Myopathies produce generalized, symmetric weakness. Reflexes are diminished, muscle tone is usually diminished, but sensation is preserved. Myopathies due to inflammatory disorders (polymyositis, dermatomyositis, polymyalgia rheumatica, and viral myositis) cause muscle pain and tenderness. Metabolic disorders affecting muscle strength (e.g., electrolyte and endocrine disorders) cause diffuse weakness without pain. Electrolyte alterations affecting muscular and cardiac function are discussed in Chapter 114.

DIAGNOSTIC TESTING

Serum electrolyte determination, with emphasis on potassium, calcium, and phosphorus concentrations, should be assessed in patients with acute weakness. An electrocardiogram (ECG) may provide an earlier clue to potassium or calcium disturbance. Thyroid function tests are recommended in cases of suspected myopathies. A creatine kinase (CK) level assesses for muscle inflammation, and if CK is markedly elevated, serial renal function studies should be obtained to assess for developing acute kidney injury.

Magnetic resonance imaging (MRI) is the preferred imaging modality for suspected cases of acute myelopathy caused by a compressive lesion. CSF analysis is indicated when Guillain-Barré syndrome or transverse myelitis is suspected.

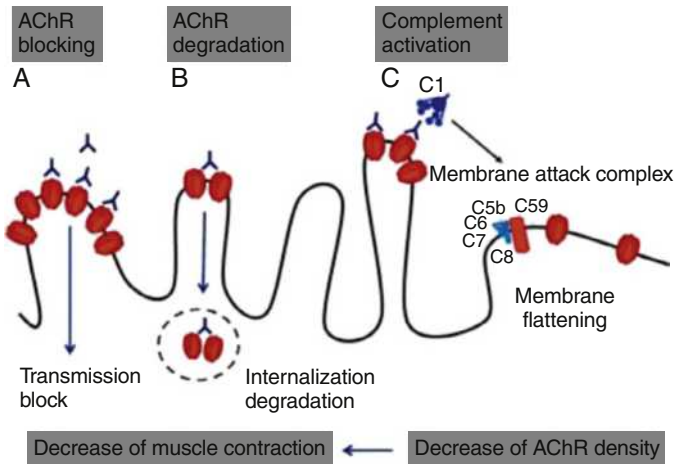

Fig. 94.2 Mechanisms of action of acetylcholine receptor *(AChR)* autoantibodies. Neuromuscular synapse in myasthenia gravis. AChR antibodies interfere with signal transduction by direct blocking of AChR (A), by cross-linking and increased degradation (B), or by immune-mediated destruction including complement activation (C). (From Sommer N, Tackenberg B, Hohlfeld R. The immunopathogenesis of myasthenia gravis. In Engel AG, ed. *Handbook of Clinical Neurology, volume 91, Neuromuscular Junction Disorders*. St Louis: Elsevier; 2008:169–212.)

DISORDERS OF THE NEUROMUSCULAR JUNCTION

Myasthenia Gravis

Principles

The age at onset of myasthenia gravis is influenced by gender; women are most commonly affected between 20 and 40 years old and men between 50 and 70 years old. Although new cases of myasthenia gravis are occasionally diagnosed in the emergency department (ED), it is much more common for patients with established disease to present with exacerbations of their disorder, often caused by precipitating factors.

In most patients with myasthenia gravis, weakness and fatigue result from circulating autoantibodies against the nicotinic ACh receptor on the junctional folds of the postsynaptic membrane. The effects are the result of several pathologic processes: direct blocking of the receptor, complement mediated destruction of the folds, and internalization and degradation of the receptors (Fig. 94.2). With

BOX 94.2 Drugs That May Exacerbate Myasthenia Gravis

- Cardiovascular
  - Beta-blockers
  - Calcium channel blockers
  - Quinidine
  - Lidocaine
  - Procainamide
- Antibiotics
  - Aminoglycosides
  - Tetracyclines
  - Clindamycin
  - Lincomycin
  - Polymyxin B
  - Tobramycin
  - Fluoroquinolones
  - Colistin
- Other
  - Phenytoin
  - Neuromuscular blockers
  - Corticosteroids
  - Thyroid replacement

repeated stimulation, fewer and fewer receptor sites are available for ACh binding, and fatigue develops. Fatigability and muscle weakness are the hallmarks of myasthenia gravis. Muscarinic receptors are also affected but to a much lesser extent, so muscular weakness is the dominant presentation of myasthenia gravis. Ocular muscle weakness is the first sign of myasthenia gravis in up to 40% of patients, although 85% of patients eventually have ocular involvement. When ptosis is present, it is often worse toward the end of the day. New-onset diplopia also may signal development of myasthenia gravis. Respiratory failure is rarely the initial symptom of myasthenia gravis. Bulbar muscles may be involved myasthenia gravis, producing dysarthria or dysphagia.[3] Facial and extremity muscles may also be involved, producing some classic symptoms of myasthenia gravis (i.e., difficulty in combing hair or brushing teeth, weakness of the muscles in the posterior neck causing a "dropped-head appearance," and a limited ability to form a full smile due to weakness of lateral facial muscles).

The prognosis for patients with myasthenia gravis has markedly improved in recent years due to the demonstrated benefit of thymectomy and the approval of the drug eculizumab for refractory cases.[4] Nevertheless, stable disease can be pushed to crisis by commonly used drugs that are known to exacerbate myasthenia gravis (Box 94.2). Even topical medications, such as tobramycin eye drops, can cause an exacerbation.[5] Assessing drug-disease interactions is a particularly important step when prescribing to patients with myasthenia gravis, even if the disease is well controlled.

Myasthenic crisis. *Myasthenic crisis* is defined as respiratory failure requiring mechanical ventilation. It occurs in 15% to 20% of patients with myasthenia gravis, usually within the first 2 years of disease onset. Although it is potentially life threatening, the mortality from this complication of myasthenia gravis has declined dramatically with appropriate care in the ED and intensive care unit (ICU) and the use of plasma exchange or immunomodulatory therapy with intravenous immune globulin (IVIG).

Crises are most often precipitated by underlying infection, aspiration, and medication changes, such as stopping anticholinergic medications or initiating a new medication that precipitates weakness. Other precipitants can be surgery and pregnancy (see Box 94.2).

Lambert-Eaton syndrome. Lambert-Eaton myasthenic syndrome is a rare disorder. Almost 50% of cases are associated with small cell carcinoma of the lung. Autoantibodies cause inadequate release of ACh from nerve terminals, affecting both nicotinic and muscarinic receptors. With repeated stimulation, the amount of ACh in the synaptic cleft increases, leading to a progressive increase in strength with muscle use, an effect opposite of that seen with myasthenia gravis. The classic syndrome includes weakness that improves with use of muscles, particularly proximal hip and shoulder muscles; hyporeflexia; and autonomic dysfunction, most commonly seen as dry mouth. Management focuses on treatment of the underlying cancer, although IVIG may be useful.

Diagnostic Testing

The diagnosis of new-onset myasthenia gravis is based on history, clinical findings, and a combination of serologic testing and electromyographic testing. In rare cases, the diagnosis is further clarified through bedside testing with the ice bag test (or, historically, the edrophonium test). Serum testing for ACh receptor antibodies is positive in 80% to 90% of patients with myasthenia gravis, but results are not available in the ED. Myasthenia gravis can be associated with a thymoma as a paraneoplastic syndrome. Initial evaluation of patients with newly diagnosed myasthenia gravis includes a contrast-enhanced computed tomography (CT) scan to evaluate for presence of a thymoma or other anterior mediastinal masses.

The edrophonium (Tensilon) test has an unacceptable number of false-positives and false-negatives and can cause serious adverse reactions through enhanced muscarinic effects of ACh. The test is rarely, if ever, indicated, and we do not recommend it.

The ice bag test can be performed at the bedside for patients with suspected myasthenia gravis and ptosis, whose diagnosis is otherwise uncertain. Cooling decreases symptoms in myasthenia gravis and heating exacerbates symptoms, so placing an ice bag to the eyelids can reduce ptosis. The degree of ptosis is measured before and after application of an ice bag. The distance from the upper to the lower eyelid in the most severely affected eye is measured first. An ice pack is applied to the affected eye for approximately 2 minutes. An improvement in the amount of ptosis of at least 2 mm is considered positive. The pooled sensitivity and specificity of the ice bag test for detecting ocular myasthenia are 0.94 and 0.97, respectively.

Management

The initial step in managing the myasthenic patient in crisis is stabilization of the airway and supporting ventilation. Respiratory failure ensues from muscle weakness, not inadequate oxygenation; therefore supplemental oxygenation does not address the problem, and mechanical ventilation is indicated. Endotracheal intubation may be necessary, but biphasic positive airway pressure (BiPAP) support may be sufficient if the patient is otherwise able to protect their airway. Capnometry monitoring can be useful in detecting respiratory fatigue well in advance of oxyhemoglobin desaturation and obvious clinical findings of respiratory distress.

Pyridostigmine, thymectomy, immunosuppressant drugs, steroids, rituximab, and eculizumab are all used for maintenance management of myasthenia gravis in the outpatient setting. The mainstays of ED myasthenic crisis management are plasma exchange or IVIG.

Plasma exchange, performed as multiple exchanges over 1 to 2 weeks, is effective in up to 95% of patients in acute myasthenic crisis and is generally considered the first line treatment for patients with severe myasthenic crisis.[5] IVIG is also effective for myasthenic crisis, usually given as 2 g/kg in divided doses over several days. Given the rarity of this condition, we recommend consultation with a neurologist with expertise in neuromuscular disease to aid in decision making between plasma exchange and IVIG and the initiation of either of these interventions. Patients treated by either IVIG and plasma exchange should also receive high-dose oral glucocorticoids, such as prednisone, 60 mg daily, beginning as soon as possible. High-dose steroids can worsen weakness, so they should be given only as a complement to plasma exchange or IVIG therapy, in consultation with a neurologist.

Ambulatory treatment of myasthenia gravis is often initiated using oral pyridostigmine, an acetylcholinesterase inhibitor. If the patient is newly diagnosed, or the patient's increased weakness is a result of discontinuation or dosage reduction of pyridostigmine, initiating or reestablishing treatment with pyridostigmine (60 to 120 mg by mouth every 4 to 6 hours) will prolong the presence and activity of ACh in the synaptic cleft and improve symptoms. Initiation or reestablishment of pyridostigmine therapy should be done in consultation with the outpatient physician from whom the patient will receive ongoing ambulatory management. The most common side effects of pyridostigmine are those of excessive cholinergic stimulation, such as increased airway secretions and increased bowel motility. These side effects can be treated with glycopyrrolate (1 mg with each dose of pyridostigmine), which preferentially blocks muscarinic cholinergic receptors that are responsible for these symptoms.

Cholinergic crisis, caused by excessive ACh activity related to acetylcholinesterase inhibitor therapy, is rarely seen, particularly with close management of pyridostigmine dosing. It may occur when patients deliberately or inadvertently take pyridostigmine in excess of the recommended dose. Cholinergic crisis is manifest by excessive cholinergic activity, which may include bradycardia, diarrhea and abdominal cramping, increased secretions, and muscle weakness, which might mimic a myasthenic crisis (Table 94.3).

Disposition

The decision to admit or to discharge a patient with myasthenia gravis from the ED is based on the potential for neuromuscular deterioration. Patients requiring plasma exchange or IVIG often require admission to ensure response to therapy and close monitoring for respiratory compromise. For some patients, a short stay in an observation unit under the care of a team comprising emergency medicine and neurology specialists will aid in evaluation of the patient's likelihood of successful outpatient treatment. Patients being admitted to the hospital should have an NIF or FVC measured to help determine the level of monitoring and care needed. These measurements need to be trended during the admission.

TABLE 94.3 Notable Differences Between Myasthenic Crisis and Cholinergic Crisis Pertaining to Myasthenia Gravis Patients

Myasthenic Crisis	Cholinergic Crisis
Generally minimal abdominal symptoms	Presence of abdominal pain, nausea and vomiting
Increased HR and BP	Decreased heart rate and blood pressure
Normal secretions	Increased secretions
Mydriasis	Miosis
Caused by undermedication of myasthenia gravis treatment	Caused by overmedication of myasthenia gravis treatment
Treat with cholinergic agent (edrophonoium)	Treat with anticholinergic agent (atropine)

Botulism

Principles

Botulism is a toxin-mediated illness that can cause weakness leading to respiratory insufficiency. In 2017, the Centers for Disease Control and Prevention (CDC) reported 182 cases of botulism in the United States: 10% food-borne, 77% infant botulism, 10% wound botulism, and 3% unknown etiology.[6] *Clostridium botulinum* is an anaerobic, spore-forming bacterium. Three of eight known toxins produced by *C. botulinum* (types A, B, and E) cause human disease. Recent outbreaks have been traced to home canned peas in New York[7] and whale flipper in Alaska.[8]

Clinical Features

The botulinum toxin blocks both voluntary motor and autonomic functions. There is no pain or sensory deficit. The onset of symptoms is 6 to 48 hours after the ingestion of toxin. Symptoms of gastroenteritis may or may not be present. The classic feature of botulism is a descending, symmetric, flaccid paralysis. Cranial nerves and bulbar muscles are affected first, causing diplopia, dysarthria, and dysphagia, followed later by generalized weakness. Because the toxin decreases cholinergic output, anticholinergic signs may be present: constipation, urinary retention, dry skin and eyes, and increased temperature and dilated, nonreactive pupils. This can help to differentiate botulism toxicity from myasthenia gravis. Deep tendon reflexes are normal or diminished.

Infantile botulism results from the ingestion of *C. botulinum* spores that are able to germinate and produce toxin in the high pH of the gastrointestinal tract of infants. Botulism spores can survive in honey, so it is recommended that honey not be fed to infants. The clinical presentation includes constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be included in the differential diagnosis of the floppy infant.

Wound botulism is a rare presentation of botulism stemming from the colonization of a wound or other skin lesion by *C. botulinum* spores, which are then able to produce toxin that can travel through the bloodstream to cause systemic effects. Wound botulism is generally seen in IV drug users, classically in users of "black tar" heroin. In addition to causing the classic symptoms of botulism as described earlier, wound botulism tends to present with fever and lesser gastrointestinal manifestations.

Diagnostic Testing

The diagnosis of botulism is made by both clinical findings and exclusion of other processes. The toxin can be identified in serum and stool, but the assay is not commonly available in most hospitals and requires a prolonged turnaround time. If the suspected food source is available, it should also be tested for the toxin. Wound cultures should be sent in anaerobic transport medium for patients with suspected wound botulism.

Management

Treatment is initially focused on stabilization of the airway and supportive measures. In 2010, the CDC announced a new equine heptavalent

botulinum antitoxin (HBAT) that is now the only antitoxin available in the United States for noninfant botulism.[9] For suspected cases and to obtain HBAT, clinicians should contact their state health departments. The CDC also maintains a 24-hour botulism duty officer at the CDC Emergency Operations Center (770-488-7100). An IV human-derived botulism immune globulin (BabyBIG) has been developed for treatment of infantile botulism and is available 24 hours/7 days through the California Department of Public Health Infant Botulism Treatment and Prevention Program on-call physician at 510-231-7600. Wound botulism patients should have emergent surgical consultation for débridement of the wound. Tetanus toxoid is administered unless previously received within the past 5 years. In addition, antibiotic coverage is recommended. Penicillin G 3 million units every 4 hours and metronidazole 500 mg every 8 hours intravenously provide effective coverage against *C. botulinum*. Aminoglycosides, tetracyclines, and polymixins are not recommended because they can potentially worsen neuromuscular blockade. The duration of treatment is generally 7 to 10 days but may need to be extended based on the severity of disease. We recommend infectious disease consultation for this rare disorder.

Disposition

All patients being treated for botulism need to be hospitalized, and most will be admitted to an ICU setting given the likelihood of progression of neuromuscular weakness. Infants and children will need to be transferred to the most appropriate neonatal intensive care unit (NICU) or pediatric intensive care unit (PICU) setting.

Tick Paralysis

Principles

This extraordinarily rare cause of an acute, ascending, flaccid paralysis is most often found in North America (Rocky Mountain region, US Pacific Northwest, and Southwestern Canada) and the east coast of Australia. Although the pathogenesis of tick paralysis is not fully understood, it is thought that a salivary neurotoxin is injected while the female tick feeds. The toxin functions like botulinum toxin to decrease the release of ACh from the presynaptic membrane of the neuromuscular junction.[10]

Clinical Features

Tick paralysis causes an acute, ascending, flaccid motor paralysis that can be confused with Guillain-Barré syndrome, botulism, and myasthenia gravis. Symptoms usually begin 1 to 2 days after the female tick has attached and begun to feed, although delays of up to 6 days have been reported. There may be associated ocular signs, such as fixed and dilated pupils, that can help to distinguish it from Guillain-Barré syndrome.

Management

The management is supportive care and tick removal. A tick can be removed by use of forceps to grasp it as closely as possible to the point of attachment. Care should be taken not to leave mouth parts in the patient's tissue. Injecting a small amount of lidocaine with epinephrine just below the tick facilitates removal by starving the animal of blood supply and encouraging it to release. Although symptoms may resolve rapidly after removal of the tick, supportive measures such as intubation should not be withheld pending resolution of symptoms. Although there is little new research on the topic, there are many reports of cases misdiagnosed as other causes of weakness (e.g., Guillain-Barré syndrome, acute inflammatory demyelinating polyneuropathy) until the offending tick was found and removed.

Disposition

These patients may begin to show improvement upon removal of the tick and may be able to be discharged from the ED. If symptoms are slow to resolve, the patient is admitted to an observation unit.

DISORDERS OF THE MUSCLES

Newly acquired weakness originating at the muscle level can be divided into two types: inflammatory and toxic-metabolic. Inflammatory disorders usually produce pain and tenderness, whereas metabolic disorders do not.

Inflammatory Disorders

Principles

The most common inflammatory myopathies are polymyositis and dermatomyositis. Polymyositis may be idiopathic in nature, occur secondary to infections (viral or bacterial), or be seen in conjunction with other disorders, such as sarcoidosis and hypereosinophilic syndromes. Inflammatory myopathies cause weakness, pain, and tenderness of the muscles involved.

Clinical Features

Dermatomyositis and polymyositis can occur at any age, although adults are more often affected than children. They can be associated with various malignant neoplasms, such as of the breast, ovary, lung, and gastrointestinal tract, and lymphoproliferative disorders. Proximal muscle weakness predominates and leads to complaints of difficulty in rising from a seated position or climbing stairs and weakness in lifting the arms over the head. There is often pain and tenderness in these proximal muscles as well. There is a decrease in reflexes proportionate to the decrease in strength. Fasciculations are not seen, and atrophy is a very late finding. Inclusion body myositis, another type inflammatory myositis, has a similar presentation to polymyositis but presents more gradually and with predominantly distal muscle weakness that extends to proximal muscle weakness with progression of disease.

Dermatomyositis is similar to polymyositis, but it is also associated with classic skin findings. These are more prominent in childhood but are also found in adults. They include a periorbital heliotrope rash and erythema and swelling of the extensor surfaces of joints. The heliotrope rash is usually photosensitive and may also involve the exposed areas of the chest and neck.

Diagnostic Testing

The diagnosis of an inflammatory myopathy requires exclusion of electrolyte abnormalities. Serum CK level is interpreted in light of the entire clinical picture; an elevated CK level does not establish the cause of weakness as a myopathy because some neuropathies can also produce an elevated CK level. Similarly, a normal CK level does not rule out a myopathy as the cause of weakness. Electromyography and muscle biopsy are used to confirm the diagnosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often normal or only mildly elevated, thus they have no role in diagnosis or prognosis. Aldolase and other specific myositis autoantibodies should be considered after consultation with a neurologist or rheumatologist.

Management

Inflammatory myositis syndromes are usually managed with oral prednisone in a dose of 1 to 2 mg/kg/day. When steroids prove ineffective and during acute exacerbations, cytotoxic drugs such as azathioprine (initial dose of 50 mg/day) and methotrexate (initial dose of 15 mg/week) are added. Fortunately, the degree of rhabdomyolysis seen with the inflammatory myopathies is not sufficient to cause renal impairment.

Disposition

The majority of these patients will likely be discharged, some following an observation period. Hospitalization should be considered for

patients with comorbidities, elders, and those who do not improve with treatment in the ED or observation unit.

Metabolic Disorders

Acute, generalized muscle weakness is seen with a number of severe electrolyte abnormalities of any cause: hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, and hypophosphatemia. (See Chapter 114.) Acute painless myopathies are also seen with endocrine disorders involving the thyroid, parathyroid, or adrenal glands (see Chapter 117).

There are several disorders referred to collectively as the *periodic paralyses,* which include periodic paralysis of the hyperkalemic and hypokalemic forms and thyrotoxic periodic paralysis, which is similar to hypokalemic periodic paralysis except that it is associated with hyperthyroidism.

Periodic Paralysis

Principles. Periodic paralysis of the hypokalemic and hyperkalemic forms is a rare hereditary disorder of ion channels resulting in intermittent attacks of flaccid extremity weakness, which can be mild to moderate or sufficiently severe that the patient goes to the ground and cannot get up. The hypokalemic form is more common. Periodic paralysis is most often associated with an inherited genetic mutation. Patients usually report a personal and family history of similar episodes. Thyrotoxic periodic paralysis is an acquired rather than inherited form of hypokalemic periodic paralysis.

The clinical picture of thyrotoxic periodic paralysis is almost identical to that of periodic paralysis, and indeed a small number of patients with hypokalemic periodic paralysis have hyperthyroidism. In thyrotoxic periodic paralysis, symptoms related to hyperthyroidism are often present at the same time the patient has weakness. The relation of the hyperthyroidism to hypokalemia is probably due to increased sodium-potassium adenosine triphosphatase (Na^+/K^+-ATPase) pump, which causes a rapid shift of potassium from the extracellular into the intracellular compartment. There is probably a genetic predisposition to this form of periodic paralysis, although it may be due to different genes in different patient populations.[11] Patients with a first episode of hypokalemic paralysis should undergo thyroid function testing.

Clinical features. Patients may suffer either isolated or recurrent episodes of flaccid paralysis. The lower limbs are involved more often than the upper, although both can be affected. Bulbar, ocular, and respiratory muscles are usually not involved. Onset is rapid often following a high oral carbohydrate intake (with subsequent insulin rise) and a period of rest. This reflects the intracellular shift of potassium rather than the total body depletion of potassium. A typical complaint is acute weakness noted on waking in the morning after a large meal.

Diagnostic testing. The ECG may demonstrate signs of hyperkalemia or hypokalemia. ECG findings of hyperkalemia include peaked T waves, prolongation of the PR interval and QRS complex, loss of P waves, and finally a sinusoidal pattern and asystole in severe cases. ECG findings of hypokalemia include flattening and inversion of T waves, prolongation of the QT interval, presence of a U wave and ectopic beats, and ventricular arrhythmias in severe cases. An immediate serum potassium level should be obtained; in the hypokalemic form, the potassium level during an attack falls to values well below 3.0 mEq/L. Magnesium and glucose levels should also be measured.

Management. Many cases resolve spontaneously with supportive care alone. The mainstay of management is the treatment of the underlying electrolyte imbalance, with awareness that the changes in potassium concentration in patients with periodic paralysis are not due to depletion or excess of potassium but rather intracellular and extracellular shifts (i.e., in the hypokalemic state, the total body potassium is not reduced but has shifted intracellularly). Thus, in the repletion of potassium, caution is necessary to prevent overtreatment. For this reason, we recommend that IV potassium be given sparingly at one or two 10-mEq IV doses of potassium chloride, each over 1 hour. This can be done in parallel with 40-mEq oral potassium repletion and retesting of serum potassium levels. IV hydration helps to redistribute the body's potassium stores; magnesium supplementation is not necessary. In the hyperkalemic state, glucose, insulin, and albuterol may be used to promote intracellular shifting of potassium. Treatment of the hyperthyroid symptoms in thyrotoxic periodic paralysis, such as tachycardia, may help the paralysis as well. Counseling should also be provided to the patient to avoid triggers. These include avoidance of sudden, high-intensity exercise followed by resting, excessive dietary potassium, and alcohol.

Disposition. In the past, most cases of periodic paralysis required an inpatient stay, but most patients can be managed in less than 24 hours in an observation unit. Admission may be necessary for patients with their first episode of periodic paralysis in the context of thyrotoxicosis.

CHAPTER 94: QUESTIONS AND ANSWERS

1. Which of the following is not found in a neuromuscular junction?
- **a.** Myelin sheaths
- **b.** Presynaptic receptors
- **c.** Postsynaptic receptors
- **d.** The synaptic cleft
- **e.** Acetylcholine

Answer: a. The neuromuscular junction is an important unit in regulating muscle function. It consists of both presynaptic and postsynaptic receptors that release and receive the neurotransmitter acetylcholine as it travels through the synaptic cleft. Myelin sheaths are important in quickening the transmission of signals along an axon but do not extend all the way to the neuromuscular junction.

2. Which of these features in a patient's history suggest a diagnosis of myasthenia gravis?
- **a.** History of small cell lung carcinoma
- **b.** Worsening of symptoms following a large meal
- **c.** Ascending paralysis
- **d.** An erythematous periorbital rash
- **e.** Improvement of symptoms following plasma exchange

Answer: e. Myasthenia gravis, along with several other neuromuscular disorders, can be treated with plasma exchange. History of small cell lung carcinoma is associated with Lambert-Eaton syndrome. Ascending paralysis is seen more commonly in Guillain-Barré syndrome and tick paralysis. An erythematous periorbital, or heliotrope, rash is seen in dermatomyositis.

3. A 40-year-old female patient with a history of myasthenia gravis presents to the emergency department with mild shortness of breath upon exertion. You are concerned for an impending myasthenic crisis. Which of the following patient factors would most suggest this diagnosis?
- **a.** Bilateral ptosis
- **b.** Inability to tolerate secretions
- **c.** A forced vital capacity (FVC) of 65 mL/kg
- **d.** A negative inspiratory force (NIF) of 40 cm H_2O
- **e.** Recent initiation of a new medication for hypertension

Answer: b. Myasthenic crisis is an emergent, life-threatening exacerbation of myasthenia gravis that involves acute weakness of the muscles of the respiratory system. Detecting signs of impending myasthenic crisis and differentiating this from a regular exacerbation of myasthenia gravis is crucial for emergency medicine providers. Pulmonary function tests, such as forced vital capacity (FVC) and negative inspiratory force (NIF) can suggest impending crisis, but these tests should not be the sole factors to consider. Physical exam findings of significant muscle weakness or respiratory distress are the most concerning signs for impending myasthenic crisis. Bilateral ptosis is a sign of acute myasthenia but, by itself, likely does not indicate a significant exacerbation. Inability of the patient to tolerate oral secretions, on the other hand, is a much more concerning exam finding and implies significant muscle weakness and impending crisis.

4. The previous patient continues to have worsening respiratory symptoms. Both neurology and critical care teams are consulted and are at bedside. The patient is started on pyridostigmine. Which of the following findings would indicate worsening myasthenic crises as opposed to overtreatment with pyridostigmine?
- **a.** An electrocardiogram showing a heart rate of 35
- **b.** Pupil size of 7 mm bilaterally
- **c.** Increasing respiratory fatigue
- **d.** Significant abdominal discomfort
- **e.** Excessive sweating

Answer: b. When treating myasthenia gravis, worsening of the patient's condition can be caused by worsening myasthenic crisis or by cholinergic crisis from overtreatment of the patient with anticholinergic agents. These two conditions can present similarly but have different causes and thus different treatments. Worsening myasthenic crisis occurs from undertreatment of the initial crisis by anticholinergic agents where cholinergic crisis occurs from overtreatment of the initial crisis. Patients in cholinergic crisis tend to present with bradycardia, abdominal pain, and increased secretions. In both cholinergic crises and myasthenic crises, increased weakness and respiratory distress can be present. However, mydriasis is much more likely to be seen in myasthenic crisis.

5. An 8-month-old infant presents to the emergency department with increasing weakness and poor feeding. Physical exam reveals an ill-appearing infant with decreased muscle tone. What is the most DEFINITIVE treatment?
- **a.** Administration of antibiotics against *Clostridium* species
- **b.** Administration of corticosteroids
- **c.** Contacting the Centers for Disease Control and Prevention (CDC) for antitoxin
- **d.** Contacting the California Department of Health for antitoxin
- **e.** Serum and stool testing for botulinum toxin

Answer: d. This patient likely has infantile botulism and the definitive treatment is obtaining IV human-derived botulism immunoglobulin, or BabyBIG, from the California Department of Health. The CDC has a heptavalent botulinum toxin for noninfantile cases. IV corticosteroids

CHAPTER 94: QUESTIONS AND ANSWERS—cont'd.

and antibiotics are not recommended for cases of infantile botulism. Serum and stool testing can diagnose botulism but often have a prolonged turnaround time and so are not useful in emergency department management.

6. Which of the following is TRUE about wound botulism?
- **a.** It is the most common form of botulism.
- **b.** Antibiotics do not have a role in wound botulism management.
- **c.** Compared with other forms of botulism, wound botulism patients more often have abdominal complaints.
- **d.** It is associated with enteroviruses.
- **e.** It is associated with topical tobramycin treatment.

Answer: c. Wound botulism is caused by infection of a wound with *Clostridium botulinum* which then causes systemic infection via hematogenous spread. It is an infrequent presentation of *C. botulinum* infection; infantile botulism is the most common form of botulism. Antibiotics as well as surgical consultation are first line in treatment. Patients with wound botulism often present with fever and less often present with abdominal symptoms compared with other forms of botulism. Enteroviruses are not associated with botulism but are associated with acute flaccid myelitis (AFM). Tobramycin treatment can be a trigger for acute myasthenia gravis but not for wound botulism.

7. A patient presents with an episode of flaccid lower extremity paralysis. He notes that he frequently gets these episodes and the condition runs in his family. His serum potassium concentration is 5.9 mEq/L. What is the next best treatment step?
- **a.** Intravenous (IV) immunoglobulin
- **b.** IV hydration
- **c.** Thyroid function testing
- **d.** Magnesium supplementation
- **e.** High-dose insulin and dextrose

Answer: b. This patient likely is having an episode of hyperkalemic periodic paralysis. Hyperkalemic periodic paralysis is due to an imbalance in the distribution of potassium at a cellular level. IV hydration helps to rebalance the body's potassium stores. Testing of thyroid function and high-dose insulin therapy may be indicated but are not the immediate next steps. IV immunoglobulin and magnesium supplementation are not indicated in this case.

8. An 8-year-old patient presents to the emergency department with diffuse weakness and myalgias. His parents note that he recently had a muscle biopsy which confirmed an unspecified illness. You also note a rash on the patient's chest. What would you likely find on the patient's physical exam?
- **a.** Difficulty in sitting upright from a supine position
- **b.** Difficulty in holding a pencil or pen
- **c.** Fasciculations of proximal muscle groups
- **d.** Atrophy of proximal muscle groups
- **e.** Increase responsiveness of the patellar reflex

Answer: a. This patient likely has dermatomyositis. Dermatomyositis is an inflammatory myopathy that most commonly affects the proximal muscle groups and spares the distal muscle groups. This patient likely would have trouble sitting up as it uses the proximal hip flexor muscles. Distal muscles, such as those in the hand, are less commonly affected. Fasciculations are not commonly seen. Atrophy is generally a much later finding in inflammatory myopathies. Patients also tend to present with decreased patellar reflexes.

9. Which of the following pairs is correct regarding a neuromuscular disease and its pathophysiology?
- **a.** Botulism—concomitant gastroenteritis is almost always present
- **b.** Myasthenia gravis—autoantibodies attack postsynaptic acetylcholine (ACh) receptors
- **c.** Periodic paralysis—hyperkalemic form is most common
- **d.** Polymyositis—distal muscle weakness precedes proximal muscle weakness
- **e.** Tick paralysis—symptoms resolve quickly after the tick is removed

Answer: b. Myasthenia gravis is caused by autoantibodies that attack postsynaptic ACh receptors at the neuromuscular junction. Botulism usually does not present with gastroenteritis. Periodic paralysis is most commonly associated with hypokalemia. Polymyositis usually presents first in proximal muscles. Tick paralysis may take days to weeks to resolve after removal of an offending tick.

Central Nervous System Infections

Benjamin H. Schnapp and Corlin Jewell

KEY CONCEPTS

- CNS infection should be considered in all patients with headache, nuchal rigidity, fever, altered sensorium, or diffuse or focal neurologic findings.
- Patients with suspected CNS infection should be asked about history focused on risk factors for CNS disease and infection and receive a full neurologic examination.
- CSF testing is the most reliable method of assessing the presence of meningitis and should be obtained in all patients in which there is a suspicion for CNS infection.
- Early initiation of empirical antimicrobial therapy is recommended in cases of suspected acute CNS infection. This should occur before imaging or lumbar puncture.
- Patients without focal neurologic symptoms, altered level of consciousness or signs of increased intracranial pressure do not require imaging prior to lumbar puncture.
- We recommend steroid treatment before or alongside treatment with antibiotics in all cases of suspected meningoencephalitis.
- First-line treatment for healthy adults with suspected bacterial meningitis is ceftriaxone or cefotaxime plus vancomycin in most countries given high antibiotic resistance.
- Acyclovir is recommended for patients with suspected encephalitis because HSV is a common pathogen.
- Clinical course and risk factors, such as immunosuppression, dictate the need to test and treat for fungal and tuberculous meningoencephalitis.
- In the absence of a clear clinical picture of viral meningitis, patients should generally be empirically covered for bacterial meningitis and admitted to the hospital.
- Antibiotic chemoprophylaxis should be given for close contacts of patients with meningitis resulting from *N. meningitidis* and contacts of patients with *H. influenzae* living with immunocompromised or unvaccinated individuals.
- CT or MRI can be used in patients with a suspected brain abscess.
- MRI with gadolinium contrast of the entire spine is the definitive imaging test for patients with suspected spinal epidural abscess.

FOUNDATIONS

Background and Pathophysiology

The etiology of CNS infections continues to change as a result of new therapeutic interventions, vaccines, and the growing number of immunosuppressed patients. Despite advances, however, the morbidity and mortality from a CNS infection remains high; good outcomes can be maximized with early recognition and treatment.

The two most common CNS infections, *meningitis* and *encephalitis,* are delineated by the tissue that is infected. Meningitis refers to an infection of the meningeal layers lying between the bony covering of the CNS and the brain tissue. If the infection is present in the brain parenchyma itself, then it is termed encephalitis. However, these disease states are not mutually exclusive and exist on a continuum of *meningoencephalitis*. Generally, greater degrees of encephalitis portend a worse prognosis, as more tissue is involved.

Bacterial Meningitis

Bacterial meningitis has a high mortality rate despite treatment, with rates variable depending on the organism, time to appropriate treatment, and patient factors. *Streptococcus pneumoniae* remains the predominant pathogen in adult patients, accounting for over half of cases despite a recent decline in incidence.[1] Other common causes in adults include *Neisseria meningitidis, Haemophilus influenzae*, and *Listeria monocytogenes. N. meningitidis* is the predominant organism in children. *Listeria* is more commonly seen in elderly adults and infants. In the first six weeks of life, Group B streptococcus species as well as *Escherichia coli* also represent common causes of bacterial meningitis. Bacterial meningitis caused by *H. influenzae* was previously responsible for a much larger proportion of cases, but the incidence has declined sharply since the introduction of the vaccine for type B (HiB).

Meningococcal disease refers to meningitis caused by *N. meningitidis,* and is most common in younger individuals, particularly those living in very close proximity to others such as in military barracks or college dormitories. A, B, and C represent the major groups. Group B is particularly prevalent in Europe, while group C is commonly isolated in the United States. A conjugate vaccine containing serogroups A, C, Y, and W-135 has been developed, as well as a separate vaccine for serogroup B. These vaccines are highly effective in children, but have yet to be broadly distributed to developing countries.

The infection process in bacterial meningitis generally begins with nasopharyngeal colonization and invasion of the mucosa. The varying capsular properties of each organism protect the bacteria. Once bacteria cross the blood-brain barrier to enter the CSF, host defense mechanisms within the CSF are often ineffective. Bacteria then proliferate, which causes the body to signal for leukocytes to enter the CSF. Meningeal and subarachnoid space inflammation is associated with the release of cytokines into the CSF, inciting an inflammatory cascade that promotes increased permeability of the blood-brain barrier, cerebral vasculitis, edema, and increased intracranial pressure (ICP). A subsequent decrease in cerebral blood flow can then lead to cerebral hypoxia.

Meningeal infection may also occur in association with a dural leak secondary to neurosurgery or trauma to the CNS. Skin flora, including coagulase-negative staphylococcus species, *Staphylococcus aureus,* and *Cutibacterium acnes* are seen most commonly in this population, though infections caused by *Pseudomonas aeruginosa* also occur.

Mortality from bacterial meningitis is highest in patients with advanced presentations, serious underlying disease or advanced age. The fatality rate is highest with *Listeria* meningitis with a mortality rate

up to 27%.[2] Overall, many survivors have some degree of residual neurologic deficit, with the highest rates found in those with pneumococcal meningitis.[3]

Meningitis from Lyme disease (*Borrelia burgdorferi*) presents similarly to other causes of bacterial meningitis, but can also cause other neurologic symptoms, including facial palsies and radiculopathies. Late Lyme infection, occurring in some cases years after initial infection, can cause encephalopathy which can manifest as migraines, psychosis, and somatoform disorders.

Viral Meningitis

Given the decrease in the incidence of bacterial meningitis, largely secondary to vaccination efforts, viral infections are now the most common cause of meningitis. Enteroviruses and herpesviruses are the most common causes,[4] often occurring in those with risk factors such as a suppressed immune system. The overall prognosis for the majority of cases of viral meningitis is excellent.

Viral Encephalitis

The same organisms responsible for viral meningitis may also be associated with encephalitis. A common mechanism of viral transmission is through the skin via insect vectors (e.g., Zika virus or West Nile virus), although clinical disease develops in only a small percentage of the people bitten. Tick-borne viral encephalitis is endemic to parts of Europe and Russia and is an important consideration for residents and recent travelers to those regions; a vaccine is available. Transmission of viral encephalitis often occurs by hematogenous spread from infections of the respiratory, gastrointestinal, or urogenital tracts. Other mechanisms include retrograde transmission along neuronal axons, as seen in the herpes virus, and direct invasion of the subarachnoid space after infection of the olfactory submucosa, as seen in rabies or herpes.

The outcomes in viral encephalitis, including permanent neurologic sequelae, are dependent on both the host and the infecting agent. Acyclovir treatment has reduced the mortality from HSV encephalitis from up to 70% down to 9%, but with 34% of surviving patients having moderate to severe neurologic disability.[5] Common complications include seizures, motor deficits, and impaired cognition. Encephalitis caused by Japanese encephalitis virus, Eastern equine virus, and St. Louis encephalitis virus is severe, with high mortality rates and high rates of neurologic sequelae among survivors. West Nile virus produces encephalitis in less than 1% of those infected but has resulted in 2000 deaths in the United States as of 2016.[6] Western equine virus and California encephalitis virus cause milder infections, and death is rare. Zika virus has been associated with the development of Guillain-Barré syndrome (GBS) as well as severe encephalitis in developing fetuses of infected mothers, resulting in devastating neurologic defects. It is not entirely clear if the virus also causes neuroinvasive disease in adults. Powassan virus, another tick-borne cause of CNS infection in North America, is known to cause severe encephalitis with a mortality of approximately 10% and a high rate of neurologic disability in survivors. CMV can also cause encephalitis, particularly in patients who are infected with HIV or are otherwise immunocompromised. Influenza virus, well-known for its respiratory effects, is another rare cause of high-mortality encephalitis in adults. Encephalitis secondary to measles and mumps has almost disappeared in the developed world due to widespread vaccination, but still can occur, particularly in those who are immunocompromised. Primary measles encephalitis is typically self-limited but carries a mortality of approximately 10% to 15%. Patients with this disease can go on to develop both subacute and chronic encephalitis (sometimes occurring years later) which is universally fatal.

Tuberculous Meningitis

Mycobacteria typically gain access to the CNS via hematogenous spread, and once present will begin to form granulomas. These can rupture, inciting an inflammatory response from the host. This can have the side effect of causing vasculitis and potentially a stroke. Tuberculous meningitis is also frequently complicated by hydrocephalus requiring neurosurgical intervention; in advanced disease, up to 25% of patients may require some neurosurgical procedure for obstruction (ventriculoperitoneal shunt or drainage). Tuberculous meningitis leads to severe disability or death in roughly half of the cases, and, as with bacterial meningitis, depends on the patient's age, comorbidities, time to diagnosis, and the progression of their disease.

Fungal Meningitis

CNS infections caused by fungal species are most commonly caused by *Cryptococcus* (typically *C. neoformans* and *C. gattii*) and have been increasing in recent years. Other common causes of fungal meningitis include *Aspergillus* species and *Coccidioides immitis.* Diabetic patients are at high risk of developing cerebral mucormycosis via direct invasion of the sinuses, and CNS invasion by *Histoplasma capsulatum* is also commonly seen in AIDS patients.

Over a million cases of fungal CNS infections are estimated to occur annually, likely via similar mechanisms as bacterial meningitis. Because these infections typically affect those with compromised immune systems, this increase is likely secondary to an increasing number of people living with iatrogenic chronic immunosuppression and HIV infection. Pulmonary exposure, followed by hematogenous spread, is the primary pathogenic mechanism in most cases of cryptococcal meningitis. Infection with *C. neoformans* is considered an acquired immunodeficiency syndrome (AIDS)-defining illness but can occur in those with immunocompromised states arising from other causes. Infection with *C. gatti* can occur even in immunocompetent patients. *Candida* species are also a major cause of fungal meningitis. These infections typically occur in those with candidemia or via the implantation of neurosurgical hardware (such as CNS shunts).

Common CNS complications of fungal meningitis include abscesses, increased ICP, neurologic deficits, seizures, bone invasion, fluid collections, and ocular abnormalities (seen in up to 40% of patients with cryptococcal meningitis). The mortality rate of fungal meningoencephalitis is usually around 20% to 30%, but may be up to 97% in untreated *Candida* meningitis, and varies with the severity of illness, timeliness of diagnosis, and administration of appropriate treatment.

Central Nervous System Abscess

CNS abscesses occur due to both local contiguous invasion as well as hematogenous spread from remote infections. They are also associated with intravenous (IV) drug use, neurologic surgery, and cranial trauma. In cases of contiguous spread, the location of the abscess within the brain is typically dictated by the source of invasive infection or the surgical procedure (Fig. 95.1). Brain abscesses secondary to otitis media are most often found within the temporal lobe or cerebellum, whereas cases arising from sinusitis usually result in abscesses in the frontal or temporal lobes. Hematogenous spread of microorganisms (most commonly from the pulmonary system) often results in multiple brain abscesses, although solitary lesions may also occur. Rarely, patients present without a clear source or the presence of risk factors. Antibiotic prophylaxis in the immunosuppressed, improved diagnostic imaging, and neurosurgical interventions have all contributed to more favorable outcomes.[7]

The spinal epidural space also represents a common site of CNS abscesses. Increasing numbers of spinal surgeries, immunosuppressed

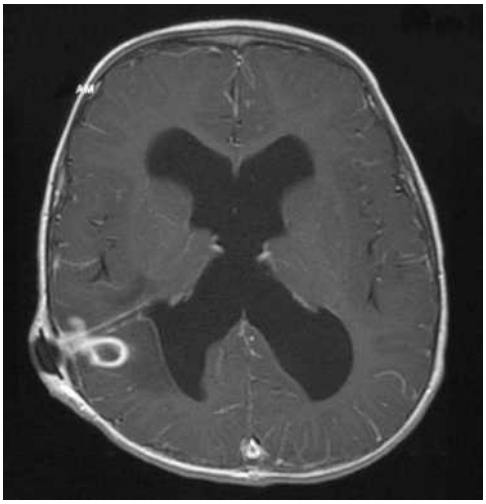

Fig. 95.1 A brain abscess which has developed adjacent to the site of a CSF shunt, as seen on MRI. CNS abscesses commonly develop adjacent to surgical sites, as this is one way bacteria can bypass the blood-brain barrier.

patients, and high rates of intravenous drug use are contributing factors to an increase in the incidence of these abscesses, which are associated with high rates of permanent neurologic morbidity. Infection typically enters the epidural space via the blood but can also arise from contiguous spread from nearby infections (e.g., psoas abscess, vertebral osteomyelitis).

CLINICAL FEATURES

Meningitis

The clinical picture of bacterial and viral meningitis is classically defined by fever, headache, photophobia, and nuchal rigidity. Unfortunately, subtle presentations lacking these classic features are common. In immunosuppressed or geriatric patients, alteration in mental status may be the only finding, and therefore requires a lower threshold for ruling out meningitis in these special populations. Clinical presentations in neonates may include a bulging fontanelle, but are often subtle, such as changes in behavior, decreased tone, or weakness as noticed by parents; consequently, guidelines universally recommend a lumbar puncture as part of the evaluation of a neonate with a suspected infection.

The physical findings in meningitis are variable depending on patient factors (e.g., age, comorbidities), pathogen, and time course of the disease (early vs. late). Two classic exam maneuvers, the Kernig sign (inability to straighten leg to a position of full knee extension when patient is lying supine with hip flexed to a right angle) and Brudzinski sign (attempts to flex the neck passively are accompanied by flexion of the hips), have a low sensitivity of less than 12%; however, they have a high specificity and strongly suggest meningitis if they are present (Table 95.1).[1]

Patients with suspected meningitis should first be examined for evidence of a structural lesion precipitating their symptoms, as these patients may require CT imaging to rule out other causes of their symptoms. Signs of mass lesions can include papilledema, decreased venous pulsations, new-onset seizures, abnormal level of consciousness, or focal neurologic deficits. An accurate fundoscopic exam can be challenging to obtain and bedside ultrasound offers an alternative tool for assessing intracranial pressure.[8] Patients without abnormal findings on neurologic examination may proceed to lumbar puncture without CT.[9]

Because meningitis can result from both contiguous and hematogenous spread, the physical examination should include a search for an inciting infection, such as a skin abscess, sinusitis, endocarditis, or osteomyelitis. Manifestations of endocarditis may be present, particularly in cases found to be due to *S. aureus*. Petechiae and cutaneous hemorrhages are widely reported with meningococcemia, typically on the extremities although they can occur anywhere on the body. Endotoxic shock with vascular collapse and DIC often develops in severe meningococcal disease, but shock may be present in the advanced stages of any bacterial meningitis. A finding of a systemic infection in a patient with signs of potential meningeal irritation should encourage rather than dissuade the clinician from considering the possibility of a concomitant CNS infection.

Cerebral venous thrombosis occurs in approximately 1% of patients with meningitis, likely due to coagulopathy induced by the robust CNS immune response; this rare complication can manifest as new-onset seizures, altered sensorium, and new focal neurologic deficits. Meningococcemia may cause Waterhouse-Friderichsen syndrome, or bilateral adrenal hemorrhage, often accompanied by other signs of severe systemic infection such as DIC and purpura.

The presentation of fungal meningitis can sometimes be subtle even in the healthy adult population. Headache, low-grade fever, malaise, and weight loss may be present but often to such a mild degree that CNS infection is not initially considered. Tuberculous meningitis, in contrast to other types of meningitis, can have a subacute or even chronic presentation, with symptoms developing months after onset of infection. Cases can be vague and nonspecific, including fever, weight loss, night sweats, and malaise, with or without headache and meningismus. In some cases, CNS involvement may be the only manifestation of tuberculosis, but CNS infection can also present alongside pulmonary tuberculosis or disseminated (miliary) infection.

Encephalitis

Encephalitis can occur from a viral, bacterial or fungal cause; it is not possible to definitively distinguish the etiology of the infection based on clinical features, although certain presentations can be suggestive. Viral encephalitis can occur secondary to primary viral invasion of the CNS, such as West Nile or rabies virus. Alternatively, it can be caused by reactivation of a previously dormant viral illness, such as varicella-zoster virus (VZV).

The diagnosis of encephalitis requires an alteration of consciousness or behavior without another known cause. Fever, headache, seizures, and disorientation can be present. The symptoms exhibited by the patient are representative of the affected area of the brain. For example, HSV has a predilection for the temporal lobes and therefore, patients with HSV encephalitis can present with psychosis, personality or behavior changes, or hallucinations, occasionally prompting an initial diagnosis of a psychiatric disorder. A thorough skin and mucosal examination may reveal the presence of herpetic lesions, as encephalitis can be associated with cutaneous outbreak in some cases. West Nile virus can result in neuroinvasive disease resulting in a wide range of symptoms, including muscle weakness, memory loss, behavioral changes, and difficulty concentrating. In cases of rabies encephalitis, patients also present with agitation, extreme hydrophobia, and muscular spasms.

Central Nervous System Abscess

The most common finding in patients with an intracranial abscess is headache. Findings seen consistently in other CNS infections, such as fever and altered mental status, may not be present. Most patients with intraparenchymal abscess have a subacute clinical course with symptoms progressing over 1 or more weeks. Just as with encephalitis, the

TABLE 95.1 Approximate Sensitivity, Specificity, Positive and Negative Likelihood Ratios of Clinical Findings and Examination Maneuvers for CSF Pleocytosis in Patients With Suspected Meningitis

	Sensitivity	Specificity	LR+	LR-
Headache	91%	16%	1.1	0.5
Fever	30%	58%	0.7	1.2
Jolt accentuation	21%	82%	1.2	1.0
Kernig sign	2%	97%	0.8	1.0
Brudzinski sign	2%	98%	1.0	1.0
Nuchal rigidity	13%	80%	0.6	1.1
Focal neurologic deficit	2%	96%	0.5	1.0
Vomiting	4%	85%	0.3	1.1
Rash	2%	96%	0.6	1.0
Physician suspicion	44%	40%	0.8	1.4

Adapted from Nakao JH, Jafri FN, Shah K, Newman DH. Jolt accentuation of headache and other clinical signs: poor predictors of meningitis in adults. *Am J Emerg Med.* 2014;32(1):24–28.

symptoms exhibited by patients depends on the site affected by the abscess. For example, those with abscesses near the frontal lobe may present with disinhibited behavior, and abscesses near the motor cortex may demonstrate focal weakness. Seizures occur in approximately 25% of patients. Abrupt neurologic deterioration and death can result from abscesses that rupture into the ventricular system.

Abscesses can also present in the epidural space in the spine, most commonly in the lumbar region.[10] However, multiple areas may be affected which can be discontiguous.[11] Like brain abscesses however, presentations can be nonspecific and mimic more benign causes of back pain. The most common presenting symptom of an abscess within the epidural space is midline pain, which is present in the majority of patients. Conversely, fever is only present in approximately half of cases, particularly early in the course. Complications of a spinal abscess primarily result from cord compression, including paralysis, motor and sensory deficits, and bowel and bladder dysfunction. These deficits may be permanent once they develop, even with prompt treatment, making prompt diagnosis critical to avoid serious morbidity.

CSF Shunt Infection

These infections typically manifest with signs of increased intracranial pressure and hydrocephalus such as headache, altered mental status, nausea, and vomiting. They most often occur within 6 months of shunt placement and are typically the result of skin flora being introduced into the CSF space.

DIFFERENTIAL DIAGNOSES

The diagnoses of acute, subacute, and chronic meningitis and the other potential pathologies that must be considered vary based on the time course of the presenting symptoms. *Acute meningitis* encompasses patients with clear signs and symptoms of meningitis who are evaluated within 24 hours of the onset of their symptoms. While other diagnoses can be considered during the initial evaluation, antibiotic therapy should be initiated as soon as possible in these patients to cover for the possibility of bacterial meningitis. In this group of patients with rapid onset of symptoms, the most important differential diagnostic considerations are viral meningitis, acute subarachnoid hemorrhage (SAH), acute arterial dissection, and the noninfectious causes of meningitis including drugs, malignancy, or autoimmune conditions.

Distinguishing between viral and bacterial meningitis is described in the Diagnostic Testing section. Because subarachnoid blood is irritating to the meninges, it will cause neck pain similar to meningitis, but can be distinguished using CT imaging and LP. Generally, patients with SAH and cervical artery dissection will lack associated infectious symptoms and signs, such as a prodrome or fever.

In *subacute meningitis,* symptoms develop over a period of 1 to 7 days. Although this time course makes viral meningitis most likely, bacterial and fungal etiologies remain possible. Brain tumor, spinal abscess, infections outside the CNS such as osteomyelitis, and drug effects are potential diagnoses. Other considerations that may mimic subacute meningitis include CNS malignancy, intracranial hemorrhage, brain abscess and nonconvulsive status epilepticus. CNS abscess should be considered especially if fever is minimal or absent or if there are focal neurologic findings. Nonconvulsive status epilepticus is a consideration in patients with altered mental status, especially if there is a seizure history or a known structural brain lesion.

The spectrum of *chronic meningitis* includes the viral meningitides, as well as meningitis caused by tuberculosis, syphilis, and fungi. Symptoms have generally been present in this group for at least 1 week and generally have a prolonged, indolent course. The potential causes of culture-negative meningitis symptoms are broad and varied, including rheumatologic, neoplastic, and medication-induced symptoms. Generally, these atypical causes will present during the timeframe for *chronic meningitis* but may occasionally be seen with a *subacute* course.

Spinal epidural abscess should be suspected in patients with back pain accompanied by fever, back pain with neurologic deficits on exam, or relatively rapid onset atraumatic back pain, though patients may not always present with classic signs and symptoms. Patients with spinal surgery and instrumentation, IV drug abuse, and immunosuppression are at higher risk, and benefit from a lower threshold for testing. Epidural hematoma, osteomyelitis, discitis, aortic aneurysm rupture, aortic dissection, and pulmonary embolism are other considerations.

DIAGNOSTIC TESTING

Blood Testing

Currently, no test can substitute for cerebrospinal fluid analysis. The complete blood count (CBC) with differential is a nonspecific adjunct in the diagnostic evaluation of a patient suspected to have a CNS infection. However, a normal leukocyte count and differential does not rule out the diagnosis of a CNS infection.

Procalcitonin has been shown in multiple studies to have some value in the discrimination between bacterial and viral etiologies of meningitis. With an estimated sensitivity of 90% and specificity of 98% for bacterial infection, it may be useful as an adjunct when the clinical picture is unclear, but it is currently not considered definitive to rule out bacterial meningitis.[12] In addition, elevation in serum erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are potentially useful but not diagnostic in the differentiation of bacterial and viral meningitis.[13]

A serum glucose level is needed to interpret the CSF glucose level. Although most patients do not require coagulation studies, patients who are taking warfarin should have their INR checked. Patients on direct oral anticoagulants can be checked for anti-Xa levels, if available, to assess for current anticoagulant activity. Coagulation status should be considered in patients on anticoagulants prior to attempting a lumbar puncture given the risk of bleeding complications.

