a sympathomimetic response characterized by tachycardia, hypertension, disorientation, agitation, and seizures (See Chapter 137).

While seizures are witnessed in the setting of withdrawal, clinical findings cannot predict who is likely to have a recurrent seizure in the ED. Signs of alcohol withdrawal (tachycardia, confusion, or tremors) do not necessarily correlate with the likelihood of seizures. Although withdrawal seizures are an important etiology, patients with a history of alcohol abuse and dependence have several other potential risk factors for seizures, including increased incidence of traumatic brain injury, hypomagnesemia related to malnutrition, hyponatremia and hyperammonemia as a consequence of decompensated cirrhosis, hypoxic-anoxic events (i.e., aspiration) and co-ingestion of other toxins. In over half of the cases, alcohol-related seizures occur as a result of concomitant factors, such as epilepsy, structural brain abnormalities, and recreational drugs.

A first-time "withdrawal" seizure must be evaluated as any first-time seizure. Other conditions must be ruled out by history, physical examination, and diagnostic testing, including electrolytes, glucose,

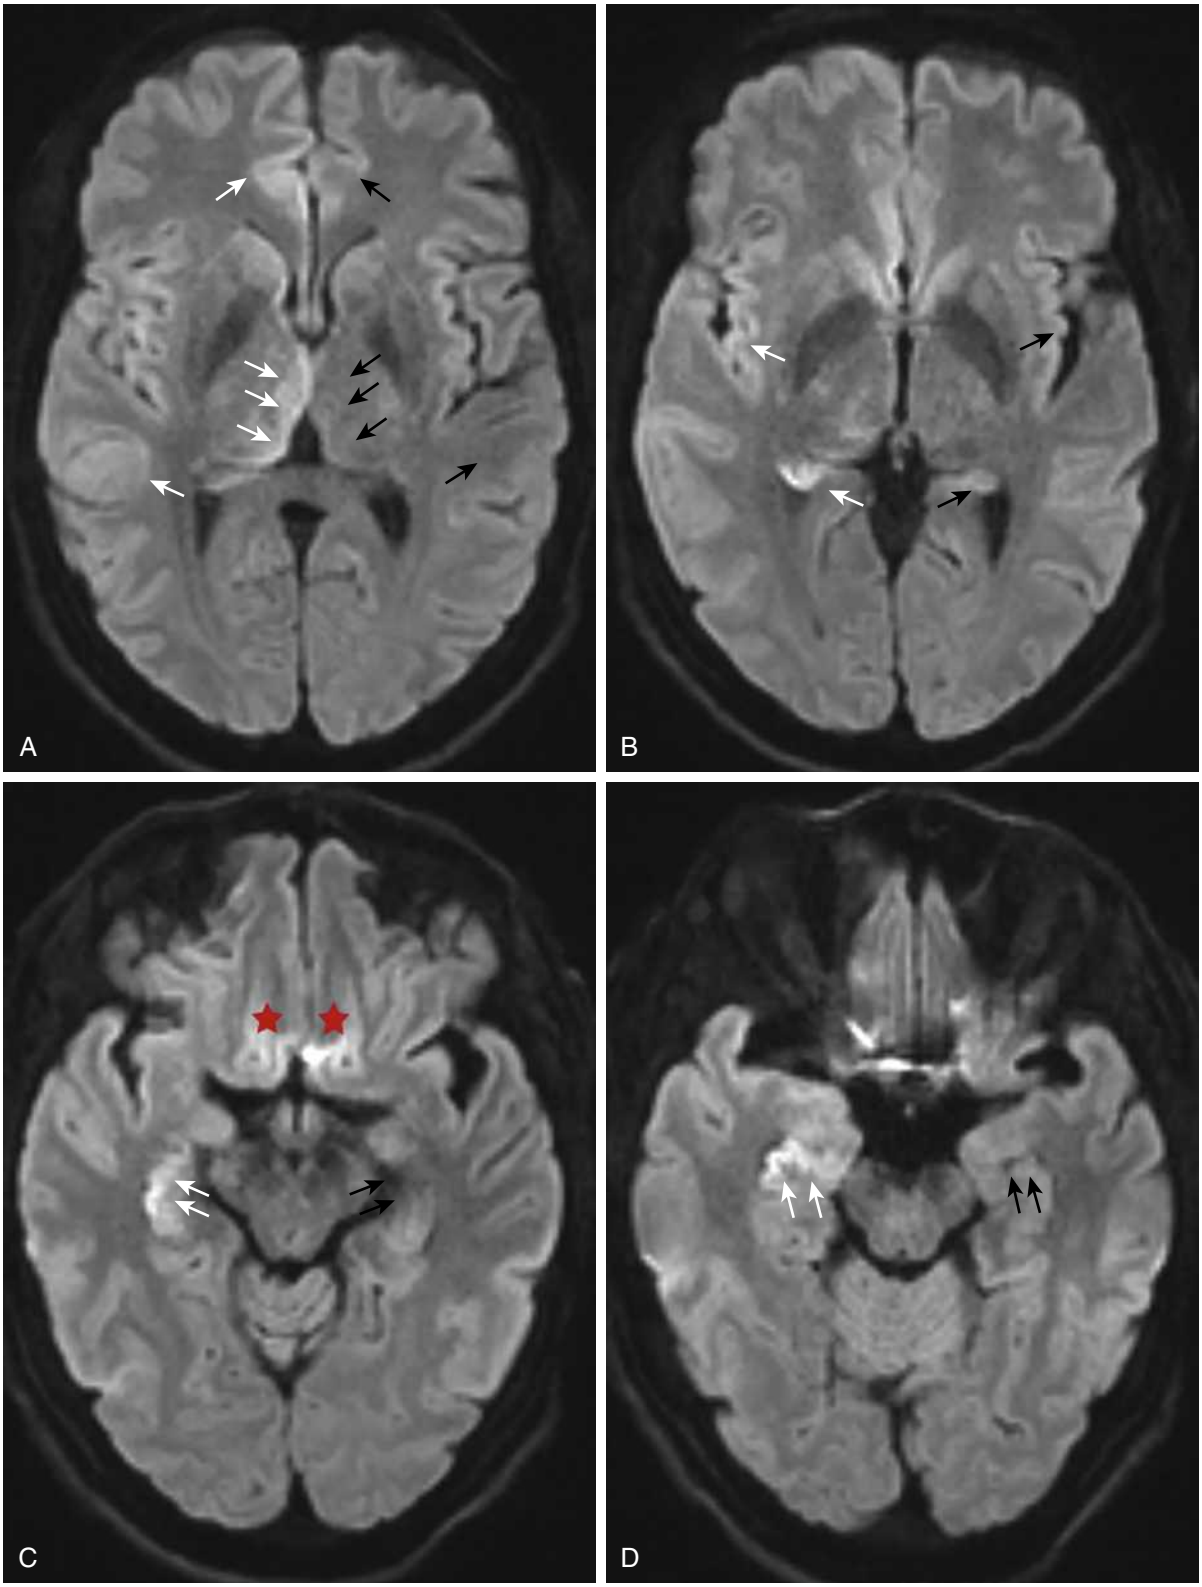

Fig. 88.1 Magnetic Resonance Imaging of Cortical Changes from Prolonged Seizures. Diffusion-weighted imaging (DWI) sequence of magnetic resonance imaging (MRI) of the brain of a 55-year-old woman with prolonged refractory status epilepticus from autoimmune etiology demonstrating restriction of diffusion (hyperintensities) in the areas of seizure involvement. From anterior to posterior, *white arrows* contrast the high signal in involved areas on the right hemisphere with the *black arrows* demarking spared areas in the contralateral left hemisphere. (A) Mesial frontal lobes, thalami, superior temporal cortex; (B) insular cortices and hippocampi; (C & D) hippocampi. *Red stars* depict artifactual symmetric hyperintensities in the inferior frontal lobes.

CT head, and lumbar puncture if indicated, particularly if fever is present. Testing results in an increased diagnostic yield in this population and is likely to affect management. After excluding other etiologies, the diagnosis of alcohol-withdrawal seizure is based on a history of recurrent events temporally related to ceasing or decreasing alcohol intake. Importantly, the presentation of alcohol withdrawal is frequently preceded by an illness or injury, leading to a decrease in alcohol consumption. A thorough history should include the precipitating reason for abstinence as well as a comprehensive assessment for concomitant illness if the cessation was not intentional. Alcohol-withdrawal seizures are usually generalized and occur between 6 and 48 hours after cessation of drinking. Judicious monitoring of these time intervals is warranted in scenarios where patients with a history of alcohol dependence are anticipated to have prolonged stays in the emergency department or are to be admitted.

Benzodiazepines are the treatment of choice in alcohol-withdrawal seizures, given the GABA-ergic pathway modulation, reducing the signs and symptoms of alcohol withdrawal and increasing the seizure threshold. All benzodiazepines appear to be equally efficacious in terminating an alcohol-withdrawal seizure; however, lorazepam is the only benzodiazepine that has been shown to decrease the incidence of seizure recurrence and decrease the need for hospitalization with a number needed to treat of 5 to prevent additional seizures in the subsequent 6 hours. Patients requiring 40 mg/h of diazepam equivalents are considered to have benzodiazepine-resistant alcohol withdrawal syndrome.[22] Adjunctive therapy such as phenobarbital[22] and ketamine (infusions ranging from 0.012 to 1.6 mg/kg/h) are potential alternatives in such cases.[23] The placement of a definitive airway may be considered in refractory withdrawal seizures where repeated intravenous bolus or infusion dosing is anticipated to control symptoms.

Seizures Related to Other Toxins

Other toxins may lower the seizure threshold by disrupting the balance between excitatory and inhibitory neuronal transmission. Treatment is supportive and relies on the use of benzodiazepines as first-line therapy in most cases. Cases of toxin-induced refractory status epilepticus pose a particular challenge because the mechanism of status epilepticus may be different from status epilepticus with other causes. Some toxins (e.g., isoniazid) cause depletion of GABA neurotransmitter. Some of the typical antiseizure medications act by sensitizing the GABA receptor, making them less effective when GABA is depleted. In these cases, early administration of pyridoxine may be advantageous because it replenishes GABA in the brain. As with alcohol-induced seizures, phenytoin is ineffective for most drug-induced seizures. In some cases, such as in theophylline or tricyclic overdose, it may be harmful due to the increased risk of cardiac toxicity given the sodium channel antagonism of phenytoin and other antiseizure drugs (Fig. 88.2).

Post-Traumatic Seizures

Post-traumatic seizures are the hallmark of acute symptomatic seizures related to acute brain injury. Early post-traumatic seizures occur within the first week, with over 50% occurring within the first 24 hours. For primary seizure prophylaxis, antiseizure drugs may be initiated in the absence of seizures on presentation following acute brain injury

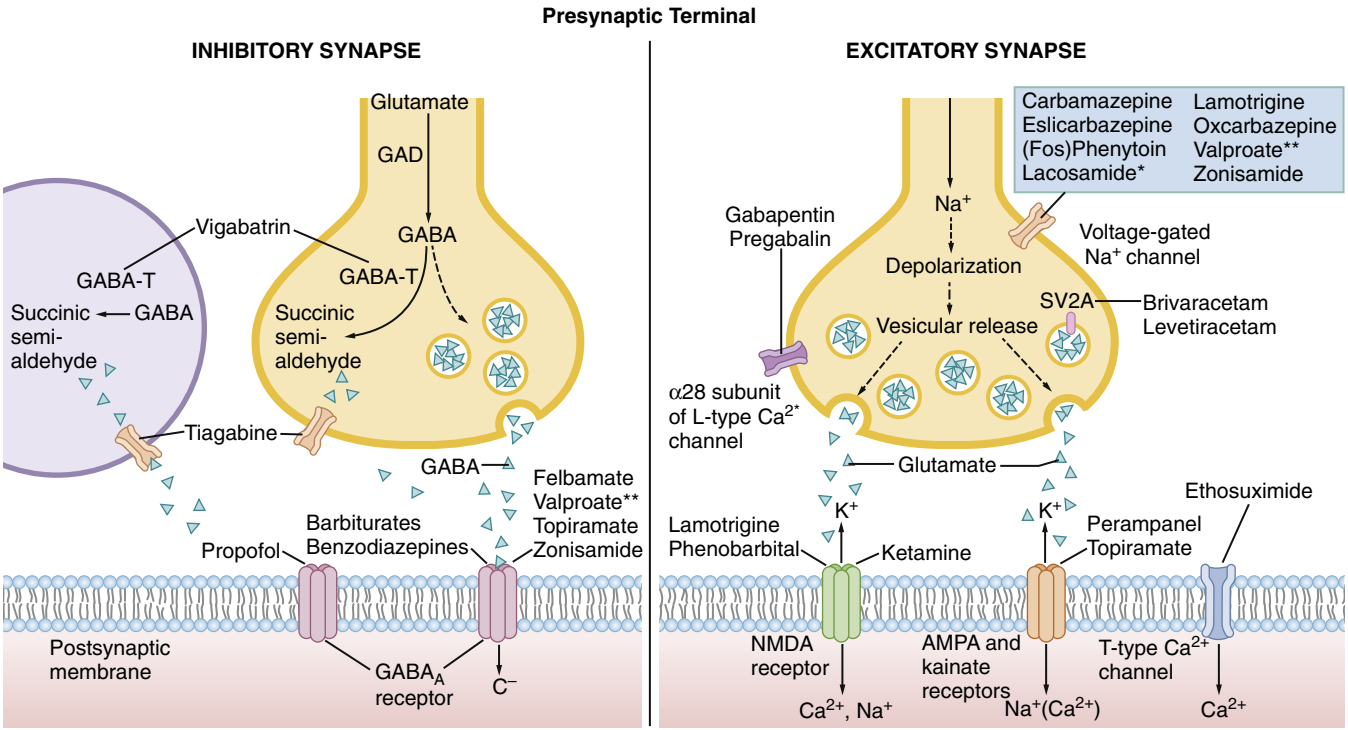

Fig. 88.2 Schematic Display Illustrating the Action Targets of Most Commonly Used Antiseizure Medications. *Lacosamide acts in Na^+ channels by enhancing the slow inactivation of voltage-gated Na^+ channels; other antiseizure drugs that target Na^+ channels act by enhancing their fast inactivation. **Valproic acid (valproate) is considered a broad-spectrum antiseizure drug because it acts in both inhibitory and excitatory pathways. The enzyme GAD is responsible for catalyzing the decarboxylation of glutamate into GABA. *AMPA*, Alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; *GABA*, gamma-aminobutyric acid; *GABA-T*, GABA transaminase; *GAD*, glutamic acid decarboxylase; *GAT1*, GABA transporter; *NMDA*, *N*-methyl-D-aspartate; *SV2A*, synaptic vesicle glycoprotein 2A. (Adapted from Morris M, Owusu K, Maciel CB. Status Epilepticus. In: Rabinstein A, ed. *Neurological Emergencies: A Practical Approach*. Vol 1. 1 ed. Springer: Switzerland; 2020:15 47.)

(e.g., traumatic brain injury, ischemic stroke, intracerebral hemorrhage, subarachnoid hemorrhage). Guidelines recommend 7 days in traumatic brain injury[24] and short-term therapy in subarachnoid hemorrhage. Although secondary prophylaxis helps reduce the risk of seizures during the subacute phase following traumatic brain injury, it fails to impact the risk of late seizures (or localization-related epilepsy).

Seizures in Pregnancy

Seizures in pregnancy are classified as one of three types: (1) those that occur in epileptic patients who are also pregnant, (2) new-onset seizures in pregnant patients, and (3) seizures that occur in the setting of eclampsia. Among patients with a history of seizure disorders, factors that may lower the seizure threshold in women who are pregnant include noncompliance, sleep deprivation, nausea and vomiting, or an increase in drug clearance resulting in subtherapeutic levels of antiseizure drugs—in particular, lamotrigine, phenytoin, carbamazepine, levetiracetam, and topiramate.[25] Additionally, pregnant patients with epilepsy commonly undergo adjustments in antiseizure regimens because several drugs are known for their teratogenic potential; these adjustments may lead to breakthrough seizures in otherwise well-controlled epilepsies. Overall, there is not an increased risk of status epilepticus during pregnancy.

Although few data guide the use of antiepileptic drugs for status epilepticus during pregnancy, the risks to the fetus from status epilepticus–related hypoxia and acidosis are greater than the potential teratogenicity of anticonvulsant medications. Therefore, patients who are actively seizing should be managed as the nonpregnant patient. In patients who are more than 24 weeks pregnant, fetal monitoring during and after a seizure should be arranged.

Pregnant patients with noneclamptic new-onset seizures should be worked up as any new-onset seizure patient, with a metabolic profile, EEG, and head CT scan with appropriate abdominal shielding. Precipitating etiologies, such as infections and drug toxicities, should also be investigated. If no source is identified, anticonvulsants should be withheld, and the patient referred for close follow-up. Cortical vein thrombosis should be on the differential for pregnant patients who present with headaches and focal seizures, given the relative prothrombotic state of pregnancy. Eclampsia is a major consideration in pregnant patients of at least 20 weeks' gestation who present with new-onset seizures. The pathophysiology may be due to disruption of cerebral autoregulation and resulting hyperperfusion and edema, similar to posterior reversible encephalopathy syndrome (PRES). Generalized seizures in pregnant women are typically preceded by preeclampsia, HELLP (hemolysis, elevated liver enzymes, low platelets), or hypertension.

Postpartum eclampsia represents 25% of eclamptic seizures, and importantly can occur up to 8 weeks after delivery without preceding preeclampsia or hypertension. Magnesium is the therapy of choice to treat acute eclamptic seizures and prevent a recurrence. It is more effective and has a better safety profile than phenytoin in preventing recurrence of convulsions and maternal death. Magnesium sulfate is also associated with benefits for the baby, including fewer admissions to the neonatal intensive care unit. Magnesium administration should not be delayed while awaiting definitive results when evaluating first-time seizures in a pregnant woman. An in-depth discussion of eclampsia can be found in Chapter 174.

First-Time Seizures

Adult patients with first-time unprovoked seizures may not have epilepsy, but should be informed that the risk of recurrence is highest in the subsequent 2 years, ranging from 21% to 45%,[26] especially in patients with prior brain insults such as trauma and stroke, those with epileptiform findings on EEG and abnormal neuroimaging, and nocturnal type of seizures. Starting secondary seizure prophylaxis reduces seizure recurrence in the initial 2 years; however, a careful risk-benefit assessment is warranted because there are conflicting data on the impact of antiseizure medicines on quality of life due to potential side effects.[26,27,28] Thus, starting an antiseizure regimen routinely in the emergency department is not recommended without input from a specialist and an individualized plan.

In children, the recurrence risk is much higher, particularly in those younger than 3 years.[29] One in three patients with newly diagnosed epilepsy remains untreated up to 3 years after diagnosis in the United States; this gap between diagnosis and adequate therapy may increase the risk of medical events and increase health care resource utilization.[30] Further, of those initiated in an antiseizure regimen, one-third discontinue treatment in the initial year.[31] The establishment of a reliable plan for follow-up care with a primary physician or neurologist is essential in patients with epilepsy.

Breakthrough Seizures

Patients with epilepsy presenting with breakthrough seizures should be evaluated for subtherapeutic levels whenever possible, as noncompliance and adjustments in regimens are common triggers. Table 88.5 includes reference levels for commonly used antiseizure drugs and suggested empiric reloading doses. A general formula for supplementing bolus of phenytoin is:

$$(\text{target total phenytoin level} - \text{current total corrected phenytoin level}) \times (\text{weight in Kg} \times 0.8).$$

A similar formula is available for valproic acid, and the volume of distribution is adjusted:

$$(\text{target total valproic acid level} - \text{current total valproic acid}) \times (\text{weight in Kg} \times 0.2).$$

Figure 88.2 includes a schematic display illustrating the action targets of most commonly used antiseizure medications.

Post-Anoxic Seizures

Post-anoxic seizures and status epilepticus are common after cardiac arrest, occurring in up to one-third of patients who remain unconscious after return of spontaneous circulation (ROSC). In the past, post-anoxic status epilepticus was associated with nearly 100% mortality, but immediate and aggressive seizure abortive measures may improve outcomes in select cases. Patients with a higher chance for recovery include those with the presence of brainstem reflexes, preserved median nerve somatosensory evoked potentials, and preserved EEG background reactivity to external stimuli.[32] In patients treated with targeted temperature management, seizures may occur at any time after ROSC, which should prompt early continuous EEG monitoring or repeated 30-minute EEG studies. No standardized antiseizure treatment has been proven beneficial in this population, and therapeutic algorithms are largely extrapolated from convulsive status epilepticus guidelines. Post-ROSC myoclonus may occur and requires EEG monitoring for an accurate diagnosis.

Nonconvulsive Status Epilepticus

The treatment of nonconvulsive status epilepticus should be individualized according to the risk of additional brain injury, extent of brain area involved by seizures, etiology of seizures, and comorbidities. No

TABLE 88.5 Loading Dose Route of Administration for Antiepileptic Drugs When Resuming Treatment in the Emergency Department

Drug	Loading Dose, Route, Therapeutic Range	Potential Adverse Effects
Carbamazepine	8 mg/kg oral suspension, single oral load Therapeutic level 4–12 μg/mL IV formulation recent; not widely available	Drowsiness, nausea, dizziness, nystagmus
Fosphenytoin	5–20 PE/kg depending on level IV at maximum rate of 150 PE/min; can also give IM Free level target ≈1.5 μg/mL; adjusted total level 15-20 μg/mL	Hypotension, bradycardia, nystagmus, dizziness, drowsiness
Gabapentin	900 mg/day oral at 300 mg tid for 3 days IV not available	Somnolence and fatigue, dizziness, myoclonus Uncommonly used as antiseizure regimen.
Lacosamide	200–400 mg IV or PO	Dizziness, somnolence, brady- or tachyarrhythmias
Levetiracetam	1000–2000 mg IV or PO	Somnolence or irritability. Usually well tolerated.
Oxcarbazepine	150–450 mg PO, single oral load IV formulation not available	Drowsiness, nausea, dizziness
Phenobarbital	15–20 mg/kg, IV or PO Therapeutic level 10–30 μg/mL	Drowsiness, sedation, hypotension
Phenytoin	5–20 mg/kg depending on level, IV or PO; if IV, infusion no faster than 50 mg/min Free level target ≈1.5 μg/mL; adjusted total level 15–20 μg/mL	Drowsiness, nausea, dizziness, nystagmus IV: Hypotension, bradyarrhythmias, extravasation injuries
Valproate	20–40 mg/kg depending on level, IV or PO Free level target 5–15 μg/mL; total level 50–100 μg/mL	Local irritation, thrombocytopenia, transaminitis, hyperammonemia

IM, Intramuscular; *IV*, intravenous; *PE*, phenytoin sodium equivalents; *PO*, by mouth
Medications were listed in alphabetic order; agent selection should be individualized.

Clinical policy: critical issues in the evaluation and management of adult patients presenting to the emergency department with seizures. *Ann Emerg Med.* 2014;63(4):437-447.e415; and Morris M, Owusu K, Maciel CB. Status epilepticus. In: Rabinstein A, ed. *Neurological Emergencies: A Practical Approach*. Vol 1. 1 ed: Springer: Switzerland; 2020:15-47.

specific guidelines address nonconvulsive status epilepticus, and treatment algorithms are extrapolated from convulsive status epilepticus literature. Nonconvulsive seizures and epileptiform patterns bordering nonconvulsive status epilepticus are associated with metabolic crisis in the acutely injured brain. The threshold for starting third-tier medications (anesthetic coma) should be ascertained based on the perceived risk-benefit assessment for each patient. For example, an older patient with focal refractory nonconvulsive status epilepticus and sepsis is not the ideal candidate for pentobarbital or high-dose midazolam, because the morbidity associated with this treatment may surpass the evidence justifying its benefits.

Inflammation-Related Seizures

Inflammation-related seizures and status epilepticus comprise a heterogeneous group of epilepsies that may be triggered by an infection, tumor (i.e., paraneoplastic syndrome), or idiopathic autoimmune response. In paraneoplastic and autoimmune cases, seizures tend to be refractory to conventional antiseizure therapies, and the role of immunotherapy has been increasingly recognized. High-dose methylprednisolone, intravenous immunoglobulin, rituximab, plasma exchange, cyclophosphamide, and more recently tocilizumab, are potential rescue therapies that have been reported with variable degrees of success. Immunotherapy for seizures and status epilepticus requires coordination of care with multiple specialties for most cases, such as hematology, neurology, and rheumatology.

DISPOSITION

Patients with status epilepticus and those with critical diagnoses require admission for continued monitoring for complications and response to therapy. Admission to the intensive or neurocritical care unit, when available, is preferred in patients who require therapeutic coma with anesthetic agents. Disposition plans are less straightforward in other scenarios, including those presenting after a first-time seizure. The best predictor of seizure recurrence is the causative etiology combined with EEG findings. This information often requires modalities that are not routinely available in the ED, and there are few ED-based studies to direct disposition. At present, there is insufficient evidence to guide the decision pertaining to admission. We recommend this decision be tailored to the patient and shared decision making be employed, taking into consideration the patient's access to follow-up care and social risk factors (e.g., alcohol use disorder or lack of health insurance). Patients with comorbidities (including those older than 60 years old), known cardiovascular disease, history of cancer, or history of immunocompromise, should be considered for admission to the hospital. Patients with medically refractory epilepsies who live in assisted care facilities are often best served by being discharged back to the facility if they have returned to their baseline following breakthrough seizures.

Patients and their families or caregivers should be counseled on basic safety measures to prevent complications during seizures. For example, patients should be advised to avoid swimming or cycling following a seizure, at least until they have been reassessed by their neurologist and their antiepileptic therapy optimized if needed. The need for a "medical alert" bracelet or other medical condition identifier should be considered, and state-specific regulations should be followed. A crucial point for seizure patients is education against driving. Although evidence remains controversial on this issue, there is general agreement that uncontrolled epileptic patients who drive are at risk for a motor vehicle collision, with potential injury to themselves and others. For this reason, most states do not allow these patients to drive unless they have been seizure-free on medications for at least 6 months to 1 year. Although physicians are required to report patients

with seizures to driving authorities in several states, mandatory reporting has not been proven to reduce the risk of motor vehicle crashes in patients with epilepsy.

Even a single seizure can induce an array of physical and psychosocial challenges that can affect the quality of life of the patient and caregivers. The psychological and social implications of the new diagnosis of a seizure disorder for the patient can be profound. Fear of seizures and stigmatization are common; employability and insurability may be adversely affected. Emergency clinicians may consider coordination with social work and the referral of patients with seizures to counseling and community-based local epilepsy support groups.

CHAPTER 88: QUESTIONS AND ANSWERS

1. Which of the following statements regarding the pathophysiology of seizures is *true?*

a. During a seizure, prompt loss of consciousness implies a cortical focus.

b. Generalized seizures involve abnormal electrical activity in one hemisphere.

c. Regarding seizure activity, acetylcholine is inhibitory.

d. The clinical seizure activity typically reflects the brain focus of initiation.

Answer: D. Clinical seizure activity typically reflects the site of seizure origin. Generalized seizures involve both brain hemispheres. Acetylcholine is an excitatory neurotransmitter, and GABA is inhibitory. Prompt loss of consciousness with a seizure implies a subcortical focus involving the reticular activating system.

2. Which of the following statements regarding epilepsy is *true?*

a. Electrolyte disturbances are the most common cause of recurrent seizures in epileptic patients.

b. Epilepsy is a condition of recurrent provoked seizures.

CHAPTER 88: QUESTIONS AND ANSWERS—cont'd

c. Epileptic seizures are always generalized tonic-clonic.
d. Epileptic seizures can be triggered by smells or lack of sleep.

Answer: D. Epilepsy is a condition of recurrent, *unprovoked* seizures. Idiopathic epilepsy almost always starts in childhood. Medication noncompliance is the most common cause of recurrent seizures in epileptic patients. Epileptic seizures can be partial seizures. Some patients with epilepsy have seizures triggered by certain specific sensory stimuli, with flashing lights being the most well-known of these.

3. Which of the following factors does not put patients at risk for seizures?
   a. Acute stroke
   b. Chronic stroke-related lesions
   c. Hyperkalemia
   d. Hypomagnesemia

Answer: C. Indwelling intracranial shunts and other lesions, and hypomagnesemia (as seen in malnourished alcohol-dependent patients) are all risk factors for seizures. Stroke is one of the most common causes of seizures in the elderly. Seizures occurring acutely with a stroke are often partial and reflect the affected brain area, whereas those that occur chronically are often generalized. Hyperkalemia does not cause seizures unless it precipitates hypotension and consequent hypoperfusion of the brain.

4. Which of the following statements regarding patients presenting with first-time seizures is *true?*
   a. All patients should have basic serum electrolyte testing.
   b. All patients should receive a loading dose of an antiepileptic drug and a prescription for an oral regimen prior to discharge.
   c. Nondiabetic patients do not need to have serum glucose checked if their mental status returns to normal.
   d. Persistent altered mental status is an indication for a lumbar puncture.

Answer: D. Persistent altered mental status should trigger consideration of a lumbar puncture, serum glucose, and an electroencephalogram (EEG) among other testing. Non-contrast CT of the head is relatively high-yield in first-time seizure patients, and most guidelines recommend performing one. Patients with no comorbidities who return to baseline mental status do not need broad-based electrolyte testing, but hypoglycemia is a common cause of seizures even in nondiabetic patients and should be routinely tested for in first-time seizure patients. Initiation of antiepileptic drugs in the emergency department (ED) for first-time seizure patients without a known structural brain lesion may do more harm than good.

5. A 23-year-old woman is brought to the emergency department (ED) for a prolonged seizure. By emergency medical service (EMS) report, the patient has no past medical history and no history of seizures. Paramedics report tonic-clonic activity for approximately 15 minutes, refractory to diazepam 5 mg intravenously in the ambulance. Upon arrival to the ED, the patient's seizure activity abruptly ceases, and she lucidly responds to the history and physical examination. She is symptom free. What would be the most appropriate intervention?
   a. A trial of oral phenytoin after an intravenous (IV) loading dose in the ED
   b. Confrontation
   c. Neurology referral for electroencephalogram (EEG) and consultation
   d. Psychiatric consultation

Answer: D. No clinical criteria are 100% specific for the diagnosis of nonepileptic activity. Seizures and nonepileptic activity may coexist. For many patients, these episodes may not be deliberate. The most prudent course of action would be to treat them as possible ictus and refer to a neurologist. Initiation of antiepileptic drugs in the ED is not indicated in first-time seizures of healthy patients who return to normal.

89

Headache Disorders

Benjamin W. Friedman

KEY CONCEPTS

- The goals of headache evaluation in the ED are (1) to distinguish between benign primary headache disorders and potentially life-threatening secondary causes of headache and (2) to treat the headache pain effectively and rapidly without causing undue side effects.
- Patients with the following headache presentations are at risk for serious underlying disease: sudden explosive headache; new-onset headache after the age of 50 years; headache associated with papilledema, alteration in or loss of consciousness, or focal neurologic symptoms; subacute headache with increasing frequency or severity; headache associated with fever, cancer, or immunosuppression; and headache triggered by exertion, sexual activity, or Valsalva maneuver.
- The need for diagnostic studies is dictated by the suspected secondary cause of headache.
- Antidopaminergic agents, such as metoclopramide or prochlorperazine, are first-line therapy for migraine.
- Opioids are not first-line therapy for the primary headaches.
- Patients with migraine treated in the ED require a discharge "rescue plan" if the headache recurs.
- High-flow oxygen will terminate the majority of cluster headaches.
- The differential diagnosis of sudden severe headache includes subarachnoid hemorrhage, cerebral venous thrombosis, cervical artery dissection, and idiopathic intracranial hypertension.
- Cerebral venous thrombosis should be suspected in women who have a new type of headache and are pregnant or on birth control pills.
- Carotid artery dissection may cause headache, ptosis, and miosis.
- Patients with post-traumatic headache should only be imaged if they have high-risk features on the Canadian CT Head rule.

Headache is divided into primary and secondary disorders. *Primary headache disorders* include migraine, cluster, and tension-type headaches, and represent the majority of headaches seen in clinical emergency practice. *Secondary headache disorders* include a variety of organic illnesses in which head pain is a symptom of an identifiable, distinct pathologic process. To facilitate a standardized approach to headache management, the International Headache Society published a classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain.[1] This comprehensive and widely accepted system includes 14 major categories of headache disorders and uses specific operational diagnostic criteria to define each headache type (Box 89.1). Most patients presenting to an ED with headache have a benign process requiring only symptomatic treatment and referral. The challenge for the emergency clinician is to identify the very small subset of patients who have headache as a symptom of a serious or potentially life-threatening disease.

PRIMARY HEADACHE DISORDERS

Migraine Headache

Principles

Migraine is a common, chronic, sometimes incapacitating neurovascular disease characterized by recurrent attacks of severe headache, autonomic nervous system dysfunction, and, in some patients, an aura causing visual, sensory, motor, or other neurologic symptoms. It is a primary headache disorder with a genetic basis.

Migraine is a common disorder; attacks typically begin in the second decade of life and peak in prevalence in the fourth decade, affecting about 1 of 4 women and 1 of 12 men. There is no gender difference in the prevalence of migraine in children. After menopause, the prevalence of migraine among women decreases.

Historically, migraine headaches were considered to be vascular in origin. However, this hypothesis is no longer tenable as alterations in cerebral blood flow do not correlate with the various phases of the headache attack or vascular territories and do not explain features of an acute migraine, such as premonitory mood disturbances, nausea, and osmophobia (aversion to odors). Rather, vascular changes are now thought to be an epiphenomenon to what is a primary neurologic event. Abnormal trigeminal nerve and thalamic activity, possibly triggered by a sterile neuropeptide-induced inflammatory process, leads to activity and sensitization of higher order neurons in the brainstem and thalamus. Descending modulation is likely to be compromised as well. It is not yet known what initiates the pathophysiologic process that leads to a migraine attack. Migraine is commonly thought of in two major categories: (1) migraine without aura, which accounts for approximately 75% of all cases (Box 89.2); and (2) migraine with aura, which has specific reversible neurologic symptoms that precede the actual headache (Box 89.3). Cortical spreading depression, a neuroelectrical event characterized by a slow wave of depolarization, is the mechanism behind the symptom of migraine aura.

Clinical Features

Migraine is by definition a chronic and recurrent disease. The headache, characteristically, is unilateral, pulsating in quality, moderate to severe in intensity, and exacerbated by routine activities. The side of the headache can vary with individual attacks, and the headache may be bilateral in 40% of patients. The onset usually is gradual, and the attacks typically last 4 to 72 hours. Headache frequency is variable;

BOX 89.1 International Headache Society Classification of Headaches

Primary Headaches

1. Migraine
2. Tension-type headache
3. Cluster headache and trigeminal autonomic cephalalgias
4. Other primary headaches

Secondary Headaches

5. Headache attributed to trauma or injury to the head or neck
6. Headache attributed to cranial or cervical vascular disorder
7. Headache attributed to nonvascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache attributed to psychiatric disorder

Painful Cranial Neuropathies, Other Facial Pains, and Other Headaches

13. Cranial neuralgias and other facial pain
14. Other headache disorders

BOX 89.2 Migraine Without Aura Criteria

A. At least five attacks fulfilling criteria in B, C, D, and E
B. Attack lasts 4 to 72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate to severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
D. During headache, at least one of the following:
   1. Nausea or vomiting (or both)
   2. Photophobia and phonophobia
E. Not attributable to another disorder

Reproduced with permission of International Headache Society, Headache Classification Committee of the International Headache Society (IHS). The International Classification of Headache Disorders, 3rd edition. *Cephalagia* 2018;38:1–211.

BOX 89.3 Migraine With Aura Criteria

A. At least two attacks that fulfill criterion B
B. Presence of at least three of the following four characteristics for a diagnosis of classic migraine:
   1. One or more fully reversible aura symptoms indicating focal cerebral cortical or brainstem dysfunction (or both)
   2. At least one aura symptom developing gradually over more than 4 minutes, or two or more symptoms occurring in succession
   3. No single aura symptom lasting longer than 60 minutes
   4. Headache beginning *during* aura or *afterward,* with a symptom-free interval of less than 60 minutes (also may begin *before* aura)
C. Exclusion of related organic diseases by means of an appropriate history, physical examination, and neurologic examination with appropriate diagnostic tests

Reproduced with permission of International Headache Society, Headache Classification Committee of the International Headache Society (IHS). The International Classification of Headache Disorder, 3rd edition. *Cephalagia* 2018;38:1–211.

those patients with more than 15 headache days per month are considered to have chronic migraine. Associated symptoms and signs include nausea, vomiting, anorexia, photophobia, phonophobia, osmophobia, blurred vision, lightheadedness, vertigo, muscle tenderness, and nasal congestion. Many patients have dramatic light and sound sensitivity and seek a dark, and quiet room. Some patients experience premonitory cognitive impairment during the days leading up to the acute attack producing forgetfulness, irritability, and depression.

The migraine aura consists of focal neurologic symptoms that usually precede the headache, though patients may experience aura without headache. By definition, the aura is fully reversible and typically lasts 10 to 20 minutes, although it may continue for as long as 1 hour. The most common aura is visual; features may include scintillating scotoma (bright rim around an area of visual loss), teichopsia (subjective visual image perceived with eyes open or closed), fortification spectra (zigzagged lines that slowly drift across the visual field), photopsias (poorly formed brief flashes or sparks of light), and blurred vision. Less common auras include somatosensory phenomena, such as tingling or numbness, motor disturbances, and cognitive or language disorders.

Retinal migraine is a rare syndrome consisting of recurrent attacks of monocular visual dysfunction, including positive features (such as scintillations) or negative features (such as blindness). As with aura, these symptoms are completely reversible.

Hemiplegic migraine is characterized by a motor aura consisting of hemiparesis or hemiplegia. The progression of the motor deficit is gradual and, in most cases, is accompanied by a visual, sensory, or speech disturbance. The neurologic symptoms last up to 60 minutes, followed by headache. Rarely, the motor deficit is persistent, resulting from a true stroke. A familial version of hemiplegic migraine is associated with genetic channelopathies.

Migraine with brainstem aura presents with an aura referable to the brainstem. Common neurologic findings include dysarthria, tinnitus, vertigo, diplopia, and altered level of consciousness.

Status migrainosus is a severe unremitting migraine headache that persists unabated for more than 72 hours.

Many factors can trigger migraine headaches in predisposed persons. Common precipitants include sleep deprivation, stress, hunger, hormonal changes, including menstruation, and use of certain drugs, including oral contraceptives and nitroglycerin. In addition, some patients report specific food sensitivities to chocolate, caffeine, and foods rich in tyramine, monosodium glutamate, and nitrates. Alcohol, specifically red or port wine, has also been implicated. In others, certain sensory stimuli, such as a strong glare or strong odors, loud noises, and weather changes, can trigger an attack.

Differential Diagnoses

Among patients without stereotypical recurrent headaches, migraine may be difficult to distinguish from secondary causes of headache, see Chapter 16 and Table 16.1. Headaches with an acute onset may have a cerebrovascular etiology. Headaches that have lingered for longer than several weeks may be due to an intracranial mass lesion or other causes of high cerebrospinal fluid (CSF) pressure. Headaches that occur in the setting of upper respiratory infections may be due to sinus inflammation. Medication overuse headache, which is a disorder characterized by worsening headache frequency in the setting of increased use of analgesic or migraine abortive medication, may coexist with migraine.

Diagnostic Testing

Neuroimaging is not necessary for patients with typical recurrent migraine headaches. Neuroimaging should be considered for older or immunocompromised patients with new-onset headaches, headaches associated with unexplained neurologic abnormalities, and new headaches with an abrupt onset. (Please see Chapter 16 for the diagnostic

TABLE 89.1 Selected Medications for Acute Migraine Attacks

Medication	Dosage and Route Administered	Comments
Oral Medication		
Ibuprofen	400 mg PO	Gastrointestinal upset
Naproxen sodium	500 mg PO	Gastrointestinal upset
Acetaminophen + metoclopramide	650 mg + 10 mg PO	Combination therapy has better efficacy than acetaminophen alone
Sumatriptan	50–100 mg PO	Use cautiously in patients with cardiovascular risk factors
Eletriptan	40 mg PO	Use cautiously in patients with cardiovascular risk factors
Ubrogepant	50–100 mg	May cause transaminitis
First-Line Parenteral Medication		
Prochlorperazine	10 mg IV	Sedation and dystonic reaction
Metoclopramide	10 mg IV	Dystonic reaction
Droperidol	2.5 mg IV	QT prolongation; dystonic reaction
Ketorolac	15 mg IV or 15 mg IM	Gastrointestinal upset; avoid this medication in elderly patients and in patients with renal insufficiency
Sumatriptan	6 mg SC	Chest pain, throat tightness, flushing Contraindicated with hypertension, coronary artery disease, peripheral vascular disease, and pregnancy Cannot be used within 24 hours of ergot use
Second-Line Parenteral medication:		
Dihydroergotamine (DHE)	1 mg IV or IM; may be repeated in 1 hour	Nausea (pretreat with antiemetic) Often causes chest pain Caution in inhibitors of enzyme CYP450 3A4
Magnesium sulfate	2 g IV	More efficacious in migraine with aura
Procedures		
Greater occipital nerve block	6 mL of bupivacaine 0.5% injected bilaterally	Can also target lesser occipital nerve
To Prevent Headache Recurrence After Emergency Department Discharge		
Dexamethasone	10 mg IV	Use cautiously in diabetics

IM, Intramuscular; *IV,* intravenous; *PO,* per os (by mouth); *SC,* subcutaneous.

algorithm.) Such patients have a higher likelihood of having a secondary cause of headache, such as an intracranial bleed or space-occupying lesion. Among patients with an acute migraine headache, laboratory testing should be limited to a pregnancy test for those who are to be treated with medications that may be teratogenic and electrolytes for those patients with marked nausea, anorexia, or vomiting sufficient to require intravenous (IV) fluid hydration.

Management

The pharmacologic treatment of migraine is divided into abortive therapies, which attempt to limit the intensity and duration of a given episode, and preventive therapies, which are intended to decrease the frequency and intensity of attacks. The goals of abortive therapy include rapid pain relief, minimization of headache recurrence and medication side effects, and restoration of the patient's ability to function.

There are several approaches to treatment of the acute headache episode, depending on the severity of the attack (Table 89.1).[2] The choice of agents depends on the patient's previous response to specific therapies, the existence of comorbid conditions, and the presence or absence of nausea or vomiting. Gastric stasis is common during acute migraine attacks and may limit the effectiveness of oral agents.

For mild to moderate attacks, simple analgesics such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen or naproxen, are often effective. In the presence of nausea or vomiting, administration of intravenous metoclopramide 20 to 30 minutes before the oral analgesic enhances the absorption and effectiveness of these medications. Appropriate doses for these and other oral medications are listed in Table 89.1.

For moderate to severe attacks, three classes of medications are recommended as initial parenteral therapy: the antiemetic dopamine antagonists, such as metoclopramide and prochlorperazine; migraine-specific agents, such as the triptans and dihydroergotamine (DHE); and parenteral nonsteroidal medications, such as ketorolac.

Dopamine antagonists, such as the neuroleptic prochlorperazine, and the antiemetic metoclopramide, are highly effective as monotherapy for acute migraine attacks. Because of their efficacy, safety, tolerability, and few contraindications, we recommend either of these agents as first-line therapy for acute migraine. Metoclopramide is a less potent antinauseant, and is less likely to induce drowsiness and sleep, which can be factored into the choice of agents, depending on the patient's circumstances. For this class of medication, the mechanism of action is not known, but migraine pathogenesis likely involves dopaminergic pathways. The most common side effects after parenteral administration include sedation and extrapyramidal symptoms, most notably akathisia, which can be treated with diphenhydramine, 25 to 50 mg IV, or midazolam, 2 mg IV.

Sumatriptan, the first-approved medication of the triptan class, a class of selective 5-HT (1B/1D) receptor agonists, is the most frequently used triptan in the ED, and is available for oral (50 to 100 mg)

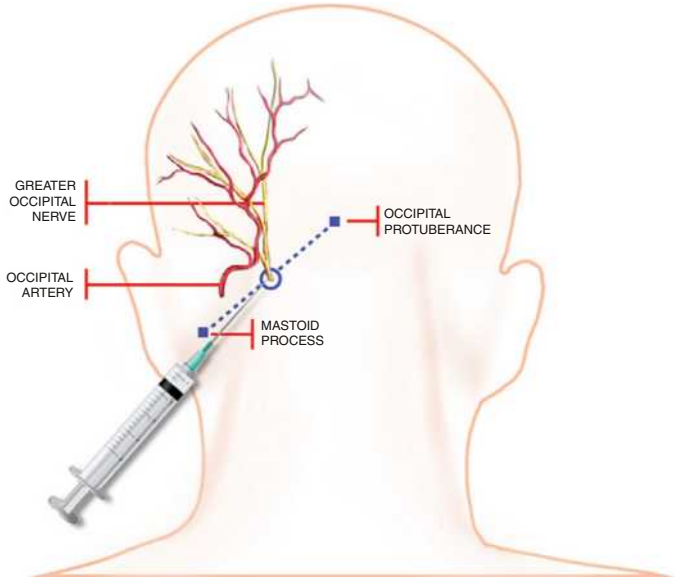

Fig. 89.1 Technique of Greater Occipital Nerve Block. The injector identified the appropriate location using landmarks on the patient's head. The medial landmark was the occipital protuberance. The lateral landmark was the mastoid process. Using these landmarks to form a line, the injector identified the correct location, which was one-third of the distance from the occipital protuberance along this line (two-thirds of the distance away from the mastoid process). The injector felt for pulsation of the occipital artery and attempted to elicit pain or paresthesia in the distribution of the GON by pressing slightly. The injector then used a fan technique, placing 1 mm of anesthetic at the correct spot, 1 mm slightly medial of the correct spot, and 1 mm slightly lateral to the correct spot.

and subcutaneous (6 mg) administration; the latter is more efficacious but also more likely to cause adverse effects. If the patient has experienced insufficient relief with sumatriptan previously, eletriptan 40 mg orally may be administered. Common side effects of triptans include tingling, flushing, warm or hot sensations, heaviness in the chest, and initial worsening of the underlying headache. Sumatriptan is contraindicated in patients with coronary artery disease and should not be used within hours of administration of an ergotamine-containing medication. Sumatriptan is classified as a category C drug for pregnancy, though there does not seem to be an increase in adverse pregnancy outcomes with its use. A smaller dose of subcutaneous sumatriptan may limit side effects.

DHE is often effective when prochlorperazine or metoclopramide have failed, and is administered intravenously in a dosage of 1 mg over 2 minutes; this can be repeated in 1 hour if pain control has not been achieved. Because DHE can cause nausea and vomiting, patients who have not already received an antiemetic, should be given metoclopramide 10 mg IV or prochlorperazine 10 mg IV at least 15 minutes before administration of DHE. Contraindications to use of DHE include pregnancy, breast-feeding, poorly controlled hypertension, coronary artery disease, and peripheral vascular disease. DHE should not be used if the patient has already taken any drug in the triptan class or if the patient is using macrolides or protease inhibitors.

Alternatively, greater occipital nerve block with bupivacaine 0.5% may be attempted among patients with symptoms refractory to first-line medications (Fig. 89.1).