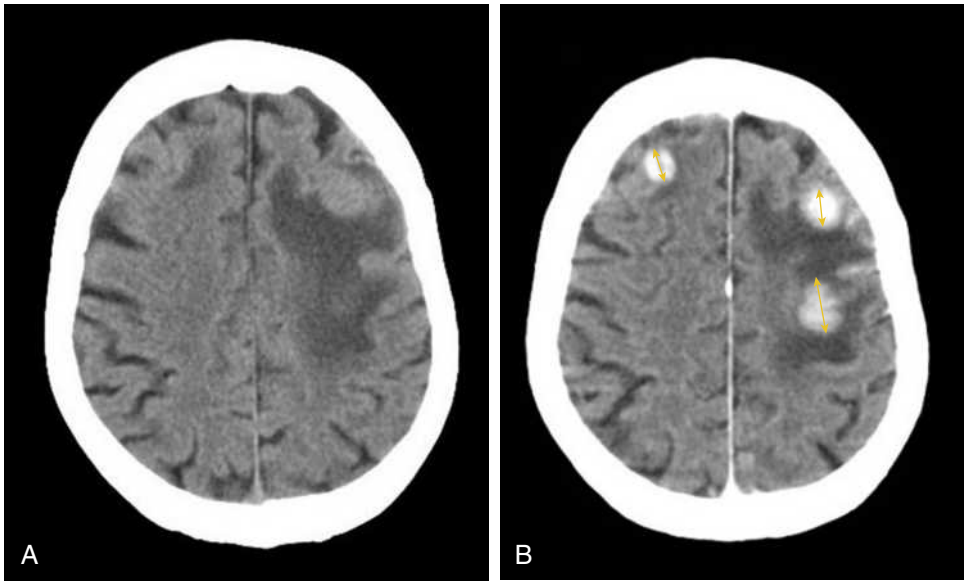

Fig. 95.2 CT image of multiple brain metastases with surrounding edema. When evaluating for CNS infection, findings such as this may suggest that LP is unnecessary or unwise.

Blood cultures should be obtained for all patients who are being evaluated for a CNS infection, ideally on arrival. However, they may still have benefit later in the patient's course even if antimicrobial therapy has already been administered, because pneumococcal and meningococcal infections may be identified in the blood of patients with these CNS infections.

Neuroimaging

A CT scan without contrast of the head or magnetic resonance imaging (MRI) scan of the brain is indicated in any patient with a suspected CNS infection in which an intracranial hemorrhage or mass lesion is suggested by history or examination. Contrast studies are more sensitive if a mass lesion is high on the differential (Fig. 95.2). A CT scan may show hypodense lesions in the temporal lobes in patients with HSV encephalitis, although an MRI scan reveals enhancement with greater sensitivity (Fig. 95.3). Neuroimaging should not delay antimicrobial therapy, which can be initiated prior to imaging, and LP should still be obtained expeditiously.

A contrast-enhanced cranial CT or MRI scan is diagnostic for a CNS abscess, though the MRI is more sensitive. Large lesions are generally visible on non–contrast-head CTs, although again, MRI is more sensitive and can show smaller lesions that may be mimicking meningitis or encephalitis. When evaluating for spinal abscess, CT imaging of the spine is insufficiently sensitive. MRI of the entire spine is the test of choice (Fig. 95.4), as lesions may be multiple and discontinuous, and can be difficult to localize by exam alone. In patients with contraindications to MRI, a CT myelogram of the spine is an alternative, although definitive testing is preferred if possible due to the high morbidity associated with missed spinal abscess. Transfer to an MRI-capable center may be appropriate if imaging is not available in a timely manner.

Bedside ultrasound of the optic nerve sheath diameter is a rapid and accurate way to evaluate for increased intracranial pressure. This is performed using a high-frequency probe placed over a closed eye. The optic nerve can be assessed in either longitudinal or transverse planes and measured 3 mm behind the globe of the eye;[14] the upper limit of normal for optic nerve sheath dilation is 5 mm (Fig. 95.5). A diameter greater than 5 mm suggests increased intracranial pressure but does not distinguish among potential causes.

Lumbar Puncture

A lumbar puncture (LP) for CSF analysis is indicated whenever meningitis or encephalitis is suspected unless the skin overlying the puncture site is infected or there is potential for brain herniation. In the majority of patients with suspected meningitis who have no focal neurologic findings (including no altered mental status), LP can be safely performed without delay and without preceding neuroimaging studies. Coagulation studies do not need to be routinely obtained prior to LP, but should be considered in those with personal or family history of coagulopathy, use of anticoagulation medications, organ failure, or evidence of DIC. A platelet count below 40,000 should also prompt consideration for delaying an LP. An INR greater than 1.4 in patients on warfarin is a relative contraindication to LP. The guidelines for DOACs depend on the agent being used; ideally these should be held at least 24 hours prior to an LP.[15] The need for a LP cannot be anticipated in most cases in the ED, however, and the emergent need for the procedure must be weighed against the increased risk of bleeding.

Herniation has been described in patients following LP, hence the recommendation to avoid a LP in patients with evidence of increased intracranial pressure. A recent study showed the risk of herniation to be only 0.1% in the first hour following LP, suggesting that some reported cases of herniation may be due to the infectious process itself.[9] Regardless, at the present time, we recommend that LP be avoided in those patients with the presence of papilledema, increased optic nerve sheath diameter on ultrasound, mass lesions on CT imaging or other signs of increased ICP. Early initiation of antimicrobial therapy should not be delayed pending LP for patients with high clinical suspicion for CNS infections. However, the CSF can be sterilized within as little as one hour post-antibiotics, so LPs should proceed as expeditiously as is feasible.

If the physician is unable to obtain CSF during the LP, consideration should be given to a prompt radiology-guided LP. If no LP can be performed, the blood cultures obtained on presentation may still be of assistance in identifying the causative microbe.

Opening Pressure

The normal upper limit of CSF pressure in an adult is 20 cm H_2O. The opening pressure is only valid for patients in the lateral recumbent position, because it may increase substantially when the patient is in

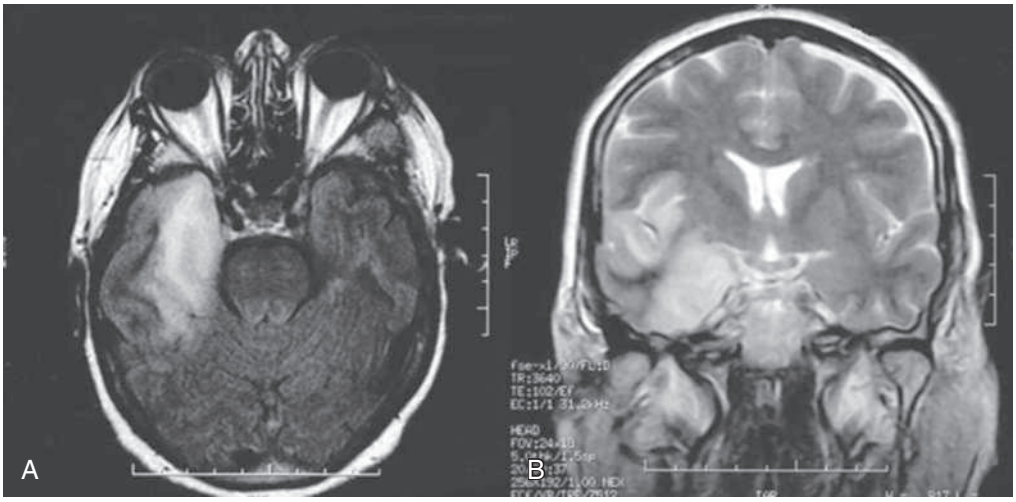

Fig. 95.3 Temporal lobe enhancement on brain MRI. This is a common imaging finding in patients with HSV encephalitis.

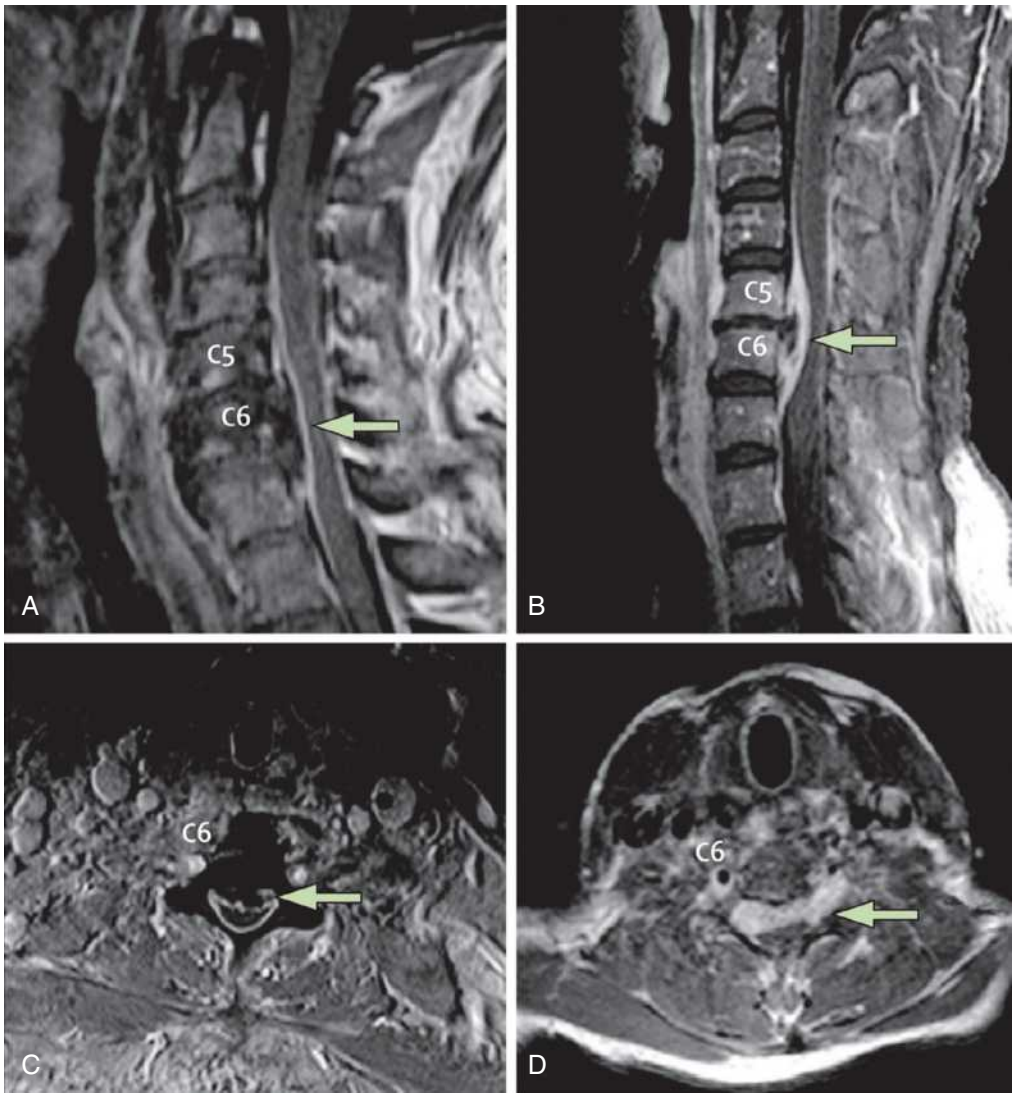

Fig. 95.4 Epidural abscess as seen on lumbar spine MRI. CT imaging may miss smaller spinal cord lesions such as these.

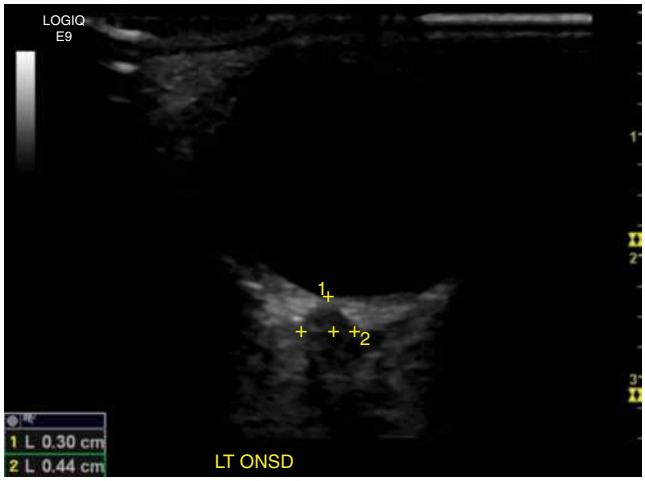

Fig. 95.5 The optic nerve sheath diameter using ultrasound is measured 3 mm behind the optic disc. This method can be used by the clinician at bedside to quickly assess patients for increased intracranial pressure.

Fig. 95.6 CSF specimens after collection. The clear appearance, indistinguishable from water, is a normal finding; any degree of cloudiness can suggest CNS infection.

the sitting position. It may also be falsely elevated when the patient is tense, has marked muscle contraction, or is obese. The pressure is often elevated in bacterial, tuberculous, and fungal meningitides and a variety of noninfectious processes, and often normal in viral meningitis. There is little data however on the sensitivity and specificity of this marker. As such, obtaining an opening pressure when possible prior to collecting CSF provides an additional data point to support a viral or bacterial clinical picture but cannot be used in isolation. If CSF collection requires the patient to sit up for mechanical reasons or patient comfort, opening pressure may be safely omitted.

Cerebrospinal Spinal Fluid Analysis

When possible, at least three sterile tubes each containing 1 to 1.5 mL of CSF should be obtained and numbered in sequence. A fourth tube is desirable in case additional studies are later necessary. The fluid should then be sent to the laboratory for immediate analysis of turbidity, xanthochromia, glucose, protein, cell count and differential, Gram stain, and bacterial culture. When only a small amount of fluid can be obtained, the most important studies are the cell count with differential, the Gram stain, and culture. Depending on the clinical scenario and patient risk factors, such as HIV, immunosuppression, travel history, or exposures, additional testing can be valuable as well. These studies can include cryptococcal antigens, acid-fast bacilli stain, or the Venereal Disease Research Laboratory (VDRL) test for neurosyphilis. Ideally, a cell count should be performed on both the first and last tubes collected to help differentiate true CSF pleocytosis from contamination of the specimen by peripheral blood from a traumatic LP.

The CSF should be assessed immediately for turbidity or cloudiness by the person performing the LP. Normal CSF is completely clear, colorless, and indistinguishable from water (Fig. 95.6); any degree of turbidity is pathologic. Changes in CSF clarity can generally be seen when leukocyte counts are greater than 200 to 500 cells/mm^3.

Cerebrospinal Spinal Fluid Cell Count

Normal adult CSF contains no more than 5 leukocytes/mm^3 with at most one granulocyte (polymorphonuclear [PMN] leukocyte); the presence of more than one PMN or a total cell count of more than 5 cells/mm^3 is evidence of CNS infection. The presence of any eosinophil in the CSF is abnormal; occasionally basophils may be seen in the absence of disease. The cell counts in bacterial meningitis often exceed 1000 cells/mm^3 with a neutrophil predominance (Table 95.2). However, the initial CSF analysis exhibits lymphocytosis (lymphocyte count greater than 50%) in approximately 10% of cases of bacterial meningitis. In some cases of *L. monocytogenes* meningitis, CSF analysis shows a cell count of less than 1000 cells/mm^3 with lymphocyte predominance but near-normal CSF glucose levels. In viral meningitis, encephalitis, tuberculous meningitis, or fungal meningitis, counts are typically less than 1000 cells/mm^3 with lymphocyte predominance. However, early (within 48 hours) viral presentations may reveal neutrophils and be indistinguishable from presentations of bacterial meningitis. Treatment with antibiotics before the LP will decrease the yield of Gram stain and cultures but likely does not affect the CSF cell counts or total CSF protein in meningitis.

A traumatic LP is suggested by the presence of 10,000 or more red blood cells (RBCs)/mm^3 or fewer RBCs in the final tube than in the initial tube. In the presence of a traumatic LP, the CSF white blood cell (WBC) pleocytosis can be estimated by subtracting one leukocyte for every 500 to 1000 RBCs.

Normal CSF cell counts, although reassuring, do not completely exclude bacterial meningitis, especially in immunocompromised patients. Lumbar puncture for brain abscess is unlikely to offer diagnostic yield except in cases of abscess rupture into the ventricular space. Although abnormalities can be seen, the CSF can also be entirely normal. Lumbar puncture is generally contraindicated in cases of spinal epidural abscess due to concern for seeding the infection.

Gram Stain

A Gram stain of a CSF specimen may identify the causative organism up to 75% of the time in cases of bacterial meningitis, however this is highly dependent on the concentration of the bacteria present. The yield is diminished to 40% to 60% when there has been prior treatment with antibiotics.[16] Gram-stain appearance of the CSF of a patient with *N. meningitidis* is shown in Figure 95.7.

Xanthochromia

Xanthochromia is the yellowish discoloration of the supernatant of centrifuged CSF specimens, detectable by visual inspection or spectrophotometry. Xanthochromia is an abnormal finding and is concerning

TABLE 95.2 Typical CSF Findings for Various Etiologies of Meningitis and Encephalitis

	Normal	Bacterial	Viral	Fungal/TB
Pressure (cm H_2O)	5–20	>30	Normal or increased	Increased
Protein (mg/dL)	18–45	Increased	Normal or increased	Normal or increased
Glucose	2/3 serum glucose	Decreased	Normal	Normal or decreased
Gram stain	Negative	60–90% positive	Negative	Negative
White blood cells	<5	Usually >1000	100–1000	50–500
WBC differential predominance	None	Neutrophils	Lymphocytes	Lymphocytes or monocytes

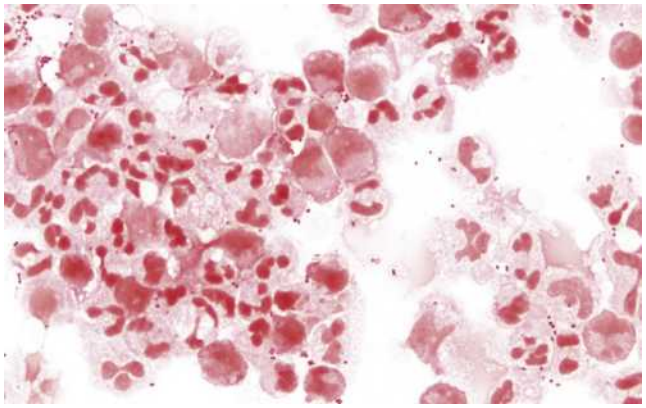

Fig. 95.7 The Gram stain appearance of a CSF sample infected with *N. meningitidis*, a gram-negative coccus. Magnification 1000x.

for SAH when detected. It results from the lysis of RBCs with the release of the breakdown pigments oxyhemoglobin, bilirubin, and methemoglobin into the CSF. This process takes hours to occur, though in patients presenting between 12 hours and 2 weeks of symptom onset, the sensitivity is close to 100% if analyzed using spectrophotometry. Visual inspection of the centrifuged specimen has been found to be much lower (47%). If a traumatic tap has introduced enough plasma to raise the CSF protein level to 150 mg/dL or more, blood pigments may cause xanthochromia. If the CSF protein level is less than 150 mg/dL, however, xanthochromia of a centrifuged CSF specimen almost always indicates that a SAH has occurred.

Glucose

The CSF glucose level is normally two-thirds of the serum glucose; when the serum glucose is within normal range, the CSF glucose is usually between 50 and 80 mg/dL. In the first 4 hours after food intake or parenteral glucose administration, however, the ratio is decreased, and the results are difficult to interpret with certainty. A CSF-to-serum glucose ratio of less than 0.5 in normoglycemic subjects is abnormal and may represent the impaired glucose transport mechanisms and increased CNS glucose use associated with bacterial meningitis. Mild decreases in the CSF glucose level may occur in viral, fungal, or tuberculous meningitis. However, bacterial meningitis should be presumed to be the cause of low CSF glucose until it is clearly excluded.

Protein

The normal CSF protein level in adults is typically below 45 mg/dL. An elevated CSF protein (higher than 100 mg/dL) commonly occurs with acute bacterial meningitis. When a traumatic LP has occurred, the CSF protein can be corrected for the presence of blood by subtracting 1 mg/dL of protein for each 1000 RBCs. Elevated CSF protein concentrations can result from any cause of meningitis, SAH, CNS vasculitis, syphilis, viral encephalitis, neoplasms, and demyelination syndromes. HSV and VZV can have higher CSF protein values than are typically seen in viral CNS infection (>100 mg/dL).

Other Stains

Historically, an India ink staining of the CSF was performed to diagnose cryptococcal meningitis. Though it is a rapid means of diagnosis, it has poor sensitivity (as low as 30% in non-AIDS patients). Cryptococcal antigen testing is now the gold standard for investigating cryptococcal infection, with baseline serum and CSF antigen titers providing a good estimate of fungal burden and prognosis but not response to therapy. Latex agglutination and enzyme immunoassay techniques have high sensitivity for cryptococcus as well but are inferior to antigen testing. Acid-fast bacilli (AFB) staining has been used for diagnosis of tuberculous meningitis but has poor sensitivity (typically <60%).

Lactic Acid

The normal reference range for CSF lactate is between 0.88 to 2.7 mmol/L. Although nonspecific, elevations in CSF lactic acid concentrations are suspicious for bacterial meningitis, while normal lactate levels (<2.7 mmol/L) are usually seen in patients with viral causes of meningitis. Recent studies have shown CSF lactate to have excellent predictive value in differentiating bacterial from viral meningitis,[17] and CSF lactate may be useful as an adjunct in the workup of suspected meningitis. We recommend its use, when available, to aid in determining the cause of CNS infection.

Antigen Detection

Nucleic acid amplification tests such as PCR have sensitivities of 67% to 100% for *H. influenza,* 79% to 100% for *S. pneumoniae,* and 91% to 100% for *N. meningitides;* specificities are nearly 100% for all three organisms.[1] The value of antigen testing has been demonstrated in multiple studies in which acute bacterial meningitis was confirmed only by PCR.[1] The sensitivity of bacterial culture is much lower and varies considerably based on the specific causative microorganism; under ideal conditions, cultures may miss a third of organisms, and sensitivity can be even lower if the patient has been treated with antibiotics. PCR testing has been demonstrated to have a sensitivity of 70% despite antibiotic therapy up to 1 week following initiation of treatment.[18]

Antigen and antibody testing have particular utility in HSV encephalitis. Although enzyme-linked immunosorbent assays (ELISAs) can detect HSV antibody production, the appearance of antibodies in CSF occurs too late to aid in any therapeutic decision analysis. PCR amplification and the identification of HSV DNA have a sensitivity of 96% and a specificity of 99% early in the disease, such that brain biopsy is no longer needed to make this diagnosis. PCR testing is sensitive for other viral infections as well, including VZV and enterovirus, though identification of the exact virus usually does not affect management. Diagnosis of VZV encephalitis is further improved by testing for IgG and IgM antibodies in the CSF.

TABLE 95.3 Common Bacterial Pathogens and Initial Antibiotic Regimens for Suspected Bacterial Meningoencephalitis,[a] Listed by Age Group and Risk Factors

Patient Subgroup	Most Common Bacterial Pathogen	Most Common Intravenous Therapy
Neonates (up to 4 weeks)	*S. agalactiae, E. coli, L. monocytogenes, S. agalactiae,* gram-negative bacilli	Ampicillin (100 mg/kg/dose q8h for 0-7 days and 75 mg/kg/dose for 8-28 days) AND Cefotaxime (50 mg/kg every 8 hrs; may increase to 50 mg/kg q6h for 8-28 days)
Infants and children	*S. pneumoniae, N. meningiditis*	Ceftriaxone (100 mg/kg every day) OR Cefotaxime (75 mg/kg every 6 hrs)
Adults	*S. pneumoniae, N. meningiditis*	Ceftriaxone (2 g every 12 hrs) OR Cefotaxime (2 g q4–6h) AND Vancomycin (loading dose: 20–35 mg/kg actual body weight [not to exceed 3000 mg] or 20–25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, then 15–20 mg/kg actual body weight every 8–12 hrs)
Elderly	*S. pneumoniae, N. meningiditis, L. monocytogenes*	Ceftriaxone (2 g every 12 hrs) OR Cefotaxime (3 g every 6 hrs) AND Vancomycin (loading dose: 20–35 mg/kg actual body weight [not to exceed 3000 mg] or 20–25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, then 15–20 mg/kg actual body weight every 8–12 hrs) AND Ampicillin (2 g every 4 hrs)
Immunocompromised	*S. pneumoniae, N. meningiditis, H. influenzae*	Ceftriaxone (2 g every 12 hrs) OR Cefotaxime (3 g every 6 hrs) AND Vancomycin (loading dose: 20–35 mg/kg actual body weight [not to exceed 3000 mg] or 20–25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, then 15–20 mg/kg actual body weight every 8–12 hrs) AND Ampicillin (2 g every 4 hrs)
Suspected hospital-acquired organism	*S. aureus, S. epidermidis,* aerobic gram-negative bacilli	Vancomycin (15–20 mg/kg every 8 hrs) AND Cefepime (2 g every 8 hrs) OR Meropenem (2 g every 8 hrs)

Adapted from Dorsett M, Liang SY. Diagnosis and treatment of central nervous system infections in the emergency department. *Emerg Med Clin North Am.* 2016;34(4):917-942.[25]

[a]In addition to dexamethasone (adults 0.4 mg/kg IV, up to 10 mg; infants and children 0.15 mg/kg, up to 10 mg

PCR has improved the diagnosis of tuberculous meningitis as well and newer assays continue to show improved performance characteristics. One of the latest assays, Xpert Ultra, was recently shown to have a sensitivity of 95% (compared to previous assays and culture with a 45% sensitivity) and has been endorsed as the initial diagnostic test of choice by the World Health Organization.[19]

Bacterial Cultures

Bacterial cultures of CSF should be performed despite some organisms, such as mycobacterium, being difficult to culture. Although results of cultures will not be available in the ED, they can be helpful to the subsequent treatment team for guiding antimicrobial therapy if positive. Bacterial culture yields can be decreased in patients pretreated with antibiotics, depending on the timing of the antibiotics and the cultures. Although antigen testing holds promise, it alone cannot replace bacterial cultures at this time.

Additional Investigations

Other ancillary investigations such as echocardiography, body fluid cultures, chest X-ray, CT of the maxillary region, and urinalysis may be undertaken as necessary to evaluate suspected coexistent disease, such as a distant infection that may be seeding the CNS.

Characteristic EEG abnormalities have been associated with HSV type 1 encephalitis, including diffuse high-amplitude slow waves, temporal lobe spike-and-wave activity, and periodic lateralized epileptiform discharges, although these changes are not specific enough to make them diagnostic. More than half of patients with viral encephalitis may have an abnormal EEG, most commonly in patients with HSV; it is not routine however to obtain an EEG emergently in the ED and EEG is unlikely to acutely change management unless nonconvulsive status epilepticus is diagnosed.

MANAGEMENT

Initial management of the patient with suspected CNS infection focuses on ensuring CNS oxygenation and perfusion. In cases of severely elevated ICP, management is with endotracheal intubation, mannitol, hypertonic saline, and maintenance of eucapnia on the ventilator.

Bacterial Meningitis

Treatment of bacterial meningitis requires bactericidal antibiotics that penetrate the blood-brain barrier and achieve therapeutic CSF concentrations. Until the causative organism is identified, broad-spectrum coverage of the most common pathogens is indicated (Table 95.3). Ceftriaxone (2 g every 12 hours) or cefotaxime (3 g every 6 hours) are the most commonly used agents, with vancomycin (15–20 mg/kg every 8 hours) added to cover potentially resistant organisms. In neonates, especially those with hyperbilirubinemia, ceftriaxone should be avoided, because it displaces bilirubin from albumin binding sites and can further increase bilirubin levels in the blood. Cefotaxime is instead recommended in this population. We recommend high-dose ampicillin (2 g every 4 hours) be added in adults over 50 years old and infants younger than 1 month old (100 mg/kg/dose q8h for 0–7 days and 75 mg/kg/dose for 8–28 days) because they are at risk for *Listeria*. If *Listeria* meningitis is suspected, gentamicin may also have a mortality benefit if added to ampicillin, though this should be used cautiously in patients with renal dysfunction.

Patients who have had a recent hospitalization, especially for surgery, may be at risk for hospital-acquired antibiotic-resistant organisms and may benefit from broader coverage with cefepime (2 g every 8 hours) instead of ceftriaxone. In patients allergic to cephalosporins, meropenem or chloramphenicol is recommended. Linezolid (600 mg

every 12 hours) or moxifloxacin (400 mg once daily) with vancomycin can be used in cephalosporin-resistant strains of pneumococcus.

Treatment with corticosteroids (0.15 mg/kg up to 10 mg IV dexamethasone every 6 hours for 4 days) decreases mortality in patients with pneumococcal meningitis and decreases the incidence of hearing loss in patients with *H. influenzae* meningitis. Interestingly, this benefit has only been shown in high-income countries and not in low-income countries, likely secondary to better access to medications and specialist care in the former.[20] Though some data suggest benefit persists if started within 12 hours of antibiotic initiation, the first dose of steroids should be given with or 20 minutes before initiation of antibiotics in suspected adult bacterial meningitis. However, a recent large, prospective study showed an increased incidence of adverse outcomes related to dexamethasone in cases of *Listeria* CNS infections and therefore steroids should be discontinued if this organism is identified.[21]

Tuberculous Meningitis

Early antimicrobial intervention in acute tuberculous meningitis improves the patient's prognosis and a strong clinical suggestion of this disease is an appropriate indication to begin antituberculous therapy. A standard treatment regimen consists of 4-drug therapy with isoniazid (5 mg/kg once daily; max dose 300 mg), rifampin (20 to 30 mg/kg once daily; max dose 600 mg), pyrazinamide (<40 kg: 35 mg/kg/dose; 40 to 55 kg: 1000 mg daily; 56 to 75 kg: 1500 mg daily; 76 to 90 kg: 2000 mg daily), and ethambutol (<40 kg: 25 mg/kg/dose; 40 to 55 kg: 800 mg daily; 56 to 75 kg: 1200 mg daily; 76 to 90 kg: 1600 mg daily). Alternative dosing strategies exist that involve less-frequent dosing and can be considered with infectious disease consultation. Neurosurgical consultation may be required in cases of hydrocephalus or mass lesions. Corticosteroids have also been shown to decrease secondary complications, and we recommend an initial dose of 0.15 mg/kg of IV dexamethasone.

Fungal Meningitis

Because fungal meningitis most often has a prolonged course and can be difficult to diagnose in the ED, the initiation of antifungal treatment is rarely required in the ED unless clinical suspicion is high. Four agents are commonly used to treat fungal meningitis: amphotericin B, flucytosine, miconazole, and fluconazole. Of these, amphotericin B, either alone or in combination with flucytosine, is the most common regimen. Fluconazole can be used if flucytosine is not available and can be used as monotherapy if amphotericin B is not available, though it is associated with higher rates of treatment failure.

Viral Meningitis

The majority of viral meningitis cases have a short, relatively benign and self-limited course followed by a complete recovery. Acyclovir (10 mg/kg IV every 8 hours) is recommended in immunocompromised patients with HSV meningitis and should be considered based on the theoretical benefit in immunocompromised patients with VZV meningitis. Benefit has not been shown in HSV or VZV meningitis in immunocompetent patients. In these cases, as with most types of viral meningitis, care is mainly supportive, because no treatments have been shown to be effective for relieving symptoms, shortening the course of disease, or preventing disease progression.

Early cases of viral meningitis may be indistinguishable from bacterial meningitis, and diagnostic certainty may not be provided by initial CSF analysis. When doubt exists about the veracity of the diagnosis, it is reasonable to initiate workup and empiric antibiotics and admit the patient to the hospital.

Viral Encephalitis

In cases of suspected viral encephalitis, empiric IV acyclovir (10 mg/kg IV every 8 hours) is recommended as it targets both HSV and VZV, two common causes of this disease. Patients with CMV encephalitis can be treated with ganciclovir (5 mg/kg every 12 hours), although this diagnosis is unlikely to be made in the ED. Otherwise, patients should largely be treated supportively.

Central Nervous System Abscess

The location, size, and number of abscesses influences the choice of medical management, surgical excision, or aspiration. Consideration of empiric antimicrobial therapy is ideally accomplished in consultation with neurosurgical providers, as it is reasonable to withhold antimicrobial therapy prior to aspiration or surgical excision if an urgent neurosurgical intervention is planned. If neurosurgery is delayed, however, we recommend initiating empiric treatment, as prolonged time without antibiotics has been associated with adverse outcomes.

Abscesses originating from sinus or ear infections are treated with cefotaxime (2 g IV every 4-6 hours) or ceftriaxone (2 g IV every 12 hours) plus metronidazole (500 mg IV every 6 to 8 hours). Abscesses related to trauma or neurosurgical procedures require vancomycin for *S. aureus* or methicillin-resistant *S. aureus* coverage. Patients at high risk for tuberculous, fungal, or parasitic abscess may also receive coverage for the suspected etiologic agent. Corticosteroids may mitigate superimposed cerebral edema and a recent meta-analysis did not show an increase in mortality with their use.[22] We therefore recommend 10 mg IV dexamethasone for CNS abscesses associated with cerebral edema.

Spinal epidural abscesses should also be managed with a combined medical and surgical approach. Neurosurgical consultation should be obtained as soon as possible to evaluate the need for emergent intervention, particularly if neurologic deficits are present. Additionally, we recommend empiric vancomycin (loading dose: 20 to 35 mg/kg actual body weight [not to exceed 3000 mg] or 20 to 25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, then 15 to 20 mg/kg actual body weight every 8 to 12 hrs) and ceftriaxone (2 g IV every 12 hours) for antimicrobial treatment. When atypical organisms such as *Pseudomonas* are present or suspected, broader coverage is recommended with a fourth-generation cephalosporin (e.g., cefepime 2 g IV every 8 hours).

CSF Shunt Infection

After obtaining neuroimaging (either CT or rapid MRI protocol), management generally includes neurosurgical consultation and empiric antibiotics directed at skin flora, including *S. aureus and Streptococcus* as well as MRSA and *Pseudomonas.* We recommend vancomycin (loading dose: 20 to 35 mg/kg actual body weight [not to exceed 3000 mg] or 20 to 25 mg/kg actual body weight not to exceed 3000 mg in patients with obesity, then 15 to 20 mg/kg actual body weight every 8 to 12 hrs) and an anti-pseudomonal beta-lactam, such as cefepime (2 g every 8 hours).

Chemoprophylaxis

The risk for developing meningococcal meningitis is increased 400 to 800 times in individuals with close contact with an infected person. Close contacts at risk include health care workers exposed to the patient's secretions (as might occur during endotracheal intubation or nasotracheal suctioning), those exposed for a prolonged period (e.g., spending more than 8 hours less than three feet away from the patient such as roommates, intimate partners, daycare attendants) or those exposed to an infected person's oral excretions. At risk contacts should be treated with four doses of oral rifampin (600 mg every 12 hours) or a single dose of oral ciprofloxacin (500 mg). Pregnant women can receive a single intramuscular (IM) dose of ceftriaxone (250 mg). In addition, close contacts should be advised to

TABLE 95.4 Recommended Population for Prophylaxis and Antibiotic Dosing Regimens, Listed by Exposure Type

	Population	Medication	Dose	Frequency
N. meningitidis	Close contacts (roommates, partners, daycare workers), health care workers exposed to secretions	Ciprofloxacin	500 mg	Once
		Rifampin	600 mg	Every 12 hours for 2 days
		Ceftriaxone	250 mg	Once (preferred in pregnancy)
H. influenzae	Immunocompromised children (including unvaccinated), contacts with unvaccinated children <4 years old	Rifampin	20 mg/kg	Daily for four days
All others (bacterial, viral, fungal)	All	None	None	None

watch for fever, sore throat, rash, or any symptoms of meningitis. If there are signs of active meningococcal disease, the close contact should be hospitalized for IV antibiotics as presented above, because rifampin is not recommended as therapy against invasive meningococcal disease.

Rifampin prophylaxis (20 mg/kg once daily; max dose 600 mg for four days) is currently recommended by the Centers for Disease Control (CDC) for contacts of patients with *H. influenzae* meningitis in households with members aged younger than 4 years who have not completed their vaccination schedule or immunocompromised children (<18 years old), regardless of their vaccination status. It is only recommended in childcare facilities caring for immunocompromised or unvaccinated children in instances where two confirmed cases have occurred. There is no current recommendation for chemoprophylaxis in pneumococcal meningitis. See Table 95.4 for a summary of the guidelines.

Immunoprophylaxis

Although vaccinations against pathogens implicated in CNS infection are not routinely administered in the ED, it is useful to be aware of currently available vaccinations so that patients and family members may be queried regarding their risk for vaccine-preventable diseases.

A quadrivalent meningococcal vaccine based on the polysaccharide capsule and conferring protection against group A, C, Y, and W-135 meningococci has been in routine use since it was approved in 1978. It is currently recommended for routine use in children and adolescents aged 11 to 21 years old. People living in close quarters with other individuals (e.g., college students, military recruits), travelers to endemic areas, as well as asplenic individuals are at increased risk of meningococcal disease and should receive the vaccine. Two vaccines targeting serogroup B also have been approved for use in the United States since 2014 but have yet to be routinely administered. The capsular polysaccharide vaccines used to immunize adults are not protective in children younger than 2 years old because of poor antibody response.

The development of a highly effective pneumococcal vaccine has been hampered by the large number of serotypes of the organism. Despite this, a single dose of the vaccine should be considered for elderly or debilitated patients, especially those with pulmonary disease, and for patients with impaired splenic function, splenectomy, or sickle cell anemia. Vaccination against pneumococcus is recommended in patients who have been treated for an episode of pneumococcal pneumonia to prevent recurrent infection. A heptavalent conjugated pneumococcal vaccine has also been developed and is recommended for universal childhood immunization by the ACIP.

A conjugate vaccine effective against Hib has been developed for use in the pediatric population and is recommended for all infants starting at 2 months.

DISPOSITION

With the exception of obvious presentations of viral meningitis, the majority of CNS infections require inpatient evaluation and treatment for IV antimicrobials, monitoring for acute decompensation, following of cultures, specialist input, and potential surgical intervention, depending on the infection. Because normal CSF cell counts do not completely exclude bacterial meningitis, patients with a high likelihood of meningitis require hospitalization with frequent reevaluation, antimicrobial therapy, and possible repeat LP.

Some patients with suspected viral meningitis should be considered for hospitalization. These include patients who are immunocompromised, patients with more severe disease or refractory symptoms, patients who are unable to tolerate oral intake, and those in whom the diagnosis is unclear.

CHAPTER 95: QUESTIONS AND ANSWERS

1. Which of the following presentations should receive a lumbar puncture to rule out CNS infection:
- **a.** 23-year-old healthy female with fever and stiff neck but minimal headache.
- **b.** 32-year-old male with diabetes and unexplained altered mental status.
- **c.** 67-year-old male with fever and new right arm weakness.
- **d.** All of the above

Answer: D. All patients with fever, headache, altered mental status or new neurologic deficits should be considered for possible meningitis or encephalitis. Lumbar puncture and CSF analysis is the most reliable method for assessing for CNS infection; imaging and blood tests are inadequate alone.

2. Patients with suspected bacterial meningitis should receive which of the following interventions FIRST?
- **a.** Non-contrast CT of the head
- **b.** MRI with contrast of the head
- **c.** Lumbar puncture to evaluate for bacterial cause
- **d.** Steroids and antibiotics for presumed bacterial infection

Answer: D. Patients with suspected bacterial meningitis should receive steroids and antibiotics first to cover for the possibility of bacterial infection. Treatment should not be delayed obtaining neuroimaging first (if necessary), or until the lumbar puncture is completed. However, lumbar puncture should still be obtained expeditiously, because culture yields begin to decrease after 1 hour.

3. Which of the following antimicrobial regimens would be appropriate coverage for suspected meningitis in a 40-year-old patient with no comorbidities in a country with high antibiotic use?
- **a.** Ceftriaxone
- **b.** Ceftriaxone and vancomycin
- **c.** Acyclovir and ceftriaxone
- **d.** Cefotaxime, vancomycin, and ampicillin

Answer: B. Ceftriaxone and vancomycin are the appropriate initial antibiotics for suspected meningitis or encephalitis in an adult patient. Ceftriaxone alone may be appropriate in lower income countries with less antibiotic use and resistance. Ampicillin is added for patients older than 50 years and neonates due to risk of Listeria. Acyclovir should be added for immunocompromised patients with suspected HSV or VZV infections. Cefepime should be used instead of ceftriaxone in patients at his risk for pseudomonas infections (e.g., recent surgical procedures).

CHAPTER 95: QUESTIONS AND ANSWERS—cont'd.

4. What is the most appropriate imaging test for a patient with low back pain, low-grade fever, and a history of IV drug use?
- **a.** CT lumbar spine without contrast
- **b.** CT myelogram of the lumbar spine
- **c.** MRI of the lumbar spine with contrast
- **d.** MRI of the cervical, thoracic and lumbar spine with contrast

Answer: D. Because exam findings can be inaccurate, patients with suspected epidural abscess should receive an MRI with contrast of their entire spine. Presentations can be subtle and may not include all of the classical features such as fever and back pain; patients must be queried for potential risk factors. CT myelogram of the entire spine is an acceptable alternative for patients unable to undergo an MRI.

5. Contacts with exposure to which of the following types of meningoencephalitis should receive prophylactic antibiotics?
- **a.** Pneumococcal
- **b.** Tuberculous
- **c.** Meningococcal
- **d.** West Nile

Answer: C. Close contacts with exposure to patients diagnosed with meningococcal meningitis or encephalitis should receive chemoprophylaxis, most commonly with oral rifampin. Chemoprophylaxis is also recommended for immunocompromised close contacts of patients with H. influenzae CNS meningitis.

Thought Disorders

Matthew P. Kelly and Dag Shapshak

KEY CONCEPTS

- Thought disorder symptoms can be precipitated by psychiatric, underlying medical, and toxicologic etiologies.
- Diagnostic testing should be patient specific and based on the particular medical processes that the clinician feels may be causing or exacerbating the thought disorder, rather than panels of routine tests.
- Consider nonphysical interventions first when appropriate, but chemical sedation or physical restraints may become immediately necessary for patients who demonstrate life-threatening aggressive and dangerous behaviors.
- Appropriate disposition depends on the etiology of the underlying psychosis and response to treatment while addressing patient and community safety considerations. Psychiatric consultation is often required.

FOUNDATIONS

Background and Importance

Patients with a history of mental disorders have a higher rate of emergency department (ED) visits than the general population. Patients with at least one primary psychiatric visit to an ED are four times more likely to become frequent ED users compared to patients with none, and the severity of mental illness correlates with the frequency of ED utilization.[1] The rate of ED visits for patients with mental disorders has increased substantially over the last several years for both adults[2] and children.[3] Schizophrenia is among the top 10 most disabling and economically catastrophic medical disorders as ranked by the World Health Organization, and the global burden of disease continues to increase,[4] affecting almost 1% of the world's population. Slightly more men than women are affected and at a younger age. The modal age of onset is between 18 and 25 years for men and between 25 and 35 years for women.

Groups at high risk for developing schizophrenia include migrants, urban dwellers, people born in late winter to early spring, and those with advanced paternal age at conception. The mortality rate for patients with schizophrenia is 2.5 times that of the general population and continues to grow, especially in populations with low socioeconomic status. Patients diagnosed with schizophrenia have a mean life expectancy almost 15 years shorter than the general population and a 5% to 10% life-time risk of death by suicide.[5] Financial costs associated with schizophrenia are disproportionally high relative to other chronic mental and physical health conditions, reflecting both direct costs of care, and indirect costs of lost productivity, criminal justice involvement, social needs, and homelessness.

Pathophysiology

Although the etiology of schizophrenia is multifactorial, it has a substantial genetic component with approximately 80% of disease expression attributed to genetic factors. In addition to genetic factors, environmental and neurodevelopmental influences increase risk of the disease.[6] Such influences include perinatal stress and hypoxia, poor nutrition, infections, and vitamin D and zinc deficiencies. Newer research is showing that schizophrenia may be detectable at earlier stages of development, prior to the first psychotic episode, which may open the window for earlier interventions.[7]

Alterations in the dopaminergic, serotonergic, cholinergic, glutamatergic, and GABA-ergic pathways have been implicated in the pathophysiology of schizophrenia. Symptoms may be caused by cortical excitatory-inhibitory imbalance and subcortical dopamine dysregulation in the frontal, temporal, and mesostriatal brain regions.[8] Imaging and postmortem studies have revealed disturbed oligodendroglia-related processes, altered gene expression, disturbed myelination, and altered numbers of oligodendrocytes in the brains of patients with schizophrenia.[9] Genetic predisposition, coupled with early neurodevelopmental disturbances during postnatal brain maturation, are thought to trigger the onset of overt schizophrenia.

Patients often present to the ED via family, police, or EMS exhibiting symptoms of disorganized thought and behavior. They may express language, ideas, and behavior found to be inappropriate and disruptive to accepted patterns of social interaction. Whether the issue involves thought content (delusions), hallucinations or thought form (structure of thinking), the clinical impression is that of psychosis (detachment from reality and societal norms). Acutely psychotic patients raise concerns for the safety of themselves, those around them, and those attempting to care for them.

The emergency clinician's role is to prevent and control violent and disruptive behavior while simultaneously determining if the underlying etiology of the psychosis is functional versus organic in nature. Functional causes include schizophrenia and schizophrenia-like illness, mania, and mood disorder–associated psychosis. Organic causes can mimic a functional psychosis. Medication effects, substance abuse,

and certain medical disorders must be excluded before symptoms of psychosis can be attributed to an underlying psychiatric illness.

CLINICAL FEATURES

Thought disorders broadly affect mental activity and can be associated with varying degrees of functional impairment. Schizophrenia is the most common thought disorder characterized by psychotic symptoms of hallucinations, delusions, and disorganized speech. The core psychopathology of schizophrenia and other thought disorders according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) includes both negative and positive symptoms. Negative symptoms include decreased motivation, diminished expressiveness, cognitive deficits involving impaired executive functions, memory, and speed of mental processing.[10]

Positive symptoms of schizophrenia are the most easily identified and can be classified as delusions, hallucinations, and abnormal motor behavior in varying degrees of severity. Significant cognitive symptoms include disorganized speech, thought, and attention, which may impair the individual's ability to communicate. Hallucinations are the perception of a sensory process in the absence of an external source. They can be auditory, olfactory, visual, gustatory, or somatic in nature. The vast majority of patients with schizophrenia suffer with auditory hallucinations.

Patients with schizophrenia typically display disorganization of behavior and cognition. They use disjointed speech patterns that reflect poor organization of thought and lack of a coherent focus of ideas. Their speech patterns are tangential and circumstantial, causing the narrative to wander away from the initial topic of conversation. More severe thought disorders include derailment, neologisms (invented words), word salad (confused, incomprehensible language), and preservations (severely repetitious language). In debilitating cases, there may be no understandable content and speech is utterly incomprehensible.

A separate group of patients with a more extreme deficit in communication are those suffering from catatonia. Catatonia includes immobility, stupor, mutism, resistance to instructions, oppositionalism, echo phenomena, and withdrawal. Although classically associated with schizophrenia because of the profound communication and thought deficiencies, recent studies highlight a strong association of catatonia with mood and medical disorders with only a minority diagnosed with schizophrenia.[11] Treatment is with benzodiazepines.[12]

The development of schizophrenia involves three phases: premorbid, progressive, and residual phases. The premorbid phase is characterized by the development of negative symptoms with deterioration in personal, social, and intellectual functioning. The first indications of schizophrenia typically appear in the late teens and early twenties. Children who later develop schizophrenia may demonstrate social awkwardness, physical clumsiness, and lower IQs than peers and siblings. There may be years of subtle changes in behavior and declining function in school and interpersonal relationships. The progressive phase is often precipitated by a stressful life event precipitating the development of positive symptoms. The progressive phase is said to begin when the patient develops the classic characteristics of schizophrenia mentioned earlier. Patients can become agitated or exhibit a hypervigilant withdrawal state characterized by rocking, staring, violence, or bizarre behavior. It is during the progressive phase that the patient is most likely to be brought to the ED by family, friends, police, or concerned bystanders. The residual phase is characterized by persistence of progressive symptoms and disability. Impaired social and cognitive ability, poor hygiene, delusions, bizarre behavior, and social isolation, and homelessness can all occur. On average, functional outcome is poor and patients have varying levels of treatment resistance, especially in those with predominantly negative symptoms.[13]

BOX 96.1 Medical Disorders That May Cause Acute Psychosis

Metabolic Disorders
- Hypercalcemia
- Hypercarbia
- Hypoglycemia
- Hyponatremia
- Hypoxia

Inflammatory Disorders
- Sarcoidosis
- Anti-NMDAR encephalitis
- Systemic lupus erythematosus
- Temporal (giant cell) arteritis

Organ Failure
- Hepatic encephalopathy
- Uremia

Neurologic Disorders
- Alzheimer disease
- Cerebrovascular disease
- Encephalitis (including HIV infection)
- Encephalopathies
- Epilepsy
- Huntington disease
- Multiple sclerosis
- Neoplasms
- Normal-pressure hydrocephalus
- Parkinson disease
- Pick disease
- Wilson disease

Endocrine Disorders
- Addison disease
- Cushing disease
- Panhypopituitarism
- Parathyroid disease
- Postpartum psychosis
- Recurrent menstrual psychosis
- Sydenham chorea
- Thyroid disease

Deficiency States
- Niacin
- Thiamine
- Vitamin B_{12} and folate

HIV, Human immunodeficiency virus.

DIFFERENTIAL DIAGNOSES

Medical Disorders

Numerous acute and chronic medical conditions can precipitate thought disorders and mimic acute psychosis (Box 96.1). Patients with underlying psychiatric diseases may develop medical conditions that can exacerbate behavioral symptoms and cloud the distinction between psychiatric and organic brain disease.

BOX 96.2 Pharmacologic Agents That May Cause Acute Psychosis

Antianxiety Agents
- Alprazolam
- Chlordiazepoxide
- Clonazepam
- Clorazepate
- Diazepam
- Ethchlorvynol

Antibiotics
- Isoniazid
- Rifampin

Anticonvulsants
- Ethosuximide
- Phenobarbital
- Phenytoin
- Primidone

Antidepressants
- Amitriptyline
- Doxepin
- Imipramine
- Protriptyline
- Trimipramine

Cardiovascular Drugs
- Captopril
- Digitalis
- Disopyramide
- Methyldopa
- Procainamide
- Propranolol
- Reserpine

Drugs of Abuse
- Alcohol
- Amphetamines
- Cannabis
- Cocaine
- Hallucinogens
- Opioids
- Phencyclidine
- Sedative-hypnotics

Miscellaneous Drugs
- Antihistamines
- Antineoplastics
- Bromides
- Cimetidine
- Corticosteroids
- Disulfiram
- Heavy metals

Primary medical conditions are more commonly associated with the new onset of symptoms, acute changes in mental status, recent fluctuations in behavioral symptoms, onset in fifth decade of life or later, the presence of nonauditory hallucinations, lethargy, abnormal vital signs, and poor performance on cognitive testing, particularly orientation to time, place, and person. The onset of psychotic symptoms after a patient has been admitted to a medical care setting is often caused by a medical disorder.

Primary psychiatric conditions are more commonly associated with auditory hallucinations, family history of psychosis, and insidious onset in the late teens to mid-twenties, stable vital signs, and normal orientation. Medical delirium is common in elders and special attention should be paid to patients who develop psychosis later in life.[14]

Patients intoxicated with drugs of abuse are often brought to the ED with bizarre or dangerous behavior. Street drugs such as cocaine, cannabinoids, kratom, amphetamines, bath salts, hallucinogens, and synthetic cannabinoids affect the serotonergic and dopaminergic pathways and can provoke psychotic reactions resembling a primary psychiatric condition, or can unmask latent schizophrenia.[15] Certain pharmacologic agents may also cause acute psychosis mimicking a thought disorder (Box 96.2).

Psychiatric Disorders

Once medical causes have been reasonably ruled out, it can be helpful to classify the type of functional psychosis the patient is exhibiting. The DSM-5 uses four classes of information to distinguish among the various types of psychosis: type of psychotic symptom, course of illness, consequences of illness, and exclusions. Each category can help distinguish schizophrenia from other psychiatric disorders that include psychosis among their symptoms. The DSM-5 definition of schizophrenia is included in Box 96.3.

BOX 96.3 Diagnostic Criteria for Schizophrenia From *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (e.g., frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (i.e., diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

F. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

A brief psychotic disorder involves the sudden onset of psychotic symptoms in response to major stress and lasts from several days up to one month. Peripartum psychosis is included under the diagnosis of brief psychotic disorder. Patients with schizophreniform disorder have similar symptoms to a brief psychotic disorder that lasts longer than one month but less than 6 months. Roughly one in three patients with schizophreniform disorder recover within 6 months; the others progress to develop clinical schizophrenia. Patients diagnosed with mood disorders may develop psychotic symptoms as part of their disease. If psychotic symptoms develop during periods of mood disturbances, the diagnosis of mood disorder with psychotic features applies. If symptoms consistent with schizophrenia persist for more than 2 weeks in the absence of prominent mood episode, the diagnosis of schizoaffective disorder is made. Patients with personality disorders may occasionally develop brief psychotic episodes, especially under duress. None of the aforementioned disturbances can be attributable to the effects of a substance or another medical condition.[16]

Delusional disorder is characterized by one or more delusions that are present for longer than one month, and the DSM-5 criteria for schizophrenia have not been met. Patients may believe famous people are in love with them (erotic type) or that they have extraordinary power or possess a special relationship with a deity or famous person (grandiose type). Other common delusions are sexual partners being unfaithful (jealous type), physical defect, or medical condition (somatic type). Function is not typically impaired, and behavior is often not bizarre separate from the impact of the delusions. Individuals may appear and behave normally when not actively discussing their delusions, but social, marital, work, and legal problems can result from the delusional beliefs.

DIAGNOSTIC TESTING

Diagnostic tests are indicated when a patient's clinical presentation cannot be explained by the history and physical examination alone. Often there is not enough information readily available to accurately ensure that the patient is suffering from a thought disorder alone. The potential medical causes of thought disorders are very broad; therefore, if a medical evaluation is indicated, testing should be patient specific and based on the particular medical processes that the clinician feels may be causing or exacerbating the thought disorder. The clinical judgment of the treating physician, rather than panels of routine tests, should be used to efficiently and appropriately guide diagnostic testing.