Calcitonin gene related peptide (CGRP) receptor antagonists and monoclonal antibodies likely will play an increasing role in the management of migraine in the coming years as multiple placebo-controlled studies have demonstrated safety and efficacy. The relative efficacy and safety of these medications vis-à-vis the antidopaminergic antiemetics is still unknown. It is clear that CGRP is released during acute migraine attacks and contributes to migraine symptoms.

Opioid analgesics are nonspecific for migraine pain, and rarely, if ever, are indicated in the treatment of acute migraine. They have not been shown to be more effective than nonsteroidal antiinflammatory agents for treatment of migraine. Opioid requests by patients with "migraine" often represent misunderstanding of effective therapy based on past experience. We recommend that opioids not be used for treatment of migraine. Rare cases may exist where a neurologist who knows the particular patient's syndrome rationally validates the use of opioids. Opioids should not be administered on the basis of a "doctor's letter" or other document produced by the patient (see Chapter 151).

Status migrainosus can often be treated successfully using the various medications or combinations of the medications discussed in the previous paragraphs.

Recurrence of migraine within 24 hours of ED discharge occurs in two-thirds of patients who initially improve after treatment in the ED, regardless of medication administered or pain intensity at discharge. Patients should be discharged home with oral medication to treat the headache recurrence, such as naproxen 500 mg or sumatriptan 100 mg. Dexamethasone 10 mg IV decreases migraine recurrence after ED discharge and should be administered to all patients without contraindications.[2]

Preventive therapy is indicated for patients who have more than two or three functionally disabling headaches per month. Several classes of medications are used for migraine prevention, including beta-blockers, tricyclic antidepressants, antiepileptic drugs, and botulinum toxin. Patients who meet criteria for preventative therapy and are not on it, and those for whom preventative therapy has failed, should be referred to a primary care physician or neurologist for evaluation.

Disposition

Most patients who present to an ED for treatment of migraine can be treated and discharged after one or several doses of medication and IV fluids if required. Only rarely do patients with migraine require hospitalization. Patients requiring admission often have chronic migraine, with more than 15 days of migraine monthly, or concomitant *medication overuse headache*. Migraine patients admitted to the hospital receive IV fluids, frequent doses of parenteral migraine medication, and detoxification from medications contributing to the overuse headache.

Cluster Headache

Principles

Cluster headache is the only headache syndrome that is more common in men than in women. It typically occurs in young to middle-aged adults who smoke, almost always onsetting before the age of 50 years. The headaches tend to occur repeatedly during a defined time interval, hence the term *cluster.* Several attacks can occur in a single day, and a typical cluster period may last weeks to months. Several precipitating factors have been implicated, most notably the ingestion of alcohol. Stress and climate changes may also play a role in susceptible persons. As with migraine, abnormal activation of the trigeminal nerve contributes to headache nociception. Typically, secondary parasympathetic activation causes ipsilateral lacrimation and rhinorrhea, a characteristic of cluster headache syndrome.

Clinical Features

Cluster headaches occur suddenly with little warning, and multiple episodes can occur within a 24-hour period. Each headache lasts from 15 minutes up to 3 hours, with a mean duration of about two hours.

TABLE 89.2 Treatment of Cluster Headaches

Medication	Dosage and Route Administered	Comments
Acute Treatment		
First-Line		
Sumatriptan	6 mg SQ	
Oxygen	At least 6–12 L/ min	
Second-Line		
Octreotide	100 micrograms SQ	GI symptoms
Metoclopramide	10 mg IV	Dystonic reaction
Discharge Treatment		
Dexamethasone	10 mg IM or IV	Most efficacious dose unknown
Verapamil	240–480 mg/day PO in 2–4 divided doses	May cause constipation, use cautiously if BP or HR are low
Melatonin	10 mg qHS	Well tolerated

The headache typically begins with a unilateral sharp, stabbing pain in the eye, which may awaken the patient from sleep. The attacks occur exclusively in the territory of the trigeminal nerve. Unlike the patient with migraine, the patient with cluster headache presents agitated and anxious, rocking, rubbing the head, and pacing. The attack subsides rapidly, often leaving the patient exhausted.

Accompanying the headache are ipsilateral autonomic symptoms, such as ptosis, miosis, and forehead or facial sweating. The eye often is injected and tearing, and many patients have unilateral nasal congestion or rhinorrhea.

Differential Diagnoses

Other headache disorders that mimic cluster headache include carotid artery dissection, trigeminal neuralgia, and rare trigeminal autonomic cephalalgias, including paroxysmal hemicranias and short-lasting uniform neuralgiform headache attacks with conjunctival injection and tearing (SUNCT). Carotid artery dissection should be excluded as the diagnosis in patients who present with unilateral face or neck pain and Horner syndrome. With trigeminal neuralgia, the pain peaks within seconds, lasts only a few minutes, and can be provoked by specific trigger points on the face or oral mucosa. The less common trigeminal autonomic cephalalgias are manifested by brief unilateral headaches that recur dozens of times per day, often accompanied by the same unilateral eye and nasal symptoms as cluster.

Diagnostic Testing

Diagnostic testing is not indicated for patients with a well-established history of cluster headache. Cluster headache is a characteristic syndrome with specific onset, distribution, duration, and accompanying symptoms, so in patients younger than 50 years without a prior diagnosis, particularly if they have a previous pattern of similar attacks, the presumptive diagnosis can be made with confidence. Patients with a presentation more consistent with carotid artery dissection, particularly neck pain, Horner syndrome, or unilateral neurologic deficit, should undergo neurovascular imaging

Management

Treatment should focus both on relieving the acute headache and preventing the next headache in the cluster (Table 89.2). Because cluster headache is brief in duration, it may resolve before a patient presents to medical attention. For acute headache relief, high-flow oxygen is first-line therapy. It should be administered at rates of 15 liters/minute or greater through a non-rebreather mask until that headache has remitted completely. High-flow oxygen aborts the headache within 15 minutes in approximately 80% of patients. Subcutaneous sumatriptan, 6 mg, is also an effective therapy for acute cluster headache if the headache fails to resolve after 20 to 25 minutes of high-flow oxygen.[8] Larger doses do not confer additional benefit and may contribute to medication side effects. Antidopaminergic agents and NSAIDs can be used if the patient does not experience relief with oxygen and sumatriptan or if the patient has contraindications to the latter. As with migraine, opioid medications are not indicated for treatment of acute cluster headache, in part because of the evanescent nature of the headache symptoms.

Once the acute attack has been relieved, focus shifts to the ongoing "cluster" of headaches that likely will recur over hours to days. Corticosteroids have long been theorized to help break the cluster, although high-quality evidence is not available. Based on retrospective data, we recommend a 10-day prednisone taper, starting with 60 mg for at least two days. Verapamil, dosed at 120 mg three times a day, may decrease the frequency of attacks by the end of the first week of therapy and should be considered for patients without calcium channel blocker contraindications who are discharged from the ED.

Disposition

Patients with cluster headache usually do not require admission to the hospital. Because these headaches are likely to continue over the following days and weeks, the patient should be referred to a physician with expertise in headache management.

Tension-Type Headache

Principles

Tension-type headache is the most common recurrent headache disorder, with one year prevalence of 40% of the population in the United States, but it is an infrequent cause of ED visits. Women are affected slightly more frequently than men, and as with migraine, peak prevalence is in the fourth decade of life. These headaches typically do not cause substantial functional disability, and patients are able to continue with their normal daily activities. Autonomic symptoms, such as nasal congestion, nausea, or vomiting are absent. By definition, episodic tension-type headache lasts as little as 30 minutes and as long as 7 days.

The pathophysiology underlying tension-type headache is not yet clear. There is no consistent evidence that increased muscle activity is present. Physical examination will reveal tender areas of the scalp and neck with both tension and migraine headaches. Despite different epidemiologic profiles, a similar response to many therapeutics suggests

that tension and migraine headaches may share pathophysiologic mechanisms.

Clinical Features

Patients typically complain of a tight, bandlike discomfort or pressure around the head that is nonpulsating and dull. They also may experience tightening of the neck muscles. A majority of patients do not seek medical assistance, because the headache usually is mild in intensity and not functionally disabling. On occasion, the discomfort can build up slowly and fluctuate in severity for several days. Unlike in migraine, the headache does not worsen with physical activity, and accompanying symptoms (such as nausea, vomiting, phonophobia, and photophobia) are unusual. Anxiety and depression may coexist with chronic tension headache, which by definition, occurs more than 15 days a month and can be daily and unremitting.

Differential Diagnoses

Tension headache is the least distinct of all of the primary headache disorders, and its diagnosis is based mainly on the absence of features that would suggest another headache diagnosis. The most common disorders mimicking tension headache are migraine, IIH, cervical spondylosis, sinus or eye disease, and intracranial masses. Subtle indolent infections (such as cryptococcal meningitis) should be considered in the immunocompromised.

Diagnostic Testing

Patients who present with a headache similar in quality to previous headaches do not require diagnostic evaluation in the ED. New-onset headache with features of tension-type headache requires evaluation in patients 50 years and older, as well as immunocompromised patients. This evaluation can take place in the outpatient setting, where a scheduled MRI offers more sensitivity for a range of pathologies than a noncontrast CT.

Management

Because the pain of tension-type headache is rarely severe or disabling, the emergency physician should try to understand why the patient with tension-type headache presented to the ED. For a majority of patients with tension headaches, simple analgesics, such as acetaminophen or an NSAID, are adequate for pain control. Opioids are never indicated and consideration of a need for any parenteral treatment, such as metoclopramide, should prompt serious concern that the diagnosis of tension headache is not correct. For chronic outpatient management, acupuncture has shown benefit for some patients. Despite muscle pain and tenderness in many of these patients, spinal manipulation therapy is unlikely to provide a benefit for most patients.

Disposition

Absent comorbidities, patients with tension-type headache do not require admission to the hospital. Chronic tension-type headache is difficult to manage; these patients often have underlying mental health or personal stress issues, and should be referred to clinicians who can evaluate them for these underlying issues and work with them over time.

SECONDARY HEADACHE DISORDERS

Subarachnoid Hemorrhage

Principles

SAH refers to extravasated blood in the subarachnoid space. (For discussion of other intracranial hemorrhages, please see Chapter 87.) Presence of the blood activates meningeal nociceptors, leading to headache and, in about one-third of cases, signs of meningismus. SAH accounts for up to 10% of all strokes and is the most common cause of sudden death from a stroke.

Approximately 80% of patients with nontraumatic SAH have ruptured saccular (berry) aneurysms, which are small (usually <15 mm diameter) aneurysms that usually form at or near the junction of major cerebral vessels, particularly within the circle of Willis. The remainder are in the posterior circulation, particularly the basilar artery and its ramifications. Approximately 25% of people with a berry aneurysm have more than one aneurysm, and most aneurysms do not rupture, but are found incidentally by cerebral imaging or by autopsy. Other etiologies requiring emergent treatment include arteriovenous malformations, cavernous angiomas, mycotic aneurysms, neoplasms, and CNS vasculitis. Perimesencephalic hemorrhage is a benign form of SAH, in which a localized hemorrhage occurs anterior to the midbrain, without extension, and with no vascular abnormalities on cerebral vascular imaging. These hemorrhages resolve spontaneously and do not require intervention. SAH may also be caused secondarily by an intraparenchymal hematoma that dissects its way into the subarachnoid space.

The risk for aneurysmal SAH increases with age; most cases occur between 40 and 60 years old. In children and adolescents, aneurysms are uncommon, and SAH usually is secondary to an arteriovenous malformation. It is estimated that 2% of the general population harbor a berry aneurysm, with the vast majority never rupturing. Risk of rupture appears to be related to the rate of growth of the aneurysm and increases with aneurysmal size. Other risk factors associated with SAH include hypertension, smoking, excessive alcohol consumption, and use of sympathomimetic drugs. Both genetic and familial associations of cerebral aneurysms have been identified, and there is association with several diseases, including autosomal dominant polycystic kidney disease, coarctation of the aorta, Marfan syndrome, and Ehlers-Danlos syndrome type IV.

Less than 1% of patients presenting to the ED with a primary complaint of headache have SAH, but the diagnosis is of great importance because of the morbidity and mortality associated with aneurysmal rupture. One-quarter of patients with SAH die before reaching the hospital. Median mortality in the United States is about one-third with approximately one-third of survivors having functional and cognitive deficits.

Clinical Features

The clinical presentation of SAH is often distinctive. Most patients present with a sudden, cataclysmic thunderclap headache, which often is described as the worst headache of one's life. The onset of headache may be associated with exertion, the Valsalva maneuver, or sexual intercourse, but the majority occur in the absence of strenuous physical activity. The headache of SAH classically peaks in intensity within seconds to minutes. Headaches that take longer than 60 minutes to peak in intensity are unlikely to be SAH. Associated signs and symptoms include syncope, nausea and vomiting, neck stiffness, photophobia, and seizures. The patient may experience sudden syncope as the initial manifestation, with headache occurring as the patient regains consciousness and increasing thereafter.

Physical findings depend on the extent of the SAH. Up to 20% have focal neurologic abnormalities. Patients may have isolated third or sixth nerve palsy or meningismus. Oculomotor (third) nerve compression secondary to an expanding posterior communicating artery aneurysm causes pupillary dilation. Approximately 50% of patients with a ruptured aneurysm are restless or have a fluctuating or altered level of consciousness. Up to one-third of patients recall an earlier, less severe episode of headache (sentinel headache) days to weeks before the diagnosis of subarachnoid hemorrhage.[3]

TABLE 89.3 Hunt and Hess Clinical Grading Scale for Cerebral Aneurysms and Subarachnoid Hemorrhage

Grade	Condition
0	Unruptured aneurysm
1	Asymptomatic or minimal headache and slight nuchal rigidity
2	Moderate or severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
3	Drowsiness, confusion, or mild focal deficit
4	Stupor, moderate to severe hemiparesis
5	Deep coma, decerebrate posturing, moribund appearance

BOX 89.4 Ottawa Subarachnoid Clinical Decision Rule

Age ≥ 40 years
Neck pain or stiffness
Loss of consciousness
Onset during exertion
Thunderclap (instantly peaking) headache
Limited neck flexion on examination

(Absence of all of these features obviates the need for further diagnostic workup.)

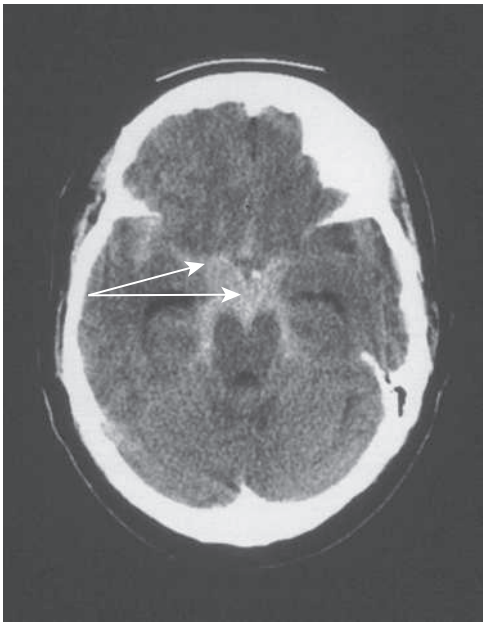

Fig. 89.2 Cerebral Aneurysm. Shown is a computed tomography (CT) scan of an aneurysmal subarachnoid hemorrhage (SAH) in a 55-year-old woman. Subarachnoid blood can be seen within the interpeduncular and ambient cisterns and the right sylvian fissure from a ruptured aneurysm at the junction of the right carotid artery and the posterior communicating artery. (From Brisman JL. Neurosurgery for cerebral aneurysm. Emedicine, updated Sep 23, 2010. Available at http://emedicine.medscape.com/article/252142-overview#a1.)

The patient's prognosis is related to neurologic status at hospital admission. The Hunt and Hess scale stratifies patients according to their clinical signs and symptoms at the time of presentation and is predictive of outcome (Table 89.3). Patients who present with a grade 1 or grade 2 hemorrhage tend to have a good prognosis. Patients with grade 4 or 5 hemorrhages tend to do poorly, presenting with an altered mental status, ranging from stupor to deep coma, together with focal neurologic signs and symptoms. Patients with grade 3 hemorrhage present with drowsiness or confusion and are at risk for rapid clinical deterioration.

Differential Diagnoses

Several clinical entities can mimic the abrupt onset headache associated with SAH. These include cervical artery dissection (CAD), cerebral venous thrombosis (CVT), reversible cerebral vasoconstriction syndrome, hemorrhagic or ischemic stroke, and primary headache disorders, including migraine and cluster headaches. CNS infections cause altered mental status and meningismus but can usually be distinguished by the presence of fever and much longer period of onset.

Diagnostic Testing

The Ottawa clinical decision rule can help risk stratify patients with possible SAH. In this rule, high (near 100%) sensitivity is achieved, but with low (less than 20%) specificity. Use of the rule may not improve accuracy compared to clinical gestalt, but a diagnosis of SAH is of sufficient gravity that high use of advanced imaging for diagnosing "positive" patients is justified (Box 89.4).

A non–contrast-enhanced head CT scan should be obtained emergently when SAH is suspected (Fig. 89.2). For acute hemorrhages less than 24 hours old, the sensitivity of third-generation multidetector row CT scanners in identifying hemorrhage is greater than 90%; however, sensitivity decreases to approximately 50% by the end of the first week, as blood is resorbed. The sensitivity of non–contrast-enhanced head CT performed within 6 hours of headache onset approaches 100%. For patients in whom CT has been performed more than 6 hours after headache onset, a normal non-contrast CT should be followed with subsequent diagnostic testing, which may include spinal fluid analysis or cerebrovascular imaging.[4] The choice of whether to perform LP or a subsequent imaging test depends upon patient preference, local availability, and what else is on the differential diagnosis. For example, if the physician is also concerned about meningitis or idiopathic intracranial hypertension, then an LP would be preferred; if the differential diagnosis includes other neurovascular etiologies such as cervical artery dissection or reversible cerebral vasoconstriction syndrome, then imaging is preferred. Options for cerebrovascular imaging include computed tomography angiography (CTA) or magnetic resonance angiography (MRA). The two-stage approach (non-contrast CT first followed by vascular imaging) is as sensitive as non-contrast CT followed by LP.

Interpretation of LP results can be challenging because up to one-third of spinal fluid analyses contain blood or blood degradation products. The presence of xanthochromia may help differentiate a traumatic LP from SAH. This yellowish pigmentation is secondary to the metabolism of hemoglobin to pigmented molecules of oxyhemoglobin and bilirubin, a process that can take up to 12 hours to occur. SAH cannot be ruled out if a substantial number of RBCs persist in tube 4; however, an RBC count of less than 100 in tube 4 indicates that aneurysmal SAH does not need to be pursued further. CSF xanthochromia in association with normal findings on the CT scan is suggestive of SAH. After the diagnosis is established, angiography should be performed to study the vascular anatomy and to identify the source of hemorrhage.

A normal non–contrast-enhanced head CT scan followed by a normal spinal fluid analysis definitively rules out SAH and does not need to be followed with angiography, even in patients at high risk of disease. However, this strategy does not rule out other causes of thunderclap headache that may be in the differential diagnosis, such as cervical

artery dissection, cerebral venous sinus thrombosis, and reversible cerebral vasoconstrictor syndrome.

Up to 90% of patients with SAH have cardiac arrhythmias or electrocardiographic abnormalities suggestive of acute cardiac ischemia, which may lead to an erroneous primary cardiac diagnosis, especially when syncope has occurred. Typical electrocardiographic findings include ST-T wave changes, U waves, and QT prolongation.

Management

The management of SAH is aimed at treating acute medical and neurologic complications, preventing recurrent hemorrhage, and forestalling the ischemic complications of vasospasm. Because of an altered level of consciousness, patients with SAH of grade 3 or higher are at risk for respiratory depression and hypercapnia, which can lead to further increases in intracranial pressure (ICP); therefore, early endotracheal intubation should be considered in these patients, using a technique consistent with that used for patients with elevated intracranial pressure (see Chapter 1). Blood pressure should be closely monitored because of the risk of continued bleeding or recurrent hemorrhage. The typical treatment goal is a systolic blood pressure below 160 mm Hg or a mean arterial pressure (MAP) below 130 mm Hg. To achieve this, the physician should use intravenous nicardipine or labetalol. Care is required to maintain MAP above 95 mm Hg, though, because iatrogenic hypotension may cause more harm than elevated blood pressure. Nimodipine, a calcium channel blocker, should be started soon after a diagnosis of aneurysmal SAH is made to lessen the likelihood of poor outcome due to vasospasm, even if the patient's blood pressure is normal. Because nimodipine may cause transient hypotension in some patients, hemodynamic monitoring is required during its administration. The recommended dosage is 60 mg by mouth or nasogastric tube every 4 hours.

Corticosteroids have not been demonstrated to be of benefit. Opioids should be used for persistent headache, though modest doses of short-acting agents should be used to avoid interference with evaluations of neurologic status. Intravenous fentanyl, titrated in 50 microgram aliquots is an appropriate first-line agent. In patients who are nauseated or at risk for vomiting, antiemetics such as metoclopramide 10 mg IV or ondansetron 4 mg IV should be administered. Agitated patients require sedation. Short-acting opioids such as fentanyl 50 micrograms IV may achieve this goal. If not, short-acting benzodiazepines such as midazolam 1 mg IV may be added. All patients should be placed on bed rest in a quiet and dark environment. Clinically evident seizures should be treated with levetiracetam or fosphenytoin. Prophylactic anticonvulsant therapy is of unknown benefit, and we recommend leaving this to the discretion of the admitting consultant or in consultation with the receiving consultant when transfer to another center is planned. For definitive management, endovascular coil embolization is preferable to neurosurgical clipping, but this decision is based on size, location, and morphologic features of the aneurysm, as well as local expertise.

Disposition

Patients with ruptured aneurysms require monitoring of hemodynamics and neurological status in an intensive care setting. Patients requiring transfer to a higher level center for care should be managed in collaboration with the receiving center, including contingency plans for complications (e.g. seizures, decreasing level of consciousness) that might arise in transport.

Intracranial Neoplasm

Principles

Headache may be a presenting complaint among patients with brain tumors, though is less common in older patients, presumably because of age-related atrophy. Headache can be caused by primary neoplasms of the CNS, as well as by metastatic lesions (Box 89.5). The most common causes of metastasis are lung and breast carcinoma, followed by malignant melanoma and carcinomas of the gastrointestinal tract.

BOX 89.5 Most Common Types of Intracranial Malignancy Causing Headache

- Metastatic
  - Breast
  - Lung
  - Gastrointestinal
  - Melanoma
- Meningioma
- Glioblastoma
- Primary CNS lymphoma
- Pituitary adenoma

The headache of intracranial neoplasms can be caused by several mechanisms, including traction on pain-sensitive structures (such as meninges or larger cerebral vessels), or it may be a symptom of increased ICP or hydrocephalus. The pain patterns produced are highly variable, depending on the location and size of the mass and the structures involved. Rapidly growing tumors are more likely to be associated with headache.

Clinical Features

The location of the headache may be ipsilateral, contralateral or bilateral and does not predict tumor location. The patient may present with complaints of a worsening headache that has been present for weeks to months. The headache may have been present initially only on awakening (most likely in patients with increased ICP), gradually becoming continuous. The classic triad of brain tumor headache—sleep disturbances, severe pain, and nausea and vomiting—is seen in a minority of patients. If increased ICP is present, the headache often is bilateral and worsened by coughing, sneezing, bending, defecation, and sexual intercourse. Other presentations of intracranial neoplasms include seizures, personality changes, and cognitive difficulties.

Differential Diagnoses

A number of disease processes can mimic brain tumor headache. These include other space-occupying lesions, such as an abscess or an intra-axial or extra-axial brain hemorrhage; diseases associated with increased ICP, such as idiopathic intracranial hypertension; and a vasculitis, such as giant cell arteritis (GCA). Once malignant causes of headache have been excluded, many of these patients will be diagnosed with a chronic headache disorder, such as chronic migraine, chronic tension-type headache, or *new daily persistent headache*, which is a primary headache disorder, characterized by abrupt onset and unremitting course.

Diagnostic Testing

The diagnosis of brain tumor headache may be suspected from the history and neurologic examination. Early in the course, patients may present with headache and an intact neurologic examination, although the majority of intracranial neoplasms will eventually cause focal neurologic deficits. Neuroimaging with CT or MRI is the most efficient way to confirm the diagnosis and is appropriate for all patients with a new persistent headache, particularly those patients older than 50 years. Contrast enhancement on CT often improves the identification of the underlying mass lesion and helps differentiate it from other causes, including abscess, hematoma, and vascular malformation.

Choice of imaging modality depends on local availability and should be tailored to the differential diagnosis.

Management

The treatment of headache associated with brain tumors depends on the type of tumor, patient functional status, and stage of the disease. Management consists of urgent referral to specialty care and treatment of any acute complications, including increased ICP and seizures. For patients who present with symptoms suggestive of increased ICP (e.g., headache, nausea, vomiting, confusion, weakness), treatment with corticosteroids to treat associated edema often provides dramatic temporary relief of headache and other symptoms of increased ICP. Dexamethasone is most commonly used. The exact dose of steroids necessary for each patient varies in accordance with histologic features, size, and location of the tumor and the amount of edema present. An appropriate starting dosage in the ED is 10 mg IV, followed by 4 mg every 6 hours. NSAIDs are appropriate initial therapy.

Patients with seizures should receive levetiracetam or fosphenytoin. Empirical or prophylactic treatment with antiepileptic medication should be avoided as this does not delay or prevent the onset of seizure activity and may expose the patient to unnecessary complications and toxicity.

Disposition

Patients with brain tumor headache should be managed in consultation with the patient's primary health care team. Hospitalization versus discharge will depend upon the severity of the patient's presentation.

Giant Cell Arteritis

Principles

GCA is an inflammatory vasculopathy that occurs in medium and large arteries with well-developed wall layers and adventitial vasa vasorum. It typically involves the major branches of the aorta and has a predilection for the extracranial branches of the carotid artery (e.g., temporal and occipital arteries). It can involve the ophthalmic, vertebral, and distal subclavian arteries, as well as the thoracic aorta. GCA is often named *temporal arteritis* because it commonly affects the superficial temporal arteries.

The mean age at onset of GCA is 71 years old, and it is rare before 50 years old. Women are affected more commonly than men. Pathologically, the arteritis causes an inflammatory infiltrate in the arterial wall resulting in intimal hyperplasia and subsequent stenosis and occlusion, leading to a variety of ischemic complications. In the vast majority of cases, loss of vision is due to anterior ischemic optic neuropathy.

Clinical Features

Temporal arteritis is the most typical presentation of GCA and presents with a broad spectrum of clinical features attributable to both ischemia and systemic inflammation (Box 89.6). Headache is the most common initial manifestation and occurs in more than 70% of patients. The headache often is of 2 to 3 months' duration and can be continuous or intermittent; it can worsen at night or on exposure to cold. The pain may be described as sharp, throbbing, boring, or aching and usually is localized to the temporal region but may occur anywhere in the head. The physical examination may reveal tenderness over the scalp in the area of the temporal artery, with exacerbation of the pain by wearing a hat or resting the head on a pillow. Patients also can experience jaw claudication secondary to vascular insufficiency of the masseter and temporalis muscles. Systemic signs and symptoms are often present, including fever, anorexia, and weight loss. Approximately 40% of patients develop symptoms of polymyalgia rheumatica, pain in their large proximal joints, with symptoms referable to the neck, torso, and lower back. The pain and stiffness are typically worse in the morning and lessen as the day goes on.

BOX 89.6 Diagnostic Criteria for Giant Cell Arteritis (Require 3 of 5)

- Age ≥ 50 years old
- New headache type, particularly in association with visual loss or jaw claudication
- Temporal artery tenderness or tenderness of other extracranial arteries
- ESR ≥ 50 mm/h or CRP ≥ 10 mg/L
- Positive imaging finding or temporal artery biopsy

The most serious complication of GCA is permanent visual loss, which occurs in approximately 15% of patients. Amaurosis fugax (transient monocular blindness) can occur before permanent visual loss. Other complications include peripheral neuropathies, transient ischemic attacks, and stroke. The physical examination may reveal abnormalities of the temporal arteries best detected by light palpation just anterior and slightly superior to the tragus of the ear. Findings include tenderness, reduced or absent pulsations, erythema, and nodularity or swelling. Visual acuity, visual field testing, and thorough funduscopic examination should be followed over time. The presence of a relative afferent pupillary defect (Marcus-Gunn pupil) should increase the suspicion for GCA, although these patients usually will also have a visual loss or a visual field defect.

Differential Diagnoses

The systemic symptoms of GCA are nonspecific. Therefore, the differential diagnosis is quite broad and includes infections, malignancies, and other vasculitides. Takayasu arteritis can affect the aorta and its primary branches as well, but it affects younger patients and visual loss is uncommon. Polyarteritis nodosa, microscopic polyangiitis, and granulomatosis with polyangiitis (formerly known as *Wegener granulomatosis*) can rarely affect the temporal artery but have different histopathology and vascular involvement. Ischemic stroke can cause headache with visual loss or amaurosis fugax. Pituitary apoplexy classically presents with thunderclap headache and bitemporal visual field loss.

Diagnostic Testing

The diagnosis of GCA is based on the history and physical examination, laboratory and imaging studies, and biopsy of the temporal artery. The majority of patients will have elevations of both the C-reactive protein (CRP), and the erythrocyte sedimentation rate (ESR), usually to more than 50 mm/hr and often more than 100 mm/hr, as well as the presence of thrombocytosis and anemia. The sensitivity of an elevated ESR or an elevated CRP has been reported in the range of 85%, but their specificity is only 30%. However, very few patients with GCA have both a normal ESR and CRP at the time of diagnosis. Ultrasonography of the temporal arteries may reveal a periluminal hypoechoic halo representing vessel wall edema. MRI of the temporal arteries has similar test characteristics as ultrasonography. The decision about which test to order should be made in consolation with the interpreting radiologist. If these imaging studies are performed in the ED, they may confirm the diagnosis and obviate the need for biopsy. Temporal artery biopsy is an imperfect test and is not required for diagnosis if the diagnosis is apparent based on clinical, laboratory, and imaging results (see Box 89.6).[4]

Management

Patients who present with visual symptoms (such as amaurosis fugax or diplopia) must be treated emergently with glucocorticoids, because

they are at risk for visual loss, which is typically permanent. Given the available evidence, we recommend methylprednisolone 1000 mg per day for 3 consecutive days to optimize immunosuppression and suppress tissue edema. For patients without visual symptoms, lower doses of steroids, in the range of 40 to 60 mg/day of prednisone should be used. Tocilizumab, a monoclonal antibody against the interleukin 6 receptor may be used in the outpatient setting to prevent relapse during corticosteroid tapering.[9]

Disposition

Patients with GCA should be managed in consultation with appropriate specialists, including neurology, ophthalmology, and rheumatology. They can be discharged if symptoms have resolved and rapid outpatient follow-up has been assured.

Carotid and Vertebral Artery Dissection

Principles

Approximately 2% of all ischemic strokes are caused by cervical artery dissection. In patients younger than 50 years old, cervical artery dissection is the most frequent cause of ischemic stroke and accounts for 10% to 25% of cases. These values likely underestimate the true incidence because patients with minimal symptoms are often not diagnosed. Although dissections may occur spontaneously, a careful history frequently identifies an association with sudden neck movement or trauma preceding the event. Reported mechanisms include neck torsion, chiropractic manipulation, coughing, minor falls, heavy lifting, various sports including basketball and volleyball, sexual intercourse, childbirth, and motor vehicle collisions. Early symptoms and signs may be subtle, and delays in diagnosis are common in the absence of neurologic findings. The median delay from symptom onset to diagnosis can be several days.

The pathologic lesion in cervical artery dissections is intramural hemorrhage within the media of the arterial wall. The hematoma can be localized or extend circumferentially along the length of the vessel, resulting in partial or complete occlusion. Damage to the intima results in platelet aggregation and thrombus formation further compromising vessel patency or causing distal embolization. The timing of these events is variable, and a patient may experience symptoms of cerebral ischemia days to years after dissection.

Clinical Features

The typical presentation of cervical artery dissection is the abrupt onset of pain in the head or neck, often in association with symptoms resulting from ischemic consequences of the dissection and emboli. Neurologic findings secondary to cerebral ischemia usually occur within the first few hours following the onset of the headache or neck pain. Although carotid dissection and vertebral artery dissection have many commonalities, their clinical presentations have some unique features.

Carotid Artery Dissection. The classic presentation of symptoms for carotid artery dissection includes (1) unilateral headache or neck pain, sometimes radiating to the ipsilateral eye; (2) ipsilateral ptosis and miosis (a partial Horner syndrome) ; and (3) either blindness, due to retinal ischemia, or contralateral motor deficits, caused by cerebral ischemia. However, this complete triad is only present in a minority of patients. The headache is often severe and throbbing but may be subacute and similar to previous headaches and may be associated with pulsatile tinnitus.

Acute severe retro-orbital pain in a previously healthy person with no history of cluster headaches is suggestive of carotid dissection. Patients with a carotid dissection are at risk of sustaining embolic cerebral ischemia. Warning symptoms include transient ischemic attacks, amaurosis fugax, episodic lightheadedness, and syncope. Spontaneous dissection of the carotid artery has a favorable prognosis and recurrence is uncommon. Factors associated with a worse prognosis include older age, occlusive disease on angiography, and stroke as the initial presenting symptom.

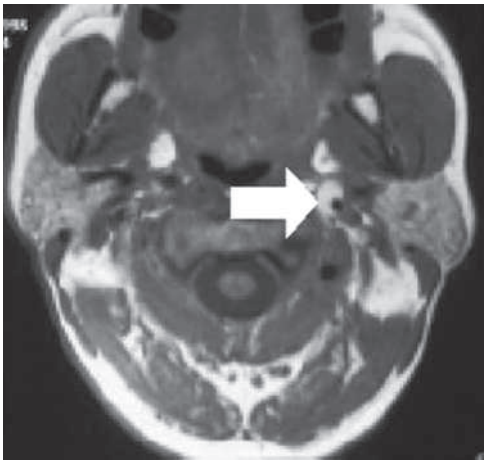

Fig. 89.3 Axial T1-weighted magnetic resonance image (MRI) demonstrating a crescent sign *(arrow)* in a patient with a left internal carotid artery dissection. (From Kidwell C. Dissection syndromes. Emedicine, updated Sep 19, 2011. Available at http://emedicine.medscape.com/article/1160482-overview.)

Vertebral Artery Dissection. Vertebral artery dissections are less common than carotid dissections. The classic presentation is that of a relatively young person with severe, unilateral posterior headache and a rapidly progressive neurologic deficit with symptoms of brainstem and cerebellar ischemia. Common findings include vertigo, severe vomiting, ataxia, diplopia, hemiparesis, unilateral facial weakness, and tinnitus. Stroke severity tends to be lower than that seen with carotid dissection. Spontaneous vertebral artery dissection appears to be relatively rare. Approximately 10% of patients who develop a vertebral dissection die during the acute phase, secondary to massive stroke. For patients who survive, the prognosis is usually good.

Differential Diagnoses

The differential diagnoses of unilateral headache and neck pain with or without Horner syndrome include migraine and cluster headache. Cluster headache in particular can present with ptosis. Cervical arterial dissection may present with an abrupt onset of severe headache, which may be confused with SAH or other vascular causes of headache. For patients who present with symptoms of cerebral ischemia, both ischemic and hemorrhagic stroke should be considered as possible etiologies. Conversely, cervical artery dissection should be considered in patients who present with acute stroke, particularly younger patients.

Diagnostic Testing

Identification of patients with dissection can be challenging, especially in the absence of cerebral ischemia. A non–contrast-enhanced head CT scan is often normal in uncomplicated dissection. Digital subtraction angiography remains the diagnostic gold standard, although several studies have found CTA and magnetic resonance angiography (MRA) to have sensitivities of approximately 95%, making them appropriate choices for initial screening. Cerebrovascular imaging of the head and neck should be considered in all patients in whom CAD is suspected and in young patients with stroke, because it is a more common cause of stroke in a younger population. Cerebrovascular imaging should be considered in unresponsive patients who may have basilar artery pathology. Figure 89.3 shows an example of carotid artery dissection on MRI.

Management

Cervical artery dissection patients with acute ischemic stroke are candidates for thrombolytic therapy or endovascular thrombectomy (see Chapter 87). Studies have shown these treatments to be safe with efficacy similar to stroke from other causes.

For patients with cervical artery dissection without acute ischemic stroke, the primary goal of treatment is the prevention of cerebral ischemic complications. Antiplatelet agents including aspirin, clopidogrel, or dipyridamole, and anticoagulation with unfractionated or low–molecular-weight heparin are comparably effective at preventing stroke, which is relatively uncommon.[5]

Disposition

Patients with cervical artery dissection should be admitted to the hospital for monitoring and further management.

Cerebral Venous Thrombosis

Principles

Thrombosis of the intracranial veins and sinuses is a rare disorder causing approximately 1% of all strokes. It typically presents with headache and disproportionately affects younger individuals without traditional cerebrovascular risk factors.

There are multiple causes for CVT, and risk factors are classically linked to the Virchow triad of blood stasis, blood vessel wall abnormalities, and a hypercoagulable state. Both genetic and acquired prothrombotic conditions have been associated with CVT. Inherited thrombophilias such as antithrombin III, protein C and protein S deficiencies, and factor V Leiden mutation are the most common genetic causes. Acquired causes for CVT include pregnancy and the puerperium, malignancy, head trauma, surgery, parameningeal infections, and exogenous hormones, such as oral contraceptives. Other causes include systemic inflammatory disorders, including vasculitis, inflammatory bowel disease and connective tissue disorders, and neurosurgical procedures.

Clinical Features

Clinical findings in CVT usually fall into two major categories, depending on the mechanism of neurologic dysfunction: (1) Those that are related to increased ICP due to impaired venous drainage, and (2) those related to focal brain injury from venous occlusion resulting in ischemia, infarction, or hemorrhage. Diffuse headache increasing in severity over days to weeks is the most common symptom experienced by patients with CVT and is often associated with increased ICP. Focal neurologic findings, when present, are related to the region of the brain that has been injured and bilateral brain involvement may occur. Seizures, both focal and generalized, frequently occur. Ocular findings associated with CVT include orbital pain, proptosis, chemosis, extraocular muscle paralysis, and papilledema.

Differential Diagnoses

The differential diagnoses of early CVT, when symptoms are limited to headache and papilledema, include brain tumor and idiopathic intracranial hypertension. Late presentations of CVT include altered sensorium, seizures, and focal neurologic deficits. At this point, the differential diagnosis includes ischemic and hemorrhagic stroke; intracranial infections, such as brain abscess, meningitis, and encephalitis; and systemic conditions, including sarcoidosis and systemic lupus erythematosus. With CVT, neurologic findings do not follow a typical arterial territory. CVT is a rare and often subtle diagnosis. To avoid missing the diagnosis, it should be considered for all patients with a new headache type who have thromboembolic risk factors or recent head or neck surgery.

Diagnostic Testing

Routine blood work including a complete blood count (CBC), chemistry panel, ESR, and clotting studies, including a prothrombin time (PT) and partial thromboplastin time (PTT), should be obtained in all patients with suspected CVT. These studies are helpful in determining the presence of an underlying hypercoagulable state, an infectious process, or an inflammatory disorder contributing to the development of CVT. A normal D-dimer can exclude this diagnosis among patients without thromboembolic risk factors or recent head or neck surgery who have a normal neurologic exam and the absence of papilledema.[6] The definitive diagnosis of CVT is based on neuroimaging of the area of thrombosis. This is best accomplished by a combination of MRI to visualize the thrombosed vessel and magnetic resonance venography (MRV) to detect nonvisualization of the same vessel. Non–contrast-enhanced CT by itself is an insensitive test, but it may reveal nonspecific late lesions, such as an infarct, hemorrhage, or edema. Occasionally, hyperdensity of a cortical vein or sinus may be seen. CTA and CTV may be used to visualize the cerebral venous system, especially in patients who have a contraindication to MRI.

Management

Patients with CVT should be anticoagulated to prevent propagation of the thrombosis and development of embolic complications. Treatment is adjusted dose unfractionated heparin or weight-based low–molecular-weight heparin in full anticoagulant doses, regardless of the presence of intracerebral hemorrhage. In patients whose clinical condition worsens despite anticoagulation, thrombolysis or thrombectomy may be considered in centers with expertise in interventional procedures. Seizures are treated with antiepileptic drugs such as phenytoin or levetiracetam.

The prognosis with CVT is based on the underlying etiology, the patient's condition at time of diagnosis, and the development of complications. The overall mortality is low compared with other types of strokes, but morbidity may be increased with delays in recognition and treatment.

Disposition

Patients with CVT require hospitalization, preferentially to a stroke unit, for systemic anticoagulation.

Idiopathic Intracranial Hypertension

Principles

Although this disease is sometimes called *pseudotumor cerebri,* the term *idiopathic intracranial hypertension (IIH)* best reflects current understanding of the pathophysiology and the fact that this disorder is not benign because permanent visual field loss can occur. Compared with other headache disorders, IIH is a relatively uncommon neurologic disease seen primarily in young, obese women of childbearing age. Several predisposing factors have been suggested, including antibiotics (most commonly tetracyclines), vitamin A and retinoids, and human growth hormone. The pathophysiologic mechanism of this disease is not understood, but it is often attributed to an imbalance between CSF production and reabsorption.

Clinical Features

Clinical and diagnostic criteria for IIH are listed in Box 89.7. The most prominent symptom is generalized headache, which may take the form of migraine or tension-type headache.[10] No specific localizing pattern has been documented, although in some patients the headache is worsened by eye movement. It may awaken the patient from sleep and is exacerbated by bending forward and the Valsalva maneuver, both of which impede cerebral venous return. Visual complaints are

BOX 89.7 Criteria for Diagnosis of Idiopathic Intracranial Hypertension

Headache that remits with normalization of CSF pressure
Papilledema (may not be appreciable in all patients)
May have CN VI palsy
Increased CSF opening pressure
  >250 mm in adults
  >280 mm in children
Normal CSF diagnostic studies
Normal neuroimaging studies
No other cause of increased ICP identified

CN, Cranial nerve; *CSF,* cerebrospinal fluid; *ICP,* intracranial pressure. It is essential to rule out space occupying lesions and inflammatory processes.

common, and patients may experience transient visual obscurations (TVOs), which are momentary blackouts of vision most likely due to temporary disruption of the microcirculation to the optic nerve head. They usually occur with postural changes and are not predictive of permanent visual loss. Patients may also complain of nausea, vomiting, dizziness, and pulsatile tinnitus. The physical examination will reveal papilledema, and visual field deficits or visual loss occurs in up to 50% of patients. Fortunately, in the majority of patients, visual defects are reversible with treatment. On occasion, a sixth nerve palsy is noted.[2]

Differential Diagnoses

The differential diagnoses of IIH include other causes of increased ICP in a patient presenting with headache. Important considerations include cerebral venous sinus thrombosis, mass lesions, obstructive hydrocephalus, and leptomeningeal infiltration by neoplastic or infectious processes.

Diagnostic Testing

Ultrasonographic measurement of the diameter of the optic nerve sheath, 3 mm behind the optic disc, is consistent with elevated intracranial pressure if greater than 5 mm. MRI with MRV or MRI with contrast is the preferred modality for diagnosing IIH. MRI should occur early in the workup of IIH because of its ability to detect not only mass lesions and hydrocephalus but also cerebral venous sinus thrombosis and other meningeal processes. If neuroimaging is normal, an LP should be performed in the lateral decubitus position to measure CSF opening pressure and to obtain CSF diagnostic studies. An opening pressure of 250 mm H_2O or more (normal is 70 to 180 mm H_2O) is necessary to make the diagnosis. Ophthalmology follow-up should be arranged for detailed visual field testing.

Management

Many patients present without visual field loss, and symptomatic therapy is all that is necessary. Historically, removal of a large enough amount of CSF (>20 mL) to decrease CSF pressure has been recommended to relieve headache. However, studies of patients with IIH reveal no association between CSF pressure and headache, and CSF is produced relatively quickly, which limits the duration of benefit.[10] Therefore, we believe treatment with NSAIDs such as ketorolac 15 mg IV or antidopaminergic medication such as metoclopramide 10 mg IV may allow the patient with an established diagnosis of IIH to avoid a therapeutic lumbar puncture. In patients with evidence of visual field loss, treatment with medications to lower ICP is indicated. Acetazolamide, starting at doses of 250 to 500 mg orally BID, can improve 6-month visual outcomes though it does not improve headache. If a patient is not responsive to medications or has progressive symptoms, an optic nerve sheath decompression or CSF diversion procedure (e.g., lumboperitoneal or ventriculoperitoneal shunt) may be indicated.

Disposition

Once the headache has been controlled, patients with IIH can be discharged, assuming visual loss is not marked and has not progressed rapidly. Because visual loss can occur early or late in the course of IIH, outpatient follow-up with ophthalmology and neurology should be recommended.

Post–Dural Puncture Headache and Other Low CSF Pressure Headaches

Principles

Post–dural puncture headache (PDPH) is the most frequent cause of low CSF pressure headache seen in the emergency department, though spontaneous intracranial hypotension can also cause orthostatic headaches. The former is a recognized complication of dural puncture, whether performed for diagnostic or therapeutic purposes or accidentally, as a complication of epidural anesthesia, whereas the latter is caused by spinal CSF leak without localized trauma.

The pathophysiology of low CSF pressure headaches is not entirely clear. The most likely explanation is a persistent CSF leak that exceeds CSF production, resulting in CSF hypotension. If sufficient CSF is lost, the brain descends in the cranial vault when the patient assumes the upright position, leading to increased traction on the pain fibers. Thus the headache is characteristically positional and increases with the upright position and decreases with recumbency. The amount of time a patient remains recumbent after lumbar puncture does not affect the incidence of PDPH.

Equipment-related factors have been implicated as causes of PDPH, including the size or diameter of the spinal needle, the orientation of the bevel during the procedure, and the amount of fluid withdrawn. Smaller-diameter needles (e.g., 20- or 22-gauge cutting needle) cause less leakage, and it is postulated that insertion of the needle with the bevel up (i.e., bevel pointing up when the patient is in the lateral position) minimizes damage to the dural fibers. Use of noncutting needles (e.g., Whitaker or Sprotte) also has been shown to reduce the incidence of PDPH.

Clinical Features

The cardinal feature of PDPH is orthostatic or positional headache that is precipitated by the upright position and relieved when the patient lies down. About 90% occur within the first 72 hours after the LP and typically resolve within 1 week, though headaches may persistent for months. Associated signs and symptoms include neck stiffness, nausea, vomiting, auditory disturbances including tinnitus and hypoacusis, and photophobia.

Differential Diagnoses

For most patients, PDPH is a benign disorder. However, in patients who do not respond to standard treatment modalities, other secondary headache disorders must be considered. This is especially true in the postpartum period when CVT and preeclampsia are important considerations.

Diagnostic Testing

The diagnosis of PDPH is based on clinical features, with a headache occurring after an LP or epidural catheter placement, and most patients have a benign course that requires no diagnostic testing. Spontaneous CSF leaks present with orthostatic headaches, which are sometimes severe and should be considered in the absence of a recent LP. The diagnosis is made when low CSF pressures are found on LP, which should be considered in patients with orthostatic headaches who have

not experienced recent dural puncture. In the postpartum period, CVT should be excluded with MRV.

Management

Most PDPHs resolve spontaneously within 5 to 7 days with bed rest, hydration, and analgesics. For persistent headaches not responding to over-the-counter analgesics, methylxanthine agents (such as caffeine 500 mg IV drip over 1 hour) and corticosteroids may be of benefit. For severe headaches that do not respond to these conservative measures, an epidural blood patch (EBP) should be used. This procedure involves the injection of 15 to 30 mL of autologous blood into the epidural space near the site of the original dural puncture resulting in a blood clot that seals off the dural hole.[7]

Disposition

The vast majority of patients with PDPH will have a benign course requiring only conservative treatment. These patients can be discharged home. For patients with persistent complaints, consultation with anesthesia or radiology for an EBP should be considered.

Post-Traumatic Headache

Principles

Headache is the most common symptom following a concussion or other traumatic brain injury (TBI). It is often part of a complex post-concussive syndrome that can include dizziness, fatigue, insomnia, irritability, memory loss, and difficulty with concentration. Persistent headache (>3 months) occurs in over 50% of patients who have suffered a TBI. Paradoxically, patients with milder injuries are more likely to report persistence of symptoms, as are patients with preexisting headache disorders. For the emergency clinician, management of post-traumatic headache (PTH) requires excluding life-threatening causes of headache and treating the headache, associated symptoms, and contributing factors (e.g., cervical strain, cranial neuropraxias). The pathophysiologic mechanism for the symptoms is unclear and may have both anatomic and functional components.

Clinical Features

By international criteria, PTH develops within 7 days of the injury or regaining consciousness. Acute PTH resolves within 3 months, whereas persistent PTH persists beyond 3 months. Patients in whom PTH develops after minor head injuries have normal findings on neurologic examination and routine neuroimaging studies. Many patients are more concerned about the cause of the headache than about the headache itself, underscoring the importance of patient education on the post-concussive syndrome.

PTH may assume a variety of characteristics, including the pulsating unilateral pain and associated features of migraine, the bland, squeezing pain of tension-type headache, or nonspecific headache often relating to the musculature of the neck.

Differential Diagnoses

In the acute setting, pathological causes of headache including intracranial hemorrhage, or skull or cervical fractures should be excluded. Cervical strain and subtle oculomotor nerve palsies are additional etiologies of PTH that should be considered. After the acute setting, it may be difficult to distinguish PTH from migraine or tension-type headache, a distinction that, as time passes, becomes less important.

Diagnostic Testing

In the acute setting following TBI, traumatic injuries to the brain, skull, and neck should be evaluated using available clinical decision rules (see Chapter 34). Patients who return to the ED with persistent symptoms after normal initial imaging should be reassured that follow-up imaging is not required, assuming the patient has a normal neurologic examination and is not using anticoagulants or antiplatelet medication. Neuroimaging is indicated in the setting of focal neurologic deficits or persistent altered mental status.

Management

We recommend that PTH be treated with the same armamentarium of medications used to treat acute primary headaches, specifically, antiemetic dopamine antagonists such as metoclopramide or prochlorperazine, and NSAIDs. Opioids should be avoided.

Disposition

Patients with PTH should be discharged home with appropriate outpatient follow-up. These patients should be informed that they may continue to suffer from headache and other symptoms over the subsequent weeks and should be provided with medication, advice about how to manage symptoms, and referrals to local physicians with relevant expertise.

Hypertensive Headache

Principles

There is uncertainty about whether elevated blood pressure can cause headache. Ambulatory blood pressure monitoring studies have not demonstrated an association, although these studies are limited by relatively modest blood pressure elevations during the study period. Nearly one-quarter of patients who present to an ED with headache have a systolic blood pressure above 150 mm Hg or diastolic blood pressure over 95 mm Hg. Patients who present with headache are more likely to have a markedly elevated blood pressure than patients with other chief complaints. However, the causal pathway, if one exists, is not apparent based on current evidence. In fact, both chronic hypertension and acute elevation in blood pressure have been linked to decreased pain sensitivity in animal and human models. International criteria attribute headache to elevated blood pressure when the pressure is greater than 180 mm Hg systolic or 120 mm Hg diastolic and when the headache resolves with resolution of the elevated blood pressure.

Clinical Features

The headache of severe hypertension is generally characterized as bilateral and throbbing. Early reports of a typical hypertensive headache come from patients with marked, untreated hypertension, who had early morning headaches that were of greatest intensity before the patient arose and typically resolved as the patient engaged in morning activities.

Differential Diagnoses

Based on population prevalence, the most likely diagnoses in patients with elevated blood pressure and headache are migraine or tension-type headache with concomitant hypertension.

Pre-eclampsia, a disorder characterized by elevated blood pressure and headache, should be considered in patients in the latter stages of pregnancy and the recent postpartum period. Posterior reversible encephalopathy syndrome (PRES) is characterized by white matter changes on diagnostic imaging. Malignant hypertension, including drug-induced hypertension, requires evidence of end-organ damage (Table 89.4).

Diagnostic Testing

In the absence of altered sensorium, focal neurologic deficits or visual deficits, a diagnostic evaluation is not indicated.

TABLE 89.4 Pathological Processes That May Present With Headache and Elevated Blood Pressure

Disease Process	Clinical Features	Diagnostic Criteria
Pre-eclampsia	Elevated blood pressure and proteinuria in the second half of pregnancy	Should be considered in all patients greater than 20 weeks pregnant with blood pressure > 140/90 mm Hg
Posterior reversible encephalopathy syndrome	Risk factors include immunosuppressant medication, chemotherapeutics, and underlying renal disease	Abnormal MRI imaging
Intracranial hemorrhage	Acute onset of focal neurologic deficits	Abnormal neuroimaging

Management

It is uncertain if strategies aimed at lowering the blood pressure acutely will alleviate the headache. We recommend use of antidopaminergic or nonsteroidal agents, with use of antihypertensive agents reserved for patients with evidence of end-organ damage. Blood pressure can be reassessed after the headache has improved. Oral antihypertensive therapy may be prescribed in the ED if timely outpatient follow-up cannot be assured (see Chapter 70).

Disposition

In the absence of objective neurologic symptoms, patients with hypertension and headache do not require admission to the hospital. Elevated blood pressure should be treated on an outpatient basis.

Reversible Cerebral Vasoconstriction Syndrome

Principles

Reversible cerebral vasoconstriction syndrome (RCVS) is a cerebral arteriopathy characterized by segmental areas of vasoconstriction within large- and medium-sized vessels. RCVS causes recurrent thunderclap headache in susceptible patients and may cause ischemic or hemorrhagic stroke. The prevalence of this presumably rare disorder is not known. RCVS is being reported with more frequency given the wide availability of noninvasive neurovascular imaging. Some data suggest that this disorder may cause the majority of thunderclap headaches.

Clinical Features

The headache of RCVS is characteristically a thunderclap headache, abrupt in onset, and severe. It is often throbbing and associated with nausea, vomiting, and photophobia. The headache may be provoked by use of vasoactive medications or substances such as recreational sympathomimetics or nasal decongestants.

Differential Diagnoses

The differential diagnoses for thunderclap headache include SAH and other hemorrhagic strokes, CVT, cervical artery dissection, and pituitary apoplexy. Unlike these other pathological diagnoses, RCVS is characterized by recurrent thunderclap headache within a discrete period of time. Thunderclap headache during sexual activity may occur pre- or post-orgasm and is classified as *primary headache associated with sexual activity* after other causes of thunderclap headaches have been excluded. Once that happens, a diagnosis of *primary thunderclap headache* is assigned.

Diagnostic Testing

Patients with the initial presentation of thunderclap headache should have a head CT and LP or neurovascular imaging performed to exclude SAH and other intracranial pathology. Repeat neurovascular imaging, or diagnostic angiography, should be pursued in patients with recurrent thunderclap headache if the diagnosis of RCVS was not confirmed by the initial imaging.

Management

There are no evidence-based treatment options available for RCVS. Goals of treatment include prevention of ischemic and hemorrhagic stroke and elimination of headache. To date, the natural history of this disorder is incompletely understood. Treatment with calcium channel blockers, such as nimodipine 30 to 60 mg PO q4h, has been described and we recommend that it be offered to patients with progressive or refractory symptoms.

Disposition

Patients with thunderclap headache who have received an appropriate diagnostic evaluation with neurovascular imaging in the ED may be discharged home with follow-up within a defined period. An inpatient workup is appropriate for patients with recurrent thunderclap headache, refractory pain, or for those with focal neurologic deficits.

CHAPTER 89: QUESTIONS AND ANSWERS

1. A 29-year-old female presents within 1 hour of the sudden onset of a severe, diffuse headache accompanied by meningismus and vomiting. Emergent computed tomography (CT) scan is negative. Lumbar puncture (LP) reveals 50,000 red blood cells (RBCs) in tube 1 and 30,000 RBCs in tube 4. Opening pressures are normal, and the sample is negative for xanthochromia. What would be the most appropriate next step?

a. Admission and observation
b. Cerebrovascular imaging study
c. Hydration, analgesics
d. Magnetic resonance imaging (MRI) scan with gadolinium

Answer: B. CT scan provides a sensitivity of approximately 90% for the detection of subarachnoid hemorrhage (SAH). A traumatic LP, even with diminishing RBC counts with sequential tubes, cannot differentiate between a SAH and traumatic tap. The lack of xanthochromia is predictable, given the acute onset of headache and the 12 hours required for cerebrospinal fluid (CSF) xanthochromia to develop. A cerebrovascular imaging study, such as computed tomography angiography (CTA), magnetic resonance angiography (MRA), or standard angiography would be required next to exclude a source of bleeding, such as an aneurysm or arteriovenous malformation (AVM).

2. A 69-year-old male presents with several months of intermittent left-sided headaches that have been worse at night and occasionally on exposure to cold air. On several occasions, he has noted increased pain while eating. He has had no other symptoms other than modest fatigue. Physical examination is unremarkable with normal vital signs and ophthalmologic and neurologic survey. Laboratory evaluation shows only a mild anemia, with a hemoglobin of 11 mg/dL and normocytic indices. What would be the most appropriate next step?

a. Computed tomography (CT) scan of the brain
b. Electrocardiogram
c. Erythrocyte sedimentation rate (ESR)
d. Neurology consultation

Answer: C. Temporal arteritis may present with intermittent or continuous symptoms, sometimes associated with fatigue, myalgias, jaw claudication, and mild anemia. The ESR is usually, but not always, diagnostic and would confirm the diagnosis if elevated. Steroids and ophthalmology consultation would then follow. The presence of temporal artery tenderness may be variable because the vasculitis may affect any artery. The diagnosis must be suspected in any elderly patient with recurrent or continuous headaches.

3. With cavernous sinus thrombosis, the clinical picture is usually dominated by which of the following?

a. Facial pain
b. Lethargy
c. Nausea and vomiting
d. Ocular findings such as pain and proptosis

Answer: D. The symptoms may also include paralysis of extraocular movements. Ocular symptoms are most common with thrombosis of the cavernous sinus, rather than one of the other sinuses.

4. A 28-year-old man with a history of migraine and no other medical history presents with a pounding, bilateral 9/10 headache associated with nausea and vomiting that has lasted for 48 hours. The patient reports experiencing a similar headache about once every few months. Physical exam is noteworthy for a blood pressure of 180/110 mm HG in his right arm and 178/111 mm HG in his left arm. Physical exam, including a detailed neurologic exam, is otherwise completely normal. The most appropriate first step in the management of this patient is the following:

a. Non-contrast CT scan of the head
b. Metoclopramide 10 mg IV
c. Labetalol 20 mg IV
d. CT angiography of the head and neck

Answer: B. For patients who present with elevated blood pressure and an otherwise normal physical exam in the setting of a typical migraine headache, treatment should first focus on relieving the acute pain. Treatment of blood pressure should commence if the blood pressure remains persistently high after adequate control of pain. Head imaging is not indicated in a patient who reports a typical exacerbation of migraine. CT angiography of the head and neck is most appropriate to rule out cervical artery dissection. Sumatriptan is an appropriate treatment of acute migraine but is relatively contraindicated in a patient with markedly elevated blood pressure.

5. An obese 37-year-old female reports worsening headache × 3 months, which first responded to ibuprofen but now no longer does. The headache is bilateral, pulsating, associated with nausea, and improves when she assumes an upright position. She reports 5-second blackouts of her vision, which occur occasionally when she changes position. A neurologic exam is unremarkable. Retinal exam is deferred because of marked photophobia. Non-contrast

CHAPTER 89: QUESTIONS AND ANSWERS—cont'd

head CT scan is normal. The most appropriate next step in the diagnostic workup is:

a. MRV
b. D-dimer
c. CT angiography
d. Lumbar puncture

Answer: D. The provided history is most consistent with idiopathic intracranial hypertension, which can only be confirmed by lumbar puncture. Lumbar puncture will demonstrate elevated cerebrospinal fluid pressure >250 mm H_2O. MRV and D-dimer can be used to exclude the diagnosis of venous sinus thrombosis, which should be considered if the CSF pressure is indeed elevated. ESR is most useful to exclude giant cell arteritis, a diagnosis that does not occur in patients younger than 50 years. CT angiography can be used to diagnose cerebrovascular pathology.

Delirium and Dementia

Gallane Abraham and Patrick J. Maher

KEY CONCEPTS

- Delirium is an acute condition characterized by an altered level of attention and awareness. It develops during a short time, and symptoms tend to fluctuate throughout the day.
- Delirium is commonly caused by medications, drug intoxication or withdrawal, infections, metabolic disorders, CNS and cardiovascular events, and autonomic nervous system disturbances.
- Dementia is a chronic condition characterized by cognitive impairment. It is slow in onset and progressive in nature. This disorder has many causes, some of which are reversible with treatment. It is essential to search for reversible underlying etiologies that may be worsening a cognitive impairment.
- Patients with either dementia or psychiatric disorders may present with superimposed delirium, often making identification of the underlying cause of their abnormal behavior difficult.
- The clinician should be wary of attributing behavioral disturbances to psychiatric illness in the presence of abnormal vital signs or abnormal sensorium.
- Nonpharmacologic methods of controlling agitation including reassurance, verbal de-escalation, and avoidance of environmental triggers should be considered in the treatment of patients with dementia.
- Antipsychotics and benzodiazepines are used cautiously in the management of acute agitation in delirium and dementia. The choice of agent is determined by side effect profile and etiology of delirium or acute agitation.
- Antipsychotics may cause QTc prolongation and extrapyramidal side effects, especially when given intravenously.
- Lower doses of medications may be appropriate in older adults to decrease risk of adverse events while effectively treating acute agitation.

OVERVIEW

Delirium and dementia are syndromes defined through impairment of specific cognitive domains including attention, social cognition, memory, language, perceptual-motor ability, and executive function. Both delirium and dementia affect cognition but in different ways and over different time courses. However, delirium can occur concomitantly in a patient with dementia, making the diagnosis challenging. Other nonspecific terms including *acute confusional state, encephalopathy,* and *organic brain syndrome* have been used to describe a number of abnormal cognitive states with often overlapping symptoms. These terms are frequently used synonymously with *delirium* to reflect an alteration of consciousness from presumptive underlying medical etiology. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) classifies these pathologies as *neurocognitive disorders,* although prior editions have used the heading *delirium, dementia, amnestic,* and *other cognitive disorders.*

Delirium is characterized by a fluctuating neurobehavioral disturbance typically progressing over a short period. It is a direct consequence of an acute systemic or central nervous system (CNS) stressor. Dementia, on the other hand, tends to follow a more gradual course, with evolution occurring over months to years. Although patients with dementia may exhibit confusion, unlike delirium, a disturbance in attention is usually absent and other acute medical abnormalities cannot explain the changes in cognition.

The evaluation of patients who present to the emergency department (ED) with a neurobehavioral disturbance is best conducted in accordance with the following basic guidelines:

1. The first step is to establish a safe and supportive environment to facilitate further diagnostic and therapeutic efforts. Verbal de-escalation and nonpharmacological means of treating agitation are preferred, but sedative adjuncts may be employed if needed.
2. The second step is to determine whether this state represents delirium or dementia by obtaining a careful history from the patient, family members, and caregivers. Screening tools for delirium and cognitive assessments for dementia can assist in the diagnosis. Clinical findings may be subtle, and distinguishing between these syndromes can be challenging, especially as acute delirium may be superimposed on chronic dementia.
3. The third step is to rapidly treat the underlying disorder in patients with delirium and to evaluate for causes of reversible dementia.

DELIRIUM

Background

Delirium is an acute or subacute state of cognitive dysfunction caused by an underlying physiologic condition.[1] Several key features are necessary for a diagnosis of delirium (Box 90.1). The hallmark finding in delirium is the disturbance in attention and awareness, manifested as an inability to focus attention and reduced orientation to the environment. Patients with delirium may show changes in several other cognitive domains including memory, language, and perception. Arousal and awareness may be normal or impaired. These disturbances tend to develop during a short time (hours to days), but in certain cases they may last weeks to months despite treatment of the underlying cause. Symptoms often have a fluctuating course over time, in distinction to the progressive changes of dementia. Deficiencies in attention may be manifested by reduced maintenance of attention, increased distractibility, or reductions in task processing speed. Memory impairments can manifest as reduced recall of recent information or repeating oneself in conversation. Either expressive or receptive language may be affected. Perceptual disturbances include hallucinations and delusions. The extent of cognitive derangement may range from mildly disturbed to grossly disorganized. The patient's sleep-wake cycle may be altered or reversed; agitation often is present during the night. The level of psychomotor activity in delirium can be specified as hyperactive, hypoactive, or a mixed level of activity. Hyperactive individuals demonstrate

BOX 90.1 Diagnostic Criteria for Delirium

Four Key Characteristics

- Disturbance in attention and awareness.
- The disturbance develops over a short time period, represents a change from baseline attention and awareness, and tends to fluctuate in severity during the day.
- There are additional disturbances in cognition, such as memory, disorientation, language, visual-spatial ability, or perception.
- The disturbances are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in context of a coma.

Chronic kidney disease
Heart failure
Sedative medications (e.g., benzodiazepines and opioids)
Malnutrition
Depression

emotional lability, agitation, and may refuse care; hypoactive individuals demonstrate sluggishness and lethargy; the mixed type describes either a normal level of psychomotor activity but with disturbance of attention and awareness, or individuals having fluctuations in activity levels. Although hyperactive delirium is the most easily recognizable presentation, hypoactive delirium is the most common form and carries the highest risk of mortality.

Delirium occurs frequently, particularly in older ED patients, and it is associated with increased morbidity and mortality, particularly when unrecognized.[2] Predisposing factors for delirium include comorbid illness, dementia, older age, male gender, medications, neurologic deficits, and psychiatric illness (Table 90.1). Drug intoxication and withdrawal (including ethanol) are the most common cause of delirium in the younger adult population. Within the older population, medication side effects are another common cause of delirium; drugs with anticholinergic properties are often implicated but many drug classes can act as a precipitant. Environmental exposures (e.g., heavy metals, insecticides, cyanide, carbon monoxide), herbal medications, and ingestion of psychoactive botanicals (e.g., nutmeg, foxglove, jimsonweed, psilocybin-containing mushrooms) are yet other causes of delirium to consider.

Delirium can be a prominent feature of any CNS or systemic infection, particularly in the very young, older patients, and immunocompromised patients. Many metabolic disorders put patients at risk for delirium, with hypoglycemia and hypoxia being the most common. Delirium is common in patients with strokes, but isolated delirium without other neurologic abnormality is not a common stroke presentation. CNS vasculitis and paraneoplastic syndromes are additional considerations.

Pathophysiology

At a cellular level, delirium is the result of a widespread alteration in cerebral metabolic activity, with secondary deregulation of neurotransmitter synthesis and metabolism. Both the cerebral cortex and the subcortical structures are affected, producing changes in arousal, alertness, attention, information processing, and the normal sleep-wake cycle.

Although the exact pathophysiologic process is not well understood, multiple neurotransmitters have been implicated in causing delirium.[3,4] Given the phenotypic heterogeneity of delirium, it is likely that a number of various neurophysiologic mechanisms underlie the clinical presentation in different patients. Delirium has classically been associated with a derangement of central cholinergic transmission. Cholinergic deficiency is most pronounced in patients experiencing delirium secondary to anticholinergic drugs. Increased glutamatergic activity and neuroinflammation are seen in hepatic encephalopathy, uremic encephalopathy, sepsis, and alcohol withdrawal. Some of the disturbances that occur in delirium are deficiencies of substrates for oxidative metabolism (e.g., glucose, oxygen); GABA-ergic deficit; imbalance of normal noradrenergic, serotoninergic, dopaminergic, and cholinergic tone; and disturbance of the neuroendocrine axis.

Drugs and exogenous toxins can produce delirium through direct effects on the CNS. Although the limbic system appears to be particularly vulnerable to the effects of drugs, the cerebral hemispheres and the brainstem also can be profoundly affected. Tricyclic antidepressants can cause delirium by cholinergic inhibition; sedative-hypnotics depress activity in the CNS, especially in the limbic system, thalamus, and hypothalamus. Narcotics affect CNS activity primarily by interacting with various opioid receptor sites. Psychedelic drugs may act via agonism at serotonin receptor sites. Phencyclidine (PCP) antagonizes the NMDA receptor and inhibits dopamine reuptake.

Hyperthermia and hypothermia can cause delirium due to changes in the cerebral metabolic rate. Patients suffering from heatstroke may have cerebral edema and degenerative neuronal changes leading to the development of oxidative stress and neuroinflammation. Normalizing the core temperature can reverse these changes. Delirium occurring at temperatures below 40°C is not usually caused solely by increased core temperature, and infection should be considered in cases not meeting the criteria for heatstroke.

Delirium caused by metabolic abnormalities, such as hyponatremia, hypernatremia, hyperosmolarity, hypercapnia, and hyperglycemic disorders, is associated with a variety of metabolic disturbances at the cellular level. Such disturbances may include impairments in energy supplies, changes in resting membrane potentials, in cellular morphology, and in the brain water volume.

Most patients with delirium have reduced cerebral metabolic activity. This reduction in cerebral metabolism is reflected by a slowing of background electrical activity on the electroencephalogram (EEG). Exceptions are hyperthermia, sedative-hypnotic withdrawal, delirium tremens, and certain drug-induced states, in which the cerebral metabolism is either normal or increased. In addition, patients experiencing delirium due to a postictal state or to nonconvulsive status epilepticus can show abnormal epileptiform discharges.

Clinical Features

Delirium can present as the first manifestation of underlying disease. The natural history of a patient's delirium can progress from apathy to marked agitation over hours (see Box 90.1). Nonspecific prodromal symptoms such as anxiety, restlessness, and insomnia may emerge in the hours to days before diagnosis.

Key aspects of cognitive impairment should become evident during a careful history and physical examination. Disturbance in attention is central to the diagnosis of delirium. The patient can be easily distractible or have difficulty remaining focused on a particular topic or interacting with a single person. Disorientation often accompanies the inattention but is not an invariable feature. The patient usually is disoriented with respect to time and occasionally to place; in extreme cases, disorientation to person also may be noted. Delirium, however, may be present in a patient who is completely oriented to person, place, and time. A mental status examination that consists solely of questions that assess orientation will not detect delirium in these instances.

The patient with delirium frequently has some degree of memory impairment, with the greatest impact on short-term memory. Thought processes and speech may be disorganized in patients with previously normal cognition. Disturbance in the sleep-wake cycle often occurs early in the course of delirium. Perceptual disturbances, including poorly formed delusions and hallucinations, are common. Delusions may involve a perception of harmful intent of others. Hallucinations are classically visual, but can also be auditory, tactile, gustatory, or olfactory. In addition, the delirious patient has a reduced capacity to modulate fine emotional expression and may demonstrate extreme emotional lability.

The cognitively impaired patient may provide an unreliable history. Valuable information often can be obtained from family, friends, in-home medical care providers, and paramedics. The baseline premorbid mental condition of the patient in relation to the current presentation should be established early in the examination. Specific inquiry should be made about the patient's current medical problems and previous medical history, including diabetes, hypertension, kidney or liver disease, immune status, and any neurologic or psychiatric problems. A detailed medication history, including the use of prescribed and over-the-counter medications, dietary supplements, and alcohol or other substances, is essential. Information about the home environment, medication bottles belonging to the patient or found near the patient, and the possibility of trauma can help clarify the underlying condition leading to the delirium.

The physical examination should begin with a careful assessment of vital signs. The delirious patient often exhibits autonomic nervous system abnormalities, including elevated or decreased pulse rate, blood pressure, respiratory rate, and temperature. The examination also includes assessment of the head for signs of trauma and the pupils for size, symmetry, and light reflex; evaluation of the neck for nuchal rigidity, bruits, and thyroid enlargement; assessment of the heart and lungs; evaluation of the abdomen for organomegaly and ascites; and examination of the extremities for cyanosis. The skin should be carefully examined for rashes, petechiae, ecchymosis, splinter hemorrhages, and needle tracks.

The neurologic examination includes assessment of the cranial nerves, motor strength, sensation, reflexes, and presence of abnormal movements (e.g., ophthalmoplegia, tremor, asterixis, myoclonus). The reflexes are assessed for symmetry and presence of hyperreflexia or hyporeflexia. Signs that suggest either a metabolic or a structural neurologic problem are helpful but can be nonspecific. For example, asterixis is a hallmark of hepatic encephalopathy but can also be seen in uremia and hypercapnia. Likewise, focal neurologic signs typically associated with structural CNS lesions also can be present in metabolic abnormalities such as hypoglycemia, hyperglycemia, hepatic encephalopathy, uremia, and hypercalcemia. A specific constellation of physical and neurologic findings may suggest a diagnosis. One such example is the classic triad of Wernicke encephalopathy: ophthalmoplegia, ataxia, and confusion. Other examples would include the classic toxidromes found in the presence of sympathomimetic, anticholinergic, sedative/hypnotic, and opioid medications.

Standardized screening tools can facilitate recognizing delirium and avoid missing the diagnosis. Similar to the diagnostic algorithm in other conditions, a fast, sensitive screen may first be applied before proceeding with a longer, more specific test. The most recent guidelines for geriatric emergency care recommend the Delirium Triage Screen (DTS) followed by the brief Confusion Assessment Method (bCAM).[5] The DTS can be performed in less than one minute and is 98% sensitive for delirium. The bCAM, a modification of the full Confusion Assessment Method (CAM) often used during inpatient evaluations, is 84% sensitive and 96% specific for delirium in older emergency department patients. The bCAM uses four key features in screening for delirium: (1) acute onset and fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. For a definitive diagnosis of delirium, the first two features, and one of the last two, must be present (Table 90.2).

In addition to the above recommended tools, there are several other delirium assessments in clinical use, but these instruments lack similar acceptance and utility within the ED setting. The Richmond Agitation-Sedation Scale (RASS) can be performed rapidly but has reduced sensitivity and specificity when used alone.[6] The Mini-Mental State Examination (MMSE) evaluates cognition in multiple domains, but it takes longer to perform and is best used for baseline assessments of dementia, rather than delirium. Other screening tools include the 4A's Test (4AT), the Nursing Delirium Symptom Checklist (Nu-DESC), and 3-Minute Diagnostic Assessment (3D-CAM), among others.[7]

TABLE 90.2 Common Emergency Department Assessments for Delirium and Dementia

Tests for Delirium	Item(S)	Application	Administered By	Time (Minutes)
Delirium Triage Screen (DTS)	2	Clinical, screening	Interviewer	1–2

Differential Diagnosis

Considerations in the differential diagnosis for delirium include dementia and psychiatric disorders. Dementia, depression, mania, paranoia, and schizophrenia all may resemble delirium but can be distinguished using historical and clinical features such as onset, time course, fluctuating mental status, and inattention (Table 90.3). Unlike delirium, dementia and psychiatric disorders tend to be insidious processes that develop over months to years. Typically, the patient's vital signs are normal. In addition, cognitive impairment of dementia exhibits little fluctuation during hours or days and occurs primarily in elders. However, patients with dementia are more likely to develop delirium, and as such, the two may often coexist.

Diagnostic Studies

Because delirium results from an underlying medical disorder, a comprehensive evaluation looking for structural, metabolic, and infectious etiologies is indicated (Table 90.4). Despite these diagnostic evaluations, no cause may ultimately be found for many patients. Basic laboratory tests, such as serum electrolytes, have variable diagnostic yield. An elevated anion gap (>15 mEq/L) may indicate the presence of unmeasured anions, such as ketoacids in diabetic or alcoholic ketoacidosis; lactate in postictal states or associated with hypotension; sulfate in renal failure; and exogenous toxins, such as ethylene glycol, methanol, and salicylates.

In addition to a pulse oximetry measurement to screen for hypoxemia, blood gas analysis from an arterial or venous sample is warranted in patients at risk for respiratory failure with hypercarbia. Urinalysis and chest radiography may be obtained to exclude an occult infection, which is the most common cause of delirium in older patients.

An electrocardiogram and troponin may be obtained to assess for an acute coronary syndrome in patients at risk for heart disease, including older patients. Thyroid hormone testing may reveal hypothyroid or hyperthyroid state. Furthermore, additional laboratory studies outside the usual scope of the ED evaluation may be appropriate when the cause of delirium remains unknown or when suggested by the clinical history and exam. These additional studies may include vitamin B_{12} and folic acid assays in cases of possible malnutrition, rapid plasma reagin test to exclude neurosyphilis, measurement of serum antinuclear antibodies if lupus encephalitis is suspected, urinary porphobilinogen assay in acute porphyria, and screens for heavy metals in intentional or accidental ingestions.

Adverse prescription medication effects, including drug-drug interactions, are another common cause of delirium and may occur at therapeutic doses and levels. A comprehensive review of all medications should be performed, with testing for levels when indicated and available. Standard toxicology screens may have limited usefulness in the evaluation of patients with delirium, since both false-positive and false-negative results may occur, and early diagnostic closure based on these tests may result in an incorrect diagnosis.

Neuroimaging with a head computed tomography (CT) scan should be performed on patients with a history or signs of trauma (especially those taking anticoagulant medications), recent neurosurgical procedures or with implanted devices (e.g., cerebrospinal fluid shunt), or focal neurologic signs to detect structural lesions causing delirium. Advanced imaging may be indicated if there is suspicion for

TABLE 90.3 Comparison of Delirium and Dementia

	DELIRIUM	DEMENTIA
Onset	Acute	Gradual
Attention	Impaired	Normal
Level of consciousness	Fluctuates	Normal
Orientation	Variable	Impaired
Memory	Often impaired	Impaired
Hallucinations	Present	Usually absent
Language	Slowed, aphasia	Word finding difficulty

TABLE 90.4 Delirium Diagnostic Studies and Clinical Findings

Diagnostic Studies	Examples of Delirium Precipitants
Vital signs	Hypoxemia, hypotension/hypertension, hypothermia/hyperthermia, pain, fever
Fingerstick glucose	Hypoglycemia/hyperglycemia
Blood gas	Hypoxemia, hypercarbia, respiratory alkalosis, metabolic acidosis
CBC: Hemoglobin, leukocyte count with differential, platelet count, mean corpuscle volume	Anemia, occult infection, thrombocytopenic purpura, megaloblastic anemia, hyperviscosity from myelogenous leukemia, polycythemia
Serum electrolytes: Glucose, sodium, calcium, chloride, bicarbonate, BUN, creatinine, magnesium, phosphate, osmolality	Hypoglycemia/hyperglycemia, hyponatremia/hypernatremia, uremia, hypo-osmolar/hyperosmolar, anion gap acidosis
Urinalysis: Nitrites, leukocytes, ketones	Occult infection, proteinuria
Chest x-ray	Occult infection, pneumothorax
Drug levels	Digoxin, lithium, quinidine, salicylate, antiepileptics
Additional tests: Troponin, liver and thyroid function studies, ammonia, PT, PTT, INR, vitamin B_{12} and folic acid assays, rapid plasma reagin test, measurement of serum antinuclear antibodies, urinary porphobilinogen assay, screens for heavy metals, toxic screens of blood and urine, methanol, ethylene glycol, carbon monoxide, cyanide	Myocardial infarction, liver failure, hypothyroid/hyperthyroid, bleeding disorder, excess anticoagulation, vitamin B_{12} or folate deficiency, occult infections, vasculitis, acute porphyria, toxins
CT Head/MRI	Cerebrovascular accident, structural lesions, traumatic head injury
LP/CSF analysis	Meningitis, encephalitis, subarachnoid hemorrhage
EEG	Nonconvulsive status epilepticus, delirium

BUN, Blood urea nitrogen; *CBC*, complete blood count; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *EEG*, electroencephalogram; *INR*, international normalized ratio; *LP*, lumbar puncture; *MRI*, magnetic resonance imaging; *PT*, prothrombin time; *PTT*, partial thromboplastin time.

early infarctions, small brainstem lesions, closed head injuries, sagittal venous sinus thrombosis, or small isodense subdural hematomas that may be missed on a CT scan. In addition, a small percentage of acute subarachnoid hemorrhages are not detected by head CT scan and require LP for diagnosis.

The role of magnetic resonance imaging (MRI) in the evaluation of the delirious patient has not been clearly established. MRI is superior to CT for detection of small intracerebral and brainstem lesions, small brain contusions, certain infectious and inflammatory encephalitides, and abnormalities of white matter (e.g., leukoencephalopathy). The posterior reversible encephalopathy syndrome (PRES) can present with confusion, visual changes, and headache in the setting of malignant hypertension, with MRI abnormalities often, but not exclusively, in the posterior cerebrum.

Cerebrospinal fluid (CSF) analysis is an essential part of the evaluation in selected patients with delirium. In patients with fever and cognitive dysfunction, a LP should be considered to rule out infectious, inflammatory or neoplastic etiologies particularly in cases of new headache, meningismus, seizures, community-living adults, recent neurosurgery, or when other testing has failed to identify an infectious source. This test is particularly important in children under age 5, older adults over age 65, and immunocompromised patients, who are less likely to show classic signs of meningitis. Patients with focal neurologic deficits, immunocompromised states, or evidence of increased intracranial pressure should undergo head CT before LP. Antibiotic therapy should not be delayed for the results of LP testing.

Although it is rarely practical in the ED setting, the EEG can be a valuable tool for ruling out nonconvulsive status epilepticus (NCSE) in the presence of delirium. Typical EEG findings in delirium from metabolic causes include nonspecific generalized slowing without epileptiform discharges. In critically ill inpatients with no alternative explanation for decreased level of consciousness, observational studies have shown up to one-third of patients had NCSE on EEG. This condition, even when diagnosed promptly, may be associated with poor patient outcomes in acutely ill patients when mental status abnormalities fail to resolve.

Management

Delirium is a medical emergency. The outcome depends on the cause, the patient's overall health status, and the timeliness of treatment. The hypoactive form of delirium tends to be more common in older adults and carries a worse overall prognosis, perhaps because it often goes unrecognized. Acute recognition and management of delirium in older patients is essential because delirium in this population is associated with increased risk of long-term institutionalization, development of dementia, and increased overall mortality.[2,8]

After recognition of delirium, patients should be screened quickly for readily treatable causes, such as hypoglycemia, hyperglycemia, hypoxia, hypercarbia, and opioid overdose. Acute intoxication due to medications or illicit substances requires prompt attention, and antidotes provided when available.

Initial management of agitation in hyperactive delirium should be accomplished with nonpharmacologic interventions such as verbal reassurance, assistance from family caregivers when present, and calming environment. When nonpharmacologic measures fail, or in the setting of immediate threat to the patient or staff, sedative medications may be administered through an intravenous or intramuscular route to prevent unsafe behavior and facilitate rapid clinical assessment and management.

Supportive care for all patients with delirium ideally includes an environment with adequate lighting and minimization of sensory overload; the patient should be placed in an area that can be easily observed by staff, and use of stretcher side rails to prevent falls. Use of "sitters" may be necessary to provide continuous supervision on a 1:1 or 1:2 basis with the patient. The patient must be protected from self-harm or from injuring other patients or staff. In cases of hyperactive delirium, the patient may need to be initially physically restrained until pharmacologic control takes effect. Physical restraints should be viewed only as a temporizing action because they can increase agitation and the risk of injury to the patient. Death in restraint is a recognized phenomenon, occurring more frequently in patients restrained in nonsupine positions and with agitated delirium.

Following the initial evaluation, care should be directed towards conditions requiring immediate medical intervention. Patients with signs of acute meningitis or sepsis should rapidly receive antibiotics along with appropriate fluid resuscitation. Other conditions that may manifest as delirium and necessitate immediate intervention include severe hypothermia, hyperthermia, and CNS vascular conditions, including hypertensive encephalopathy, acute epidural or subdural hematoma, subarachnoid hemorrhage, and stroke. Patients with Wernicke encephalopathy require immediate treatment with 200 to 500 mg of intravenous (IV) thiamine, with titration of additional doses until the ophthalmoplegia resolves. Traditionally, glucose administration in patients with severe thiamine deficiency was deferred given concern for precipitating Wernicke encephalopathy, but evidence for this phenomenon occurring is poor.

The specific treatment of delirium tremens (and other alcohol withdrawal syndromes) involves the substitution of a long-acting drug that is cross-tolerant with the alcohol. Benzodiazepines are the agents of choice in treatment of delirium due to sedative withdrawal, but caution should be used with these medications in other conditions because they may worsen delirium severity. Treatment for delirium secondary to dehydration or electrolyte abnormality begins in the ED, but care is needed to prevent overcorrection in patients with sodium abnormalities because this can lead to permanent neurologic damage. In patients with hepatic or renal disease, inpatient treatment with medications for hepatic encephalopathy or dialysis for renal disease may be required before disturbances in cognition resolve.

Pharmacologic interventions are a cornerstone of behavioral management while the underlying medical condition that caused the delirium is being addressed. Antipsychotics and benzodiazepines have been used in the management of acute agitation in the undifferentiated patient with delirium (Table 90.5); opioids have no role.

Antipsychotic medications used to treat delirium include the typical antipsychotics, especially the butyrophenones including haloperidol and droperidol, and the newer atypical antipsychotic agents. Evidence for the superiority of any individual agent is limited, and no one drug is ideal for treatment of all cases. The typical antipsychotic, haloperidol, a potent dopamine-blocking medication with minimal anticholinergic and vasodilatory side effects, is recommended as monotherapy for controlling agitation in acute delirium on the basis of extensive clinical experience and best evidence base.[9] The main acute response to the drug is tranquilization. The incidence of extrapyramidal side effects in patients receiving IV haloperidol for management of delirium with agitation is relatively low, generally less than 10% of patients.

As with all the antipsychotics, haloperidol can prolong the QTc interval, more so when given intravenously, but this effect is clinically insignificant in most patients and does not require a pretreatment electrocardiogram. Caution is warranted with use of this agent in patients taking medications that prolong the QTc and in patients with acute coronary ischemia, uncompensated congestive heart failure, or hepatic dysfunction. Another agent in this class, droperidol, received a "black-box" warning from the US Food and Drug Administration (FDA) in 2001 for concerns of QTc prolongation. Although an effective therapy

TABLE 90.5 Medications for Agitation

Etiology	Agent	Dose	Notes
Acute undifferentiated agitation	Typical antipsychotics		
	• Haloperidol	0.5–1 mg IV or 1–2.5 mg IM	Maximum of 10–20 mg/day. Black-box warning of increased mortality in older patients with dementia-related psychosis.
	• Droperidol	2.5–5 mg IV or 5 mg IM Q30 minutes as needed	Maximum dose of 20 mg/day. Black-box warning for QT prolongation.
Parkinson dementia with agitation; acute undifferentiated agitation	Atypical antipsychotics		
	• Quetiapine	12.5–25 mg PO one to three times daily	Black-box warning of increased mortality in older patients with dementia-related psychosis.
	• Olanzapine	2.5–5 mg IM or IV every 2–4 hours	Maximum of 30 mg/day based on patient toleration. Black-box warning of increased mortality in older patients with dementia-related psychosis.
Agitation from acute intoxication or withdrawal syndromes; acute undifferentiated agitation	Benzodiazepines		
	• Lorazepam	0.5–1 mg IM or IV every 4–6 hours as needed	Maximum 4 mg per episode. Has additive CNS depressant effects with other medications.
	• Midazolam	2.5–5 mg IV or IM every 15 minutes as needed	Maximum 10 mg per episode. Has additive CNS depressant effects with other medications.

for agitation in many patients, this warning led to a reduction in the use of droperidol and research into its effects in comparison to other agents. Large observational studies of droperidol use in the emergency department have not supported this concern and we consider droperidol a viable option in the management of acute agitation.[10]

Dosing of haloperidol should be adjusted for the patient's level of agitation, age, weight, and response to treatment. In most patients, 2.5 to 5 mg intramuscularly or intravenously (adjusted according to weight and comorbidities) is well tolerated as an initial dose, and levels can be titrated as needed. For older patients, a lower initial dose of 0.5 to 1 mg is recommended. In highly agitated patients, combination therapy with haloperidol and lorazepam, 0.5 to 2 mg IV or IM, may be more effective than monotherapy with haloperidol. Combinations of sedatives with anticholinergics, such as diphenhydramine, is discouraged, given the likelihood of prolonging the delirium state.

The newer atypical antipsychotic agents (risperidone, olanzapine, ziprasidone, aripiprazole) may have similar efficacy but different side effect profiles, which may be desirable in some cases of acute agitation. The mechanism of action includes antagonism of alpha$_1$-adrenergic, serotonin, dopamine, and histamine receptors. These drugs can also block the reuptake of dopamine and serotonin. Olanzapine, since it has both IV and IM formulations, has received support in the literature as being a safe and effective treatment for acute agitation in the ED, with reduced need for additional sedation in comparison to haloperidol.[11-13] Because of the limited dopamine antagonism effect, atypical antipsychotics are preferred over haloperidol for patients with Parkinsonism and agitation, although benzodiazepines may be a better choice in this population given concerns about increased mortality with the use of atypical antipsychotics in Parkinson disease.[14]

Benzodiazepines are another means to effectively sedate patients with acute undifferentiated agitation, but they are especially useful in cases of substance intoxication or withdrawal syndromes. Lorazepam, with onset of sedation within 2 to 3 minutes, is the preferred agent for treatment of withdrawal symptoms. Midazolam has a similar onset of action to lorazepam, but shorter duration of effect, and may be preferable in some cases. Diazepam should be avoided as an agent for treatment of agitated behavior in most delirious patients because of its long half-life and risk of drug accumulation with repeated dosing. Both midazolam and diazepam have prolonged half-lives in hepatic and renal impairment.

The management of acute behavior change in elderly patients in the emergency department has been identified by national groups as an area requiring further research.[15] Based on the best available evidence, we recommend screening and treatment of readily reversible causes of delirium and initial nonpharmacologic management followed by a selection of pharmacologic agents based upon the etiology of delirium and patient comorbidities.[2] We recommend an antipsychotic (typical or atypical) be used as monotherapy for undifferentiated patients with agitated delirium, or benzodiazepines for patients suspected of having substance intoxication or withdrawal who require sedation. As an alternative, a combination of a low-dose antipsychotic plus benzodiazepine (e.g., haloperidol 5 mg plus lorazepam 2 mg IM) can be used in combative patients with immediate safety threats. The combination approach has been found to be superior to monotherapy in the control of undifferentiated acute agitation.[11,16]

Disposition

Patients with delirium secondary to acute drug intoxication may be discharged from the ED provided the process resolves during a short

period of observation and the drug has no potentially serious delayed toxicity. For most patients with delirium from metabolic, infectious, or CNS processes, hospitalization is necessary for further diagnostic evaluation and treatment. The only readily reversible metabolic problem associated with delirium that can be completely managed in the ED is hypoglycemia.

For most patients with treatable medical illness who have delirium, the outcome is full recovery. Time for return to baseline function can be prolonged, particularly in older patients. In some patients, a persistent decline in their baseline level of functioning may occur despite resolution of the acute cognitive dysfunction. Delirium in older adults hospitalized without baseline dementia is associated with higher 1-year mortality rates, higher rates of institutionalization, and a greater risk for development of dementia. These long-term consequences can occur despite optimal supportive multidisciplinary care.

DEMENTIA

Principles

Background

Dementia is a gradual progressive cognitive decline in complex attention, executive function, learning and memory, language, perceptual motor function or social cognition that interferes with daily function and independence. Dementia may be a primary progressive irreversible neurodegenerative disease, a secondary potentially reversible non-neurodegenerative disease or a mixed dementia arising from multiple etiologies. The predominant dementia is Alzheimer dementia representing 60% to 80% of all cases; vascular dementia represents 20% of all cases, and dementia from multiple etiologies represents 20%.

Dementia is not a single disease entity but rather a highly variable clinical syndrome characterized by the gradual progressive deterioration of cognitive function. Prognosis depends on the underlying cause (Box 90.2). Dementia onset may be categorized as "presenile" when arising before age 65, or "senile" dementia otherwise. Severity is classified according to the degree of cognitive impairment. Mild dementia implies some impairment of work and social activities; however, the capacity for independent living remains intact. With moderate dementia, independent living is hazardous, and some degree of supervision is necessary. With severe dementia, continual supervision and often custodial care are needed.

Primary neurodegenerative dementias include Alzheimer disease, dementia with Lewy bodies, subcortical dementias involving the basal ganglia and thalamus (e.g., progressive supranuclear palsy, Huntington chorea, Parkinson disease), and dementia of the frontal lobe type, which includes Pick disease. Dementia with Lewy bodies, clinically manifested by persistent, well-formed visual hallucinations and prominent extrapyramidal movements, has been found to be the third most common type of dementia. With advanced aging, dementia may have mixed causes, with Alzheimer disease and vascular dementia frequently coexisting. A smaller percentage of dementias are attributable to causes such as anoxic encephalopathy, hepatolenticular degeneration, tumors, alcohol abuse, and slow virus infections.

Potentially reversible secondary non-neurodegenerative dementias are caused by adverse drug reactions, endocrinopathies, metabolic abnormalities, intracranial processes, and depression. The disorder may manifest clinically as acute or gradual progressive cognitive impairment that reverses once the underlying etiology is addressed and resolved. Drug-induced dementia occurs primarily in older adults and can be caused by various psychotropic drugs, antihypertensive medications, anticonvulsants, anticholinergics, and miscellaneous medications, such as L-dopa.[17] Dementia also may be caused by heavy metals and other exogenous agents, such as carbon monoxide, carbon disulfide, and trichloroethylene.

Endocrinopathies and metabolic abnormalities that can cause secondary and potentially reversible dementia include hypothyroidism, hyperthyroidism, parathyroid disease, Addison disease, Cushing disease, and panhypopituitarism. Metabolic abnormalities such as nutritional deficiencies that cause dementia include thiamine deficiency (Wernicke syndrome), niacin deficiency (pellagra), vitamin B_{12} deficiency, and folate deficiency.

Intracranial processes, space-occupying lesions, and hydrocephalus may also cause dementia. Repetitive intracranial trauma resulting from contact sports can produce a chronic organic brain syndrome without evidence of hematoma or significant contusion (dementia pugilistica).