The evaluation of a "first-time" psychosis or thought disorder presentation in an emergency patient differs substantially from the evaluation of a patient with chronic disease who is experiencing recurrent symptoms. The evaluation for the first-time thought disorder patient may include a larger, more detailed laboratory and radiological evaluation. Complete blood counts, electrolyte panels, glucose levels, thyroid function, urine testing, vitamin B_{12}, and rapid plasma regain (RPR) testing are useful in certain clinical situations and should be ordered as appropriate for individual patients.

Neuroimaging for intracranial injury, vasculitis, demyelinating diseases, tumor, cerebrovascular disease, or abscess may be indicated based upon findings noted on the history and physical examination. A 2017 guideline from the American College of Emergency Physicians (ACEP) recommends the use of individual patient risk assessment to guide the ordering of brain imaging in the ED for patients presenting with new-onset psychosis without focal neurologic deficit.[17] The ACEP medical clearance guidelines are included in Box 96.4.

The new onset of primary thought disorders is rare in older adults. Medical illness often presents differently in elders, and a complete history and physical examination alone may not detect important medical presentations.[18] Geriatric medical assessment is more complex due to increased comorbidities, medication use, and variable baseline functional status with vague and nonspecific symptoms. Even for patients who have a previous psychiatric history or diagnoses, the presence of organic processes that may be exacerbating or contributing to the psychiatric decompensation should be considered. Most often, infections, electrolyte abnormalities, and medication side effects are the offending process. In one study, even after extensive ED testing was performed, a significant percentage of patients admitted to a geriatric psychiatric unit still required transfer out to a medical unit. The authors however concluded that further ED testing would not have prevented the transfers, which likely were related to the ongoing complex medical management issues rather than being related to missed opportunities for diagnosis in the ED.[18]

Ancillary testing beyond that required for medical clearance of psychiatric emergency patients rarely alters care, especially for patients with an established diagnosis of schizophrenia or other chronic thought disorders. Policies that require panels of testing prior to psychiatric admission are costly and unnecessary.[19] One of the largest unnecessary costs is incurred with the routine use of urine drug screens, which have been found to rarely alter disposition for psychiatric patients from the ED, especially when combined with a good substance abuse history. Greater emphasis should be placed on identifying a clinical toxidrome and history of use when attempting to determine if drugs and medications are contributing to the symptoms of psychosis.

BOX 96.4 Summary of ACEP Medical Clearance Guidelines

Level B Recommendation

1. In adult ED patients with primary psychiatric complaints, diagnostic evaluation should be directed by the history and physical examination.
2. Routine laboratory testing of all patients is of low yield and need not be performed as part of the ED assessment.

Level C Recommendations Regarding UDS

1. Routine urine toxicologic screens for drugs of abuse in alert, awake, cooperative patients do not affect ED management and need not be performed as part of the ED assessment.
2. Urine toxicologic screens for drugs of abuse obtained in the ED for the use of the receiving psychiatric facility or service should not delay patient evaluation or transfer.

Level C Recommendations Regarding EtOH

1. The patient's cognitive abilities, rather than a specific blood alcohol level, should be the basis on which clinicians begin the psychiatric assessment.
2. Consider using a period of observation to determine if psychiatric symptoms resolve as the episode of intoxication resolves.

MANAGEMENT

Maintaining patient and staff safety are important when a patient presents with aggressive and unpredictable psychotic behavior. Risk factors for violence in patients with schizophrenia include extreme excitement, prior violence, auditory hallucinations, systematization of delusions, incoherence of speech, and long duration of illness. In contrast, traits such as substance abuse and antisocial episodes are not recognized as significant violence-associated factors. Strategies to control disruptive and violent behavior in psychosis and thought disorders include de-escalation techniques, chemical sedation, and physical restraints.

Although chemical and physical intervention can be appropriate when patients are demonstrating dangerous behavior, verbal de-escalation should be considered first. The clinician should demonstrate a calm, nonjudgmental demeanor while showing appropriate concern and avoiding excessive stimulation, posturing, and prolonged eye contact. The patient should be given an opportunity to express their concerns, as well as identify unmet needs that can be easily corrected (e.g., inadequate pain control, communication failures, or social concerns). If available, consider recruiting trusted others (e.g., family, friends, case managers) to help prevent further agitation.

TABLE 96.1 Common Drugs for Sedation

Drug	Usual Adult Dose	Adverse Events
Midazolam	2.5 to 5 mg IM (rapid onset)	Respiratory depression Oversedation Hypotension Paradoxical excitation reaction in patients with organic brain disease
Lorazepam	1 to 2 mg PO or IM	
Diazepam	5 to 10 mg PO or IM (longer acting)	
Haloperidol	5 to 10 mg PO or IM	Increased mortality risk in elderly dementia-related psychosis
Ziprasidone	10 to 20 mg PO or IM	
Olanzapine	5–10 mg PO or IM	
Loxapine	10 mg PO or INH	Caution in prolonged QT or history of neutropenia

IM, Intramuscular; *INH*, Inhaled; *PO*, per os (by mouth).

When verbal de-escalation is ineffective or inappropriate, physical restraint or use of seclusion may be necessary. Risk factors predicting the need for restraint or seclusion include referrals initiated by a third party, patients arriving to the ED in restraints, and clinician perception of the patient as severely disruptive, already exhibiting psychosis, or experiencing a manic episode.

Chemical restraint for psychomotor agitation is a common and necessary intervention. Speed of onset and reliability of delivery are two important factors to consider when selecting a route of administration of sedation in the behaviorally disturbed patient. Oral sedation is indicated when the patient can be safely verbally de-escalated, is not at imminent risk of harm to self, and agrees to take oral medications. When more expedient sedation is required, parenteral and inhaled routes have the advantage of immediate effect and titration of dosing. Inhaled loxapine has also been found to be a safe and effective alternative medication to reduce agitation with rapid onset[20,21] and reduces risks of needle sticks in an un-cooperative patient. The goal of titration in this setting is the induction of rousable sleep, not unconsciousness.

Benzodiazepines and antipsychotics are the two medications most commonly used for chemical restraint with the trend of moving towards use of second-generation antipsychotics.[22,23] Using a single agent or, for more disturbed patients, a combination of the two classes, can be considered. Common agents and dosages are listed in Table 96.1.

Combined with concurrent physical restraint and the risk of previously ingested intoxicants, there is significant risk for over-sedation and respiratory compromise. The combination of haloperidol and lorazepam can cause respiratory depression in patients, with a significant number experiencing a hypoxic event. As a result, we recommend the use of pulse oximetry or CO_2 monitoring in chemically restrained patients to detect early signs of respiratory depression. In addition to monitoring of airway and level of consciousness, sedated and restrained patients should have frequent behavioral monitoring. The use of physical restraints may cause excess pressure on the patient's neck, chest or abdomen, and requires ongoing direct visualization. Potentially hazardous articles and possessions should be removed from the patient's area. Restrained patients are known to forcibly remove Foley catheters without deflation of the balloon if their limbs are released prior to removal of the catheter, resulting in urethral injury.

DISPOSITION

Making an appropriate disposition for patients with decompensated thought disorders is often difficult in today's emergency medicine practice environment. Although institutional and community psychiatric resources vary widely by region, there appears to be a nationwide trend of diminishing psychiatric referral resources in the presence of rising numbers of psychiatric-related ED visits. The number of inpatient psychiatric beds nationwide has decreased, and many EDs "board" psychiatric patients for extended periods of time.

Appropriate disposition is based on the etiology of the underlying psychosis, response to treatment, consideration of patient and community safety, and the availability of an appropriate outpatient follow-up plan. Patients who are actively suicidal, dangerous to others, possess severe mental debilitation precluding self-care, or are having their first psychotic episode should be hospitalized.[17] The evaluation and disposition of potentially suicidal patients is discussed in Chapter 101. Psychiatric consultation can help confirm safety for discharge, help facilitate inpatient admission or transfer, and aid in developing an outpatient follow-up plan. Telemedicine is emerging as a technology that may ease the growing lack of adequate psychiatric resources for ED patients by facilitating urgent psychiatric consultation. Telemedicine can often be used safely and is not associated with significant differences in care when compared with face-to-face psychiatric evaluations.

Medication noncompliance is a common reason for a known schizophrenic to present to the ED with a decompensated psychotic episode. A patient whose psychosis stabilizes in the ED with medication can sometimes be safely discharged back into the community. Safe discharge planning can be accomplished provided that the patient has adequate ability to care for self and does not pose a risk of harm to self or others. Insight by the patient and judgment to adhere to an agreed course of action, including taking medication, is typically required. Patients with severe underlying psychiatric illnesses may have some degree of persistent mental disability even when optimally treated. For these patients, recruiting family or friends familiar with the patient can help establish that the patient is back to his or her baseline to ensure safety.

A safe transition to the community setting requires adequate social support, including follow-up with a mental health service. However, even when appropriately discharged, patients with a history of alcohol or drug dependence, dementias, psychotic disorders, autism, impulse control disorders, and personality disorders are at high risk for ED recidivism with repeat visits within 12 months. Uninsured status was also highly associated with repeat psychiatric admission and ED visits.[24]

CHAPTER 96: QUESTIONS AND ANSWERS

1. Which of the following pharmacologic agents have been implicated in causing acute psychosis?
- **a.** Aripiprazole, hydralazine, nitroglycerin
- **b.** Diazepam, rifampin, captopril
- **c.** Hydrochlorothiazide, acetaminophen, albuterol
- **d.** Lorazepam, salsalate, rocuronium
- **e.** Penicillin, ceftriaxone, risperidone

Answer: B. Box 96.2 provides an extensive list of other agents that may cause psychosis.

2. Rapid tranquilization using a neuroleptic agent would be indicated in which of the following cases?
- **a.** An intoxicated schizophrenic
- **b.** Anticholinergic psychosis
- **c.** A lactating schizophrenic
- **d.** A phencyclidine overdose
- **e.** A pregnant schizophrenic

Answer: A. Neuroleptics are contraindicated in choices B to E. They should not be the sole agent for alcohol withdrawal but would be useful for acute psychotic agitation.

3. A 45-year-old woman presents to the ED complaining of severe anxiety and unrest. She has a history of moderate schizophrenia, for which she was placed on olanzapine 2 months prior. She has been compliant. Physical examination is remarkable for the presence of anxiety, clear sensorium and orientation, and normal speech. She is restlessly pacing the room and reports being compelled to keep moving. Urine drug screen is negative. What would be the most appropriate therapy?
- **a.** Benztropine orally
- **b.** Lorazepam orally
- **c.** Olanzapine intravenously
- **d.** Psychiatry consultation
- **e.** Ziprasidone intravenously

Answer: A. Akathisia is a state of motor restlessness characterized by a physical need to be constantly moving. The patient does not want to do so but feels compelled. It is most commonly seen in middle-aged patients within the first few months of starting treatment. It may be mistaken for an acute deterioration, but psychotic features are not increased. Treatment is with oral beta-blockers and anticholinergics (benztropine).

4. What is the most common adverse effect seen with neuroleptic agents?
- **a.** Akinesia
- **b.** Dystonia
- **c.** Orthostatic hypotension
- **d.** Pseudoparkinsonism
- **e.** Tardive dyskinesia

Answer: B. Dystonia occurs in 1% to 5% of this patient population. The reaction occurs because of a dopaminergic pathway disruption with a resulting cholinergic predominance. Anticholinergics should be administered parenterally (Benadryl 25 to 50 mg intravenous [IV] or Cogentin 1 or 2 mg IV), followed by 48 to 72 hours of oral follow-up treatment to prevent recurrence. Patients may experience tongue protrusion (buccolingual crisis), upward eye deviation (oculogyric crisis), back arching (opisthotonus), and, rarely, laryngospasm. Symptoms may lessen with voluntary muscle action and increase with stress.

CHAPTER 96: QUESTIONS AND ANSWERS—cont'd

5. A 27-year-old known schizophrenic is brought to the ED for altered mental status. His only known medication is clozapine, which he started 4 weeks ago with subsequent dose increases. He has no other past history. Physical examination reveals a muscular man who is somnolent and diaphoretic. He withdraws all extremities stiffly and grimaces in pain. Vital signs are temperature, 40.5°C; heart rate, 146 beats per minute; blood pressure, 205/125 mm Hg; and respiratory rate 28 breaths per minute. Rectal examination is guaiac positive. Foley placement shows brown urine. What should be the next diagnostic maneuver?

a. Creatine kinase level
b. Head computed tomography (CT) scan
c. Lumbar puncture
d. Thyroid hormone levels
e. Urine drug screen

Answer: A. Neuroleptic malignant syndrome is an idiopathic condition clinically similar to serotonin syndrome and malignant hyperthermia. Milder cases may be confused with serotonin syndrome. Severe cases, related to possible hypothalamic dysfunction, present with fever, rigidity, altered mental status, autonomic instability, elevated creatine phosphokinase (CPK), and possibly rhabdomyolysis. It is seen with both typical and atypical antipsychotics and generally occurs in the first few weeks of treatment. Complications may include hepatic/renal failure, gastrointestinal (GI) hemorrhage, and respiratory failure. Severe cases may require intravenous dantrolene or dopamine agonists (e.g., bromocriptine).

97

Mood Disorders

Leslie S. Zun and Joshua B. Nathan

KEY CONCEPTS

- Patients with apparent mood disorders should be evaluated for medical disorders, medication effects, or substance abuse or withdrawal because these conditions can mimic both depression and mania.
- Mood disorders should be suspected in patients with multiple, vague, nonspecific complaints and in patients who are frequent, heavy users of medical care.
- Patients with mood disorders should be assessed for their suicide potential.
- Pharmacologic treatment and linkage to care after discharge are important parts of managing mood disorders in the emergency setting.

FOUNDATIONS

Background and Importance

Mood is a subjective emotional state. It is normal human experience to have fluctuations in mood in response to occurrences in everyday life. A change in mood becomes a "mood disorder" when it significantly impairs functioning. In the emergency department (ED), patients with mood disorders often present grossly debilitated, with thoughts of suicide, homicide, or profound self-neglect. These patients frequently present in moments of emotional crisis, but this may not be their presenting complaint. Approximately one-fourth to one-third of ED patients screen positive for mood disorders.

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), divides mood disorders into two broad categories: depressive disorders and bipolar disorders.[1] Mood disorders may also be due to a general medical condition or substance-induced mood disorders. Because the specific pathophysiologic mechanisms of these disorders are not fully understood, they are categorized by groupings of symptoms that persist for defined lengths of time.

EPIDEMIOLOGY

The World Health Organization (WHO) ranks major depressive disorder as one of the most prevalent and disabling diseases in the world.[2] The 12-month prevalence for major depressive disorder is 5% and the lifetime prevalence is 13%. Patients with major depressive disorder frequently have other comorbid mental health issues, including anxiety disorders, personality disorders, and substance use disorders.

The lifetime prevalence of bipolar spectrum disorders is approximately 4%. Both severe depression and mania are serious and potentially life-threatening. Up to 80% of patients with bipolar disorder will exhibit suicidal behavior, and half will attempt suicide. Suicidal behavior can occur during all phases of bipolar disorder, but patients experiencing a depressed or a mixed episode are at higher risk, especially those with severe depressive symptoms and a sense of hopelessness.

Doctors, including residents and medical students, die by suicide at twice the rate of the general population, with 300 to 400 physicians dying by suicide every year. This also means doctors are in the highest risk profession for suicide. Unlike the general population, male and female physicians have equal rates of suicide attempts and suicide completion. While the high rate of suicide among physicians may seem counterintuitive, concerns about privacy, accessibility of services, and lack of time are commonly stated barriers to physicians seeking help. As a result, doctors fare worse with burnout, depression, and suicide than almost anyone else.[3]

Neuroanatomy

Neuroimaging studies of the brain suggest that abnormalities in certain areas and the interconnections between those areas may be involved mood disorders. A common magnetic resonance imaging (MRI) finding in patients with mood disorders, especially bipolar disorder, is an increased occurrence of subcortical hyperintensities in the periventricular areas, basal ganglia, and thalamus. High-resolution MRI demonstrates reduced volumes in the hippocampus, orbital cortex, and anterior cingulate. These findings are associated with more severe illness, bipolar disorder, and increased cortisol levels. Volume reduction in the hippocampus is associated with high illness chronicity.

The amygdala is a clustering of nuclei that process emotional stimuli, especially fear, anger, and sadness. Functional neuroimaging suggests that amygdala activity is increased when the subject is exposed to emotionally relevant stimuli. The amygdala has connections throughout the brain. A decreased amygdala volume has been associated with unipolar depression.

PATHOPHYSIOLOGY

The pathophysiology of the mood disorders is not well established, but much is known about the neurophysiology, genetics, and psychosocial aspects of the disorders.[4,5]

Neurophysiology

Antidepressants work by increasing the availability and activity of serotonin and norepinephrine at the synapse to stimulate the postsynaptic neuron. This is done by direct binding to the presynaptic and postsynaptic receptors, blocking reuptake of the neurotransmitter or inhibiting the enzymatic breakdown of the neurotransmitter. Because norepinephrine and serotonin systems traverse large portions of the brain, monoamine deficiency is hypothesized as a cause of depression. Depletion of oral tryptophan and tyrosine, amino acids essential for the production of serotonin and norepinephrine, respectively, can induce

a depressive episode in subjects with a history of depression but not in healthy controls. Monoamine metabolite levels in cerebrospinal fluid, plasma, urine, and postmortem brains of patients with depression have not been reliably found to be deficient, indicating that there could be downstream effects involving second-messenger systems, such as cyclic adenosine monophosphate and phosphatidylinositol.

Other neurotransmitter systems may play a role in the development of depression. Decreased levels of both glutamate and γ-aminobutyric acid (GABA) have been found in the prefrontal cortex of depressed subjects. Intravenous (IV) ketamine, an *N*-methyl-D-aspartate (NMDA) antagonist, induces a rapid antidepressant effect and suggests a role for glutamate in the pathophysiologic process of depression. The brain relies on the actions of protective and regenerative cytokines, such as brain-derived neurotrophic factor (BDNF). All known antidepressants raise levels of BDNF and subsequently result in neurogenesis of certain brain regions, such as the hippocampus. Other theories include the melatonergic system and related abnormalities in circadian rhythm, decreased neurosteroid synthesis, impaired endogenous opioid functioning, monoamine-acetylcholine imbalance, inflammatory effects of cytokines, and dysfunction of specific brain structures and circuits.

The neurophysiology of bipolar disorder is less well understood than unipolar depression, in part because of the fluctuating mood states and the heterogeneity of the disorder. Bipolar disorder may in part arise from abnormalities in the connections within and between structures in the brain.[5] Specifically implicated are circuits interconnecting the amygdala, hypothalamus, striatum, and subdivisions of the frontal cortex, all of which are involved in both the generation and regulation of emotion.[6]

Endocrine System

Physiologic changes such as increased alertness, decreased appetite, increased heart rate, and activation of the hypothalamic-pituitary-adrenal (HPA) axis occur when a person is stressed. The HPA axis may play a role in depression, especially in cases of early childhood and chronic stress. Activation of the HPA axis releases corticotropin-releasing hormone (CRH) from the hypothalamus. Although not specific, patients with depression may have increased levels of free cortisol in the plasma, cerebrospinal fluid, and urine. Increased CRH has been demonstrated in cerebrospinal fluid, and increased levels of CRH messenger RNA and protein have been demonstrated in limbic brain regions. Although none of these measures is reliable as a diagnostic tool, successful treatment to remission has been shown to reverse some of these abnormalities, and antiinflammatory agents have demonstrated benefit in the treatment of depression in small controlled trials.[5]

Genetics

Genetic vulnerability to mood disorders has not been traced to a single gene. It is likely to be due to the additive effects of many genes and environmental influences on how these genes are expressed. Family, twin, and adoption studies provide evidence that major depressive disorder is a familial disorder but is less heritable than bipolar disorder. Bipolar disorder is one of the most heritable medical illnesses with a heritability of 80% to 85% and a monozygotic twin concordance of about 40%.

Psychosocial Factors

The etiology of most psychiatric problems, including mood disorders, involves complex interactions between both biologic and psychosocial factors.[1] The complex neural mechanism that regulates mood responds to and is modified by each person's experience, including events in early childhood, such as childhood sexual abuse, reward and punishment during growth and development, other lifetime trauma, marital problems, low social support, and various kinds of loss. Psychosocial theories of mood disorder form the basis for psychotherapy.

CLINICAL FEATURES

Major Depressive Disorder

Major depressive disorder is characterized by one or more major depressive episodes, as defined by DSM-5 criteria (Boxes 97.1 and 97.2).[1] A major depressive episode is characterized by disturbances in four major areas: mood, psychomotor activity, cognition, and vegetative function. The patient must have at least five symptoms for a minimum of 2 weeks and one of the five must be depressed mood or anhedonia (decreased interest or pleasure).[1]

Mood Disturbances

Patients in a depressed state often feel profoundly hopeless and helpless. There are many words and phrases that can be used to describe feeling depressed; some patients will not recognize that they are "depressed" but rather they may describe the feeling in some other manner. Someone feeling no emotion (profoundly depressed) may answer "no" when asked about depressed mood.

On the other hand, a person may meet criteria for a major depressive episode and not be experiencing a depressed mood. Depression can also be manifested as a decreased capacity to experience pleasure or interest in otherwise pleasurable activities. This loss of interest is known as *anhedonia.*

As noted previously, the patient must exhibit a depressed mood or anhedonia to meet DSM-5 criteria for a diagnosis of a major depressive episode.[1]

Disturbances in Psychomotor Activity

Physical activity in depression can be either increased or decreased. Psychomotor retardation is a significant slowing of physical activity. When suffering from psychomotor retardation, thinking and speaking can be slow, causing delayed responses to answers. Depressed patients often describe feeling fatigued with a general lack of energy and motivation. Conversely, patients may display psychomotor agitation, which can be manifested as fidgeting, pacing, hand-wringing, or restlessness.

Vegetative Disturbances

Vegetative symptoms include disturbances in three major areas: sleep, appetite, and sexual function. Depressed patients may complain of insomnia or hypersomnia. Insomnia may be manifested as difficulty in falling asleep, frequent awakenings throughout the night, or early-morning wakening. Depressed patients with hypersomnia may report sleeping 12 to 14 hours or more a day. Alterations in appetite and eating patterns can also occur, resulting in significant weight gain or loss during a short time. Loss of interest in sexual activity and impaired sexual functioning may also accompany depression, although this is not listed as a DSM-5 criterion.

Thought Process and Content

Depressed patients often describe impaired concentration and forgetfulness. Executive functioning can also be impaired. In severe cases, this results in a decreased ability to perform basic activities of daily living.

Thought content tends to be negatively biased, such as recurrent thoughts of guilt, failure, worthlessness, and self-criticism. Patients in a depressed episode are at increased risk for suicide. Suicidal thoughts may range from vague notions that life is not worth living (passive) to fully envisioned suicide plans with definitive intent to kill themselves (active). All depressed patients must be questioned about suicidal

BOX 97.1 Summary of *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition,* Criteria for a Major Depressive Episode

A. Five or more of the following symptoms have been present almost every day during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure. *Note:* Do not include symptoms caused by a general medical condition.
   1. Depressed mood (can be irritable mood in children and adolescents)
   2. Loss of interest or pleasure in activities
   3. Significant weight loss when not dieting or weight gain, or decrease or increase in appetite
   4. Insomnia or hypersomnia
   5. Psychomotor agitation or retardation
   6. Fatigue or loss of energy
   7. Feelings of worthlessness, or excessive or inappropriate guilt
   8. Diminished ability to think or concentrate, or indecisiveness
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation, or a suicide plan or attempt

B. Symptoms cause clinically significant distress or impairment in social, occupational, or other functioning.

C. Symptoms are not caused by direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition (e.g., hypothyroidism).

D. Symptoms are not better explained by another mental health disorder.

E. There has never been a manic or hypomanic episode.

Modified from: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

BOX 97.2 Mnemonics for the Symptoms of Depression and Mania

Mnemonic for the Symptoms of Depression
Sig E Caps
Sleep amount increased or decreased
Interest (anhedonia)
Guilt
Energy level decreased
Concentration decreased
Appetite increased or decreased
Psychomotor activity increased or decreased
Suicidal ideation

Mnemonic for the Symptoms of Mania
Dig Fast
Distractibility
Irritability
Grandiosity
Flight of ideas
Activity increased
Sleeplessness
Thoughtlessness (impulsivity, increased risk-taking)

thoughts. Because patients are not often forthcoming with their thoughts on suicide, a thorough review of risk factors and protective factors needs to form the basis of clinical decisions for providing the necessary level of care.

Patients with severe depression may have psychotic symptoms. The hallucinations and delusions that accompany depression are usually mood-congruent, meaning that the themes of the psychotic content are consistent with the depressed mood.

Masked Depression

Mood disorders may not be clear at presentation. The depressed patient may have only vague somatic symptoms. Common complaints include weakness, fatigue, headache, and abdominal pain with medical evaluations occurring in response. Patients may not be aware of their depression and are often heavy users of medical care. Over half of patients with major depressive disorder initially present with somatic symptoms only, which can mask a hidden depression. Clues that suggest a mood disturbance include the recent onset of a set of unusual behaviors, significant social disturbance, such as job loss, financial stress, and marital difficulties, and self-destructive behavior (e.g., substance abuse, sexual promiscuity).

Special Considerations

Children and Adolescents. Criteria for depression in children and adolescents are the same as for depression in adults. Depression in these age groups can, however, present differently. Prepubertal children are more likely to have somatic complaints, psychomotor agitation, and mood-congruent hallucinations and less likely to have disturbances in sleep and appetite. Some children are misdiagnosed as having attention deficit disorder, especially if symptoms involve poor concentration, listlessness, agitation, and withdrawal from daily activities.

Adolescents with depression may show increased irritability, oppositional behavior, and substance abuse. Other characteristics include social withdrawal, increased rejection sensitivity, and decline in school performance. Some adolescents may be first diagnosed with depression on receiving treatment for drug and alcohol problems.

Disruptive Mood Dysregulation Disorder. A newly described phenomenon for children who may have been previously diagnosed with depression or bipolar disorder is disruptive mood dysregulation disorder. Children and adolescents given this diagnosis display severe, recurrent outbursts that are out of proportion for the situation and are inconsistent with developmental level. The outbursts must occur three or more times a week, and the mood in between outbursts is irritable or angry most days. There are duration criteria of 12 months with no periods of three or more consecutive months not meeting criteria. Symptoms must occur prior to age 10.[1]

Geriatric Patients. Depression is more common in elders because of more frequent occurrences of loss, comorbid health issues, and loss of autonomy. The elderly have a tendency to report more somatic complaints when depressed. They are also more vulnerable to development of melancholic depression, which is characterized by early morning awakening, diurnal variation in mood, low self-esteem, and low mood reactivity. Older depressed patients can also present with symptoms involving memory loss, inattention, withdrawal from daily activities, and lapses in personal and social hygiene that suggest dementia rather than depression. When such symptoms are from depression, the condition is called *pseudodementia*. Serious depression in elders is a highly treatable, reversible condition.

Other Depressive Disorders

Peripartum Depression

Postpartum depression is a depressive disorder that occurs during pregnancy or within 4 weeks of delivery and would allow for the specifier "with peripartum onset." Symptoms of depression are common in the perinatal period. As noted in the DSM-5, between 3% and 6% of women will experience the onset of major depression during pregnancy

or within the following weeks to months.[1] Similarly, but less severe, up to 65% of mothers report some depressed mood after childbirth, often called *postpartum blues*. Symptoms are generally mild and transient; although in 10% of mothers, it may lead to a full-fledged episode of major depression.

Postpartum mood episodes with psychotic features can be particularly dangerous. Infanticide is most often associated with command hallucinations to kill the infant or associated delusions. The risk for this is most closely related to a past history of postpartum episodes with psychosis, a history of depression or bipolar disorder, or a family history of bipolar disorder.

Persistent Depressive Disorder

Persistent depressive disorder is a new diagnosis that combines two former diagnoses: chronic major depressive disorder and dysthymic disorder. Specific criteria include the following: depressed mood most of the day, most days for at least 2 years; two or more of the following: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feelings of hopelessness; never more than 2 months of the 2 years without symptoms; and must cause significant distress or impairment in functioning. Exclusion criteria include a history of hypomania or mania and a history of psychotic illness. Also, it cannot be due to a substance or medical condition.[1] There are multiple specifiers that can be applied to this diagnosis.

Premenstrual Dysphoric Disorder

Premenstrual dysphoric syndrome is a new diagnosis included in the DSM-5. At least five of the listed symptoms must be present in the final week before the onset of menses and start to improve within a few days after the onset of menses, and be absent or minimal in the week post menses. These symptoms must be present for most cycles over the preceding year. The onset can occur at any point after menarche. Risks for development include stress, history of interpersonal trauma, seasonal changes, and sociocultural aspects of female sexual behavior.

Seasonal Affective Disorder

Seasonal affective disorder is not a separate mood disorder, but rather, a specifier of major depressive disorder. An example of the use of a specifier is "major depressive disorder, recurrent, moderate, with seasonal pattern." This specifier can only be used with a recurrent major depressive disorder. The criteria for this include the following: a regular temporal relationship between the onset of a depressive episode and a particular time of year, full remissions at a specific time of year, two depressive episodes within 2 years that demonstrate a temporal relationship, no nonseasonal episodes within the same period, and substantially more seasonal depressive episodes than nonseasonal episodes over the person's lifetime.[1] Melatonin, a hormone secreted in the brain and produced at high levels in the dark, has been implicated in the etiology of this disorder. Phototherapy is an effective and safe treatment of seasonal depression. Light exposure to the eyes seems to be essential, but the exact mechanism of action is still unknown.

Bipolar Disorders

Bipolar disorder is a chronic, progressive illness with onset for men between their mid-teens and mid-twenties and for women between their mid-teens and mid-thirties. The illness involves extreme mood episodes associated with exacerbation of other symptoms and deterioration of function. Patients with bipolar disorder may require different forms and intensities of treatment at different stages of the illness. *Bipolar I disorder* includes at least one manic episode, and patients have typically had one or more major depressive episodes, although a depressive episode is not necessary for diagnosis. *Bipolar II disorder* involves a hypomanic episode and at least one major depressive episode. A hypomanic episode includes the features of a manic episode without psychosis, marked impairment of function, or the need for hospitalization.[1]

Manic Episode

During a manic episode (see Boxes 97.2 and 97.3), the disturbance in mood must be severe enough to include psychosis, the need for hospitalization, or marked impairment in functioning. Bipolar disorders are much less common than major depressive disorder. The overall prevalence of a manic episode is about 2% in both women and men.

In many cases, manic patients are brought to the ED by someone else (e.g., family, police, or emergency medical services). Patients who are experiencing a manic episode may present with extreme mood lability; at time gregarious, humorous, and engaging, alternating suddenly with belligerence and irritability. Patients may display pressured speech, in which they keep talking, often rapidly and loudly without pauses between thoughts or sentences and are difficult to interrupt. The thought process in mania is characterized by illogical associations and flight of ideas. An inflated self-esteem and grandiose delusions may lead them to also be argumentative, impatient, and condescending. Grandiosity often centers on very broad dramatic or universal themes, such as religion or politics. The patient may describe a massive undertaking, such as "uniting the world's churches" or "solving world poverty." These severe symptoms are usually accompanied by a profound lack of insight. Despite obvious altered behavior, impaired judgment, and poor impulse control, the patient may insist that there is nothing wrong or blame problems on others.

BOX 97.3 Summary of *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, Criteria for a Manic Episode

A. Distinct period of abnormally and persistently elevated, expansive, or irritable mood, and abnormally and persistently increased goal-directed activity or energy lasting at least 1 week (or any duration if hospitalization is necessary).
B. During the period of mood disturbance and increased energy or activity, three or more of the following symptoms have persisted (four, if the mood is only irritable) and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity
   2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
   3. More talkative than usual or pressure to keep talking
   4. Flight of ideas or subjective experience that thoughts are racing
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., buying sprees, sexual indiscretions, foolish investments)
C. Mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or social activities or to necessitate hospitalization to prevent harm to self or others, or psychotic features are present.
D. Symptoms are not caused by direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition (e.g., hyperthyroidism).

Modified from: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

Manic patients have decreased or no need for sleep and typically report being awake for days. They may be involved in a massive project (e.g., writing a novel), may completely disregard consequences of actions, may have difficulty with spending (e.g., credit cards revoked), and may engage in risky behavior (e.g., sexual liaisons with strangers, risky driving). Because the patient's abnormal thought process can make the history of present illness unreliable, whenever possible, a corroborating history should also be obtained from family or others who know of the patient's behavior.

Manic patients may present as trauma patients, injured by an action reflecting the patient's grandiosity (e.g., attempting to fly), impulsivity, or belligerence (e.g., fighting, resisting arrest). A manic episode may be punctuated by abrupt periods of tearfulness and profound depression, including suicidal ideation. When depressive and manic features occur concurrently in such a manner, the episode is termed *mixed* or *bipolar, mixed phase.*

Cyclothymic Disorder

Cyclothymic disorder is characterized by chronic mood swings that do not meet criteria for a hypomanic or depressive episode. The mood episodes must occur over at least 2 years, present for at least half the time, and the individual cannot be symptom-free for more than 2 months at a time.[1]

Mood Disorders Caused by a General Medical Condition

This diagnosis requires a prominent and persistent period of depressed mood or anhedonia that predominates the clinical picture, with evidence that the disturbance is the direct pathophysiological consequence of a medical condition, and not better explained by another mental disorder or occurring during the course of delirium.[1] Bipolar disorder requires a prominent and persistent period of abnormally elevated, expansive, or irritable mood; and abnormally increased activity or energy that predominates the clinical picture, with evidence of direct pathophysiological consequence of another medical condition, and it is not better explained by another mental disorder or occurs during the course of delirium.[1]

Certain medical illnesses have a well-known association with mood disorder. In Parkinson disease, electrical stimulation to a certain area of the substantia nigra alleviates symptoms of depression. Stimulation of an area only 2 mm away can cause acute reversible symptoms of depression, such as crying, not wanting to live, and hopelessness. Parkinson disease has a well-known association with depression, with up to 40% of patients demonstrating major depression.

Certain malignant neoplasms have a well-known association with depression, including pancreatic carcinoma, brain neoplasm, and disseminated malignant disease (e.g., lymphoma). Coronary artery disease, myocardial infarction, stroke, end-stage renal disease, acquired immunodeficiency syndrome, several endocrine diseases, and connective tissue disease are also associated with major depressive disorder. After a myocardial infarction, patients with depression have a 3.5-fold increase in cardiovascular mortality compared with nondepressed patients. The development of stroke, diabetes, and osteoporosis is more likely in patients with depression than in those who are not depressed.

Depression related to medical conditions may be different in some respects from primary depression and responds less favorably than primary depression to antidepressant medication. Treatment-resistant depression, defined as depression that has not responded to at least two adequate trials of medication, should prompt clinical investigation for a general medical condition causing the depressive episode.

Mood Disorders Caused by Medications or Other Substances

These are very similar to mood disorders caused by medical conditions, with the exception that the symptoms must develop during or soon after substance intoxication or withdrawal, or after exposure to a medication capable of producing the symptoms.[1]

Many medications are associated with symptoms of mood disorders. Multiple antihypertensives, anticonvulsants, and hormones have been associated with depressive symptoms, and certain antibiotics and steroids are associated with manic symptoms. Intoxication with or chronic heavy use of alcohol, sedatives, hypnotics, anxiolytics, narcotics, and other depressants can cause symptoms of a major depressive episode. Stimulants such as cocaine, phencyclidine, hallucinogens, and amphetamines can cause symptoms of a manic episode. Mood disorder symptoms can also develop during withdrawal. To qualify for this diagnosis, the symptoms must not occur exclusively during a course of delirium, must cause significant distress or impairment of functioning, and must develop within a month of either substance intoxication or withdrawal. When the mood disorder predates the period of substance abuse or lasts longer than 1 month after the period of abuse, the diagnosis may be an underlying mood disorder, such as a major depressive disorder or bipolar disorder, with a comorbid substance use disorder.

DIFFERENTIAL DIAGNOSES

Medical Disorders, Medications, and Substance Abuse or Withdrawal

Medical disorders, medications, and substance abuse or withdrawal can either cause or mimic mood disorders. The patient with symptoms and signs of depression may have an unrecognized malignant neoplasm or sedative intoxication. Differential diagnostic considerations for manic symptoms include stimulant abuse (e.g., cocaine, amphetamines), hallucinogen abuse, alcohol or sedative withdrawal, delirium, hyperthyroidism, and other medical conditions causing agitation. See the previous section for further information. Patients may be treated with antidepressant medication for a variety of disorders other than depression, such as anxiety, obsessive-compulsive disorder, posttraumatic stress disorder, pain syndromes, smoking cessation, and vasodepressor syncope.

Grief and Bereavement

Grief and bereavement are normal human reactions to the acute loss of another person, health, social position, or job. The period of mourning is characterized by sadness, diminished sense of well-being (somatic complaints), sleeplessness, and sadness triggered by thoughts of the loss. Normal grief, however, does not include loss of self-esteem, feelings of worthlessness, suicidal intent, psychomotor retardation, or occupational dysfunction. The duration of normal grief and bereavement differs among cultures and among individuals within cultures, but severe symptoms normally resolve within 6 to 12 months.

Adjustment Disorders

Adjustment disorders are behavioral or emotional disorders that occur in response to an identifiable stress or stressors, with marked distress that is out of proportion to the severity of the stressor. The emotional component can involve sadness, low self-esteem, suicidal behavior, hopelessness, helplessness, or other self-threatening behavior. Acute adjustment disorder occurs within 3 months of the stressor and does not last longer than 6 months.[1] The stressors are typically not as severe as those precipitating bereavement reactions, and the responses are often more maladaptive.

Borderline Personality Disorder

Borderline personality disorder is characterized by unstable personal relationships, unstable self-image, and self-destructive behaviors. The disorder may include chronic feelings of emptiness, which may

be misdiagnosed as depression, or reactivity of mood, which may be mistaken for mania or hypomania. These patients typically live lives of crisis and constant conflict.

Dementia

Dementia can be confused with depression but is characterized by abnormal mental status, including abnormalities in tests of memory, calculation, and judgment (see Chapter 90).

Diagnostic Testing

History and physical examination should focus on determining if the patient has a mood disorder or the possibility that drug abuse, medications, or a general medical condition may be responsible for the patient's condition instead. It is essential to identify medical conditions that may exacerbate a psychiatric presentation. The psychiatric history should ask about current symptoms, precipitating events (e.g., job loss or relationship), past psychiatric and substance use history, history of self-harm or suicide attempts, and identification of support systems. Even if not suggested by the patient, careful questioning of suicidal thoughts is necessary. If possible, history should be confirmed by speaking with the patient's regular health care providers and interviewing family, friends, or eyewitnesses to the events that precipitated the ED visit. A tentative diagnosis can be established by use of DSM-5 criteria.

Laboratory tests to investigate medical conditions may be necessary based on the specifics of the clinical presentation, but no tests can confirm or exclude mood disorders. Patients with new symptoms compatible with mood disorders need a more extensive medical and psychiatric investigation than those with a known disorder.

MANAGEMENT

Patients presenting with mood disorder symptomology are frequently in crisis, often overwhelmed, and frankly scared. The ED is a chaotic, stimulating environment that may cause or exacerbate the patients' level of agitation. Creation of a safe and stable environment for the patient is a high priority. Individuals experiencing an acute manic episode may be disruptive, refuse medical evaluation, and make repeated attempts to leave the ED. The initial step in treating such a disruptive patient is to offer assistance in reducing the agitation, which may begin with verbal de-escalation.[7] One key is offering anxiolytic medication early in the patient's presentation. If de-escalation techniques and medication do not resolve the agitation, the patient may need to be placed in seclusion or restraints for his or her safety and that of others. This is a last resort after other de-escalation measures have failed. Chapter 185 discusses the use of seclusion and restraints in the ED. If a medical cause for agitation is found, treatment is aimed at the underlying cause (e.g., oxygen for hypoxic delirium). Often in the ED, treatment may need to begin prior to the cause of the agitation being fully recognized.[8,9] Figure 97.1 shows a simple algorithm for approaching the agitated patient.

Treatment of depression in the ED is more controversial. Selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) are the main treatments for depression. For the patient who is awaiting inpatient psychiatric placement, these medications can be initiated in consultation with the admitting service. Patients with mild to moderate depression, not requiring hospitalization, may be started on an SSRI as long as they have close follow-up arranged. SSRIs are known to have a myriad of side effects that can lead to premature discontinuation.[10] For the patients who are already on psychotropic medications but have discontinued them for a reason unrelated to adverse effects, it is reasonable to restart these medications in the ED.

A non-agitated manic patient may be able to inform the treatment team about what has worked well in the past. There are two medication choices for acute mania: antipsychotics and mood stabilizers.[11] All of the atypical, or second-generation, antipsychotics have been approved to treat acute mania as monotherapy or as an adjunctive therapy, except paliperidone and iloperidone. Lithium, valproic acid/divalproate, and carbamazepine are the most well-studied mood stabilizers. Lithium and carbamazepine need to be titrated, but valproic acid can be loaded in the ED at 20 to 30 mg/kg a day in a healthy person with normal liver function.

The atypical antipsychotic medicines, including ziprasidone, risperidone, olanzapine, aripiprazole, quetiapine, asenapine, and lurasidone, have a lower risk of acute side effects (such as acute dystonia) than conventional antipsychotic agents. Oral doses should be offered first, and several agents, including risperidone, olanzapine, and aripiprazole, are available in rapidly dissolving tablet form. Two are available as a short-acting intramuscular injection: ziprasidone (Geodon) and olanzapine (Zyprexa). Ziprasidone 10 mg every two hours or 20 mg every four hours is effective; however, its use is limited to 40 mg per 24 hours. Olanzapine 2.5 mg to 10 mg is effective, but is limited to 30 mg per 24 hours. Also, olanzapine is associated with postural hypotension so should not be used in combination with parenteral benzodiazepines because of the risk of cardiopulmonary depression. It is valuable to obtain psychiatric consultation during the initiation of agitation treatment, because these patients will generally require significant ED treatment or psychiatric hospitalization.

DISPOSITION

To determine the appropriate disposition for patients presenting with a mood disorder, a suicide risk assessment is required. The Substance Abuse and Mental Health Services Administration developed a practical tool referred to as the Suicide Assessment Five-Step Evaluation and Triage (SAFE-T).[12] Current suicidal thoughts, risk factors, and protective factors should be identified, as well as past suicidal thoughts, plans, or acts. Chapter 101 provides an in-depth discussion of suicide assessment. It is only after considering this information that an appropriate intervention can be determined. With the help of social workers or a mental health worker, many patients can be safely discharged home with close follow-up. Patients receiving initial treatment in the ED, without a proper handoff to outpatient care, are at an increased risk for return. If available, it is preferred that a social worker or mental health worker connect discharged patients with outside agencies and services, rather than providing patients with a referral list.

CHAPTER 97: QUESTIONS AND ANSWERS

1. What is the lifetime suicide risk for people with major untreated depression?

a. 5%
b. 10%
c. 15%
d. 20%
e. 25%

Answer: c. Patients with major depression have a high lifetime suicide risk, and although episodes of acute decompensation with even higher risk can be identified and treated, a certain number of patients succeed in committing suicide.

2. Which of the following abnormalities of central nervous system neurotransmitters is associated with clinical depression?

a. Decreased hypothalamic-pituitary-adrenal (HPA) activity
b. Depressed serotonin levels
c. Elevated gamma-aminobutyric acid (GABA) levels
d. Elevated norepinephrine levels
e. Unchanged dopamine levels

Answer: b. The central biochemical features toward which pharmacologic management is directed are depressed levels of norepinephrine and serotonin. Data are also emerging that suggest decreased dopamine levels. The HPA axis may also be altered with elevated cortisol levels.

3. Which of the following statements regarding depression in children and elders is *true?*

a. Children with depression rarely present with somatic complaints.
b. Depression in children may be misdiagnosed as attention deficit disorder (ADD).
c. Depression presents differently from dementia in elders.
d. Diagnostic criteria for depression in children are different.
e. Serious depression in elders is generally refractory to treatment.

Answer: b. Depression in children and adolescents can be misdiagnosed as ADD. Somatic complaints are a common feature of children and adolescents presenting with depression, but the diagnostic criteria are not different. Geriatric depression may be manifested in a manner similar to dementia (pseudodementia), but unlike dementia, the depression is highly treatable and reversible once it is recognized.

4. A 31-year-old attorney is brought to the emergency department (ED) by his family for a chief complaint of agitation and a behavioral change. He has no past medical history and takes no medications. The family reports decreased sleep, increased talkativeness, marked increased time and involvement at work, and an uncharacteristic buying spree. Your examination is remarkable for distractibility, gregarious and pressured speech, flight of ideas, and mild psychomotor agitation. Laboratory examination and urine drug screen results are negative. The patient is adamant that he has important things to do and needs to leave. Which of the following statements regarding this patient's most likely diagnosis is true?

a. Antipsychotic agents are not effective.
b. Hallucinations would be atypical.
c. If treated, intravenous valproic acid is indicated.
d. Initiating treatment in the ED is not indicated.
e. Multiple antibiotics can cause this clinical picture.

Answer: e. This patient has a fairly classic presentation for acute mania with pressured speech, distractibility, grandiosity, increased involvement (in this case with work), and decreased need for sleep. Multiple drugs may precipitate this, including acyclovir, isoniazid, sulfonamides, the floxins, and chloroquine. An acute manic episode may be manifested with hallucinations and mimic an acute psychosis. ED treatment is usually indicated for this disorder. Acute stabilization is generally effective with major tranquilizers, such as haloperidol.

98

Anxiety Disorders

Leslie S. Zun and Joshua B. Nathan

KEY CONCEPTS

- Patients who present with predominant symptoms of anxiety may be suffering from medical disorders, medication effects, or substance abuse or withdrawal.
- Anxiety may accompany the onset of serious medical disease, cause significant metabolic demands, and stress a marginally compensated organ system.
- Anxiety caused by non-psychiatric illness is usually suggested by the patient's physical examination findings but may require testing to further delineate the cause.
- Oral, intravenous, or intramuscular medication may be necessary for patients who are a significant threat to themselves or others and for anxious patients with significant medical illness.
- Limited benzodiazepine therapy may be helpful for select patients.

FOUNDATIONS

Background and Importance

Anxiety is a specific unpleasurable state of tension that forewarns the presence of danger, real or imagined, known or unrecognized, and is often verbalized as an intense feeling of worry. Anxiety is often a normal adaptation to life events or stressors, and in many circumstances, could be considered appropriate given the context and would represent a reasonable emotional response to a perceived threat or circumstance. Even extreme levels of anxiety could be considered appropriate given the level of perceived threat. An anxiety disorder, however, describes a condition in which a response to a given circumstance or threat becomes significantly disproportionate or uncontrollable, leading to the deterioration of performance and an inability to cope. As the level of dysfunction increases, the patient is much more likely to have a true anxiety disorder. Anxiety disorders are considered to be among the most prevalent of mental health behavioral and emotional disorders worldwide.

Acute anxiety is common in emergency department (ED) patients who have primary anxiety disorders, concomitant anxiety disorders, and crisis situations. Emergency physicians are frequently called upon to diagnosis and treat anxiety disorders in the ED and therefore need to be familiar with both the diagnostic criteria as well as the differential diagnoses and treatment modalities. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) criteria for anxiety disorders include general anxiety disorder, panic disorder, agoraphobia, and specific phobia. Obsessive-compulsive disorders (OCD), post-traumatic stress disorder (PTSD), and acute stress disorder, which have now been moved to their own category in the DSM-5, will also be discussed in this chapter.[1]

Epidemiology

The most recent available national statistics on past-one-year and lifetime prevalence of anxiety disorders amongst adults (age 18 or older) is derived from the National Comorbidity Study Replication (NCS-R) originating from the Harvard Medical School National Comorbidity Survey (NCS). Data updated as of 2007 reveals 19.1% past-year prevalence with a female predominance (23.4% versus 14.3%) and an overall lifetime prevalence of 31.1% among all adults in the United States (US).[2]

Many patients seeking primary health care have significant mood and anxiety symptoms, such as panic disorder, generalized anxiety disorders (GAD), and depression, but almost half of these symptomatic patients never receive appropriate treatment. Patients with chronic illness and those who make frequent medical visits have higher rates of anxiety and depression. The prevalence of anxiety disorders surpasses that of any other mental health disorder, including substance abuse. There is a close relationship between alcohol abuse and anxiety disorders.

Anxiety disorders in children and adolescents lead to anxiety disorders in adulthood, but anxiety disorders often go unrecognized and untreated in the pediatric population.[3] The same is true of geriatric patients with a prevalence rate of 1.2% to 15%. Except for generalized anxiety disorder and agoraphobia, anxiety disorders typically start earlier in life.[4]

The incidence of specific anxiety disorders varies: specific phobia is 7% to 9%, social anxiety is 7%, panic disorder is 3%, and GAD is 3%. The lifetime risk for post-traumatic stress disorder (PTSD) is about 9%, but the 12-month prevalence is approximately 4%. Substance or medication-induced anxiety and anxiety due to a medical condition have an unknown prevalence but may be relatively high in those seeking emergency medical care.

A different form of anxiety related to fear of suffering from an illness, now known as *illness anxiety disorder* (formerly hypochondriasis), may be as high as 8% in ambulatory medical populations.[2] In these cases, patients may disguise their anxiety, presenting with a physical complaint rather than bear the perceived stigma associated with psychiatric complaints. This is distinct from patients with a somatoform disorder.

Pathophysiology

There are many forms of anxiety disorders and the precise mechanisms underlying the development of anxiety have not been fully established. However, the serotonin, noradrenergic gamma-aminobutyric acid (GABA) and dopaminergic systems are the most studied neurotransmitter systems implicated in anxiety disorders[5] (see Box 98.1). It is hypothesized that low serotonin system activity and elevated

BOX 98.1 Neurotransmitters Involved in Anxiety Disorders

Neurotransmitter	Neuroanatomical Association and Mechanism
Serotonin	Amygdala. Periaqueductal gray matter increased in AD
Dopamine	Mesolimbic mesocortical and nigrostriatal cortex; evidence of role in AD
Norepinephrine and epinephrine	Autonomic nervous system directly correlated in AD
GABA	Inhibitory neurotransmitter decreased in AD

The relationship between epilepsy and anxiety disorders. *Curr Psychiatry Rep*. 2019 Apr 29;21(6):40. https://doi.org/10.1007/s11920-019-1029-9. PMID: 31037466. Vismara M, Girone N, Cirnigliaro G, et al. Peripheral biomarkers in DSM-5 anxiety disorders: an updated overview. *Brain Sci*. 2020;10(8):564. Published 2020 Aug 17. https://doi.org/10.3390/brainsci10080564.

noradrenergic system activity may play a role, and thus selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) are frequently used as treatment. There is also considerable comorbidity with depressive disorders, with evidence showing genetic and neurobiologic similarities, especially related to serotonin.

The well-established effectiveness of benzodiazepines in the treatment of anxiety has led to the study of the GABA system and its relationship to anxiety. GABA is the principal inhibitory neurotransmitter in the central nervous system, and benzodiazepines act on the $GABA_A$ receptors. Studies have also focused on the role that corticosteroids may play in fear and anxiety. Steroids are thought to induce chemical changes in select neurons that strengthen or weaken certain neural pathways to affect behavior under stress.

Family research suggests that genetic factors play a role in anxiety, but the precise nature of the inherited vulnerability is unknown. Five major anxiety disorders (panic disorder, GAD, phobias, OCD, and PTSD) share genetic and environmental risk factors. Psychological and environmental factors also contribute to the generation of anxiety in biologically predisposed individuals.

CLINICAL FEATURES

Anxiety may be a manifestation of another medical disorder or an expression of an underlying psychiatric disorder. It may be difficult to make the distinction between anxiety as a symptom and anxiety as a syndrome in the ED. The physical symptoms of autonomic arousal (e.g., tachypnea, tachycardia, diaphoresis, lightheadedness) may be the only manifestations of anxiety. Classic panic disorder symptoms of chest pain, shortness of breath, and the sense of impending doom will often lead the patient to the ED, especially if it is the very first episode. Box 98.2 lists clinical predictors of anxiety caused by an underlying medical disorder. Patients may also exhibit anxiety associated with experiencing uncertainty about their illness and the potential implications of the illness. In addition, many patients seeking care in the ED may experience anxiety related to encountering internal and external dangers, such as assaults on body integrity in the form of uncomfortable procedures and forced intimacy with strangers.

Clinical manifestations of specific anxiety disorders are considerably different, warranting a review of each of the major types.

BOX 98.2 Predictors of Anxiety Caused by an Underlying Medical Issue

Onset of anxiety symptoms after 35 years old
Lack of personal or family history of an anxiety disorder
Lack of childhood history of significant anxiety, phobias, or separation anxiety
Lack of avoidance behavior
Absence of significant life events generating or exacerbating the anxiety symptoms
Poor response to antianxiety agents

BOX 98.3 Characteristics of a Panic Attack

Abrupt surge of intense fear or discomfort that reaches a peak within minutes, in which four or more of the following occur:
Palpitations
Sweating
Trembling
Shortness of breath or feeling of being smothered
Feeling of choking
Chest pain or discomfort
Nausea or abdominal distress
Feeling dizzy or lightheaded
Chills or heat sensations
Paresthesias
Derealization or depersonalization
Fear of losing control or going "crazy"
Fear of dying

Adapted from: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

Panic Disorder

Panic disorder (PD) is a diagnosis of exclusion, even in patients with known psychiatric illness, because several mental illnesses cause panic attacks as a secondary manifestation. For a diagnosis of panic disorder, one must experience recurrent, unexpected panic attacks (Box 98.3), as well as either persistent concern of future attacks or a maladaptive behavioral change related to the attacks. As with other disorders, the disturbance should not be better explained by substance use, another medical condition, or another psychiatric illness.[2]

A panic attack, differentiated from panic disorder, is an abrupt fear or discomfort that reaches a peak within minutes and has associated physical and cognitive symptoms.[2] It may occur with any anxiety disorder or as part of another psychiatric or other medical disorder. A panic attack is not a diagnosis but rather an indication of an underlying disorder. The presence of panic attacks often influences the treatment and outcome of the primary illness. An attack can be replicated by intentional hyperventilation, which can be distinguished from medical hyperventilation by its irregularity and interruptions. When there is doubt, formal psychiatric evaluation is indicated, particularly before a potentially dangerous or addictive drug therapy is prescribed.

Generalized Anxiety Disorder

GAD is defined as excessive worry that occurs most days over a 6-month period involving several events or activities.[2] The anxiety must cause significant distress or impairment in functioning. GAD has been linked to overuse of medical services and often is not recognized, which leads to ineffective treatment.