BOX 90.2 Causes of Dementia

Primary Degenerative Dementias
Alzheimer disease
Lewy bodies disease
Frontal lobe disease (Pick disease)

Subcortical Dementias
Parkinson disease
Huntington disease

Vascular Dementia
Multi-infarct dementia

Intracranial Processes
Space occupying lesions (tumor, subdural hematoma)
Hydrocephalus
CNS infections (i.e., HIV-1, neurosyphilis, chronic meningitis, encephalitis secondary to measles, John Cunningham (JC) virus, rubella, *Candida albicans*, Creutzfeldt-Jakob disease (CJD), and variant CJD subacute spongiform viral encephalopathies, or slow virus infections)
Repetitive head trauma

Endocrinopathies
Addison and Cushing diseases
Thyroid and parathyroid disease

Nutritional Deficiencies
Thiamine
Niacin
Folate
Vitamin B_{12}

Toxic Exposures
Heavy metals
Carbon monoxide
Carbon disulfide

Drugs
Psychotropics
Antihypertensives
Anticonvulsants
Anticholinergics

Depression
Pseudodementia

BOX 90.3 Diagnostic Criteria for Dementia

A. Cognitive decline from a previous level of performance in one or more cognitive domains: Complex attention, executive function, learning and memory, language, perceptual motor function, or social cognition.
B. The disorder has an insidious onset and gradual progression.
C. The deficits do not occur exclusively during the course of a delirium.
D. The cognitive deficits are not better explained by another mental disorder, such as major depression or schizophrenia.

Adapted from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

Intracranial processes that may eventually lead to a chronic organic brain syndrome include infections with slow viruses, human immunodeficiency virus type 1 (HIV-1) infection, chronic meningitis (tubercular or fungal), brain abscess, and neurosyphilis. In addition to primary HIV-1 CNS infection, toxoplasmosis, cryptococcal meningitis, malignant disease, and infections due to herpesvirus, cytomegalovirus, varicella-zoster virus, and JC virus (progressive multifocal leukoencephalopathy) can cause progressive cognitive impairment in this compromised group of patients and must be excluded.

Worldwide, approximately 24.3 million persons suffer from dementia, and as the population ages, 4.6 million new cases are diagnosed yearly. The prevalence of dementia is approximately 10% in adults over 65 years old and 50% in adults over 85 years old. The incidence of dementia in the United States is expected to increase as life expectancy continues to increase, but rates may decline as risk factors are controlled in older adults.[18] ED-based studies of cognitive impairment report that up to 70% of older adults seen with cognitive impairment have undiagnosed dementia. Dementia is a strong predictor of mortality, which varies with age and subtype. Older adults with dementia have high rates of ED utilization, with greater numbers of comorbidities and higher rates of admission compared to those without dementia.[19]

DSM-5 criteria for the diagnosis of dementia are presented in Box 90.3. There must be cognitive impairment that interferes with independence in one of six domains: complex attention, executive function, learning and memory, language, perceptual-motor function, or social cognition. Several clinical features deserve emphasis. Impairment in memory must involve both short-term and long-term memory. The cognitive impairment commonly involves abstract thinking, judgment, and other higher cortical functions. The cognitive impairment must interfere with interpersonal relationships, work, and social activities. Although mild decline in intellectual functioning characterized as inability to learn and retain new information without impairment of daily functions can be part of the normal aging process, gross intellectual impairment of short- and long-term memory or confusion is not normal. Mild cognitive impairment is distinct from early dementia.

The goals of ED evaluation for suspected dementia are (1) to recognize the signs and symptoms of undiagnosed and potentially reversible forms of dementia, (2) to identify the manifestations of acute illness in the demented patient promptly, and (3) to assess the clinical findings in lieu of the patient's cognitive impairment and facilitate a safe disposition and expedited follow-up.

Pathophysiology

Alzheimer disease is the best-understood dementia and involves several characteristic anatomic, pathologic, and neurochemical changes. The predominant change is cortical atrophy most prominent in the temporal and hippocampal regions caused by progressive synaptic and neuronal loss in the cerebral gray matter. This atrophy generally is followed by loss of white matter (subcortical atrophy). The degree of neuronal loss correlates with symptomatic severity of Alzheimer dementia and is typically beyond the amount expected in normal aging. Not all patients with histopathologic features of Alzheimer disease will have extensive neuronal losses. There is no ischemic component to Alzheimer disease.

Histologic features characteristic of Alzheimer disease include extracellular deposition of β-amyloid protein and intracellular neurofibrillary tangles contributing to neuron loss. The abnormal processing of β-amyloid protein is likely central to the pathogenesis of Alzheimer disease. The neurofibrillary tangles are intraneuronal paired helical filaments composed of the abnormally phosphorylated protein tau, the structural protein involved in the regeneration of neurites. Senile plaques are extracellular lesions composed of the degenerating neuronal processes and abnormal β-amyloid protein. These plaques are extensively spread throughout the cerebral cortex and do not correlate with the severity of dementia. Other consistent neurohistopathologic changes in Alzheimer disease include granulovascular degeneration (membrane-bound bodies within vacuoles of hippocampal pyramidal cells containing small basophilic granules), Hirano bodies (eosinophilic rod-shaped bodies in hippocampal pyramidal cells composed of actin-associated protein aggregates), β-amyloid deposition in the small cortical blood vessels, and neuronal loss in the limbic area.

Many biochemical abnormalities have been described in patients with Alzheimer disease. A decrease in the neurotransmitter acetylcholine is characteristic. Levels of the enzyme choline acetyltransferase, which synthesizes acetylcholine in the brain, can be reduced to 20% of that in age-matched control subjects.

Risk factors for Alzheimer and vascular dementia range from potentially modifiable cardiometabolic and lifestyle factors to genetic factors. The Framingham Cardiovascular Risk Profile (FCRP) and Cardiovascular Risk Factors Aging and Dementia (CAIDE) risk score reflect the common risk factors of high cholesterol, high blood pressure, diabetes.[20] In addition, advancing age, gender, smoking, air pollution, depression, family history, low education level, and head trauma are associated risk factors for the development of cognitive impairment and dementia. The apolipoprotein E epsilon 4 allele on chromosome 19 has been associated with both familial and sporadic late-onset Alzheimer disease. Apolipoprotein E is responsible for transporting of the cholesterol and phospholipids necessary for dendritic and synaptic repair. There are several allelic variants, but those homozygous or heterozygous for the E4 variant have an increased risk for the development and expression of the disease. Abnormalities on chromosomes 1 and 14 also have been associated with Alzheimer disease.

The frontotemporal dementias are less prevalent than Alzheimer disease and are categorized by a frontal and temporal atrophy caused by cell death. The most common histologic finding in the frontotemporal dementias is the combination of prominent cell loss and gliosis in frontal and temporal regions of the cortex, termed *dementia lacking distinctive histology* (DLDH).

Approximately 15% to 20% of dementias are caused by multiple vascular insults to the CNS; the resulting deficit is termed *multi-infarct dementia.* The multiple infarcts typically involve the cerebral hemispheres and basal ganglia. Multi-infarct dementia often has an earlier age at onset than Alzheimer disease and occurs more often in adult men and patients with risk factors for atherosclerosis. Approximately 20% of dementias are mixed combinations of both ischemic cerebrovascular disease and Alzheimer dementia.

Inflammatory conditions of the CNS contribute to the development of dementia and can be caused by conventional viruses or fungal infections including subacute sclerosing panencephalitis from measles virus infection, progressive multifocal leukoencephalopathy from infection by the John Cunningham (JC) virus (a papovavirus), progressive

rubella encephalitis, HIV disease, and *Candida albicans*.[20] The unconventional viral infections include kuru, Creutzfeldt-Jakob disease (CJD), and variant CJD (which appears to be linked to bovine spongiform encephalopathy, the pathologic process in "mad cow disease"). The infectious agents in these diseases are virus-like particles known as *prions*. A prion is a proteinaceous infectious particle with the apparent ability to start a chain reaction that changes the shape of benign protein molecules into abnormal, slowly destructive forms. These diseases cause a fine vacuolation of the nervous tissue and hence are referred to as *subacute spongiform viral encephalopathies*. With these diseases, months to years pass between infection and the appearance of clinical illness.

One of the most prevalent slow virus infections causing progressive dementia is HIV-1 infection. HIV may produce a primary neurotrophic disorder in addition to causing the immunologic compromise that permits other viruses to replicate and damage nervous tissue. HIV dementia or acquired immunodeficiency syndrome (AIDS) dementia complex occurs in approximately one-fourth of patients with AIDS. It is believed to be caused by the HIV-1 virus targeting the microglial cells and the macrophages, which may produce cytotoxic substances, such as tumor necrosis factor and interleukins. Pathologic changes occur mostly in the hippocampus and basal ganglia and include atrophy, ventricular dilation, and fibrosis.

Several of the potentially reversible causes of dementia also are associated with neuropathologic or neurochemical abnormalities. Normal-pressure hydrocephalus generally affects younger people; 50% of patients are younger than 60 years. Most of the conditions that cause hydrocephalus involve a defect in uptake of CSF by arachnoid villi, which results in gradual ventricular dilation.

Chronic, heavy ethanol consumption is associated with dementia. The neurotoxicity of ethanol appears to be independent of thiamine deficiency. Heavy chronic alcohol consumption causes cerebral cortical atrophy, but no single alcohol-related dementia syndrome exists.

Clinical Features

Family or friends often bring the patient to the ED because of a sudden worsening in mental status, a change in the patient's activities (e.g., refusal to eat), or a change in the ability of the caregiver to manage the patient. Presentations vary by the cause of the dementia and the stage of progression. Many older adults with dementia have a superimposed delirium on presentation.

The symptoms, signs, and progression of chronic cognitive impairment rarely are so diagnostic as to permit identification of the specific cause of the dementia. Alzheimer disease begins insidiously. Signs and symptoms of cognitive dysfunction may be present for months to years before the diagnosis is made. The earliest symptoms and signs of Alzheimer disease often are vague and nonspecific; patients manifest anxiety, depression, insomnia, frustration, and somatic complaints that often are more prominent than the memory loss. Patients often deny any cognitive deficits and change the subject of the conversation frequently rather than admit their increasing forgetfulness. Physicians often overlook the subtle signs of dementia in this phase of the disease. Family and close informants are often the source of a reliable history of cognitive and functional changes for patients with chronic cognitive impairment. Various tests of cognitive function can be used to improve the detection rate of subtle cases, document a change in level of cognition or assist in determination of competency (see Table 90.2).

Depression often is the initial manifestation of Alzheimer disease and is present in up to 40% of cases. Early in the illness, short-term memory is affected with forgetfulness of recent events, such as appointments and names of new acquaintances. Patients often repeat questions. The memory impairment may cause them to withdraw from social situations and recreational pursuits. Attempts to perform complex tasks may produce anxiety and confusion. The patient often has difficulty with interpersonal relationships. Affect may be shallow and labile, and minor events may trigger inappropriate laughter or tears. Compensation for early deficits includes excessive orderliness and avoidance of situations in which the defects may be observed. Patients in this early phase who are treated with antidepressants with anticholinergic properties may experience worsening of their symptoms. Sedative-hypnotics prescribed for anxiety also may accelerate cognitive dysfunction.

As dementia progresses, cognitive deficits are more obvious and should be readily apparent on a mental status examination. Problems with recent memory, impairment of remote memory, language deficits, and difficulty with spontaneous speech may be noted. With moderate severity of the disease, patients have difficulty naming objects (dysnomia). As many as 50% of patients have delusions, usually of the paranoid type. Atypical presentations of Alzheimer disease include aphasia, visual agnosia, right parietal lobe syndrome, focal neurologic findings, extrapyramidal signs, gait disturbances, and pure memory loss. In the final stage of dementia, patients exhibit marked cognitive impairment, apraxia, and personality changes. They often are bedridden and unable to perform the routine activities of daily living.

Because Pick disease dementia affects the frontal and temporal lobes, patients often have frontal lobe release signs, including dramatic behavioral changes of disinhibition and social inappropriateness. Basal ganglia degenerative disorders that have dementia as a prominent feature are Huntington chorea, Parkinson disease, and Wilson disease. One of several features that distinguish cortical from subcortical dementias is a prominent movement disorder, including posturing, ataxia, tremor, and chorea, that tends to occur early in the illness. Other features of these dementias include slowness of speech, hypotonia, and dysarthria, which can progress to mutism.

Patients with vascular dementia have a stepwise deterioration in memory and cognitive function with each cerebrovascular insult. The clinical presentation may follow one of two scenarios. In the more common scenario, the patient suffers several strokes that involve large volumes of cortical and subcortical structures in both hemispheres. The patient then exhibits dementia along with other neurologic disabilities (e.g., focal weakness, hyper-reflexia, extensor plantar response). In a second group of patients, the presentation is subtle. These patients characteristically are hypertensive and suffer multiple tiny infarcts (lacunae) that involve deep subcortical structures. There may be no focal neurologic residua except progressive dementia with psychomotor retardation. Antihypertensive management in older adults moderately reduces the incidence of dementia and Alzheimer disease for patients with hypertension.[21]

The clinical manifestations of slow virus CNS infections are protean. After an insidious onset of mental deterioration in subacute sclerosing panencephalitis, a rapid progression ensues that is associated with myoclonic jerks, incoordination, and ataxia. In progressive multifocal leukoencephalopathy, neurologic signs and symptoms reflect diffuse asymmetrical involvement of both cerebral hemispheres. Sporadic CJD, of unknown etiology, tends to affect older people, with a rate of disease of one case per million people per year. Among these patients, rapidly evolving dementia with myoclonus is characteristic. The hallmarks of the disorder are mental deterioration, multisystem neurologic signs, myoclonus, and typical electroencephalographic changes that evolve during months. Variant CJD affects younger patients (median age of 24 years) with key features that include early affective symptoms progressing to cognitive impairment and gait disturbances and ultimately leading to progressive neurologic deterioration. The incubation period appears to be in the range of 10 to 15 years, and most patients die within 14 months after the clinical onset of symptoms.

The classic triad of progressive dementia, ataxia, and urinary incontinence occurs in patients with normal-pressure hydrocephalus. Hydrocephalus secondary to previous head trauma or infection carries a more favorable prognosis than that for primary hydrocephalus.

In approximately 20% of reversible cases, dementia is secondary to an intracranial mass. Patients may exhibit focal or nonfocal neurologic signs. Of the reversible dementias, 10% to 15% are caused by medications or chemical intoxications, frequently compounding a history of heavy alcohol use. Older adults have increased susceptibility to the toxicities owing to polypharmacy and age-related changes in metabolism. The clinical presentation of a patient with a drug-related or toxin-related dementia may be indistinguishable from that of a patient with a primary degenerative process.

In addition, chronic traumatic encephalopathy (CTE) is a controversial diagnosis that is proposed to be caused by repetitive mild traumatic brain injuries though well-designed studies have not eliminated confounders that could contribute to the process.[22] It is characterized by progressive neurodegeneration, deposition of hyperphosphorylated tau (p-tau) as neurofibrillary tangles in a distinct pattern and may present as dementia and cognitive impairment. This form of encephalopathy is proposed to develop many years after trauma and progresses to dementia, gait and speech abnormalities, and Parkinsonism. It is unclear if CTE is unique to trauma and its symptomatology overlaps with other types of dementias.

Differential Diagnosis

Senescent Forgetfulness

Subacute or chronic cognitive decline may be caused by a dementing illness or can be a manifestation of senescent forgetfulness, delirium, or depression. Senescent forgetfulness is an almost inevitable reality of aging. Mild impairment of both short-term and long-term memory is usual. Unlike dementia, the cognitive disturbance in senescent forgetfulness does not interfere with work or customary social activity.

Delirium

In most cases, the distinction between delirium and dementia is obvious (see Table 90.3). The onset of symptoms, progression of signs and symptoms, perceptual disturbances, abnormalities on assessment of vital signs, and fluctuations in the level of consciousness are key distinguishing features. However, dementia is a risk factor for delirium, and it is more difficult to differentiate delirium when superimposed on a patient with dementia.

Depression

Depression in older adults may closely mimic dementia. Diagnosis of pseudodementia or depression masquerading as dementia can be difficult and may require therapeutic interventions to confirm the clinical diagnosis. Confounding the issue, depression often coexists with dementia; one study found that 40% of patients with dementia were depressed. Depression, anxiety, and apathy are common in the prodrome and course of Alzheimer disease. Several distinguishing features suggest that the problem is depression rather than dementia. The onset of cognitive changes in pseudodementia often can be pinpointed, and symptoms usually are of short duration before medical help is sought. The progression of symptoms is rapid, and the family usually is aware of the severity of the dysfunction. A history of psychiatric illness is common. Patients with pseudodementia usually complain of cognitive dysfunction and emphasize their failures and disabilities. The affective change often is pervasive, and the patient makes little effort to perform simple tasks. Loss of social skills usually occurs early in the illness, and patients communicate a strong sense of distress and inability to function. Intellectual functioning in pseudodementia often is difficult to assess because of lack of patient cooperation or inconsistent findings on neuropsychometric testing. Attention and concentration often are intact, but patients commonly give answers such as "I don't know" on tests of orientation, concentration, and memory. Memory losses for recent and remote events usually are equally severe, and variability in the performance of tasks with similar degrees of difficulty may be marked. Tasks of high capacity (e.g., testing of delayed memory with distraction) may be helpful in identifying the depressed patient.

BOX 90.4 Elements of the Mental Status Examination in the Evaluation of Dementia

Routinely Observed
Appearance, behavior, and attitude
Mood and affect

Require Inquiry
Sensorium and intelligence: Cognitive impairment
Disorders of thought: Suicidal and homicidal ideation
Insight and judgment: Knowledge about illness
Disorder of perception: Hallucinations and delusions

Diagnostic Testing

The evaluation of the patient with suspected dementia includes a focused medical, psychiatric, and medication history plus a collateral history from family and friends. Physical examination should include a detailed neurologic examination with a mental status evaluation. Dementia often goes unrecognized in the patient who is alert, pleasant, and cooperative. A validated cognitive evaluation test can play a key role in the early identification of dementia in patients who have maintained social and conversational ability.

Cognitive Evaluation

A mental status examination should be performed in all patients suspected to have cognitive dysfunction. In the demented patient, mental status testing can uncover subtle forms of delirium. Assessment of orientation to person, place, and time are not sensitive enough to establish cognitive dysfunction. A cognitive assessment should include both psychiatric and neurologic components (Box 90.4).

Several standardized tools for rapid cognitive assessment have been successfully applied in the ED and can be performed in 7 to 10 minutes. Mini-mental status exam (MMSE) testing includes assessment of orientation, memory, attention, and concentration; several tests also incorporate assessments of constructional tasks, spatial discrimination, arithmetic ability, and writing. Memory assessment requires testing of the patient's ability to repeat short series of words or numbers (immediate recall), to learn new information (short-term memory), and to retrieve previously stored information (long-term memory). Constructional apraxia is assessed by having the patient perform tasks, such as drawing interlocking geometric figures or clock faces and connecting dots. Dysnomia (inability to name objects correctly) and dysgraphia (impaired writing ability) are two of the most sensitive indicators of delirium superimposed on dementia. Almost all acutely confused patients exhibit writing impairments, including spatial disorganization, misspelling, and tremor. Therefore, if patients screen positive for delirium the standardized tools cannot be used to assess for dementia.

No single bedside cognitive test that can be administered quickly is ideal. There are various tests of cognitive function, some of which have been tested in the ED (see Table 90.2). The MMSE developed by Folstein and colleagues has been validated more than any other test

and is regarded as the reference standard for dementia diagnosis in most studies in the ED as well. For hospitalized patients, this test has a sensitivity of 87% and a specificity of 82% for detection of organic brain syndrome. Limitations of the MMSE include copyright protection, meaning that official tests must be ordered individually through its distributor although multiple free versions are available online, concerns about false positives in certain lower socioeconomic groups and non-English speakers, and length of the test in comparison to brief screening tools.

The MMSE consists of a short series of questions that test orientation, registration (memory), attention, calculation, recall, and language scored on a 30-point scale. The time for the test to be administered can be reduced to 5 minutes by elimination of the writing and drawing components with only a modest reduction in sensitivity. The registration section tests both immediate and short-term memory; the recall section also assesses short-term memory. The ability to recall two of three objects has 81% sensitivity and 74% specificity for exclusion of organic brain syndrome. Asking the patient to subtract "serial sevens" backward from 100 assesses attention, concentration, and arithmetic ability. This test is specific but not sensitive for absence of an organic brain syndrome; up to 40% of nondelirious, nondemented people fail to perform the tasks of this test correctly, reflecting limitations due to language ability and education. A total score of 23 or less is considered markedly abnormal and indicates an organic brain syndrome. Generally, patients with mild cognitive impairment have a score of 18 to 26 out of 30, those with moderate impairment have a score of 10 to 18, and those with severe impairment have a score of less than 10.

The most recent Geriatric Emergency Department Guidelines, endorsed by the American College of Emergency Physicians and the American Geriatrics Society, suggest the Short Blessed Test (SBT) for ED Dementia Screening. The SBT is a 6-item screening tool evaluating a combination of orientation, registration, and attention. SBT scores correlate well with full MMSE testing, can be performed in 5 to 10 minutes, and has high diagnostic accuracy. Other tests include the clock drawing test, Montreal Cognitive Assessment (MoCA), Abbreviated Mental Test (AMT-4), and Brief Alzheimer's Screen.[23] The clock drawing test is scored on a 6-point scale from no errors to no reasonable representation of a clock. MoCA testing includes assessment of visuospatial, language (naming), memory, attention, recall, and orientation domains of cognition, for a total of thirty possible points. Both the AMT-4 and Brief Alzheimer's Screens are shorter mental status exams validated in the ED as screening tools to prompt more comprehensive testing. The AMT-4 focuses on memory and orientation, and the Brief Alzheimer's Screen includes a spelling item.

The screening tests provide limited detection of mild cognitive impairment (without dementia) or early dementia. In addition, bedside tests of cognition represent cognitive functioning at only one point in time and can be influenced by the patient's level of education and general intelligence; therefore, further history and testing is recommended to establish the diagnosis in symptomatic patients.

Alzheimer disease is a clinical diagnosis typically made on probability; no routine available laboratory tests have been found to confirm the presence of the disorder. MRI scans, functional scans looking at regional blood flow or glucose metabolism, assays for specific biomarkers, and CSF analysis can increase the probability of the presence of the disease. The physical examination is rarely helpful in detecting treatable dementias because of the considerable clinical overlap with irreversible dementias.

Laboratory Tests and Imaging Studies

Data clearly supporting or refuting the ordering of "routine" laboratory studies for evaluation of dementia are lacking; however, several studies are recommended to exclude treatable causes (see Box 90.2). For symptomatic ED patients with suspected undiagnosed dementia, a baseline laboratory evaluation, including CBC, comprehensive metabolic panel, and urinalysis, is recommended. If neurosyphilis is clinically suspected based on risk factors such as HIV co-infection or possible sexual exposure, a serum fluorescent treponemal antibody absorption test should be performed in addition to a Venereal Disease Research Laboratory (VDRL) test because the serum VDRL assay may yield negative results in patients with tertiary syphilis. Rapid Plasma Reagin (RPR) accuracy may be inferior compared to the VDRL for neurosyphilis. The radiologic evaluation may include a non–contrast-enhanced head CT scan. The CT scan is used to diagnose or to exclude the presence of hydrocephalus or space-occupying lesions, and CT findings may support a vascular etiology.

Patients may require additional laboratory tests on follow-up evaluation; such tests may include determination of serum vitamin B_{12} and folate levels, thyroid function studies, erythrocyte sedimentation rate, fluorescent antinuclear antibody assay, measurement of urine corticosteroid levels, and, if indicated by history, urine screens for drugs and heavy metals. Selected patients, particularly those younger than 60 years of age, those with rapidly progressive symptoms or patients in whom confirmatory biomarker testing is desirable, should undergo a LP with CSF analysis. Neuroimaging with head CT or MRI is controversial but indicated in patients with acute onset or rapid deterioration of cognitive impairment to identify rapidly progressive dementia and cerebrovascular accidents. An MRI finding of medial temporal atrophy suggests Alzheimer disease but is not specific or sensitive for diagnosis of this disorder. Confirmatory options in certain patients, most typically performed in outpatients being evaluated for Alzheimer disease, would include formal neuropsychological testing, testing of visual evoked potentials, brainstem auditory evoked potentials, and somatosensory evoked potentials. The EEG rarely is helpful in establishing the diagnosis of senile dementia, although in CJD characteristic slowing and periodic complexes may be electroencephalographic features.

Management

Initial management focus is on accurate diagnosis, symptomatic treatment of behavioral and sleep changes, nonpharmacologic environmental and safety interventions, management of chronic comorbid medical conditions, and specific pharmacologic therapies. Accurate and rapid identification of reversible dementias and conditions that cause worsening of baseline dementia require early diagnosis and disease-specific management. Determination of reversible causes of dementia during the ED evaluation occasionally is possible based on the history (including medication history), physical examination, and head CT scan. Patients with acute changes in mental status or a relatively rapid onset of symptoms will require hospitalization for comprehensive evaluation. Patients presenting with recent gradual decline in cognitive function without an underlying acute medical condition may undergo further evaluation and management on an outpatient basis.

Pharmacotherapy approved by the FDA for the treatment of mild to moderate Alzheimer disease includes the cholinesterase inhibitors donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). There are multiple randomized, placebo-controlled, large-scale clinical trials with these drugs establishing efficacy in improving cognitive functions and activities of daily living in patients with mild to moderate dementia. These drugs are not considered disease modifying, and there are limited data at present on the benefit of these drugs beyond 2 or 3 years (a significant number of patients discontinue medications because of side effects). The most common side effect of these agents is due to the cholinergic effects, including nausea, vomiting, and diarrhea.

Memantine (Namenda) is a disease-modifying agent that helps regulate the excitatory effects of glutamate by antagonizing the *N*-methyl-D-aspartate receptor. Whether this drug alters the underlying disease process is unclear, but short-term studies show improved cognition in patients with moderate and moderate to severe Alzheimer disease. There are conflicting studies on the effectiveness of other agents, such as gingko biloba, vitamin E, nonsteroidal agents, and statins. Estrogen replacement is not indicated for cognitive improvement or maintenance in women with Alzheimer disease and can be detrimental. Ultimately, the key to altering the course of the disease is halting neuron loss. In severe dementia, the goal of management is supportive care, and we recommend that initiation and maintenance of medical therapy be conducted by a patient's primary clinician or by a specialized clinic with a focus on dementia treatment.

Many therapies currently are under investigation for the modulation and early treatment of Alzheimer disease. These therapies include antibiotics (directed against *Chlamydophila pneumoniae*), secretase modulators to reduce serum β-amyloid levels, immunization to reduce amyloid plaque burden, chelators to promote dissolution of β-amyloid, nonsteroidal antiinflammatory medications, supplementation with omega-3 fatty acids, and testosterone. In addition, aerobic exercise, diet, cardiovascular and metabolic risk factor modification are recommended.

Increasing evidence suggests that certain nonpharmacologic measures, including behavioral methods and avoidance of environmental triggers, may be effective in reducing agitation and anxiety in patients with dementia. On occasion, medications are needed for behavioral symptoms of dementia. Affected patients typically do not improve with anxiolytics. Adverse effects offset the modest advantages in the efficacy of antipsychotic drugs for the treatment of psychosis, aggression, or agitation in many patients with Alzheimer disease, and these drugs should be avoided when possible. However, despite the lack of consensus in the indication for use and dosages in older demented patients, butyrophenones (such as, haloperidol, 1 to 2.5 mg IM) or atypical antipsychotic olanzapine (2.5 to 5 mg IM) have been found to be effective in the management of acute agitation.

Clozapine may be effective in treating psychosis associated with both Alzheimer- and Parkinson-type dementias. However, the FDA issued a black-box warning that the use of atypical antipsychotics to treat older patients with dementia-related psychosis was associated with an increased risk for death due to cardiovascular and infectious causes compared with placebo, thus the risks and benefits of using these drugs must be considered as part of a unified treatment strategy with the patient's outpatient clinicians, with the above shorter-acting agents used for acute agitation in the ED.

A clear treatment choice for agitation and psychosis in those with dementia has not been identified. The antipsychotics raise a concern for QT prolongation, extrapyramidal symptoms, sedation, and anticholinergic and drug-drug interaction; the benzodiazepines have a risk of falls, confusion, memory impairment, and oversedation. Regardless of intervention used, the lowest dose possible should be used and then titrated carefully to effect.

Agitation in patients with dementia may occasionally be due to unrecognized pain, depression or sleep disturbances. A trial of adequate pain management or selective serotonin reuptake inhibitors (SSRIs) (such as citalopram 20 mg PO) may be warranted. Selection of a SSRI should be based upon side effect profile and drug interactions, and the medication should be initiated only with a plan for follow-up assessments by a clinician capable of monitoring its effect. Sleep disturbances may be treated with temazepam (7.5 mg oral), though the half-life of temazepam is 8 to 10 hours, potentially placing patients at an increased risk for falls.

Disposition

Patients with dementia present to the ED because of an acute deterioration, behavioral change, or crisis due to family stress. A brief observation, acute inpatient medical or psychiatric hospitalization, nursing home stay, or other institutional stay (respite program) may stabilize the patient and give the family time to mobilize resources to resume the home care regimen. Social workers can play a vital role in attempting to facilitate continued management. A key to successful disposition planning is to use screening tools to assess the cognitive, functional, and psychosocial status of patients with delirium and dementia. Anticipating and addressing cognitive or functional barriers to compliance with discharge and transitional care planning is essential.

CHAPTER 90: QUESTIONS AND ANSWERS

1. Which of the following characteristics helps distinguish dementia from delirium?
   - **a.** Acute onset
   - **b.** Memory impairment
   - **c.** Disorientation
   - **d.** Delusions

Answer: A. Delirium is characterized by an acute onset of impaired cognition, in comparison to the slower onset of delirium. Memory impairment and disorientation can occur in either process. Delusions are more common in delirium, but can occur in the later stages of dementia as well.

2. A 78-year-old woman presents with 3 days of decreasing ability to concentrate, memory and cognition breakdown, sleep cycle disruption, and fluctuating levels of agitation. Her current medications include levofloxacin (Levaquin) 500 mg/day for a bladder infection, tramadol PRN for knee arthritis, and hydrochlorothiazide 25 mg/day for essential hypertension. Her examination is normal except for a baseline tachycardia, moderate agitation and restlessness, and orientation to person only. Laboratory analysis shows glucose 198 mg/dL, sodium 131 mEq/L, potassium 3.8 mEq/L, creatinine 1.4 mg/dL, white blood cell (WBC) count 11,300 cells/mm^3, hemoglobin 12 g/dL, bicarbonate 25 mEq/L, and a normal urinalysis. What is the most likely etiology for her delirium?
   - **a.** Early sepsis
   - **b.** Hyperglycemia
   - **c.** Hyponatremia
   - **d.** Medication effect

Answer: D. Medications are the most common cause of delirium in the older adult population. Common inciting medications include antibiotics (quinolones and macrolides), analgesics, sympathomimetics, antiinflammatories, sedatives, and cardiovascular agents. This level of hyponatremia would not be expected to cause delirium. Likewise, a modest hyperglycemia without associated acidosis would be an unlikely culprit.

3. An 82-year-old man presents with acute delirium. On examination, he is alert and mildly agitated. He is oriented to person and place but not time. He is easily distracted and exhibits a mild bilateral upper extremity resting tremor without asterixis. His neurologic examination is nonfocal. His short-term memory is impaired. What is the central component most key to the diagnosis of delirium in this case?
   - **a.** Agitation
   - **b.** Disorientation
   - **c.** Inattention
   - **d.** Memory dysfunction

Answer: C. Disturbance in attention is central to the diagnosis of delirium. Disorientation often accompanies this but is not invariably present. The patient is usually disoriented to time and, less often, place. The delirious patient may also experience visual, auditory, tactile, and olfactory hallucinations; may lose the ability to modulate emotional expression; and often exhibits fluctuating symptoms. Short-term memory is usually impaired, but this is also seen in dementia.

4. Which of the following associations is correct?
   - **a.** Droperidol: QT prolongation
   - **b.** Haloperidol: Dysphoria
   - **c.** Lorazepam: Excessive half-life
   - **d.** Meperidine: Cholinergic effects

Answer: A. This may also be seen with haloperidol and the phenothiazines. Meperidine causes dysphoria and possibly some anticholinergic effects. Diazepam results in the longest terminal *T*½ of the benzodiazepines.

5. A 63-year-old man presents with acute-onset delirium. He is a known alcoholic, and the family reports a cessation of alcohol intake 36 hours before presentation. He has no other known medical problems. Examination is remarkable for an acutely delirious patient who has active visual and auditory hallucinations and a tremor. Neurologic examination is otherwise negative. Finger-stick glucose is normal. Thiamine 100 mg intravenously fails to improve his symptoms. Which of the following is the intervention most likely to prevent further worsening?
   - **a.** Dextrose
   - **b.** Haloperidol
   - **c.** Lorazepam
   - **d.** Magnesium

Answer: C. This patient presents with symptoms of alcohol withdrawal. Wernicke encephalopathy should be considered and thiamine supplementation may be necessary, but lorazepam will prevent progression to withdrawal seizures. Magnesium acts as a cofactor for thiamine, and should also be repleted if levels are found to be low.

Brain and Cranial Nerve Disorders

Joshua Wallenstein

KEY CONCEPTS

Multiple Sclerosis

- The clinical picture of multiple sclerosis (MS); is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve over days and slowly resolve over weeks.
- Magnetic resonance imaging (MRI) is a high-yield diagnostic test for MS. When the emergency department (ED) MRI is an option, it should be considered as it may expedite follow up and initiation of treatment.
- MS relapse is treated with high-dose methylprednisolone, typically 1000 mg IV over a course of 3 to 5 days. There is emerging evidence supporting oral therapy as efficacious in the treatment of relapse.

Cerebral Venous Thrombosis

- Cerebral venous thrombosis (CVT) should be suspected in patients (particularly female patients under age 50) presenting with stroke symptoms without risk factors, unexplained new seizures or refractory headaches, or signs of intracranial hypertension.
- The combination of MRI and magnetic resonance venography (MRV) is considered the gold-standard for diagnosis of CVT, though contrast-enhanced computed tomography (CT) with venous phase imaging is an alternative.
- Primary treatment of CVT in the ED is anticoagulation with a weak recommendation for low molecular-weight heparin over unfractionated heparin. Neuro-interventional treatment may have a role in severe cases, and hospital transfer may be needed for advanced neurological care.

Trigeminal Neuralgia

- Trigeminal neuralgia (TN) is characterized by intermittent, unilateral, severe and sharp facial pain precipitated by innocuous sensory stimuli and not explained by other local causes.
- Secondary TN can be associated with MS and other cranial nerve disorders and neurologic conditions. A careful history and physical examination can help identify these causes though imaging may be needed.
- Sodium-channel blockers are first line therapy, either carbamazepine (200 to 400 mg/day, titrated up to 1200 mg/day) or oxcarbazepine (300 to 600 mg/day in two divided doses, titrated up to 1800 mg/day); adverse side effects may lead to treatment failure. While secondary therapies are available, treatment failure with sodium-channel blockers is an indication for surgical referral.

Facial Nerve Paralysis

- The diagnostic dilemma related to facial nerve paralysis typically revolves around distinguishing Bell's palsy from other causes. While diagnostic imaging is not needed to make a diagnosis of Bell's palsy, it may be indicated in cases where the etiology of facial weakness is unclear.
- Patients at high risk for stroke and infection or with features atypical for Bell's palsy (particularly intact forehead movement or bilateral facial paralysis) should be considered for an alternate diagnosis and often require additional diagnostic testing.
- Corticosteroids improve the outcome in Bell's palsy and should be started as soon as possible to maximize their benefit. We recommend 5 days of prednisone, 60 mg, followed by a taper over 5 days.
- Adding antiviral therapy to corticosteroids confers little or no benefit and evidence supporting its use is very weak except in cases of Ramsay Hunt Syndrome.

Vestibular Schwannoma

- Vestibular schwannomas are a common cause of sensorineural hearing loss and may lead to other distressing neurological symptoms. The primary role of the emergency clinicians is referral for testing and treatment when the diagnosis is suspected or confirmed.

Diabetic Cranial Mononeuropathy

- The differential diagnosis for diabetic cranial mononeuropathy includes aneurysm and stroke; a careful history and physical examination can identify cases that require neuroimaging.
- Diabetic patients presenting with a CN III palsy with spared pupillary response and no other deficits in general do not require neuroimaging.

MULTIPLE SCLEROSIS

Foundations

MS is an inflammatory disease of the central nervous system (CNS) manifested by demyelination of discrete regions (plaques) with a relative sparing of axons. An environmental trigger superimposed on genetic susceptibility appears to be a likely etiology. One theory proposes that this trigger establishes autoreactive T cells in the CNS that after a long latency period become reactivated on subsequent exposure to a systemic trigger, such as a viral infection or superantigen. This sets off a complex immunologic cascade that leads to demyelination.

MS presents with highly variable symptoms, making the illness difficult to definitively diagnose on a patient's first presentation. Symptoms evolve over time with a broad range of severity. Women are more commonly affected than men, with a peak age of onset between 25 and 30 years. Management of MS continues to evolve, and early treatment with disease-modifying therapy results in improved outcomes.[1] The emergency clinician will encounter patients with established diagnoses presenting with acute exacerbations (relapse) and undiagnosed patients presenting with initial symptoms. While familiarity with treatment options for managing relapse is necessary, arguably the most important role for the clinician is to recognize symptoms of MS and expedite testing and referral.

TABLE 91.1 Clinical Features of Multiple Sclerosis

Function	Symptoms and Findings
Cranial nerves	Optic neuritis, diplopia, nystagmus, facial paresis, and pain
Motor	Weakness, spasticity, exaggerated deep-tendon reflexes
Sensory	Numbness, tingling, "pins and needles" paresthesia, coldness
Cerebellar	Gait imbalance, dysarthria, truncal ataxia.
Bladder, bowel and sexual dysfunction	Urinary incontinence, constipation, erectile dysfunction.
Cognition	Poor memory, distractibility, cognitive impairment

Clinical Features

The clinical picture in MS is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve over days and slowly resolve over weeks. Variability occurs in age at onset, location of CNS lesions, frequency and severity of relapses, and degree and time course of progression. Four basic disease courses have been identified by the International Advisory Committee on Clinical Trials of MS. (2) The most common form is relapsing and remitting MS (RRMS, 85%), characterized by clearly defined attacks of new or increasing neurologic symptoms that are followed by periods of partial or complete recovery. The less common primary and secondary progressive MS syndromes are characterized by worsening neurologic function and accumulation of disability, either from symptom onset (primary), or after RRMS (secondary). The remaining course, radiologically isolated syndrome (RIS), has been used to classify those with radiographic abnormalities of MS who have no neurological symptoms or findings.

The clinical features of MS are divided into areas of specific CNS impairment and are described in Table 91.1: cranial nerves, motor pathways, sensory pathways, cerebellar pathways, bowel/bladder/sexual dysfunction, and cognition. While MS has no single pathognomonic finding, optic neuritis has a particularly strong association with the disease. Optic neuritis is a unilateral syndrome characterized by pain in the eye and a variable degree of visual loss primarily affecting the central vision. It is the most common cranial nerve dysfunction related to MS, and not infrequently the first presenting symptom for which patients will seek care. It is the initial presentation in about 20% of MS patients. One study found that 65% of patients who presented to an ED with a first episode of optic neuritis were diagnosed with MS within one year.[2] Other common cranial nerve symptoms include diplopia and nystagmus. The nystagmus may be severe enough to cause oscillopsia (a subjective oscillation of objects in the visual field). Cranial nerve impairment may also include impairment of facial sensation, which is relatively common. Unilateral facial paresis also may occur. In addition, the occurrence of trigeminal neuralgia in a young person may be an early sign of MS.

Motor pathways, specifically the corticospinal tract, are commonly involved. Paraparesis or paraplegia occurs with greater frequency than upper extremity lesions owing to the common occurrence of lesions in the motor tracts of the spinal cord. In patients with motor weakness, spasms of the legs and trunk may occur on attempts to stand from a seated position. This dysfunction is manifested on physical examination as spasticity that is typically worse in the legs than in the arms. The deep tendon reflexes are markedly exaggerated, and sustained clonus may be demonstrated. Although these symptoms may be bilateral, they are generally asymmetric. Sensory manifestations are a frequent initial feature of MS and will be present in nearly all patients at some point during the course of the disease. Sensory symptoms are commonly described as numbness, tingling, "pins and needles" paresthesias, coldness, or a sensation of swelling of the limbs or trunk.

Impairment of the cerebellar pathway may result in gait imbalance, difficulty with coordinated actions, and dysarthria. Physical examination reveals the typical features of cerebellar dysfunction, including dysmetria, dysdiadochokinesis (an impairment of rapid alternating movements), breakdown in the ability to perform complex movements, intention tremor in the limbs and head, truncal ataxia, and dysarthria. Impairment of bowel, bladder, and sexual function is also common with patients complaining of constipation, incontinence, and erectile dysfunction. Finally, cognitive impairments in MS are common, and may be underreported by patients, and underrecognized by care providers.

Differential Diagnoses

Given the marked heterogenicity of MS symptoms, the differential diagnosis is vast and includes central and peripheral nervous system disorders, ophthalmologic and neuropsychiatric disorders, and a large number of systemic and inflammatory/autoimmune disorders. Considerations will vary based on presenting symptoms, but may include ischemic and hemorrhagic stroke, CNS infection or malignancy, neuropathy, and rheumatologic conditions such as systemic lupus erythematosus. Several conditions can also present with radiographic features similar to MS. These include CNS tumors, spinal cord compression, vasculitides, Behçet disease, neuro-sarcoidosis, encephalomyelitis, HIV encephalopathy, Lyme disease, and vitamin B_{12} deficiency. The evolution of symptoms over time can be an important diagnostic finding in differentiating symptoms of MS from other conditions.

Diagnostic Testing

Patients previously diagnosed with MS presenting with acute exacerbations should be evaluated for an acute precipitating trigger, though most often one will not be found. The two most high-yield tests for diagnosing MS are a lumbar puncture (LP) and MRI of the brain and spinal cord. CT of the brain, with or without contrast, is not a useful test in evaluating MS but may be used to investigate other potential diagnoses. CSF analysis is abnormal in most cases of MS, but there is no definitive diagnostic biomarker and many of the more specialized CSF tests may not be done within the ED visit. Nevertheless, LP with CSF analysis can be useful in considering other causes of symptoms, and individual CSF proteins have been demonstrated to be biomarkers of disease activity and progression.[3]

The initial imaging test to aid in the diagnosis of MS is gadolinium-enhanced MRI of the brain and spinal cord. MRI is a sensitive test for the detection of lesions consistent with MS and also is useful to assess disease severity. Lesions usually are multiple and commonly are found in the periventricular white matter. Recent studies point to the important role of ED MRI in patients with suspected MS: In one study, concordance between signs of demyelination of ED-based MRI and later final diagnosis of demyelinating disorder was approximately 52%.[4] Given the importance of timely diagnosis and initiation of treatment, emergency clinicians should consider obtaining an MRI when feasible.

Management

Early treatment with disease-modifying therapies can lower relapse rates, reduce disability progression and improve survival. Management

of MS in the ED typically entails treating MS relapse. Ongoing therapies, including disease-modifying therapies and management of MS-related complications are best made by a patient's neurologist or primary care physician.

Treatment with high-dose IV corticosteroids diminishes the duration of symptoms and is an accepted best practice to manage MS relapse; however, there is no agreed upon best dosing regimens or durations of therapy. A common treatment regimen is IV methylprednisolone, 500 to 1000 mg daily for 3 to 5 days with or without a tapering dose of oral steroids (whether there is any benefit to divided doses versus a single daily dose is unclear).

There is an emerging body of evidence supporting the use of high-dose oral prednisone alone (typically 500 to 1250 mg daily) in the treatment of MS relapse. A recent meta-analysis failed to demonstrate clear-cut differences in efficacy and safety outcomes between oral and IV strategies.[5] Outpatient oral prednisolone therapy may reduce health system and patient-borne expenses related to IV infusions, hospital stay, and lost work productivity, as well as minimize patient discomfort and improve patient satisfaction. The decision of oral versus IV therapy should ideally be made through shared decision-making and in consultation with the patient's MS specialist. Other potential therapies of acute exacerbation include repository corticotrophin injection, plasmapheresis, and intravenous immunoglobulin.

Disposition

Patients with a history of MS who seek treatment for relapse must first be evaluated to rule out a worrisome acute trigger, and admission may be required for an identified systemic illness, infection, or other acute condition which is thought to have triggered the MS relapse. While patients initiated on IV steroids therapy will generally require admission for continued treatment, initiation and discharge home with high-dose oral prednisolone therapy is safe and effective. In these cases, the clinician should consider safety at home related to any neurologic disability brought on by the relapse, as well as management of pain and other symptoms.

When a new diagnosis of MS is suspected clinically or based on imaging results, further testing and treatment evaluation can often be performed as an outpatient, again assuming adequate mobility, home safety, and symptom control. Current consensus on quality standards for MS patients suggests that patients with new symptoms be referred to a neurologist within 4 weeks if not sooner.[6] While often an achievable goal after ED discharge, hospital admission for advanced diagnostic testing and neurology consultation may be considered, particularly when access-to-care is a concern.

CEREBRAL VENOUS THROMBOSIS

Foundations

Cerebral venous thrombosis (CVT) accounts for 0.5% to 1.0% of all strokes, often occurring in otherwise healthy young adults, though any age can be affected. The mean age at presentation is about 40 years, with the majority of cases (80%) presenting before the age of 50 years. Women are three times more commonly affected than men. Risk factors include thrombophilias (protein C and S deficiencies, factor V Leiden mutation), pregnancy and the post-partum period, oral contraceptives, infections of the head and neck, cancer, chronic inflammatory states, head trauma, and recent lumbar puncture or neurosurgical procedures. At least one risk factor is identified in 85% of patients, and multiple risk factors are found in 50% of patients.

CVT is caused by systemic or local imbalances in thrombotic and thrombolytic pathways, leading to thrombus formation in cerebral dural sinuses or veins. As the flow of venous blood from the brain is impeded, an increase in venous and capillary pressure occurs. Anastomoses of the cerebral venous system can initially compensate for increases in pressure, but when this capacity is overwhelmed a disruption of the blood-barrier occurs, leading to a decrease in cerebral perfusion pressure. This in turn, can lead to cerebral edema, infarction, and hemorrhage.

TABLE 91.2 Cavernous Venous Thrombosis Clinical Syndromes

Clinical Syndrome	Features
Intracranial hypertension	Persistent headache, decreased visual acuity, papilledema
Focal neurological deficits	Motor weakness, aphasia
Seizures	Focal, generalized, status epilepticus
Encephalopathy	Altered mental status, coma

Clinical Features

There are four major CVT syndromes, which overlap in presentation and are detailed in Table 91.2. The most common, isolated intracranial hypertension, typically presents with headache. Headache from CVT will often be described as localized, persistent or gradually worsening, though it may also be sudden, diffuse and severe, mimicking subarachnoid hemorrhage. Decreased visual acuity and papilledema may also result. Headache may worsen with transient increases in intracranial pressure (coughing, Valsalva). The second and third syndromes, focal neurologic deficits and seizures, are each found in approximately 30% to 40% of CVT cases. Motor weakness (which may be unilateral or bilateral) is the most common focal symptom, and aphasia may also be present. Sensory deficits are possible, though less common. Seizures may be focal or generalized and may present as status epilepticus. CVT should be considered in an at-risk patient presenting with both focal neurologic deficit and seizure. The final syndrome, encephalopathy, may present as altered mental status and confusion. This syndrome is less common and may be seen in more severe cases of thrombosis.

Differential Diagnoses

The differential diagnosis of CVT is vast owing to its highly variable clinical presentations. Depending on the clinical presentation, this may include the broad differential diagnoses of headache, papilledema, motor weakness, seizure, and altered mental status. It is vital to check for risk factors for CVT in considering this often easily overlooked diagnosis. Though only a subset of at-risk patients, women who are pregnant, postpartum, or on oral contraceptives should be considered for further testing when presenting with these symptoms in the absence of an identified cause.

Diagnostic Testing

Routine laboratory testing, including CSF analysis, may be helpful in considering alternative diagnoses of seizure, altered mental status, and other presenting symptoms, but generally have little value in the diagnosis of CVT. Studies evaluating the use of d-dimer in the evaluation of CVT have demonstrated its role; one recent study found that a normal d-dimer had a negative predictive value of 99% and concluded that the test may help guide further diagnostic testing.[7] The authors however noted a need for replication of this single-site study, and did not advocate relying solely on a negative d-dimer as exclusion in at-risk patients.

Imaging is the standard of care when CVT is suspected. The noncontrast head CT may demonstrate an elongated hyper-attenuating

clot ("cord sign") but is more likely to show indirect signs of CVT such as sulcal effacement and decreased grey/white matter differentiation, or it may not demonstrate any abnormality. Although this is an appropriate initial test, it is inadequate to rule out CVT. CT venography or MR venography (MRV) are far more sensitive in demonstrating signs of CVT, and MRI in combination with MRV is generally considered the gold standard. Given the young age of many patients with suspected CVT, radiation exposure further supports the choice of MRI/MRV when available. That said, CT venography has a sensitivity and specificity of 75% to 100% depending on anatomic location of the clot, and recent guidelines suggest that CT venography can be used as a reliable alternative to MRV.[8]

Management

Current therapeutic consensus strongly recommends systemic anticoagulation to prevent further clot formation and to promote recanalization, even in patients with intracranial hemorrhage on initial imaging. There is some evidence to support the use of low-molecular-weight heparin (LMWH) over unfractionated heparin (UFH) based on improved outcomes with LMWH and lower hemorrhagic complications when compared to UFH. This recommendation does not apply to patients with contraindication to LMWH or in situations when rapid-reversal (such as surgical intervention) may be desired. The use of new oral anticoagulants such as rivaroxaban and dibigatran after initial heparin therapy has been evaluated, but there is insufficient evidence to support their use, particularly in the acute phase.

There is insufficient evidence to recommend the routine use of acetazolamide or steroids in the treatment of symptoms or signs thought to be related to increased intracranial pressure due to CVT. There is some evidence to recommend the short-term use of antiepileptic drugs in patient with supratentorial lesions who have had seizures as prophylaxis to prevent early recurrent seizures, but no evidence to support their long-term use. Finally, endovascular mechanical thrombectomy (EMT) may have a role in severe or refractory CVT and has been demonstrated to be an effective strategy with a reasonable safety profile.[9]

Disposition

All patients with confirmed or suspected CVT should be admitted to a unit capable of providing a high level of care with neurologic consultation. Considerations for hospital transfer include the need for and availability of neurocritical care with neurosurgical and/or interventional neuroradiology consultation.

CRANIAL NERVE DISORDERS

The cranial nerves are 12 paired nerves that emerge from the brainstem and primarily transmit information to and from structures in the head and neck, including sense organs and muscles controlling facial expression, eye movement, and mastication. Owing to these varied functions, cranial nerve disorders often lead to sense-organ dysfunction, as well as facial pain and motor weakness. Cranial nerve dysfunction can occur through multiple etiologies including compression, infection and inflammation, ischemia, and trauma (including injury resulting from surgery). Given the multiple diverse causes of cranial nerve dysfunction, there is no well-defined at-risk population, though cancer, immunocompromise, and microvascular disease certainly may be relevant risk factors for select patients.

Cranial nerve disorders can present either with sensory dysregulation, motor weakness, or as a mixed disorder. Many of these symptoms can also be related to inflammation of local facial structures as well as systemic infections, leading to a broad differential diagnosis. Table 91.3 describes the normal function and pathologic considerations for each cranial nerve.

Trigeminal Neuralgia (Cranial Nerve V)

Foundations

Trigeminal neuralgia (TN) is an often debilitating illness causing bouts of severe facial pain, often associated with chronic underlying pain. Triggers are usually innocuous sensory stimuli, and attacks can be unpredictable, leading to a marked disruption of normal daily activities. The term *tic douloureux,* often used synonymously with TN, describes the characteristic wince patients may exhibit with a pain paroxysm. TN is slightly more common in women than in men, and most frequently affects individuals over the age of 50 years.

Trigeminal neuralgia is an idiopathic disorder, though evidence points to vascular compression of the trigeminal nerve root in many cases. This compression may be caused by a tortuous arterial or venous loop in the posterior fossa, an arteriovenous malformation, or rarely a tumor.

Clinical Features

TN is defined by three or more attacks of unilateral facial pain occurring in one or more divisions of the TN that have at least three of the following four characteristics: recurring in paroxysmal attacks, severe intensity, electric shock-like or sharp/stabbing in quality, and precipitated by innocuous stimuli to the affected side of the face. The pain is commonly associated with physical triggers such as chewing and swallowing, facial hygiene (brushing, shaving, washing), and exposure to hot or cold temperature. Patients tend to experience the pain in clustered episodes that last a few seconds to several minutes. TN can be subclassified as TN with purely paroxysmal pain or with concomitant persistent pain, which can be seen in up to 50% of affected patients. TN most frequently affects the second and third trigeminal divisions with symptoms occurring slightly more commonly on the right side of the face. Bilateral TN is very rare and should raise suspicion for an alternate or underlying cause. Autonomic symptoms such as tearing and rhinorrhea may also occur during a pain episode.

TN can also be subclassified as idiopathic/classical, or as secondary TN caused by other neurological disease such as MS or cerebellopontine tumor. As such, patients may present with additional neurological symptoms or findings. Although there are no diagnostic physical examination findings of TN, special attention should be paid to alternate possible sources of facial pain, including the teeth, temporomandibular joints, sinuses, and ears. The skin of the face and scalp should be examined for the painful vesicular eruption of zoster. Though pain is not the dominant feature of other cranial nerve disorders, it can be an associated symptom and the cranial nerves should be carefully examined.

Differential Diagnoses

Other painful facial conditions that are considered in patients with facial pain include odontogenic infections, sinus disease, otitis media, acute glaucoma, temporomandibular joint disease, and herpes zoster. Although the temporal components of the pain in these conditions are not similar to the sudden onset, lancinating pain of TN, the distribution is similar and these diagnoses should be considered before anchoring on a diagnosis of trigeminal neuralgia. There is an association between TN and MS, and though not common, TN can be the first presenting symptom of MS, and this diagnosis should be considered in the presence of other unexplained neurologic findings.

TABLE 91.3 Cranial Nerve Function and Pathologies

Cranial Nerve	Clinical Function Relevant to Emergency Medicine	Pathologic Features	Possible Causes
CN I: Olfactory nerve	Sense of smell	Unilateral anosmia	Trauma: Skull fracture or shear injury interrupting olfactory fibers traversing the cribriform plate Tumor: Frontal lobe masses compressing the nerve
CN II: Optic nerve	Vision	Unilateral vision loss	Trauma: Traumatic optic neuropathy Tumor: Orbital compressive lesion Inflammatory: Optic neuritis (MS) Ischemic: Ischemic optic neuropathy
CN III: Oculomotor nerve	Extra oculomotor function via motor fibers to levator palpebrae, superior rectus, medial rectus, inferior rectus, inferior oblique muscles Pupillary constriction via parasympathetic fibers to constrictor pupillae and ciliary muscles	Ptosis caused by loss of levator palpebrae function Eye deviated laterally and down Diplopia Dilated, nonreactive pupil Loss of accommodation	Trauma: Herniation of the temporal lobe through the tentorial opening, causing compression and stretch injury to the nerve Ischemic: Especially in diabetes; microvascular ischemic injury to nerve causes extraocular muscle paralysis but usually is papillary sparing (often painful) Vascular: Intracranial aneurysms may press on the nerve, leading to dysfunction Myasthenia gravis can lead to atraumatic ocular muscle palsy
CN IV: Trochlear nerve	Motor supply to the superior oblique muscle	Inability to move eye downward and laterally Diplopia Patients tilt head toward unaffected eye to overcome inward rotation of affected eye	Trauma is the most common cause of nerve dysfunction
CN V: Trigeminal nerve	Motor supply to muscles of mastication and to tensor tympani Sensory to cornea, face, scalp, oral cavity (including tongue and teeth)	Partial facial anesthesia Episodic, lancinating facial pain associated with benign triggers, such as chewing, brushing teeth, light touch	Trauma: Facial bone fracture may injure one section, leading to area of facial anesthesia Tic douloureux
CN VI: Abducens nerve	Motor supply to the lateral rectus muscle	Inability to move affected eye laterally Diplopia on attempting lateral gaze	Tumor: Lesions in the cerebellopontine angle Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve Elevated ICP: Because of its position and long intracranial length, increased ICP from any cause may lead to injury and dysfunction of the nerve
CN VII: Facial nerve	Motor supply to muscles of facial expression Parasympathetic stimulation of the lacrimal, submandibular, and sublingual glands Sensation to the ear canal and tympanic membrane	Hemifacial paresis: Lower motor neuron lesion leaves entire side of face paralyzed Upper motor neuron lesion leaves forehead musculature functioning Abnormal taste Sensory deficit around ear Intolerance to sudden loud noises	Lower motor neuron: Infection (viral): The likely cause of Bell's palsy Lyme disease: The most common cause of bilateral CN VII palsy in areas where Lyme disease is endemic Bacterial infection extending from otitis media Upper motor neuron: Stroke, tumor
CN VIII: Vestibulocochlear nerve	Hearing and balance	Unilateral hearing loss Tinnitus Vertigo, unsteadiness	Tumor: Acoustic neuroma Mimics Ménière disease, perilymphatic fistula

Continued

TABLE 91.3 Cranial Nerve Function and Pathologies—cont'd.

Cranial Nerve	Clinical Function Relevant to Emergency Medicine	Pathologic Features	Possible Causes
CN IX: Glossopharyngeal nerve	General sensation to posterior third of tongue Taste for posterior third of tongue Motor supply to the stylopharyngeus	Clinical pathology referable to the nerve in isolation is very rare Occasionally painful paroxysms beginning in the throat and radiating down the side of the neck in front of the ear but behind the mandible	Brainstem lesion Glossopharyngeal neuralgia
CN X: Vagus nerve	Motor to striated muscles and muscles of the pharynx, larynx, and tensor (veli) palatini Motor to smooth muscles and glands of the pharynx, larynx, thoracic and abdominal viscera Sensory from larynx, trachea, esophagus, thoracic and abdominal viscera	Unilateral loss of palatal elevation: Patients complain that on drinking liquids, the fluid refluxes through the nose Unilateral vocal cord paralysis: Hoarse voice	Brainstem lesion Injury to the recurrent laryngeal nerve during surgery
CN XI: Spinal accessory nerve	Motor supply to the sternocleidomastoid and trapezius muscles	Downward and lateral rotation of the scapula and shoulder drop	Trauma to the nerve
CN XII: Hypoglossal nerve	Motor supply to the intrinsic and extrinsic muscles of the tongue	Tongue deviations: Upper motor neuron lesion causes the tongue to deviate toward the opposite side Lower motor neuron lesion causes the tongue to deviate toward the side of the lesion, and the affected side atrophies over time	Stroke or tumor can cause upper motor neuron lesion Amyotrophic lateral sclerosis can cause bilateral lower motor neuron lesion with atrophy Metastatic disease to the skull base may involve the nerve

Diagnostic Testing

The diagnosis of TN is primarily based on history and physical as there are no definitive laboratory or imaging tests. Patients with normal findings on the head and neck examination and no neurologic deficits who have episodic, unilateral facial pain associated with nonpainful triggers are likely to have TN. The presence of a neurologic deficit should prompt suspicion of a structural lesion, such as aneurysm or tumor. Patients with a neurologic deficit require urgent imaging studies, typically MRI, to rule out a mass or vascular abnormality. As classical and secondary TN cannot be confidently separated based on history and exam, MRI of the brain and brainstem has been proposed as part of the early workup on TN,[10] though in the absence of a neurologic deficit there is no recommendation for imaging in the ED.

Management

The first-line treatment of TN is sodium channel blockers, either carbamazepine (200 to 400 mg/day, titrated up to 1200 mg/day) or oxcarbazepine (300 to 600 mg/day in two divided doses, titrated up to 1800 mg/day). Generally, sodium channel blockers are effective in most TN patients; however, high dosages are often necessary, leading to frequent adverse side effects including drowsiness, dizziness, tremor, and rash. Treatment failure is typically not due to drug inefficacy, but rather to side effects leading to treatment interruption or dosage reduction to ineffective levels. Oxcarbazepine may be preferred by patients due to its more favorable side effect profile, but its higher cost may put it out of reach for some. An ECG should be obtained prior to initiating therapy as both drugs are contraindicated in patients with atrioventricular block. A complete blood count and liver function studies are performed periodically to monitor for hematologic and hepatic side effects.

Combination treatment can be considered when carbamazepine or oxcarbazepine are not effective alone or not tolerated at higher dosages. Additional agents that have been used to treat TN include phenytoin, baclofen, lamotrigine, gabapentin, and levetiracetam. That said, guidelines recommend surgical consultation as a reasonable next step if sodium channel blockers prove ineffective. Microvascular decompression is the first-choice treatment for many patients, as it provides the longest duration of pain freedom compared to other surgical techniques. While major complications are rare, sensory loss and other mild or transient cranial dysfunction are more common. Stereotactic ("gamma knife") radiosurgery, is minimally invasive but less efficacious with more frequent minor complications.

Disposition

Patients with newly suspected trigeminal neuralgia should be referred for specialty evaluation and possible neuroimaging. In patients with established diagnoses presenting for management of symptoms, consultation with a neurologist can help in therapeutic decision making. Patients with an established diagnosis who present with uncontrolled pain refractory to maximum pharmacologic management may benefit from a neurosurgical referral.

Facial Nerve Paralysis (Cranial Nerve VII)

Foundations

The facial nerve (CN VII) has motor, sensory, and parasympathetic components. It controls facial musculature, sensation to portions of the external auditory meatus and taste to the anterior two-thirds of the tongue. It also controls salivary and lacrimal glands through its parasympathetic pathways. Facial nerve dysfunction can cause facial weakness and asymmetry, abnormalities of taste, as well as dry eyes and dry

TABLE 91.4 Clinical Features Associated With Causes of Facial Nerve Paralysis

Condition	Common Clinical Features
Bell's palsy	Abrupt onset of unilateral facial weakness involving forehead improving over weeks. May include mild to moderate pain, altered taste, hyperacusis, dry eye and mouth
Stroke	Forehead sparing facial weakness, other neurological deficits.
Neoplastic	Insidious onset, minimal improvement over time or recurrent episodes, other cranial neuropathies.
Ramsey-Hunt syndrome	Pronounced pain, vesicular eruptions, vestibulocochlear dysfunction
Lyme disease	Bilateral symptoms, rash, arthralgia, exposure to endemic area
Ear infection	Ear pain, fever, hearing loss

mouth. There are multiple etiologies of facial nerve dysfunction including stroke, compression or disruption from mass lesions and trauma, infection, and others. The most frequent cause of facial nerve paralysis, Bell's palsy, is incompletely understood, though the proposed mechanisms include viral infection and ischemia.

Facial weakness can be caused by lesions of the upper motor neurons in the contralateral motor cortex, or lower motor neurons in the ipsilateral facial nerve. The bilateral innervation of forehead musculature by upper motor neurons leads to a key distinguishing characteristic: upper motor neuron lesions spare the forehead while lower motor neuron lesions typically cause weakness affecting the entire ipsilateral face.

Facial nerve paralysis, while often transient, can be a devastating event for patients causing functional and esthetic issues, particularly when recovery is delayed or incomplete. The underlying etiology may impose additional morbidity and mortality, and there are a variety of etiologies with divergent treatment strategies that may be encountered. A careful history and physical exam (particularly of the face and neurologic system) are the primary diagnostic tools, with imaging indicated in select cases.

Clinical Features

The medical history in patients with facial paralysis focuses on the distribution, onset and timing of the paralysis, concentrating on forehead involvement (involved in peripheral disease and spared in central disease as the result of crossed innervation), rapidity of onset, and associated signs and symptoms. Common clinical features associated with causative conditions are described in Table 91.4.

Bell's palsy is characterized by an abrupt onset of a lower motor neuron paresis that typically develops over 72 hours and can progress over 1 to 7 days to complete paralysis. A prodromal viral-like illness is described by 60% of patients. Symptoms and signs frequently associated with the facial paresis include ear pain, perception of sensory change on the involved side of the face, decreased tearing, overflow of tears on the cheek, sound sensitivity (hyperacusis), and impaired taste.

To make the diagnosis of Bell's palsy, both the upper and lower facial muscles must be involved. If only lower face involvement can be appreciated, there should be a suspicion for a central lesion, such as a cerebral infarct or neoplasm. Other red flags that should prompt consideration of an alternative diagnosis include vestibular or hearing abnormalities (other than hyperacusis), severe pain, rash, an unwell appearing patient, and history of cancer or tick bite.

Ramsay-Hunt syndrome may present with paresis similar to Bell's palsy, but is also characterized by a herpetiform vesicular eruption, vestibulocochlear dysfunction, and marked pain. The vesicular eruption, which may follow the facial paralysis by a few days, may occur on the pinna, external auditory canal, tympanic membrane, soft palate, oral cavity, face, and neck as far down as the shoulder. The pain is considerably more severe than that associated with Bell's palsy, and it frequently is out of proportion to physical findings. In addition, outcomes are worse than with Bell's palsy, with a lower incidence of complete facial recovery and the possibility of sensorineural hearing loss.

Systemic symptoms or bilateral facial paresis should raise the possibility of Lyme disease or other systemic infection. Lyme disease is the most frequent vector-borne infection in the United States. It is caused by the spirochete *Borrelia burgdorferi* and is spread by the bite of *Ixodes* genus ticks. Neurologic manifestations can arise in any phase of the disease, and facial palsy accounts for up to 50% of the neurologic presentations. In regions in which Lyme disease is endemic, it is the leading cause of facial paralysis in children. Infectious mononucleosis can also cause bilateral facial paralysis.

Facial paralysis can be caused by acute bacterial infections of the middle ear, mastoid, or external auditory canal. While it is very rare for an uncomplicated ear infection to result in facial paralysis, this may be seen with malignant otitis externa. This disease entity is most commonly seen in immunocompromised patients and usually is caused by *Pseudomonas* infection.

Differential Diagnoses

In addition to the disorders previously discussed, paralysis of CN VII can be caused by disruption of the nerve as a result of trauma or surgical procedures. Neoplasia, either tumors of the facial nerve itself or tumors that compress the nerve, can also lead to facial nerve paralysis. The course is typically (though not always) of slower onset than Bell's palsy. Although very rare overall, a neoplastic cause should be suspected in patients who suffer from recurrent ipsilateral facial paralysis, significant pain, prolonged symptoms, or any other concomitant CN abnormality.

Diagnostic Testing

The diagnostic evaluation of acute facial nerve paresis is based on whether the clinical picture is suggestive of a disease process other than Bell's palsy, highlighting the importance of a focused history and physical examination. In the absence of atypical features or identifiable risk factors, routine laboratory testing and diagnostic imaging are not recommended.[11] The presence of a "central" seventh nerve paralysis (upper face sparing) should prompt imaging with CT or MRI, and consideration given to the possibility of an acute stroke or other hemispheric lesion. History or physical findings suggestive of a possible tumor require imaging to rule out a neoplasm. A history that poses potential exposure to Lyme warrants serologic evaluation for the disease.

Management

The primary medical therapy for Bell's palsy is corticosteroids. Multiple studies have demonstrated that corticosteroids reduce the incidence of post infection residual facial weakness. A recent meta-analysis calculated the number needed to treat (NNT) as 10 in order to prevent one person left with facial weakness.[12] Guidelines recommend a 10-day course of oral corticosteroids with at least 5 days of high dose (prednisolone 50 mg for 10 days or prednisone 60 mg for 5 days with a 5-day taper).[13] Early treatment improves outcomes and therapy should be started as soon as possible, ideally within 72 hours of symptom onset.

Reflecting on the theory that herpes simplex virus may be a cause of Bell's palsy, a number of studies have considered the use of antivirals, either alone or in combination with corticosteroids. One meta-analysis demonstrated that antivirals alone were less effective than corticosteroids alone, and that the addition of antiviral therapy to corticosteroid therapy added little to no benefit over steroids alone.[14]

The treatment of Ramsey-Hunt syndrome is similar to that of Bell's palsy; however, antiviral treatment (acyclovir 400 mg five times daily or valacyclovir 1000 mg TID) is recommended. Both prednisone and antiviral therapy should be continued for 7 to 10 days. Other infectious causes of facial nerve paralysis (Lyme disease, infectious mononucleosis, malignant otitis externa) should be treated with directed antimicrobial therapy; severe local infection (such as malignant otitis externa) may require surgical debridement.

Patient education regarding meticulous eye care is of key importance. Inability to close the eyelids combined with decreased lacrimation can lead to corneal abrasions, keratitis, and ulcers. Prophylactic eye care includes barrier precautions (protective glasses, eye patches) as well as artificial tears, ideally with a thicker protective ointment during sleep.

Disposition

Most patients who have a seventh CN paralysis will have a clinical diagnosis of Bell's palsy and may be discharged with referral for short-term follow-up. Patients with a possible hemispheric process, such as stroke or tumor, require further evaluation and often hospitalization. Patients thought to have Lyme disease require immediate initiation of antibiotic therapy. Patients should be counselled regarding their expected timeline for recovery. Although mild paresis typically recovers within 2 to 3 weeks, complete paralysis may take up to 6 to 12 months for recovery, and some patients may not fully recover all function.

Vestibular Schwannoma (Cranial Nerve VIII)

Foundations

Vestibular schwannomas (VS) are tumors of the vestibular nerve, that though histologically benign, can impact the quality of life through hearing loss, imbalance, and other symptoms. VS, also referred to as acoustic neuroma, account for 80% of all cerebellopontine angle tumors. The incidence has increased over recent decades, though this is likely related to increased frequency of neuroimaging for other causes and identification of VS as an incidental finding. The median age of onset is about 50 and hearing loss is almost always unilateral (bilateral disease occurs in approximately 5% of cases and generally associated with type 2 neurofibromatosis).

Vestibular schwannomas arise from the Schwann cells covering the vestibular branch of the CN VIII as it passes through the internal auditory canal. The tumor may compress the cochlear (acoustic) branch of the CN VIII, causing hearing loss, tinnitus, and disequilibrium. Continued growth of the tumor may result in compression of structures in the cerebellopontine angle, where CN V and CN VII may be compressed and damaged. Larger tumors may further encroach on the brainstem and, if large enough, may compress the fourth ventricle, ultimately resulting in signs of increased intracranial pressure (ICP).

Clinical Features

Asymmetrical sensorineural hearing loss is the hallmark of vestibular schwannoma. Up to 15% of patients with this tumor, however, will have normal results on audiometry. These patients typically have symptoms such as unilateral tinnitus, imbalance, headache, fullness in the ear, otalgia, and facial nerve weakness. Thus, patients with asymmetrical symptoms should be further evaluated for vestibular schwannoma even with normal findings on audiometry. Vestibular schwannomas are extremely slow-growing tumors, averaging a 1-mm increase per year, although some do not grow at all. The median time from symptom onset to diagnosis is 12 months.

Differential Diagnoses

While symmetrical sensorineural hearing loss has numerous causes, asymmetrical sensorineural hearing loss has few causes other than VS. Ménière disease may present with asymmetrical findings, but it can be differentiated from VS in that the tinnitus of Ménière disease is usually intermittent, whereas that of VS is continuous. In addition, patients with Ménière disease typically describe true vertigo, whereas those with a VS are more likely to describe imbalance or disequilibrium. Meningiomas, the second most common cerebellopontine angle tumor, more frequently cause symptoms of facial palsy or trigeminal nerve abnormality. However, there can be some clinical similarity between the two tumor types.

Diagnostic Testing

In general, diagnostic testing for VS can be performed as an outpatient. When suspected, testing includes MRI and audiometry. MRI is extremely sensitive and has led to earlier diagnosis and a decrease in mean size at detection of vestibular schwannoma. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of VS. The smaller the tumor at the time of diagnosis, the more options there are for therapy and the better the prognosis.

Management

There are currently three main approaches for managing newly diagnosed VS: observation with active surveillance, surgical resection, and stereotactic radiation therapy. Observation may be appropriate for elderly patients with comorbidities, small tumor size, and absence of symptoms. Due to the continued growth of most tumors however, observation is often associated with progressive hearing loss. In appropriately selected patients, there is little difference in long-term quality-of-life based on surgical resection versus radiotherapy. In general, tumors larger than 3 cm are recommended for microsurgery because radiation poses a risk of brain stem compressions due to posttreatment edema. Smaller tumors may be treated with surgery or radiation.

Disposition

Patients with suspected acoustic neuroma should be referred for audiometry or MRI and evaluation by a specialist in either otolaryngology or neurosurgery.

Diabetic Cranial Mononeuropathy

Foundations

Cranial mononeuropathies are uncommon and are usually a complication of diabetes. They most often affect the extraocular muscles causing ophthalmoplegia. The oculomotor nerve (CN III) is most commonly affected, followed by the trochlear (CN IV) and abducens (CN VI) nerves. CN palsies occur in 1% of diabetics versus 0.1% of nondiabetics. They are more likely to occur in patients over the age of 50 years. The pathologic basis of diabetic mononeuropathy appears to be ischemia caused by occlusion of an intraneural nutrient artery serving the nerve. This occlusion leads to injury located primarily in the core fibers, whereas the peripheral nerve fibers are less affected because they also are supplied by collateral vessels. In the oculomotor nerve, the preservation of the circumferentially located parasympathetic fibers explains the pupillary sparing that usually is found in this condition.

The anatomy of the third CN is particularly important to consider. Centrally located motor fibers controlling extraocular movement are likely to be affected by vascular ischemic disease. Parasympathetic

fibers associated with the pupillary light reflex run superficially within the nerve; while pupillary findings can result from microvascular ischemia, they should raise concern for compression of CN III from aneurysm in the posterior cerebral arteries.

Clinical Features

Diabetic cranial nerve palsy often results in diplopia, which may be worsened by the direction of gaze. Physical examination may demonstrate asymmetric positioning of the eyes at rest or with directional gaze. The physical manifestations of a CN III palsy include the inability to move the eye superiorly and medially (leading to the "down and out" position at rest), accompanied by ptosis. The pupillary light reflex usually is present. Although it is a less common finding, CN IV and CN VI may be affected. Patients with a CN IV palsy are unable to move the eye inferolaterally, and those with a CN VI palsy are unable to move the eye laterally. Because of the long intracranial course of CN VI, a patient with an isolated sixth nerve palsy should be evaluated for an intracranial lesion or increased ICP.

Differential Diagnoses

Diabetic mononeuropathy is generally a diagnosis of exclusion. Considerations in the differential diagnosis include trauma, tumor, vertebrobasilar ischemia, aneurysm, and brainstem hemorrhage. Unequal pupils or an abnormal pupillary light reflex should be considered a red flag for a more worrisome cause.

Diagnostic Testing

The key clinical dilemma in a diabetic patient presenting with new onset oculomotor neuropathy relates to the use of diagnostic imaging to rule out potentially life-threatening etiologies. There is no clear clinical consensus on neuroimaging, with a recent meta-analysis demonstrating discrepancies in practice between neurologists and ophthalmologists (with neurologists being more likely to use imaging).[15] It is generally accepted that pupillary involvement warrants evaluation for aneurysm with either MR or CT angiography. Similarly, if other CN are involved or there are other acute neurologic deficits, neuroimaging for stroke is warranted. While there is not a clear treatment recommendation for the ED provider, clinical history and physical examination are thought to be sufficient in the majority of cases, and there is no evidence that diagnostic imaging is required in the diabetic patient presenting an isolated CN III palsy with sparing of the pupillary light reflex and no other neurologic abnormalities.

Management

Treatment consists of patching the affected eye and administration of analgesics and antiplatelet therapy. The prognosis is good and the neuropathy generally resolves within 3 to 6 months.

Disposition

Assuming aneurysm and stroke have been excluded as causes of cranial mononeuropathy, patients may be discharged home. There is some evidence demonstrating that patients with diabetes diagnosed with a CN palsy have a higher risk of subsequent ischemic stroke.[16] While the evidence for this is limited, there is certainly no downside to using the clinical encounter to identify modifiable risk factors for stroke and encourage treatment compliance and outpatient follow up.

CHAPTER 91: QUESTIONS AND ANSWERS

1. A 30-year old woman with no past medical history presents complaining of weakness and spasms in both legs. She describes prior episodes of numbness in her feet that lasted for a few weeks at a time before resolving. She also notes right eye pain, and unilateral papilledema is noted on fundoscopic exam. What is the most appropriate next step in this patient's management?

a. Lumbar puncture
b. Ophthalmology consultation
c. Discharge home and referral to neurologist
d. MRI of the brain and spinal cord
e. IV corticosteroids

Answer: d. This patient is presenting with symptoms suggesting a new diagnosis of Multiple Sclerosis. Early diagnosis and initiation of therapy has been shown to improve outcomes. MRI is a sensitive test in identifying lesions consistent with MS. While MRI may not always be an option in the ED, it should be strongly considered and pursued when available. Lumbar puncture is also a useful test in the evaluation of possible MS, and while there are characteristic CSF findings, LP is of less initial utility than MRI. Non-contrast head CT may be useful in investigating other causes, but it will not identify MS lesions. Discharge home with neurology home is appropriate, but MRI in the ED would likely expedite diagnosis and initiation of therapy.

2. A 65-year-old woman with a history of MS presents with worsening pain, paresthesias, and weakness in her right leg over the last 3 days, which she describes as common symptoms during relapse. She has 4/5 motor strength and increased deep tendon reflexes in her right leg. These findings are noted on prior ED notes. She has a temperature of 102.6°F and otherwise normal vital signs: What is the most appropriate next step in this patient's management?

a. Obtain CBC, chest x-ray, and urinalysis
b. CT of brain
c. Rapid initiation of IV antibiotics followed by lumbar puncture
d. Discharge home with NSAIDs for fever and pain
e. Discharge home with oral corticosteroids

Answer: a. This patient is presenting with an exacerbation of MS. A relapsing and remitting pattern is characteristic. Infection is a common precipitating cause of MS relapse, and investigating the source of infection can help determine the need for and selection of antibiotic therapy. While there may be a need for lumbar puncture and imaging of the brain, these are not necessarily indicated in this scenario. In addition to a possible need for antibiotic therapy, IV or oral corticosteroids can be used to manage the symptoms of MS relapse.

3. A 38-year-old woman presents 8 weeks postpartum with a 1-week history of severe headache and progressively altered mental status, which culminated in a seizure several minutes before presentation. On examination, she is normotensive, appears postictal, but has no focal neurologic findings. Ophthalmoscopic examination reveals papilledema, and non–contrast-enhanced head computed tomography (CT) reveals a dense sagittal sinus and a small venous hemorrhage in the occipital region. What is the most appropriate next step in this patient's management?

a. 325 mg aspirin
b. Dexamethasone 10 mg IV push
c. Hypertonic saline 500-mL bolus
d. Mannitol 1 g/kg
e. Systemic anticoagulation with unfractionated heparin or low-molecular-weight heparin (LMWH)

Answer: e. The patient presents with a venous sinus thrombosis. Although large, randomized trial data do not exist, case series and expert consensus strongly suggest improved outcomes with systemic anticoagulation, even in the setting of venous hemorrhage on head CT. Osmotic agents and steroids have no proven benefit in the management of sinus thrombosis and may cause harm. Antiplatelet agents may be considered if absolute contraindications to anticoagulation exist but probably have lower therapeutic efficacy.

CHAPTER 91: QUESTIONS AND ANSWERS—cont'd.

4. A 26-year-old man presents with a left facial droop. The symptoms began painlessly 3 days ago without a prodrome. Examination reveals a left facial droop with an inability to wrinkle the forehead without other associated physical examination abnormalities. What is the most appropriate next step in this patient's management?
   a. Discharge home with reassurance that symptoms usually resolve in a few weeks
   b. Initiation of oral antiviral therapy
   c. Initiation of oral corticosteroids
   d. Serologic testing for Lyme disease
   e. Urgent non–contrast-enhanced computed tomography (CT) scan of the head

Answer: c. The patient has Bell's palsy, which is a painless left facial nerve palsy. The primary symptom is a left peripheral nerve paralysis often with unilateral dysgeusia, hyperacusis, and external canal and pharyngeal numbness. Facial sensation is intact. Corticosteroids have been shown to improve outcomes, and they should be initiated as soon as possible. Antiviral therapy in combination with corticosteroids may be considered (conflicting evidence exists) but they are less efficacious than corticosteroids when given alone. Given the classic picture and lack of other associated neurologic findings, CT scan of the head is not required and is not likely to provide benefit. Testing for Lyme disease should be considered in Lyme endemic areas or in patients with a history of a tick bite.

5. Which of the following clinical features would make a diagnosis of Bell's palsy less likely?
   a. Increased sensitivity to sound
   b. Decreased tearing on the affected side
   c. A prodromal viral-like illness
   d. Rash
   e. Altered sensation of taste

Answer: d. In addition to the unilateral facial weakness involving the forehead, Bell's palsy may present with increased sound sensitivity (hyperacusis), altered sense of taste (dysgeusia). Decreased tearing may also occur, and viral illness is known to be a precipitating cause. Rash is not characteristic of Bell's palsy, and the presence of a herpetiform vesicular eruption should raise suspicion for Ramsey-Hunt syndrome. Other features that raise suspicion for an alternative diagnosis include vestibular symptoms, bilateral or forehead-sparing distribution, involvement of other cranial nerves, and signs of systemic illness.

6. A 62-year-old woman presents with one day of episodic sharp unilateral facial pain brought on often by combing her hair. She has had several similar episodes over the last year. Examination of the head and neck, as well as cranial nerves, is unremarkable. Which of the following is the most appropriate next step in this patient's management?
   a. The patient should be started on carbamazepine and referred to a neurologist
   b. Neuroimaging
   c. Discharge with short course of oral prednisone.
   d. Timely referral to a neurosurgeon
   e. NSAIDs and reassurance that condition generally resolves without therapy

Answer: a. This patient has met diagnostic criteria for trigeminal neuralgia (TN). TN can be a debilitating condition and is marked by episodic severe episodic facial pain brought on by innocuous stimuli. TN is a clinical diagnosis, and while some suggest that MRI be part of the diagnostic process to evaluate secondary causes of TN, urgent neuroimaging is not indicated in the absence of neurologic deficit or other concerns. First line therapy are sodium-channel blockers such as carbamazepine. Patients who continue to have symptoms with pharmacologic therapy should be referred to a surgeon for consideration of microvascular decompression.

7. A 58-year-old woman presents with progressive right-sided hearing loss along with a sensation of fullness in the ear and otalgia. Her otic canal and tympanic membrane appear normal and she has no mastoid tenderness. Her cranial nerve exam demonstrates right sensorineural hearing less, and the remainder of her neurologic exam is normal. Which of the following is the most appropriate next step in this patient's management?
   a. Admission for IV steroid therapy
   b. Discharge home with instructions for outpatient workup
   c. Head CT
   d. Prompt otolaryngology consultation
   e. Discharge home with otic hydrocortisone/neomycin/polymyxin for pain control

Answer: b. This patient likely has a vestibular schwannoma (VS), a slow-growing tumor of the vestibular nerve that is the most common cause of asymmetric sensorineural hearing loss. Patients may also complain of headache, disequilibrium, and tinnitus. Workup of potential VS, which includes MRI and audiometry, can generally be performed as an outpatient, with subsequent referral to an otolaryngologist or neurosurgeon. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of vestibular schwannoma.

8. A 54-year-old man with a history of poorly controlled diabetes presents with diplopia. Physical exam reveals the inability to move the right eye superiorly and medially, accompanied by ptosis. The right pupil in larger than the left, and poorly responsive to light. Which of the following is the most appropriate next step in this patient's management?
   a. Oral corticosteroid therapy
   b. Discharge with patient education on importance of blood sugar control to minimize risk of stroke.
   c. Prompt referral to an ophthalmologist
   d. MRI brain
   e. Initiation of systemic anticoagulation therapy

Answer: d. Cranial neuropathies are uncommon and usually a complication of diabetes. They most often affect extraocular muscles, causing ophthalmoplegia. The oculomotor nerve (III) is most commonly involved, leading to the inability to move the affected eye superiorly and medially. The etiology of diabetic mononeuropathy is thought to be microvascular ischemia. Fibers controlling pupillary size and light reflex run superficially, and while they can be affected by microvascular ischemia, they are more suspectable to external compression. Ophthalmoplegia with pupillary involvement should raise concern of a posterior cerebral artery aneurysm causing compression of CN III. MRI or CT angiogram is indicated in this situation. In the absence of pupillary involvement or other cranial nerve abnormalities, there is not a clear requirement for imaging in the ED. Attention to modifiable risk factors is important as there may be an association of diabetic mononeuropathy with subsequent stroke risk.

92

Spinal Cord Disorders

Adam D. Hill and Micah J. Nite

KEY CONCEPTS

- Nontraumatic spinal cord disorders can be intrinsic or extrinsic, some of which require prompt diagnosis, advanced imaging, and specialist intervention to prevent or limit permanent neurologic dysfunction.
- The bulbocavernosus reflex is cord-mediated. Return of this reflex following a spinal injury marks the termination of spinal shock.
- Anterior cord syndrome is marked by symmetrical motor loss but intact proprioception and vibration sense.
- In patients with sudden severe back pain, consider spinal subarachnoid hemorrhage (SSAH) or spinal epidural hematoma (SEH), both of which are diagnosed using magnetic resonance imaging (MRI).
- Transverse myelitis is inflammation of the spinal cord often associated with a prior viral infection resulting in paraplegia and a defined sensory level impairment. MRI with contrast enhancement is the diagnostic modality of choice. Roughly one-third of patients have a good outcome.
- Cauda equina syndrome can be difficult to differentiate from conus medullaris lesions because both can result in bladder retention, fecal incontinence, leg weakness, and sensory loss in the perineum. Conus lesions are more typically bilateral, whereas cauda equina syndrome may be unilateral. Upper motor neuron findings are expected with conus lesions while cauda equina syndrome is associated with hypo- or areflexia.
- Central cord syndrome is often due to a hyperextension injury. Physical findings are represented with the mnemonic **MUD**: **M**otor deficits > sensory, **U**pper extremities > lower, **D**istal extremity findings > proximal.
- Brown-Séquard syndrome is due to a functional hemisection of the spine (frequently traumatic) resulting in ipsilateral loss of motor function, proprioception, and vibration with contralateral loss of pain and temperature sensation below the level of injury.
- The diagnostic imaging of choice in the majority of suspected spinal disorders is MRI with contrast.
- A syrinx is a cavitary lesion in the spinal cord that presents with a sensory disassociation predominately in the upper extremities. With progression, it can lead to upper extremity weakness and wasting. Symptom exacerbation with cough or Valsalva is typical.
- With compressive lesions of the spinal cord, neurologic status at the time of intervention and the duration of symptoms are directly related to outcome.
- Autonomic dysreflexia is a complication of spinal cord injury that can result in life-threatening hypertension. Hypertension may be the result of bladder distention, fecal impaction, pain, or infection. Treatment focuses on blood pressure management and the identification and treatment of inciting noxious stimuli.

FOUNDATIONS

This chapter focuses on nontraumatic processes affecting the spinal cord, both extrinsic and internal. The ultimate neurologic outcome of patients with many of these disorders depends on expeditious recognition and management in the emergency department (ED).

Anatomy

In adults, the spinal cord is approximately 40 cm long and extends from the foramen magnum, where it is continuous with the medulla oblongata, to the body of the first or second lumbar vertebra (L1 to L2). The spinal cord is covered in the same three meningeal layers as the brain: the pia mater (innermost), arachnoid mater (middle), and dura mater (outermost). Inferiorly, the cord tapers into the conus medullaris (L1), where several segmental levels are represented in a small area. The lumbar and sacral nerve roots form the cauda equina as they descend caudally in the thecal sac before exiting the spinal canal at the respective foramina. The filum terminale, a non-neural strand of fibrous tissue composed of pia whose function is to suspend the cord in the subarachnoid space, runs from the tip of the conus and inserts into the dura at the level of the second sacral vertebra (S2).

Two symmetrical enlargements of the spinal cord contain the segments that innervate the limbs. The first occurs at the junction of the cervical (C) and thoracic (T) vertebrae. The *cervical enlargement* (C5 to T1) gives rise to the brachial plexus and peripheral nerves of the upper extremity. The second area is located at the junction of the thoracic and lumbar (L) vertebrae. The *lumbar enlargement* (L2 to S3) gives rise to the lumbosacral plexus and peripheral nerves of the lower extremity. The space surrounding the cord at these particular levels is reduced leaving it more vulnerable to external compression. At each segmental level, anterior (ventral) and posterior (dorsal) roots arise from rootlets along the anterolateral and posterolateral cord surfaces. Anterior roots convey the outflow of the motor neurons in the anterior horn of the spinal cord while posterior roots contain neurons and fibers that convey sensory inflow.

The arterial supply of the spinal cord is derived primarily from two sources (Fig. 92.1). The single anterior spinal artery arises from the paired vertebral arteries at the base of the skull. It runs the entire length of the cord in the midline anterior median sulcus and supplies the anterior two-thirds of the spinal cord. Blood supply to the posterior third of the spinal cord is derived from the smaller paired posterior spinal arteries that arise from the vertebral arteries near the skull base and run bilaterally along the posterior cord. These three major spinal arteries receive segmental contributions from radicular arteries throughout their caudal projection, the largest being the artery of Adamkiewicz, which typically originates from the aorta between T8 and L4. The venous drainage of the cord largely parallels the arterial supply.

The internal anatomy of the spinal cord is divided into central gray matter, containing cell bodies and their processes, and surrounding white matter, where the ascending and descending myelinated fiber tracts are located. These white matter fiber tracts are organized into discrete bundles; the ascending tracts convey sensory information while the descending tracts convey the efferent motor impulses and visceral innervation.

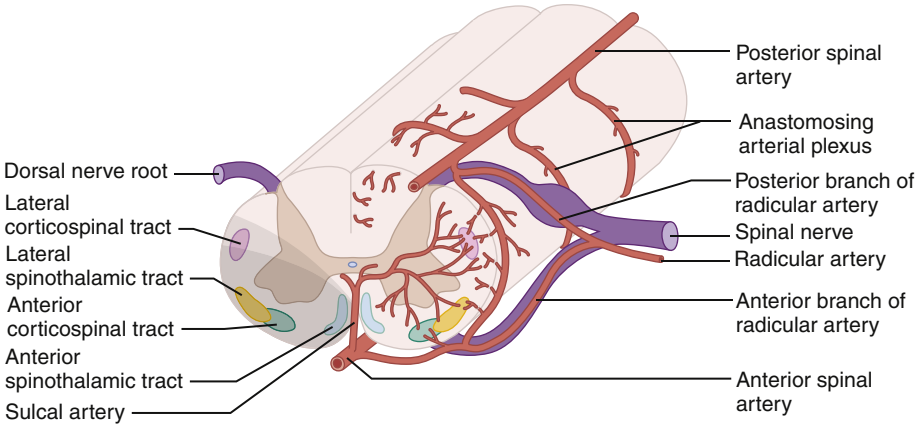

Fig. 92.1 Arterial blood supply to the spinal cord. The anterior spinal artery supplies blood to most of the anterior spinal cord, as well as the lateral column area of the cord (*darkly shaded area*). Some areas of the cord are supplied blood by both the anterior and posterior circulation (*light gray–shaded area*); there is variation among individuals. The anterior horn cells and lateral spinothalamic tracts rely on the anterior spinal artery for blood supply. (Modified from: Yang ML, Connolly AM. Other Motor Neuron Diseases of Childhood. In: Swaiman KF, Ashwal S, Ferriero DM, et al., eds. *Swaiman's Pediatric Neurology*, ed 6. Philadelphia: Elsevier; 2017.)

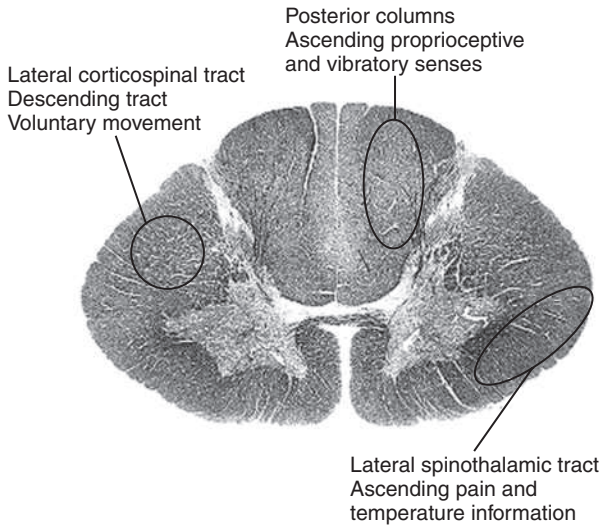

Fig. 92.2 Simplified spinal cord anatomy showing clinically essential motor and sensory tracts. (Photomicrograph courtesy John Sundsten, Digital Anatomist Project, University of Washington.)

For clinical purposes, neuroanatomy of the spinal cord may be greatly simplified, as depicted in Figure 92.2. Tracts are named starting with the point of origin followed by the destination; the spinothalamic tract, for example, arises in the spinal cord and travels to the thalamus. Major ascending sensory tracts are labeled on the right side of the figure, with descending motor tracts on the left. The posterior column (dorsal column) carries afferent ascending proprioceptive and vibratory information on the ipsilateral side of the cord from the area stimulated to the brain; crossing of these fibers occurs in the medulla resulting in contralateral cortical representation. Within the cord, the posterior column is arranged with the sacral fibers existing medially and the cervical fibers laterally. The lateral spinothalamic tract conveys afferent information about pain and temperature in a portion of the lateral column of white matter. The tract is arranged so that sacral fibers are located laterally and cervical fibers medially, a reversal from the posterior column arrangement. Crossing of fibers from this tract occurs near the level of entry of the spinal nerve resulting in contralateral representation in the cord. This is why an isolated cord lesion affecting a spinothalamic tract results in decreased or absent pain and temperature perception below the level of injury on the opposite side of the body.