BOX 98.4 Characteristics of Post-Traumatic Stress Disorder*

Exposure to actual or threatened death, serious injury, or sexual violence.
Presence of intrusion symptoms associated with the traumatic event.
Persistent avoidance of stimuli associated with the traumatic event.
Negative alterations in cognition and mood associated with the traumatic event.
Marked alterations in arousal and reactivity associated with the event.
Duration is greater than 1 month.
Disturbance causes clinically significant distress or impairment.
Disturbance is not attributable to the physiological effects of a substance or another medical condition.

* Specifiers include "with dissociative symptoms" and "with delayed expression."
Adapted from: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

Post-Traumatic Stress Disorder

PTSD is caused by experiencing or witnessing a highly traumatic event. Those with PTSD manifest symptoms of re-experiencing the event, avoidance of triggers, changes in cognition and mood, and changes in arousal and reactivity (Box 98.4). Rates of PTSD are higher among military veterans and those whose occupation involves risk of traumatic exposure.[2] ED staff are also at risk for experiencing PTSD related to unusual traumatic events and unexpected deaths. Those suffering from PTSD may also be suffering from other disorders such as OCD, personality disorders, and substance use disorders, and may even exhibit suicidal ideations.

Specific Phobias

A phobia is an irrational fear that results in avoidance behavior. Phobia becomes a disorder when it interferes with day-to-day function in an individual's life. Social phobia, now termed *social anxiety disorder,* is characterized by clinically significant anxiety about one or more social situations in which the individual may be scrutinized.[2] This fear often leads to avoidance or other changes in behavior for such activities, such as public speaking, performing, visiting people, sitting in classrooms, attending social events using public showers or restrooms, or eating in public places.

Obsessive-Compulsive Disorder

OCD is characterized by recurrent, intrusive, unwanted thoughts (obsessions), such as fears of contamination, or compulsive behaviors or mental acts (compulsions) that a person feels compelled to perform, such as handwashing or counting. OCD is considered an anxiety disorder because (1) anxiety or tension is often associated with obsessions and resistance to compulsions, (2) anxiety or tension is often immediately relieved by yielding to compulsions, and (3) OCD often occurs in association with other anxiety disorders.[2] In summary, the obsessions and intrusive thoughts increase anxiety, and the compulsions and repetitive behaviors decrease anxiety but with significant disruption of one's life.

Hyperventilation Syndrome

Hyperventilation syndrome is a disorder characterized by intermittent episodes of increases in minute ventilation, together with feelings of doom and anxiety, associated with somatic symptoms such as dyspnea, chest pain, lightheadedness, perioral numbness and tingling, and muscle spasm of the hands and feet. Underlying conditions that may cause or contribute to this syndrome include primary psychological or neurologic dysfunction as well as cardiopulmonary etiologies. The diagnosis of hyperventilation syndrome may be challenging since there are no widely accepted diagnostic criteria. Patients presenting with new-onset hyperventilation require an extensive history, as well as physical examination and screening laboratories to rule out lethal etiologies. Patients with known hyperventilation syndrome from a psychological etiology can benefit from reassurance, breathing therapy, and low doses of benzodiazepines. A study of patients presenting to an ED with hyperventilation syndrome found 30% had previous episodes and more than 50% had a psychiatric comorbidity.[6]

Somatic Symptoms and Related Disorders

Although not necessarily categorized as anxiety disorders, this group of disorders has an undefined but established link to anxiety and depressive disorders and includes somatic symptom disorder, illness anxiety disorder (formerly hypochondriasis), conversion disorder (formerly functional neurological symptom disorder), and psychological factors affecting other medical conditions. With somatic disorders, the patient will complain about one or more physical symptoms, which cause impairment notwithstanding a negative evaluation. These symptoms are not intentionally feigned, as in the case of malingering or factitious disorder. A high utilization of medical services is correlated with these disorders, independent of comorbidity. Patients with somatoform disorders may seek as much psychiatric attention as do those with panic disorder.

DIFFERENTIAL DIAGNOSIS

It is important to differentiate the origin of anxiety to provide appropriate treatment. Many medical conditions mimic anxiety disorders, and up to 42% of patients initially thought to have anxiety disorders are later found to have a medical etiology.

Emergency clinicians should be able to distinguish between anxiety disorders and other medical illness (see Box 98.2) and, if necessary, treat both entities. Because anxiety states cause an increase in metabolic demands, they can cause a marginally compensated organ system to fail.

In patients who present with predominant symptoms of anxiety, even when the patients have known anxiety disorders, before considering which of the previously discussed DSM-5 anxiety-related diagnoses the patient might have, the clinician should first consider the possibility of medical and pharmacologic-related conditions associated with anxiety.

Patients with anxiety disorders may present with an apparently different medical disease, and many medical diseases are strongly associated with symptoms of anxiety. Several factors help distinguish an anxiety syndrome caused by an underlying medical issue from a primary anxiety disorder (see Box 98.2).

Anxiety may be the most obvious symptom of an underlying disease or condition, and therefore, the patient should be evaluated for exacerbation of known preexisting disease, as well as for the onset of new illness, because of the increased risk of acute medical exacerbation of chronic illness.

Anxiety disorder classifications in the DSM-5 include anxiety caused by another medical condition.[2] Post–myocardial infarction patients with anxiety have poorer outcomes than those without documented anxiety. Patients with respiratory diseases, such as asthma and chronic obstructive pulmonary disease, often have anxiety associated with long-standing illnesses. In addition, many of the medications used to treat these illnesses may induce anxiety. One of the most common medical causes of anxiety is alcohol and drug use from either intoxication or, more typically, withdrawal states.

Cardiac Diseases

Approximately 25% of patients with chest pain who present to the ED have panic disorder, which often goes undiagnosed, resulting in multiple visits and expensive cardiac evaluations. Symptoms of anxiety, like those of a myocardial infarction or angina pectoris, may include crushing chest pain, shortness of breath, nausea, palpitations, heavy perspiration, and a feeling of impending doom. The associated chest pain is usually described as atypical, and patients are generally female and younger. Because of the morbidity and mortality of cardiovascular disease, a patient warrants an appropriate cardiac evaluation when the differentiation between myocardial infarction and acute anxiety is unclear.

Cardiac dysrhythmias can also cause symptoms similar to a panic attack including palpitations, discomfort, dizziness, respiratory distress, and even syncope. Mitral valve prolapse syndrome can be associated with palpitations and panic attacks indistinguishable from a panic disorder. Benzodiazepines can be used to provide symptomatic relief to patients who experience chest pain due to anxiety.

Endocrine Diseases

The most common endocrinologic conditions associated with anxiety states are hypoparathyroidism, hyperthyroidism and hypothyroidism, hypoglycemia, pheochromocytoma, and hyperadrenocorticism. Anxiety is the predominant symptom in 20% of patients with hypoparathyroidism. Studies indicate a higher incidence of anxiety in the subset of patients with surgically removed parathyroid glands. Even though other symptoms may improve with supplementation, patients have been found to have significant depression, anxiety, somatization, and phobic anxiety, even after being given calcium and vitamin D.

Anxiety symptoms are seen in up to 40% of people with diabetes mellitus, and 14% of diabetic patients suffer from anxiety disorders.[7] There is evidence that people with diabetes mellitus and anxiety have worse glycemic control when anxiety is untreated.

Pheochromocytomas are rare tumors that produce elevated levels of catecholamine in the body. Pheochromocytoma attacks may manifest similar to panic attacks and can be precipitated by emotional stress. Elevated urinary catecholamine or plasma metanephrine levels confirm a pheochromocytoma.

Hyperthyroidism is one of the most frequently encountered endocrine diseases associated with anxiety. As with panic disorders, hyperthyroidism is associated with acute episodic anxiety. Thyrotoxicosis causes anxiety, palpitations, perspiration, hot skin, rapid pulse, active reflexes, diarrhea, weight loss, heat intolerance, proptosis, and lid lag. A substantial portion of patients continue to have psychiatric manifestations even after treatment.

Psychiatric presentations can be the first sign of hypothyroidism, occurring as the initial symptom in 2% to 12% of reported cases along with deficits of impaired recent memory and learning. The severity of anxiety disorders in hypothyroid states is related to the rapidity of thyroid hormone level changes and not to the absolute hormone levels. In general, checking serum thyroid-stimulating hormone and free thyroxine levels will suffice in the ED to establish the diagnosis of thyroid disease.

Respiratory Diseases

Most conditions causing airway compromise or impairment of gas exchange do not mimic psychiatric disorders. However, some conditions that cause hypoxemia or hypercarbia may lead to the development of significant anxiety. Up to a third of the patients with chronic obstructive pulmonary disease meet the criteria for anxiety disorder.

Patients who have severe asthma are twice as likely to have an anxiety disorder and almost five times as likely to have a phobia compared with nonasthmatics. Acute dyspnea from a pure panic attack with good air movement and normal lung sounds is easily differentiated from an asthma attack, but studies consistently show that anxiety disorders increase asthma morbidity and mortality.

Acute shortness of breath in any patient should not be immediately attributed to anxiety, especially because pulmonary embolism can present with only shortness of breath as the major symptom. Fortunately, pulmonary embolism can almost always be distinguished by history and physical examination, assessment of risk factors for thromboembolic disease, and laboratory testing (e.g., pulse oximetry, electrocardiography, chest radiography, and D-dimer assay) as indicated. The Multidimensional Dyspnea Profile tool uses the verbal subjective descriptors of feeling depressed, air hunger, and breathing concentration to help differentiate patients with pulmonary disease with and without panic disorder.[8]

Neurologic Disorders

Many neurologic conditions are associated with anxiety symptoms. For example, stress is one of the most common reported causes of seizures. Those who report stress as a trigger tend to have higher scores on anxiety tests, and the stress may be either acute or chronic.[12] Temporal lobe seizures, complex partial seizures, tumors, arteriovenous malformation, and cerebral ischemia or infarction have all been reported with panic attacks. Anxiety disorders also occur in the aftermath of traumatic brain injury (TBI). Approximately 23% of those who sustain a mild TBI are at risk for developing an anxiety disorder; this is frequently found in military personnel. In Huntington disease, anxiety is the most common prodromal symptom. Anxiety occurs in up to 40% of patients with Parkinson disease and up to 37% of patients with multiple sclerosis. Similarly, anxiety symptoms are common in moderate Alzheimer disease.

Drug Intoxication and Withdrawal States

Amphetamines, cocaine, and other sympathomimetic drugs are abused for their stimulant and mind-altering properties. Patients often present agitated and anxious, particularly when these drugs are taken in large doses and with prolonged use. Caffeine is a very commonly used stimulant, and studies suggest that about 400 mg/day is the threshold for toxicity in healthy adults (19 years or older), 100 mg/day in healthy adolescents (12-18 years old) and 2.5 mg/kg/day in healthy children (11 years old or younger). With the consumption of higher doses, caffeine intoxication may result, causing restlessness, nervousness, excitement, insomnia, diuresis, gastrointestinal disturbance, tachycardia, psychomotor agitation, as well as other unpleasant symptoms.[2] The acute symptoms of caffeine intoxication and GAD are almost identical.

Marijuana use may result in depersonalization that provokes severe anxiety, fearfulness, and symptoms of agoraphobia. Cannabis intoxication is associated with behavioral or psychological changes, such as anxiety, and physical signs, such as conjunctival injection, dry mouth, and tachycardia. Although marijuana use is sometimes associated with anxiety reduction, there is evidence to suggest that therapy for anxiety disorder using cannabis is limited with the potential harm out weighing the risk.[7]

Lysergic acid diethylamide (LSD), phencyclidine (PCP), and ecstasy (3,4-methylenedioxy-methamphetamine [MDMA]) are hallucinogens that can produce anxiety and paranoia from chronic use or "bad trips." Flashbacks affect some users of LSD; the person may experience the symptoms of anxiety and paranoia weeks or months after use.

Sedative, hypnotic, or anxiolytic drugs (e.g., benzodiazepines, barbiturates) are taken to relieve anxiety or sleeplessness, but their discontinuation can cause sedative withdrawal and rebound anxiety.[2] The severity of the withdrawal syndrome depends on the drug, dosage, duration of use, and speed of elimination. Symptoms include hyperalertness, motor tension, muscle aches, agitation, anxiety, insomnia, tremulousness, nausea, vomiting, convulsions, delirium, and even death.[2]

Although antidepressants are rarely abused, their abrupt cessation can cause a discontinuation syndrome, which may present as sensory and gastrointestinal-related symptoms, insomnia, lethargy, and extreme anxiety.[9]

Alcohol withdrawal can appear 6 to 12 hours after the last drink or significant reduction in consumption. Patients often have a detectable serum alcohol level at this time. Anxiety is one of the first and most prominent symptoms and is seen within 24 to 48 hours of the withdrawal state. Symptoms of anxiety, insomnia, and autonomic dysfunction can last up to 6 months following alcohol withdrawal.[2]

DIAGNOSTIC TESTING

The initial history and physical examination should focus on the presenting complaints to determine if the patient has an anxiety disorder or anxiety caused by drug abuse, medication use, or a general medical condition. The psychiatric history should, at minimum, include current symptoms, precipitating events and significant life stressors, past psychiatric and substance history, history of self-harm or suicide attempts, and identification of support systems. A thorough risk assessment for suicidality is key. Among ED patients, panic attacks have been found to be closely associated with suicidal ideation (43%) and intent (55%). Chapter 101 discusses suicide risk assessment.

A physical examination focused on any bodily area of complaint is necessary, even when there is no overt evidence of disease. Abnormal vital signs suggest an organic medical cause of the anxiety symptoms. Laboratory tests may be necessary based on the clinical presentation, but no tests can confirm or exclude anxiety disorders.[11] Patients with new symptoms require a more extensive medical and psychiatric investigation than those with a known disorder.

MANAGEMENT

The patient should be placed in a quiet area for evaluation. Some patients experience calm when they are removed from a chaotic ED environment. If that is not possible, reducing environmental stimulants, such as dimming lights, can be helpful. If the clinician encounters difficulty in calming the patient, supportive family members may help.

Pharmacologic Treatment

Use of oral, intravenous, or intramuscular medication may be necessary when an anxiety state results in the threat to safety for the patient or others. Medication may also be appropriate for the anxious patient experiencing a significant medical illness or undergoing a medical procedure. Low doses of benzodiazepines (e.g., lorazepam) in small increments can be helpful in alleviating the anxiety associated with substance withdrawal states. Midazolam reduces anxiety and increases amnesia for ED procedures.

SSRIs and SNRIs have become first-line treatment of most anxiety disorders because of their broad spectrum of efficacy and high tolerability by most patients. They have a low potential for dependence and are safer than older classes of antidepressants and anxiolytics. Improvement is usually seen in 4 to 6 weeks, but doses may have to be adjusted. Patients with known anxiety disorders may need a refill of their prescribed medication in the ED. Patients with new-onset anxiety may be started on an SSRI/SNRI in the ED in consultation with a psychiatrist or primary care physician who will see them in follow-up for a thorough evaluation of the type of anxiety and provide a long-term treatment plan. There is no difference in efficacy in drugs in the same class nor between SSRI and SNRI for all anxiety disorders except social anxiety disorders.[10]

Benzodiazepines can be prescribed for motivated patients with acute exogenous anxiety for time-limited stress. Benzodiazepines are an attractive alternative to the delayed response of an SSRI when an immediate reduction of symptoms is desired or a short-term treatment is needed. Benzodiazepines have a role in emergency medical treatment, but their use is questionable for long-term treatment. In most circumstances, benzodiazepines should be prescribed for a week or less. Patients may need to be prescribed several weeks of benzodiazepines until SSRIs/SNRIs take effect. Patients with a history of alcoholism or drug abuse, who are emotionally dependent, or who become anxious in response to normal stress are at greater risk of drug dependency and are not good candidates for this treatment. Hydroxyzine has also been used in select patients as an alternative to benzodiazepines for rapid anxiolytic effect, and are indicated for the treatment of anxiety.

Monoamine oxidase inhibitors and tricyclic antidepressants have been effective in treating anxiety but have been largely supplanted by SSRIs and SNRIs. Buspirone, a 5-hydroxytryptamine receptor 1A agonist, has been shown to work well for generalized anxiety disorders in some studies with few side effects but requires 1 to 3 weeks to become effective.[13]

Nonpharmacologic Therapy

Patients with associated agitation may need verbal de-escalation as first-line treatment prior to the use of medications. Supportive therapy can be used to calm patients and give them room to problem-solve. Emergency clinicians and staff can also use psychoeducation to normalize perception and to teach skills of coping such as breathing techniques. It is also particularly useful to educate the patient on the role that stimulants (e.g., caffeine) and depressants (e.g., alcohol) play in promoting anxiety.

There are multiple longer-term therapies that can be helpful for treating anxiety but are not applicable in the acute care setting. Psychotherapy may be helpful for individuals whose psychological makeup, coping style, interpersonal dynamics, and situational stressors contribute to their pathologic anxiety. The use of supportive, insight-oriented, or family therapy is helpful when these factors appear prominently in the patient's presentation. Cognitive-behavioral therapy helps the patient correct the cognitive misperceptions and overreactions that occur. Psychotherapy is as effective as medication in treating anxiety, but requires commitment from the patient. Meditation, biofeedback, and suggestive hypnosis may also have a role in long-term treatment.[13]

DISPOSITION

Patients receiving initial treatment in the ED without a proper referral to outpatient care are at an increased risk for return. If available, it is preferred that a social worker or mental health worker connect discharged patients with outside agencies and services, rather than providing patients with a referral list.

Most patients with an anxiety disorder can be safely discharged with close primary care physician or psychiatrist follow-up. Some who may have difficulty navigating the outpatient setting may benefit from a short stay in psychiatric observation or in a crisis stabilization unit even if suicide risk is low. Patients with an anxiety disorder associated with suicidal or homicidal ideation or with severe depression require urgent psychiatric attention and hospitalization.

CHAPTER 98: QUESTIONS AND ANSWERS

1. Which of the following is the most common mental health disorder?
- **a.** Anxiety
- **b.** Bipolar
- **c.** Depression
- **d.** Schizophrenia
- **e.** Substance abuse

Answer: A. Many of these patients never receive appropriate care, in part because they choose to present with a physical complaint and disguise their anxiety. Patients with chronic illnesses have higher rates of anxiety and depression than the rest of the population.

2. What is the most common cause of organic anxiety, anxiety that results from a physiologic origin?
- **a.** Adrenal disorders
- **b.** Alcohol and drug use
- **c.** Cardiac disease
- **d.** Hyperthyroidism
- **e.** Pulmonary embolus

Answer: B. This may be from intoxication or withdrawal states.

3. A 52-year-old woman presents with 2 months of recurrent episodes of anxiety, mild chest pain, subjective palpitations, hand paresthesias, and occasional muscle spasms. They have occurred weekly in the past but are now increasing in frequency. Her only past history is a thyroidectomy 4 months prior. She is taking levothyroxine (Synthroid) and had normal thyroid levels 2 weeks ago. Her vital signs, physical examination, and electrocardiogram are normal. Laboratory evaluation shows sodium 141 mEq/L, potassium 4.1 mEq/L, creatinine 1.0 mg/dL, bicarbonate 26 mEq/L, chloride 100 mEq/L, and calcium 7.1 mg/dL; a complete blood count is normal. Which of the following should be the next step in her management?
- **a.** Outpatient clonazepam
- **b.** Parathyroid hormone level
- **c.** Psychiatry consultation
- **d.** Thyroid hormone levels
- **e.** Urine drug screen

Answer: B. Anxiety is the predominant symptom in 20% of patients with hypoparathyroidism. Other symptoms include paresthesia, muscle cramps, and spasms. Most cases are idiopathic or due to inadvertent parathyroid gland harvest during thyroidectomy. The diagnosis is suggested by a low serum calcium and an elevated phosphate and is confirmed by a depressed parathyroid level.

4. Which of the following statements regarding anxiety and endocrine disorders is true?
- **a.** Anxiety can often be traced to reactive hypoglycemia.
- **b.** Anxiety is not a manifestation of hypothyroidism.
- **c.** Diabetics treated with antianxiety agents have improved hemoglobin A1c levels.
- **d.** Less than 5% of diabetics experience anxiety.
- **e.** Patterns of diaphoresis in pheochromocytoma mimic those of a panic attack.

Answer: C. Approximately 15% of diabetics have an anxiety disorder. Treatment improves hemoglobin A1c levels. Anxiety due to reactive hypoglycemia is rare despite the common perception among patients. Pheochromocytoma causes whole-body diaphoresis, whereas panic disorders primarily cause sweaty palms. Hyperthyroidism or hypothyroidism can cause significant anxiety manifestations. It is more related to the rate of change than the level of thyroid hormones.

5. A 23-year-old woman with a history of asthma presents with increasingly frequent episodes of panic attacks. Her medications are an inhaled beta-agonist and an intermittent steroid inhaler. She reports subjective increasing asthma severity as her panic episodes have worsened. When counseling the patient, which of the following statements is most correct?
- **a.** An anxiety disorder in an asthmatic patient does not increase morbidity.
- **b.** Anxiety does not precipitate asthma attacks.
- **c.** Anxiety does not worsen airflow.
- **d.** Asthmatics are more likely to have an anxiety disorder.
- **e.** It is difficult to differentiate dyspnea related to asthma from anxiety.

Answer: D. Anxiety can precipitate and prolong an asthma attack. Morbidity and mortality are increased in asthmatic patients who have a coexisting anxiety disorder. Patients who have asthma are twice as likely to have an anxiety disorder and five times as likely to have a phobia. Acute dyspnea from "panic" dyspnea can be differentiated from asthma by clear lungs on auscultation.

6. Which of the following syndromes is not associated with anxiety?
- **a.** Left hemispheric strokes
- **b.** Multiple sclerosis
- **c.** Right hemispheric strokes
- **d.** Transient ischemia attack
- **e.** All of the above can be associated with anxiety.

CHAPTER 98: QUESTIONS AND ANSWERS—cont'd

Answer: E. Anxiety may be a component of seizures, tumors, arteriovenous malformations, and ischemic events. It may be the only manifestation of some disorders (e.g., right hemispheric strokes and transient ischemic attacks [TIAs]). The coexistence of anxiety plays an important role in the prognosis and impairment of stroke patients.

7. A 38-year-old woman with a long history of anxiety and panic disorder presents with anhedonia, melancholy, sleep disruption, crying episodes, and some hostility feelings. She has no current anxiety symptoms. Her only medication is clonazepam. She has no known medical illness. Which of the following statements regarding this patient's symptoms is true?

a. Approximately 50% of patients with panic disorder develop major depression.
b. Depression with anxiety and hostility is usually refractory to treatment.
c. The first diagnostic step should be a thyroid panel.
d. The majority of patients with depression have panic attacks.
e. This is likely a drug-induced depression.

Answer: A. Approximately 50% of patients with a primary panic disorder will later develop major depression. Twenty percent of patients with depression have panic attacks. Depression with panic attacks is less responsive to treatment, but depression with anxiety and hostility responds well to antidepressants. Although benzodiazepines can exacerbate symptoms of depression, there is already a high spontaneous rate of depression with anxiety disorders.

8. Which of the following statements regarding benzodiazepine use and anxiety is true?

a. Benzodiazepines are first-line agents for anxiety disorders.
b. Several weeks of treatment are indicated after initial diagnosis.
c. Short-acting benzodiazepines produce a more severe abstinence syndrome.
d. They are particularly useful in patients with alcohol abuse.
e. Withdrawal rebound is less common than with selective serotonin reuptake inhibitors (SSRIs).

Answer: C. SSRIs are the first-line agents for anxiety and panic disorders, but the primary disadvantage is the several-week lag needed for maximal clinical benefit. Benzodiazepines work best for motivated, dependable patients when an immediate reduction of symptoms is indicated or a short-term treatment is necessary. Patients who do not benefit from benzodiazepines within a week are unlikely to do so. Patients with a history of alcoholism or drug abuse, who are excessively/emotionally dependent, or who become anxious from normal stress are at greater risk for dependency. Rebound withdrawal is more likely after short-acting agents.

9. A 29-year-old Caucasian female presents with excessive daytime somnolence. She states that she had been suffering from anxiety associated with her paralegal occupation, and 1 week ago her psychiatrist had started her on a 2-week course of once-daily benzodiazepine therapy, which she takes in the morning. Her anxiety symptoms are well controlled. She asks if you can change her to a new medication because the somnolence is significantly affecting her job performance. What would be the most appropriate course of action?

a. Counsel the patient that she should continue the medication as prescribed because she will soon adapt and the somnolence will likely subside.
b. Discontinue the benzodiazepine and refer her back to her psychiatrist.
c. Have her try dosing the benzodiazepine at bedtime, because this will likely continue to control her anxiety and limit daytime somnolence.
d. Switch the patient to a selective serotonin reuptake inhibitor (SSRI) and refer her back to her psychiatrist.
e. Switch the patient to a shorter-acting benzodiazepine.

Answer: C. Instituting an SSRI should be reserved for primary care physicians or psychiatrists who can monitor the patient more closely, because the response will be delayed. Some patients do adapt to the sedative effects of benzodiazepines but usually only after long-term use. Stopping the benzodiazepine may ultimately be necessary but at the risk of recurrent anxiety. Dosing benzodiazepines at bedtime may minimize daytime sedation and still provide an anxiolytic effect. Shorter-acting benzodiazepines produce a more severe abstinence syndrome when stopped abruptly, and thus most prescribers prefer longer-acting agents.

10. A 52-year-old male construction worker presents with chest pain. He states his symptoms began early this morning and have progressively worsened throughout the day. His symptoms include nervousness, tremors, chest pain, shortness of breath, and palpitations. He states that he has had anxiety for 30 years but has controlled it with the consumption of alcohol. He became unemployed 1 week ago, and his daily alcohol use has diminished significantly. His vital signs are blood pressure (BP) 185/95 mm Hg, heart rate 123 beats per minute, respiratory rate of 20 breaths per minute, and temperature of 98.9°F. His physical examination is remarkable for diaphoresis, tongue fasciculation, both resting and intention tremors, and mild psychomotor agitation while maintaining orientation with a congruent anxious mood and affect. What is the most likely etiology of this patient's symptoms?

a. Acute alcohol withdrawal syndrome
b. Exacerbation of endogenous anxiety secondary to diminished alcohol intake
c. Exacerbation of exogenous anxiety secondary to change in employment status
d. Hypertensive emergency with acute coronary syndrome
e. Reactive anxiety secondary to the onset of chest pain

Answer: A. Hypertensive emergency is unlikely given the level of this patient's BP. On the basis of the history alone, it may be difficult to differentiate organic versus functional anxiety or identify an exogenous trigger, but the abnormal vital signs and physical examination associated with a recent cessation of long-term alcohol consumption makes acute alcohol withdrawal the most likely cause. Given the significant morbidity associated with withdrawal states, this must be addressed acutely. Appropriate diagnosis and management of underlying psychiatric disease will be a secondary concern after the patient's withdrawal is managed.

99

Somatic Symptoms and Related Disorders

Karl Huesgen and J. Adrian Tyndall

KEY CONCEPTS

- Several conditions previously classified in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) as somatoform disorders are now classified under DSM-V as *Somatic Symptom and Related Disorders* (SSRD). These include somatic symptom disorder (SSD), illness anxiety disorder (IAD), and conversion disorder. They share a common feature of patients' maladaptive and inappropriate psychological response to somatic (bodily) symptoms.
- SSRD patients have approximately twice the rate of medical disease seen in the general population. It is unclear whether this is the consequence of more frequent health care use or whether an increased disease burden prompts these patients to have a greater concern for bodily sensations.
- *SSD* is characterized by disproportionate or persistent health-related thoughts, anxiety, and time and energy devoted to somatic (bodily) symptoms, resulting in disruption of daily life.
- Patients with *IAD,* formerly known as hypochondriasis, have excessive anxiety regarding the possibly having or acquiring a serious medical illness in the presence of minimal or absent somatic symptoms.
- *Conversion disorder,* also known as *functional neurologic symptom disorder,* is characterized by abnormal sensory or voluntary motor function that is found to be incompatible with known neurologic or medical conditions, and that causes significant distress or life impairment.
- The differential diagnoses for SSRD may be broadly divided between (a) psychiatric disorders that manifest somatic symptoms and (b) medical conditions with signs or symptoms that might be attributed to psychiatric disorders.
- A "positive review of systems" in an emergency department (ED) evaluation is similar to a high score on SSRD symptoms severity scales and thus may serve as an inadvertent screen for SSRD. Further research is needed to ascertain whether this is clinically reliable.
- ED care goals for patients with SSRD include establishment of rapport, building a therapeutic alliance, legitimizing the patient's distress, and enhancing the patient's ability to function despite the symptoms.
- Multiple care modalities are available for SSRD treatment. These are typically managed by the patient's primary care physician or psychiatrist.

FOUNDATIONS

Somatic symptom and related disorders (SSRD), formerly known as somatoform disorders, are described as the borderland between psychiatry and medicine and are responsible for some of the most challenging and the least understood patient encounters in the emergency department (ED). Individuals who suffer from these disorders must be identified and treated appropriately to avoid patient suffering, inappropriate resource use, and iatrogenic injuries.

Box 99.1 lists the disorders classified in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) as SSRD. They include somatic symptom disorder (SSD), illness anxiety disorder (IAD, formerly known as hypochondriasis), conversion disorder, psychological factors affecting medical illness, and factitious disorder (discussed separately in Chapter 100). Body dysmorphic disorder (excessive concern for a perceived defect in physical features) is no longer included in this group.

Although prior versions of the DSM emphasized medically unexplained symptoms and their putative psychological causes, current descriptions of these disorders focus on patients' maladaptive and inappropriate cognitive and affective responses to somatic symptoms rather than the lack of explanation for them.[1,2] These disorders are thought to be mediated by abnormal sensory perception, processing, interpretation, attribution to pathologic causes, and subsequent hypervigilance toward further sensations.[3–7]

SSRD are common, with a prevalence of approximately 5% to 7% of the adult population, and are present in many patients with medically unexplained symptoms.[1,8] The defining features of these disorders, a maladaptive response to bodily sensations, cause patients to seek help for their illness through medical routes rather than psychiatric avenues. However, the SSRD are typically formally diagnosed only via structured psychiatric interview, and these disorders may take many years to diagnose even in longitudinal primary care settings.[9] The disorders are even more challenging to diagnose during a brief ED encounter prioritizing life-threatening illness.

Difficulty identifying the root cause of patients' distress may cause frustration for both patients and physicians. For example, patients with SSD may have excessive anxiety regarding nonpathologic sensations, whereas patients with IAD may be certain they have a serious medical condition despite contradictory evidence. Thus, after a negative ED work-up, the very nature of the patients' psychiatric condition may leave them feeling that their concerns have not been adequately addressed, prompting pursuit of extensive, expensive, and invasive medical evaluations. SSRD patients have approximately twice the rate of medical disease seen in the general population. It is unclear whether this is the consequence of more frequent health care use or whether an increased disease burden prompts these patients to have a greater concern for bodily sensations.[10]

Clinicians may also feel frustrated by encounters with patients with SSRD. Frequent ED use by patients with unrealistic expectations and subsequent frustrations may cause physicians to feel these encounters were suboptimal. These patients frequently exhibit an extensive "positive review of symptoms," which clinicians may feel obligated to evaluate. Even when clinicians suspect SSRD, they are often unwilling to ascribe patient concerns to psychiatric illness at the exclusion of rare but consequential medical diagnoses with nonspecific presentations. However, if the patients' concerns are recognized and addressed within

BOX 99.1 Somatic Symptom and Related Disorders

Somatic symptom and related disorders share a common feature of patients' maladaptive and inappropriate psychological response to somatic (bodily) symptoms
Somatic symptom disorder
Illness anxiety disorder
Conversion disorder (functional neurologic symptom disorder)
Psychological factors affecting other medical conditions
Factitious disorder

BOX 99.2 Differential Diagnosis of Somatic Symptom Disorder

Psychiatric Conditions	Medical Conditions
Depression disorders	Transient ischemic attack
Anxiety disorders	Multiple sclerosis
Obsessive-compulsive disorder	Systemic lupus erythematosus
Schizophrenia	Thyroid and parathyroid disorders
Personality disorders	Electrolyte disorders
Substance abuse disorders	Human immunodeficiency virus (HIV)
Malingering	Anti-NMDA receptor encephalitis

a patient-centered framework, clinicians may recognize that the "difficult patient" with a "positive review of systems" may have a psychiatric illness requiring further evaluation in an outpatient medical or psychiatric setting.

CLINICAL FEATURES

Patients with SSRD experience physical symptoms associated with significant distress and impairment that cannot be adequately explained by demonstrable physical pathology despite appropriate medical investigation. These disorders are most common in women of lower socioeconomic status in their 20s and 30s but may be present in any demographic group. Depressive and anxiety disorders are common comorbid conditions, as are nonpsychiatric medical diagnoses.[1]

Somatic Symptom Disorder

Patients with SSD have disproportionate or persistent health-related thoughts, anxiety, and time and energy devoted to somatic (bodily) symptoms, resulting in disruption of daily life. Previous editions of the DSM described a causal relationship between a patient's emotions and subsequent symptoms (termed somatization). The disorder criteria now focus upon the abnormal psychological response to bodily sensations rather than to a lack of medical explanation for symptoms.[1] Research indicates these patients have abnormal autonomic activity and reactivity, as well as measurably altered emotional processing and bodily awareness.[7] A subset of SSD patients includes patients for whom pain is the primary concern. Previously called pain disorder, this diagnosis is now termed *SSD with predominant pain*. For these patients, pain may represent normal bodily function in conjunction with spinal or higher-CNS sensitization from prior experience and genetic factors.[1,11] Of note, because the diagnosis of SSD depends upon the maladaptive psychological response to bodily sensations rather than the lack of medical explanation alone, the symptoms alone from fibromyalgia, irritable bowel syndrome, or multiple chemical sensitivities do not meet criteria for SSD.[1]

Illness Anxiety Disorder

Patients with IAD have minimal or absent somatic symptoms but present with excessive anxiety regarding possibly having or acquiring a serious medical illness. Formerly known as hypochondriasis, IAD is now the preferred nomenclature to avoid pejorative connotations. IAD persists despite repeatedly negative medical evaluations, and the anxiety associated with this condition can produce either excessive health-related behaviors or maladaptive health care avoidance, resulting in care-seeking and care-avoidant subtypes, respectively. Care-seeking subtypes are at risk for iatrogenic complications of excessive testing.[1]

Conversion Disorder

Patients with conversion disorder, now commonly referred to as *functional neurologic symptom disorder*, have altered sensory or voluntary motor function that is found to be incompatible with known neurologic or medical conditions and that causes the patient significant distress or life impairment. This disorder may have a variety of presentations, including seizure-like activity, focal weakness, memory disturbances, dysphonia, blindness, or alterations of any sensory system. Upon medical examination, however, no pathologic correlates are identified, and serial neurologic examinations often demonstrate inconsistent disability. For example, in the Hoover test, a supine patient may demonstrate normal hip extension (pushing down) with a "paralyzed" leg when asked to flex (lift) the contralateral hip. Similarly, patients may demonstrate inability to turn their head toward a "paralyzed" side but use the "paralyzed" sternocleidomastoid to turn from it. Coincident life stress is associated with but not essential for the diagnosis. The presence of *la belle indifference* (i.e., an inappropriate lack of concern regarding a seemingly profound disability) is also associated with but not specific to this disorder. Proven intentionality is not necessary for the diagnosis.[1]

Factitious Disorder

In contrast to conversion disorder, factitious disorder is characterized by purposefully deceptive falsification of disease signs or symptoms for the sole purpose of causing others to see the person with the disorder as ill. In the case of Munchausen by proxy, the person induces symptoms in another patient, typically a child.[1,12] These disorders are discussed in greater detail in Chapter 100.

Psychological Factors Affecting Medical Illness

Psychological factors affecting medical illness is a separate category included in SSRD due to the predominance of somatic symptoms and propensity to present in medical settings. This includes psychological factors that exacerbate or delay recovery from medical conditions, reduce adherence to medical treatment, or pose additional risk harm. Examples include anxiety-exacerbated asthma, or stress-induced Takotsubo cardiomyopathy.[1]

DIFFERENTIAL DIAGNOSES

Other psychiatric disorders may initially present with somatic symptoms, including major depressive disorder and anxiety disorders. The differential diagnoses for the SSRD may be broadly separated into two groups: psychiatric disorders that manifest somatic symptoms and medical conditions with signs or symptoms that might be attributed to psychiatric disorders (Box 99.2).[1,13] For example, psychiatric patients with panic disorder may present with complaints of palpitations and dyspnea, and patients with major depressive disorder might present with sleep disturbances. Alternatively, many medical diagnoses can have subtle or variable presentations which might be attributed to psychiatric disorders (e.g., hypothyroidism-induced fatigue attributed to

depression, sensory loss due to multiple sclerosis, or behavioral disturbances secondary to anti-N-methyl-d-aspartate (NMDA) receptor encephalitis).[14]

DIAGNOSTIC TESTING

The very nature of SSRD often prompts repeated and extensive evaluations of patients' somatic complaints. Diagnostic testing for possible organic diagnoses should be based upon a physician's standard practice for evaluating a presenting medical complaint and not upon a patient's desire for additional testing to reassure them that an undiagnosed medical disorder is not present. Unnecessary testing may put patients at risk for diagnostic false-positives and iatrogenic injury. The exception to this rule is the patient with functional neurologic symptom disorder or conversion disorder. Neurologic disorders such as transient ischemic attacks, multiple sclerosis, and atypical migraine headaches may have subtle presentations. In these cases, it may require imaging studies and both neurologic and psychiatric consultations to avoid the misdiagnosis of a patient who requires intervention.

Specific SSRD diagnoses are suggested by the overall clinical picture rather than single discrete findings. For example, excessive anxiety despite a negative chest pain work-up would suggest SSD, or an inappropriate lack of concern regarding a hemiparesis would suggest conversion disorder. Diagnostic reliability for SSRD is improved with formal structured clinical interviews, typically in psychiatric or primary care settings.[15] Self-report questionnaires have shown promise in these settings.[16,17] Clinicians typically have neither the time nor the clinical training to perform structured clinical interviews for formal SSRD diagnosis; however, brief 2- to 3-minute self-report instruments (e.g., SSD-12) are available for outpatient screening of patients' symptom-related thoughts, feeling, and behaviors, although further research is needed regarding whether these are applicable to an emergency setting.[18,19] It is notable that tests of SSRD patients' symptoms severity (e.g., Patient Health Questionaire-15 [PHQ-15]) resemble a standard emergency medicine review of symptoms (e.g., has the patient had chest pain, shortness of breath, dizziness, nausea, headaches in the past month, and whether these symptoms bothered patient not at all, a little, or a lot). On this test, a score at greater than 10 indicates high risk for somatoform disorders.[20] Therefore a positive review of systems in a normal ED evaluation may serve as an inadvertent screen for SSRD. If organic causes of patients' symptoms are not identified, psychiatric consultation or referral could be considered for formal SSRD diagnosis.

MANAGEMENT

The management of patients with SSRD is challenging. Whereas most patients trust their doctors' conclusions, SSRD produce an inherent conflict between the patient beliefs and physician reassurance. Even patients with insight into their disorder may harbor unshakable beliefs of physical illness despite evidence to the contrary. On the other hand, one must be aware of the possibility of an unexplained medical illness that can confound diagnosis and management. It is thus incumbent upon the physician to build rapport by demonstrating attention, empathy, and the desire to alleviate the patient's suffering. One should recognize and communicate understanding of the life impact of the patient's somatic and psychiatric symptoms. After building a therapeutic alliance, it may be helpful to discuss the patient's illness with them in terms of a chronic disease that can be mitigated but not fully alleviated. In this way, patients may focus on maximizing life function in spite of their disorder rather than eliminating the symptoms.[13] Naming the disorder itself may improve the therapeutic alliance.[21] Long-term treatment of SSRD typically involves the use of medications (e.g., SSRIs) with or without therapy (e.g., cognitive behavioral therapy) that is best managed by primary care physicians or psychiatrists. These treatments are not initiated by an emergency clinician but may be started by a psychiatric consultant.[22]

DISPOSITION

In the absence other factors necessitating medical or psychiatric admission, patients with SSRD may be discharged with outpatient primary care or psychiatric follow-up. They should be told that acute life-threatening diagnoses have been ruled out and that further testing and additional medications are not indicated at this time. Emphasize to the patient that even in the absence of a satisfactory explanation for their symptoms, psychiatric intervention may be useful in mitigating life impacts of their symptomatology.

CHAPTER 99: QUESTION AND ANSWERS

1. Which of the following characterizes patients with somatic symptom disorder (SSD)?
- **a.** Patients have an inappropriate lack of concern for profound disability.
- **b.** Patients intentionally and deceptively falsify symptoms.
- **c.** Patients strongly believe they have a particular serious medical illness.
- **d.** Patients have a maladaptive psychological response to bodily symptoms.

Answer: d. The defining feature of SSD is the psychological response to somatic symptoms.

2. A patient presents with the inability to move the left side of his body, but he is easily able to turn his head to the right. He also appears relatively unworried about his symptom severity. This presentation suggests which somatic symptom and related disorder (SSRD)?
- **a.** Somatic symptom disorder.
- **b.** Illness anxiety disorder.
- **c.** Conversion disorder.
- **d.** Psychological factors affecting medical illness.

Answer: c. Normal sternocleidomastoid function ipsilateral to the otherwise-paralyzed side and presence of *la belle indifference* suggest conversion disorder.

3. A patient presents multiple, nonspecific symptoms and believes that she has cancer despite multiple previous evaluations in emergency, primary care, and specialist settings. She says she is certain of this diagnosis, that it causes a significant amount of anxiety and that she spends several hours each day researching the subject. Your standard work-up for her presenting symptoms is negative. What should you do?
- **a.** Perform a few more tests to reassure the patient.
- **b.** Tell the patient that this is "all in your head" and promptly discharge.
- **c.** Place the patient under an involuntary psychiatric hold for self-harm.
- **d.** Seek therapeutic alliance, provide reassurance, and refer the patient to primary care or psychiatry for management.

Answer: d. This patient's presentation is consistent with illness anxiety disorder, formerly known as hypochondriasis. Note that patients with this disorder may have few or no somatic symptoms.

4. A predominance of pain is a subtype of which of the somatic symptom and related disorders?
- **a.** Somatic symptom disorder.
- **b.** Illness anxiety disorder.
- **c.** Conversion disorder.
- **d.** Psychological factors affecting medical illness.

Answer: a. Predominant pain is a subtype of somatic symptom disorder in which pain is the defining symptom. This may be due to prior neural sensitization or genetic predisposition.

5. Which of the following is considered the gold standard for diagnosing somatic symptom and related disorders (SSRD)?
- **a.** Elimination of other possible medical conditions via extensive medical testing.
- **b.** Structured clinical interview.
- **c.** A positive review of symptoms.
- **d.** Emergency physician gestalt.

Answer: b. SSRD diagnoses are suggested by overall clinical picture and may be supported by self-report questionnaires. However, final diagnosis is typically based upon formal structured clinical interview in psychiatric or primary care settings. Note that a "positive ROS" is similar to high scores on SSRD symptom severity questionnaires.

Factitious Disorders and Malingering

Henry W. Young II and Joseph E. Thornton

KEY CONCEPTS

- Patients who have consciously synthesized symptoms and signs may be divided into two broad diagnostic categories: (1) those with obvious secondary gain (malingering), who control their actions, and (2) those with a motivation of achieving the sick role (factitious disorders), who cannot control their actions.
- The initial management of patients suspected of fabricating disease should include a caring, nonjudgmental attitude and a search for objective clinical evidence of treatable medical or psychiatric illness. Review of old medical records and interviews of family members are often helpful.
- Unnecessary tests, medications, and hospitalizations should be avoided in the absence of objective evidence of a medical or psychiatric disease, and patients should be referred for ongoing primary care.
- In cases of suspected factitious disorder imposed on another (FDIA) involving children or elders, protection of the victim takes first priority.

FOUNDATIONS

Patients may present to the emergency department (ED) with symptoms that are simulated or intentionally produced. The reasons that cause this behavior define two disorders: factitious disorders and malingering.

Factitious disorders are characterized by symptoms or signs that are intentionally produced or feigned by the patient in the absence of apparent external incentives.[1,2] These patients constitute up to 3% of general psychiatric referrals.[3] However, the prevalence of factitious disorders in emergency departments is thought to be higher because these patients rarely accept psychiatric treatment and are frequently undiagnosed.[2,4] These patients are often seen in other health care settings including infectious disease for fever of unknown origin, epilepsy clinics for psychogenic seizures, and nephrology clinics for renal stones.[3] Factitious disorders have been associated with costs up to $1 million per case.[3] Early diagnosis of factitious disorder can have a significant impact on the utilization of unnecessary investigations, treatments, and hospital admissions within a health care system.[3]

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) classifies factitious disorders into two types: factitious disorder imposed on self (FDIS) and factitious disorder imposed on another (FDIA).[1]

Munchausen syndrome, the most dramatic form of FDIS, was originally described in 1951.[8] This rare syndrome takes its name from Baron Karl F. von Munchausen (1720–1797), a revered German military officer and noted raconteur who had his embellished life stories stolen and parodied in a 1785 pamphlet.[4] While commonly discussed, the incidence of Munchausen syndrome is estimated to be approximately 0.5 to 2 per 100,000 children.[5] Other names used to describe FDIS include the "hospital hobo syndrome" (patients wander from hospital to hospital seeking admission), peregrinating (wandering) patients, hospital addict, polysurgical addiction, and hospital vagrant.[3,6]

Factitious disorder imposed on another (FDIA) involves the simulation or production of a factitious mental or physical disease in an individual by a caregiver. It was first described in 1977.[1] Due to the difficulty in identification, the prevalence of FDIA is not known.[5] This condition often involves a child and a mother. The condition excludes straightforward physical abuse or neglect and simple failure to thrive; mere lying to cover up physical abuse is not FDIA. The key discriminator is motive: the caregiver is making the child ill so that they can vicariously assume the sick role with all its benefits.[3] FDIA has a mortality rate of 6% to 30%.[6,7] Permanent disfigurement or permanent impairment of function can occur directly from induced disease or indirectly from invasive procedures, multiple medications, or major surgery. Other names applied to this condition include *Polle syndrome* (Polle was a child of Baron Munchausen who died mysteriously), *factitious disorder by proxy, pediatric condition falsification, Munchausen syndrome by proxy,* and *Meadow syndrome.*[3,7]

Malingering is the simulation of disease by the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives, such as avoidance of military responsibility, avoidance of work, obtaining financial compensation, evading criminal prosecution, obtaining medication, hospital admission (for the purpose of obtaining free room and board), or securing of better living conditions.[1] The most common goal among such "patients" presenting to the ED is to obtain medications, whereas in the office or clinic the gain is more commonly insurance payments or industrial injury settlements. The true incidence of malingering is difficult to gauge because of underreporting, but estimates include a 1% incidence among mental health patients in civilian clinical practice, and as high as 10% among inpatient psychiatric patients with suicidality.[8-10] In one review, 33% of patients assessed in a psychiatric emergency department were suspected of malingering.[8] Some clinicians are resistant to document malingering in a patients' chart due to concern for lack of reimbursement and legal liability.[8,9] The most likely conditions to be feigned are conditions that are difficult to exclude objectively, such as suicidal ideations, depression, mild head injury, fibromyalgia, chronic fatigue syndrome, and chronic pain.[3,7,11-13]

CLINICAL FEATURES

Factitious Disorders

Factitious Disorders Imposed on Self

The diagnosis of FDIS depends on specific criteria (Box 100.1).[1] With a factitious disorder, the production of symptoms and signs is compulsive; the patient is unable to refrain from the behavior even when its risks are known. The behavior is voluntary only in the sense that it is deliberate and purposeful (intentional) but not in the sense that the acts can be fully controlled. The underlying motivation for producing

BOX 100.1 DSM-5 Criteria for the Diagnosis of Factitious Disorder Imposed on Self

1. Falsification of psychological or physical signs or symptoms, or induction of disease or injury associated with identified deception.
2. The individual presents to others as injured, ill, or impaired.
3. The deceptive behavior is apparent even in the absence of external incentives.
4. The behavior is not better explained by another mental disorder.

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

these deceptions, securing the sick role, is primarily unconscious.[1,2] Individuals who readily admit that they have produced their own injuries (e.g., self-mutilation) are not included in the category of factitious disorders. Presentations may be acute, in response to an identifiable recent psychosocial stress (termination of romantic relationship, threats to self-esteem), or a chronic life pattern, reflective of the way in which the person deals with life in general. The symptoms involved may be either psychological or physical.[3,5,7]

Psychological Symptoms. Individuals may intentionally produce or feign psychological (often psychotic) symptoms suggestive of a mental disorder. Stimulants may be used to induce restlessness or insomnia; hallucinogens, to create altered levels of consciousness; and hypnotics, to produce lethargy. This psychological factitious condition is less common than factitious disorders with physical symptoms and is almost always superimposed on a severe personality disorder.[1,3,5]

Physical Symptoms. The intentional production of physical symptoms may take the form of fabricating symptoms without signs (e.g., feigning abdominal pain), simulation of signs suggesting illness (e.g., fraudulent pyuria, induced anemia), self-inflicted conditions (e.g., the production of abscesses by injection of contaminated material under the skin), or genuine complications from the intentional misuse of medications (e.g., hypoglycemic agents).[3] These patients are predominantly unmarried women younger than 40 years old.[1] They typically accept their illness with few complaints and are generally well-educated, responsible workers or students with moral attitudes and otherwise conscientious behavior. A majority of individuals with factitious disorder are employed in health care settings, including laboratory technicians, nurses, and physicians. There is an increased rate of personality disorders and depression among individuals with factitious disorder.[2-5,7]

These patients are willing to undergo incredible hardship, limb amputation, organ loss, and even death to perpetuate the masquerade.[4] Although multiple hospitalizations often lead to iatrogenic physical conditions, such as postoperative pain syndromes and drug addictions, patients continue to seek hospitalization for its own sake. They typically have a fragile and fragmented self-image and are susceptible to psychotic and suicidal episodes.[3] Interactions with the health care system and relationships with caregivers provide the needed structure that stabilizes the patient's sense of self.[4] Some patients are driven by the conviction that they have a real but as yet undiscovered illness. Consequently, artificial symptoms are contrived to convince the physician to continue a search for the elusive disease process. Factitious illness behavior has also emerged on the internet. "Virtual support groups" offering person-to-person communications through chat rooms or websites have been perpetrated by individuals, under the pretense of illness or personal crisis, for the purpose of extracting attention or sympathy, acting out anger, or exercising control over others.[4]

Munchausen Syndrome. The uncommon patient with true Munchausen syndrome has a prolonged pattern of "medical imposture," usually years in duration. The diagnosis may be delayed several years.[12] The average age at presentation is 34 years, and the syndrome is most commonly found in women. Patients' entire adult lives may consist of trying to gain admission to hospitals and then resisting discharge. The majority of patients work in the health care field.[2,3,14] The quest for repeated hospitalizations often takes these patients to numerous and widespread cities and states.[6]

These individuals see themselves as important people, or at least related to such persons, and their life events are depicted as exceptional. They possess extensive knowledge of medical terminology. There is frequently a history of genuine disease, and the individual may exhibit objective physical findings.[4]

The symptoms presented are "limited only by the person's medical knowledge, sophistication, and imagination."[1] Common presentations are those that most reliably result in admission to the hospital, such as abdominal pain, self-injection of a foreign substance, feculent urine, bleeding disorders, hemoptysis, paroxysmal headaches, seizures, shortness of breath, asthma with respiratory failure, chronic pain, acute cardiovascular symptoms (e.g., chest pain, induced hypertension, and syncope), renal colic and spurious urolithiasis, fever of unknown origin, and profound hypoglycemia.[3] Some self-induced conditions are highly injurious or even lethal.[15]

The patient usually presents during evenings or on weekends so as to minimize accessibility to psychiatric consultants, personal physicians, and past medical records. In teaching institutions, these patients often present in July, shortly after the change in resident house officers. They relate their history in a precise, dramatic, even intriguing fashion, embellished with flourishes of pathologic lying and self-aggrandizement. *Pseudologia fantastica,* or pathologic lying, is a distinctive peculiarity of such patients. In a chronic, often lifelong behavior pattern, the patient typically takes a central and heroic role in these tales, which may function as a way to act out fantasy.[16] The history quickly becomes vague and inconsistent, however, when the patient is questioned in detail about medical contacts. Attempts to manage the complaint on an outpatient basis are adamantly resisted. Once admitted, the patient initially appeals to the physician's qualities of nurturance and omnipotence, lavishing praise on the caregivers. Behavior rapidly evolves, however, as the patient creates havoc on the ward by insisting on excessive attention while ignoring both hospital rules and the prescribed therapeutic regimen. When the hoax is uncovered and the patient confronted, fear of rejection may abruptly change into rage against the treating physician, closely followed by departure from the hospital against medical advice.

Factitious Disorder Imposed on Another

The diagnosis of FDIA depends on specific criteria (Box 100.2).[2] FDIA is also referred to as Munchausen by proxy or medical child abuse, or a subset of battered child syndrome.[4,7,17] The diagnostic term is applied to the perpetrator of an abuse of a child, which is a criminal event and in most states requires referral once suspected.[4,18,19] The presenting complaints typically evade definitive diagnosis and are refractory to conventional therapy for no apparent reason. They usually present with more than five symptoms, presented in a confused picture; they are unusual or serious and, by design, unverifiable. Gold standard diagnostic methods include a separation test and covert video surveillance.[3,19]

Simulated illness, faked by the caregiver without producing direct harm to the patient (e.g., the addition of blood to a urine specimen), is present in 25% of cases. Produced illness, which the caregiver actually inflicts on the patient (e.g., the injection of feces into an intravenous line), is found in 50% of cases. Both simulated and produced illnesses are found in 25% of cases.[4]

BOX 100.2 DSM-5 Criteria for the Diagnosis of Factitious Disorder Imposed on Another

1. Falsification of psychological or physical signs or symptoms, or induction of disease or injury in another, associated with identified deception.
2. The individual presents another individual (victim) to others as injured, ill, or impaired.
3. The deceptive behavior is apparent even in the absence of external incentives.
4. The behavior is not better explained by another mental disorder.

Source: American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, ed 5. Arlington, VA: American Psychiatric Association; 2013.