The major descending motor tract is represented in the lateral corticospinal tract, originating in the cortex of the brain and traveling to the spinal cord. Crossing of this tract occurs in the medulla, similar to the ascending posterior column, meaning that motor signals from one side of the brain ultimately descend down the opposite cord side and result in motion of the contralateral body. This tract is organized similar to the lateral spinothalamic, with sacral fibers located laterally and the cervical fibers medially. The cell bodies of the lower motor neurons (anterior horn cells) are in the ventral portion of the gray matter of the spinal cord.

Classification of Spinal Cord Syndromes

The anatomic organization of the spinal cord lends itself to a corresponding anatomic-pathophysiologic classification of cord dysfunction (Table 92.1). Any of the different cord syndromes may be the final clinical picture of a variety of pathologic processes. These syndromes do frequently exist in partial or incomplete forms, adding to the diagnostic challenge.

Complete (Transverse) Spinal Cord Syndrome

Complete spinal cord lesions may be manifested as either acute or subacute processes. It is defined as a total loss of sensory, autonomic, and voluntary motor innervation distal to the spinal cord level of injury. Neural responses mediated at the spinal level, such as deep tendon reflexes, may persist but may also be absent (early stages) or hyperreflexic (later stages). Autonomic dysfunction may be manifested acutely with hypotension (neurogenic shock) or priapism. The most common cause of a complete cord syndrome is trauma, though other etiologies are possible including infarction, hemorrhage, and extrinsic compression. In patients with complete syndromes that persist for more than 24 hours, functional recovery almost never occurs. Any evidence of preserved cord function below the level of injury denotes a partial rather than complete lesion. Signs such as persistent perineal sensation (sacral sparing), reflex rectal sphincter tone or voluntary rectal sphincter contraction, and even slight voluntary toe movement suggest a partial cord lesion, which carries a better prognosis than a complete lesion.

TABLE 92.1 Spinal Cord Syndromes

Syndrome	Sensory	Motor	Sphincter Involvement
 Central cord syndrome	Variable	Upper extremity weakness, distal > proximal	Variable
 Brown-Séquard syndrome	Ipsilateral position and vibration sense loss Contralateral pain and temperature sensation loss	Motor loss ipsilateral to cord lesion	Variable
 Anterior cord syndrome	Loss of pain and touch sensation Vibration, position sense preserved	Motor loss or weakness below cord level	Variable
 Transverse (complete) cord syndrome	Loss of sensation below level of cord injury	Loss of voluntary motor function below cord level	Sphincter control lost
Conus medullaris syndrome	Saddle anesthesia may be present; Sensory loss may range from patchy to complete transverse pattern	Weakness may be of upper motor neuron type; Bilateral	Sphincter control impaired
Cauda equina syndrome	Saddle anesthesia may be present; Sensory loss may range from patchy to complete transverse pattern	Weakness may be of lower motor neuron type; Unilateral	Sphincter control impaired

Spinal shock refers to the loss of muscle tone and reflexes with a complete cord syndrome during the acute phase of injury. It typically lasts less than 24 hours but has been reported to occasionally last days or weeks. A marker of spinal shock is loss of the bulbocavernosus reflex, which is a normal cord-mediated reflex that may be preserved in complete cord lesions. The bulbocavernosus reflex involves involuntary contraction of the anal sphincter in response to a squeeze of the glans penis, clitoris, or outward tug on a Foley catheter. Termination of the spinal shock phase of injury is heralded by the return of the bulbocavernosus reflex, with increased muscle tone and hyperreflexia following later.

Incomplete (Partial) Spinal Cord Lesions

Incomplete lesions are characterized by functional preservation of various portions of the spinal cord. Of the many possible incomplete lesions, most can be classified as one of three clinical syndromes based on functionality: (1) central cord syndrome, (2) Brown-Séquard syndrome, or (3) anterior cord syndrome.

Central Cord Syndrome. Central cord syndrome is the most common of the partial cord syndromes. Because of the anatomic organization of the spinal cord, a central cord injury is characterized by bilateral motor paresis. The upper extremities and distal muscle groups are affected to a greater degree than the lower extremities and proximal muscle groups. Sensory impairment and bladder dysfunction are variable features. At times, burning dysesthesias in the upper extremities may be the dominant clinical feature. The mnemonic "MUD" can aid in recall of these features: **M**otor greater than sensory, **U**pper greater than lower, **D**istal greater than proximal.

Central cord syndrome affects the central gray matter and the central portions of the corticospinal and spinothalamic tracts. It is

most often caused by a hyperextension injury, frequently from falls or motor vehicle accidents. The postulated mechanism is squeezing of the cord anteriorly and posteriorly due to inward bulging of the dorsally located ligamentum flavum resulting in a contusion to the spinal cord which most affects the central cord. This injury often occurs in elders with degenerative arthritis and spinal stenosis in the cervical area but can affect patients with cervical canal narrowing of any etiology (i.e., disc protrusion, tumor, or congenital narrowing as in achondroplasia). The prognosis depends on the degree of injury at presentation as well as the patient's age, with advanced age predicting decreased functional outcome. In patients younger than 50 years old, more than 80% regain bladder continence and approximately 90% return to full ambulatory status; in patients older than 50 years, only 30% regain bladder function and approximately 50% regain the ability to ambulate.

Brown-Séquard Syndrome. Brown-Séquard syndrome is the result of an anatomic or functional hemisection of the spinal cord. Usually associated with penetrating injuries, Brown-Séquard syndrome also may be seen with compressive or intrinsic lesions. It has been reported in association with spinal cord tumors, spinal epidural hematomas, vascular malformations, cervical spondylosis, degenerative disc disease, herpes zoster myelitis, radiation injury, and as a complication of spinal instrumentation. In its pure form, it is characterized by ipsilateral loss of motor function, proprioception, and vibration sense with contralateral loss of pain and temperature sensation below the level of injury. Because fibers associated with the lateral spinothalamic tract ascend one or two spinal cord segments before crossing to the contralateral side, ipsilateral anesthesia (pain and temperature modalities) may be noted one or two segments above the lesion, although this observation is variable. Most patients with this syndrome incur only partial sensory and motor impairment, so the classic pattern is not always seen. Brown-Séquard syndrome carries the best prognosis of any of the incomplete spinal cord syndromes. Fully 80% to 90% of patients regain bowel and bladder function, 75% regain ambulatory status, and 70% become independent in their activities of daily living.

Anterior Cord Syndrome. Anterior cord syndrome is characterized by loss of motor function, pinprick, and light touch below the level of the lesion with preservation of the posterior column modalities, including position, vibration, and some touch. Although most reported cases of anterior spinal cord syndrome follow aortic surgery, it may also occur after severe hypotension, infection, myocardial infarction, vasospasm from drug reaction, and aortic angiography. Mechanically, the lesion may be caused by cervical hyperflexion resulting in a cord contusion or by protrusion of bone fragments or herniated cervical disc material into the canal. Rarely, it is produced by laceration or thrombosis of the anterior spinal artery or a major radicular vessel. Functional recovery varies, with most improvement occurring during the first 24 hours and little improvement thereafter. Although anterior cord lesions from ischemia usually are incomplete, patients without motor function at 30 days have little or no likelihood of regaining any motor function by 1 year. Only 10% to 20% of patients regain some muscle function, and even in this group there is little power or coordination.

Conus Medullaris and Cauda Equina Syndromes

The differentiation between conus medullaris and cauda equina lesions in clinical practice is difficult because the two disorders overlap in their clinical presentation. In addition, a combined lesion can mask clear clinical symptoms or signs of either an upper or a lower motor neuron type of injury.

Physical features of conus medullaris syndrome may involve disturbances of urination (usually from a denervated, spastic, autonomic bladder that manifests as overflow incontinence) and sphincter impairment (decreased rectal tone) or erectile dysfunction. Sensory involvement may affect the sacral and coccygeal segments, resulting in saddle anesthesia. Pure lesions of the conus medullaris are rare. Upper motor neuron signs, such as increased motor tone and hyperreflexia, may be present, but their absence does not exclude the syndrome.

Conus medullaris syndrome can be caused by central disc herniation, neoplasm, trauma, or vascular insufficiency. Because the conus is such a small structure, with lumbar and sacral segments represented in a minimal area, a lesion will usually cause bilateral symptoms. This finding may help distinguish conus medullaris lesions from those in the cauda equina, which often are unilateral.

Cauda equina (Latin for "horse's tail") is the name given to the lumbar and sacral nerve roots that continue on within the dural sac distal to the conus medullaris. Not a true "cord syndrome" as the cord itself is unaffected, cauda equina syndrome represents dysfunction at the level of nerve roots. The anatomic clustering of nerve roots within the lumbar dural sac allows insult to multiple nerve roots to occur simultaneously.

Cauda equina syndrome is usually caused by the midline rupture of an intervertebral disc most commonly at the L4 to L5 level, but any compressive mass can cause it. As in conus medullaris syndrome, patients generally present with progressive symptoms of fecal or urinary incontinence, impotence, decreased rectal tone, distal motor weakness, and saddle anesthesia. Deep tendon reflexes may be reduced. All of these findings have low sensitivity but moderately good specificity in the diagnosis, with saddle anesthesia and bowel/bladder changes having a specificity range of 70% to 89%.[1] Of note, a complaint of low back pain may or may not be present.

CLINICAL FEATURES

History

Weakness, sensory abnormalities, and autonomic dysfunction are the cardinal manifestations of spinal cord dysfunction. The tempo and degree of impairment often reflect the disease process. Past medical history is vital because an underlying coagulopathy or other systemic process may be elicited. A history of cancer suggests the possibility of metastatic disease. Recent trauma raises the possibility of vertebral fracture or disc protrusion. The acuity of pain can help narrow the differential diagnosis as well, with sudden pain or dysfunction more likely to be a vascular catastrophe, and slower onset, midline pain in the setting of fever points toward an infectious source.

Physical Examination

The physical examination pertinent to spinal cord dysfunction involves testing in three areas: (1) motor function, (2) sensory function, and (3) reflexes. Each component is best tested with the anatomic organization of the spinal cord in mind to help determine the level of dysfunction. A detailed description of neurologic deficits and their correlating spinal level can be found in Chapter 35.

Motor Function

Testing of motor function encompasses examination of muscle bulk, tone, and strength. Muscle bulk is easily examined in large motor groups, such as the thigh, the calf, or the upper arm. Inspection of intrinsic hand muscles may also be helpful in determination of bulk; wasting may be evident as hollowed or recessed regions of the hand. Any decreased mass, asymmetry, or fasciculations should be noted. Tone is tested with repeated passive knee, elbow, or wrist flexion, or by rapid passive forearm pronation-supination, with the examiner assessing for abnormally increased or decreased resistance. Increased

TABLE 92.2 Grading of Neuromuscular Weakness

Grade	Physical Findings
0	No firing of the muscle is present.
1	The muscle fires but is unable to move the intended part.
2	The muscle is able to move the intended part with gravity eliminated.
3	The muscle is able to move the intended part against gravity.
4	The muscle is able to move the intended part but not at full strength.
5	Full muscle strength is present.

tone may indicate spasticity or an upper motor neuron lesion whereas decreased tone corresponds with lower motor neuron, motor end-plate, or muscle problems. Motor strength is then graded in the upper and the lower extremities. Motor grading for the neurologic examination is relatively straightforward; scored on a scale of 0 to 5, as shown in Table 92.2.

A rectal examination and the bulbocavernosus reflex (involuntary anal sphincter contraction in response to a squeeze of the glans penis or clitoris or a tugging on a Foley catheter) are performed to assess voluntary sphincter contraction and resting tone. Although not commonly thought of as a physical examination maneuver, a post-void residual (PVR) urine volume is useful to evaluate bladder function. A PVR of more than 100 to 200 mL in a patient without prior voiding difficulty suggests bladder dysfunction of a neurologic cause.

Sensory Function

Sensory testing requires a cooperative patient and an attentive examiner. Assessment of the patient's response to pinprick and light touch (contralateral spinothalamic tract) and proprioception (ipsilateral posterior column) in all four extremities is necessary. Testing of sacral dermatomes is indicated, as sparing suggests that a lesion may be incomplete. The sensory fibers from these dermatomes are more peripherally located in the ascending fiber bundles, thus, central or partial cord lesions may ablate sensation in the extremities yet allow some perception in the sacral area.

Reflexes

Deep tendon (muscle stretch) reflexes are graded on a scale of 0 to 4+, with 2 being normal. Hyperactive reflexes suggest upper motor neuron disease (affecting the neurons or their outflow from the brain or spinal cord) as do sustained clonus and Babinski sign. If present, hyperactive or abnormally brisk reflexes may be a key finding suggesting a myelopathy. However, absence of hyperreflexia does not exclude one. Reflexes may be diminished or absent when sensation is lost, when spinal shock is present, or in diseases of muscles or the neuromuscular junction. In acute cord injury, reflexes can be diminished in the acute phase, therefore, the bulbocavernosus reflex may be helpful in this assessment.

DIFFERENTIAL DIAGNOSES

The prime principle in management of spinal cord dysfunction is to consider and diagnose potentially treatable and time-sensitive conditions. The clinician should rule out any nonstructural cause of neurologic dysfunction (e.g., hypoglycemia, hypokalemia) early in the evaluation process. Once a true neurologic entity is suspected, the next step is to differentiate the location of the lesion (i.e., brain, spinal cord, nerve or motor end-plate). When the pathologic process is suspected to be spinal in origin, liberal use of specialist consultation and imaging is generally warranted. Spinal cord disorders may mimic many other disease processes, and neither the history nor physical examination can reliably enable a true diagnosis until appreciable neurologic dysfunction has developed.

The picture of a complete (transverse) spinal cord syndrome with paraplegia, sensory loss at a clear anatomic level, and sphincter dysfunction cannot be fully mimicked by other anatomic lesions; incomplete or evolving spinal cord syndromes, however, can. Ataxia, for example, is often a finding in cerebellar disease but has been reported as a rare, isolated finding in spinal cord compression.

In general, pathologic processes involving the spinal cord may be divided into those affecting the cord or its blood supply (e.g., demyelination, infection, or infarction) and ones that compress the cord. Of note, *myelitis* is a comprehensive term for spinal cord inflammation with dysfunction. The clinical presentation is often similar across the many etiologies of cord compression, but the tempo of the process may yield a different clinical picture. In chronic compression, muscle wasting and abnormal reflexes may be present, whereas both of these findings are likely to be lacking in acute compression.

DIAGNOSTIC TESTING

The purpose of diagnostic testing in patients suspected of having spinal cord dysfunction is to detect or exclude extrinsic compressive lesions or other potentially treatable entities. Conventional radiographs and computed tomography (CT) scans are essential in patients with trauma or suspected bony involvement by tumor or degenerative process because they better define bone and can show some soft tissue abnormalities. However, due to its ability to clearly define the spinal cord and the soft tissue structures around it, magnetic resonance imaging (MRI) is the preferred modality in assessing spinal cord disorders. It may also detect tissue damage patterns within the cord, such as hemorrhage and edema, as well as bone pathology. When utilized, MRI assessment of the entire spine should be considered because lesions can frequently occur at multiple levels.

MRI with gadolinium contrast enhancement is indicated when looking for pathology that affects the blood–central nervous system (CNS) barrier. Specific indications include primary or metastatic tumor, multiple sclerosis (MS), and spinal infections (i.e., spinal epidural abscess, discitis, and osteomyelitis). An example of the utility of gadolinium enhancement is seen in Figure 92.3. CT myelography is an option when MRI is unavailable or contraindicated, although it does not yield the same level of detail.

After imaging studies exclude compressive lesions or other masses affecting the spinal cord, the possibility of inflammatory or demyelinating disorders remains. In these cases, lumbar puncture with cerebrospinal fluid (CSF) analysis may be diagnostic.

MANAGEMENT

The treatment of many of the disease processes causing spinal cord dysfunction is nonspecific and based on limited evidence. Steroids have been used with many nontraumatic causes of cord compression, particularly spinal cord tumors, despite the lack of rigorous clinical studies supporting this practice. Radiation treatment is recommended for cord compression by tumor; surgical consultation for decompression may be considered, although the indications and timing for surgery are controversial.

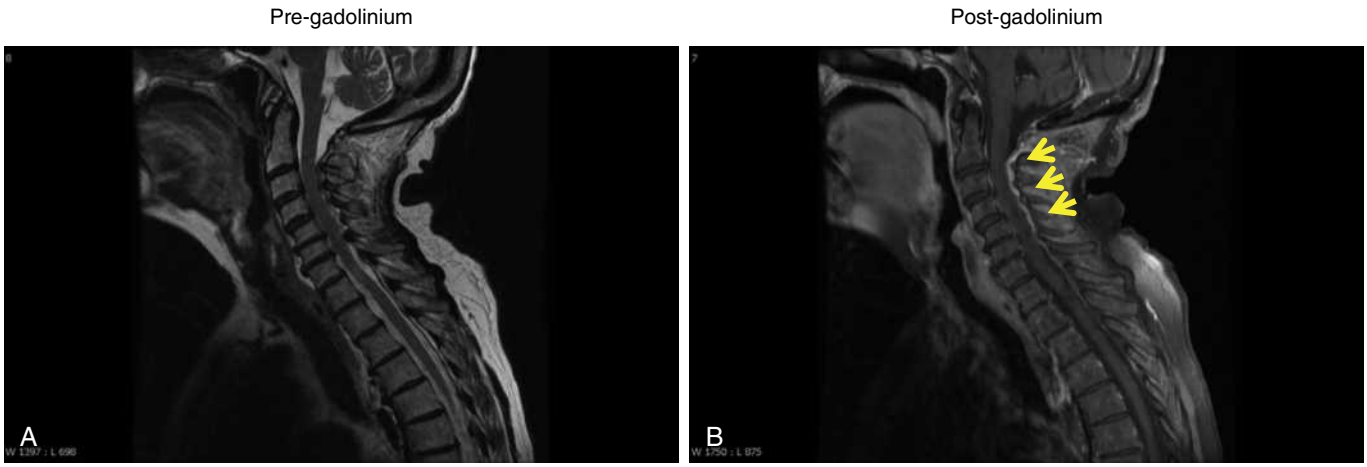

Fig. 92.3 90-year-old female with recent pyelonephritis presenting with severe neck pain. Pregadolinium sequence (A) compared with postgadolinium sequence (B) demonstrates posterior spinal epidural abscess (SEA) *(yellow arrowheads).*

TABLE 92.3 Causes and Characteristics of Nontraumatic Spinal Cord Dysfunction

Disease Process	Symptoms/Examination Findings	Testing	Treatment
Intrinsic Lesions			
Multiple Sclerosis	Symptoms include sensory, visual (optic neuritis), GI, fatigue, weakness, labile mood, hyperreflexia.	MRI, LP, consider biopsy	Steroids + disease-modifying medications
Transverse Myelitis	Paraplegia, transverse sensory impairment, and sphincter disturbance.	MRI	±Glucocorticoid therapy (etiology dependent)
Spinal Subarachnoid Hemorrhage	Usually have focal deficits on examination at level of bleed. May also complain of headache and/or demonstrate nuchal rigidity on exam.	MRI +/– LP	Anticoagulation reversal +/– clot evacuation
Syringomyelia	Headache with neck pain and sensory disturbances. Frequently demonstrate lower limb hyperreflexia with hand weakness and dissociative anesthesia.	MRI	Neurosurgical consultation vs. outpatient follow-up
HIV Myelopathy	Advanced HIV infection with weakness, gait disturbance, and sensory abnormalities.	Diagnosis of exclusion	Supportive therapy, HAART
Spinal Cord Infarction	Findings depend on location of infarction but anterior cord syndrome is most common.	Diagnosis of exclusion	Dependent on etiology
Surfer's Myelopathy	Back pain, paresis, and urinary retention.	MRI	Conservative therapy
Extrinsic Lesions			
Spinal Epidural Hematoma	Sudden severe radicular back pain usually presents prior to onset of deficits. Exam findings depend on location of hematoma.	MRI	Decompressive laminectomy
Spinal Epidural Abscess	Classically febrile with progressive neurological deficits. Back pain may be worse with percussion.	MRI	IV antibiotics ± surgery vs. needle decompression
Discitis	Children with back pain at level of lesion. Subacute presentation with fever but no neurologic deficits.	MRI	IV antibiotics
Neoplasm	Nighttime pain worse with lying flat. Deficits depend on location of lesion.	CT or MRI	Glucocorticoid therapy + radiation therapy or surgery

SPECIFIC DISEASE PROCESSES

Spinal cord disorders are grouped into lesions resulting from processes intrinsic to the cord or vasculature and lesions causing extrinsic compression (Table 92.3).

Intrinsic Cord Lesions

Multiple Sclerosis

Demyelination denotes a disease process with the prominent feature of partial or complete loss of the myelin surrounding the axons of the CNS. Multiple sclerosis (MS) is the most common example of such a process. The spinal cord is involved in as many as 90% of MS patients. In approximately 20% of patients, the spinal cord lesions will be the only area where plaques are identified. The pathophysiology, diagnosis, and management of MS is discussed in Chapter 94.

Transverse Myelitis

Foundations. *Acute transverse myelitis* (TM) refers to acute or subacute spinal cord dysfunction characterized by paraplegia, a transverse level of sensory impairment, and sphincter disturbance. It

is often considered part of a heterogeneous group of inflammatory processes known as neuromyelitis opticum spectrum disorders (NMOSD).[2] TM affects the spinal cord by interrupting the ascending or descending pathways. The presentation may be mimicked by compressive lesions, trauma, infection, or malignant infiltration.

The pathogenesis of transverse myelitis is unknown, although it is noted to follow a viral infection in approximately 30% of patients and therefore often termed *postinfectious myelitis*. Other postulated etiologies include infectious, autoimmune, and idiopathic disorders. It can be seen with a wide variety of connective tissue diseases, such as lupus, Sjögren syndrome, antiphospholipid syndrome, and other mixed connective tissue diseases. More recent research points to the presence of anti-AQP4 antibodies, particularly in cases thought to be part of NMOSD.[3] No cause is identified in 30% of patients. Progression of symptoms is usually rapid, with 66% of the cases reaching maximal deficit by 24 hours. However, symptoms may progress over days to weeks. The thoracic cord region is affected in 60% to 70% of cases, with the cervical cord being rarely involved. When TM lesions span 3 or more spinal cord levels, it is termed *longitudinally extensive transverse myelitis* (LETM) and is considered a hallmark of NMOSD.[4]

Clinical Features. In addition to motor, sensory, and urinary disturbances, patients with acute transverse myelitis may complain of back pain as well as a low-grade fever, raising concern for SEA. As with MS, the examination may reveal weakness progressing to paresis, hypertonia, hyperreflexia, clonus, Babinski response, and anal sphincter dysfunction. A distinct sensory level deficit is usually present. Autonomic dysfunction may also be noted as hyper- or hypotension and tachy- or bradycardia.

Differential Diagnoses. Considerations in the differential diagnosis for transverse myelitis include MS, SEA, spinal epidural hematoma (SEH), primary or metastatic spinal neoplasm, spinal cord infarct, surfer's myelopathy, and vitamin B_4 deficiency.[3]

Diagnostic Strategies. MRI with gadolinium enhancement is the diagnostic modality of choice for suspected transverse myelitis (Fig. 92.4). In cases of diagnostic uncertainty, a lumbar puncture may be performed; however, the results of CSF studies are normal in 40% of cases, with only mildly elevated protein levels or pleocytosis in the remaining 60%. The most essential aspect of the evaluation is to eliminate a potentially treatable cause. If testing is available, serum can be sent to detect the presence of specific antibodies (e.g., antiphospholipid, anti-AQP4, ANA).

Management. Treatment is tailored to the suspected underlying etiology. There are no good studies supporting a role for steroids. The exception for this would be in the setting of NMOSD-related TM, where steroids and immunosuppressant agents are the current recommended treatment. Methylprednisolone 1 gram IV is commonly administered. Neurologic consultation is suggested and hospitalization is usually required.

The clinical course of acute transverse myelitis varies widely, ranging from complete recovery to death from progressive neurologic compromise. Most patients with idiopathic disease have at least partial recovery, which usually begins within 1 to 3 months. Maximal improvement usually is obtained within 3 to 6 months with 30% of patients having "good" recovery, 25% "fair" recovery, and 30% having a "poor" outcome; there is 15% mortality at 5 years.

Fig. 92.4 Sagittal T2 MR shows a long segment of abnormal hyperintensity *(blue arrowheads)* and expansion of the visualized spinal cord, characteristic of transverse myelitis. (From: Merrow AC, Hariharan S. Transverse myelitis. In: Merrow AC, Hariharan S, eds. *Imaging in Pediatrics*, ed 1. Philadelphia: Elsevier; 2018.)

Spinal Subarachnoid Hemorrhage

Foundations. Intraspinal hemorrhage is rare and may occur in the same anatomic locations as intracranial hemorrhages; epidural, subdural, subarachnoid, and intramedullary hemorrhages are all possible. Spinal subarachnoid hemorrhage (SSAH) is usually caused by an arteriovenous malformation. Hemorrhage from tumors or cavernous angiomas and spontaneous hemorrhage secondary to anticoagulation therapy have also been reported. Diagnostic lumbar puncture is documented as a rare cause.[5] Bleeding may occur exclusively in the subarachnoid space or within the spinal cord tissue itself.

Clinical Features. Patients with SSAH present with excruciating back pain of a sudden and severe nature at the level of the hemorrhage. This pain may be in a radicular distribution or extend into the flank. Patients can complain of headache and exhibit cervical rigidity if the blood migrates into the intracranial subarachnoid space, simulating an intracranial subarachnoid hemorrhage. Variable neurologic deficits depend on the magnitude and anatomic location of the hemorrhage. These deficits typically include extremity numbness, weakness, and sphincter dysfunction. Nuchal rigidity or signs of meningeal irritation may also be present.

Differential Diagnoses. Considerations in the differential diagnosis include disc herniation, tumor, ischemia from aortic dissection, and anterior spinal artery thrombosis.

Diagnostic Testing. Because bone artifact may obscure the presence of blood in the spine, the diagnostic study of choice in patients with suspected SSAH is MRI without contrast. Lumbar puncture can help to confirm the presence of blood in the CSF. Angiography may be recommended if arteriovenous malformation is suspected. CT may be of benefit in detecting SSAH if MRI is not immediately available, but a negative CT does not definitively rule out the disease.[6]

Management. The treatment of spinal subarachnoid hemorrhage depends on the etiology of the hemorrhage. Neurosurgical referral is obtained for further evaluation and potential clot evacuation if compression is present. Reversal of anticoagulant medications should be considered in the proper clinical setting.

Syringomyelia

Foundations. Syringomyelia is the presence of a cavitary lesion within the tissue of the spinal cord. The word *syrinx* is derived from the Greek *surinx* for "pipe" or "channel." A syrinx is usually a chronic, progressive lesion with its specific location within the cord determining the constellation of neurologic findings. Ninety percent of patients with syringomyelia have a Chiari I malformation (projection of the cerebellar tonsils and medulla into the spinal canal) with nearly 5% of these patients requiring urgent surgical decompression due to acute neurologic deterioration.[7] This particular pathology, however, can be seen in almost all types of craniocervical junctional malformations.[8] Other etiologies of syringomyelia include spinal cord trauma (often months to years post-injury), compressive tumors, postinfectious (meningitis), and postinflammatory (transverse myelitis, MS).

Clinical Features. Headache and neck pain are the most common presenting complaints of patients with syringomyelia, followed by sensory disturbance, gait disorder, and lower cranial nerve dysfunction (CN IX–XII). Symptoms may be exacerbated by activities that increase intracranial pressure: sneeze, cough, or Valsalva maneuver. Patient-specific symptoms of syringomyelia develop and progress in accordance with the intracavitary pressure and anatomic location of the syrinx.

The most common features on physical examination are lower limb hyperreflexia, upper limb/hand weakness and muscle wasting, dissociated sensory loss, and gait abnormality. The classic pattern of sensory deficit involves a loss of pain and temperature sensation in the upper extremities with preservation of proprioception and light touch. This phenomenon is described as a "dissociative anesthesia" because of the discrepant loss of sensory modalities. This deficit often is described as being in a "capelike" distribution over the shoulders and arms. The anatomic basis for the neurologic features of a syrinx is the location near the central canal. Crossing fibers of the lateral spinothalamic tract carrying pain and temperature fibers are impaired while crude touch, position, and vibratory sensation from the posterior columns are unaffected. Sensory fibers from the lower limbs are similarly spared. Motor fibers from the corticospinal tract, when affected, will often result in upper extremity weakness due to the anatomic layout of the tract and the predominant cervical location of most syrinxes.

Differential Diagnoses. Considerations in the differential diagnosis for syrinx include intrinsic spinal tumor, demyelination, and trauma resulting in central cord syndrome.

Diagnostic Testing. Syringomyelia is best seen on MRI (Fig. 92.5). No other modality currently in widespread use is equivalent in diagnostic ability.

Management. When the diagnosis of syringomyelia is considered, emergent imaging in the ED may not be necessary if follow-up evaluation can be arranged; in approximately two-thirds of patients this condition is a slowly progressive process. If MRI studies are obtained and the diagnosis is made, referral to a neurosurgeon is indicated. Patients with acute neurologic deterioration, however, likely benefit from a more expedited evaluation, as urgent surgical decompression may be indicated in specific anatomic malformations (i.e., Chiari I malformations).

Human Immunodeficiency Virus Myelopathy

Human immunodeficiency virus (HIV) myelopathy typically occurs in patients with advanced HIV infection, often in conjunction with a very low CD4 count.[9] Weakness, gait disturbance, sphincter dysfunction, sensory abnormalities, and signs of spasticity are all features of this progressive process. Because diseases such as toxoplasmosis, lymphoma, varicella-zoster, and cytomegalovirus may produce a similar clinical picture in immunocompromised patients, HIV myelopathy is a diagnosis of exclusion. It more often affects the thoracic cord, so symptoms are frequently localized to the lower extremities. Treatment is primarily supportive, but improvement may be seen with utilization of highly active antiretroviral therapy (HAART).

Fig. 92.5 T2-weighted magnetic resonance imaging of a patient with Chiari malformation and syringomyelia. (From: Batzdorf U. Syringomyelia. In: Shen FH, Samartzis D, Fessler RG, eds. *Textbook of the Cervical Spine*, ed 1. Maryland Heights: Saunders; 2015.)

Spinal Cord Infarction

Spinal cord infarction is extremely rare and considered a diagnosis of exclusion, but certain clinical clues may point to it. Aortic dissection, aortic surgery, and global ischemia are the most common causes. It can also occur as a complication of lupus or vasculitis or be cryptogenic. The clinical picture depends on the extent of infarct as well as the vascular territory affected (anterior versus posterior spinal artery). An anterior spinal cord syndrome is the most common clinical picture. Recovery is variable and etiology dependent.

Surfer's Myelopathy

Surfer's myelopathy is a recently described etiology of atraumatic cord dysfunction.[10] It is most often seen in novice or first-time surfers presenting with back pain, paresis, and urinary retention. Anesthesia or hyperesthesia may be present. The suggested mechanism is static hyperextension of the spine that occurs when lying prone on a surfboard with arms extended and head up for long periods of time, resulting in transient cord ischemia. Recovery is generally favorable but permanent paresis is possible. Awareness of this etiology is important, as it's symptoms mimic transverse myelitis.

Extrinsic Cord Lesions

Spinal Epidural Hematoma

Foundations. Spinal epidural hematoma (SEH) is a relatively rare condition where blood accumulates in the epidural space and can cause compression of the spinal cord. A hematoma may occur spontaneously but is more commonly traumatic or iatrogenic following lumbar puncture, epidural anesthesia, spinal surgery, and even acupuncture. SEH can occur at any level of the spine and can even extend to the cranium. It is more likely to occur in anticoagulated or thrombocytopenic patients such as those with liver disease or alcoholism. Spontaneous bleeding is rare but may arise from a spinal or dural arteriovenous malformation or a vertebral hemangioma. One-quarter of all cases are associated with anticoagulation therapy, including low-molecular-weight heparin and direct thrombin inhibitors.

Clinical Features. Patients usually present with sudden, severe, constant back pain. The pain is frequently radicular and may occur after a straining episode; it is often worsened by percussion over the spine and by maneuvers that increase intraspinal pressure (cough, sneeze, Valsalva).[11] Due to the severity of pain, patients are often in distress and seek care prior to the development of neurologic signs, which may actually lead to a delay in diagnosis. Neurologic deficits follow the onset of pain and may progress over a period of hours to days. Motor and sensory findings are variable because they depend on the level and size of the hematoma. Symptoms can include weakness, paralysis, loss of bowel or bladder function, and virtually any sensory deficit.

Differential Diagnoses. Considerations in the differential diagnosis include SEA, epidural neoplasm, acute disc herniation, and SSAH. SEH has even been known to mimic a stroke. This diagnosis should be considered in a patient presenting with a stroke syndrome who also has acute neck or back pain.

Diagnostic Testing. MRI with and without IV contrast is the diagnostic study of choice. CT myelography will frequently pick up the hematoma or show contrast medium in the subarachnoid space. The hematoma may initially be identified on CT due to its high density but is inferior to MRI in localizing and characterizing the lesion.

Management. In patients with SEH, recovery without surgery is rare. Neurosurgical consultation for emergent decompressive laminectomy is indicated as soon as the diagnosis is considered. Functional recovery is related both to the length of time the symptoms are present and to the initial neurologic status. Recovery after 72 hours of symptoms is rare but has been reported even without surgery, primarily in younger patients with rapidly improving symptoms. In the setting of anticoagulation therapy that is reversible, measures should be taken to do so.

Spinal Epidural Abscess

Foundations. Spinal epidural abscess (SEA) is an infectious process usually confined to the adipose tissue of the dorsal epidural space where there is a rich venous plexus. Abscesses that form in this space are limited by the bony confines of the spinal column. Damage to the spinal cord can be caused by direct compression on neural or vascular structures, but septic thrombophlebitis and vascular occlusion secondary to bacterial and inflammatory substances may also cause injury. Major risk factors for the development of SEA include underlying disease (immunosuppression, diabetes, chronic renal failure, alcoholism), spinal abnormality, recent spinal intervention (surgery, epidural analgesia), or local or systemic infection (skin and soft tissue infections, cystitis, sepsis, osteomyelitis, endocarditis, IV drug abuse), but the disease can be seen in individuals without any risk factors. The incidence of this disease is increasing, likely due to a higher rate of spinal instrumentation, an aging population, and higher prevalence of IV drug use. An acute or subacute presentation is most frequently seen in the ED, though some patients may develop a chronic form.

The thoracolumbar spine is the most frequent site of infection because the epidural space is larger and contains more adipose tissue. Infection typically extends over multiple vertebral segments but can also occur at noncontiguous locations. The dura mater limits the spread of an epidural infection, making subdural or intraspinal spread uncommon. Hematogenous spread to the epidural space from a discrete infection occurs in about half of the cases via the epidural space or the adjacent vertebra with subsequent extension into the epidural space. Local spread of bacteria occurs in another third of cases with the remainder having no clear source of infection identified.

Skin and soft tissue infections are the most frequently identified source of bacteria. *Staphylococcus aureus* is the most prevalent organism, cultured in nearly two-thirds of cases; the percentage of cases caused by MRSA has been increasing in recent years. Other frequently identified pathogens include gram-negative pathogens (*Escherichia coli*, *Pseudomonas aeruginosa)*, *Streptococcus*, and coagulase-negative *Staphylococcus*. Anaerobic or fungal causes are rarely identified. *Mycobacterium tuberculosis* should be considered as a potential cause in the developing world. Multiple organisms are identified in 10% of cases.

Clinical Features. The clinical presentation of SEA begins with back pain localized to the level of the affected spine, often associated with tenderness to percussion. Symptoms usually progress over a few days but may extend for weeks. Radicular symptoms develop as the disease progresses to involve the nerve root radiating from the involved vertebrae. Without treatment, myelopathic signs will result, usually beginning with bowel and bladder disturbance. Weakness and sensory deficits develop, followed by paraplegia or quadriplegia. Once paralysis develops it quickly becomes irreversible within 24 to 48 hours. Bacteremia, either as a cause or as a result of SEA, may be present in over 50% of patients. Patients should be questioned about fevers, chills, or rigors, as they are present in up to 75% of cases. The classic triad of back pain, fever, and progressive neurologic deficits is rarely present and thus a delay in clinical diagnosis is common. In rare cases, SEA may also present as acute delirium.

Differential Diagnoses. SEA is frequently misdiagnosed on initial presentation, especially in a patient who is neurologically intact. In someone with infectious symptoms, more common causes such as cystitis, pneumonia, bacteremia, or osteomyelitis may be incorrectly diagnosed. Any compressive spinal lesion can mimic the neurologic manifestations of SEA.

Diagnostic Testing. MRI with IV contrast is the imaging modality of choice and should be performed emergently if the diagnosis of SEA is considered (see Fig. 92.3). CT myelography is also highly sensitive (>90%) in diagnosing SEA but MRI is more useful for surgical planning and differentiating a mass from an abscess.[12] Plain radiographs or noncontrast CT may show bony vertebral lysis but should not replace MRI.

A white blood cell (WBC) count is usually elevated and may support the diagnosis but is neither sensitive nor specific. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) tests, although not highly specific for epidural abscess, are virtually always elevated with this condition and have been studied as screening tests for SEA in certain "at-risk" populations.[12] Blood cultures are not beneficial in diagnosis but should be obtained as they may help to identify the causative organism. Lumbar puncture is relatively contraindicated with known or suspected SEA, because the procedure may further seed the infection. If performed, CSF findings are consistent with a parameningeal infection, showing protein elevation and increased inflammatory

cells. The Gram stain is usually negative and CSF cultures are no more useful than blood cultures.

Management. Urgent surgical consultation for possible decompression is required for SEA. Antibiotics effective against the most common pathogens (particularly *S. aureus*) should be started empirically to cover gram-positive and gram-negative organisms: We recommend IV vancomycin (15 to 20 mg/kg IV every 8 to 12 hours) plus a third- or fourth-generation cephalosporin (e.g., ceftriaxone 2 g every 12 hours) or meropenem (2 g every 8 hours). If MSSA is a concern, nafcillin or oxacillin should be added. Cefepime (2 g every 8 hours) should be used in cases of known or suspected pseudomonas. CT-guided needle decompression is an option for drainage, particularly if the abscess is located posteriorly and the patient is a high-risk surgical candidate. Independent risk factors for failure of a nonoperative management plan include a motor deficit at the time of presentation, a pathologic or compression fracture, active malignancy, diabetes, and sensory changes.[13]

Outcome in SEA is related to the speed of diagnosis before the development of neurologic deficits. The primary indicator of final outcome is the patient's neurologic status just prior to the operating room. Even if treated, the disease can be fatal, and patients with neurologic changes rarely improve if surgical intervention is delayed more than 12 to 36 hours after onset of paralysis. Patients operated on before development of neurologic symptoms generally have good outcomes.

Discitis

Foundations. Discitis is an uncommon primary infection of the vertebral disc, specifically the nucleus pulposus, with secondary involvement of the cartilaginous end plate and vertebral body. Bacteria can spread to the disc by direct inoculation after surgical procedures, by local spread from infected tissue, or hematogenously. Children are more likely to develop primary infections of this space due to persistent vascular supply of the vertebral disc. Higher rates occur in immunocompromised patients and patients with systemic infections. The lumbar spine is the most common site of disease.

Clinical Features. Clinical presentation can be quite variable. In general, patients present with moderate to severe pain localized to the level of involvement and exacerbated by almost any movement of the spine. The hallmark of diagnosis, however, is a usual lack of neurologic deficits. In neonates or infants, cases are usually severe and present as sepsis with multiple infectious foci. In older children, symptom onset tends to be gradual; they may refuse to crawl, walk, or stand and demonstrate general irritability. Low-grade temperature elevations are noted in most patients. Radicular symptoms are present in 50% to 90% of cases. Because of the lack of neurologic deficits in the early stage, there is often a latent period (2 to 8 weeks) between the onset of back pain and the development of significant clinical findings on the physical examination. *S. aureus* is the most common pathogen, but gram-negative, fungal, and tuberculous infections have all been recognized. *Kingella kingae*, identified by PCR in a number of culture-negative cases of discitis, is an emerging pathogen in young children.[14]

Differential Diagnoses. Considerations in the differential diagnosis of discitis include vertebral osteomyelitis, spinal epidural abscess, neoplasm, and hematoma.

Diagnostic Testing. MRI with IV contrast is the radiographic study of choice for suspected discitis, because it not only enables diagnosis but also rules out paravertebral or epidural abscess. Plain radiographs usually are not helpful for early diagnosis of discitis, but destruction of the disc space is highly suggestive if present. Radiographic findings become abnormal after 2 to 4 weeks of disease. In addition to disc space narrowing, plain films may show irregular destruction of the vertebral body endplates. Aspiration of the affected disc for culture is generally not performed. Laboratory studies often show an elevated ESR, but the WBC count is often normal and blood cultures are frequently negative.

Management. With timely diagnosis and treatment, outcome is usually very good and medical treatment with IV antibiotics that cover *Staphylococcus* and *Streptococcus* in accordance with local resistance patterns is usually curative. An antibiotic regimen similar to that recommended for the treatment of SEA is appropriate. Of note, *K. kingae* is covered by this treatment regimen. In a patient with a severe penicillin allergy or contraindication to a cephalosporin, meropenem (2 g IV) or aztreonam (2 g IV) may replace the cephalosporin. Finally, in patients with a vancomycin allergy or high resistance, linezolid (600 mg IV) is recommended. Surgery is generally not necessary.

Neoplasm

Foundations. Spinal cord tumors are classified according to their relationship to the dura and spinal cord (extradural, intradural extramedullary, and intradural intramedullary). Primary spinal cord tumors are generally benign but produce neurologic symptoms by compression, invasion, or destruction of myelinated tracts. The resulting neurologic symptoms are directly related to the growth rate and the location of the tumor. Overall, primary spinal cord tumors account for less than 10% of CNS tumors and only 1% of all cancers.

Most tumors affecting the spinal cord are metastatic in origin. Approximately 10% of patients with known cancer are diagnosed with a spinal metastasis at some point in the course of their disease; 5% to 10% of patients ultimately diagnosed with cancer first present with spinal metastases. Lung, breast, and prostate cancer represent the majority of the primary malignant neoplasms that subsequently develop spinal metastases, spreading both hematogenously and via direct extension. Intramedullary spinal cord metastases are rare. Multiple myeloma and lymphoma are generally more widespread at diagnosis but may also cause symptoms of cord compression. Most spinal lesions occur in the thoracic spine, but nearly 20% of patients with metastases will have lesions at multiple levels.[15]

Clinical Features. In nearly all patients with spinal neoplasm, the initial complaint is pain, either in the back at the level of the tumor or in a radicular distribution. Pain often is characterized as dull, constant, and aching and may worsen with recumbency (whereas pain from a herniated disc is classically improved when lying flat). Nighttime pain that is severe is characteristic of spinal neoplasm. Any action that increases intraspinal pressure may be associated with increased pain. Neurologic deficits vary by the location of the lesion. Metastatic spinal cord compression may present as a Brown-Séquard syndrome. Motor deficits are estimated to be found in almost half of patients at the time of initial diagnosis while sensory changes are less often reported. Besides a thorough neurologic examination, a search for possible primary sites of malignancy should be performed during the patient assessment.

Differential Diagnoses. Considerations in the differential diagnosis of spinal neoplasm include any of the compressive lesions (e.g., hematoma, infection, disc herniation). Tumors can also mimic intrinsic spinal cord lesions, such as transverse myelitis and cord infarction.

Diagnostic Testing. Patients presenting with new back pain (<6 weeks) and no risk factors or neurologic deficits on examination generally do not require imaging. If imaging is performed, plain radiographs are usually the initial modality in patients with minimal risk factors for or no previous diagnosis of cancer. The sensitivity and specificity of plain radiographs in detecting abnormalities consistent with malignancy are 60% and 95%, respectively.[15] In the presence of normal radiographs, an ESR measurement is helpful in that a cancer diagnosis is very unlikely in a patient with a normal ESR, normal radiographs, no clinical findings, and no or low risk for neoplasm. Patients with neurologic abnormalities, a history of cancer, and

suspicious findings on plain films or elevated ESR are candidates for emergent MRI with IV contrast; in contrast-allergic patients, MRI without contrast is recommended.[13] CT myelography is an option if MRI is unavailable or the patient has contraindications.

Management. Acute compressive myelopathy from neoplasm constitutes an oncologic emergency. Immediate treatment is required to preserve function and prevent deterioration. With onset of paraplegia and incontinence, less than 5% of patients regain ambulatory status. Of patients who are ambulatory at the time of diagnosis, 60% will remain ambulatory. Spinal instability or neurologic deficits are indications for immediate surgical decompression. In patients with symptoms of cord compression, high-dose glucocorticoid therapy is recommended (i.e., 10 mg dexamethasone IV followed by 4 mg orally every 6 hours). Higher initial doses of dexamethasone have not been associated with better outcomes. Steroids are generally not initiated in patients with small lesions or in the presence of a normal neurologic examination.[16] Radiation therapy is frequently indicated in the treatment of spinal cord tumors and can be combined with surgical intervention, if indicated.

CHRONIC COMPLICATIONS OF SPINAL CORD INJURY

Autonomic Dysreflexia

Foundations

Autonomic dysreflexia (AD) is defined as the loss of coordination between heart rate and vascular tone in response to increased demand. It can be seen in spinal cord injury (SCI) due to a disruption of splanchnic innervation that occurs when the lesion is at or above the T6 level. Noxious stimuli below the injury level can result in an uninhibited sympathetic response causing vasoconstriction and resultant hypertension that is not overcome by compensatory parasympathetic activity (bradycardia and vasodilation) above the lesion. Over 50% of SCI patients suffer from AD with most developing symptoms within the first year post-injury. Common examples of noxious stimuli are bladder distention, bowel impaction, pain (even from sources as seemingly benign as in-grown toenails), pressure ulcers, tight clothing, and infection. AD will persist until the underlying cause is resolved.

Clinical Features

AD is defined as an elevation in systolic blood pressure 20 to 40 mm Hg or greater from baseline (15 to 20 mm Hg in pediatric population) or a systolic reading of 150 mm Hg or greater with symptoms in the absence of a known baseline; 88% of patients will present with severe headache and diaphoresis above the spinal level. Other possible symptoms include nasal congestion, blurred vision, anxiety, and nausea. There may be accompanying bradycardia due to the parasympathetic compensation but the absence of it does not rule out AD.

Management

Treatment centers on managing blood pressure while working to identify and treat the underlying cause. Assessing for bladder distention and, if present, relieving by catheterization or the flushing of an obstructed indwelling catheter may be necessary. Digital rectal exam will help assess for fecal impaction and a full skin examination will identify pressure ulcers, skin infections, or lesions. Removing tight clothing and sitting the patient upright if possible may help to engage hydrostatic redistribution.

Topical, oral, or IV anti-hypertensive medications may be indicated when an elevated blood pressure persists in order to prevent acute complications of severe hypertension. Application of 1 to 2 inches of 2% nitroglycerin paste to the skin above the spinal lesion is recommended to relax vascular smooth muscles and cause vasodilation. Likewise, IV nitroglycerin (5 mcg/minute increasing by 20 mcg/minute every 1 to 3 minutes to a maximum of 400 mcg/min) for severe cases is indicated. Beta blockers are avoided to prevent potential uninhibited alpha-adrenergic activity but not contraindicated. Oral anticholinergics and botulinum toxin injections into the bladder have been used to help manage neurogenic detrusor overactivity, the most common cause of bladder distention resulting in AD, but would be of little benefit in severe, acute cases in the ED.