FDIA most commonly arises with factitious bleeding, seizures, central nervous system (CNS) depression, apnea, diarrhea, vomiting, fever, and rash. Reported techniques of simulation or production of disease include fever manipulations and administration of drugs or toxins (e.g., chronic arsenic poisoning, mercury poisoning, ipecac, warfarin, salt, imipramine, laxatives, or CNS depressants), or caustics applied to the skin.[4,17] Techniques of asphyxiation include (1) covering the mouth or nose with one or both hands, a cloth, or plastic film, and (2) inserting the fingers into the back of the mouth. In such instances, even struggling infants may sustain no cutaneous markings. Cases involving seizures are common and may involve third-party witnesses. On personal questioning, however, these witnesses frequently deny the occurrence of seizure activity.[4]

Perpetrator Characteristics. Ninety-eight percent of perpetrators are biological mothers who come from all socioeconomic groups.[7,17,18] Many have a background in health professions or social work, or a past history of psychiatric treatment, marital problems, or suicide attempts. Depression, anxiety, and somatization are common, but overt psychotic behavior by the mother is atypical.[7] Perpetrators of FDIA are skilled in manipulating health care workers and child protection services. They are pleasant, socially adept, cooperative, and appreciative of good medical care. They often display a peculiar eagerness to have invasive procedures performed on their child. They often prefer to stay in the hospital with their child, cultivate unusually close relationships with hospital staff, and thrive on staff attention. This affable relationship with the medical team rapidly changes to excessive anger and denial when the perpetrator is confronted with suspicions.[7,18]

Most of these mothers have had an abusive experience early in life, and they use the health care system as a means to satisfy personal nurturing demands.[7] They often cannot distinguish their needs from the child's and satisfy their own needs first. They derive a sense of purpose from the medical and nursing attention gained when their children are in the hospital. Alternatively, the behavior may enable the mothers to escape from their own physical or psychological illnesses, marital difficulties, or social problems.[4]

Victim Characteristics. Victims of FDIA are equally male and female children. The proper diagnosis for the victims of FDIA is the coding for confirmed or suspected child physical abuse (995.4) and the appropriate injury code.[1,4] The child or vulnerable adult may also suffer physical or psychological consequences of unnecessary medical procedures. The mean age at diagnosis is 40 months, and the mean duration from the onset of signs and symptoms to diagnosis is 15 months.[17,18] A known physical illness that explains part of the symptoms is common among these children.[13] Most have a history of significant failure to thrive and have been hospitalized in more than one institution. Delays in many areas of performance and learning, difficulty with family relationships, attention deficit disorder, or clinical depression may coexist. Some of these victims may have factitious disorder later in life or even PTSD.[4] Elders may also be victims of FDIA, although this is uncommon.[4]

BOX 100.3 Characteristics of Malingering

1. Medicolegal context of the presentation (e.g., the patient was referred by his or her attorney)
2. Marked discrepancy between the person's claimed stress or disability and objective findings
3. Poor cooperation during the diagnostic evaluation or poor compliance with previously prescribed treatment regimens
4. The person exhibits or has a history of antisocial behavior

Malingering

Malingering is frequently found in association with antisocial personality disorder and substance abuse.[20] On questioning, malingerers are vague about prior hospitalizations or treatments. The physicians who previously treated them are usually unavailable. At times, malingerers may be careless about their symptoms and abandon them when they believe no one is watching. Common sources for secondary gain include opiate drug administration, shelter among the homeless, financial gains or avoidance of incarceration.[8,13] Since pain is a subjective experience, providers may have little objective evidence to quantify the degree of pain an individual is having. Malingerers who pursue drugs may report an unusually large number of drug allergies to persuade the physician to prescribe their drug of choice or simply insist on a specific drug (e.g., meperidine [Demerol] or hydromorphone [Dilaudid]). Unfortunately, the internet offers a wide availability of quality medical advice on how to convincingly feign pain and disability. In other persons, the external incentive may be obscure.

In contrast to the person with factitious disorders, the malingerer prefers counterfeit mental illness, because it is objectively difficult to verify or to disprove. Suicidal ideation is the most common psychological presentation, followed by psychosis, depression, and withdrawal syndromes.[8]

Malingering should be strongly suspected with any combination of certain factors (Box 100.3).[1] A definitive diagnosis of malingering is rare and can be established only with the patient's confession. Because malingering could constitute criminal behavior, documentation of this diagnosis must be made with care. In the absence of proof of wrongdoing, it is best to assume that the patient is not a malingerer but rather a somatizer. Due to the possible implications for diagnosing a patient as a malingerer, it is most appropriate to document the individual's behaviors.[27]

The clinical interview is especially important in identifying an individual that is malingering, with additional care to identify atypical presentations. The health care provider should be mindful in phrasing their questions to avoid providing insight on the typical presentation and begin the interview with open-ended questions, first allowing the individual to recount their symptoms in their own words and then asking more specific questions. Also be aware that patients who malinger often have true illnesses such as substance abuse or paranoia.[16,20,21]

DIFFERENTIAL DIAGNOSES

The most important diagnoses to be excluded are genuine medical and psychiatric conditions that might account for the presenting symptoms. Patients with conversion disorder, somatic disorder, delusional disorder of somatic type, and borderline personality disorder can present with symptoms similar to FDIS. The differences can be subtle and psychiatric consultation or referral is indicated.

Patients with factitious disorders are distinguished from malingerers because their desired hospitalization or surgery seems to offer no secondary gain other than to play the sick role.[1] The clinical presentation of the majority of patients with factitious disorders, unlike those with Munchausen syndrome, is relatively subtle and convincing. The complaints are generally chronic in nature rather than emergent and precipitous, and there are no obvious associated behavioral aberrations. The chronicity of malingering is usually less than that associated with factitious disorder, and malingerers are more reluctant to accept expensive, possibly painful, or dangerous tests or surgery.[4,21]

It can be useful to consider factitious disorders along a continuum of malingering, which are symptoms consciously produced for obvious secondary gain; factitious disorders, which are symptoms which are intentionally produced without obvious secondary gain; and somatization disorders, which are symptoms unconsciously produced for unconscious psychological gain. In fact, even within a patient, clinical presentations may present along this continuum at different times.[5,22] Additionally, it is important to know that there is significant morbidity and occasionally mortality associated with this spectrum of disorders. When a clinician suspects that there may be a factitious component to the clinical presentation due to an unexpected clinical course, it is useful to continue to think of a comprehensive and systematic differential diagnosis, but instead of aggressive pursuit of a rare diagnosis, to consider with the patient what problems the patient is facing and how their symptoms impact those problems.[4] The clinician can then formulate a treatment plan that addresses the root cause of these somatic symptoms.

DIAGNOSTIC TESTING

Unnecessary tests, medications, and hospitalizations should be avoided in the absence of objective evidence of a medical or psychiatric disease, and patients should be referred for ongoing primary care.

Factitious Disorder

The initial diagnosis of FDIS is often delayed because the possibility of factitious disease is not considered, physicians may be unfamiliar with this problem, or the physician is concerned about the consequences of making a mistaken diagnosis of FDIS.[9,23] Diagnosis may be confounded by genuine medical illnesses predating and coexisting with a factitious disorder. For example, patients with factitious hypoglycemia may have a history of insulin-dependent diabetes mellitus, or factitious skin disorders may be preceded by true dermatologic diseases.[4] Identification of a factitious disorder is usually made when (1) the patient's account of symptoms is patently inconsistent, (2) the patient's symptoms are too consistent with textbook descriptions, (3) laboratory findings are inconsistent (e.g., low C-peptide in context of high insulin confirms exogenous administration of insulin), (4) the patient is accidentally[4] discovered in the act, (5) incriminating items are found, (6) a combination of the preceding, or (7) the diagnosis is made by a historical pattern of medical documentation and exclusion.[4,21]

There has been increasing recognition of factitious illness produced by children. These children, ranging in age from 8 to 18 years old, are typically "bland, flat and indifferent during their extensive medical interventions, depressed, socially isolated, and often obese."[4] Among the most common presentations are fever without clear etiology, diabetic ketoacidosis, purpura, and recurrent infections. The prognosis is good if identification and psychotherapeutic intervention can be carried out at a young age.[4,12]

Suspected FDIA requires a detailed description of the event or illness and a search for caregiver witnesses, who should be interviewed personally. Although it is essential to see the child when the symptoms are present, the caretaker often makes this difficult.[7,11] Additional history of unusual illness in siblings and parents should be sought. Child victims who are verbal should be interviewed in private about foods, medicines, and their recollection of the symptoms or events. Prior medical records of the victim and, if possible, the siblings should be examined, although parents may impede such data-gathering.[5,11]

The major obstacle to early discovery of FDIA is its omission from the differential diagnosis. When it is considered, the diagnosis is generally made easily and quickly.[11] A suspected diagnosis may be confirmed through separation of the parent from the child or individual (with consequent cessation of symptoms), covert video surveillance during hospitalization, or toxicologic screens.[7] The caregiver may attempt to induce episodes surreptitiously while in the hospital.[7]

Malingering

There have been several tools designed to assist with the identification of malingerers. Two common tools are the Structured Interview of Reported Symptoms (SIRS) and the Miller Forensic Assessment of Symptoms Test (M-FAST). Although both tools have been assessed in a variety of populations, neither has been thoroughly assessed in the ED. The SIRS questionnaire has been well studied and validated, but its duration makes it less suitable for performance in an emergency setting. Although the M-FAST is considerably shorter, highly sensitive, and easy to interpret, there is inadequate data to recommend this tool for clinical use in the ED at this time.[10] Similarly, tests designed to assess malingered pain currently lack validity studies involving known populations with malingered pain and have not been found to reliably detect malingering pain.[24]

MANAGEMENT

The initial management of patients suspected of fabricating disease should include a caring, nonjudgmental attitude and a search for objective clinical evidence of treatable medical or psychiatric illness.

Factitious Disorders

Treatment options for factitious disorders depend on the patient's characteristics. Although it is challenging, management of common forms of factitious disorder can be more rewarding, especially with adolescents, than management of Munchausen syndrome.[5] The prognosis is more favorable for cases with an underlying depression than for those associated with borderline personalities.[5]

The best approach to patients with factitious disorder, other than Munchausen syndrome and FDIA, is controversial. Direct nonaccusatory confrontation has been advocated as "the foundation of effective management" when it is coupled with the assurance that an ongoing relationship with a physician will be provided. This may be the first step in the acceptance of outpatient therapy.[25]

Others point out that confrontation is ineffective in most patients and may even be counterproductive in that it threatens to undermine a needed psychological defense. Enforced recognition of external objective reality, while simultaneously disallowing the patient's subjective experience, may generate even more dysfunction directed at legitimizing and maintaining symptoms and may even place the patient at risk for escalation of symptoms.[9,25] Because emergency clinicians rarely, if ever, provide longitudinal care to patients with factitious disorders, we recommend referral for ongoing care, rather than direct confrontation in the ED.

Individuals with Munchausen syndrome typically demonstrate sociopathic traits or a borderline personality disorder and are demanding and manipulative, especially regarding analgesics. They can be difficult to treat. Early confrontation or limit-setting, especially regarding

drug use, is recommended. Although Munchausen patients typically do not want to be examined extensively, a thorough physical examination should be performed to rule out physical disease.[12,24,25]

FDIA constitutes a form of child (or elder) abuse, and appropriate action to protect the victim, including notification of state social service agencies, should take immediate priority. If available, a pediatrician who has expertise in child abuse should assess the case.[5,11] When the diagnosis has been established and the parents have been confronted, psychiatric care should be made immediately available to the parents because escalation of symptoms, including repeat abuse, abuse of siblings, and even fatalities, have been reported.[26]

Malingering

Malingerers do not want to be treated. Because they are "gaming the system" for personal gain, they do not want an accurate identification of their behavior and appropriate intervention. The emergency clinician should maintain clinical neutrality, offering the reassurance that the symptoms and examination are not consistent with any serious disease.[25] If there is no medical issue necessitating admission, admission is not recommended for malingerers. Among patients found to be malingering, admission was more likely in those feigning suicidality or seeking housing or social services.[8]

Some authors have characterized patients' use of medical resources under false pretenses as criminal behavior, and several states have enacted legislation against the fraudulent acquisition of medical services with successful prosecution of such behavior.[9,27] Conversely, patients with malingering disorders can and do sue.[27] In dealing with such patients, it is advisable to involve hospital administration and risk management. Clandestine searches are inadvisable, and respect for the patient's confidentiality should be maintained.[25]

DISPOSITION

Patients suspected of having a factitious disorder should be referred for primary care follow-up, and if it is acceptable to the patient, psychiatric referral should also be arranged. Referral to other medical specialists or hospitalization should be avoided when possible.[8,25]

The manner of presentation and the unavailability of past medical history often allow patients with Munchausen syndrome to achieve hospital admission. If the patient is discharged from the ED, outpatient primary care follow-up and psychiatric referral should be offered, although both are likely to be refused.

Because perpetrators of FDIA typically induce symptomatic episodes soon after hospitalization, admission of the victims (children or elders) without taking appropriate precautions may actually place them at increased risk. Visits by the suspected perpetrator should be closely supervised, and no food, drink, or medicines should be brought in by the family.[5] Protective services should be notified. Out-of-home placement of children in established cases of FDIA is recommended, and the best outcomes are seen among children taken into long-term care at an early age without access to their mother.[5] Children allowed to return home have a high rate of repeated abuse.[5] After the removal of the index child, the subsequent abuse rate of previous siblings is as high as 50%.[5]

After courteous but assertive reassurance, suspected malingerers should be offered primary care follow-up if the symptoms do not resolve. These individuals may become threatening when they are either denied treatment or overtly confronted.

There is a risk for escalation by the patient when they do not receive the therapy or outcome that they desire. This escalation can include threats of harm to the staff and/or the patient. While prior studies suggest that threats of suicide in these circumstances are usually not acted upon, the risk should be assessed. If necessary, consider involving psychiatry for a safety evaluation.[25]

Because prior encounters involving malingering and factitious disorder are important to recognizing similar presentations in the future, it is important to record visits for factitious disorder and malingering in the electronic medical record in a manner that is easily located such as in the problem list or past medical history. Included with the diagnosis should be a narrative including subjective and objective events during that encounter that were used to identify this disorder. In doing so, it is possible to limit unnecessary testing in the future. The goal of inclusion of this information is not to encourage cognitive bias for future providers, but to inform them of features of prior encounters that were concerning. It is important that every new complaint and encounter is evaluated, and that all identified medical needs are addressed.[25]

Once a decision for discharge is made, there should be a discussion with the treatment team including the concern that the patient may not receive the notice of discharge positively. A plan should be made with the treatment team to prepare for possible escalation by the patient. Consider having security presence nearby, if needed. All prescription orders and necessary forms should be prepared and readied to be provided to the patient at the conclusion of the conversation. During the discussion with the patient, direct language and a neutral tone should be used. After the patient is discharged, a debrief should be conducted among the treatment team to identify opportunities to improve the process in the future.[25]

CHAPTER 100: QUESTIONS AND ANSWERS

1. Which of the following statements regarding factitious disorder is true?

a. It involves voluntary and controllable symptom production.
b. Patients are generally well educated and otherwise responsible.
c. Presentations are not related to an identifiable event.
d. The symptoms produced are always physical ones.
e. The underlying motivation is a conscious one.

Answer: B. Many such patients are actually employed in the health care industry. The act of producing symptoms is voluntary but not controllable and derives from a subconscious motivation. Presentations are very often related to a "traumatic" event, such as a breakup. Produced symptoms may be physical (e.g., hematuria) or psychological. The typical patient is an unmarried female younger than 40 years. Despite undergoing invasive procedures and associated hardships, these patients seek more medical care and hospitalization.

2. Which of the following statements concerning Munchausen syndrome by proxy is true?

a. A known physical illness in the child is common.
b. Most perpetrators are demanding, uncooperative, and socially inept.
c. Most maternal perpetrators are not a biologic parent.
d. Psychosis is common in the maternal perpetrator.
e. The mean age of victim diagnosis is 7 to 9 years.

Answer: A. Victim children often have a legitimate illness. Mean age at diagnosis is 40 months. Most have a history of failure to thrive and multiple hospitalizations. The perpetrator receives some personal fulfillment from the care and attention of the hospital staff, which is often admiration for her persistence, willingness to sacrifice, and patience; and she is typically pleasant, medically savvy, and socially skilled. Invasive procedures on the child are often welcomed. Although psychosis is very unusual in the parent, depression, anxiety, and somatization are typical in the perpetrator.

CHAPTER 100: QUESTIONS AND ANSWERS—cont'd

3. A 2-year-old female presents with new-onset seizures. Her past medical history is unremarkable. Laboratory evaluation reveals blood glucose of 20 mg/dL. The patient's mother denies a family history of diabetes or having medications the child might have ingested at home. She works as a nurse at a local hospital and has been with the child all day. The child's symptoms improve with glucose administration and a meal. Your colleague remembers evaluating the child recently for hematuria with a negative evaluation. If you suspect Munchausen syndrome by proxy, which of the following tests would be most helpful in establishing the diagnosis?
   a. Basic metabolic panel
   b. Computed tomography (CT) scan of head
   c. C-peptide and insulin level
   d. Electroencephalography (EEG)

Answer: C. The diagnostic criteria for factitious hypoglycemia include high-serum insulin levels along with the absence of serum C-peptide. The C-peptide is removed during the purification of commercial insulin, and so its absence suggests the presence of endogenously administered insulin. In patients with insulinoma, both C-peptide and insulin levels are elevated and detectable.

4. A prison inmate presents after falling from the top bunk in his cell. He is complaining of lower lumbar pain and states he is unable to move or feel his lower extremities from his waist down. On physical examination, lower extremity reflexes are present but the patient denies feeling pain or light touch sensation below the waist. Lumbar spine CT and MRI are negative. Which of the following conditions is most likely?
   a. Cord contusion
   b. Factitious disorder
   c. Malingering
   d. Munchausen syndrome

Answer: C. Malingering is the intentional symptom production for secondary gain. There is a marked discrepancy between claimed disability and the actual objective findings. Confessions and proof are rare.

101

Suicidal Behavior

Henry W. Young II and Michael A. Shapiro

KEY CONCEPTS

- Many suicidal individuals see a physician shortly before their death. An ED visit for suicidal thoughts or behaviors represents an opportunity for a critical intervention that may prevent a subsequent suicide.
- Suicidal thoughts or behaviors are often triggered by short-term crisis, and most survivors are grateful to be alive.
- An empathetic, patient-centered, collaborative approach that incorporates information from collateral sources (e.g., family) can optimize care.
- Suicide precautions in the ED include appropriate use of staff to monitor the patient to prevent attempts of self-harm while in the ED.
- Routine laboratory tests provide little value for most ED patients with self-harm behaviors. Evaluation should be directed to specific concerning signs or symptoms.
- Suicide risk changes over time, and estimation of imminent risk is not currently evidence-based.
- Brief risk assessment by the clinician can identify patients in need of a comprehensive evaluation and consultation with a mental health specialist.
- Patients at low risk of suicide may be discharged to a safe and supportive environment where access to firearms or risk of overdose or poisoning is minimized.
- Discharged patients should receive education and safety planning in the ED and be referred for early mental health follow-up.

FOUNDATIONS

Background and Importance

Emergency clinicians care for many patients with suicidal ideation and self-harm behaviors. Two facts are especially important to remember in the care of suicidal patients. First, many suicide attempts occur during an acute crisis, such as a personal loss or the exacerbation of an underlying psychiatric disorder. This acute crisis is usually time-limited and is often resolvable or treatable. Second, suicidal patients are usually ambivalent about dying and grateful for help. An empathetic, patient-centered, and evidence-based approach by emergency care providers offers the opportunity to save lives.

Medical literature contains numerous terms to describe different types and degrees of suicidal thoughts and behaviors. *Suicidal behavior* refers to any observable mental state or outward behavior related to ending one's life. *Suicidal ideation* refers to thoughts of killing oneself. *Suicidal intent* refers to the desire to proceed with suicide. A *suicidal plan* refers to a conceived specific method in which a person would attempt suicide, such as by firearm, hanging, poisoning/overdose, or cutting oneself. *Lethal means* refers to someone having accessibility to a method in which to carry out a suicidal plan, for example, having physical possession of a firearm.

A suicide attempt is a self-directed act with the intent to die. *Non-suicidal self-injury* (NSSI) is an intentional act of self-harm without the intent to die as a result of the behavior. Terms to avoid because of implicit value judgement of a derogatory nature include *committed* or *successful* suicide, *suicidal gesture, manipulative act,* and *suicide threat.*[1]

Epidemiology

Suicide was the tenth leading cause of death in the United States in 2017.[2] It is the second leading cause of death for people 10 to 34 years of age, the fourth leading cause among people 35 to 54 years of age, and the eighth leading cause among people 55 to 64 years of age.[3] There were more than one million suicide attempts and 47,000 suicide deaths in the United States in 2017, and rates continue to rise.[3,4] It is estimated that in 2017 there were almost 500,000 visits to emergency departments (EDs) nationally for intentional nonfatal injuries.[5,6]

Contrary to popular belief, the majority of individuals (54%) in the United States who die by suicide do not have a known mental illness at the time of death; these individuals are much more likely to be male (84%) and to die by firearm (55%).[4] Of the individuals who die with known mental health conditions, the majority are still male (69%) and more likely to die by firearm (41%) or suffocation (31%).[4] Although women make up a higher proportion of suicide attempts, men are more likely to die by suicide due to use of more lethal methods.[4]

The ED plays a critical role in acute stabilization and initiation of appropriate preventative efforts to reduce subsequent suicide mortality.[7,8] It is estimated that 1 in 5 suicide fatalities are seen in an ED in the month prior to their death, which suggests 9,000 suicide deaths each year could be reduced through improved ED suicide prevention efforts.[9] An empathic, patient-centered, and evidence-based approach offers the opportunity to save lives.

Risk Factors

Precipitating Factors

Many precipitating factors are associated with suicide attempts among individuals with and without mental illnesses. The most common precipitants to suicide are "dynamic" factors such as interpersonal relationship stressors (42%), recent crises (29%), problematic substance use (28%), physical health problems (22%), financial circumstances, (16%), criminal or legal issues (9%), and homelessness (4%).[4] The most important risk factor for suicide is a previous suicide attempt.

At Risk Populations

In addition, there are also several "static" factors associated with increased risk of suicide, including age, ethnicity/race, geography, employment, and other population characteristics.

In a national survey of high school students in the United States, in the previous year 17% had serious thoughts of suicide, 13% made a suicide plan, and 8% made a suicide attempt.[10] Unfortunately, only half of the youths with suicide-related behavior sought mental health care or support.[10] Similar to adults, girls are more likely to attempt suicide, whereas boys are more likely to die by suicide; however, the rates for girls has been climbing.[4] History of suicide attempt and of non-suicidal self-injury are particularly strong risk factors in this population.[10]

Suicide rates are also particularly high in the geriatric population, especially older white men, who account for over 80% of suicide deaths among elders.[11] Older adults are more likely to die from suicide attempts because of the use of more lethal methods, more advanced planning, and a lower likelihood of asking for help or of having warnings recognized by others. Depression is the strongest risk factor for suicide among elders, with a prevalence of up to 80% among older suicide decedents.[11] Additional important risk factors in elders include cognitive dysfunction, decreased functional ability, bereavement or other stressful life events, social isolation, and loneliness.[11]

Suicide rates are highest across the life span among non-Hispanic American Indian/Alaska Native and non-Hispanic White populations. Other Americans disproportionately impacted by suicide include veterans and other military personnel. Among military personnel, suicide risk is increased in males and those with psychiatric history, alcohol abuse, or previous deployment.[12]

Certain occupations also convey higher suicide risk, including the health professions and physicians. Worldwide, physicians have a suicide rate almost twice that of the general population and the highest suicide rate of any profession, with the highest rates in the United States.[13] Female physicians have a suicide rate 250% to 400% higher than females in other professions and, unlike the general population, female physicians may be at higher risk for suicide than male physicians.[13] Physicians may also not seek help for their mental health for reasons that may include busy professional schedules, the de-emphasis of professional support or avoiding risk of disclosure.

Gender and sexual minorities, particularly youth, bear a large burden as well, and experience increased suicidal ideation and at-risk behaviors compared to their non–sexual minority peers.[14]

Suicide rates vary geographically, with higher rates in rural communities and in areas with higher levels of firearm ownership.[15] The rate of suicide with firearms is almost twice as high among rural compared to urban residents.[15] Important risk factors for suicide in rural areas include social isolation, lack of access to health care, socioeconomic factors such as unemployment and poverty, and sociocultural factors like increased mental illness stigma that prevent help-seeking.[15] In addition, the risk of death by suicide in rural settings is compounded by a decreased likelihood of rapid life-saving intervention as well as reduced timely access to emergency medical services and trauma centers.[15]

Mental Illness

The presence of a mood disorder, especially major depressive disorder, is a strong independent risk factor for suicide. The most common mental disorders presenting to the ED with suicidal ideation are adjustment disorders, mood disorders, and personality disorders.[16] However, many other psychiatric disorders are associated with increased rates of suicide. Overall, the risk of suicide in patients with mental illness increases with the presence of prior attempts, recent psychiatric hospitalization, male gender, more severe symptoms, comorbid psychiatric disorders, use of alcohol or drugs, and family history of suicide. In patients hospitalized for psychiatric disorders, the risk for suicide is greatest in the first month after discharge, and especially in the first week.[16]

Alcohol and Substance Abuse Disorders

Both chronic and acute alcohol abuse are associated with suicide.[17,18] Individuals with alcohol use disorder who die from suicide usually have multiple risk factors, including major depression, unemployment, medical illness, and interpersonal loss.[17] Acute alcohol use is associated with increased risk of suicide in both those with and without chronic alcohol abuse, and this risk persists for 24 to 48 hours, particularly after heavy drinking.[18] This effect is largest among younger adults and is more often associated with violent means of suicide (e.g., firearms or hanging).[18] Substance abuse is associated with increased frequency and lethality in suicide attempts, and illicit substances are often detected at the time of suicide.

Chronic Illness

Many chronic medical illnesses are associated with increased risk of suicide, particularly those that affect the central nervous system such as epilepsy,[19] or those with chronic pain or impairment in activities of daily living.[20] Infection with human immunodeficiency virus (HIV) or presence of the acquired immunodeficiency syndrome (AIDS) remains associated with increased risk of suicide, but specific risk factors may vary based on nationality, socioeconomic status, age, and comorbidity with mental illness.[21]

Pathophysiology

The etiology of a suicide attempt is a complex mix of social, genetic, and psychological factors, what psychiatrists would refer to as a "bio-psycho-social" model.[22] Several genetic and neurobiological factors have been proposed as contributors to suicide risk, including abnormalities in the serotonin transport system, the stress response systems (hypothalamic–pituitary–adrenal (HPA) axis and polyamine system), neuroinflammation, and lipid metabolism.[22] Psychological factors associated with the highest suicide risk are hopelessness and impulsivity.[23]

The social contributions to risk of suicide have perhaps the most immediate, temporal relationship with suicide attempts. Many of the most prevalent precipitating factors associated with suicide occur in the social domain, namely relationship problems, recent crises, financial problems, criminal or legal problems, and homelessness.[4] There is a growing body of evidence suggesting that adverse childhood experiences are strong risk factors for future suicide that affect individuals on biological, psychological, and social levels.[22,24,25]

Methods of Suicide

Firearms account for half of all deaths from suicide for patients with and without mental illness,[4] as this is the most lethal method with little to no opportunity for the individual to experience regret or ask for help. There is a well-established relationship between the presence of a firearm in the home and higher rates of suicide.[26,27]

The next most lethal method is hanging or suffocation (25%), followed by poisoning or overdose (16%).[4] Overdose and poisoning attempts are relatively common, and account for over two-thirds of ED visits for suicide attempt or self-harm.[28] Intentional overdose is particularly common among adolescents; 63% of all overdoses for patients ages 13 to 19 years were intentional.[28] These attempts are less frequently lethal due to delayed lethality from absorption, ability for the individual to express regret and ask for help, and opportunities for emergent treatment once help is obtained. Death by suicide from overdose is most commonly due to opioids, although it is often difficult in

public health records to distinguish death by suicide from deaths due to unintentional overdose, abuse, or misuse.[29] Children and adolescents use whatever is readily available, such as commonly used over-the-counter medications like acetaminophen and ibuprofen, which can be quite lethal or lead to severe complications.[30]

CLINICAL FEATURES

Initial Recognition and Screening

Due to stigma and fear of repercussions, patients who present to the ED following a traumatic event may not disclose the cause of their injury was a suicide attempt. The potential for suicide should be considered in patients who present with unintentional overdose or accidental gunshot wounds, lacerated wrists, automobile crashes, or falls from heights. Patients who are not overtly suicidal but who exhibit one or more of these high-risk presentations require assessment in an empathic but direct manner using a "graduated" approach. Rapport can first be established during a general medical and psychiatric history, with an evaluation of the patient's home, work, and social situation, followed by specific questions about recent psychosocial stressors, signs and symptoms of depression, and the presence of suicidal thoughts. Such questioning does not cause a person to consider suicide who has not already been considering it. This approach can be described as *indicated screening* of those with acute risk factors.[31]

A more systematic screening approach would be *selective screening* of all patients in high-risk groups, such as those with chronic risk factors for suicide including prior suicide attempts or mental illness.[32] *Universal screening* for suicidal risk involves questioning all patients about suicidal thoughts or behaviors.[32] Universal screening is supported by evidence suggesting that approximately 10% of all ED patients have recent suicidal ideation or behaviors, and 40% of suicide victims have visited an ED within the prior year.[33] For ideal functioning, any screening program can be integrated into available electronic medical records and work flow to optimize efficiency, increase provider uptake, and maximize impact.[34,35]

History and Physical Examination

The history includes details about the patient's suicidal thoughts (including onset and frequency), plans (including method, intent to act, and access to lethal means), and behaviors (including prior or recent attempts, as well as aborted or interrupted attempts). Other important points include prior medical and psychiatric conditions, prior outpatient or inpatient psychiatric care, current medications, and current drug or alcohol use (including recent use). The history also assesses for symptoms suggestive of concomitant medical illness. Intoxication does not preclude taking an initial history, but it is important to repeat interviews when patients are sober to ensure accuracy.

The physical examination assesses for evidence of drug ingestion, trauma, or associated medical illness, as well as evidence of self-harm behavior such as cutting. Roughly 10% of individuals presenting to the ED for suicidal ideation have an associated injury.[6] An evaluation of the patient's cognitive status, vital signs, pupils, skin, and nervous system are helpful in detecting organic conditions, particularly toxidromes associated with common ingestions (see Chapter 135).

The clinician should identify medical conditions requiring immediate treatment in the ED or acute or chronic conditions that may require less urgent but timely intervention, and note incidental findings requiring further outpatient management or conditions that may affect psychiatric care.

DIFFERENTIAL DIAGNOSES

Normal Colloquialisms and Expressions of Suffering

People in nonclinical settings may use colloquialisms such as "I could die!" to express exasperation or suffering that may be misinterpreted in clinical settings.[36] Individuals who have suffered with chronic illnesses or pain may vocalize statements akin to a "wish to hasten death," which could have many meanings aside from an intent to end one's life.[4] Such statements may serve to communicate feelings, thoughts, or wishes about suffering, relief, help, and concerns about the illness or dying process. These thoughts and statements typically have a theme of suffering and loss of control.[4] It is important to carefully ascertain the presence of true suicidal ideations in these circumstances.

Malingering

Malingering is not a psychiatric illness; it is the intentional fabrication of symptoms, such as that of a mental illness, or even a claim, exaggeration, or feigning of suicidality for the purpose of obtaining an external gain.[37] There are no indicated treatments for malingering and no role for hospitalization. Studies have suggested that up to 10% of patients admitted to psychiatric hospitals have fabricated or exaggerated suicidal ideation to gain hospital admission. Suicidal ideation is the most frequently malingered psychiatric symptom, likely because of its subjective nature and the implicit additional leverage associated with the risk of mortality if unaddressed.

Non-Suicidal Self-Injury

The term *non-suicidal self-injury* (NSSI) refers to "the direct, deliberate destruction of one's own body tissue in the absence of intent to die," such as cutting or burning oneself.[38] There is conflicting evidence regarding whether NSSI and suicidal behavior are diagnostically distinct or exist on a spectrum of self-harm behavior. There is, however, sufficient evidence to suggest that NSSI is a risk factor for future suicide attempts.[38] There are cases where NSSI may have potentially lethal consequences, even if the intent was not suicide, so it is critical to consider both lethality and intent when performing a safety assessment.

Unintentional Injury or Ingestion

Over three-quarters of all overdoses are classified as unintentional, including most cases in children ages 5 years and younger.[28] In almost a quarter of single-substance overdoses that involved pharmaceutical substances, the reason for exposure was intentional, compared to only 4% when the exposure involved a nonpharmaceutical substance. The ingestion of multiple drugs is more reflective of an intentional overdose, and generally leads to more serious and potentially lethal complications.[28]

Substance Intoxication, Abuse, or Misuse

Patients may make suicidal statements while intoxicated or when presenting with an injury that may be a result of a suicide attempt. Patients may also make suicidal statements or inflict self-harm while intoxicated, then deny suicidal ideation later. An electronic medical record study in the United Kingdom showed that patients who presented as an emergency due to any alcohol-related cause had a three-times higher risk of future suicide; and when they were admitted to the hospital, the risk was 22-fold higher in women and 5-fold higher in men. When the diagnosis was "toxic effects of alcohol or poisoning through alcohol," the risk was 30-fold higher for women and 18-fold higher for men, a risk even higher than for those with a previous mental health disorder.[39]

Suicide attempts using illicit drugs are relatively uncommon. Overdose with an illicit drug or a prescription pain medication may be lethal and intentional, but not with death as a desired outcome.

Opioids are the most frequent cause of fatal overdoses today, yet many of these are likely not suicides, but rather abuse, misuse, or the development of tolerance leading to high-dose use and fatal overdoses.[28]

Suicidal Obsessions or Preoccupations

Suicidal ideation must be differentiated from having "thoughts of suicide" or "thinking of hurting oneself," without the desire, intent, or plan to pursue an act of ending one's life. Such thoughts may represent obsessions, such as occur in obsessive-compulsive disorder (OCD), or the ruminations or preservative thinking that occurs in autism spectrum disorder (ASD).[40,41] It is important to note that individuals with OCD and ASD can experience frank suicidal ideation as well. To make the differentiation, it is helpful to clarify whether the patient prefers death over life, or harbors a desire, intent, or plan to end his or her life.

DIAGNOSTIC TESTING

Emergency clinicians are often asked to provide "medical clearance" for patients with psychiatric emergencies. However, this term substantially undervalues the importance of a focused medical assessment of patients who may have active acute or chronic conditions, to determine stability and appropriateness for treatment in a psychiatric setting.[42] Obtaining an adequate patient history and physical examination is essential in the focused medical assessment.

Mandatory nontargeted diagnostic testing of all suicidal patients is not necessary and has not demonstrated any clinical benefit, particularly in younger patients.[42,43] Less than 1% of suicidal patients have their disposition changed through use of testing believed to be unnecessary by the emergency clinician.[43] Targeted diagnostic testing should be based on clinical indications, including the new onset of psychiatric symptoms in those with no known past psychiatric history.[42,43] There is little evidence to show that screening urine drug testing alters management or disposition of the psychiatric patient in the ED.[42,43] However comorbid substance use is an important factor in subsequent treatment, and receiving psychiatric facilities may request this study, as it is a time-sensitive study and may affect the direction of further mental health treatment.[42,43] Local practices vary and some mental health facilities may require routine baseline testing. EDs and local receiving psychiatric facilities should create guidelines to clarify minimal testing required for medical clearance.

MANAGEMENT

Overview

Care of potentially suicidal patients requires an empathetic and patient-centered approach. Patients feel more comfortable discussing personal issues when health care personnel are friendly, nonjudgmental, and supportive.[44] Providers can improve the ED experience by explaining to patients what to expect from the evaluation, stating the estimated length of wait for evaluation and disposition, and focusing initially on basic comforts.[44] The use of a patient-centered approach can also enhance patient satisfaction and the likelihood of outpatient follow-up.[44] Attitudes towards suicide prevention are highly correlated with effective suicide prevention skills of emergency medical service providers.[44,45,46] Personal beliefs or inadequate training of clinical providers, or lack of time or personnel to provide appropriate psychiatric evaluation, can result in inadequate patient assessment and adversely impact outcomes.

The priority in management is immediate medical stabilization and treatment of injuries, poisonings, or overdose. Following stabilization, a focused medical assessment should be performed to identify and treat associated medical conditions that may underlie a patient's altered mental status or suicidal behavior. Hospitalization for significant injury, poisoning, or other acute medical problems is imperative so that medical problems can be treated as patients remain under constant observation for suicide risk and later receive appropriate psychiatric evaluation.

Suicide Precautions

Protocols for managing potentially suicidal individuals focus on patient safety and the prevention of self-harm. While the practice of constant physical observation by ED personnel of all patients exhibiting suicidal behavior may be considered essential, alternative means of monitoring through careful patient selection and use of technology may be similarly effective.[44,47,48] The effectiveness of electronic bracelets and other forms of virtual monitoring are currently being evaluated.[48]

As part of standard procedure, patients being evaluated for suicidal behavior are searched during the initial assessment for possible weapons, medications, and other possessions that might be used to inflict injury (e.g., belts, neckties, and long shoelaces),[44] and are evaluated in an area cleared of all potentially harmful objects, including medications, instruments, and glass objects.[44,47] Use of restraints is rarely necessary. Mechanical and chemical restraint use is most commonly employed for patients who are agitated or physically aggressive, but such measures are a last resort because they can be traumatic, impair rapport, exacerbate an underlying psychiatric condition, or impair early psychiatric evaluation.[44]

Pharmacologic Treatment

Prescription psychiatric medications are commonly used to treat depression and other underlying psychiatric disorders, but they are generally not effective for acute suicidality and may take weeks to become effective.[49]

Children, adolescents, and young adults may have increased suicidal thoughts or attempts soon after the initiation of antidepressant medications.[50] Although current studies do not support a direct causation between antidepressant medication and suicidality in youth, clinicians should recognize the time period around initiation of antidepressant therapy as one requiring heightened scrutiny for suicidal thoughts or behaviors.[51]

There are no generally accepted or evidence-based protocols for drug treatment of suicidal ideation in the ED. However, ketamine and its enantiomer, esketamine, have demonstrated promise as a potential acute treatment for suicidal ideations.[52-56] Ketamine at sub-anesthetic doses has been used in several studies for treatment-resistant depression, and such studies show that ketamine encompasses a specific and rapid suppression of suicidal ideation.[52,53,54] Meta-analyses have revealed single-dose intravenous (IV) infusion of ketamine to be associated with reduction of suicidality within as little as 40 minutes and lasting as long as 3 days to 2 weeks.[52-54] The intranasal form of esketamine was approved by the United States Food and Drug Administration for treatment-resistant depression in 2019, but patients must be monitored by a health care provider in a doctor's office, clinic, or hospital for at least 2 hours following administration due to risk of sedation and dissociation.[55]

Ketamine's application is not straightforward, as repetitive doses are required due to the short duration of action.[52-54] Additionally, use may be hindered by the drug's potential for abuse, dependence, and dissociative effects.[55] Despite increasing evidence showing the suicide-mitigating effect of ketamine, the underlying neurobiology is poorly understood, and a preliminary study suggests that the antidepressant effects of ketamine may actually be due to its action

at opioid receptors.[56] We do not recommend the routine use of ketamine for this purpose in the ED in the absence of psychiatric consultation.

Risk Assessment

Analogous to the evaluation of chest pain and other physical complaints, the emergency clinician's role in managing potentially suicidal patients lies in assessing suicide risk, providing brief interventions, and facilitating consultation with specialists as indicated.[57]

Suicide risk assessment should be performed when the patient is sober, although intoxicated patients who endorse suicidal thoughts may still be at risk, even if they disavow these feelings when sober.[58] Risk assessment includes collateral information from a family member or friend who can provide additional background information and discuss whether there are sufficient resources available to support a safe discharge if considered.[59] Such contacts are most appropriately made with the consent of the patient, if possible, but can occur without consent in cases when disclosure of protected health information is required to prevent or mitigate an imminent, serious safety threat to an individual or the public.[59]

Assessing hopelessness, desperation, and a wish or intent to die are also important predictors of future suicide.[60-62] Assessment of risk of the lethality of a plan for death by suicide is paramount even though patients with strong suicidal ideations without a plan may still remain at high risk.[60] Patients who initially hide or conceal their suicide attempt may also be at higher risk of death.[60-63]

A practical, stepwise approach to suicide risk assessment (see Fig. 101.1) consists of both brief and comprehensive steps. *Brief risk assessment* typically involves a short set of questions to assess suicide risk and help determine the most appropriate actionable steps.[64,65] An example is the short version of the Columbia-Suicide Severity Rating Scale (C-SSRS; see Fig 101.2), which is available for free in English and Spanish with suggested cut-points for referral and consultation.[66] The C-SSRS can be modified for use by clinicians in a variety of settings, including the ED. It is a quick 6-item questionnaire that helps triage patients as acutely low, medium, or high risk for suicide and allows for individual EDs, hospitals, or hospital systems to use the tool appropriately within their system depending on what resources are available.

A *comprehensive* or *formal risk assessment* involves more-detailed questions about a patient's various suicide risk and protective factors and is most often performed by a mental health consultant.[65] In cases where psychiatric consultation is not possible, the clinician can complete a comprehensive suicide risk assessment assisted by a validated tool such as the Suicide Assessment Five-step Evaluation and Triage (SAFE-T; see Fig. 101.3) tool. The SAFE-T is available as a pocket card or smartphone application. It guides one in assessing a patient's risk, the presence of protective factors and the specifics of suicidal thoughts or plans, and then combines these factors to estimate a level of suicide risk.[67]

The Ask Suicide-Screening Questions (ASQ) Toolkit is a free combined brief and comprehensive risk assessment developed by the National Institute for Mental Health (NIMH) and the Substance Abuse and Mental Health Services Association (SAMHSA) specifically for youth at risk for suicide.[32,68]

Ultimately, suicide risk assessment remains a matter of clinical judgment with tools such as the C-SSRS and SAFE-T to inform, reinforce, and justify the provider's decision making.[65]

Documentation

Documentation of the evaluation of potentially suicidal patients is important because of the variable nature of suicide risk, low compliance rates of follow-up with outpatient care, and the difficulty of predicting imminent risk. It is especially important when patients are either hospitalized involuntarily or discharged. If a patient requires involuntary hospitalization, providers should document why the patient is a danger to self or others. If the patient is discharged, appropriate documentation includes the decision making as to why the patient was considered to be at low risk of imminent self-harm, referencing access to potentially lethal methods of suicide, information from collateral sources, and the follow-up plan.[69] Use of standardized electronic health record templates may prove useful in ensuring sufficient system-wide documentation of suicide assessment and decision making.[70]

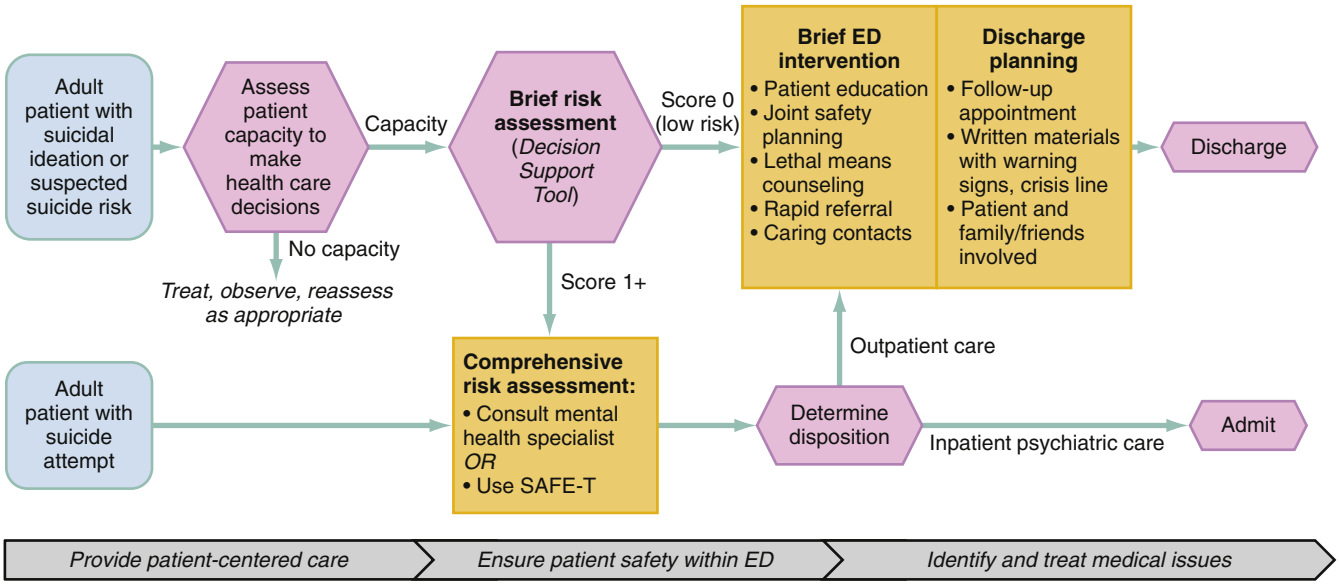

Fig. 101.1 Framework for using the decision support tool and emergency department (ED)-based suicide prevention interventions. (Adapted from: Capoccia L, Labre M. *Caring for Adult Patients With Suicide Risk: A Consensus-Based Guide for Emergency Departments*. Waltham, MA: Education Development Center, Inc., Suicide Resource Prevention Center; 2015.)

Columbia-suicide severity rating scale
screen with triage points for ***emergency department***

Ask questions that are bolded and underlined.	Past month	
Ask questions 1 and 2	**YES**	**NO**
1) ***Have you wished you were dead or wished you could go to sleep and not wake up?***		
2) ***Have you actually had any thoughts of killing yourself?***		
If YES to 2, ask questions 3, 4, 5, and 6. If NO to 2, go directly to question 6.		
3) ***Have you been thinking about how you might do this?*** E.g. *"I thought about taking an overdose but I never made a specific plan as to when where or how I would actually do it.…and I would never go through with it."*		
4) ***Have you had these thoughts and had some intention of acting on them?*** As opposed to *"I have the thoughts but I definitely will not do anything about them."*		
5) ***Have you started to work out or worked out the details of how to kill yourself? Do you intend to carry out this plan?***		
6) ***Have you ever done anything, started to do anything, or prepared to do anything to end your life?*** Examples: Collected pills, obtained a gun, gave away valuables, wrote a will or suicide note, took out pills but didn't swallow any, held a gun but changed your mind or it was grabbed from your hand, went to the roof but didn't jump; or actually took pills, tried to shoot yourself, cut yourself, tried to hang yourself, etc.	**Lifetime**	
If YES, ask: *Was this within the past three months?*	**Past 3 months**	

Item 1 behavioral health referral at discharge
Item 2 behavioral health referral at discharge
Item 3 behavioral health consult (psychiatric nurse/social worker) and consider patient safety precautions
Item 4 immediate notification of physician and/or behavioral health and patient safety precautions
Item 5 immediate notification of physician and/or behavioral health and patient safety precautions
Item 6 over 3 months ago: Behavioral health consult (psychiatric nurse/social worker) and consider patient safety precautions
Item 6 3 months ago or less: Immediate notification of physician and/or behavioral health and patient safety precautions

Fig. 101.2 Columbia-Suicide Severity Rating Scale Triage and Risk Identification Tool from The Columbia Lighthouse Project. (From: Posner K, et al. The Columbia-Suicide Severity Rating Scale: initial validity and internal consistency findings from three multisite studies with adolescents and adults. *Am J Psychiatry.* 2011 Dec;168(12):1266-1277. PMID: 22193671. Available at https://cssrs.columbia.edu/the-columbia-scale-c-ssrs/risk-identification/.)

DISPOSITION

Determining the most appropriate disposition for the potentially suicidal patient involves integrating information about the precipitating crisis and event, the patient's current emotional state and prior mental health history, and the presence or absence of a safe and supportive environment. Addressing the crisis that precipitated a suicide attempt can substantially diminish the risk of suicide. Emergency psychiatric evaluation and psychiatric hospitalization are often strongly considered to ensure this crisis can be resolved.

Psychiatric Hospitalization

Voluntary hospitalization is preferable to involuntary hospitalization.[71] The efficacy of hospitalization as a long-term preventive measure is controversial and is not proved to prevent future suicide.[72-74] Still, hospitalization remains a primary intervention when patients are deemed acutely suicidal as a means to provide a safe environment for close monitoring where medical or somatic therapies can be started, positive coping skills can be taught and reinforced, and social supports can be mobilized.[75] Depending upon outpatient resource availability, other options may include partial hospitalization programs, intensive outpatient programs, and assertive community treatment.

Statutes regulating involuntary hospitalization, otherwise known as civil commitment, differ between states and regions. Most states have emergency involuntary commitment provisions that typically require that a patient both have a mental illness and pose a threat to self or others.[76] The length of emergency commitments varies by state, from 72 hours to 15 days.[76-79] In some states, patients who agree to hospitalization may still need involuntary commitment documentation completed for transport to a receiving psychiatric facility; this provides the legal basis for holding patients if they change their mind during transportation.

1. Identify risk factors

- **Suicidal behavior**: prior suicide attempts or self-injurious behavior
- **Current/past psychiatric disorders**: especially mood disorders, psychotic disorders, alcohol/substance abuse, ADHD, TBI, PTSD, Cluster B personality disorders, conduct disorders (antisocial behavior, aggression, impulsivity)
- **Key symptoms**: anhedonia, impulsivity, hopelessness, anxiety/panic, insomnia, command hallucinations
- **Family history**: of suicide, attempts, or Axis 1 psychiatric disorders requiring hospitalization
- **Precipitants/Stressors/Interpersonal**: triggering events leading to humiliation, shame or despair (e.g., loss of relationship, financial or health status—real or anticipated); ongoing medical illness (esp. CNS disorders, pain); intoxication; family turmoil/chaos; history of physical or sexual abuse; social isolation
- **Change in treatment**: discharge from psychiatric hospital, provider or treatment change
- **Access to firearms**

2. Identify protective factors

- **Internal**: ability to cope with stress, religious beliefs, frustration tolerance
- **External**: responsibility to children/pets, positive therapeutic relationships, social supports

3. Conduct suicide inquiry

- **Ideation**: frequency, intensity, duration–in last 48 hours, past month, and worst ever
- **Plan**: timing, location, lethality, availability, preparatory acts
- **Behaviors**: past attempts, aborted attempts, rehearsals (tying noose, loading gun), vs. non-suicidal self-injurious actions
- **Intent**: extent to which the patient (1) expects to carry out the plan and (2) believes the plan/act to be lethal vs. self-injurious
- **Explore** ambivalence: reasons to die vs. reasons to live

4. Determine risk level & intervention

- **Assessment** of risk level is based on clinical judgment, after completing steps 1–3

Low risk	Moderate risk	High risk
• Denial of suicidal thoughts, plan, intent • No or mild sadness or anger; no psychosis • No or 1 recent attempt with low lethality • No or limited substance use • Good support, accepting of help, hopeful for future	• Suicidal ideation, plan, intent, or attempt • Moderate depression, anger, hopelessness • Frequent ideation or threats; low lethality • Substance abuse • Moderate support, unwilling to accept help • Access to lethal means	• Frequent, intense, enduring ideation • Specific plans • High intent (e.g., attempt with high lethality) • Impaired self-control, severe dysphoria, hopelessness, worthlessness • Poor corroborative history • Many risk factors, refusing help

5. Document

- Risk level and rationale; treatment plan to address/reduce current risk (e.g., setting, medication, psychotherapy, ECT, contact with significant others, consultation); firearm instructions, if relevant; follow-up plan
- For youths, treatment plan should include roles for parent/guardian

Fig. 101.3 Suicide assessment five-step evaluation and triage. (Modified from: Davidson CL, Olson-Madden JH, Betz ME, et al. Emergency department identification, assessment, and management of the suicidal patient. In: Koslow SH, Ruiz P, Nemeroff CB, eds. *A Concise Guide to Understanding Suicide*. Cambridge, UK: Cambridge University Press; 2014: 244–255; Suicide Assessment Five-Step Evaluation and Triage [SAFE-T]. Substance Abuse and Mental Health Services Administration. Available at http://store.samhsa.gov/product/Suicide-Assessment-Five-Step-Evaluation-and-Triage-SAFE-T-/SMA09-4432; and Substance Abuse and Mental Health Services Administration [SAMHSA]. Suicide safe: the suicide prevention app for health care providers, free from SAMHSA. Available at http://store.samhsa.gov/apps/suicidesafe/.)

Patients may lack capacity to refuse hospitalization but maintain the capacity to accept or refuse other treatments, such as management of medical conditions and administration of medications for pain or agitation.[80]

Discharge

Some patients who report suicidal thoughts can be safely managed as outpatients if the risk of subsequent suicide is judged to be acceptably low. Although the emergency clinician can make this determination in many cases, evaluation by a mental health professional can be useful if the safety of outpatient management is in doubt. The patient can be discharged to a stable and supportive home environment with a willing friend or family member, and without access to guns or lethal medications. The discharge planning process ideally includes (1) brief patient education, (2) joint safety planning, (3) lethal means restriction counseling, (4) referral for outpatient care, and (5) provision of "caring contacts."[77,81-83]

Brief Patient Education

Brief patient education for suicide prevention includes the use of verbal and written information and "teach back" techniques whereby the patient explains the information back to the provider.[81] Information can include a personalized list of risk and protective factors, home care and follow-up instructions, and warning signs that would trigger a call for help. The educational process engages the patient in an empathetic and respectful manner and can, with patient consent, include family members or close friends.[81] Educational materials are available from a number of national organizations.

Joint Safety Planning

In joint safety planning, a provider works with a patient to develop a plan regarding what to do if symptoms worsen.[77,81] The plan should be in the patient's own words and easy to understand, and it includes warning signs, a list of coping strategies, and resources such as hotlines or contact information for trusted family or friends (specify "adults" in the case of suicidal children or adolescents). The National Suicide Prevention Hotline (1-800-273-TALK [8255]) and/or text line (741-741) is a helpful resource for all discharged patients; in late 2019 the Federal Communications Commission (FCC) approved using 988 as a three-digit suicide prevention hotline number.[84] Importantly, safety planning is not the same as a "contract for safety" or "no suicide contract." Such "contracts" not only lack evidence of effectiveness but may deter patients from being truthful in disclosing future episodes of suicidality.[83] These contracts may create a false sense of security regarding safety and should not be used.

Lethal Means Restriction Counseling

Counseling about lethal means restriction—one of only two suicide prevention approaches with a strong empirical foundation—is another valuable resource.[84-85] Many suicidal crises are acute and short-lived and are impulsive (sometimes with only minutes or seconds between the decision to act and the attempt). The method chosen may be the one most readily available, and the lethality of the chosen method affects the likelihood of mortality. Numerous studies have shown a consistent association between firearm access and death by suicide, even after controlling for other risk factors, with a strong correlation amongst males.[26,86-87] Safe gun-storage practices—namely keeping firearms locked, unloaded, and separate from ammunition—can mitigate the risk of suicide. At a population level, firearms regulations such as waiting periods and training requirements are associated with reduced rates of firearm-related suicide.[87,88]

ED counseling about lethal means safety can affect patient behavior, and lethal means counseling for suicidal patients is supported by multiple physician organizations and listed as a best practice for suicide prevention.[89] Clinicians should counsel potentially suicidal patients and their families to remove guns temporarily from the home for storage off-site in an appropriate location, or to use gun locks or cabinets to which the patient has no access.[90]

Referral for Outpatient Care

Suicide risk remains high shortly after discharge from the ED, so it is important to arrange short-term outpatient care, ideally within 72 hours of discharge.[89] Evidence-based outpatient treatment can reduce future suicide risk, and emergency clinicians play a key role in linking patients to care.[89] A significant number of discharged ED patients do not keep their follow-up appointments, but compliance with follow-up may be increased by making a specific appointment for patients. Employing the support of family or friends helps ensure that the patient keeps the follow-up appointment. In addition, it may be helpful to provide physician contact information or to provide a list of community mental health resources. With the patient's consent, the physician can send visit information to the patient's primary care provider or outpatient referral provider to enhance continuity of care.

Caring Contacts

Other promising interventions for discharged patients include caring contacts, or brief communications from the ED after discharge.[91,92] These empirically supported interventions take a variety of forms, including text messages, emails, phone calls, and postcards, and they may be unidirectional or bidirectional. An automated system, supported by the electronic health record, can facilitate the process, or the contacts can be made by a clinical or nonclinical ED staff member. Such continued contacts have been shown to improve follow-up to outpatient appointments and lower suicide risk.[92]

ADDITIONAL ETHICAL CONSIDERATIONS

Do-Not-Resuscitate Orders

The presence of a do-not-resuscitate (DNR) order in a patient with a suicide attempt raises ethical and legal dilemmas.[93] Policies vary among states, and there are unfortunately no definitive guidelines for emergency care providers.[81] When possible, consultation with an ethics consultant or committee or legal representation from the hospital can be helpful, but in emergent time-sensitive conditions it is preferred to err on the side of resuscitation.

The principle of beneficence dictates that treatment be pursued when a suicidal patient may not be capable of making decisions about his or her own welfare. Because DNR orders and palliative care generally apply to progressive terminal illnesses and do not exclude or limit all other care, it is necessary to treat self-inflicted conditions even in the presence of a DNR order.[89] Treatment does not have to be indefinite and can be discontinued later following appropriate consultation with ethics and legal experts. Institutions have a responsibility to examine these issues proactively and pursue policies that address how to respond to patients with a DNR order who attempt suicide.[93] Such policies need to address specific state laws regarding prehospital DNR orders.

Physician-Assisted Dying

As of 2018, five states and the District of Columbia have passed legislation legalizing assisted dying, with other jurisdictions considering such legislation.[94] Physician-assisted dying refers to patients who voluntarily and orally ingest medications that are prescribed to them only after they pass a series of safeguards. Such safeguards typically include (1) having a prognosis of fewer than 6 months, confirmed by two physicians: (2), retaining medical decision-making capacity: and (3) making multiple requests separated by time to allow adequate reflection and reconsideration. Although EMS and ED involvement may be rare (approximately 1% of cases in Oregon), when they do occur, they require rapid decision making, often with limited information and challenging emotions.[42] As more states allow physician-assisted dying, it is expected that more such cases will come to clinical attention in the ED. It is appropriate to involve palliative care and ethics consultations in such cases with supporting institutional protocols in place that achieve consensus on recommendations for action.[94] The legal authorization of physician-assisted dying intent draws a sharp distinction in these cases from an impulsive suicide attempt, and ED providers must be prepared to adapt to new state laws and their application in medicine.

CHAPTER 101: QUESTIONS AND ANSWERS

1. Which of the following statements regarding suicide is true?
- **a.** Many suicide attempts occur during an acute crisis.
- **b.** Suicide rates are highest in older men.
- **c.** Suicidal behavior may be chronic.
- **d.** Suicidal patients are usually ambivalent about dying.
- **e.** All of the above are true.

Answer: E. Many suicide attempts occur in response to a crisis that may be time-limited or resolvable. Suicide rates are particularly high in older white men. With the exception of psychotic patients, suicidal patients are usually ambivalent about dying. An example of chronic suicidal behavior is drinking in the face of liver disease.

2. Which of the following statements regarding suicide is true?
- **a.** Blacks attempt suicide more than whites.
- **b.** Men attempt suicide more than women.
- **c.** Marriage decreases the likelihood of suicide.
- **d.** Pregnancy increases the risk of suicide.
- **e.** Suicide rates are highest among female teens.

Answer: C. Marriage and pregnancy/motherhood decrease suicide risk. Whites attempt suicide more than blacks, with the highest rate among older white men. Women attempt suicide far more often than men but do not choose lethal means and therefore have a lower success rate.

3. Which of the following is a risk factor for suicide?
- **a.** Prior suicide attempt
- **b.** Access to firearms
- **c.** Alcohol abuse
- **d.** Veteran status
- **e.** All of the above

Answer: E. Additional suicide risk factors include, but are not limited to: adolescence and older age; male gender; certain races/ethnicities (White, American Indian, Alaskan Native); mental disorders; substance abuse; prior suicide attempt; psychosocial stressors (e.g., recent psychiatric hospital discharge, history of trauma or abuse, terminal illness, chronic pain, hopelessness, impulsiveness); environmental stressors (e.g., job loss, bereavement); and sociocultural factors (e.g., isolation, poor access to mental health care, stigma against seeking help, or media exposure to suicide).

4. Most completed suicides involve which of the following?
- **a.** Falls
- **b.** Firearms
- **c.** Piercing
- **d.** Poisonings
- **e.** Suffocation

Answer: B. Fifty percent of completed suicides involve firearms. Seventy percent of attempted suicides involve poisoning.

5. Discharge planning for suicidal patients should include which of these elements?
- **a.** Counseling about reducing access to guns and toxic medications.
- **b.** Involvement of family or friends.
- **c.** Rapid referral to outpatient mental health.
- **d.** Written materials with warning signs and hotline numbers.
- **e.** All of the above.

Answer: E. All of the listed elements are recommended components of ED care and discharge planning for patients evaluated for suicidal thoughts or behaviors but deemed safe for discharge home.

6. A 33-year-old Caucasian man presents with agitation and suicidal ideation. He has a long history of schizophrenia and is currently taking olanzapine and occasional clonazepam. He was hospitalized 3 weeks prior for an accelerated psychotic episode and released on an increased dose of olanzapine. His family brought him here today after visiting him in his apartment and finding him in a room with all the lights off. They note he has been unable to work for more than 2 years. He was formerly employed as an engineer. Your examination is remarkable for a blunted affect, moderate pressured speech, and a depressed mood. What is the most appropriate intervention?
- **a.** Addition of sertraline to olanzapine, 2-day follow-up
- **b.** Admission to psychiatry unit
- **c.** Increase olanzapine, release with family
- **d.** Overnight emergency department (ED) observation, 2-day psychiatry follow-up
- **e.** Parenteral ziprasidone, release with family

Answer: B. Approximately 10% of schizophrenic patients will kill themselves. Psychotic patients who kill themselves are often unmarried Caucasians of high intelligence. A recent psychiatric hospitalization is a suicide risk factor, particularly during the first month post discharge. This patient is high risk and needs admission.

7. Which of the following statements concerning risk assessment of suicidal patients is true?
- **a.** An empathetic approach will reinforce malingering behavior and subsequent ED visits.
- **b.** For patients at low risk of imminent suicide, providers can consider discharge without formal consultation with a mental health professional.
- **c.** Intoxicated patients who, once sober, disavow prior suicidal statements do not need a suicide risk assessment.

CHAPTER 101: QUESTIONS AND ANSWERS—cont'd

d. Routine screening labs should include serum chemistries and urine toxicologic panels.
e. Suicidal patients can be permitted to leave the ED prior to a risk assessment as long as they sign "Against Medical Advice" paperwork.

Answer: B. In a step-wise manner, the ED provider can complete a brief risk assessment to identify which patients do (or do not) require a comprehensive evaluation with a mental health professional. Diagnostic testing should be targeted to individual patients as clinically indicated. An empathetic approach can enhance patient evaluation and care and should be used with all suicidal patients. Acute and chronic alcohol use are both suicide risk factors; even if a patient denies suicidality once sober, a risk assessment may be prudent. No suicidal patient should be allowed to leave the ED before the risk assessment is complete.

8. Which of the following statements regarding involuntary commitment is true?
a. It is not associated with adverse psychiatric consequences.
b. It lowers the rate of future suicides.
c. Most states mandate attempts at involuntary commitment if there is imminent self-harm.
d. Patients who volunteer for admission may still need commitment papers.
e. Statutes are consistent among the states.

Answer: D. Statutes vary widely among the states. Some states require commitment papers even in cases of voluntary admission. Only two states mandate commitment in the face of suspected imminent self-harm. Involuntary commitment does not lower the rate of future suicides and is associated with adverse psychiatric consequences.

102

Arthritis

Korin Hudson, Miguel Agrait-Gonzalez

KEY CONCEPTS

1. Arthritis can be considered in three broad classes: degenerative, infectious, and inflammatory. The number of joints involved, time course, and presence of other systemic symptoms can help in classification.
2. Septic (acute infectious) arthritis should be considered in any patient presenting with acute monoarticular arthritis.
3. No singular physical examination finding, serum test, or synovial fluid test in isolation can diagnose or exclude the diagnosis of a septic joint.
4. Arthrocentesis can aid in diagnosis and should be considered if the diagnosis is unclear or any time infection is suspected.
5. Crystal arthritis and septic arthritis can and do frequently coexist. The presence of crystals in joint aspirate should not be used to exclude infection.
6. Gram stain of synovial fluid is positive only in 50% of patients with confirmed infection and should not be used in isolation to exclude infection.
7. Many common arthritis conditions, including gout, rheumatoid arthritis, and osteoarthritis, can be managed in the outpatient setting. Analgesics, specifically antiinflammatory medications, are the mainstay of initial therapy.
8. A systematic history and physical examination should be performed to evaluate for multiple joint involvement or signs of systemic disease.
9. Intra-articular corticosteroid injections can be considered in select patient populations where systemic therapy is either contraindicated or presents a significant risk to the patient.
10. Consider ultrasound evaluation of acutely painful joints to better evaluate for the presence of joint effusion requiring aspiration.

GENERAL APPROACH TO ARTHRITIS

Foundations

Background

Arthritis and its related conditions were among the earliest diseases described. Ancient cultures including the Romans, Greeks, and Egyptians all referenced conditions such as gout and rheumatoid arthritis (RA), while Hippocrates and others contributed to the further description and classification. In modern times, arthritis has become a common cause of disability in the United States and around the world. More than 20% of adults in the United States carry the diagnosis of arthritis, leading to millions of prescriptions, procedures, and profound activity limitations.[1] Patients with arthritis may present to the emergency department (ED) for a variety of reasons. First among these is pain related to their primary condition; however, complications related to systemic illness are also common in patients with autoimmune or inflammatory conditions. Furthermore, the medications and treatments used to manage these conditions may themselves have side effects which lead patients to seek emergency care.

Pathophysiology

Arthritis typically occurs in synovial or diarthrotic (moving) joints. These joints are made up of two ends of subchondral bone, each covered with articular cartilage and surrounded by a fibrous capsule (Fig. 102.1). This capsule is supported by ligaments, tendons, and muscle. The capsule is lined with a thin synovial membrane and contains synovial fluid, a viscous, lubricating substance which allows near frictionless movement of the joint. The bones of the joint are lined by a specific form of hyaline cartilage known as articular cartilage, which allows load bearing and contributes to the friction-free movement of the joint when combined with synovial fluid. Numerous conditions and specific processes will lead to degradation of these tissues and ultimately to degeneration and arthritis.

Clinical Features and Differential Diagnosis

When evaluating a patient with a complaint of joint pain, it is important to use a systematic approach and consider several key factors (Box 102.1).

It is also helpful to think of arthritis in three broad categories: degenerative/osteoarthritis (OA) including posttraumatic arthritis, infectious or septic arthritis, and inflammatory arthritis. Table 102.1 and Fig. 102.2 outline the differential diagnosis and decision pathways that may be used when evaluating patients with an acutely painful joint.

History

The acutely painful joint or joints is usually the primary complaint for the patient presenting with arthritis. The patient's age, as well as the timing of symptoms, specific location and description of pain, presence of associated symptoms, and factors that aggravate or alleviate symptoms, can provide clues to the etiology. Once the history and characteristics of the pain have been reviewed, further classifying the problem as monoarticular or polyarticular is of great importance. In cases of polyarticular arthritis, care should be taken to assess for the presence of symmetric versus asymmetric symptoms. These specific characteristics can be used when creating a differential diagnosis, as detailed in Table 102.1.

OA or degenerative joint disease is a clinical finding expected in the older population and is uncommon in younger patients except in the setting of previous traumatic injuries or prior surgeries or in patients

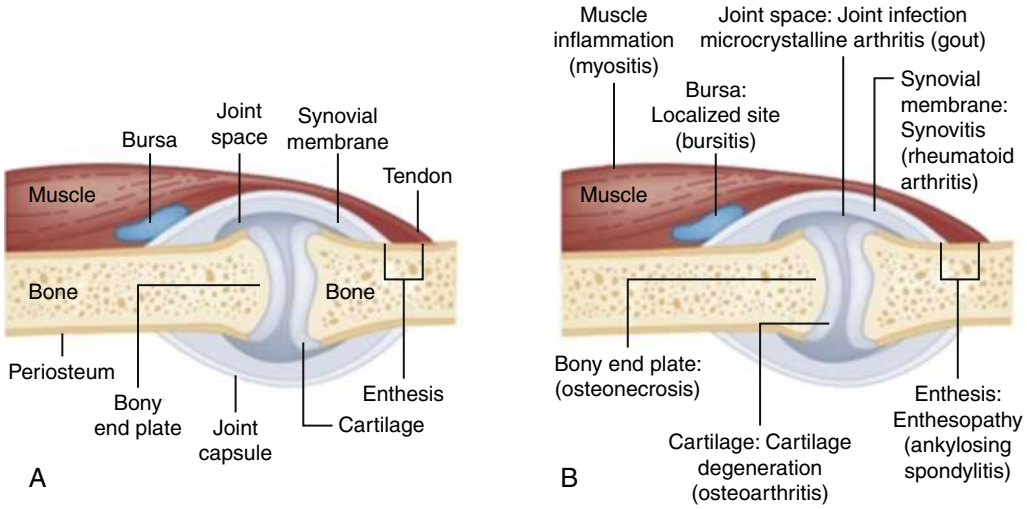

Fig. 102.1 Panel A: Example of a diarthrotic joint; Panel B: Sites of periarticular and articular disease and pain. (Redrawn from Goldman L, Ausiello DA, editors: *Cecil Medicine*, ed 23, Philadelphia, 2008, Saunders/Elsevier.)

BOX 102.1 Clinical Factors to Consider in the Evaluation of Joint Pain

Age
Single vs. multiple joint(s)
Time course:
- Acute (hours to <7 days)
- Subacute (7 days to 2–3 weeks)
- Chronic/progressive (>3 weeks to months)

History of acute or remote trauma to the joint
Associated systemic symptoms
Description and specific location of pain
Aggravating and alleviating factors

with certain comorbidities such as diabetes or obesity. OA will often present with pain in and around the joint, which worsens with activity. This pain is often accompanied by swelling, warmth, and discomfort to palpation diffusely around the joint. The most commonly affected joint in patients presenting to the ED will be the knee, but the shoulder, fingers, low back, or other joints may also be affected. In general, true arthritis pain will be more poorly localized in and around the joint. When the patient's pain is well localized and easily reproduced by palpation, common mimics such as bursitis or tendinitis should be considered.

Inflammatory or rheumatologic joint pain classically presents with symmetric and bilateral distribution with a predilection for the small joints of the hands. Inflammatory arthritides are more common in females and are usually diagnosed at an earlier age than degenerative arthritis. In general, the pain associated with inflammatory arthritis is worse in the morning and is associated with significant joint stiffness which improves with activity throughout the day. It is important to query the patient regarding the presence of systemic symptoms, because inflammatory conditions are often associated with symptoms distant from the affected joint. Many of the most common systemic symptoms are listed in Table 102.2. In addition, a careful medication history is important because many drugs can cause joint pain that mimics inflammatory arthritis. Certain viral conditions can also mimic inflammatory arthropathies and are discussed separately.

Acute monoarticular arthritis should always raise concern for the possibility of infectious arthritis, often referred to as septic arthritis, which is the most important condition to consider in the patient who presents to the ED with acute joint pain. There is significant morbidity and mortality associated with any delay in diagnosis of a septic joint. Therefore it is important to ask the patient about rapid progression of symptoms, associated skin changes, presence of fever, and any recent procedures or breaks in the skin that may have led to infection in the joint. Unfortunately, there are no adequately sensitive or specific findings either on history or physical examination that can safely rule out the possibility of a septic joint without a joint aspiration and analysis of joint fluid.

Physical Examination

General examination. The initial examination should focus on the affected joint or joints and should also assess for systemic or distant findings which may provide clues to the underlying problem. Vital signs, specifically presence of fever or tachycardia, should be noted because they may indicate infection, although most patients with confirmed septic arthritis will be afebrile on presentation.[2] The examination should begin with evaluation of general appearance, patient's position of comfort, and an assessment of ambulatory gait. A focused physical examination follows, directed by the patient's history and complaints.

Joint examination. The examination of the painful joint is performed in a systematic manner following the general principle of inspection, palpation, range of motion (ROM), neurovascular evaluation, special tests, and imaging when appropriate. Although the general examination is the same for all joints, each joint has different aspects to its exam and will be discussed independently. See Table 102.3.

Inspection. Begin the examination by watching the patient move in the exam room. Gait can provide important clues to discomfort and disability because pain, swelling, or weakness can all affect ambulation. The extent to which an affected joint is used and positions of comfort can also provide valuable information. Paired joints are compared, assessing each for deformity, skin integrity, erythema, swelling, ecchymosis, effusion, previous surgical scars, or rashes. Findings can suggest inflammation, infection, trauma, or prior surgery.

Palpation. When palpating, begin with an assessment of joint warmth. Large joints, such as the knee, should feel cool to the touch

TABLE 102.1 Differential Diagnosis of Arthritis

Monoarticular	Polyarticular: Symmetric	Polyarticular: Asymmetric
Septic arthritis	Rheumatoid arthritis	Gonococcal arthritis
Gout	Psoriatic arthritis	Lyme arthritis
Pseudogout	Polymyalgia rheumatica	Acute rheumatic fever
Osteoarthritis	Enteric arthritis	Reactive arthritis
Trauma, hemarthrosis	Ankylosing spondylitis	Viral arthritides

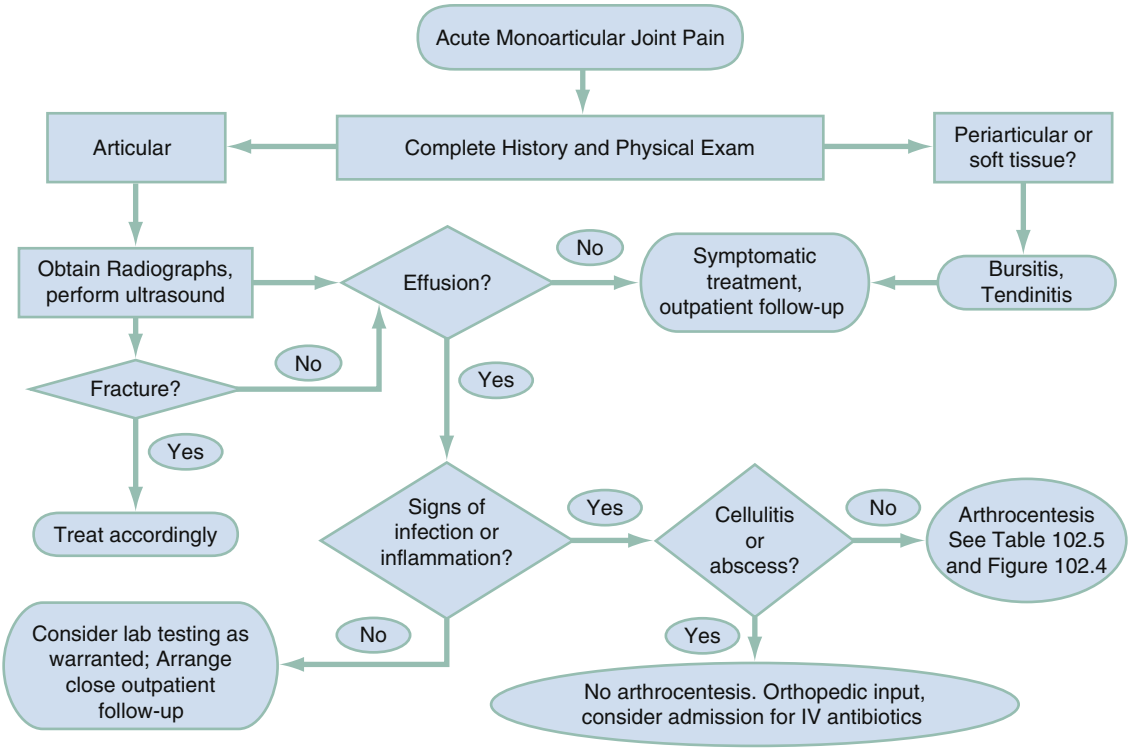

Fig. 102.2 Algorithm for Acute Monoarticular Joint Pain.

TABLE 102.2 Associated Systemic Findings for Common Arthritides

Condition	Findings
Rheumatoid arthritis	C-spine instability, pericarditis, pulmonary nodules, anemia
Psoriatic arthritis	Cutaneous plaques (most commonly on elbows, knees), inflammatory bowel disease
Ankylosing spondylitis	Uveitis/Iritis, cardiac abnormalities, aortic regurgitation, inflammatory bowel disease
Reactive arthritis	Conjunctivitis, genital/urethral discharge, oral ulcerations
Lyme disease	Erythema chronicum migrans, cardiac conduction abnormalities, Bell palsy
Gout	Tophi (usually nontender collections of uric acid crystals found most commonly in the subcutaneous tissue near affected joints)
Acute rheumatic fever	Erythema marginatum, chorea, carditis, subcutaneous nodules

or similar in temperature to the tissue proximal and distal to the joint. If a joint is found to be warm to the touch, this finding is suggestive of an inflammatory process or joint effusion. When a joint is hot to the touch, an infectious etiology should be considered.

Systematic palpation of the joint space and surrounding structures is performed with particular attention to areas of significant focal tenderness. Evaluate bony landmarks, ligamentous attachments, tendinous insertions, and nearby bursae. Identifying pain as articular (from the joint itself) or periarticular (due to proximate extra-articular structures) is important in determining diagnosis and management.

Range of motion. Both active and passive ROM should be assessed and compared with the unaffected extremity whenever possible. Active ROM refers to the patient moving the affected joint through its ROM, whereas passive ROM is performed by the physician without effort by the patient. Joints should be evaluated through their full ROM, which may be in multiple planes depending on the affected area. Pain with only active ROM or pain that is much worse with active ROM suggests a periarticular cause such as tendinopathy or bursitis, whereas pain with both active and passive ROM is more indicative of a true articular cause. Restricted or limited active and passive ROM due to severe pain suggests an inflammatory or infectious etiology.

TABLE 102.3 Components of a Comprehensive Joint Examination

Joint	Inspection	Palpation	Range of Motion (with normal ROM)	Neurovascular	Special Tests
Shoulder	Deformity Swelling Erythema Ecchymosis Muscle washing	Bony: SC joint, AC joint, scapular spine, grater tuberosity of humerus Soft tissue: subacromial space/bursa, biceps tendon	Forward flexion: 180° Extension: 35–45° Abduction: 180° IR and ER: 90° (both with arm adducted at side with elbow flexed and with arm adducted to 90°)	Neuro: Axillary nerve (deltoid sensation), radial, median, and ulnar nerves distally Vascular: radial and ulnar arteries at wrist	Numerous eponymic tests of variable clinical significance. No tests specifically for arthritis. Neer, Hawkins, O'Brien all evaluate RTC or labral pathology
Elbow	Deformity Specific location of pain (e.g., olecranon vs. radial head) Erythema Bruising Tophi (uric acid depositions)	Bony: olecranon, radial head, medial and lateral epicondyles of humerus Soft tissue: triceps tendon, distal biceps tendon	Supination and pronation Flexion: 150° Extension: 0°[a]	Neuro: Median, radial, ulnar nerves distally in forearm, wrist, and hand Vascular: radial and ulnar arteries at wrist	Valgus and varus stress at extension and slight flexion Resisted supination and resisted pronation
Wrist/Hand	Deformity Erythema Ulnar deviation Symmetric vs. asymmetric findings	Distal radius, scaphoid, anatomic snuffbox, ulnar styloid, CMC joint, TFCC, carpal tunnel, metacarpals	Wrist: Extension: 70° Flexion 80° Radial/ulnar deviation: 20° Supination 75°–90° Pronation: 90° Fingers/Thumb: Flexion, extension, abduction, adduction	Neuro: Radial, ulnar, median nerves, grip strength Vascular: radial and ulnar arteries at wrist, capillary refill in digits	Tinnel at carpal tunnel Finkelstein/Eichoff for De Quervain tenosynovitis
Hip	Observe gait Leg positioning at rest Shortening compared to contralateral leg	Bony: Greater trochanter, ischial tuberosity, pubic symphysis, iliac spine Soft tissue: proximal hamstring tendon, proximal quadriceps, inferior abdominal walls	Flexion: 90°–110° (Hyper)extension: 30° Abduction: 40° Adduction: 20° External rotation: 50° Internal rotation: 40° (performed with patient supine and hip flexed to 90° or by passive "log roll" with leg extended)[b]	Neuro: Evaluate strength and sensation in the foot to identify subtle muscle weakness or sensation deficits, patellar and Achilles ankle reflex Vascular: Dorsalis pedis in foot, posterior tibialis in ankle	FABER: Flexion, ABduction, External Rotation FADIR: Flexion, ADduction, Internal Rotation Log roll with internal and external rotation
Knee	Observe gait Swelling Erythema Fullness Calf or lower leg swelling	Bony: Patella, fibular head, distal femur, posterior patellar faces Soft tissue: peripatellar area, quad tendon, popliteal fossa, joint space, hamstring tendons, MCL, LCL Palpate for fluid in suprapatellar pouch	Flexion to 135° Extension to 0°	Neuro: Leg extension and flexion strength, patellar reflex Test strength more distally to find subtle weakness Vascular: Dorsalis pedis in foot, posterior tibialis in ankle	Lachman/anterior drawer Varus/valgus stress McMurray
Ankle/Foot	Swelling Erythema Bruising Arches	Bony: 5th metatarsal base, 1st MTP, medial and lateral malleoli, calcaneus, Lisfranc joint Soft tissue: Tibialis anterior tendon, Achilles insertion and tendon	Dorsiflexion: 20° Plantar flexion: 40° Inversion: 30° Eversion: 20° Toe flexion, extension	Neuro: Inversion (L4) Eversion (S1) Great toe extension strength (L5) Vascular: Dorsalis pedis in foot, posterior tibialis in ankle, capillary refill in toes	Anterior drawer Talar tilt Thompson test (Achilles)

Neurovascular evaluation. Strength and sensation should be assessed in the affected joint, as well as the joints directly above and below the painful area. Strength is best assessed by testing small muscle groups whenever possible, because this allows the clinician to find subtle strength differences which may be missed when evaluating only large muscle groups (e.g., evaluate L4 with ankle inversion or L5 using great toe extension rather than testing leg extension). Distal pulses should be palpated and compared with the unaffected side. In the setting of severe peripheral vascular disease or difficult to palpate pulses, doppler or ultrasound may be useful in assessing peripheral arterial flow.

Diagnostic Testing

Radiographic Tests

Plain radiographs. Plain radiographs or X-rays (XR) are useful in determining possible etiologies of acute arthritis. Although they are more helpful in patients who have long-standing disease and therefore more obvious radiographic findings, even in the acute setting, radiographs may guide therapy by demonstrating soft tissue swelling, foreign bodies, or fractures. Whenever possible, weight-bearing images (Fig. 102.3) should be considered for lower extremity joints because they may provide information such as presence of joint space narrowing or significant degenerative changes (Table 102.4). XR has limited utility in the evaluation for joint effusion.

Fig. 102.3 Knee X-ray shows osteoarthritis with narrowing of the medial compartment bilaterally *(arrows)* on this weight-bearing radiograph.

Ultrasound. Bedside ultrasound may be used to complement the physical examination in cases of acute joint pain. The simple evaluation for joint effusion is safe, noninvasive, and easily learned by even novice ultrasound users. Evaluation of, and comparison with, the unaffected side allows direct, real-time visualization of the joint and surrounding areas, providing more expeditious diagnosis and disposition. Determining whether an effusion is present, as compared with a soft tissue abnormality such as an abscess or cellulitis without effusion, will inform the treatment course. Ultrasound may also be used to visualize the largest pocket of fluid in an effusion to help plan for and perform an arthrocentesis. Likewise, the use of bedside ultrasound has also been shown to decrease the incidence of nondiagnostic or "dry" joint taps. In rheumatologic illness, ultrasound has proved useful in determining active disease as well as the need for additional treatment modalities.

Computed Tomography and Magnetic Resonance Imaging. Advanced imaging modalities may add to the evaluation by showing the presence or absence of osteomyelitis, joint effusions, abscesses or other fluid collections, occult fractures, foreign bodies, and ligament or tendon injuries. Magnetic resonance imaging (MRI) is expensive, time-consuming, and generally not used in the ED for nonemergent indications. MRI should be considered when indicated to evaluate for specific conditions. For example, if the clinical suspicion for osteomyelitis is high, MRI is the diagnostic modality of choice. Computed tomography (CT) imaging can be useful if there are suspected fractures that were not visualized on XR, although the use of ionizing radiation should be minimized when feasible. In general, neither MRI nor CT should be used to guide the decision regarding performance of an arthrocentesis in the ED because the decision should be based on clinical findings and concern for infection. CT and MRI may show an effusion but will not be able to specify whether the effusion is infected or not.

Laboratory Testing

Aside from arthrocentesis and joint fluid analysis, specific laboratory tests lack adequate sensitivity or specificity to reliably exclude a septic joint. A serum white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), or C-reactive protein (CRP) may be helpful, although it cannot be used to rule out an infectious cause and thus should not be used in isolation to guide ED decision making. An ESR level greater than 30 mm/h or CRP level of greater than 1.5 mg/mL has a sensitivity of greater than 90%, although it is poorly specific for septic arthritis, with specificities of approximately 20%.[2] Serum uric acid, although commonly ordered and elevated in patients with gouty arthropathies, provides little additional value in helping with diagnosis and patient

TABLE 102.4 Common Radiographic Findings in Arthritis

Arthritis	Findings
Acute arthritis (gout, pseudogout, septic)	Soft-tissue swelling
Late septic arthritis (>7–8 days)	Subchondral bone destructions, periosteal reaction, loss of joint space
Late pseudogout (knee, hip, radiocarpal, MCP)	Linear calcification in joint, asymmetric joint space narrowing
Degenerative arthritis (AC, CMC, MTP, DIP, knee, hip, c-spine, lumbosacral spine)	Asymmetric joint space narrowing (more pronounced on weight-bearing views), sclerosis of juxta-articular bone, bone spurs and cysts, minimal to no osteoporosis
Late rheumatoid arthritis (wrist MCP, PIP, MTP, 1st IP foot, atlantoaxial, glenohumeral)	Symmetric joint space narrowing, osteoporosis of periarticular bone marginal erosions

AC, Acromioclavicular; *CMC,* carpometacarpal; *DIP,* distal interphalangeal; *IP,* interphalangeal; *MCP,* metacarpophalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal.

TABLE 102.5 Arthrocentesis Techniques by Joint

Joint	Patient Positioning	Landmarks	Needle trajectory	Ultrasound
Shoulder	Seated with arm flexed resting on thigh with hand supinated Or Lateral decubitus with affected arm internally rotated	Palpate posterolateral edge of acromion Coracoid process	Insert inferior to posterior acromial edge guided toward coracoid process	Performed in-plane: Probe on posterior aspect of acromion (parallel to floor if seated), needle from lateral to medial into joint
Elbow	Arm flexed and pronated Use supination and pronation to find radial head	Palpate lateral epicondyle of humerus and then anterior to it, palpate radial head. "Soft spot" between the two is joint space	Insert into soft spot just anterior to lateral epicondyle	Place probe on tip of lateral epicondyle and find radial head. Probe will be parallel to arm. Guide needled out of plane into joint space
Wrist	Wrist pronated resting on a towel in slight flexion	Lister's tubercle on dorsal radius and extensor pollicis longus tendon located radial to tubercle	Insert needled just ulnar to tendon and just distal to Lister's tubercle	Out of plane approach: Probe long to radius visualizing both radius and scaphoid. Joint space is between.
Hip	Supine in stretcher with leg neutral or slight external rotation if using US Internal rotation if performing without US	Greater trochanter (if not using US)	Insert needle superior to trochanter, horizontal and parallel to the stretcher. Aspirate throughout. Redirect slightly cephalad if bone encountered[a]	Low frequency curvilinear probe used for in-plane approach Find femoral head and neck, guide needled from distal to proximal (side to side on screen) to touch bone at femoral head-neck junction[b,c]
Knee	Supine with knee flexed ~20°	Lateral edge of superior half of patella	Lateral to medial guided to area just posterior to patella	Probe positioned transverse just superior to patella with quad tendon in short axis. Fluid will be inferior to tendon, superior to femur. Guide needle in plane from lateral to medial
Ankle	Supine with plantarflexed foot	Tibialis anterior tendon and anterior edge of medial malleolus	Insert between tibialis anterior and medial malleolus aiming directly posterior	Slight out of plane approach lateral to medial BELOW tibialis anterior tendon into joint space. Tibialis anterior tendon will be in long axis at top of screen
MTP	Supine or sitting with neutral foot, slight flexion of the affected toe	Distal metatarsal head, extensor tendon, and base of first phalanx	Insert dorsally medial to the extensor tendon	Out of plane. Probe is parallel to toe (short to joint), needle will be inserted from medial aspect of foot/toe into joint

[a]Not recommended.

[c]Find and mark arteries to avoid in needle path.

disposition from the ED. Many patients with known gout and gouty arthritis have normal uric acid levels and many patients with elevated uric acid levels do not have gout. We therefore do not recommend the routine use of serum uric acid levels in the evaluation of acute arthritis in the ED setting.

Arthrocentesis and Synovial Fluid Analysis

Arthrocentesis. Joint fluid aspiration with synovial fluid analysis is the most important modality used to diagnose the cause of an acutely painful joint. Whenever possible, the procedure should be done with the aid of ultrasound which has demonstrated greater success rates in both aspiration and therapeutic injection when compared with palpation-guided techniques.[3] Arthrocentesis methods for various joints are discussed in Table 102.5.

Indications and contraindications. Indications for urgent arthrocentesis include (1) to obtain joint fluid for analysis for possible infection or crystals, (2) to drain a large hemarthrosis secondary to trauma or injury, (3) to inject medication into the joint, and, less frequently, (4) to evaluate a laceration for possible extension into the joint. Arthrocentesis should be considered for any patient with a newly swollen and painful joint in the absence of trauma.

Contraindications to the procedure are relative and should be discussed with the patient. It is generally accepted practice that arthrocentesis should not be performed if the needle must be inserted through an area of cellulitis or infected skin overlying a joint. Coagulopathy is a relative contraindication, although these procedures have been performed successfully with a less than 0.5% complication rate even in patients with therapeutic international normalized ratio (INR) levels. We recommend performing arthrocentesis in patients with suspected septic arthritis even if currently on therapeutic anticoagulation. A prosthetic joint should only be aspirated after discussion with the operating surgeon, and, in general, patients with prosthetic joints should have neither joint aspiration nor intra-articular injections until the case is discussed with an orthopedist. However, if orthopedic consultant is not available and suspicion for a septic joint remains high, arthrocentesis can be performed by the ED clinician.[4]

Complications. Patients should be counseled about the potential risks of the procedure, the most serious of which include inoculation of infection or bleeding, either into the joint or externally. Less serious complications include pain, allergic reaction to medication, or adverse outcomes when instilling corticosteroids or local anesthetics into the joint space. It is possible that the

aspiration attempt may be unsuccessful, although if ultrasound is used, the fluid can generally be visualized to maximize the chance for success.

Synovial fluid examination. Analysis of the joint fluid obtained via arthrocentesis is a critical step in determining the cause of acute arthritis. Examination should be based on the general appearance of the fluid, color, fluid WBC count, crystal analysis, Gram stain, and ultimately on bacterial fluid culture (Fig. 102.4 and Table 102.6).

General appearance. Visual inspection of the fluid upon aspiration can aid in diagnosis, although no findings are diagnostic without microscopic fluid analysis. Normal fluid is mostly clear and colorless but develops increased viscosity and a more intense yellow color with increased inflammation. Turbid, opaque, or grossly purulent fluid is more suggestive of acute infectious process. A hemarthrosis suggests internal derangement of the joint, including occult fracture or ligamentous injury. A lipohemarthrosis, identified by fat droplets in the aspirate, suggests a fracture, classically seen in a knee arthrocentesis with an occult tibial plateau fracture.

White blood cell count. The synovial WBC count is helpful in distinguishing different causes of arthritis. Although the number of WBCs is generally used to determine the cause of the effusion, there is significant overlap in accepted values among causes of arthritis and

the absolute numbers can be misleading. Classically, septic arthritis presents with greater than 50,000/mm^3 WBC in the synovial fluid, but it has been repeatedly shown that early, or partially treated, septic arthritis may present with significantly lower absolute numbers of WBCs. Nonetheless, the likelihood for septic arthritis increases along with the absolute number of WBCs. The relative number of neutrophils (polymorphonuclear [PMN] cells) is also used to diagnose septic arthritis with levels greater than 90% generally accepted to be associated with infection. No absolute number should be used to diagnose or exclude the presence of a septic joint when the clinical suspicion is high.

In inflammatory arthritis, WBC counts tend to be lower than in septic arthritis, in the range of 25K to 50K/mm^3. However, there may be significant overlap between inflammatory and septic arthritis, and there are instances where patients with RA or gout may have synovial fluid WBC counts well above 50,000/mm^3. We recommend that any synovial sample with a WBC count greater than 50,000/mm^3 be treated as presumptive septic arthritis until further information confirms another etiology.[5]

Prosthetic joints have significantly lower thresholds for diagnosis, and a WBC count greater than 1100/mm^3 should be considered diagnostic of infection.

Lactate and C-reactive protein. Much like synovial WBC count and pleocytosis, increasing lactate and CRP levels in the synovial fluid correlate with an increased likelihood of infection. However, these tests have not been shown to be significantly better than the synovial WBC count or PMN pleocytosis for predicting infection.[6] Due to the associated cost and unlikely additional benefit, we do not recommend the routine use of these tests in the evaluation of possible septic arthritis in the ED.

Crystal evaluation. Analysis under light microscopy to evaluate for monosodium urate or calcium pyrophosphate is used to diagnose gout or pseudogout, respectively. Monosodium urate crystals seen in gout are needle-shaped and negatively birefringent, whereas calcium pyrophosphate crystals seen in pseudogout are rhomboid-shaped and positively birefringent. Importantly, the presence of crystals does not rule out the possibility of infection and in fact, gout is a risk factor for septic arthritis due to chronic joint damage predisposing to hematogenous spread of bacteria into the joint.

Gram stain and culture. A positive Gram stain is diagnostic of septic arthritis though is only found in 30% to 50% of confirmed infections. A negative Gram stain does not exclude the possibility of a septic joint and thus should not be used in isolation to exclude infection. Gonococcal (GC) infections in particular are difficult to identify in synovial fluid and their diagnosis may depend on cultures of genital discharge or oral lesions taken at the same time. Whenever GC septic arthritis is suspected, we recommend obtaining samples from mucosal or skin lesions, as well as urine for nucleic acid amplification testing (NAAT) or Gram stain and culture.

A positive synovial fluid culture is the gold standard for the diagnosis of septic arthritis, but the results are not immediately available in the ED setting. For patients who are discharged, a mechanism should be in place for the follow-up of culture results with the patient. Blood cultures are recommended if septic arthritis is strongly suspected, because they may be positive in up to 50% of septic arthritis cases and may aid in identifying the causative organism if synovial cultures are negative.

Management

The mainstays of treatment of acute arthritis are antiinflammatory medications and, in the case of septic arthritis, antibiotics. The management of specific causes of acute arthritis are discussed in subsequent sections of the chapter.

Disposition

The ultimate disposition of the ED patient with acute arthropathy will depend on clinical findings. Although most patients with acute exacerbations of chronic conditions can be managed with oral medications in the outpatient setting, the challenge for the emergency clinician remains in identifying patients who are at risk for rapid deterioration, progressive disease, or permanent joint disability. When septic arthritis is suspected, hospital admission, parenteral antibiotic therapy, and orthopedic input remain prudent. Patients with known or suspected rheumatologic conditions can typically be followed on an outpatient basis. Patients with other noninfectious causes of joint pain can often be treated with analgesics or antiinflammatory medications until seen in follow-up by a primary care physician.

ACUTE MONOARTICULAR JOINT PAIN

Acute joint pain, when confined to a single joint and particularly if associated with erythema, warmth, or systemic infectious symptoms, should prompt urgent evaluation for a septic joint. However, acute trauma and inflammatory conditions of the periarticular tissues can also cause monoarticular joint pain. Therefore conditions such as bursitis, tendonitis, synovitis, and sprains or other trauma should also be considered.

Nongonococcal Bacterial Septic Arthritis

Foundations

The incidence of septic arthritis is approximately 6 per 100,000 population per year in industrialized countries. This number increases to 30 to 60 per 100,000 population per year in patients with underlying disease or prosthetic joints. Young children and elders are at greater risk, as are patients with immune compromise, diabetes, and history of hemodialysis or IV drug use. Patients with prosthetic joints or those who have had recent intra-articular steroid injections are at particular risk. The presence of chronic joint inflammation such as RA or gout is also a significant risk factor for joint infection, particularly as many of these patients are on chronic immunosuppression. Exacerbations of crystal arthropathies can coexist with infectious arthritis, and the presence of crystals should not be used to eliminate the possibility of septic arthritis. Box 102.2 lists factors that increase the risk of septic arthritis.

The most common method of joint space inoculation is by hematogenous spread although direct inoculation from local injury or infection in surrounding tissues may also occur. Once the joint space is inoculated, there is little defense against rapid bacterial proliferation. This unchecked bacterial growth and the associated inflammatory cascade typically leads to severe pain, synovial proliferation, neovascularization, and extensive

BOX 102.2 Factors Increasing Risk of Septic Arthritis

Age >80
Diabetes
Rheumatoid arthritis
Gout/pseudogout
Recent joint surgery
Hip or knee prosthesis
Skin infection
Prosthesis PLUS skin infection

Endocarditis
Human immunodeficiency virus (HIV) disease

TABLE 102.7 Common Pathogens in Septic Arthritis

Group	Organisms
Neonates and infants	*Staphylococcus aureus,* group B *Streptococcus*
Children	*S. aureus,* group A *Streptococcus, Streptococcus pneumonia, Kingella Kingae,* Lyme
Adolescents and young adults	*Neisseria gonorrhea, S. aureus*
Older adults	*S. aureus, Streptococcus,* gram-negative rods
Sickle cell anemia	*S. pneumonia, Salmonella* (although more commonly causes osteomyelitis)
Intravenous drug use	Pseudomonas, *S. aureus,* gram-negative rods
Prosthetic joint	Coagulase-negative *Staphylococcus, S. aureus,* gram-negative rods, *Streptococcus* species

damage of the articular cartilage if not quickly identified and appropriately treated.

The most common bacterial causes of non-GC septic arthritis include gram-positive organisms such as methicillin-resistant or methicillin-sensitive *Staphylococcus aureus* and *Streptococcus* species, which are found in almost 80% of culture-confirmed infections. Anaerobes and mycobacteria are less common causes. Likewise, *Haemophilus* and pneumococcal species are less common in the postvaccine era. *Neisseria gonorrhoeae* accounts for less than 20% of monoarticular arthritis and more frequently presents as polyarticular arthritis. Certain patient populations are more likely to develop specific infections as discussed in Table 102.7.

Prosthetic joint infections deserve specific mention, with these infections classically being described as either early, defined as occurring within a month of surgery, or late. Late infections develop via hematogenous spread or by organisms introduced into the joint space during surgery, which may not become clinically evident for up to a year later. Arthrocentesis should be performed in discussion with, or optimally by, an orthopedic surgeon when feasible. In the prosthetic joint, a synovial WBC count of more than 1,100/mm^3 or PMNs greater than 60% are both sensitive and specific for joint infection. In the setting of a prosthetic joint, the host immune response and antibiotic delivery to the joint space are both impaired, and thus the management of infection can be complex.

Clinical Features and Differential Diagnosis

Patients with septic arthritis will often present with fever, joint pain, and effusion, most often in a large joint such as the knee. Fever response may be blunted in elders or those who have a suppressed immune system. At particular risk are patients with autoimmune arthritis, overwhelming sepsis, or meningococcal infections. Up to 20% of patients with septic arthritis may present with polyarticular involvement. Physical examination findings, such as decreased ROM, joint tenderness, or erythema, have inadequate sensitivity and specificity for determination of septic arthritis.

Diagnostic testing. Laboratory testing, including a serum WBC, ESR, and CRP, is commonly performed although often is of limited utility. Elevated values only slightly increase the likelihood of septic arthritis, and normal values do not exclude the condition. Likewise, radiographs are of limited utility in diagnosing a septic joint but may occasionally identify alternative diagnoses. Although plain radiographs may help to identify osteomyelitis, the bony changes associated with septic arthritis are a late finding. CT or MRI may be useful in identifying early changes associated with septic arthritis or may help to assess joints that are difficult to evaluate clinically, including joints that are challenging to aspirate.

TABLE 102.8 Empiric Antibiotics for Suspected Septic Arthritics Intravenous

Gram Stain Results	Antibiotic Regimen (IV Dosing)
Unavailable or negative Gram stain	Vancomycin loading dose: 20 to 35 mg/kg actual body weight (not to exceed 3000 mg) or 20 to 25 mg/kg actual body weight (not to exceed 3000 mg) in patients with obesity, then 15 to 20 mg/kg actual body weight every 8 to 12 hrs IV WITH IV cephalosporin (ceftriaxone 2 g, cefepime 2 g, ceftazidime 2 g) OR aztreonam 2 g IV OR daptomycin 6 mg/kg IV WITH IV cephalosporin OR linezolid 600 mg IV WITH IV cephalosporin
Gram-positive cocci	Vancomycin loading dose: 20 to 35 mg/kg actual body weight (not to exceed 3000 mg) or 20 to 25 mg/kg actual body weight (not to exceed 3000 mg) in patients with obesity, then 15 to 20 mg/kg actual body weight every 8 to 12 hrs IV OR daptomycin 6 mg/kg IV OR linezolid 600 mg IV
Gram-negative bacilli	Ceftriaxone 2 g IV OR aztreonam 2 g IV
Gram-negative diplococci	Ceftriaxone 2 g IV, can consider adding azithromycin 1000 mg orally (PO) for chlamydia coverage

The gold standard test for the patient with acute monoarticular arthritis remains joint aspiration and synovial fluid analysis. Elevated synovial fluid WBC count, increased proportion of PMNs, and elevated synovial fluid lactate all increase the likelihood of septic arthritis. A fluid Gram stain and aerobic and anaerobic cultures should be performed. Synovial fluid should also be evaluated for characteristic crystals of gout or pseudogout.

Management

Early identification and treatment of septic arthritis is crucial. Delays in definitive care can lead to increased morbidity and mortality. Hospitalization for intravenous (IV) antimicrobial therapy is appropriate. Empiric antibiotic therapy should be directed at organisms found on Gram stain, or alternatively, broad-spectrum therapy is appropriate and can be tailored once speciation and sensitivity results are available. Table 102.8 details recommended antibiotic therapy for suspected septic arthritis.

Depending upon the specific joints involved, either surgical drainage or repeated joint aspirations are often required. Early coordination with an orthopedic surgeon is critical in the management of infection in prosthetic joints. Antibiotics are often continued for several weeks and infectious disease input may be helpful in selecting the most appropriate antibiotic regimen.

CHRONIC MONOARTICULAR ARTHRITIS

Osteoarthritis

Foundations

OA or degenerative joint disease is the most common form of arthritis among adults and is more common in obese patients and elders. Changes in load on the joint, due to excess weight or trauma, combined with biochemical and genetic factors, lead to changes in cytokine signaling and thus alterations in composition of the extracellular matrix. This ultimately leads to overgrowth of subchondral bone, degradation of the articular cartilage, and inflammation of the synovium.

Clinical Features

Although OA most commonly involves multiple joints, patients often present complaining of severe pain in a single joint. Pain associated with OA is often described as worse with activity and improved at rest. Patients may have a joint effusion but rarely have signs of severe inflammation, such as warmth and erythema. There is often associated crepitus in the affected joint with both active and passive ROM. Associated systemic symptoms are not characteristic, which helps to differentiate OA from rheumatoid or inflammatory arthritis.

Diagnostic Testing

Plain radiographs often reveal asymmetric joint space narrowing, osteophyte formation, or subchondral cyst formation. However, there is no direct correlation between radiographic findings and the degree of symptoms. The role for laboratory testing in the evaluation of OA is limited, although laboratory evaluation may help in differentiating OA from infectious arthritis if the latter diagnosis is suspected. Synovial fluid may be more difficult to aspirate in patients with OA and fluid analysis classically reveals a mildly inflammatory pattern with few PMNs.

Management

The goal of ED management of OA pain is symptom relief. Many pharmacologic and nonpharmacologic treatment modalities have been used. Among nonpharmacologic options, weight loss, exercise, and ice may be effective for some patients. Bracing, splints or orthoses, and appropriate footwear may also be beneficial. Nutritional supplements such as glucosamine and chondroitin have demonstrated limited benefit.[7] Pharmacologic treatments include topical medications, oral analgesics, nonsteroidal antiinflammatory drugs (NSAIDs), or corticosteroids. Fig. 102.5 details considerations regarding therapeutic modalities and medication coadministration.

Oral analgesics represent the mainstay of OA treatment. The use of acetaminophen is supported by multiple clinical trials and is recommended as first-line therapy for most patients with OA. Adverse effects associated with acetaminophen are less frequent and less severe than those associated with other oral medications.[8] More recent data suggest minimal impact on pain control with the use of oral acetaminophen as monotherapy in knee arthritis.[9,10]

NSAIDs should be considered when acetaminophen fails to provide adequate pain relief. They have been shown in several studies to be more effective than acetaminophen in terms of pain control, although the side effect profile of NSAIDs precludes long-term use in many patients, especially those with renal disease, cardiovascular risk factors, or history of gastrointestinal (GI) bleeding. The cyclooxygenase-2 (COX-2) inhibitors are associated with a lower risk of GI bleeding than other NSAIDs, but concerns about increased risk of cardiovascular events with long-term use remain. Fig. 102.5 details NSAID use and risk factors. Oral duloxetine, a centrally acting serotonin and norepinephrine reuptake inhibitor most frequently used in the treatment of mood disorders, has shown some

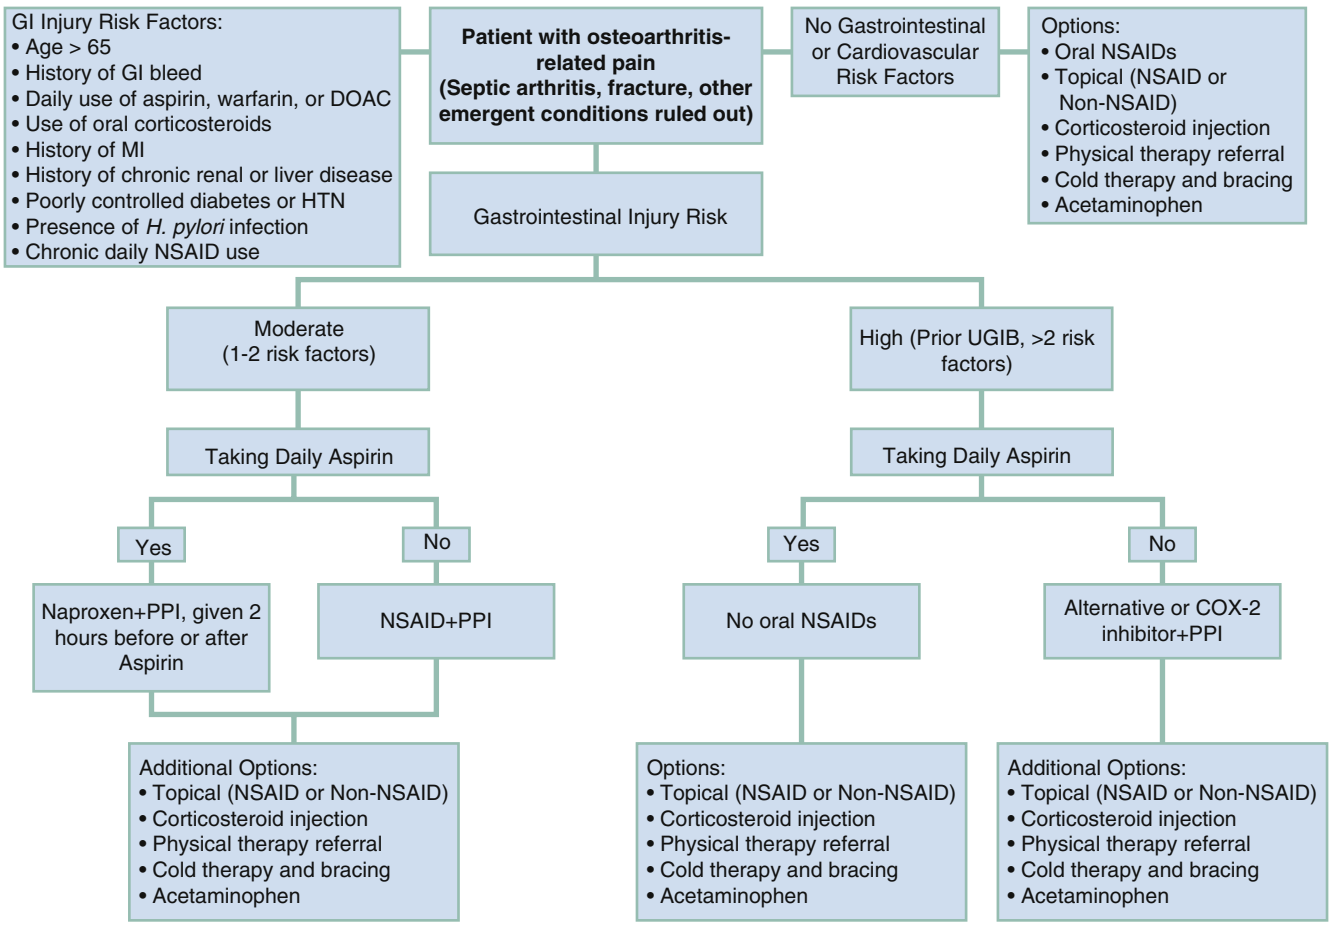

Fig. 102.5 Algorithm for weighing the risks associated with the use of nonsteroidal antiinflammatory drugs *(NSAIDs). COX-2*, Cyclooxygenase-2; *PPI*, proton pump inhibitor; *UGIB*, upper GI bleed. (From Young S, Bothwell J, Walsh R. Safely managing acute osteoarthritis in the emergency department: An evidence-based review. *Journal of Emergency Medicine* 51:6 648-657, 2016.)

efficacy in chronic musculoskeletal pain, including knee OA. It is not routinely used acutely in the ED setting and should generally be initiated in the outpatient setting, unless close follow-up has been arranged.[11]

Topical medications may be useful in treating patients with OA who are at risk of complications from oral NSAIDs. Several studies have shown that topical NSAIDs, such as diclofenac gel, have similar efficacy to oral NSAIDs, with lower risks of GI side effects. Topical capsaicin may help with OA pain either as a primary or adjunctive therapy, particularly in the small joints of the hands, with a low risk of systemic toxicity, although a moderate to high risk of local skin reaction limits its usefulness in many patients. Topical anesthetic (e.g., lidocaine) and topical salicylic acid preparations are also available, although there are no large studies confirming their long-term efficacy or safety. It is important to note that many topical and transdermal preparations may not penetrate deeply enough to be particularly effective for many patients with OA pain.