Spasticity

More than 60% of SCI patients will develop spasticity to some degree, defined as a velocity-dependent increase in muscle tone (hyperexcitability). It is thought to be caused by disruption of descending inhibitory modulation of alpha-motor neurons. Care should be taken when evaluating spasticity because a sudden increase in patient or caregiver reported spasticity may be indicative of occult infection.

Treating spasticity is not only difficult but may not be beneficial as spasms and contractures can aid the patient or caregiver in transfer or other activities. Any suggested treatment should focus on functionality and often starts with physical therapy (stretching, braces) and progresses to include medications such as baclofen (5 mg PO 1 to 3 times daily, increasing by 5 mg per dose every 3 days up to 80 mg/day in divided doses), tizanidine (2 mg PO at bedtime, initially, increasing by 4 mg daily dose every 3 to 4 days up to 36 mg/day given in 3 to 4 doses), and benzodiazepines; unfortunately, these medications have little proven efficacy aside from tizanidine and are frequently limited by their sedative properties.

Infection

Pneumonia is a frequent complication of SCI with roughly 50% of SCI patients developing it during their acute hospital stay post-injury; it is often the ultimate cause of death in SCI patients. Pressure ulcers, frequently located over bony prominences, are an additional nidus of infection and a thorough skin exam should be performed on any SCI patient presenting with infectious signs or symptoms.

Urinary tract infections (UTIs) occur at an estimated rate of 2.5 episodes per patient per year and are the third leading cause of death among this population. This high rate is primarily due to patients with chronic indwelling catheters but also includes patients who void, have suprapubic catheters, or intermittently catheterize. In the latter group, it is thought that frequent catheterization not only introduces bacteria but the scheduled nature of the procedure allows for large volumes of urine to collect in the bladder prior to drainage, increasing the risk of infection. Symptomatic UTIs frequently present with fevers, foul-smelling urine, increased spasticity, or autonomic dysreflexia and should be treated with antibiotics. Asymptomatic bacteriuria, however, should not be treated as doing so has no effect on the frequency of symptomatic infections and risks increasing microbial resistance. An additional consideration in the management of symptomatic UTI is to consider a diagnosis of infected renal calculi in that up to 20% of SCI patients have hypercalciuria from altered bone metabolism which contributes to higher rates of nephrolithiasis.

CHAPTER 92: QUESTIONS AND ANSWERS

1. A 43-year-old man with a history of alcohol abuse and liver cirrhosis presents with a complaint of one week of progressive difficulty ambulating and low thoracic back pain. He is noted to be febrile on examination. Which of the following diagnostic modalities is most appropriate in this patient?

a. Blood cultures
b. CT myelography
c. Lumbar puncture
d. MRI with IV contrast
e. White blood cell (WBC) count

Answer: D. The patient has a presentation concerning for spinal epidural abscess (SEA). MRI is the imaging modality of choice and should be done emergently. Lab tests may be helpful in supporting the diagnosis but are neither sensitive nor specific. CT may show bony abnormalities concerning for SEA but should not replace MRI. Blood cultures are not useful as a diagnostic tool but may reveal the causative organism and help to guide antibiotic therapy. Lumbar puncture is relatively contraindicated in these patients because it may further seed the infection.

2. Which feature most often distinguishes a conus medullaris from a cauda equina lesion?

a. Back pain
b. Bilateral symptoms
c. Distal motor weakness
d. Sacral anesthesia
e. Urinary incontinence

Answer: B. Because the conus medullaris is a small structure with lumbar and sacral segments represented in a minimal area, a lesion will likely result in bilateral symptoms. As cauda equina is not a true cord lesion but rather reflects dysfunction at the level of nerve roots, the symptoms are frequently unilateral. Both can result in urinary retention, fecal incontinence, saddle anesthesia, and distal motor weakness. Conus medullaris may have upper motor neuron signs (hyperreflexia and increased tone), which will be absent in cauda equina.

3. A 27-year-old woman presents with complaints of back pain and difficulty walking. Her symptoms have been progressive for 2 days. She has no significant past medical history. On history it is discovered that she recently recovered from a bout of "the flu" approximately 3 weeks ago. Physical examination is remarkable for lower extremity hyperreflexia, moderate symmetrical lower extremity weakness, moderate increased tone, a T10 level of sensory loss, and a PVR urine volume of 350 mL. What should be the next intervention?

a. Antibiotics
b. Complete blood count, erythrocyte sedimentation rate (ESR), and antinuclear antibody levels
c. MRI scan with gadolinium enhancement
d. Emergent neurosurgical intervention
e. Steroids

Answer: C. Transverse myelitis is postinfectious in 30% of cases and also idiopathic in 30%. Other causes are autoimmune disorders and infections. Symptoms are typically rapid in onset and progress during 1 or 2 days. Symptoms are often sensory loss below the level of insult, extremity weakness, decreased sphincter tone, and urine retention (often exhibited with an elevated PVR). Back pain may accompany it. Emergent MRI is indicated to rule out other causes. There is no proven efficacious treatment, although steroids have been used. There is an association with multiple sclerosis (MS). Prognosis for recovery is only fair.

4. A 23-year-old male patient with no past medical history presents with longstanding, recurrent headache and neck pain that he reports has been gradually worsening over several months. He denies any fevers, weakness, numbness, vision changes, back pain, or bowel/bladder changes. He notes that he is often afraid to cough or sneeze because that makes the symptoms worse. What is another clinical feature of this patient's most likely diagnosis?

a. Normal gait
b. Loss of pain and temperature sensation in the upper extremities
c. Lower extremity weakness
d. Bladder dysfunction
e. Loss of proprioception and light touch

Answer: B. Syringomyelia typically presents with headache, neck pain, and variable upper extremity dissociative anesthesia: symmetrical loss of pain and temperature sensation with preserved posterior column function. With progression, upper extremity weakness or wasting and lower extremity upper motor neuron changes are expected. Exacerbation with cough and the Valsalva maneuver is typical. There is a 90% association with type I Arnold-Chiari malformation (cerebellar tonsils and medulla projecting into the spinal canal—often the cause of the typical occipital headaches). MRI is diagnostic.

5. In the majority of patients with an extrinsic compressive lesion, surgical outcome is most dependent on which of the following factors?
   - **a.** Age
   - **b.** Laterality of symptoms
   - **c.** Location of lesion
   - **d.** Neurologic status at the time of procedure
   - **e.** Primary source of neoplasm

Answer: D. In patients with SEH or SEA, prognosis is intimately linked with neurologic function at time of decompressive laminectomy or operative intervention. Patients who have had symptoms greater than 72 hours with SEH are unlikely to regain lost function. In SEA, neurologic status rarely improves if intervention is delayed longer than 12 to 36 hours from onset of paralysis.

6. A 37-year-old female with a prior history of transverse myelitis at the T4 level one year ago presents with several hours of sweating, nausea, and headache. At baseline, she is paraplegic to the lower extremities, performs intermittent bladder catheterization, and is insensate inferiorly to the T4 level. She has never had these symptoms before. Her vitals are: blood pressure 270/130, heart rate 54, respiratory rate 16, oral temperature of 97.2°F. ECG performed in triage shows no signs of ischemia or infarct. Which of the following actions should be taken next?
   - **a.** Manage blood pressure with nitrates and perform a thorough physical examination including bladder scan and rectal exam.
   - **b.** Administer aspirin and obtain cardiology consult.
   - **c.** Obtain an emergent CTA of chest to assess for aortic dissection.
   - **d.** Administer benzodiazepines.
   - **e.** Order an MRI with IV contrast.

Answer: A. The patient is experiencing autonomic dysreflexia, seen frequently in patients with spinal cord injuries above the T6 level. Her severe hypertension, diaphoresis, nausea, and headache can mimic other diagnoses, but her history of spinal cord lesion must be taken into consideration. Management focuses around aggressive blood pressure management with nitrates and investigation into the possible noxious stimuli that is causing the syndrome. Bladder-related etiologies (particularly distention or detrusor overactivity) cause most episodes of autonomic dysreflexia. Other causes are fecal impaction, pain, tight clothing, and infection.

7. A 34-year-old male presents after a motorcycle versus car collision. The patient was wearing a helmet but thrown from his bike. He reports burning discomfort and significant weakness to both arms. He also reports some mild numbness but no clear bladder symptoms. What additional findings would you expect to find on physical examination?
   - **a.** Decreased rectal tone
   - **b.** Loss of pain and temperature below the level of the injury
   - **c.** Distal muscle groups are affected more than proximal muscle groups
   - **d.** Loss of position, vibration, and light touch sensations
   - **e.** Lower extremity weakness

Answer: C. The patient has likely suffered a cervical hyperextension injury resulting in a central cord syndrome. Remember the pneumonic "MUD" for central cord syndrome: motor > sensory, upper > lower, distal > proximal. Patients with central cord syndrome have variable sensory impairment and bladder dysfunction and these symptoms are not hallmarks of this partial cord syndrome. Brown-Séquard syndrome is characterized by ipsilateral loss of motor function, proprioception, and vibration with contralateral loss of pain and temperature sensation below the level of injury. Anterior cord syndrome is characterized by loss of motor function, pinprick, and light touch below the level of the lesion with preservation of the posterior column modalities.

8. An 11-month-old female presents to your emergency department with low-grade fevers and progressive refusal to crawl or pull up. Mom reports she took the patient to her pediatrician last week but they didn't find any abnormalities. However, her symptoms have continued to worsen. On exam, you see an otherwise healthy infant who now appears somewhat irritable. Vital signs are as follows: HR 110, RR 18, T 100.2°F. The patient is being held by mom and resists movement. Most of her physical exam appears normal, including a nonfocal neurologic exam, but she cries as you palpate the lumbar spine. Which of the following is true of the likely diagnosis?
   - **a.** Blood cultures frequently reveal the causative organism.
   - **b.** WBC is a helpful finding if elevated.
   - **c.** Plain radiographs are sufficient for diagnosis.
   - **d.** IV antibiotics are usually curative.
   - **e.** The lack of associated neurologic deficits is unusual in this case.

Answer: D. The child has a presentation consistent with discitis. These children may present with sepsis and, as this is an unusual diagnosis, the provider should maintain a broad differential. Children are more likely to develop infections in the vertebral disc and usually have developed symptoms over several weeks. A hallmark of the diagnosis is that patients have normal neurologic exams. MRI is the imaging modality of choice as it is diagnostic and helps to rule out other conditions. The white blood cell (WBC) count is usually normal and blood cultures are usually negative. IV antibiotics are effective at treating discitis and surgery or aspiration are rarely needed.

Peripheral Nerve Disorders

Ethan E. Abbott and E. Bradshaw Bunney

KEY CONCEPTS

- The diagnosis of a specific peripheral neuropathy generally requires confirmatory ancillary testing; approach in the ED should focus on identifying one of seven categorical patterns.
- Diagnostic approach to peripheral neuropathies involves combining three clinical features: (1) right-left symmetry or asymmetry, (2) proximal-distal location, and (3) sensorimotor modalities affected.
- Any patient with symmetrical weakness, distributed both proximally and distally, with loss or diminution of deep tendon reflexes (DTRs) and variable sensory abnormalities should be treated as having Guillain-Barré syndrome (GBS).
- Respiratory compromise is the primary life-threatening event seen in some peripheral neuropathies; GBS is by far the most common peripheral neuropathic cause of respiratory arrest.
- The definitive treatments for GBS are plasma exchange or intravenous immune globulin (IVIG).
- Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than in the upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally.
- High-level evidence supports the use of pregabalin, gabapentin, and the serotonin and norepinephrine reuptake inhibitor duloxetine in the treatment of diabetic distal symmetrical polyneuropathy (DSPN).
- Radial nerve mononeuropathies are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseus muscle.
- Humeral shaft fractures are associated with radial nerve injury, with "wrist drop" being the hallmark clinical finding.
- The ulnar cutaneous innervation to the hand branches from the main trunk proximal to the nerve entering the Guyon canal. Thus, a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.
- The most specific finding for carpal tunnel syndrome (CTS) is splitting of the sensation on the fourth digit (i.e., normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial] palmar side of the same finger).
- Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked.
- The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion.
- The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure.
- ALS is the most common form of motor neuron disease (MND), and diagnosis requires the presence of both upper and lower motor neuron findings.

OVERVIEW

Principles

The nervous system is divided into central nervous system (CNS) and peripheral nervous system (PNS) components. The PNS is subdivided into 12 cranial and 31 spinal nerves. Disorders of the cranial nerves are discussed in Chapter 91. Because diseases of the neuromuscular junction and the myopathies are located distal to the neuron itself, they are also considered separately in Chapter 95. Radiculopathies, which are disorders of the roots of the PNS, are so commonly associated with musculoskeletal neck and back pain that they are mentioned only briefly here and are discussed in detail in Chapter 36.

Current estimates suggest that about 2.4% of the population suffers from peripheral neuropathy, rising to 8% for those over 50 years of age. Diabetes mellitus is a leading contributor.

The simplest approach to categorizing diseases of the PNS is to distinguish focal from nonfocal disease. In the PNS, the first broad category is the focal group, which is divided into those with evidence of single versus multiple lesions of peripheral nerves, known respectively as *simple mononeuropathies* and *multiple mononeuropathies* (or *mononeuropathy multiplex*). The second broad category, which constitutes the nonfocal group of peripheral neuropathies, contains the polyneuropathies. These tend to produce bilaterally symmetrical symptoms and signs, reflecting the widespread nature of the underlying pathologic processes.

The evaluation of PNS disease involves a goal-directed history and physical examination targeted at answering the three questions, each of which corresponds to a stratum of the algorithm presented in Figure 93.1:

1. Are the sensorimotor signs and symptoms symmetrical or asymmetrical?
2. Are the sensorimotor signs and symptoms distal or both proximal and distal?
3. Is the modality involved exclusively motor, sensory, or mixed sensorimotor?

By systematically combining responses to these questions, seven discrete categories of peripheral neuropathy are identified, each of which contains a finite set of possible diagnoses. Because pure motor or pure sensory findings tend to occur mainly in an asymmetrical, distal distribution, this is the only category in Figure 93.1 subdivided into pure motor and pure sensory abnormalities.

The spinal component of the PNS is shown schematically in Figure 93.2. The anterior and posterior nerve roots exit the spinal cord at each segmental level. Just distal to the dorsal root ganglion they converge to form a mixed (motor and sensory) spinal nerve, of which there are 31

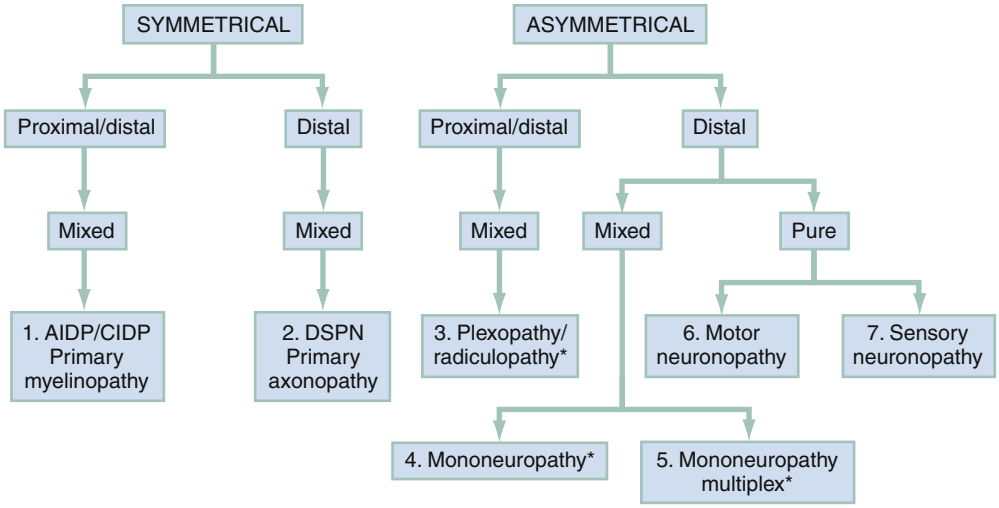

Fig. 93.1 An approach to peripheral neuropathy in the emergency department. *AIDP,* Acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome); *CIDP,* chronic inflammatory demyelinating polyneuropathy; *DSPN,* distal symmetrical polyneuropathy. *A proximal distribution of sensorimotor findings may dominate the clinical picture in patterns 3, 4, and 5, depending on the location of the lesions.

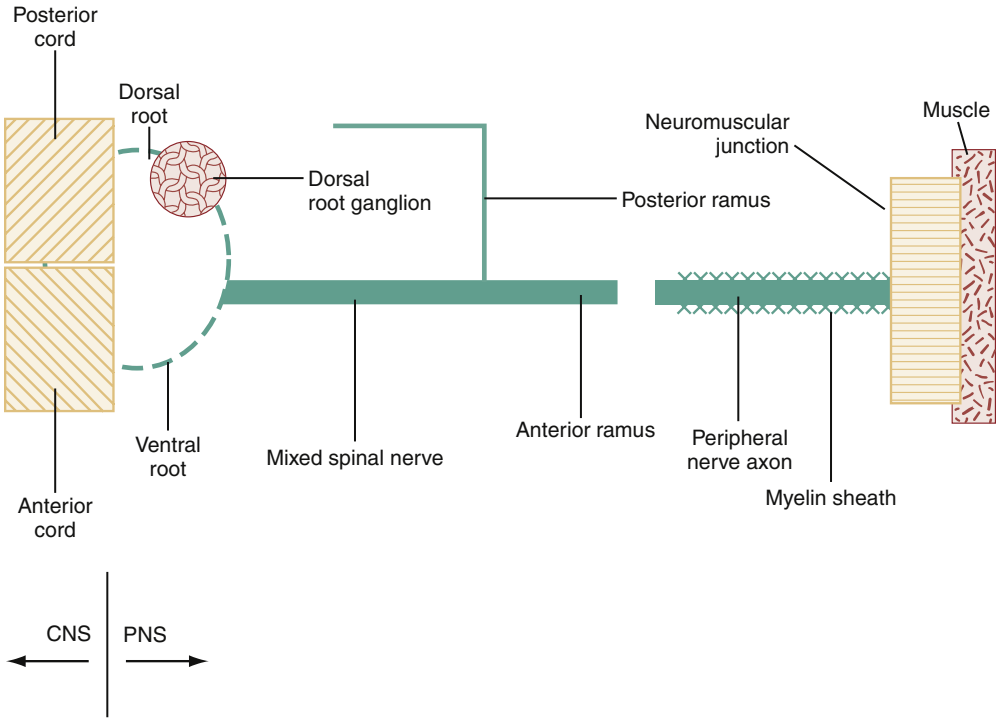

Fig. 93.2 Schematic representation of macroscopic and microscopic anatomy of the peripheral nervous system *(PNS)* and its interface with the central nervous system *(CNS).* See the text for an explanation.

pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The spinal nerves immediately bifurcate into anterior (ventral) and posterior (dorsal) rami. The posterior ramus travels to the back. The anterior ramus innervates the anterolateral portion of the body and supplies all peripheral nerves for the upper and lower extremities through the brachial and lumbosacral plexus, respectively. Interweaving of fibers occurs within a plexus, producing a mixed sensorimotor innervation of peripheral nerves exiting the plexus.

In addition to the motor and sensory modalities of the PNS, the autonomic nervous system has a peripheral component. Anatomically and functionally, the autonomic nervous system is divided into two parts: (1) a sympathetic (thoracolumbar) component and (2) a parasympathetic (craniosacral) component. Autonomic dysfunction may cause systemic abnormalities, such as orthostasis, or local problems, such as atrophic, dry skin.

The PNS has three basic categories of pathology (see Fig. 93.2): (1) the myelinopathies, in which the primary site of involvement is limited to the myelin sheath surrounding the axon; (2) the axonopathies, in which the primary site of involvement is the axon, with or without secondary demyelination; and (3) the neuronopathies, in which the cell body of the neuron itself is the primary site of involvement, ultimately affecting the entire peripheral nerve. Although overlap occurs, each of

BOX 93.1 Causes of Acute, Emergent Weakness and Possible Respiratory Compromise

- Autoimmune
  - Demyelinating
    - Guillain-Barré syndrome (GBS)
    - Chronic inflammatory demyelinating polyneuropathy
  - Myasthenia gravis
- Toxic
  - Botulism
  - Buckthorn
  - Seafood
    - Paralytic shellfish toxin
    - Tetrodotoxin (puffer fish, newts)
  - Tick paralysis
  - Metals
- Arsenic
- Thallium
- Metabolic
  - Dyskalemic syndromes
    - Acquired (especially with thyrotoxicosis)
    - Familial
  - Hypophosphatemia
  - Hypermagnesemia
  - Porphyria
- Infectious
  - Poliomyelitis
  - Diphtheria

Note: Although several of the disorders listed are myopathies (see Chapter 95) rather than peripheral neuropathies, they are combined here to emphasize the importance of identifying patients at risk for respiratory failure early in the course of their evaluation.

these prototypes has a distinctive clinical presentation, electrophysiologic profile, and microscopic appearance.

Differential Diagnosis

The differential diagnosis for any patient presenting with sensory, motor, or sensorimotor complaints, particularly if they are localized to the extremities, should include a peripheral neuropathy. Within this group, patients with focal weakness are most concerning, because they are at greatest risk for respiratory compromise. Box 93.1 lists the causes of acute weakness that may affect respiration.

As soon as the emergent causes of weakness have been excluded, the individuals with focal weakness are next assessed to exclude CNS disease (e.g., stroke; see Chapter 87). After a CNS cause has been exonerated, the systematic evaluation of peripheral neuropathy is performed. The distinguishing features of each of the seven peripheral neuropathic patterns are described by distribution and modality and represented by a disease prototype (see Fig. 93.1; Table 93.1).

Diagnostic Testing

Testing in the evaluation of the patient with a suspected peripheral neuropathy is presented in Box 93.2. Electrophysiologic testing (nerve conduction studies [NCSs] and needle electromyography [EMG]) detects underlying pathologic abnormalities. Because neither test is readily available in the acute care setting, they are discussed only briefly here. Information gathered from these tests can be used to obtain objective information regarding the anatomic distribution of involvement (symmetrical versus asymmetrical and distal versus proximal and distal) and the modalities involved (sensory, motor, or mixed).

TABLE 93.1 Patterns and Prototypes of Peripheral Neuropathies

Type	Pattern Distribution	Prototypical Disease Modalities
1	Proximal and distal, symmetrical, sensorimotor polyneuropathy	GBS
	Proximal and distal	Symmetrical
	Motor > sensory	
2	Distal, symmetrical, sensorimotor polyneuropathy	Diabetic DSPN
	Distal	Symmetrical
	Sensory > motor	
3	Proximal and distal, asymmetrical, sensorimotor neuropathy	Brachial plexopathy
	Proximal and distal	Asymmetrical
	Sensory and motor	
4	Distal, asymmetrical, sensorimotor mononeuropathy	CTS (median mononeuropathy)
	Distal	Asymmetrical
	Sensory and motor	
5	Distal, asymmetrical, sensorimotor mononeuropathy multiplex	Vasculitic mononeuropathy multiplex
	Distal	Asymmetrical
	Sensory and motor	
6	Distal, asymmetrical, pure motor neuronopathy	ALS
	Distal	Asymmetrical
	Motor	
7	Distal, asymmetrical, pure sensory neuronopathy	Pyridoxine toxicity
	Distal	Asymmetrical
	Sensory	

ALS, Amyotrophic lateral sclerosis; *CTS*, carpal tunnel syndrome; *DSPN*, distal symmetrical polyneuropathy; *GBS*, Guillain-Barré syndrome.

NCSs and EMG can also identify the level of the neuraxis affected by the disease process (i.e., root, plexus, or nerve). If the nerve is affected, electrophysiologic testing can help determine whether the lesion is mononeuropathic (either an isolated mononeuropathy or mononeuropathy multiplex) or polyneuropathic.

Finally, EMG and NCSs can distinguish axonal from myelin disease, further narrowing the differential diagnosis. Prognosis is determined by the nature of pathologic involvement of the PNS. Primary demyelination spares the axon and thus carries the best prognosis. The prognosis is worse in axonopathies because reestablishment of nerve function is dependent on the much slower process of axonal regeneration. Neuronopathies, which begin with primary destruction of the nerve cell body, produce pure motor or pure sensory syndromes. Eventually the entire nerve is affected, resulting in the worst prognosis of the three.

Antibody tests are commercially available that aim to aid in the diagnosis of peripheral neuropathies, especially those that are immune-mediated in etiology. However they are controversial, lack sensitivity and specificity, and may offer limited benefit beyond the focused neurologic examination and existing screening tests.

BOX 93.2 Ancillary Diagnostic Testing in Suspected Peripheral Neuropathy

Obtained in Most Patients

Complete blood count
Erythrocyte sedimentation rate
Glucose
Creatine kinase
Creatinine

Obtained in Some Patients Based on History

Human chorionic gonadotropin
Magnesium
Phosphate
Vitamin B_{12}
Hemoglobin A_{1c}
Serum protein electrophoresis with immune fixation electrophoresis
Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin screen with fluorescent treponemal antibody absorption test, as appropriate
Thyroid function
Human immunodeficiency virus (HIV) titer
Lyme enzyme-linked immunosorbent assay and Western blot
Rheumatoid factor and antinuclear antibody
Blood, urine, hair, or nails for metal, depending on suspected chronicity of exposure
Specific serum antibodies to components of peripheral nervous system (PNS)
Cerebrospinal fluid (CSF) for cells, protein, Lyme titer
Electrodiagnostic testing
- Nerve conduction studies (NCS)
- Electromyography (EMG)

Neurodiagnostic imaging
- Magnetic resonance imaging (MRI)
- Computed tomography (CT)
- Sonography

Quantitative sensory testing
Nerve biopsy
- Sural
- Intraepidermal nerve fiber density

SPECIFIC TYPES OF NEUROPATHIES

Type 1: Demyelinating Polyneuropathy (Guillain-Barré Syndrome)

Principles

The pattern of symmetrical weakness, usually worse distally, accompanied by variable sensory findings is characteristic of acute Guillain-Barré syndrome (GBS). It is a heterogeneous and unpredictable disorder, characterized by areflexic paralysis with albuminocytologic dissociation, with marked variation in latency between antecedent infection and symptom onset.

Mortality rates in Europe and North America are estimated between 3% and 7% and up to 20% of patients remain disabled after six months, unable to ambulate without assistance.[1]

The most common form of GBS is an acute inflammatory demyelinating polyneuropathy, representing 90% of the cases seen in the United States. Less common variants are acute motor axonal neuropathy, acute motor and sensory axonal neuropathy, and the Miller Fisher syndrome. Acute motor axonal neuropathy, which accounts for most of the remaining cases seen in the United States, afflicts those of Asian descent more often. Miller Fisher syndrome is a rare form of GBS characterized by the triad of ophthalmoplegia, ataxia, and areflexia (Box 93.3).

BOX 93.3 Demyelinating Polyneuropathies

Guillain-Barré syndrome (GBS)
- Acute inflammatory demyelinating polyradiculoneuropathy
- Acute motor axonal neuropathy
- Acute motor and sensory axonal neuropathy
- Miller Fisher syndrome

Chronic inflammatory demyelinating polyradiculoplexoneuropathy
Malignant disease
Human immunodeficiency virus (HIV) infection
Hepatitis B
Buckthorn
Diphtheria

Campylobacter jejuni infection is the most commonly associated etiology for GBS with a frequency reported in 25% to 50% of adult cases.[2] Cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumonia* have also been associated with the subsequent development of GBS.

Clinical Features

The majority of patients with GBS seek treatment days to weeks after resolution of an upper respiratory or gastrointestinal illness; patients present with progressive, symmetrical distal (and usually to a lesser extent proximal) weakness. Symptom progression ranges from rapidly progressive to a more insidious course over days to weeks. Signs and symptoms are usually worse in the lower extremities and are associated with diminution or loss of deep tendon reflexes (DTRs) in the affected limbs, variable sensory findings, and sparing of the anal sphincter. The presence of distal paresthesias increases the likelihood of GBS as the diagnosis.

About half of patients with GBS have autonomic dysfunction, experience a peak of disease severity within a week of onset, have some form of cranial nerve involvement (usually cranial nerve VII), and suffer long-term sequelae of their illness.

Patients with neck or bulbar weakness are more likely to require mechanical ventilation than those patients without. Predicting outcomes among GBS patients can be challenging and several scoring systems are available to aid with prognosis in the inpatient setting. The Erasmus GBS outcome score (EGOS) is a validated prognostic scoring tool, performed at 14 days of admission, that utilizes three measures: age of onset of disease, the presence or absence of diarrhea, and then folds in another scoring system, the GBS disability score, to predict inability to ambulate independently at 6 months. A modified EGOS (mEGOS) utilizes Medical Research Council score (MRC) instead of the GBS disability score and can be used earlier, at one week of admission. There is no score to predict outcomes from the ED, however.

Diagnostic Testing

GBS is typically diagnosed on clinical findings, but additional testing with EMG is indicated when the diagnosis is uncertain. The most frequent finding of demyelination includes nerve conduction slowing with prolonged distal motor latency.

In addition to electrophysiologic testing, cerebrospinal fluid (CSF) analysis and respiratory function testing may aid in the diagnosis of GBS. CSF analysis is useful when it demonstrates the characteristic picture of markedly elevated protein with only a mild pleocytosis (albuminocytologic dissociation). In the clinical setting of suspected GBS, this finding is highly specific. Early in the disease, however, patients may have normal CSF values. One study noted only 50% of patients had elevated protein and mild pleocytosis in the first week of symptoms, rising to 75% in the third week. Consequently, normal CSF

cannot be used to exclude GBS, though a lumbar puncture performed early in the disease process can help identify infectious or neoplastic causes that may present similarly to GBS. Because of the potential for a missed diagnosis, a lumbar puncture should be performed in the emergency department for patients in whom there is concern for GBS.

Individuals with suspected GBS should have their respiratory function tested, as they may present without overt signs of respiratory distress. A decrease in forced vital capacity (FVC) to less than 20 mL/kg is associated with pending respiratory failure and the need for intubation, whereas patients with an FVC of more than 40 mL/kg do not usually require intubation. Likewise, patients with a negative inspiratory force of less than 30 cm H_2O are more likely to require mechanical ventilation. Other tests, such as the forced expiratory volume in 1 second (FEV_1) and peak flow rate (PFR), can also be used to assess respiratory function, but there has been limited study of these modalities. A PFR of less than 250 L/min increased the likelihood of needing mechanical ventilation in a retrospective study of patients with GBS. Patients unable to perform these tests and those with less than 100% of predicted values should have a blood gas performed to assess for hypercapnia and an impending need for mechanical ventilation. However, hypercapnia may be a late sign of weakness, and therefore, the decision to intubate should be made considering the overall clinical picture.

Management

In practice, patients with symmetrical weakness of relatively acute onset, decreased or absent DTRs, and variable degrees of sensory loss are managed as if they have GBS or one of its variants. These patients are at risk for respiratory compromise, which develops in 20% of patients. Conversely, patients with predominantly sensory signs and symptoms are less likely to develop acute respiratory distress and have a more favorable prognosis.

The definitive treatments for GBS are plasma exchange or intravenous immune globulin (IVIG). Both of these treatments are supported by well-designed studies, although there are no studies comparing IVIG to placebo. Combination or sequential therapy confers no therapeutic advantage over either intervention alone. Plasma exchange is cumbersome and not available at many hospitals. IVIG is more readily available and is usually administered in a dose of 400 mg/kg per day for 5 days. However, IVIG is expensive, costing roughly double a standard course of plasma exchange.

Corticosteroids are not recommended; oral steroids have been shown to delay recovery, and intravenous steroids alone have no benefit. The combination of intravenous steroids and IVIG may hasten recovery but does not have an effect on long-term outcome and is not currently recommended.[3]

Disposition

Patients with suspected GBS should receive neurologic consultation and admission for respiratory monitoring and treatment with either plasma exchange or IVIG. Evidence of alveolar hypoventilation (elevated carbon dioxide [P_{CO_2}]) in a patient with an unsecured airway requires an intensive care level of monitoring, as these patients may require intubation.

Type 2: Distal Symmetrical Polyneuropathy

Principles

Distal symmetrical polyneuropathy (DSPN) is the most common type of peripheral neuropathy. Diabetes, alcoholism, human immunodeficiency virus (HIV) disease, and toxic metabolic causes are the most frequent etiologies (Box 93.4). DSPN in diabetics, termed *diabetic polyneuropathy,* is the most common chronic complication of diabetes mellitus.

BOX 93.4 Distal Sensorimotor Polyneuropathies

- Diabetes mellitus
- Alcoholism
- Neoplastic or paraneoplastic
- Hereditary motor and sensory neuropathies (Charcot-Marie-Tooth)
- Cryptogenic sensorimotor polyneuropathies
- HIV infection
- Toxins
  - Organic or industrial agents
    - Acrylamide
    - Allyl chloride
    - Carbon disulfide
    - Ethylene oxide
    - Hexacarbons
    - Methyl bromide
    - Organophosphate-induced delayed polyneuropathy
    - Polychlorinated biphenyls
    - Trichloroethylene
    - Vacor
  - Metals
    - Arsenic
    - Gold
    - Mercury (inorganic)
    - Thallium
  - Therapeutic agents
    - Amiodarone
    - Antiretrovirals
    - Dapsone
    - Disulfiram
    - Isoniazid
    - Metronidazole
    - Nitrofurantoin
    - Paclitaxel (Taxol)
    - Phenytoin
    - Statins (HMG-CoA reductase inhibitors)
    - Thalidomide
    - Vinca alkaloids (vincristine, vinblastine)
  - Nutritional
    - Beriberi (thiamine or vitamin B_1)
    - Pellagra (niacin, B vitamins)
    - Pernicious anemia (vitamin B_{12})
    - Pyridoxine deficiency (vitamin B_6)
  - End-organ dysfunction
    - Acromegaly
    - Chronic pulmonary disease
    - Hypothyroidism
    - Renal failure (uremic neuropathy)
  - Paraproteinemias
    - Amyloidosis
    - Monoclonal gammopathy of unknown significance
    - Multiple myeloma
    - Waldenström macroglobulinemia
  - Porphyria

HIV, Human immunodeficiency virus; *HMG-CoA,* hydroxymethylglutaryl coenzyme A.

Although the association between alcoholism and peripheral neuropathy has been well established for centuries, demonstration of a direct neurotoxic effect of alcohol remains elusive. The preponderance of evidence from both observational studies in humans and

experimental data from animal models suggests that the association between alcohol and peripheral neuropathy may be confounded by nutritional status (i.e., deficiency states might be the true underlying cause of alcoholic peripheral neuropathy).

With the widespread use of highly active and effective antiretroviral treatment, peripheral neuropathies have become the most common neurologic complication of HIV infection. The typical HIV neuropathy is a DSPN, estimated to affect up to 35% of the HIV population; the pathogenesis is currently unknown.

Clinical Findings

Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than in the upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally. Motor weakness and loss of DTRs, which lag behind the sensory features, follow a similar pattern of progression from distal to proximal. The diffuse, distal, symmetrical nature of this pattern is most consistent with a toxic-metabolic disease process that causes a length-dependent axonopathy.

Initial symptoms usually consist of "positive" sensory complaints (e.g., dysesthesias, such as tingling and burning) beginning on the plantar surfaces of both feet. At the early stages of a typical DSPN, there may be some asymmetry. At this juncture, it may be impossible to distinguish a focal neuropathic process such as a mononeuropathy from a polyneuropathy, although this location strongly favors a polyneuropathy. As the process advances, the plantar surfaces of both feet become dysesthetic before the dorsum of either foot is involved.

Weakness of dorsiflexion of the big toe is usually the first motor sign, followed by weakness of foot dorsiflexion, footdrop, loss of the Achilles reflex, and later a "steppage gait," in which footdrop causes the toes to point downward and scrape the ground while walking, requiring the patient to lift the leg higher than normal when walking.

Sensory loss continues to move proximally, and before it reaches the knees, the fingertips are usually involved. DTRs are progressively lost, as is proprioception. If loss of proprioception becomes severe, patients may develop sensory ataxia. As the neuropathy continues to progress, sensory abnormalities ultimately involve all modalities and extend to a diamond-shaped periumbilical area. Far-advanced disease may affect sensation over the skull vertex and facial midline structures. Atrophy and areflexia occur as weakness worsens. Severely impaired patients may be unable to ambulate or to grasp objects. These symptoms have an impact on the patient's quality of life, affecting not only physical functioning but also sleep and emotional and social functioning. Many of these patients display signs of depression or anxiety. Polyneuropathies can be difficult to diagnose and are best approached by the performance of electrodiagnostic studies for patients with a constellation of symptoms and signs suggesting a particular neuropathy.

Diabetic foot ulcers are a common and often late complication of diabetes, ranging from 2% to 10% of the population. Repetitive stress or unperceived minor trauma is the leading cause, likely from the associated polyneuropathy.

The clinical picture of alcoholic neuropathy is similar to that of diabetic DSPN. However, in alcoholism, severe myopathy and cerebellar degeneration often complicate the clinical picture. Autonomic skin changes with atrophy and hair loss accompany the sensorimotor abnormalities. Often, other systemic effects of alcoholism are so severe that the patient may not notice the neuropathic symptoms.

Differential Diagnosis

Box 93.4 lists the differential diagnoses of DSPN. On the basis of results from a case-control study, the statins have been added to the list of drugs that are implicated.

Diagnostic Testing

Electrodiagnostic studies are commonly employed in the evaluation of DSPN. This includes both NCSs and needle electromyelography. Screening laboratory tests should be considered for all patients who present with DSPN. The high yield tests in evaluating a DSPN include blood glucose, serum B12, and serum protein immunofixation electrophoresis. A complete blood count (CBC), comprehensive metabolic panel, hemoglobin A1c or oral glucose tolerance test, and thyroid-stimulating hormone (TSH) are recommended as part of the initial workup.

Management

In diabetic DSPN, the initial steps in management focus on tight glucose control and lifestyle modifications. Tight glucose control in type 1 diabetes is associated with a more profound reduction in the incidence of DSPN than is found among those with type 2 diabetes. If discomfort is severe, the etiology of the neuropathy seems likely to be diabetic, and referral is delayed, it may be necessary to provide the patient with some symptomatic relief. Because the treatment of neuropathic pain has traditionally been linked to etiology, the choice of pharmacologic agents is empirical with substantial practice variation. Nonsteroidal antiinflammatory drugs (NSAIDs) have little proven efficacy and a high potential for renal impairment; therefore they are not a first-line therapy. Pregabalin, duloxetine, and tapentadol have all received regulatory approval by the US Food and Drug Administration for the treatment of DSPN, with duloxetine and pregabalin considered first-line treatments.[4] Pregabalin has a mechanism of action similar to that of gabapentin and is dosed at 50 to 150 mg/day in divided doses. Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor, is effective at a dose of 60 mg per day. Tapentadol ER, dosed at 50 mg twice daily, also provides pain relief in patients with diabetic neuropathy, however, given the risk of addiction with opioids, it is not considered a first-line agent.[5] Other evidence supports the use of tricyclic antidepressants, anticonvulsants, and the serotonin and norepinephrine reuptake inhibitor duloxetine. Imipramine or amitriptyline are started at a daily dose of 25 mg at bedtime (10 mg in the elderly) and titrated slowly up to a dose of 100 mg. Gabapentin 900 to 3600 mg per day in divided doses are also effective treatments. Tramadol, a centrally acting analgesic and mixed opioid, has been effective in several trials for the treatment of DSPN, but safety concerns regarding its abuse potential make it a less desirable option. Topical capsaicin provides relief in some patients, but the burning associated with its application has limited its use. Topical lidocaine patches, 5%, are yet another option.

We recommend pregabalin, duloxetine, or gabapentin at a low dose to manage the pain from DSPN; this is best done in consultation with the patient's primary physician who can then titrate to therapeutic effect on follow-up. In patients who have localized symptoms, who cannot tolerate the side effects or have the potential for adverse drug interactions, topical agents such as lidocaine patches or capsaicin cream can be offered. In addition to pain management as discussed earlier, all patients with suspected alcoholic DSPN should receive dietary supplements and referral for outpatient management.

There are no first-line agents for the treatment of HIV-associated neuropathy, and limited randomized controlled trials have not demonstrated any specific analgesic that is more effective over placebo.

Type 3: Asymmetric Proximal and Distal Peripheral Neuropathies (Radiculopathies and Plexopathies)

Radiculopathies and plexopathies often result from trauma (Box 93.5). In general, a plexopathy, whether brachial or lumbosacral, is identified by process of elimination (i.e., a pattern of sensorimotor and reflex

abnormalities that fit neither a radicular nor an individual peripheral nerve distribution). Although this approach does not exclude a mononeuropathy multiplex on physical examination alone, a careful history should determine whether the patient is at risk for development of a mononeuropathy or plexopathy based on underlying disease

Most plexopathies are seen in young men after motor vehicle accidents, many of whom present for evaluation of radicular pain several months after the initial injury. Therapeutic intervention is often delayed to maximize the potential for spontaneous recovery. Several surgical repairs exist, including neurotization.

Radiation (actinic) plexopathy occurs after a variable period of latency following treatment, which may extend to 20 years or more. Almost all series include women who received radiation treatment for breast cancer. Among neoplastic causes, most originate from the lung or breast. Patients with probable neoplastic brachial plexopathy need imaging studies and may require immediate radiation therapy. Pain control is the focus of management.

Thoracic outlet syndrome (TOS) describes a constellation of symptoms caused by compression of the neurovascular bundle at the thoracic outlet. As our understanding of this condition has improved, treatment has evolved but remains controversial. Manifestations include both neurogenic and vascular (arterial or venous) TOS. It is estimated that over 90% of cases are neurogenic in origin; 3% to 5% are venous, and less than 1% are arterial.

Neurogenic TOS is caused by compression of the brachial plexus, presenting with upper extremity weakness, numbness, paresthesias, and pain in a nonradicular distribution. Symptoms are usually present during normal daily activities and sleep. Treatment is typically nonsurgical, involving education, activity modification, and physical therapy.

Vascular TOS can be either arterial or venous and is characterized by swelling of the upper extremity, pain, and a feeling of heaviness after exertion. Discoloration can also be seen. If arterial TOS is occurring, caused by compression of the subclavian artery, the typical findings of arterial insufficiency can be seen—pain, numbness, coolness, pallor. Treatment is typically surgical, involving decompression of the thoracic outlet.

Because of the complexity of plexopathies, the goal in the ED is to localize the probable pathologic process to the brachial or lumbosacral plexus. Depending on severity and suspected etiology, the patient should either be admitted or referred to a neurologist with experience in PNS disease.

Type 4: Isolated Mononeuropathies

The pattern of asymmetrical, sensorimotor, usually distal, peripheral neuropathy is characteristic of a mononeuropathy. Mononeuropathies are of two main types: isolated and multiple. The isolated mononeuropathies are discussed in this section; the multiple mononeuropathies, also termed mononeuropathy multiplex, are discussed in the next section as a Type 5 peripheral neuropathy.

Isolated mononeuropathies are usually caused by trauma, either blunt or penetrating (Box 93.6). If the trauma is blunt, the injury may be secondary to compression from an internal or external source. Entrapment neuropathies are a subset of compression neuropathies occurring at anatomic locations where nerves traverse potentially constricting compartments or tunnels. Isolated mononeuropathies may be acute, intermittent, or chronic and continuous. Antecedent peripheral neuropathy may be a risk factor for the development of compression neuropathy (so-called double-crush syndrome), particularly in diabetics.

Radial Mononeuropathy

Principles. The radial nerve arises from the C5 to T1 roots. After exiting the brachial plexus, it passes behind the proximal humerus in the spiral groove and takes a lateral (radial) course down the upper arm (Fig. 93.3). At about the level of the antecubital fossa, it bifurcates into the posterior interosseous (pure motor) and superficial radial (pure sensory) nerves.

The radial nerve controls extension of the fingers, thumb, wrist, and elbow (triceps). In contrast to the median and ulnar nerves, the radial nerve provides only *extrinsic* motor innervation to the hand (i.e., it does not supply motor fibers to any muscles that both originate and insert within the hand). In further contrast to the median and ulnar nerves, which supply most of the sensation to the hand, the radial nerve makes a contribution only to a cutaneous dorsal area overlying the first dorsal interosseus muscle, sometimes extending part of the way up the dorsa of the thumb, index, and long fingers.

Radial mononeuropathy caused by involvement at the level of the axilla is uncommon. When it occurs, it is usually associated with other upper extremity mononeuropathies or a brachial plexopathy. Although improper use of crutches may cause this syndrome, it usually occurs after an extended period of unconsciousness during which the arm is positioned in such a way that prolonged, deep compression is applied to the axilla. The most common are due to the so-called "Saturday night palsies," which is derived from the association of radial mononeuropathy with improper positioning of the arm during deep, commonly inebriated sleep. Consequently, the radial nerve is trapped for a prolonged period between the humeral shaft and some firm surface, causing

BOX 93.6 Isolated Mononeuropathies

Upper Extremity

Radial nerve

- Fifth metatarsal base (distal)

Plantar nerve
- Distal to tarsal tunnel
- Interdigital neuropathies (Morton neuroma)

Obturator mononeuropathy

an external compression mononeuropathy. "Bridegroom's palsy" is another eponym for radial mononeuropathy, so named because the radial nerve may be compressed by the bride's head resting on the bridegroom's arm during sleep. Axillary radial mononeuropathy is distinguished from the more common humeral form by the finding of triceps involvement in addition to typical wrist and finger drop. Triceps involvement occurs because the innervation to the triceps is proximal to the point where the nerve is most vulnerable as it winds around the humeral shaft (see Fig. 93.3).

Clinical Findings. Because innervation of the wrist and finger extensors occurs distal to this area of the humeral shaft, findings

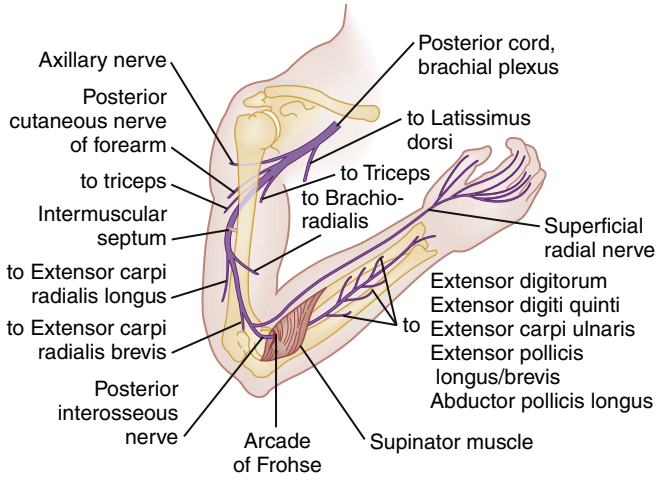

Fig. 93.3 Radial nerve, major branches, right arm, lateral view. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseus muscle. Depending on the level, degree, and duration of compression, some fascicles of the nerve may remain functional, resulting in a partial radial mononeuropathy. Thus the superficial radial nerve may remain intact, resulting in no loss of sensation, or loss of wrist and finger extension may be incomplete.