Corticosteroids can be considered for severe exacerbations of OA pain. Although systemic (oral or injectable) corticosteroids may be an option for some patients, most often, clinicians will consider intra-articular steroid injections. Intra-articular injections may provide acute pain relief and an improvement in symptoms for several weeks in some patients, although their effect can be unpredictable. Intra-articular steroids are unlikely to provide long-term benefit and may cause worsening of arthritis particularly with repeat injections. Intra-articular hyaluronic acid may provide improved function and decreased disability. It is best studied in the knee but may not provide long-term benefit and is generally unavailable in the ED setting. Intra-articular injections of amide anesthetics (e.g., lidocaine), either alone or in combination with corticosteroids, have been used for many years to provide pain relief in patients with acute discomfort. However, recent studies have suggested that intra-articular instillation of local anesthetics may be chondrotoxic.

There is little evidence to support the use of other oral analgesics. Tramadol has not been shown to have significant effect in patients with OA and is associated with significant risk of adverse outcomes with prolonged use.[12] Other opioid analgesics may be appropriate for short-term exacerbations of severe pain, particularly in patients with contraindications to other medications. However, risks of opioid use outweigh the benefit for long-term use in patients with OA.

ACUTE POLYARTICULAR JOINT PAIN

There are several conditions that may lead to polyarticular joint pain. These include gout, pseudogout, Lyme arthritis, GC arthritis, or various rheumatologic conditions. When classifying polyarticular arthritis, it is often helpful to consider whether the symptoms are acute or chronic, whether the involved joints are symmetric or asymmetric, and whether large or small joints are affected. It remains important to consider that a significant proportion of patients diagnosed with a septic joint may present with multijoint involvement; therefore considering septic arthritis in your differential is vital. GC arthritis in particular remains a key consideration in the setting of multijoint pain or effusions. Box 102.3 reviews the differential diagnosis of polyarticular arthritis. Viral causes of arthritis are reviewed in Table 102.9. An approach to polyarticular pain is outlined in Fig. 102.6.

Gonococcal Arthritis

Foundations

The US Centers for Disease Control and Prevention (CDC) estimates that there are approximately 820,000 new cases of gonorrhea in the United States each year,[13] and the World Health Organization (WHO) estimates 87 million cases annually worldwide.[14] Although GC arthritis represents only 1% of all septic arthritis cases, it remains the most

BOX 102.3 Differential Diagnosis of Polyarthritis

Polyarthritis:
Infectious: Lyme disease. Endocarditis. Gonococcal. Viral.
Rheumatic fever
Seronegative spondyloarthropathies:
Ankylosing spondylitis, psoriatic arthritis, reactive arthritis
Rheumatoid arthritis
Crystal arthropathies
Systemic rheumatologic illness

TABLE 102.9 Selected Viral Arthritides

Virus	Arthritis Presentation	Duration of Symptoms	Therapy
Hepatitis B	Symmetric, migratory joint symptoms	Subsides with onset of jaundice	Supportive
Hepatitis C	Symmetric rheumatoid arthritis-like mimic, or intermittent monoarticular arthritis	Variable, intermittent	Supportive; rheumatoid arthritis treatments are often helpful
Human immunodeficiency virus (HIV)	Often monoarticular arthritis involving feet and ankles, sometimes involving tendon, bursae, skin, or muscle inflammation	Variable	Generally treating underlying HIV is most important aspect of treatment. Otherwise, supportive treatment for joint symptoms
Parvovirus B19	Fifth disease in childhood, causes a connective tissue syndrome in adults	Self-limited but may recur	Supportive
Rubella virus, rubella vaccine virus	30% of females and 6% of males with rubella show symptoms of arthritis	Symptoms appear within 2 weeks of vaccination or a week of rubella infection; self-limited	Supportive
Alphaviruses (Ross River, Chikungunya, Mayaro)	Mosquito-borne, often seen in epidemics	May be abrupt or insidious onset; symptoms can last 3–6 months—some patients experience years of discomfort	Largely supportive; corticosteroids were once contraindicated but have more recently been demonstrated effective
Flaviviruses (Dengue, Zika, West Nile)	Mosquito-borne, often seen in epidemics	Usually acute joint and bone pain along with high fever	Supportive

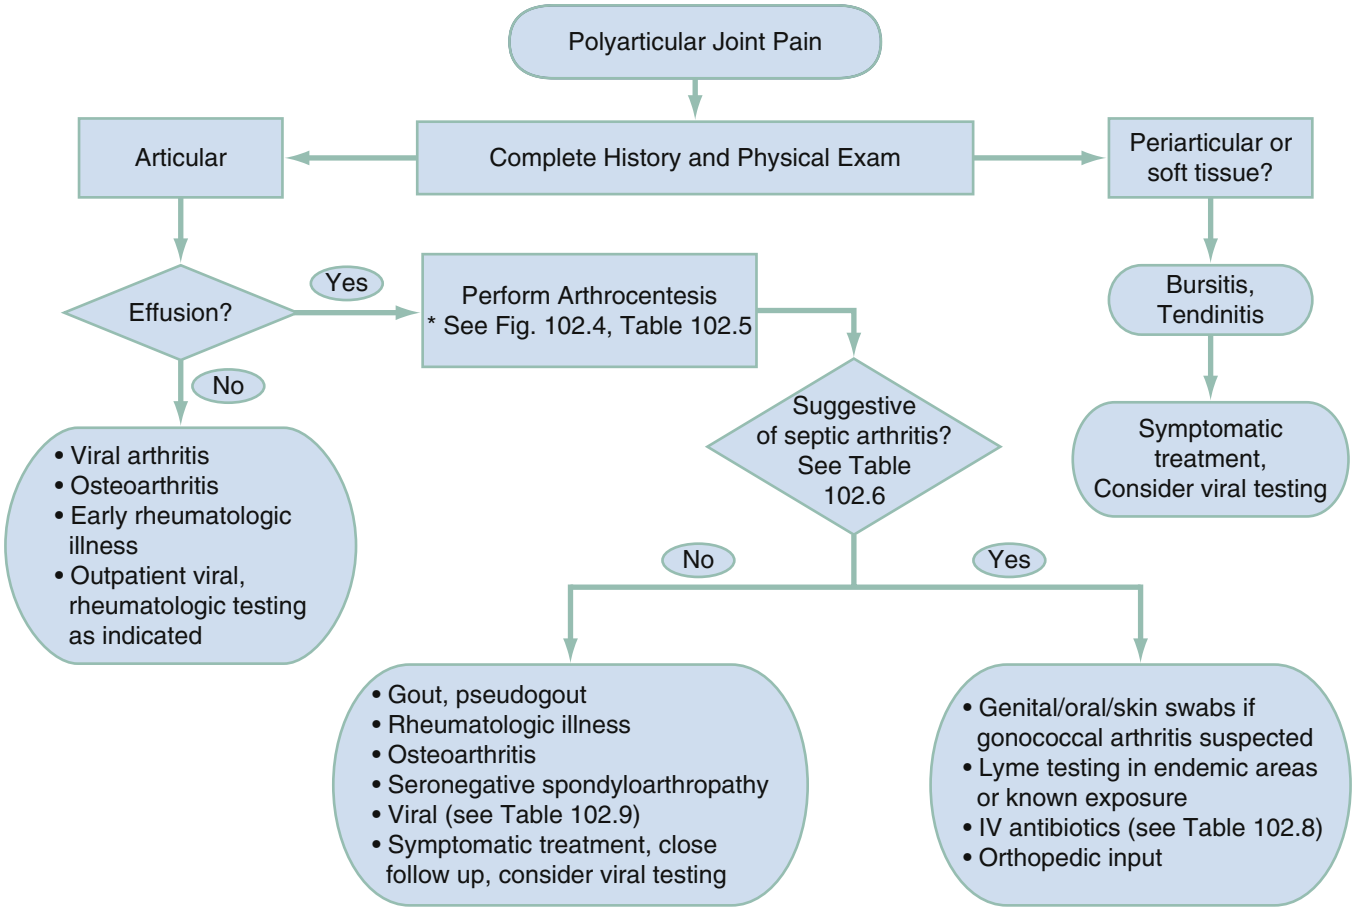

Fig. 102.6 Algorithm for Polyarticular Joint Pain.

common form of joint infection in the young, sexually active population. Hematogenous dissemination of the initial mucosal infection occurs in less than 3% of cases overall and is thought to play a major role in the pathogenesis of GC arthritis. The risk of dissemination is higher in immunocompromised patients, women (particularly during pregnancy), IV drug users, and patients with multiple sexual partners. The time from initial infection to presentation with arthritis symptoms may be 1 to 3 months.

Clinical Features

Although GC arthritis may present in a single joint, it often manifests as an oligoarthritis, affecting two to four joints simultaneously, often in the wrist, knee, or ankle. The effusions associated with this condition may be modest compared with other infections. Diffuse, migratory arthralgias and fever are also common. Simultaneous skin findings, also resulting from hematogenous spread, may also be present with small painless, nonpruritic lesions that may be papular, pustular, or vasculitic.

Management

The diagnosis of GC arthritis can be particularly challenging because cultures of blood and synovial fluid may be negative, although diagnostic yield is greatly improved when polymerase chain reaction (PCR) testing is performed. When GC infections are suspected, all possible sites should be tested, including blood, synovial fluid, oropharynx, genitalia, and any suspect skin lesions. When the diagnosis is made, hospitalization is advised, and treatment should be initiated with ceftriaxone 2 g IV or intramuscular (IM) every 24 hours. Antibiotic sensitivity results will assist the transition to appropriate oral antibiotics. Simultaneous treatment for chlamydia is advised with azithromycin 1 g PO, as is testing for other sexually transmitted infections. Repeated arthrocentesis is rarely required, and when diagnosed and treated promptly, residual joint damage is rare.

Gout

Foundations

Acute gout occurs in approximately 4% of adults in the United States, impacting approximately 5% of adult males and 3% of adult females. Gout is more prevalent among older adults.[15] Risk factors include obesity, hypertension, diabetes, and use of thiazide diuretics or cyclosporin. Acute gout attacks may be precipitated by a purine-rich diet including meats, beer, legumes, and seafood, especially shellfish or anchovies. Uric acid is a normal by-product of purine metabolism, and hyperuricemia results from its undersecretion by the kidney or, less commonly, from overproduction caused by inborn errors in metabolism. Acute attacks result from inflammation that occurs when uric acid crystals precipitate from supersaturated extracellular fluid. During an acute attack, these crystals are ingested by PMN cells, resulting in release of cytokines and an inflammatory reaction of the synovium. Asymptomatic hyperuricemia may exist for years, and the absolute serum uric acid level does not correlate well with the risk or frequency of acute attacks.

Clinical Features

Gouty attacks occur most commonly in the first metatarsophalangeal (MTP) joint, causing the condition termed podagra. The knee, ankle,

tarsal joints, and hand are also frequently affected. Usually patients experience an acute flair in a single joint, but up to 20% of patients have polyarticular involvement or associated bursitis, tenosynovitis, and skin changes that can resemble cellulitis (Fig. 102.7). Onset of pain is sudden, and the pain may be exquisite, both with movement and while at rest. Systemic symptoms, including fever, may be present and should raise concern for the possibility of septic arthritis. Acute episodes of gout are self-limited, usually with peak symptoms within 1 to 2 days and resolution within a week. If left untreated, attacks may become more frequent, involve more joints, and may have lasting sequelae including bony erosion and tophi, which are gritty, chalk-like nodules composed of deposits of monosodium urate crystals which are generally painless. These are most commonly found in the subcutaneous tissue, although they may also be found in bursae, joint space, or soft tissues.

Diagnostic Testing

Diagnostic evaluation for gout includes arthrocentesis and evaluation of joint fluid particularly in patients who are having their first episode of gout. Patients who have an established history of gout and are otherwise well appearing without other risk factors for septic arthritis may be treated without a joint aspiration. The acute gouty joint will have synovial fluid crystals visible that appear negatively birefringent when viewed with a polarizing microscope. Serum laboratory tests are largely unhelpful because gouty attacks can occur in patients with normal uric acid levels, and some patients may have elevated uric acid levels without signs or symptoms of clinical disease. Serum WBC count may be elevated, but this is also a nonspecific finding. It is reasonable to evaluate renal function because there is an association between gout and renal insufficiency and many of the treatments for gout are nephrotoxic.

Fig. 102.7 Patient with confirmed gout in the second metacarpophalangeal joint mimicking hand cellulitis.

Plain radiographs of the acutely affected joint may show only the associated soft-tissue swelling. However, patients with long-standing disease may show signs of asymmetric, sclerotic-appearing bony erosions outside the joint capsule. Ultrasound may be useful in the evaluation of the acute gouty joint: The crystalline material reflects sound waves, revealing an irregular, hyperechoic signal along the surface of the articular cartilage, sometimes referred to as the "double contour sign"—one representing the crystals and the second the hyperechoic bony surface below. Chronic tophi may also be visible on ultrasound and are described as having the appearance of "wet clumps of sugar" with a heterogenous center and hypoechoic rim (Fig. 102.8).

Management

The management of gout is divided into therapies to treat acute attacks and those aimed at long-term treatment and prophylaxis against future attacks. Patients often present to the ED for symptoms related to an acute exacerbation. Contrary to previous guidelines, long-standing prophylactic medications, such as allopurinol, febuxostat, or probenecid, may be continued—although they should not be initiated—in the setting of an acute gout flare.[16] The mainstays for ED management of acute gout include NSAIDs, corticosteroids, or colchicine.

Although NSAIDs are often considered first line, there is little evidence to suggest superiority of one drug over another, or even to suggest that NSAIDs are better than other pharmacologic options. When started promptly after the onset of symptoms, relief typically occurs within 24 hours, and the NSAID should be continued for at least another 24 hours after symptom resolution. Indomethacin, naproxen, and ibuprofen are all reasonable choices. NSAIDs should be avoided in patients with a history of peptic ulcer disease, GI bleeding, renal insufficiency, or other known contraindications.

Colchicine acts by inhibiting the formation of microtubules, thereby inhibiting the inflammatory response to the presence of crystals in the synovium and has been shown to be effective for the treatment of gout. However, it is contraindicated in patients with renal or hepatic insufficiency, can cause GI distress in many patients, and has a narrow therapeutic window making it potentially lethal in overdose. Because it shares similar contraindications to NSAIDs as well as a similar efficacy, we recommend traditional NSAIDs over colchicine for acute symptom management.

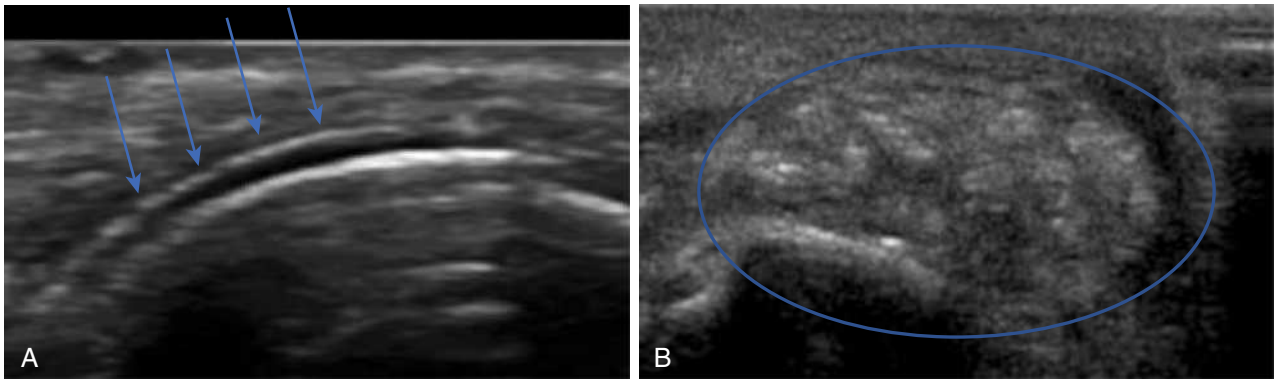

Fig. 102.8 Ultrasound Appearance of Gout. (A) Double contour sign showing gout in a metatarsal phalangeal joint. (B) Tophus seen on ultrasound showing "clump of sugar" appearance.

Steroids, whether oral or intra-articular, can also be beneficial in an acute gout attack. Intra-articular steroids may be most effective but should not be used in any patient with possible septic arthritis, and their use may be impractical in patients with small joint disease or when multiple joints are involved. Oral steroids, such as prednisone 40 mg daily for 5 to 7 days or a tapered pack of solumedrol, may also be effective.

Combination therapy, such as intra-articular steroid injection combined with colchicine or NSAIDs, is a reasonable option, particularly for patients with debilitating symptoms and those who have required such treatment previously. Oral corticosteroids with simultaneous NSAID use are not recommended due to the risk of GI side effects. Other treatment options include a short course of opioid analgesics, regional anesthetic blocks, or short-term cessation of diuretic therapy. Nonpharmacologic treatments such as ice, elevation, oral hydration, or avoidance of known triggers may also be helpful.

Pseudogout

Foundations

Calcium pyrophosphate deposition disease (CPPD), also known as pseudogout, is caused by deposits of calcium complex crystals on the articular surfaces. These deposits are evident on plain radiographs as chondrocalcinosis. The precipitation of these crystals leads to an inflammatory synovitis. Although the pathophysiology of the condition is not well understood, it is most commonly seen in elders and those with prior trauma or recent joint surgery. There is also an association with hemochromatosis, amyloidosis, hypothyroidism, and hyperparathyroidism. This condition is most often asymptomatic, but when acute inflammation occurs, the resulting condition is known as pseudogout.

Clinical Features

The acute presentation of pseudogout is similar to gout, although patients with pseudogout tend to be older and the knee is the most commonly affected joint. A warm and swollen joint that is acutely tender is typical, and it may be difficult to differentiate between the two conditions based on history and physical examination findings alone. However, compared with gout, acute pseudogout attacks may take longer to reach maximum symptom intensity and symptoms may persist for up to 2 to 3 months despite therapy.

Many patients with CPPD crystal deposition follow a chronic, progressive course of articular degeneration known as pseudo-OA. This may manifest in multiple joints, often involving the knees, wrists, metacarpophalangeal (MCP) joints, hips, shoulders, spine, elbows, or ankles. Approximately half of these patients will experience acute attacks of pseudogout superimposed on their chronic symptoms, whereas the remainder may present with signs and symptoms more consistent with classical OA.

Diagnostic Testing

Diagnostic testing for pseudogout is similar to that for gout. Plain radiographs may demonstrate chondrocalcinosis within the articular cartilage or in the joint capsule, although these radiographic findings may be present in less than half of cases. Given the association with systemic disease, laboratory testing may be warranted in select cases, including serum electrolytes, alkaline phosphatase, thyroid studies, or iron studies. Joint fluid analysis reveals weakly positive birefringent crystals that are rhomboid-shaped. As with gout, the symptoms may mimic septic arthritis, and it is important to note that crystals and acute infection may be present simultaneously.

Management

Asymptomatic CPPD does not require acute treatment unless it is directed at the underlying conditions (e.g., hypercalcemia due to hyperparathyroidism). When considering acute exacerbations of pseudogout, there are no specific pharmacologic agents that directly target the deposition of calcium crystals, and available anticrystal agents have not yet been proved to be effective in humans. In small studies, methotrexate, interleukin-1 (IL-1) inhibitors, and anti–tumor necrosis factor (TNF) alpha agents show promise in decreasing the frequency and severity of acute attacks, particularly in periarticular disease. Thus treatment is typically initiated using antiinflammatory medications. NSAIDs remain a mainstay of therapy, although they may be contraindicated in some older adults or those with comorbidities. Steroids, either systemic or intra-articular, can provide rapid symptomatic relief. Much like for gout, colchicine can be effective for acute exacerbations through its effect on PMNs; however, its narrow therapeutic window limits its utility.

Lyme Disease

Foundations

The spirochete *Borrelia burgdorferi* causes the infection responsible for Lyme disease, one of the most common vector-borne diseases in the Western Hemisphere. Transmitted by the *Ixodes* tick, the CDC estimates nearly 300,000 cases of Lyme disease per year in the United States.[17]

Clinical Features

Lyme disease presents as an unfolding pattern of symptoms which develop over weeks to months following infection. The early symptoms occur within weeks or months after a tick bite and may include rash as well as migratory myalgias or arthralgias without evidence of discrete arthritis. However, arthritis is the hallmark of the late stage of disease, and when untreated, approximately half of patients develop asymmetric arthritis within 6 months of initial infection. Lyme disease typically affects the large joints, in particular the knees, and if left untreated may cause intermittent episodes that persist for years. The arthritis associated with Lyme disease appears to be an autoimmune effect rather than a direct result of the spirochete infection. Early antibiotic therapy reduces the incidence of subsequent joint involvement.

Diagnostic Testing

The history of a tick bite, particularly in Lyme-endemic areas, or the classic erythema migrans rash may aid the clinician in making the diagnosis. However, many patients may not recall either the tick exposure or the resulting rash. The patient presenting with acute Lyme arthritis will typically have large joint effusions but may not have other systemic symptoms such as fever. Joint aspirate will reveal an inflammatory pattern with a predominance of PMNs. Although *B. burgdorferi* is difficult to culture from the synovial fluid, PCR testing may provide more accurate results when performed prior to the initiation of antibiotic therapy. Synovial fluid analysis and culture should be used to help exclude other etiologies, including septic arthritis. Lyme serologies (IgM and IgG) may be helpful in the outpatient setting but are of little utility in the ED. Routine lab testing is otherwise unhelpful.

Management

Prophylaxis against Lyme disease is not typically recommended unless an engorged *Ixodes* tick is found attached to a patient for greater than 24 to 36 hours in a Lyme-endemic area. In such cases, a single dose of doxycycline 200 mg PO (4.4 mg/kg in children) is recommended for prophylaxis. In the acute phase of disease, when patients present with

rash, myalgias, or arthralgias, the treatment is doxycycline 100 mg PO twice daily for 10 days. Lyme arthritis is treated with a 28-day course of doxycycline 100 mg PO twice daily. Amoxicillin 50 mg/kg/day divided every 8 hours (max 500 mg per dose) may be substituted for doxycycline in children, pregnant women, or the setting of tetracycline allergy. IV therapy, typically with a second- or third-generation cephalosporin (e.g., ceftriaxone 2 g IV daily), is reserved for patients with moderate or severe, persistent arthritis despite adequate oral antibiotic therapy. A small subset of patients may experience ongoing symptoms even after appropriate therapy, but a more prolonged course of antibiotics is unlikely to be beneficial.[18]

Acute Rheumatic Fever

Foundations

Acute rheumatic fever (ARF) is a complex systemic disease triggered by a hyperimmune response that follows pharyngitis due to group A streptococcal infection. The cellular and humoral response to the infection affects joints as well as cardiac tissue. The incidence of ARF has declined in recent years due to several factors including improved hygiene, increased antibiotic use, and mutations in prevalent group A *Streptococcus* strains. The worldwide incidence may be as high as 20 per 100,000, but in the United States and other developed nations the incidence is less than 2 per 100,000. In certain indigenous populations, including Australia and New Zealand, the incidence among children aged 5 to 14 years is significantly higher.

Clinical Features

The diagnosis of ARF is based on the Jones Criteria and the presence of two major criteria and one or more of the minor criteria (Table 102.10). Laboratory evidence of antecedent group A streptococcal infection is also required. Arthritis occurs in up to 75% of patients with ARF and presents as a migratory polyarthritis typically affecting the large joints and lasting 2 to 3 days per joint. Joints may appear inflamed and patients often display pain out of proportion to the apparent severity of the arthritis.

Diagnostic Testing

The value of laboratory testing for ARF is limited in the ED setting. Evaluation of synovial fluid reveals a sterile, inflammatory pattern. If suspected, obtain formal two-dimensional (2D) echo and Doppler imaging to evaluate for cardiac involvement.

Management

Recommended treatment of ARF includes IM benzathine penicillin 1.2 million units or a 10-day course of oral penicillin (penicillin V 500 mg PO 3 times daily for 10 days or amoxicillin 500 mg PO twice daily for 10 days). Oral clarithromycin 250 mg PO twice daily for 10 days may be used in penicillin-allergic patients. High-dose NSAIDs, such as oral aspirin 50 to 100 mg/kg/day divided into four daily doses may be used to treat arthritis and fever but do not have an effect on the cardiac sequelae. Small studies have suggested that oral or IM corticosteroids such as hydrocortisone 1 to 2 mg/kg/day PO slowly tapered over 2 to 4 weeks may be better than aspirin in patients with cardiac involvement. Recurrence may occur at a rate of 8% to 10% within 5 years; and monthly antibiotic prophylaxis with oral or IM penicillin for at least 5 years, or until adulthood, is recommended.

TABLE 102.10 Jones Criteria for Rheumatic Fever

Major Criteria	Minor Criteria
Joint pain (polyarthritis)	Arthralgia
Carditis (echo/Doppler used to diagnose)	Fever
Subcutaneous nodules	Elevated erythrocyte sedimentation rate (ESR) (>60 mm) or C-reactive protein (CRP) (>3.0 mg/dL)
Erythema marginatum	
Sydenham chorea	Prolonged PR interval

Two major criteria or one major with two minor criteria required for diagnosis. Also requires either elevated streptococcal antibody titer or positive throat culture/rapid streptococcus test.

CHRONIC POLYARTHRITIS

Rheumatoid Arthritis

Foundations

Although RA is typically a chronic condition with insidious onset and progression, approximately 20% of patients with RA present with acute exacerbations. With a worldwide prevalence of approximately 1%, incidence peaks between the ages of 35 and 50 years, and the condition is approximately 3 times more common in women. It is characterized by immune complexes that stimulate PMN cells to produce and release enzymes that lead to joint destruction. Over time, the number of synovial cells dramatically increases, leading to progressive release of inflammatory substances and progressive joint damage.

Clinical Features

At the time of initial diagnosis, patients may report weeks or months of fatigue, weakness, malaise, and joint pain, with or without associated fevers or weight loss. Over time, joint pain, swelling, and inflammation may progress often starting symmetrically in the proximal interphalangeal (PIP) and MCP joints of the hands, associated with stiffness that is worse in the morning. Over time, patients with RA may develop persistent symmetric polyarthritis of hands and feet, progressive articular deterioration with characteristic deformities including ulnar deviation, swan neck, and boutonniere deformities of the hands (Figs. 102.9 and 102.10). Patients may also have associated tenosynovitis and signs of extra-articular disease, including constitutional symptoms and difficulty performing activities of daily living. During an acute exacerbation, patients may present with only warm, swollen, or tender joints, which may be difficult to differentiate from other arthritides.

Diagnostic Testing

In the emergency setting, the evaluation of a patient with known or suspected RA should be directed at identifying other possible causes of acute arthritis, particularly septic arthritis. An elevated ESR and CRP may be seen in patients with either acute or chronic disease and remain nonspecific findings. Early radiographic findings are similarly nonspecific and include soft-tissue swelling or joint-space narrowing; subluxation or other bony deformities are late findings (see Fig 102.10). Synovial fluid analysis tends to reveal a nonspecific inflammatory pattern, although it may be useful in excluding crystal arthropathy or acute infection in selected patients.

Management

Care of patients with RA includes both pharmacologic and nonpharmacologic therapies. Pharmacologic options include NSAIDs, both biologic and nonbiologic disease-modifying antirheumatologic drugs (DMARDs), immunosuppressants, and corticosteroids. In acute exacerbations, relative rest and antiinflammatory medications are appropriate, including NSAIDs or low-dose systemic corticosteroids. Short-term use of additional analgesic medication may also be required.

Fig. 102.9 Example of severe deformities including swan neck deformity of multiple digits in poorly controlled rheumatoid arthritis.

Fig. 102.10 X-ray demonstrating severe deformities associated with long-standing untreated rheumatoid arthritis. Note profound ulnar deviation *(small arrows)*, joint subluxations *(large arrow)*, and swan neck deformity *(circle)*.

Studies have shown that biologic agents may be the most effective option in patients who have failed other treatments as well as in patients who have not yet been started on any chronic maintenance therapy for their RA. Early initiation of biologic or nonbiologic DMARDs has become routine as they can lead to remission of symptoms as well as limit progression of disease. Nonpharmacologic interventions are generally directed at long-term mitigation of symptoms and include interventions such as exercise, diet, stress reduction, cryotherapy, physical therapy, massage, or surgery including synovectomy, arthroplasty, or arthrodesis.

Seronegative Spondyloarthropathies

Foundations

The seronegative spondyloarthropathies are a broad category of conditions that share the clinical features of sacroiliac joint involvement and inflammatory arthropathy affecting multiple distal/peripheral joints with pathologic changes seen at the entheses (ligament and tendon insertion sites, see Fig. 102.1). Rheumatoid factor is typically absent, and HLA-B27 may be positive. The most common of these conditions include ankylosing spondylitis (AS), reactive arthritis, psoriatic

arthritis, and arthropathy associated with inflammatory bowel disease, so-called enteropathic arthritis.

Ankylosing Spondylitis

Clinical features. Patients with AS are more likely to be male and younger (younger than 40 years of age) and often report chronic back pain with insidious onset. This may be associated with radiographic evidence of sacroiliitis or the characteristic "bamboo spine," as well as extra-articular disease, most commonly uveitis. Urethritis and vasculitis may also occur, including potentially life-threatening disease affecting the aortic root. Up to 30% of patients may have associated enthesopathies such as plantar fasciitis or Achilles tendinopathy.

Management. Acute therapies are directed at managing pain and reducing inflammation. Therefore analgesics and antiinflammatory medications are appropriate. Biologic or nonbiologic DMARD therapy will be appropriate for chronic management and to prevent disease progression.

Reactive Arthritis (Formerly Termed Reiter Syndrome)

Clinical features. Reactive arthritis, formerly termed Reiter syndrome, generally occurs in patients 20 to 40 years of age following infection with *Chlamydia*, *Salmonella*, *Shigella*, *Yersinia*, or *Campylobacter* species, with symptoms of arthritis presenting 2 to 6 weeks after an episode of dysentery, or cervicitis/urethritis in the case of *Chlamydia* species. The condition presents with asymmetric polyarticular pain, often affecting joints of the lower extremities. Associated conjunctivitis, uveitis, or oral ulcers may also be seen.

Diagnostic testing. In reactive arthritis, synovial fluid demonstrates an inflammatory pattern. The joint fluid is sterile, although antigen testing for *Chlamydia, Salmonella*, or *Yersinia* may be positive. Radiographs may reveal abnormalities at tendon insertion sites.

Management. Patients with reactive arthritis respond well to antiinflammatory treatment with NSAIDs. Antibiotics may be appropriate in patients with *Chlamydia* but have not been shown to improve the clinical course in patients with reactive arthritis following dysentery.

Psoriatic Arthritis

Psoriatic arthropathy may occur in 20% of patients with psoriasis, causing a range of clinical presentations such as asymmetric oligoarthropathy, symmetric polyarthropathy, spondylitis, distal interphalangeal (DIP) joint involvement—in distinction from other rheumatoid conditions that tend to affect the PIP or MCP joints—or arthritis mutilans, a particularly severe condition in which there is evidence of bone resorption with associated collapse of the soft tissue. First-line treatment is with NSAIDs, and local corticosteroid injections may also be considered. There is little evidence for systemic steroid use, and DMARDs are often initiated early.

Enteropathic Arthritis

Up to 40% of patients with inflammatory bowel disease will experience musculoskeletal manifestations. This may present as an acute, asymmetric, migratory, inflammatory polyarthritis, commonly affecting the knees. The acute exacerbations of joint pain often accompany acute flares of GI symptoms. Although NSAIDs are first-line treatment for joint pain, they may exacerbate GI symptoms. Sulfasalazine and intra-articular corticosteroid injections are alternatives for symptom management.

Other conditions such as fibromyalgia, polymyalgia rheumatica, and scleroderma may also have characteristic musculoskeletal pain and joint stiffness. These conditions tend to cause more widespread pain, rarely present with acute arthropathy or joint effusions, and do not represent a true arthritis.

CHAPTER 102: QUESTIONS AND ANSWERS

1. A 72-year-old male with history of gout presents to the emergency department (ED) with worsening knee pain and swelling. He states this pain is worse than previous gout episodes. A diagnostic arthrocentesis is performed. Which of the following synovial fluid results would be most consistent with a diagnosis of septic arthritis?

- **a.** Gram stain negative, positive crystals (needle-shaped), synovial white blood cell (WBC) count 25K, polymorphonuclear (PMN) 70%, turbid appearance
- **b.** Gram stain negative, negative crystals, synovial WBC count 12K, red blood cell (RBC) 1K, fat globules in aspirate
- **c.** Gram stain negative, positive crystals (needle-shaped), synovial WBC count 40K, PMN 92%, turbid appearance
- **d.** Gram stain negative, positive crystals (rhomboid-shaped), synovial WBC count 35K, PMN 60%

Answer: c. A synovial fluid sample with PMN greater than 90% is presumed to be consistent with septic arthritis regardless of total synovial WBC count. Answer choices **a** and **d** may represent septic arthritis in certain scenarios, but neither is diagnostic. These represent acute gout and pseudogout, respectively. Answer **b** is representative of a lipohemarthrosis consistent with intra-articular fracture. A positive Gram stain would also be diagnostic of septic arthritis, although approximately 50% of cases of septic arthritis are associated with a negative Gram stain.

2. A 38-year-old previously healthy female presents to the emergency department with a complaint of worsening elbow pain and swelling. She plays recreational soccer and fell on her elbow one week ago. There was a small laceration over the elbow, but she has been trying to keep it covered with gauze. Over the last two days, the elbow has become more swollen, red, and painful. Joint aspiration confirms septic arthritis with gram stain showing gram positive cocci. What is true about the treatment of this patient with septic arthritis?

- **a.** Intra-articular antibiotic treatment is the gold standard and should be given immediately.
- **b.** Septic arthritis can safely be treated with oral antibiotics as the first line of treatment as long as the patient does not have a fever.
- **c.** Synovial fluid aspiration is rarely helpful in the treatment of septic arthritis. Blood cultures are sufficient.
- **d.** Vancomycin is a good choice for initial antibiotic treatment in this patient with septic arthritis.

Answer: d. A is incorrect because intraarticular antibiotics do not play a role in the treatment of septic arthritis. IV antibiotics are the gold standard. B is incorrect because IV antibiotics are the first line of treatment. Fever is not always present with septic arthritis. C is incorrect because synovial fluid aspiration is extremely important in the treatment of septic arthritis. Drainage of the joint is important, but it can also guide your antibiotic choice. D is correct because vancomycin 15–20 mg/kg/dose every 8 to 12 hours is a good starting antibiotic, with a positive gram stain showing a gram positive organism. Ceftriaxone 2 g IV (or other cephalosporin, see Table 102.8) can be added if gram stain is inconclusive or if results are not readily available.

3. Which of the following statements regarding septic arthritis is true?

- **a.** *Streptococcus pneumonia* is the most common cause of bacterial arthritis
- **b.** Older patients are more likely to present with fever
- **c.** Synovial fluid C-reactive protein (CRP) is more accurate than serum CRP
- **d.** Blood cultures should be obtained when bacterial arthritis is suspected

CHAPTER 102: QUESTIONS AND ANSWERS—cont'd

Answer: d. Blood cultures are recommended in all suspected septic arthritis cases because bacteremia is a relatively common finding. The most common pathogen is *Staphylococcus aureus*. Older patients are less likely to present with a fever. Synovial and serum CRP levels are similar in diagnostic value.

4. A previously healthy 19-year-old female presents with an acutely swollen and painful left knee starting a few days ago. She denies trauma or any previous history of similar episodes. She denies fever or chills but has had minor pelvic discomfort and a vaginal discharge, as well as bilateral wrist pain that resolved spontaneously. In addition to performing diagnostic joint aspiration, what tests should be ordered on this patient?
   a. Oral and genital swabs for polymerase chain reaction (PCR)
   b. C-reactive protein (CRP) and sedimentation rate
   c. Serum uric acid levels
   d. Lyme titers

Answer: a. This patient has gonococcal arthritis. This bacterium is notoriously difficult to find in synovial samples, and it is recommended to obtain oral and genital samples, in addition to samples of any skin lesions that may be present, to maximize diagnostic possibilities. CRP or sedimentation rate may aid in diagnosis of a septic joint but are not helpful in distinguishing the actual causative agent. Uric acid level has limited utility in this setting. Lyme disease is less likely in this patient who also has complaints of vaginal discharge, but this may be considered in endemic areas with known or possible tick exposure.

5. A 54-year-old male with poorly controlled hypertension and coronary artery disease on daily aspirin presents with a swollen first metatarsophalangeal (MTP) joint on the right foot. You make the diagnosis of gout. Which of the following is the most appropriate initial treatment for this patient with a presumptive diagnosis of gout?
   a. Naproxen 550 mg twice daily
   b. Naproxen 550 mg twice daily coupled with daily proton pump inhibitor (PPI) therapy
   c. Colchicine
   d. Allopurinol and colchicine
   e. Febuxostat and naproxen

Answer: b. This patient is moderate risk for gastrointestinal (GI) injury due to history of poorly controlled hypertension and daily aspirin use; thus an oral nonsteroidal antiinflammatory drug (NSAID) coupled with daily PPI use is reasonable. If the patient had no cardiac or GI risk factors, use of NSAID alone would be appropriate. Colchicine is an alternative therapy, although given its side effect profile, another NSAID is generally preferred. Allopurinol and febuxostat are medications that may be used to prevent gout attacks but should generally not be started during an acute flair and are not typically initiated in the ED setting.

Tendinopathy and Bursitis

Christopher Hogrefe and Emily M. Jones

KEY CONCEPTS

Tendinopathy

- Mechanical overload and repetitive microtrauma are key underlying mechanisms in the development of tendinopathy. Patients most often present with a history of progressively worsening localized pain after repetitive work- or sports-related activities.
- Tendinopathy may also be associated with nonmechanical causes, including systemic manifestations of diseases, infectious etiologies, and the use of fluoroquinolones or statins.
- Most patients with tendinopathy can initially be treated with conservative measures, such as activity modification/protection, icing, medications (e.g., short-term use of nonsteroidal antiinflammatory drugs [NSAIDs] or nitroglycerin patches for certain tendinopathies), bracing/splinting, ergonomic modifications, and graduated exercises.
- Overuse syndromes can take at least 6 to 12 weeks to heal. Advise patients accordingly and provide appropriate referral for follow-up to a musculoskeletal specialist (e.g., a sports medicine, orthopedic, or physical medicine and rehabilitation specialist).
- Emergent imaging may be indicated in the ED when fracture or a condition such as calcific tendinopathy is suspected. The use of point-of-care ultrasound to evaluate tendinopathy can help to identify tendon disruption/rupture.
- Operative treatment may be indicated for selected cases of tendon injury that require primary repair (e.g., rupture of the Achilles tendon) or that have failed to respond to conservative treatment (e.g., rotator cuff tendinopathy).

Bursitis

- Consider the possibility of an infectious cause in all cases of acute bursitis.
- The definitive diagnosis of bursitis is made by aspiration of the bursa and evaluation of the fluid.
- Septic bursitis is most commonly caused by *Staphylococcus aureus*.
- Nonseptic bursitis may be traumatic, rheumatologic (e.g., gout and pseudogout), or idiopathic in nature. It is prudent to consider other conditions, such as septic arthritis, osteomyelitis, or an underlying fracture, in the differential diagnosis of bursitis.
- The management of bursitis includes treatment with appropriate medication (antibiotics for septic bursitis, NSAIDs for nonseptic bursitis), rest, application of ice, compression, elevation, and prompt referral for appropriate follow-up. Hospitalization should be considered for severe local infections, for patients who are immunosuppressed, and in the presence of systemic toxicity.

TENDINOPATHY

Foundations

Background and Importance

Tendons are collagenous, dynamic structures that connect muscle to bone. They transmit forces originating in muscles to bone by stiffening, thereby enabling joint motion. *Tendinopathy* is an umbrella term that also encompasses tendinitis and tendinosis. The diagnosis of *tendinitis,* a commonly used term implying "inflammation of the tendon," has long been associated with numerous overuse injuries. Many practitioners now advocate use of the term *tendinosis* as a more accurate reflection of the pathologic process, representing a degenerative process without evidence of inflammation. To date, reliable, well-conducted epidemiologic studies have not been performed for most tendinopathies; however, histopathologic analysis often reveals degenerative tendon pathology with few inflammatory cells. This chapter will utilize the term *tendinopathy*, referring to a painful, impaired tendon that encompasses the various pathologic processes.

Approximately 30% of all musculoskeletal evaluations performed in the emergency department (ED) or urgent care settings are attributed to tendinopathy, and the incidence is rising. A contributing factor is the increasing level of daily participation in athletics and fitness-related activities, up 3.6% across a recent 12-year period.[1] Nearly half of all sports participants will be injured at some point, with up to 50% of injuries involving tendinopathy. For instance, with approximately 1.5% of the population running on a daily basis the number of affected runners accumulates quickly.[1] One study found that over one year, 27% of novice runners, 32% of long distance runners, and 52% of marathon participants sustained injuries with the majority related to overuse.[2] In another investigation, 70% of professional and 25% of youth basketball injuries were due to tendinopathy.[3]

Exercise is not the only culprit precipitating tendinopathy, however. Occupational exposures are a prominent cause of tendinopathy, resulting from lower demand, highly repetitive tasks (contrasted with higher demand, explosive sporting activities). Professions that involve repetitive motion, localized contact stress, awkward positions, vibrations, or forceful exertion are more likely to result in overuse injury such as tendinopathy. Shoulder tendinopathies are particularly common in the workplace, representing up to 13.6% of all musculoskeletal complaints regardless of one's occupation.[4] The nature of such work is further

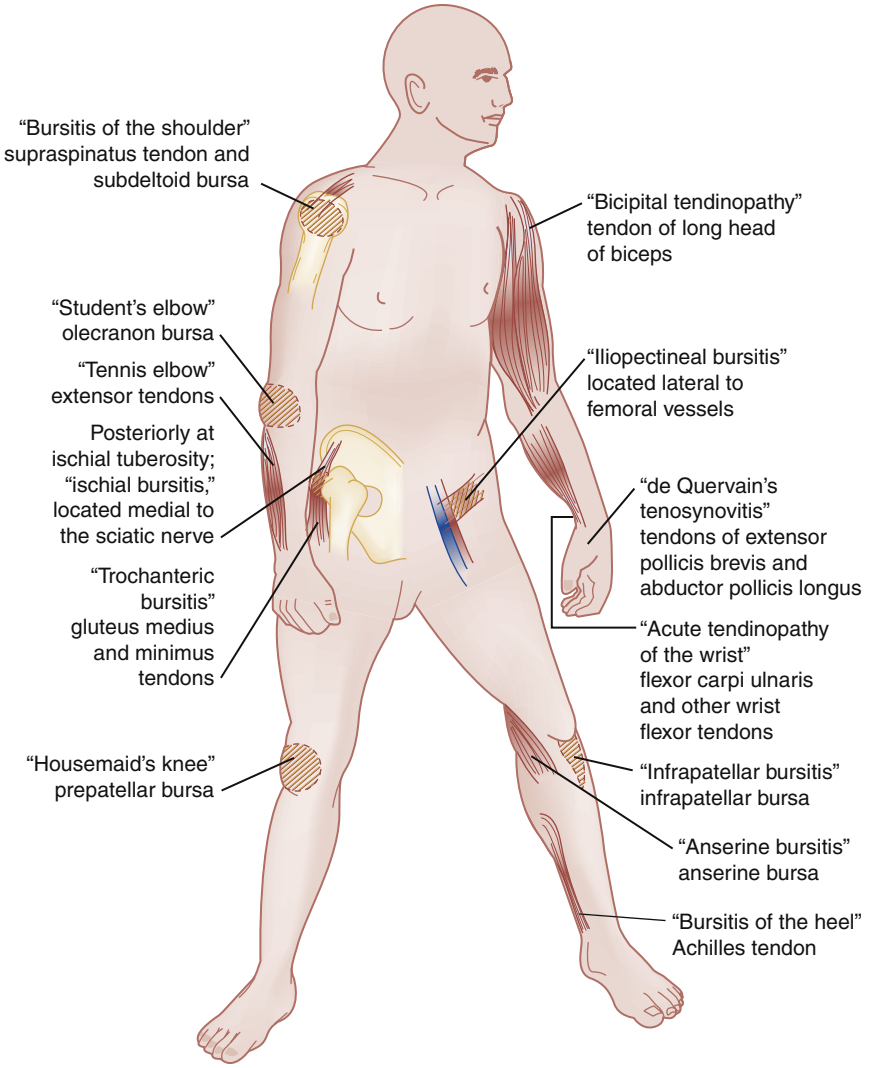

Fig. 103.1 Location of common sites for tendinopathy or bursitis. (Modified from Branch WT. *Office Practice of Medicine,* ed 2. Philadelphia: Saunders; 1987.)

compounded by longevity; those working 25 to 35 years are 7.1 times more likely to develop tendinopathy. The economic end result is staggering, with an estimate of nearly $800 billion in health care costs over a 3-year span attributed to these conditions.[5] Furthermore, for all nonfatal injuries in the United States (U.S.), tendinopathies account for the fifth most days away from work, totaling on average 14 days (with only fracture-related injuries accounting for more lost days of work).[6] Ergonomic and medical intervention programs may reduce the incidence of work-related injuries and decrease their socioeconomic impact.

Aside from the acute pain and functional limitations, tendinopathies often become chronic (i.e., greater than 3 months in duration) and can be disabling. Patients may experience symptoms for extended periods despite appropriate therapy and recurrence is common, affecting 49% of athletes with patellar tendinopathy.[7] Meanwhile, 40% to 50% of patients with rotator cuff tendinopathy exhibit symptoms at 6 to 12 months.[8]

Mechanical overload and repetitive microtrauma to the musculotendinous unit are thought to be the major precipitating causes of most tendinopathies. While the affected tendon is primarily under tensile overload, compression of the tendon occurs as well (e.g., fiber bundles contacting each other or friction/shearing against bone). Broadly, there are intrinsic and extrinsic factors that modify the pathophysiologic state of the tendon. Intrinsic factors such as age, gender, blood type O, adiposity, tobacco use, malalignment, joint laxity, muscle weakness, and imbalance can result in excessively high or frequent mechanical loads during normal activity. Extrinsic factors such as ergonomics, equipment changes, abnormal movements, excessive duration of activity, increased frequency or intensity of activity, and environmental conditions can also contribute to the development of tendinopathy.

Other potential contributing etiologies include excessive protein intake, systemic disease (e.g., coronary artery disease, diabetes mellitus, and gout), or medication use. An increased incidence of tendinopathy and tendon rupture, particularly of the Achilles tendon, has been attributed to fluoroquinolone antibiotics. This risk appears greatest within the first month of use, in those over age 60 years, in patients receiving corticosteroid treatment (4.68-fold increase for all tendons and 14.72-fold increase for Achilles tendon rupture), and in those with renal disease.[9] Statins have been implicated as contributing to tendinopathy as well (2% incidence), although simvastatin is thought to actually decrease this risk.[10] Overall, most tendinopathies are multifactorial in origin. Several of the common areas affected by tendinopathy are shown in Fig. 103.1.

Under optimal conditions, such as appropriately graduated athletic training, the musculotendinous units adapt to tension overload. This

results from the ability of bone to increase its load-bearing capacity combined with an increase in size and strength generated by the hypertrophy of existing muscle fibers. An enhancement of tendon and ligament strength occurs through an increase in collagen content, collagen cross-linking, and mucopolysaccharide content. Unfortunately, many athletes may not allow sufficient time for this adaptive process to occur. For example, a soccer player may increase the number of games played, the duration of time per game played, participation intensity, or any combination of these factors with haste, restricting the cellular changes required to adapt to the increased stress. Poor running technique, suboptimal playing surfaces, environmental conditions, or improper equipment (particularly footwear) may also contribute to the development of an overuse syndrome.

Pathophysiology

The pathophysiologic mechanism of tendon healing has mainly been described in the context of acute injury (e.g., rupture), and correlation to the healing process in tendinopathy remains under investigation. Acutely injured tendons go through several stages in the healing process, starting with the hemorrhagic phase as blood accumulates and clots at the site of injury. The inflammatory stage then follows as neutrophils and macrophages initiate phagocytosis, removing the existing necrotic material. Healing then progresses to the proliferative phase where extrinsic cells (e.g., tendon sheath, fascia, periosteum) and intrinsic cells migrate and proliferate at the injured tendon.[11] At this point, type III collagen is synthesized, which tends to be thinner and possesses less tensile strength than the tendon's original type I collagen. The process then advances to the formative stage, which can last upwards of 2 months. In this stage, collagen fibers mature and orient themselves to handle tension forces. Finally, the remodeling phase features a shift toward the normalization of the ratio between type I and type III collagen followed by the reintroduction of physiologic load into the tendon.[11] It may take up to 12 weeks for the tendon to regain its former strength. As the healing process ensues, unrestricted activity is generally avoided. However, atrophy associated with immobilization should also be avoided as the strength in healing tendons and ligaments increases more rapidly when controlled forces are applied. Consequently, optimal loading is now advocated as a means of advancing from rest to a balanced, incremental rehabilitation program. Such rehabilitation focuses on flexibility forces, core strengthening, eccentric strength training, and a measured return to resistive exercises so long as pain is minimal. Most patients with overuse tendinopathies fully recover within 3 to 6 months.

Clinical Features

General Tendinopathy

The history of the patient presenting with a tendinopathy can vary, although certain clinical features are characteristic. Recent repetitive stress may be reported due to work activities, changes in the workplace environment, or alterations in sport or recreational activities. It is important to ask patients to consider the weeks to months preceding the onset of symptoms to identify a potential inciting event or change (e.g., workplace ergonomics, protective footwear, new sports equipment). Occasionally, no cause is identified for a mechanical overload. A history of fluoroquinolone therapy, statin use, infectious disease, or other systemic illness (e.g., coronary artery disease, diabetes mellitus, gout) should also be obtained as initial presentations of rheumatologic disorders or infections, such as those from *Mycobacterium,* have been described.

Nonradiating, increasing pain at the site of the affected tendon is the most common presenting symptom of tendinopathy. The discomfort is frequently described as more severe following periods of rest. Unlike the discomfort of morning stiffness associated with arthritis, the pain of tendinopathy may resolve after initial movement only to be manifested as a throbbing pain after the cessation of exercise. Individuals may report similar prior episodes, whereas continued episodes may be accompanied by increased pain severity. Consequently, it may be helpful to inquire about a related previous diagnosis, how it was made, and which treatments (if any) were effective in resolving the prior episode.

BOX 103.1 Differential Diagnosis for Tendinopathy

- Tendon rupture
- Ligamentous injury
- Inflammatory arthritis (e.g., rheumatoid)
- Fractures (e.g., avulsion, stress)
- Tumors
- Tenosynovitis
- Osteochondrosis (e.g., Osgood-Schlatter disease)
- Bursitis
- Septic arthritis
- Osteoarthritis
- Foreign bodies
- Rhabdomyolysis
- Osteomyelitis
- Nerve entrapment syndromes
- Tendon sheath infections (e.g., pyogenic)

When evaluating a patient suspected to have tendinopathy, a thorough, directed musculoskeletal examination offers valuable diagnostic information. Edema, swelling, erythema, atrophy, deformity, asymmetry, or visible signs of trauma may be identified. Palpate the tendon, noting warmth or crepitus (particularly with movement), or tenderness over the tendon, especially when localized and reproducing the patient's pain. Although tendon palpation can be sensitive for reproducing tendinopathy-related symptoms, it is nonspecific in determining the affected structure. Check for underlying bone tenderness and consider the differential diagnoses listed in Box 103.1. Motor function (particularly passive and active range of motion), strength (and evidence of weakness or pain), and joint involvement/stability should be noted.

In narrowing the diagnosis, it is important to determine whether the source of pain is articular (within the joint capsule) or periarticular (around the joint capsule). Arthritis typically produces generalized joint pain, warmth, swelling, and diffuse tenderness. The discomfort of arthritis increases with both passive and active motion of the joint. Conversely, the pain of a tendinopathy tends to be more localized. Tenderness and swelling do not occur uniformly across the joint, and pain may be produced only with certain movements, particularly with resisted active contraction or passive stretching of the affected muscles or tendons. Mechanical hyperalgesia (i.e., increased pain with passive and active range of motion) may reduce the specificity of the commonly used clinical tests discussed later in this chapter.

Specific Tendinopathies

Shoulder. Tendinopathies of the shoulder joint include impingement syndrome (which includes subacromial bursitis or rotator cuff tendinopathy), bicipital tendinopathy, calcific tendinopathy, and adhesive capsulitis (frozen shoulder syndrome).