Because the finger drop of radial mononeuropathy places the hand at a mechanical disadvantage, examination of ulnar function by testing of the interossei may produce false-positive findings of weakness. To adjust for this, the examiner should ask the patient to place the palm on a horizontal supporting surface, such as a stretcher. With the fingers extended and no longer "dropped" at the metacarpophalangeal joints, interosseous strength can now be fairly tested. Failure to perform this maneuver may cause misdiagnosis of a simple radial mononeuropathy as a brachial plexopathy in an effort to explain what appears to be radial and partial ulnar nerve involvement.

About 90% of radial nerve palsies occurring during sleep, coma, or anesthesia recover fully, usually within 6 to 8 weeks. Evidence of denervation on EMG studies predicts a slower rate of recovery. Tourniquet injuries to the radial nerve usually recover spontaneously within 2 to 4 months. If axonal degeneration is seen on electrophysiologic testing, recovery may take longer, although virtually all radial mononeuropathies caused by tourniquets eventually resolve.

The radial nerve courses closely to the humerus, so it follows that about 22% of humeral shaft fractures are associated with radial nerve injury, with "wrist drop" the hallmark injury. Spontaneous resolution has been reported between 60% and 92%, so many authors suggest observation of these injuries is appropriate. In contrast, surgical intervention is needed to free the nerve from entrapment associated with complex fractures.

Diagnostic Testing. There exists no diagnostic test per se for this disease entity beyond the physical examination. EMG testing is employed to aid in predicting recovery times.

Management. While patients are waiting for spontaneous recovery to occur, the hand should be maintained in about 60 degrees of dorsiflexion. Although a simple dorsal plaster or fiberglass splint treats the wristdrop, atrophy and contractures can be minimized, and function of the hand can be improved if wide rubber bands anchored to the splint at a point proximal to the wrist are attached to individual fingers to provide passive dorsiflexion.

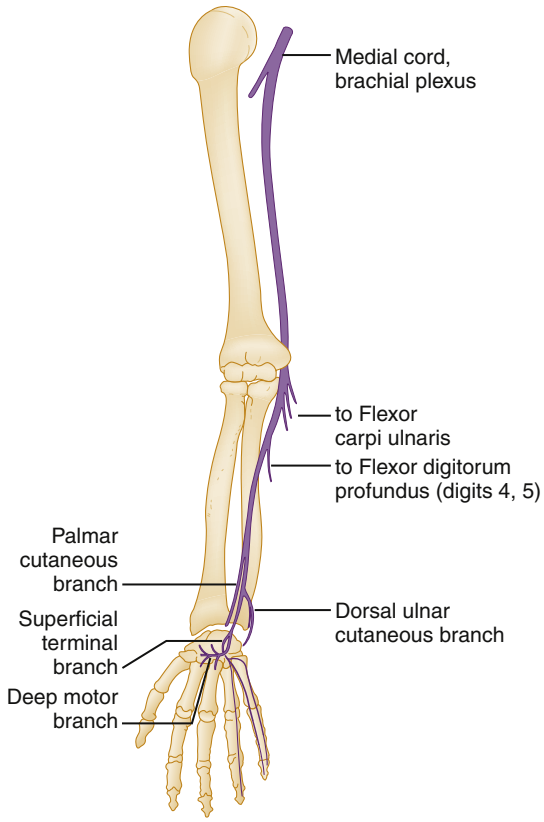

Fig. 93.4 Ulnar nerve, major branches, right arm, anterior view. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

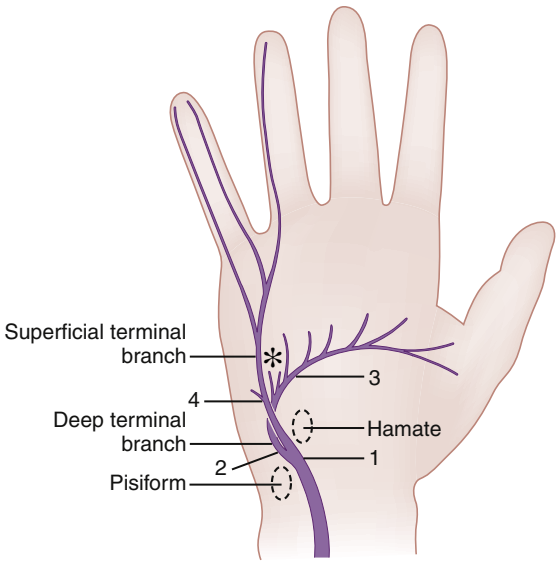

Fig. 93.5 Distal ulnar nerve and branches, right hand, palmar view. *Numbers* indicate four main sites of distal ulnar mononeuropathy in the wrist and hand. Asterisk *(*)* denotes hypothenar branches. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

Ulnar Mononeuropathy

Principles and Clinical Findings. The ulnar nerve includes C7 to T1 roots and passes through the brachial plexus to descend medially, without branching, to the ulnar (medial) condylar groove at the elbow. It then enters the cubital canal, where it gives off branches to the ulnar wrist flexor and the deep flexors of the fourth and fifth digits.

Just proximal to the wrist, two important sensory branches leave the main trunk to supply cutaneous sensation to part of the hand (Fig. 93.4). These are the palmar and dorsal cutaneous branches, which do *not* pass through the Guyon canal. The palmar branch supplies sensation to the hypothenar eminence and the dorsal branch innervates the ulnar side of the dorsum of the hand, extending out nearly to the tip of the fifth and ulnar half of the fourth digit.

At the wrist, the nerve enters the Guyon canal (Fig. 93.5) between the pisiform and hook of the hamate, then bifurcates into the superficial terminal sensory branch and the deep motor branch.

The superficial sensory nerve supplies ulnar sensation to the palmar side of the fifth and half of the fourth digit (see Fig. 93.5). The deep motor nerve supplies the hypothenar muscles, then crosses to the radial side of the palm to innervate the ulnar intrinsics (all interossei and the ulnar lumbricals of the fourth and fifth digits), terminating in the first dorsal interosseus. The interossei abduct and adduct the fingers and are all innervated by the ulnar nerve. The lumbrical muscles flex the metacarpophalangeal joints and are evenly divided between the ulnar (fourth and fifth) and median (second and third) digits. The ulnar nerve can be thought of as the complement to the median nerve in the hand, because it supplies all of the muscles and all palmar sensation not innervated by the median nerve.

The ulnar nerve may be injured at two locations near the elbow: in the ulnar condylar groove and distally in the cubital canal. Because the condylar groove is shallow, the ulnar nerve runs superficially in this location and is vulnerable to injury, usually from external pressure or from a fracture or dislocation. The ulnar nerve has a propensity to develop a "tardy ulnar palsy," occurring years after a traumatic event. Many of these delayed ulnar mononeuropathies can be localized to the elbow on electrophysiologic testing.

Some ulnar mononeuropathies occur secondary to compression just proximal to entry into the cubital canal or are entrapped within the canal itself. Transient symptoms may occur during prolonged flexion or with repeated flexion and extension at the elbow.

Although it is difficult to distinguish a condylar from a cubital ulnar mononeuropathy, it is usually possible to localize the problem to the region of the elbow or the wrist. In addition to prior probability heavily favoring the elbow, the presence of sensory abnormalities in an ulnar distribution in the hand and fingers (i.e., usually including the fifth digit and "splitting" the fourth digit) strongly suggests that the lesion is at the level of the elbow rather than the wrist. The ulnar cutaneous innervation to the hand branches off from the main trunk proximal to the nerve entering the Guyon canal (see Figs. 93.4 and 93.5). Thus a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.

Compression of the ulnar nerve within the Guyon canal is rare. When it does occur, it affects all of the ulnar intrinsics (i.e., the two ulnar [fourth and fifth] lumbricals) and all the interossei. However, the ulnar extrinsics (i.e., the deep flexors of the fourth and fifth digits) are not affected, nor is the ulnar flexor of the wrist. The only sensory abnormalities are those in the distribution of the superficial terminal sensory branch, sparing other areas of ulnar innervation (see Fig. 93.5).

There are three ulnar mononeuropathies that occur distal to the Guyon canal in the hand. The two most common ones involve the deep terminal branch, either proximal or distal to the separation of the hypothenar branches (see Fig. 93.5). If the lesion is proximal, it produces weakness of all the ulnar-innervated muscles of the hand without sensory loss. If it is distal, the hypothenar ulnar intrinsics are spared, but the picture is otherwise similar. Usually, this occurs secondary to a laceration or repeated compression in the hand from use of certain tools, a cane, or the handle of a crutch.

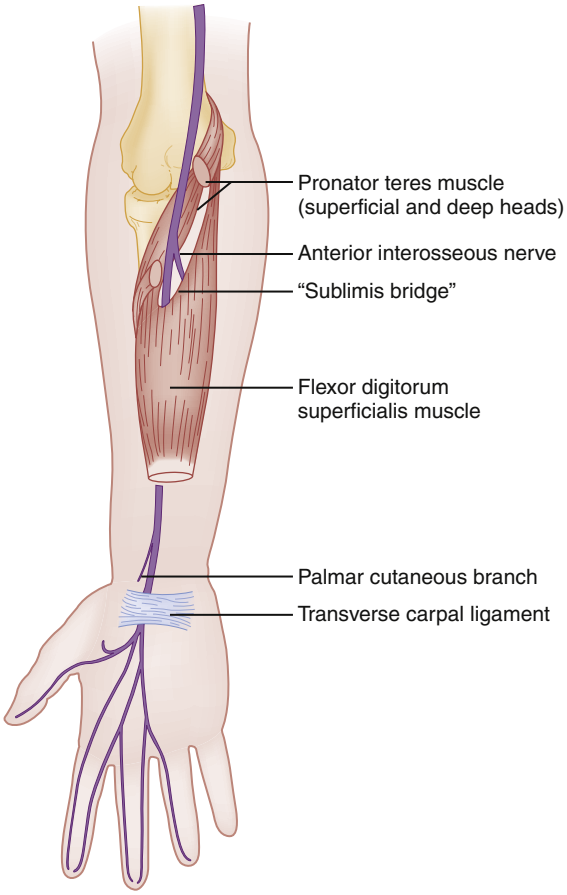

Fig. 93.6 Median nerve, major branches, right arm, anterior view. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

Involvement of the superficial terminal branch (see Fig. 93.5) produces a pure sensory loss of the palmar surface of the fifth digit and ulnar half of the fourth digit caused by direct compression of this branch just distal to the Guyon canal. The dorsal surface of these two digits should have normal sensation except for the distal tips. This configuration of findings is due to the intact innervation provided by the dorsal and palmar cutaneous branches that enter the hand without passing through the Guyon canal (see Fig. 93.4).

Diagnostic Testing. There exists no true diagnostic entity for this disease process beyond the physical examination.

Management. Most ulnar mononeuropathies will spontaneously resolve. The evidence and options for nonoperative management are limited, but include splinting or padding, limiting flexion at the elbow, and activity modification. However, if muscle atrophy, particularly in the hypothenar area, is detected, surgery may be considered. There is no noted difference in outcomes between the two surgical options of simple decompression and decompression with transposition.

Median Mononeuropathy

Principles. The median nerve arises from the C5 to T1 spinal nerve roots and exits the brachial plexus through the lower trunk (Fig. 93.6). Median mononeuropathy is usually diagnosed as carpal tunnel syndrome (CTS), which is the most common of all entrapment neuropathies. The incidence of CTS is estimated at 1 in 1000 for the general population and a lifetime risk of 10%.[6] It is defined by the Academy of Orthopedic Surgeons as "a symptomatic compression neuropathy of the median nerve at the level of the wrist."

BOX 93.7 Conditions Associated With Carpal Tunnel Syndrome

Acromegaly
Amyloid
Diabetes mellitus
Hypothyroidism
Obesity
Pregnancy
Renal failure
Rheumatoid arthritis

Clinical Findings. Although the patient may complain of bilateral symptoms, a careful history usually reveals that symptoms in one hand preceded those in the other. A common symptom of CTS is awakening at night and shaking the hand. Symptoms are often worsened by activity. For unclear reasons, the pain may spread as high as the arm or shoulder, although the paresthesias are generally confined to the fingers. Many patients initially state that their entire hand is involved, although this is not elicited by careful sensory examination. Patients may note, progressively over time, that their hands are clumsy or weak, and also note associated loss of fine motor function. The skin of the fingers innervated by the median nerve may be drier and rougher to the touch than the corresponding ulnar skin, depending on the duration of entrapment.

When motor involvement occurs in CTS, it is confined to the median intrinsics, which innervate the *l*umbricals (flexion of the metacarpophalangeal joints) and subserve thumb *o*pposition, *a*bduction, and *f*lexion, known as the *LOAF* muscles. However, the hallmark of CTS is sensory involvement, with motor abnormalities occurring later. The typical pattern of sensory innervation of the hand by the median, ulnar, and radial nerves shows marked individual variation. The most specific finding for CTS is splitting of the fourth digit (i.e., normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial] palmar side of the same finger). The most sensitive finding is abnormal sensation of the distal palmar tip of the index finger. If sensory findings are absent in the presence of motor findings consistent with median nerve involvement, it is highly unlikely that the patient has CTS, and an alternative diagnosis should be sought.

CTS appears to be associated with the conditions listed in Box 93.7. Of these, the two most common are diabetes mellitus and pregnancy.[7] CTS associated with systemic illness is commonly bilateral. CTS in pregnancy appears to be common, but the prevalence varies widely in the literature from 30% to 60%; resolution occurs among the majority of patients postpartum, but several studies have demonstrated that symptoms can persist for months to years among a subset of patients even after delivery.

Diagnostic Testing. The Tinel sign (percussion of the median nerve at the wrist) and Phalen sign (maximal palmar flexion at the wrist) are provocative tests to reproduce the sensory symptoms of CTS if neither sensory nor motor symptoms are evident on initial examination. Unfortunately, neither sign has adequate sensitivity or specificity to determine which patients should be referred for electrodiagnostic studies. Dropping of objects is indicative of severe CTS. The best way to examine patients for sensory findings is to touch the distal palmar tips very lightly, asking the patient whether the sensation feels "abnormal."

A nerve conduction study is an objective test that provides information on the physiologic health of the median nerve across the carpal tunnel and is the diagnostic gold standard. Magnetic resonance

imaging (MRI) delineates the site of the nerve compression with a sensitivity of 96% but a specificity of 33% to 38%. Ultrasonography may be useful, particularly in patients with symptoms and a normal NCS. The most reliable ultrasonographic measurement is to obtain the cross-sectional area of the median nerve at the level of the pisiform. Thus, if all diagnostic studies in a symptomatic patient are normal, or if only the MRI result is abnormal, they should be repeated within three months if symptoms do not resolve. This recommendation is based on the theory that the CTS will progress over time to the point that an objective indicator, such as the NCS, will become positive.

Management. There are a variety of nonsurgical treatments, with splinting and steroid injections being the most common. A neutral wrist splint, typically worn at night during sleep, has commonly been used as the initial treatment. A Cochrane review found splinting more effective than no treatment in the short term, but the evidence that supported this conclusion was not robust.[8] A randomized trial comparing the effectiveness of night splinting versus a single corticosteroid injection found steroid injection benefit at six weeks, but at six months outcomes between the two treatment groups were the same.[9] We recommend providing patients with a splint to be worn during the night time hours and education regarding hand positioning or avoidance of repetitive activities that could lead to exacerbation of their symptoms. Oral NSAIDs can be offered, but there is no good quality supporting evidence.

Because of the possibility of a disabling "median hand" after inadvertent direct injection of the median nerve, we recommend that emergency clinicians defer the injection of the carpal tunnel with steroids to the consulting hand surgeon who can also obtain NCS and determine if splinting, injection, or surgical division of the transverse carpal ligament is indicated. Surgical treatment involves the division of the transverse carpal ligament, which reduces pressure on the median nerve by increasing the space in the carpal tunnel. This carpal tunnel "release" surgery can be performed open or endoscopically with no significant difference in outcomes noted.

Sciatic Mononeuropathy

Principles. The sciatic nerve includes L4 to S3 spinal nerve roots that pass through the lumbosacral plexus and divides into two terminal branches: the common peroneal and tibial nerves. The nerve exits the pelvis through the sciatic notch, passes behind the hip, and remains deep in the thigh until its terminal bifurcation in the proximal popliteal fossa (Fig. 93.7).

Lesions of the sciatic nerve occur with posterior hip dislocation or with virtually any form of penetrating or blunt trauma that causes formation of a buttock hematoma. Other causes include deep gluteal injection and prolonged supine immobilization on a firm surface. Because the sciatic nerve innervates the hamstrings and provides all sensorimotor function distal to the knee, a complete sciatic mononeuropathy is a devastating injury.

Clinical Findings. Ambulation is extremely difficult because of inability to flex the knee and a flail foot (i.e., neither flexion nor extension is possible at the ankle). Fortunately, many sciatic mononeuropathies are incomplete. For unknown reasons, a partial lesion typically involves only the trunk of the sciatic nerve, which subsequently becomes the common peroneal nerve, sometimes making the two difficult to distinguish from one another clinically.

Diagnostic Testing. This condition is mainly diagnosed by physical findings. If used, electrophysiologic studies show evidence of involvement of gluteal muscles or of any muscles innervated by the tibial nerve. This readily distinguishes a partial sciatic mononeuropathy from a lesion of the common peroneal nerve.

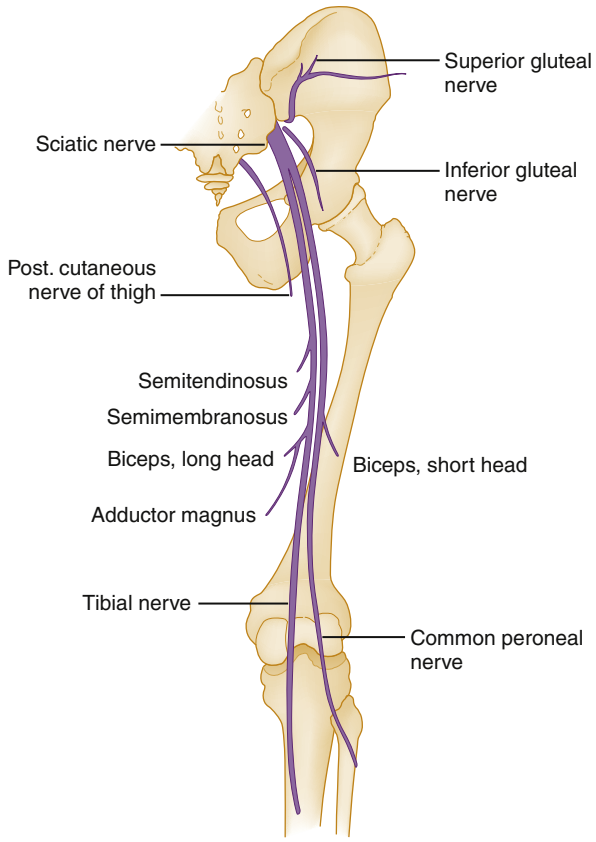

Fig. 93.7 Sciatic nerve, major branches, right leg, posterior view. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

Management. Treatment of footdrop requires a posterior splint to maintain the ankle at 90 degrees until a brace can be obtained (see the Common Peroneal Mononeuropathy section).

Lateral Femoral Cutaneous Mononeuropathy

Principles. Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is a common syndrome believed to be caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked. Along with facial nerve neuropathy, meralgia paresthetica is one of the most commonly reported mononeuropathies associated with HIV infection. Risk factors include obesity, diabetes, pregnancy, and wearing tight-fitting clothing or belts. In addition, patients who have undergone surgical procedures of the hip and spine are also at risk for developing the syndrome.

Clinical Findings. Numbness and dysesthesia over the skin of the upper lateral thigh is typically found on physical examination.

Diagnostic Testing. There is no diagnostic test for this disease process beyond the physical examination.

Management. Resolution usually occurs spontaneously. In select patients, such as obese patients with BMI of 30 or greater, recommendations to avoid tight-fitting clothing or belts and/or to lose weight should be made. Ultrasound-guided nerve blocks utilizing corticosteroids and lidocaine are an option. Recurrence is possible and may require an inguinal ligament surgical release procedure.

Common Peroneal Mononeuropathy

Principles. The common peroneal nerve is a continuation of one trunk of the sciatic nerve. It is most vulnerable to injury where it winds around the fibular neck (Fig. 93.8). It then passes through the fibular

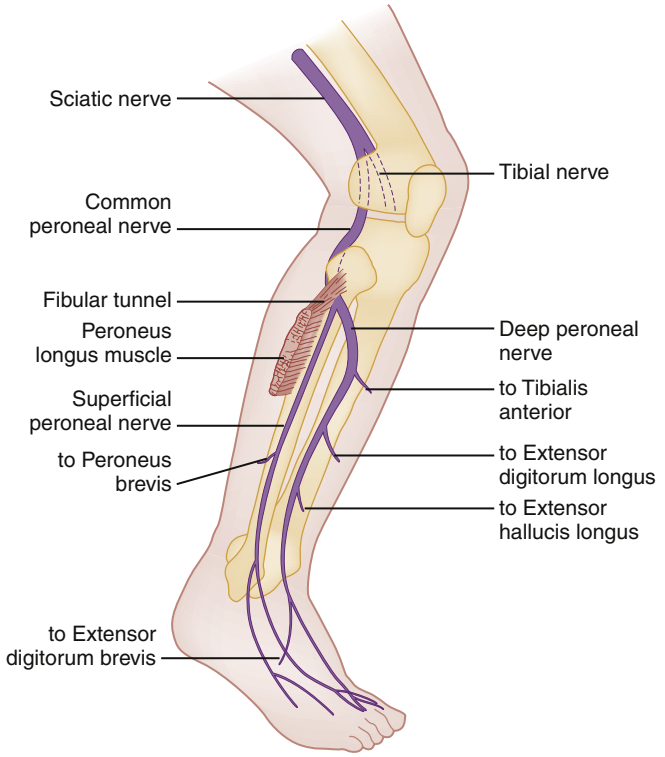

Fig. 93.8 Common peroneal nerve, major branches, right leg, anterolateral view. (From Stewart JD. *Focal Peripheral Neuropathies*, ed 3. Philadelphia: Lippincott Williams & Wilkins; 2000.)

canal and bifurcates into its terminal branches, the superficial and deep peroneal nerves. The superficial peroneal nerve innervates the peroneal muscles (foot evertors) and supplies sensation to the lateral, distal lower leg and dorsum of the foot. The deep peroneal nerve traverses the anterior compartment and supplies innervation to the dorsiflexors of the foot and toes plus cutaneous sensation between the first and second toes.

Most common peroneal mononeuropathies are idiopathic and thought to be related to compression where the nerve is superficially located lateral to the fibular neck. Because this common neuropathy is often noted on awakening, it may be secondary to position during sleep. Leg crossing may also be a risk factor for development of this mononeuropathy.

Clinical Findings. The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion. At testing, the evertors of the foot are also weak, but the inverters, which are innervated by the tibial nerve, remain strong. This is the single most reliable clinical feature distinguishing sciatic from common peroneal mononeuropathy. Analogous to radial mononeuropathy in the upper extremity, sensory abnormalities in the leg and foot are inconsistent and easily overlooked in peroneal mononeuropathy.

Diagnostic Testing. Most patients with peroneal palsy recover. Those who do not should be studied electrophysiologically to ensure that the point of compression is not proximal to the fibular neck (i.e., in the popliteal fossa). If the point of peroneal injury appears to be in the region of, or distal to, the fibular neck on EMG, patients whose footdrop does not resolve should be considered candidates for exploration to determine whether the nerve is compressed within the fibular canal.

Management. Treatment of common peroneal palsy requires a posterior splint to maintain the ankle at 90 degrees until the nerve regenerates. This splinting prevents the foot from falling into sustained equinus (plantar flexion), which in turn allows the intermalleolar distance to narrow, effectively locking the talus out of the ankle mortise.

The treatment of isolated mononeuropathies depends on their etiology, location, and natural history of spontaneous recovery. All penetrating neuropathies should have surgical exploration and repair performed. Blunt trauma may cause a mononeuropathy indirectly by entrapment of a nerve within a fracture, hematoma, or compartment, requiring surgical intervention. Alternatively, nerves may be injured at a point where they are superficial, either by a single direct blow or by sustained pressure caused by immobility (pressure palsies). Most of these resolve spontaneously over time, depending on the severity of injury and length of the nerve. If entrapment can be confirmed by imaging or electrophysiologic studies, a release procedure is indicated. The mononeuropathies that do not require timely surgical exploration should be referred for further evaluation to confirm the location of the neuropathic lesion.

BOX 93.8 Mononeuropathy Multiplex

- Vasculitis
  - Systemic vasculitis
    - Polyarteritis nodosa
    - Rheumatoid arthritis
    - Systemic lupus erythematosus
    - Sjögren syndrome (keratoconjunctivitis sicca)
  - Nonsystemic vasculitis
- Diabetes mellitus
- Neoplastic
  - Paraneoplastic
  - Direct infiltration
- Infectious
  - Lyme disease
  - HIV infection
- Sarcoid
- Toxic (lead)
- Transient (polycythemia vera)
- Cryoglobulinemia (hepatitis C)

HIV, Human immunodeficiency virus.

Type 5: Mononeuropathy Multiplex

Principles

Mononeuropathy multiplex is characterized by an asymmetrical, sensorimotor, usually distal pattern of peripheral neuropathy (Box 93.8). Common causes include vasculitis, diabetes, and Lyme disease.

Clinical Findings

As with isolated mononeuropathies, sensory abnormalities tend to be located in the same general anatomic region as the accompanying motor findings. Whether DTRs are affected depends on which nerves are involved. For example, if the process includes the femoral nerve, the patellar reflex is likely to be diminished or absent.

Lyme Disease. The PNS manifestations of Lyme disease are divided into early and late. The early PNS syndromes commonly include facial nerve involvement (rarely other cranial nerve palsies) and radiculoneuritis. Late PNS involvement occurs as a DSPN, mononeuropathy multiplex, or radiculoneuropathy. The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure. Patients may also complain of headache and constitutional symptoms. Early in the course of Lyme disease, severe neuritic pain may develop in a radicular distribution, often in or near the dermatome where the tick bite occurred. There may also be associated sensory changes,

motor weakness, and decreased reflexes consistent with nerve root involvement.

Patients with chronic Lyme disease present with sensory symptoms, particularly distal paresthesias in the lower extremities. Less commonly, they develop a picture consistent with mononeuropathy multiplex or a radiculopathy, which is much less severe than the early radiculoneuritis of Lyme disease.

Diagnostic Testing

Vasculitis-related multiple mononeuropathy is diagnosed with a sural nerve biopsy.

The most useful diagnostic tests for patients with suspected Lyme disease are a serum enzyme-linked immunosorbent assay, Western blot, and CSF examination. CSF abnormalities suggestive of Lyme disease are a lymphocytic pleocytosis, elevated protein level, and normal glucose concentration. The CSF is almost always abnormal in early radiculitis, sometimes abnormal with isolated facial palsy, and typically normal in chronic Lyme disease.

Management

Facial nerve palsy in Lyme disease without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous (IV) ceftriaxone is the drug of choice for all other neurologic syndromes associated with Lyme disease. The adult dosage is 2 g/day, and the pediatric dosage is 50 to 75 mg/kg per day. The standard course of treatment with IV ceftriaxone is at least 2 weeks.

Type 6: Amyotrophic Lateral Sclerosis

Principles

Although *amyotrophic lateral sclerosis (ALS)* and *motor neuron disease (MND)* are often used synonymously, the latter represents a spectrum of diseases ranging from primary lateral sclerosis, in which degeneration is confined to upper motor neurons, to progressive muscle atrophy, in which only lower motor neurons are involved. ALS, which requires the presence of both upper and lower motor neuron findings, resides in the middle of this spectrum, representing the most common form of MND. The incidence of ALS is 1.5 to 2.5 per 100,000. Most develop symptoms in middle-adult life, with motor weakness in the extremities, spasticity, paralysis, and eventually death, typically within 3 to 5 years of symptom onset.

In ALS, the primary pathologic process in the PNS component of the disease is a neuronopathy of the anterior horn cell. Because this structure is located proximal to the point where motor and sensory fibers merge to form mixed spinal nerve roots, the signs and symptoms of MND are purely motor (see Fig. 93.2). In the CNS, there is a loss of Betz cells from the motor cortex with secondary degeneration of the corticospinal tracts.

Clinical Findings

Box 93.9 lists some representative upper, lower, and mixed motor signs. Patients typically demonstrate asymmetrical distal weakness without sensory findings. Positive motor phenomena in the form of fasciculations are found in almost all patients at diagnosis but are rarely an initial complaint. Although there is electrophysiologic evidence of autonomic involvement in ALS, this is generally subclinical.

Diagnostic Testing

All patients in whom this diagnosis is suspected should be referred for electrophysiologic confirmation against standardized criteria, with denervation combined with the physical findings typically confirming the diagnosis. Confirmation is particularly important because multifocal motor neuropathy, a rare disease that masquerades as ALS, responds dramatically to cyclophosphamide and immune globulin administration.

BOX 93.9 Objective Clinical Findings Consistent With Amyotrophic Lateral Sclerosis

Upper Motor Neuron Signs
- Hyperreflexia
  - Sustained clonus, especially at ankle
  - Finger flexors and jaw jerk
- Spasticity, especially of gait
- Presence of Babinski sign

Lower Motor Neuron Signs
- Positive motor phenomena
  - Fasciculations
  - Cramps
- Negative motor phenomena
  - Asymmetrical distal weakness
  - Atrophy

Combined Upper and Lower Motor Neuron Signs
- Dysarthria
- Dysphagia
- Respiratory compromise

Management

Riluzole and edaravone are the only two drugs approved for treatment of ALS by the FDA. A systematic review found that riluzole increased median survival time by 2 to 3 months.[10] Edaravone, only recently approved for ALS in 2017, demonstrated a 33% decrease in ALS severity scores over six months and improved quality of life measures.[11] The development of a multidisciplinary team approach has had a much higher impact on overall quality of life for patients with ALS. This team includes ALS-focused neurologists, nurses, occupational therapy, and speech therapy amongst others. Patients presenting to the emergency department with undifferentiated or early signs of ALS can be challenging to diagnose and will benefit from prompt neurologic consultation to avoid a delay in diagnosis. Those with an established diagnosis of ALS and demonstrated disease progression are at high risk for aspiration pneumonia and respiratory compromise and may require admission to the hospital, which should be done with consideration for the patient's advanced directives and long-term goals of care.

Type 7: Sensory Neuronopathy (Ganglionopathy)

Principles

This category of peripheral neuropathy is characterized by a selective or predominant involvement of the dorsal root ganglion, producing a relatively pure sensory syndrome analogous to the pure motor syndrome of ALS.

Clinical Findings

Although all sensory modalities are affected, proprioception is profoundly altered, leading to sensory ataxia and loss of DTRs without weakness. The distribution is typically asymmetrical and distal at the outset, but depending on severity and extent of progression, it may become functionally symmetrical.

BOX 93.10 Sensory Neuronopathies (Ganglionopathies)

- Herpes
  - Herpes simplex 1 and 2
  - Varicella-zoster (shingles)
- Inflammatory sensory polyganglionopathy
- Paraneoplastic
- Primary biliary cirrhosis
- Sjögren syndrome (keratoconjunctivitis sicca)
- Toxin induced
  - Pyridoxine (vitamin B_6) overdose
  - Metals
    - Platinum (cisplatin)
    - Methyl mercury
- Vitamin E deficiency

Diagnostic Testing

Sensory ganglionopathies can be confirmed by MRI of the spinal cord and surrounding areas, showing degeneration of central sensory projections that localize the disease process to the dorsal root ganglion. Some of the more common causes of this type of peripheral neuropathy are listed in Box 93.10.

Management

The management of sensory neuropathies is symptomatic in nature and best left to the patient's primary physician.

CHAPTER 93: QUESTIONS AND ANSWERS

1. Which category of peripheral neuropathy tends to occur in an asymmetrical, distal distribution?
- **a.** Autonomic neuropathy
- **b.** Large-fiber neuropathy
- **c.** Mixed motor and sensory neuropathy
- **d.** Pure motor neuropathy

Answer: D. Pure motor and pure sensory peripheral neuropathies tend to occur in an asymmetrical distal pattern.

2. A 26-year-old woman presents with a chief complaint of weakness. She notes a 1- or 2-day onset of easy fatigability and diminished ability to navigate stairs. She has no past history and takes no medications. Vital signs are normal. Physical examination reveals absent lower extremity deep tendon reflexes (DTRs); symmetrical weakness of the quadriceps, calf muscles, and foot/toe dorsiflexion; and minimal sensory loss. Cranial nerve and upper extremity examination is normal. Which of the following is likely?
- **a.** An antecedent viral illness
- **b.** Lack of anal sphincter tone
- **c.** Onset of ocular muscle dysfunction
- **d.** Sparing of the autonomic nervous system

Answer: A. Guillain-Barré syndrome (GBS) is characterized by fairly acute onset of ascending weakness, loss of deep tendon reflexes (DTRs), and variable sensory loss. Antecedent infections often trigger, with common organisms being campylobacter, cytomegalovirus, Epstein-Barr virus, and mycoplasma. Rarely, symptoms begin in the upper extremities. Urinary retention is common, but anal tone is preserved. Ocular muscles are usually spared. Autonomic neuropathy is common, with marked variations in heart rate and blood pressure. Patients with predominantly sensory symptoms tend to have less risk of respiratory embarrassment and a more favorable prognosis. Lumbar puncture shows cerebrospinal fluid (CSF) pleocytosis or may be normal early on.

3. A 26-year-old woman presents with lower extremity weakness and difficulty walking. Examination is remarkable for lower extremity symmetrical weakness with mild symmetrical sensory loss and absent lower extremity deep tendon reflexes (DTRs). Symptom onset has been during 2 days. What should be the next step?
- **a.** Emergent magnetic resonance imaging (MRI)
- **b.** Intravenous immune globulin (IVIG)
- **c.** Lumbar puncture and antibiotics
- **d.** Pulmonary function studies

Answer: D. All patients with Guillain-Barré syndrome (GBS) are at risk of respiratory failure. A forced vital capacity (FVC) of less than 20 mL/kg and a negative inspiratory force of less than 30 cm H_2O are associated with impending ventilatory failure and the need for intubation.

4. Among patients with Guillain-Barré syndrome (GBS) who have normal pulmonary function, which of the following can be monitored to predict impending ventilatory failure?
- **a.** Deltoid strength
- **b.** Extensor neck strength
- **c.** Hand grip strength
- **d.** Masseter strength

Answer: B. Extensor muscle strength has been shown to correlate with ventilatory muscle strength.

5. A 53-year-old diabetic presents with a complaint of increasing difficulty walking in the last several months. He has no other past history but has been an insulin-dependent diabetic for 23 years. Current glucose level is 138 mg/dL, and chemistries and complete blood count are otherwise unremarkable. Examination is remarkable for bilateral lower extremity numbness extending symmetrically to above the knees, loss of the Achilles reflex bilaterally with footdrop, and steppage gait. Which of the following is true?
- **a.** Autonomic neuropathy is unlikely.
- **b.** Facial numbness would necessitate MRI.
- **c.** Hand numbness is expected.
- **d.** Erythrocyte sedimentation rate is likely to be elevated.

Answer: C. Diabetic neuropathy is a progressive, ascending mixed polyneuropathy. Hand numbness and upper extremity symptoms usually begin before the lower extremity symptoms ascend to the knees. Extensive motor loss can occur with gait and grip abnormalities. Skull and face numbness can occur. Autonomic dysfunction is expected.

Neuromuscular Disorders

Jeremy Rose, Trent She

KEY CONCEPTS

- In patients presenting with acute neuromuscular weakness, complaints of difficulty in breathing or swallowing are signs of bulbar nerve or respiratory muscle compromise with potential airway or ventilatory failure. In such patients, forced vital capacity (FVC) of less than 15 mL/kg or maximal negative inspiratory force of less than 15 mm H_2O is a potential indication for mechanical support, either by intubation or by noninvasive ventilation.
- Initiating new medications in patients with myasthenia gravis may precipitate a crisis. Commonly prescribed cardiovascular agents, including calcium channel blockers, beta-blockers and antidysrhythmics; commonly used antibiotics; and other agents, including corticosteroids, require particular vigilance.
- Myasthenic crisis is treated with either plasma exchange or intravenous immune globulin (IVIG).
- Botulism usually arises as a painless descending paralysis, often first affecting the cranial nerves (with diplopia) and bulbar innervated muscles, without sensory deficits or alteration of consciousness. The treatment is airway management with ventilatory support and administration of antitoxin.
- Injection drug use remains an important cause of wound botulism outbreaks.
- Botulism is an important consideration in evaluation a weak and floppy infant.
- Hypokalemic periodic paralysis is caused by intracellular shift of potassium and so requires frequent serum potassium measurement to avoid overcorrection during treatment with potassium infusion.
- Patients with newly diagnosed hypokalemic periodic paralysis should be evaluated for hyperthyroidism.

FOUNDATIONS

Disorders of the neuromuscular unit result in clinical presentations that range from subtle symptoms to acute respiratory failure. In most cases, the pathophysiologic mechanisms and characteristics of these disorders are well understood, which permits an organized approach to diagnosis and treatment based on the distribution and severity of the neuromuscular system affected.

The neuromuscular unit has four components: the anterior horn cells of the spinal cord, the spinal and peripheral nerves, the neuromuscular junctions, and the muscles. The level of the pathologic process determines associated signs and symptoms (Fig. 94.1 and Table 94.1). *Myelopathies* involve the spinal cord; *radiculopathies* involve the nerve roots as they leave the spinal cord; *neuropathies* involve the peripheral nerves; and *myopathies* involve the muscle. The use of physical signs to differentiate these disorders is discussed in Chapter 9.

Neuropathies involve the axon or the myelin sheath of the nerve. Nerve conduction studies can differentiate the locations of involvement. As the conduction along the axon is disrupted, the subsequent delay in transmission first causes symptoms in the muscles controlled by longer nerve axons, resulting in ascending weakness. Progression of the destruction or axonal degeneration causes a slowly progressive course of symptoms.

The neuromuscular junction comprises the presynaptic membrane, the postsynaptic membrane, the synaptic cleft, and the neurotransmitter acetylcholine (ACh), which carries the signal across the cleft between the two membranes. The neuromuscular junction features postsynaptic nicotinic ACh receptors, distinct from muscarinic ACh receptors that effect autonomic nervous system functions. Disorders of these postsynaptic nicotinic receptors produce weakness. Postsynaptic ACh receptors are continually turned over at a rate that is related to the amount of stimulation. A disorder of transmission often leads to an increase in the density of ACh receptors. Myasthenia gravis is the archetype of neuromuscular diseases.

CLINICAL FEATURES

History

Initial history of patients with complaints of weakness focuses on the acuity of the process and the potential for airway compromise. A complaint of difficulty in breathing or swallowing indicates possible bulbar or respiratory muscle compromise with the potential for life-threatening deterioration. As with other neurologic diseases, the anatomic distribution of symptoms can be the key to diagnosis. Neuromuscular diseases are often progressive or intermittent in nature, so a detailed history of the chronology of symptoms is important. Specific historical features, such as diarrhea (botulism), tick exposure (tick neurotoxin–mediated paralysis), or recurrent episodes of weakness over time (hereditary hypokalemic paralysis) may be helpful. Factors elicited during the history help to guide further history taking, targeted physical examination, and testing, as the differential diagnosis forms and is narrowed by the historical information the patient provides.

Physical Examination

The clinician should first assess adequacy of airway protection and ventilation before a more generalized examination evaluates for the degree of weakness and the location of the lesion. The presence of swallowing and a strong cough suggest that the patient has sufficient protective and ventilatory reserve. The muscles used to lift the head off the bed may weaken before those of respiration and should be assessed. A patient who is not yet intubated but is complaining of shortness of breath or difficulty in breathing should have frequent measurements of forced vital capacity (FVC). Normal FVC ranges from 60 to 70 mL/kg; when

the FVC reaches 15 mL/kg, ventilatory support is necessary. Maximal negative inspiratory force (NIF), also called a maximal inspiratory pressure (MIP), is an alternative to FVC. An NIF or MIP of less than 15 cm H_2O suggests the need for intubation. Neuromuscular disorders interfere with ventilation not oxygenation, so capnography is a better monitoring modality than pulse oximetry in these cases. Hypercarbia is a late finding and should be regarded as a sign of impending respiratory failure. A subnormal PCO_2 may also represent developing respiratory failure. As the patient's respiratory effort falls, tidal volume is reduced, and alveolar CO_2 is not exhaled sufficiently (hypopneic hypoventilation).

A systematic neurologic examination assesses the patient's mental status, cranial nerves, motor and sensory function, deep tendon reflexes, and coordination, including cerebellar function. The motor examination begins by determining whether the weakness is unilateral or bilateral and which muscle groups are involved. Key components of the examination include motor strength, muscle bulk, and presence of fasciculations. Box 94.1 provides the grading system used in motor strength assessment. Table 94.2 provides the findings used to distinguish upper motor neuron from lower motor neuron processes.

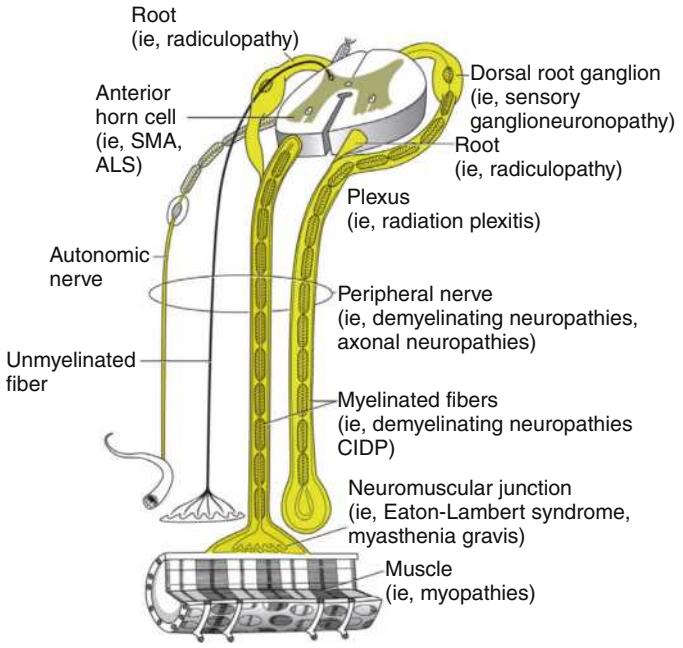

Fig. 94.1 The anatomic elements of the peripheral nervous system and related neurologic disorders. *ALS,* Amyotrophic lateral sclerosis; *CIDP,* chronic inflammatory demyelinating polyneuropathy; *SMA,* spinal muscular atrophy. DIFFERENTIAL DIAGNOSIS

Myelopathies

Myelopathies are spinal cord disorders that are manifested with signs of upper motor neuron dysfunction, such as muscle weakness with increased spinal reflexes, including an extensor plantar reflex (Babinski sign). There may be bladder and bowel involvement. When sensory findings are present, they often define the level of the lesion. The presence of back pain suggests a compressive lesion, such as a herniated intervertebral disk, tumor, or epidural hematoma. Concomitant systemic signs, such as a fever, or a history of intravenous (IV) drug use, can suggest an epidural abscess. Increasing postprocedural pain, for example following lumbar puncture, epidural anesthesia, or spine surgery, warrants consideration of an epidural hematoma. Acute, painless spinal cord lesions include transverse myelitis and spinal cord infarction.

Motor Neuron Disease

The characteristic findings of motor neuron disease combine signs of both upper and lower motor neuron dysfunction, including hyperreflexia, muscle wasting, and fasciculations. Pain is not a component of the clinical picture. Amyotrophic lateral sclerosis (ALS; Lou Gehrig disease) is the archetypal motor neuron disease.

BOX 94.1 Grading Score for Motor Strength

5 = Normal strength
4 = Weak but able to resist examiner
3 = Moves against gravity but unable to resist examiner
2 = Moves but unable to resist gravity
1 = Flicker but no movement
0 = No movement

TABLE 94.1 Clinical Characteristics of Neuromuscular Diseases

Disease	History	Strength	Deep Tendon Reflex	Sensation	Wasting
Myelopathy	Trauma, infection, cancer	Normal to decreased	Increased	Normal to decreased	No
Motor neuron disease (ALS)	Progressive difficulty swallowing, speaking, walking	Decreased	Increased	Normal	Yes
Neuropathy	Recent infection Ascending weakness	Normal or decreased Distal > proximal	Decreased	Decreased	Yes
Neuromuscular junction disease	Food (canned goods) Tick exposure Easy fatigability	Normal to fatigue	Normal	Normal	No
Myopathy	Thyroid disease Previous similar episodes	Decreased Proximal > distal	Normal	Normal	Yes

ALS, Amyotrophic lateral sclerosis.

TABLE 94.2 Distinguishing Upper Motor Neuron From Lower Motor Neuron Involvement

Motor Neuron	Deep Tendon Reflex	Muscle Tone	Atrophy	Fasciculations	Babinski Response
Upper motor neuron	Increased	Increased	No[a]	No	Present
Lower motor neuron	Decreased	Decreased	Yes	Yes	Absent

[a]Not significant but can occur.

Poliomyelitis affects the anterior horn cells and results in lower motor neuron disease without sensory involvement. The weakness is often asymmetric. Patients initially have a clinical picture similar to that of viral meningitis with fever and neck stiffness. The cerebrospinal fluid (CSF) analysis resembles that of viral meningitis. Polio has been eradicated in many parts of the world but remains prevalent in areas of conflict where public health systems have eroded.[1] The United States has seen an increase in acute flaccid myelitis (AFM), a paralyzing illness affecting pediatric patients that is described as "polio-like." AFM appears to have a temporal relationship with enteroviruses D68 and A71, but it is unclear if these viruses are the cause of the syndrome.[2]

Neuropathies

Weakness from a neuropathy is often noted first in distal muscles and then progresses centrally. Decreased grip strength and foot drop are common initial presentations. The differential diagnosis includes Guillain-Barré syndrome, toxic neuropathies, diabetic neuropathy, and tick paralysis (which is caused by inhibition of both nerve conduction and function of the neuromuscular junction). Neuropathies are discussed in Chapter 93.

Diseases of the Neuromuscular Junction

Disorders of the neuromuscular junction cause motor fatigability. The initial depolarization at the nerve end plate stimulates a maximum number of ACh receptors on the muscle cell, producing a normal or nearly normal strength response. Repeated stimulation leads to diminishing motor strength, which is caused by one of three mechanisms: blockage of the receptors, as in myasthenia gravis, decrease in the amount of ACh released, as in botulism, or inactivation of ACh by irreversible binding, as in organophosphate poisoning.

A decrease in the release of ACh can cause a combination of nicotinic and muscarinic effects. The clinical manifestations of this are anticholinergic findings, such as dilated pupils, confusion, urinary retention, tachycardia, low-grade fever, and dry, flushed skin. In the case of Lambert-Eaton myasthenic syndrome, weakness is more pronounced at the beginning of muscle use and improves with repeated use as more ACh builds up in the synaptic cleft with each stimulation. Muscle tone is generally diminished and sensation is preserved in diseases of the neuromuscular junction.

Myopathies