Impingement Syndrome and Rotator Cuff Tendinopathies. The shoulder joint is predisposed to soft tissue injury because of its extensive range of motion and unique anatomic structure (Fig. 103.2). Although inherently unstable, the muscles of the rotator cuff (supraspinatus,

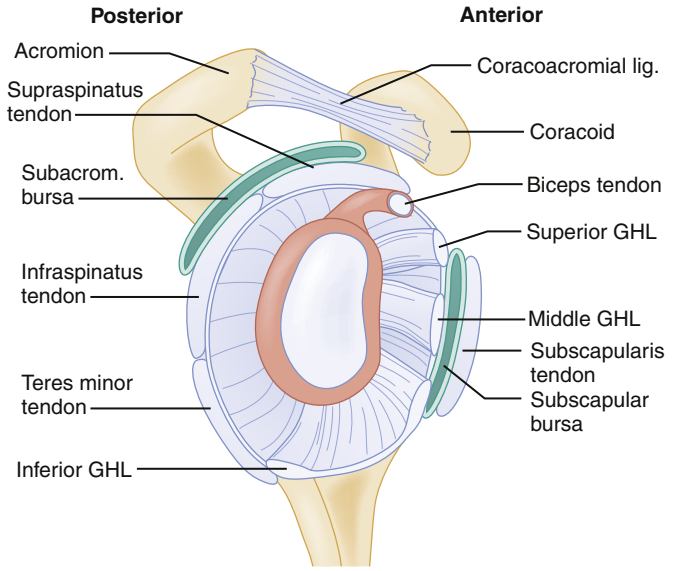

Fig. 103.2 Anatomy of the shoulder rotator cuff and supporting ligaments. *GHL*, Glenohumeral.

infraspinatus, teres minor, and subscapularis) and the glenohumeral ligaments (GHL) stabilize the joint. The muscles of the rotator cuff originate from the scapula and their tendinous insertions are found on the fibrous capsule of the glenohumeral joint after traversing through the subacromial space. The presence of the subacromial bursa serves to ensure fluidity of movement though may become inflamed as a part of an impingement syndrome.[12] Impingement of the tendons occurs because of their position interposed between the humeral head and the acromion. The functional arc of the elevated shoulder is forward and in the anterior plane. As a result of this position, the greater tuberosity of the humerus may compress (impinge) the tendons of the rotator cuff (usually the supraspinatus) against the undersurface of the anterior third of the acromion. Additionally, the long head of the biceps may be involved in impingement syndrome due to its location between the supraspinatus and subscapularis tendons in the rotator interval. This compressive component may combine with tensile loads on the rotator cuff to predispose patients to a chronic tendinopathy. Development of this tendinopathy may be the result of overuse of the extremity that leads to microtrauma of the tendinous fibers, individual anatomic differences (congenital or from the process of aging, such as osteophytic changes), or both. Other entities that may coexist and complicate an impingement syndrome include subacromial bursitis, bicipital tendinopathy, or calcific tendinopathy.

Ninety-five percent of rotator cuff tears are associated with impingement, exclusive of tears due to a one-time traumatic event. Three progressive stages of impingement syndrome as a result of overuse have been described. The first stage is frequently seen in athletes younger than 25 years of age who participate in sports that require repetitive overhead motions of the shoulder (e.g., swimming, volleyball, baseball). The pain is usually described as a dull ache over the anterolateral shoulder, extending from the shoulder to the middle upper arm, often occurring after an activity involving flexion and abduction of the arm. Point tenderness may be elicited over the greater tuberosity without the presence of weakness or loss of motion. This condition is generally believed to be reversible with appropriate treatment. In the second stage, as mechanical trauma continues, fibrosis and thickening of the tendon and subacromial bursa can occur. This generally affects patients between 25 and 40 years of age. The pain becomes constant and may worsen at night. Active motion may be limited by pain and any activity involving overhead movement can exacerbate the symptoms. Passive range of motion is generally preserved and on physical examination the pain is more diffuse and intense. The third stage resembles the second stage but may also involve a prolonged history of shoulder problems. At this point, the range of motion of the shoulder is usually decreased owing to either disuse or a partial rotator cuff tear. On pathologic examination, tendon degeneration may be present. Partial-thickness tears may occur or extend with stress or minor trauma. Complete tears of the rotator cuff, biceps tendon rupture, or osteophytic bone changes are sometimes seen.

Specific physical examination maneuvers can exacerbate the symptoms of shoulder impingement and suggest a diagnosis of rotator cuff tendinopathy. Because the supraspinatus tendon is most often involved, the *empty can test* (describing the position of the arm and hand as one empties an aluminum can, also referred to as the *Jobe sign*) is helpful in assessing the supraspinatus tendon via resistance testing. With the arm abducted at 90° in the scapular plane (30° anterior to the coronal plane), the arm is internally rotated with the thumb pointed downward. The examiner places a downward force on the distal upper extremity and the patient is instructed to resist the examiner and to keep the arm parallel to the floor (Fig. 103.3A). Weakness or pain is considered a positive finding. When assessing for supraspinatus tendinopathy, the empty can test has a sensitivity of 62% with a specificity of 54%. If the patient is unable to resist the force of the examiner, a supraspinatus tear should be suspected.

Another sign of rotator cuff tendinopathy is elicited by the *Neer test,* which suggests mechanical impingement due to a decrease of the subacromial space. The examiner forward flexes the arm to 180°, which causes impingement of the greater tuberosity of the humerus against the anterior and inferior edge of the acromion. A positive result elicits pain produced at the end range of the arc. Studies assessing the utility of this test report significant variability, with sensitivities ranging from 75% to 86% and specificities from 48% to 49%.

The *Hawkins-Kennedy test,* also indicative of mechanical shoulder impingement, is performed by forcibly internally rotating the proximal humerus while the shoulder is forward flexed to 90° and the elbow flexed to 90°. Pain with this maneuver constitutes a positive finding. Again, there is fluctuation in the literature regarding this test's sensitivity (75% to 82%) and specificity (44% to 48%).

A complete rotator cuff tear can be evaluated via the *drop arm test,* in which the arm is passively abducted at 90° and the patient is asked to slowly maintain control of the arm while adducting it (i.e., returning the arm to one's side) (Fig. 103.3B). If the arm drops to the side, a significant rotator cuff tear should be considered. Previous studies suggest that this test is 74% sensitive, although more recent literature reported a 10% sensitivity for full-thickness supraspinatus tears. The specificity is much better, cited as 98%. The *shrug sign* is exhibited when a patient with acute macrotrauma to the rotator cuff is asked to abduct the arm at 90° and appears to be giving a shrug with that side. This movement stems from the rotator cuff's inability to assist in abducting the arm. While such a finding may be secondary to other shoulder pathology (e.g., glenohumeral osteoarthritis or adhesive capsulitis), a positive result may suggest rotator cuff pathology.

Bicipital Tendinopathy. The tendon of the long head of the biceps, given its passage between the supraspinatus and subscapularis tendons in the anterior shoulder, can be associated with impingement syndrome. Patients with bicipital tendinopathy may describe pain in the anterior shoulder radiating to the elbow. Discomfort may occur when the individual rolls onto the shoulder at night, attempts to reach into a pocket, or turns a door handle. Focal tenderness may be provoked via direct palpation of the groove between the greater and lesser tuberosities of the anterior humerus. While the sensitivity (57%

Fig. 103.3 Illustrations of the proper positioning for (A) *empty can test* and (B) *drop arm test* when assessing for rotator cuff tendinopathy or a rotator cuff tear.

Fig. 103.4 A depiction of the *Yergason test* in the evaluation of biceps tendinopathy, which entails resisting a patient's supination.

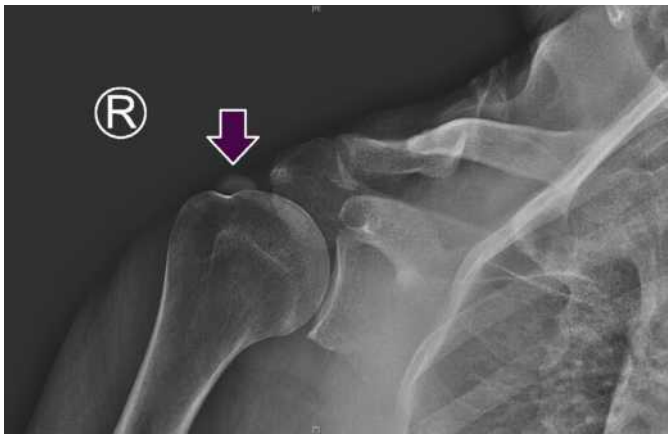

Fig. 103.5 Plain films of the right shoulder revealing a prominent calcium deposit in the supraspinatus tendon resulting in acute pain and decreased range of motion secondary to calcific tendinopathy.

to 85%) and specificity (49% to 72%) of this finding suggest that the test has utility, the accuracy of a clinician in directly palpating the long head of the biceps tendon has been questioned.[13] This accuracy can be further enhanced with the use of ultrasound.[14] The *Yergason sign* can also assist in the diagnosis of bicipital tendinopathy. This test is performed by having the patient flex the elbow to 90° with the arm against the body and the provider resisting the individual's forearm supination (Fig. 103.4). Pain in the area of the proximal tendon is considered a positive finding and indicative of biceps tendinopathy. Although the sensitivity is low (37%), the specificity (83%) and positive likelihood ratio (2.20) of this test are stronger.[15]

Another physical examination tool in the diagnosis of bicipital tendinopathy is *Speed's test*. With the elbow extended, the forearm supinated (i.e., palm facing upward), and the shoulder adducted at 60°, the patient is instructed to resist forward flexion of the shoulder. Pain in the area of the bicipital groove is indicative of a positive finding. Although Speed's test may be suggestive of glenohumeral labral pathology as well, meta-analyses suggest that it is more sensitive (61% to 83%) for bicipital tendinopathy with similar specificity (33% to 71%).[13,15]

Calcific Tendinopathy. Calcific tendinopathy is an acutely or chronically painful condition associated with the deposition of calcium crystals in or around tendons. Although it can impact any tendon, the condition appears to be more prevalent in the rotator cuff. The underlying cause is still debated though has been attributed to tissue hypoxia and degeneration due to overuse. More common in females, studies have shown an association with diabetes mellitus, thyroid disorders, and nephrolithiasis along with a potential genetic predisposition. While it can affect any of the rotator cuff tendons, it seems to have a predilection for the supraspinatus, up to 80% of the time. The symptoms are similar to those of an impingement syndrome and the condition generally affects individuals between the ages of 30 and 60 years. Calcium deposition occurs over time and then undergoes spontaneous resorption. This resorptive phase is thought to contribute to the observed pain, though the severity of the symptoms is not correlated with the size of the deposit. Pain is believed to be in response to the local chemical pathologic disorder or direct mechanical irritation. On physical examination, there may be specific tenderness over the greater tuberosity as well as symptoms consistent with impingement. Plain film radiographs may show calcification in or around the rotator cuff tendons (Fig. 103.5). The presence of calcium in the tendon does not necessarily confirm the origin of the pain because

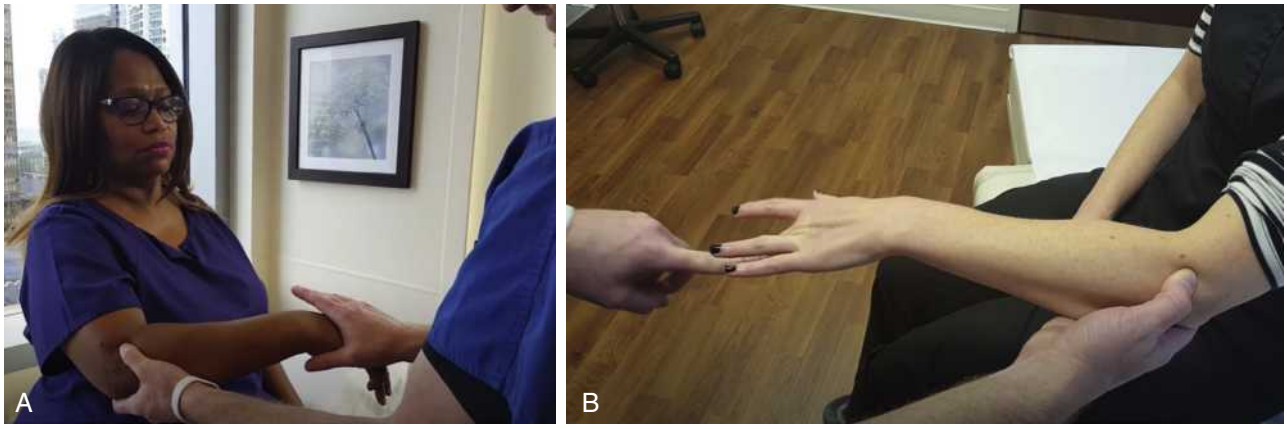

Fig. 103.6 When evaluating for lateral epicondylitis, (A) *Cozen's test* and (B) *Maudsley's test* may aid in confirming the diagnosis.

asymptomatic patients may demonstrate evidence of calcification on a routine radiograph. Ultrasound has proven useful in both the diagnosis and treatment (i.e., percutaneous needle lavage) of calcific tendinopathy.

Elbow. Increasingly, athletes of all ages and skill levels are participating in sports involving overhead arm motions. Consequently, the incidence of elbow injuries is rising. Such maladies also result from everyday life, including household chores and workplace exposures. From an anatomic and functional perspective, the extensors and supinators of the wrist attach to the lateral elbow, and the flexors and pronators attach medially.

Lateral Epicondylitis. Lateral epicondylitis ("tennis elbow") is a painful elbow condition that occurs at the insertion of the common extensor tendon (extensor carpi radialis brevis) onto the lateral epicondyle of the humerus. Although it occurs in many tennis players, epidemiologic studies suggest that less than 5% of patients with such a syndrome actually play tennis. Activities such as turning screws, using a wrench, and repetitive work on an assembly line have also been implicated. In fact, the prevalence of lateral epicondylitis in the workforce approaches 14.5%.[16] Symptoms often begin as a dull ache along the lateral aspect of the elbow. The discomfort can be exacerbated by activities that involve extension or supination of the wrist, such as grasping and twisting. *Cozen's test* is performed by grasping the patient's forearm with the one hand while resisting the patient's wrist extension (on the affected side) with the other hand. A positive finding includes the reproduction of pain at the lateral epicondyle and is associated with a sensitivity of 74%.[17] Studies have demonstrated poor specificity for this test.

Active extension of the middle finger (third digit) against resistance with the elbow in extension, or *Maudsley's test,* can also reproduce the pain over the lateral epicondyle at the insertion of the extensor carpi radialis brevis. Additionally, patients will typically note tenderness to palpation just distal to the lateral epicondyle, over the origin of the extensor carpi radialis brevis. With a sensitivity of 54%, its clinical utility in isolation is limited and it also offers poor specificity for this malady.[17] Illustrations of *Cozen's* and *Maudsley's tests* can be found in Figure 103.6.

Radiographs can be beneficial in cases of atypical or prolonged symptoms to rule out other pathologic conditions. Approximately 20% of patients demonstrate tendon calcification or a reactive exostosis at the tip of the epicondyle. The differential diagnosis of lateral epicondylitis includes fractures, posterior interosseus nerve entrapment (motor aspect of the radial nerve in the forearm), plica lesions, synovitis, chondromalacia, or adolescent osteochondral defects.

Medial Epicondylitis. Less common than its lateral counterpart, medial epicondylitis ("pitcher's elbow" or "golfer's elbow") can result from microtrauma at the site of the insertion of the flexor carpi radialis on the medial epicondyle. It is important to differentiate medial epicondylitis from other causes of medial elbow pain, including a medial ulnar collateral ligament injury. As a result of repetitive valgus stress placed on the joint, microtrauma and valgus instability at the ligament can also occur leading to disruption of the medial ulnar collateral ligament. Subsequently, abnormal stress is placed on the articular surfaces, which may lead to degenerative changes and osteophyte formation. Another diagnostic possibility worth considering is stress reactions/fractures. In the case of medial epicondylitis, patients will generally report tenderness over the flexor pronator origin slightly distal and anterior to the medial epicondyle. The pain of medial epicondylitis can be reproduced with resisted wrist flexion or resisted forearm pronation and may result in decreased grip strength. One should also evaluate for concomitant injuries elsewhere in the ipsilateral arm, which may be present in up to 84% of work-related injuries.

Wrist

de Quervain's Tenosynovitis. The wrist and hand include several tendons that pass through thick, fibrous retinacular tunnels. These help to prevent subluxation of the tendons and serve as a pulley system. Overuse syndromes are thought to result from changes of the synovial lining between these tendons and the retinaculum. de Quervain's tenosynovitis involves the synovial lining of the abductor pollicis longus and extensor pollicis brevis tendons. Although the term *tenosynovitis* suggests inflammation of the tendon sheath, it has been noted that there are many potential forms of tenosynovitis. Classic acute inflammatory changes that are characteristic of tenosynovitis may be related to systemic manifestations of disease (e.g., rheumatoid arthritis or gout). Tenosynovitis related to de Quervain's syndrome is referred to by some clinicians as *stenosing tenosynovitis.* The pathologic process of de Quervain's tenosynovitis does not generally involve inflammation but instead likely thickening of the extensor retinaculum covering the first dorsal compartment of the wrist combined with fibrous tissue depositions and increased vascularity in this region. It has been suggested that de Quervain's disease is a result of intrinsic degenerative mechanisms rather than extrinsic inflammatory ones.

The patient's history may consist of chronic, repetitive trauma or otherwise uncommon repetitive efforts, such as firmly grasping an object and moving the hand radially. However, studies have not found a causal relationship between this condition and specific occupational risk factors.[18] Direct trauma, such as a direct blow or fall,

Fig. 103.7 *Finkelstein's test* can be useful in identifying de Quervain's tenosynovitis. The provider should then deviate the wrist toward the ulna. Note the position of the thumb. The patient should not enclose the thumb in a fist, which constitutes *Eichhoff's test.*

has occasionally been implicated. Yet, in most cases of de Quervain's tenosynovitis the onset is gradual. The discomfort of de Quervain's tenosynovitis is typically localized over the radial styloid process. Radiation of pain proximally to the forearm or distally down the thumb has been described. The pain is generally constant but may be exacerbated by movements that include grasping, abduction of the thumb, or ulnar deviation of the wrist.

On physical examination, swelling (sometimes subtle) may be appreciated over the radial styloid. Crepitus may be palpated over the abductor pollicis longus and extensor pollicis brevis tendons with flexion and extension of the thumb. An increase in the tensile load (passive stretching or active contraction) of these tendons increases pain. The *Finkelstein's test* is the most pathognomonic physical sign of de Quervain's tenosynovitis. While the provider holds the thumb in a neutral position, the patient deviates the wrist toward the ulna (Fig. 103.7). Pain is elicited near the radial styloid, which is also the point of tenderness, reflecting a positive finding. This test is often confused with the *Eichhoff's test*, which entails the patient placing the affected thumb in the palm, making a fist, and then deviating the wrist toward the ulna. Finkelstein's test is preferred when assessing for de Quervain's tenosynovitis given its specificity of 100% (compared with 89% for Eichhoff's test).[19]

Radiographs are characteristically normal. The pertinent differential diagnosis includes scaphoid fracture (tenderness in the anatomic snuffbox or at the scaphoid tubercle) and osteoarthritis of the carpometacarpal joint (pain precipitated by longitudinal traction and compression involving that joint). It should be noted that Finkelstein's test can produce pain at the carpometacarpal joint, potentially reducing its specificity. Rarely, infections such as tuberculosis or disseminated gonococcal infections can manifest as tenosynovitis as well.

Knee

Patellar Tendinopathy. Patellar tendinopathy ("jumper's knee") commonly occurs in sports featuring a prominent jumping component, although it can also occur as the result of other sporting activities or occupations. Patients report pain at the inferior pole of the patella. The discomfort may abate with activity in the early stages of this tendinopathy but later progresses to the point of discomfort with both exercise and rest. When the quadriceps musculature is relaxed with the knee flexed at 30°, tenderness may be localized to the deep surface of the proximal attachment of the patellar tendon at the inferior pole of the patella. It should be noted that healthy active athletes sometimes have tenderness in this location on physical examination.

The differential diagnosis for patellar tendinopathy includes patellofemoral syndrome, which arises from imbalances in the forces that control patellar tracking during knee flexion and extension. Patients usually complain of anterior knee pain, described as "behind" or "around" the patella, which is classically worse with ascending or descending stairs or upon rising from a seated position. Occasionally, there is tenderness of the medial or lateral retinacula or facets.

Imaging with ultrasonography or magnetic resonance imaging (MRI) may reflect tendon degeneration, irregularity, or calcifications within the tendon. However, these findings should serve as an adjunct to the distinctive history and physical examination findings. It should be noted that some asymptomatic "jumping" athletes may have imaging findings similar to those of symptomatic individuals; thus, prognosis and outcomes are not predicted by imaging findings alone.

Ankle

Achilles Tendinopathy. Achilles tendinopathy is a common overuse syndrome that historically was thought to affect male athletes more frequently than their female counterparts, although that is currently subject to debate.[20] The Achilles tendon arises from the medial and lateral heads of the gastrocnemius muscle and the deep layers of the soleus muscle, inserting on the calcaneal tuberosity. Its major function is plantar flexion of the foot. The strongest and largest tendon in the body, it can withstand tensile loads more than 12 times the body's weight during running.

The Achilles tendon is vulnerable to injury from either trauma or overuse. A tendinopathy can also develop as a result of systemic disease (e.g., diabetes mellitus, renal disease, ankylosing spondylitis, reactive arthritis [previously known as Reiter's syndrome], gout, or pseudogout). The use of fluoroquinolones and statins have been associated with Achilles tendinopathy. Additionally, moderate alcohol use (7 to 13 units per week for men or 4 to 6 units per week for women) may predispose to this condition. The same association was not found for heavy alcohol use.[20]

The occurrence of Achilles tendinopathy is highest among individuals who participate in middle- and long-distance running, track and field, tennis, badminton, basketball, volleyball, or soccer. Some studies have noted a 5.2% incidence of Achilles tendinopathy in all runners and a 7.4% incidence in marathon runners.[21] Most cases of Achilles tendinopathy are thought to be multifactorial in origin. Anatomically, the vascular supply to the tendon creates a watershed area approximately 2 to 6 cm above the calcaneal insertion. This is responsible for the clinical symptoms and pathologic disruption commonly seen at this site. Otherwise, body mechanics and environmental factors (e.g., uneven terrain) may apply valgus or varus stress to the tendon. Activity technique (e.g., running form) and equipment (e.g., type of shoes) can also contribute to the development of tendinopathy.

The patient's history provides most of the information necessary to make the diagnosis. Pain, a cardinal symptom of Achilles tendinopathy, is often the impetus for an individual to seek medical evaluation. Some have argued that a patient's symptoms reflect the degree of tendon pathology, which has been validated in MRI studies assessing abnormal signal within the Achilles tendon. However, studies focusing on other changes associated with Achilles tendinopathy, such as neovascularization, have not shown a correlation with pain severity.[22] Regardless, as with many tendinopathies, pain after strenuous activity is reported in the early phase, whereas pain in the later phase occurs both during activity and at rest. Once an individual reaches this point, work and sporting activities are often limited by symptoms.

On physical examination, inspect the contour of the muscle-tendon unit while also assessing for swelling and erythema. In acute Achilles

tendinopathy, the tendon may be diffusely swollen and reveal tenderness to palpation, usually most prominent over the middle third. Typically, in such patients the area of swelling and tenderness does not move with dorsiflexion of the ankle joint. On palpation, warmth, crepitus, or palpable tendon nodules or defects may be noted. Examination for ankle instability and biomechanical faults (e.g., excessive ankle supination or pronation) should be entertained.

Achilles Tendon Rupture. Although rupture of the Achilles tendon most often occurs when it is preceded by tendon damage, it is possible for untrained athletes to apply excessive force and rupture the tendon in the absence of prior changes of tendinopathy. Partial and complete rupture may occur, most commonly in men between 30 to 40 years of age. Complete rupture is more common in the middle-aged recreational athlete. Historically, the patient may note a "pop" followed by acute weakness and an inability to continue with activity. Patients may report feeling as though they were "struck" in the posterior ankle.

On physical examination, a defect in the tendon can sometimes be palpated. If enough time has elapsed to allow hematoma formation, bogginess may be noted over the injured area. The ability to plantar flex the foot does not rule out a complete rupture of the Achilles tendon. There are multiple plantar flexors of the foot and toes. Muscles such as the tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus brevis, and peroneus longus can remain functional and therefore disguise a complete rupture given the persistent ability to plantar flex the foot.

Several observations can aid in the diagnosis of an Achilles tendon rupture by placing the patient in the prone position. Assess for decreased resting plantar flexion compared to the contralateral side, which is normally 20° to 30°. The *Thompson (Simmonds') test* can also be performed to evaluate for a complete rupture. With the patient prone and feet hanging over the edge of the bed, the examiner squeezes the calf muscles at their widest point and looks for passive plantar flexion. The absence of plantar flexion is considered a positive finding, indicative of a complete tear of the Achilles tendon. The presence of induced plantar flexion does not, however, eliminate the possibility of a partial tear of the Achilles tendon. Overall, the diagnosis of an Achilles tendon rupture can be made with 2 or more of the following findings on physical examination: palpable defect 2 cm to 6 cm proximal to its insertion, positive Thompson test, increased passive ankle dorsiflexion, and decreased plantar flexion strength. The absence of the first three of these findings has a negative predictive value of 100%, effectively ruling out the diagnosis of an Achilles tendon rupture.

Differential Diagnoses

The differential diagnoses of tendinopathy are listed in Box 103.1.

Diagnostic Testing

The diagnosis of tendinopathy is typically made on clinical grounds. While plain radiographs may be helpful in identifying calcific tendinopathy and in excluding bony abnormalities, ultrasonography has been recommended by some practitioners as the modality of choice for the evaluation of pathologic tendon conditions. Ultrasonography can be especially useful when other conditions, such as gouty arthritis, obscure the findings of concomitant tendinopathy. Emergency clinicians are proficient in identifying tendon injuries with point-of-care ultrasound, operating with 100% sensitivity and 95% specificity in such contexts. In cases of acute or chronic tendinopathy, one or more of the following features may be visualized: loss of the fibrillar echotexture, focal tendon thickening (Fig. 103.8), diffuse thickening, focal hypoechoic areas, extended hypoechogenicity, irregular and ill-defined borders, microruptures, intratendinous calcifications, or peritendinous inflammatory edema. Hypoechoic areas surrounding tendons are consistent with surrounding soft tissue inflammation. Tendon tears, both partial and complete, can also be delineated by ultrasonography.

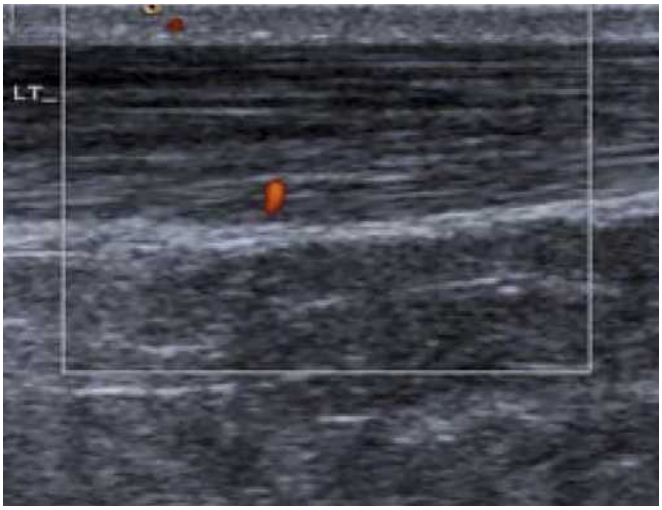

Fig. 103.8 A longitudinal view of the Achilles tendon showing focal thickening with peritendinous fluid.

MRI has been utilized to visualize pathologic conditions of the tendon. It provides high intrinsic tissue contrast, which permits the distinction between normal tendons and abnormal tendons as well as high spatial resolution that facilitates the identification of detailed anatomic structures. MRI has superb resolution of the soft tissue structures and can aid in the diagnosis of a variety of tendon disorders. Although the accuracy in identifying clinically relevant tendinopathy appears to be good (70%), perhaps counterintuitively, the sensitivity of MRI in these patients has been found to be as low as 50%. Additionally, cost, availability, the need to have the patient remain still during the examination, and the loss of the dynamic component compared with ultrasound examination remain relative disadvantages.

Management

General Tendinopathy

The management of tendinopathy is summarized in Box 103.2. Cryotherapy (cold treatments, 20 minutes at a time every several hours, for the first 24 to 48 hours) may be beneficial in reducing pain. However, there are no high-quality studies supporting its use to resolve the underlying tendinopathy or to increase load tolerance of the tendon. The role of NSAIDs in treating tendinopathy remains controversial. They can provide short-term analgesic benefits in some patients, although the efficacy is variable. The mechanism of their benefit remains unclear though likely relates to the progressive nature of the condition and associated inflammation of surrounding tissues. However, studies have shown that NSAIDs can impair long-term tendon healing. Thus, emergency clinicians should use their clinical judgement when considering NSAIDs for the treatment of tendinopathy, with a preference for a short course (e.g., one week) when prescribed.

Additional treatment modalities include graduated range-of-motion exercises. Aside from ruptures, complete rest is relatively contraindicated due to the subsequent loss of muscle power, decrease in mechanical properties of the tendon, and effect on the kinetic chain. Although pain may be immediately reduced with rest, it will increase again when the tendon is loaded due to the aforementioned physiologic sequelae. Unless the provider has in-depth

BOX 103.2 Components of Tendinopathy Management[8]

Identify the cause of discomfort
Eliminate the sources of the primary tendinopathy
Institute treatment modalities
- Analgesic medications (e.g., NSAIDs)
- Protection
- Relative rest
- Optimal loading (e.g., ergonomic alterations)
- Application of ice, compression, and elevation as necessary

Educate patients regarding the underlying mechanical causes
Modify patient behavior to minimize or eliminate sources of continuing irritation (e.g., biofeedback, coaching)
Enhance the patient's diet (e.g., add vitamin D sources)
Refer patients for appropriate follow-up care and early rehabilitation.

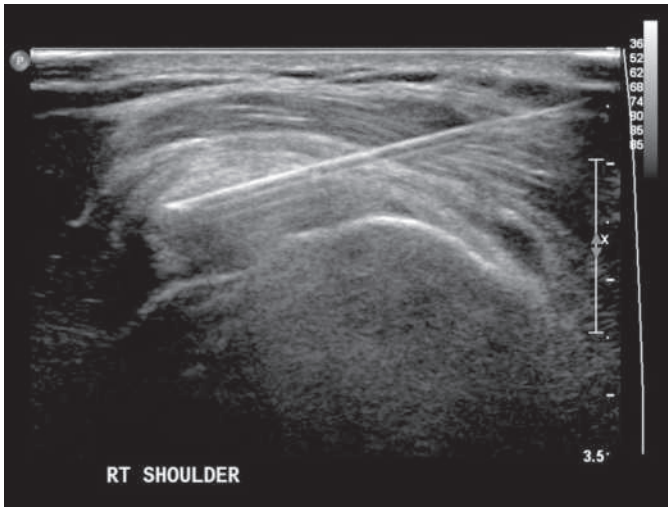

Fig. 103.9 Ultrasound-guided aspiration of a calcific deposit from the supraspinatus tendon causing calcific tendinopathy.

knowledge regarding the optimal rehabilitation regimen for a given tendinopathy (e.g., graduated eccentrics integrated with concentric exercises), it is prudent to avoid making specific recommendations. Instead, refer the patient to physical therapy, sports medicine, or an orthopedic specialist.

Corticosteroid injections have been utilized for short-term pain relief in the setting of tendinopathy. However, they likely have detrimental effects on both tendon pain and function for up to one year. Intratendinous corticosteroid injections should be avoided, particularly in the Achilles and patellar tendons, due to their potential for subsequent rupture. There are certain conditions that warrant consideration of peritendinous corticosteroid injections (i.e., de Quervain's tenosynovitis). Of interest, systemic corticosteroids may have a different impact on the healing process when administered after the early inflammatory stage of tendinopathy (e.g., post-injury day 5). A study in animal models assessing Achilles tendon injuries found that a five-day course of systemic dexamethasone starting at post-injury day 5 resulted in greater peak force, increased (beneficial) tendon stiffness, and decreased tendon thickness when compared to placebo.[23] While sufficient supporting evidence in humans has not yet been widely reported, this is an area of clinically relevant research to monitor moving forward.

The use of nitroglycerin patches has been shown to be effective in the treatment of certain tendinopathies. Questions remain as to whether their efficacy is due to an analgesic effect or promoting healing of the affected tendon. Medial and lateral epicondylitis, noninsertional Achilles tendinopathy, and rotator cuff tendinopathy typically respond well to this intervention.[24] However, no significant benefit in patellar tendinopathy has been reliably supported by the literature. Overall, chronic tendinopathies seem to respond better to nitroglycerin compared with acute injuries. Patients prescribed this treatment should be aware of the potential side effects, which include headaches and contact dermatitis. The use of nitroglycerin patches for tendinopathy remains off-label and is more likely to be prescribed by a musculoskeletal specialist.

Platelet-rich plasma (PRP) injections, a process by which a patient's platelets are concentrated in a centrifuge and then injected into the affected tendon, are utilized by some specialists in the management of tendinopathy. The literature on the efficacy of this intervention is widely variable. There is some support for this modality, although it is not definitively beneficial. It can be safely asserted that PRP should not be utilized as a first-line treatment and is most efficacious when administered under ultrasound guidance.[25,26] Accordingly, while some patients may reach this point in the treatment algorithm of tendinopathies, it is not advocated for use in the ED setting at this time.

Specific Tendinopathies

Impingement Syndrome and Rotator Cuff Tendinopathies. The treatment of rotator cuff tendinopathies and impingement syndrome follows the treatment of tendinopathy in general. Emphasis is placed on physical rehabilitation and graduated strengthening exercises. A significant proportion of patients will improve with conservative management; otherwise, surgical intervention (e.g., acromioplasty, debridement, or repair) may be considered.[27]

Calcific Tendinopathy. The initial treatment of calcific tendinopathy is mainly conservative and consists of analgesia and brief immobilization (e.g., a shoulder sling for rotator cuff calcific tendinopathy) because prolonged immobilization may result in decreased range of motion. Both extracorporeal shock wave therapy (akin to that which is used for nephrolithiasis) and ultrasound-guided needle lavage and aspiration (Fig. 103.9) are effective treatments for this condition. The latter option has been shown to result in improved pain and functional outcomes compared to extracorporeal shock wave therapy or corticosteroid injection.[28] A small percentage of patients who do not respond to these interventions may need surgery. Follow-up care from the ED is important because calcific tendinopathy has been described as the most well-known cause of reactive cuff failure.

Lateral and Medial Epicondylitis. In up to 95% of patients, epicondylitis will improve with time and conservative therapy. Initial efforts include making the patient more comfortable with the standard principles of protection, compression, medications (e.g., NSAIDs for significant pain), biomechanical or ergonomic adjustments, and physical therapy modalities. *Relative rest* is appropriate and implies the avoidance of overuse as opposed to the absence of activity. Activities that aggravate pain should be eliminated and an attempt to protect the tendon through strategies such as a reduction in playing time or intensity should be entertained. The use of a counterforce brace should be recommended in order to control force loads and improve performance technique. This intervention has been shown to significantly reduce the frequency and severity of epicondylitis-related pain in the short term (i.e., 2 to 12 weeks) as well as improve elbow function at 26 weeks.[29] Corticosteroid injections remain a commonly employed treatment despite ample evidence that they are ineffective. At 4 to 6 weeks, patients may note a reduction in pain. However, at

26 weeks, outcomes (e.g., pain and function) were worse in those who received a corticosteroid injection compared to those who received a saline injection or no treatment.[30] In fact, corticosteroid injections may serve to increase the risk of nonoperative treatment failure.[31] Consequently, corticosteroid injections should be avoided in the ED while follow-up with a musculoskeletal specialist is pursued.

de Quervain's Tenosynovitis. The initial treatment of de Quervain's tenosynovitis consists of immobilization with a thumb spica splint, antiinflammatory medications, and prompt referral. Corticosteroid injections have been shown to be a beneficial treatment of de Quervain's disease, and failure to respond may be due to anatomic variation or poor technique (Fig. 103.10). Studies have shown this intervention to be effective in resolving the associated pain 52% of the time.[32] A mixture of 20 mg of methylprednisolone acetate or triamcinolone combined with 1 mL to 2 mL of lidocaine or bupivacaine is appropriate for this injection. The associated benefit may be further enhanced when combined with a thumb spica splint or similar orthosis.[33] Surgical decompression of the first dorsal compartment may be indicated if these treatments fail.

Fig. 103.10 The proper needle placement for a corticosteroid injection to address de Quervain's tenosynovitis.

Achilles Tendinopathy and Rupture. In addition to routine conservative treatment, patients with Achilles tendinopathy should be referred for orthopedic evaluation and correction of limb malalignment with the use of orthotics or heel lifts. Eccentric loading exercises (Fig. 103.11) and low-energy shock wave therapy are typically effective therapies for Achilles tendinopathy.

The management of Achilles tendon rupture may be either operative or nonoperative, depending on patient circumstances. In the ED, acute Achilles tendon ruptures should be treated with a posterior lower leg splint featuring the ankle placed in approximately 20° of equinus (i.e., plantar flexion). If this is not feasible for any reason, a walking boot with 2 inches of heel lift can suffice. This management brings the affected ends of the ruptured tendon closer to reapproximation, decreasing the amount of remodeling necessary to reconstitute the tendon. The individual should remain nonweightbearing until consultation by a musculoskeletal specialist is completed. Some authors contend that complete ruptures in active athletes should be treated surgically in most cases. And while scenarios differ, the outcomes for the nonoperative and operative management of Achilles tendon ruptures are similar, leaving both as viable options for many patients.[34]

Disposition

Most patients with tendinopathy are safely discharged home with proper instructions, relative rest of the tendon, analgesia, and appropriate follow-up care. Exceptions include elders and disabled patients

Fig. 103.11 Demonstration of eccentric Achilles tendon rehabilitation exercises, emphasizing bilateral toe raises (A). One should then lower the heel below neutral (B).

who may be unable to perform activities of daily living due to the tendinopathy. Although appropriate rest and analgesia provide symptomatic relief, underlying causes should be considered and addressed in follow-up.

BURSITIS

Foundations

A *bursa* is a closed sac lined by synovial membrane, which occurs in areas of friction between two layers of tissue. It permits fluid movement of soft tissue over areas of potential impingement (e.g., subacromial bursa) or friction (e.g., olecranon and prepatellar bursae). There are more than 150 bursae throughout the body. They develop after birth, most likely as a result of pressure or friction from movement. Superficial bursitis most commonly occurs in the olecranon and prepatellar bursae, which are located on the extensor surface of the elbow and knee, respectively.

Bursitis is most often due to trauma (acute direct trauma to or prolonged pressure on the bursa), systemic inflammation (from disorders such as gout, pseudogout, rheumatoid or psoriatic arthritis), or infection (most commonly due to *Staphylococcus aureus*). However, there are cases of idiopathic bursitis as well. Septic bursitis is most commonly due to spread from a nearby cellulitis, direct inoculation from trauma, or as a result of aspiration or injection.

Clinical Features

Olecranon and Prepatellar Bursitis

About one-third of patients with olecranon or prepatellar bursitis are found to have septic bursitis. Distinguishing septic from nonseptic bursitis can be difficult because clinical information and diagnostic data can be similar. Patients with septic bursitis generally present earlier in their clinical course and tend to have more pain, tenderness, erythema, and warmth compared to those with nonseptic bursitis. While septic and nonseptic bursitis are both frequently caused by trauma, septic bursitis is almost always preceded by some kind of trauma, including minor and repetitive microtrauma. Other predisposing factors include chronic illness (e.g., diabetes mellitus or alcohol abuse), chronic skin conditions (e.g., atopic dermatitis), and previous noninfectious inflammation of the bursae (e.g., rheumatoid arthritis or gout). It is also more common in people whose occupation results in repetitive knee or elbow trauma.

The olecranon bursa, found on the extensor surface of the elbow, is the only bursa of the elbow joint and is easily traumatized, which can result in inflammation, pain, and swelling. Infection can also occur from local trauma (e.g., puncture wounds or lacerations), but may also present without any preceding history of trauma. Hematogenous bacterial seeding is rare due to the limited vascular supply to the bursal tissue.

On physical examination, localized swelling and fluctuance are usually present over the bursa. There may or may not be evidence of trauma. Tenderness and warmth are typical in most patients with septic bursitis. Erythema with overlying cellulitis is also common in septic bursitis, and a fever can suggest infection, although this is inconsistent and reported to be present in 20% to 77% of patients. Tenderness, erythema, and warmth can also be seen in patients with purely inflammatory causes of bursitis, though the frequency and severity of these findings are less and patients with septic bursitis usually present earlier in their clinical course.

Passive range of motion should not produce noteworthy pain except for full flexion, at which point there may be discomfort as the inflamed bursa is compressed. Evidence of significantly diminished range of motion, generalized joint swelling, or other signs and symptoms of joint involvement (e.g., joint pain, warmth, effusion) should raise concern for septic arthritis. Although the olecranon and prepatellar bursae generally do not communicate with the joint space, septic arthritis should be considered in the differential diagnosis, especially if trauma is involved and the integrity of the underlying joint is disrupted. Arthrocentesis to assess for septic arthritis should be considered in these cases.

Subacromial Bursitis

The subacromial bursa lies between the rotator cuff tendons and the undersurface of the acromion, the acromioclavicular joint, and the deltoid muscle. Subacromial bursitis is thought to be nearly synonymous with supraspinatus tendinopathy and may be involved in the stages of rotator cuff impingement. Pain and tenderness to palpation, localized to the lateral aspect of the shoulder, in addition to signs of impingement may be noted on physical examination *(Neer test or Hawkins-Kennedy test)*. Septic subacromial bursitis is rare, but a few cases have been reported in the literature.[35]

Trochanteric Bursitis

The trochanteric bursa has both deep and superficial components. The deep bursa is located between the greater trochanter and the tensor fasciae latae; the superficial bursa is located between the greater trochanter and the skin. Trochanteric bursitis is more common in middle-aged women, who usually report acute or chronic pain over the bursal area as well as the lateral thigh. Lying on the hip and walking may exacerbate the pain. It can also occur as a complication of rheumatoid arthritis. On examination, the pain of superficial bursitis may be reproduced by direct palpation and hip adduction while the pain of deep trochanteric bursitis may be reproduced with hip abduction. The hip joint itself usually has normal examination findings. Septic trochanteric bursitis is rare but has been described.

Ischiogluteal Bursitis

The ischiogluteal bursa is located adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Inflammation, known as *weaver's bottom,* is described as pain over the center of the buttocks with radiation down the back of the leg. It can be caused by prolonged sitting, running, repetitive jumping, or kicking. Sitting on a hard surface exacerbates the pain, and palpation over the ischial tuberosity causes discomfort.

Iliopsoas Bursitis

The iliopsoas bursa has been shown to be the largest bursa in the body. It lies between the iliopsoas tendon and the lesser trochanter. The pain of iliopsoas bursitis usually manifests as anterior hip pain that can radiate down the medial thigh to the knee and is exacerbated by hip extension.

Pes Anserine Bursitis

The anserine bursa lies deep to the three tendons (sartorius, gracilis, and semitendinosus) that form the pes anserinus ("foot of the goose") and superficial to the medial collateral ligament of the knee. Patients with anserine bursitis usually complain of medial knee pain approximately 2 or 3 cm distal to the joint line. There is usually tenderness to palpation in this area and occasionally swelling. Risk factors for pes anserine bursitis include osteoarthritis of the knee, diabetes mellitus, and possibly obesity.[36]

Differential Diagnoses

Conditions that mimic bursitis include underlying fracture, osteomyelitis, septic or inflammatory joint arthritis, and cellulitis. Radiography

BOX 103.3 Differential Diagnosis for Atraumatic, Nonseptic Bursitis

- Rheumatoid arthritis
- Pseudogout
- Ankylosing spondylitis
- Hypertrophic pulmonary osteoarthropathy
- Oxalosis
- Gout
- Scleroderma
- Systemic lupus erythematosus
- Whipple disease (an infectious bacterial disease that affects many different organ systems, including the musculoskeletal system with joint involvement)
- Idiopathic hypereosinophilic syndrome

and bone scan or MRI may be necessary to evaluate for these alternative conditions. Box 103.3 lists the differential diagnoses for atraumatic, nonseptic bursitis.

Diagnostic Testing

When there are signs of acute inflammation, aspiration of the bursa should be considered to exclude the presence of infection or crystal-induced disease. Bursal aspiration is performed with sterile technique utilizing an 18- to 20-gauge needle. A lateral approach to the aspiration of any bursa, when feasible, has been recommended to lower the risk of iatrogenic sinus tract formation, although the relation between the two is unclear. A distal approach can also be used when the olecranon bursa is aspirated. In cases of septic bursitis, the aspirate usually appears purulent though can occasionally appear serosanguinous or straw-colored. In the case of nonseptic bursitis, the aspirate varies from bloody to straw-colored. The bursal fluid is typically evaluated for white blood cell count with differential, crystal analysis, Gram stain, appropriate cultures and sensitivities, and glucose level. Peripheral blood is typically sent for complete blood cell count with differential, C-reactive protein, erythrocyte sedimentation rate, and glucose. A bursal fluid to serum glucose ratio of less than 50% was initially thought to be diagnostic of septic bursitis, though recent studies have shown this comparison to be unreliable.

The identification of organisms on either Gram stain or culture is diagnostic for septic bursitis. There are no definitive guidelines regarding the use of WBC count to distinguish between septic and nonseptic bursitis. A bursal fluid WBC count higher than 1000/μL^3 is almost always seen, and a value greater than 5000/μL^3 suggests bursal fluid infection, even in the presence of a negative Gram stain. However, counts can be much lower in septic bursitis or above this threshold in nonseptic cases. Culture is the definitive test though will not be available during the initial evaluation. *S. aureus* is by far the most common organism in bursal infection, followed by streptococcal and other staphylococcal species, remaining unchanged in the last several decades. Because most cases of septic bursitis occur in the olecranon or prepatellar bursae, the diagnosis is made clinically in conjunction with aspiration. MRI can be used to aid in the diagnosis of inflammation or infection of deep bursae. Ultrasonography has also been used as a modality for aspiration of deep bursae.

Management

Septic Bursitis

Large-scale clinical prospective trials are lacking, thus the optimal treatment of septic bursitis remains unclear. Debate persists regarding the use of outpatient (oral) or inpatient (intravenous [IV]) antibiotics, duration of therapy, role of needle aspiration or incision and drainage, and the need for operative intervention.

Patients who have bursal inflammation with suspicion (clinical or laboratory) of infection should be treated with appropriate antibiotics. Empirical therapy (including coverage for *S. aureus* and streptococcal species) is indicated until definitive culture results are available. A recent study on septic bursitis revealed the incidence of methicillin-resistant *S. aureus* (MRSA) as a causative pathogen to be around 17%.[37] It is more common in the United States compared to Europe, and MRSA was found to be the most common cause of community-onset adult septic bursitis in one case series from an ED population. Therefore, empirical coverage for this organism in septic bursitis should be considered. A trial of oral antibiotic therapy (up to 14 days) and treatment on an outpatient basis in the patient with uncomplicated septic bursitis and no underlying disease is reasonable. We recommend oral dicloxacillin (500 mg PO four times daily), trimethoprim/sulfamethoxazole (160 mg/800 mg strength, one to two tablets PO twice daily), or oral clindamycin (300 mg PO four times a day) for penicillin-allergic patients, as first-line therapy. However, failure in up to 50% of cases has been reported for outpatient treatment of septic bursitis. One of the largest observational studies on the successful outpatient treatment of septic bursitis showed an admission rate of only 1 of 118 patients, though all patients in this study received sequential IV antibiotics for approximately 4 days at an outpatient clinic followed by a course of oral antibiotic therapy. Consequently, treatment in an observation unit or inpatient setting with IV antibiotics is a consideration for patients with significant symptoms, overlying cellulitis, or those unlikely to receive close follow-up. For such patients, we recommend IV vancomycin (loading dose: 20 to 35 mg/kg actual body weight [not to exceed 3000 mg] or 20 to 25 mg/kg actual body weight [not to exceed 3000 mg] in patients with obesity, then 15 to 20 mg/kg actual body weight every 8 to 12 hours) as initial empirical treatment.

Needle aspiration is a technique commonly used for the diagnosis and management of septic bursae. Successful treatment of septic bursitis can typically be achieved in patients receiving oral antibiotics on an outpatient basis following initial needle aspiration. One study showed no difference between patients who received aspiration and those who did not, though patients who had more severe disease were also more likely to be selected for drainage. These patients were also initially treated with parenteral antibiotics. Furthermore, the diagnosis of septic bursitis was confirmed by culture in only 26% of patients, potentially underestimating the importance of bursal drainage in individuals with true septic bursitis. As needle aspiration is utilized in the diagnosis of septic bursitis, initial drainage at the same time seems reasonable. Those with a purulent aspirate may require repeated aspiration at 1- to 3-day intervals if the effusion persists. In all cases, appropriate follow-up to assess response to therapy should be arranged. Warm soaks and wound care are also indicated. Surgical incision and drainage or bursectomy may become necessary in severe, recurrent, or refractory cases.

Nonseptic Bursitis

Most cases of nonseptic bursitis improve with conservative therapy, although complete recovery can take many months. Initial treatment typically consists of NSAIDs, compression to prevent recurrent fluid accumulation, and occasionally aspiration of the bursa to relieve pain and increase range of motion. Systemic causes of bursitis (e.g., crystalline disease) should be treated as indicated. Avoidance of local trauma is important for treatment and successful prevention of bursitis. Recurrent olecranon bursitis may be caused by underlying anatomic disorders, such as bone spurs.

Bursal injection with a combination of local anesthetics and steroids at the time of diagnostic aspiration is often therapeutically

beneficial for inflammatory bursitis of deeper areas, such as the subacromial, pes anserine, medial collateral ligament, or trochanteric bursae. Injections into superficial bursae have been used as a treatment modality, but multiple complications have been described, including skin atrophy over the bursa, persistent pain, development of septic bursitis, bleeding, postinjection flare as a result of release of microcrystals, and tendon rupture. However, a systematic review of the treatment of olecranon bursitis found that patients who received a corticosteroid injection were no more likely to develop an infection or persistent pain than those who did not. A recent randomized trial comparing compression and NSAIDs versus aspiration alone versus aspiration and steroid injection showed no appreciable differences between groups in treatment success rates.[38] At this point in time, we recommend starting with noninjection treatment (e.g., compression, NSAIDs, and possible aspiration) for suspected inflammatory bursitis of superficial bursae.

Disposition

Patients without underlying medical problems who present with uncomplicated septic bursitis can usually be discharged with appropriate oral antibiotics. Those with underlying diseases (e.g., immunocompromise, leukopenia, diabetes mellitus) or those with systemic toxicity or signs of severe bursal infection (e.g., purulent drainage) are candidates for IV antibiotics and inpatient therapy. Patients with a purulent aspirate or persistent infection may require serial aspirations. Close follow-up is necessary to ensure an appropriate response to therapy. Patients with presumed nonseptic bursitis require close follow-up as well.

CHAPTER 103: QUESTIONS AND ANSWERS

1. What is the etiology of most tendinopathies?
   - **a.** Direct blow to the tendon
   - **b.** Recent or previous complete tendon rupture
   - **c.** High-grade inflammation of the tendon
   - **d.** Mechanical overload and repetitive microtrauma

Answer: D. Tendinopathies are thought to be precipitated by repetitive microtrauma and mechanical overload rather than true inflammation of the tendon

2. Which of the following interventions should routinely be used when treating patients with tendinopathies?
   - **a.** Activity modification
   - **b.** NSAIDs
   - **c.** Intratendinous corticosteroid injection
   - **d.** Immobilization of the affected tendon/joint

Answer: A. Patients with tendinopathy should be advised to modify their activities (including ergonomic workplace adjustments, when pertinent) to avoid exacerbating pain and further tendon injury. Some patients may benefit in the near term from a short course (e.g., one week) of NSAIDs, although this can result in impaired tendon healing in the long term. Thus, their use should be dependent on the circumstances of presentation, such as the severity of pain or comorbid conditions. Intratendinous corticosteroid injections and immobilization should not be routinely utilized as they may prove detrimental in the long term.

3. A 38-year-old male presents after feeling a "pop," followed by pain to the back of his leg while playing basketball. You note a defect to his Achilles tendon, decreased resting plantar flexion of the ankle, and a positive Thompson test on examination. What should be the next step in the patient's management?
   - **a.** Provide crutches and advise the patient to remain non-weightbearing until follow-up.
   - **b.** Splint the affected leg in an equinus position and refer for prompt follow-up.
   - **c.** Obtain emergent magnetic resonance imaging (MRI).
   - **d.** Perform a steroid injection to the affected tendon.

Answer: B. This patient meets the diagnostic criteria for an Achilles tendon rupture. Although MRI can be a useful adjunct when evaluating tendon injuries, obtaining such imaging in the acute care setting is not essential when the clinical diagnosis is obvious. The same can be stated for point-of-care ultrasound. Treatment consists of splinting the leg in 20° of equinus (plantar flexion) and close follow-up with a musculoskeletal specialist (e.g., sports medicine or orthopaedist) for either operative or nonoperative treatment. Implementing non-weightbearing status without proper splinting is insufficient in most cases.

4. What is the most important predisposing factor in septic bursitis?
   - **a.** Chronic obstructive pulmonary disease
   - **b.** Diabetes mellitus
   - **c.** Human immunodeficiency virus (HIV)
   - **d.** Trauma

Answer: D. Trauma is the most common predisposing factor in patients who develop septic bursitis.

5. What is the causative organism in the majority of cases of septic bursitis?
   - **a.** Beta-hemolytic streptococci
   - **b.** *Pseudomonas aeruginosa*
   - **c.** *Staphylococcus aureus*
   - **d.** *Prototheca wickerhamii*

Answer: C. *S. aureus* is the most common cause of infectious bursitis.

6. A 42-year-old female without significant past medical history presents with 4 days of edema, mild warmth, and mild erythema in the area of the right olecranon bursa. She is afebrile and has minimal tenderness to palpation of the bursa. Aspiration of the bursa reveals a white blood cell count of 1500/μL.[3] What is the most appropriate next step in the patient's management?
   - **a.** Admit for intravenous (IV) antibiotics.
   - **b.** Apply a compression dressing and give ibuprofen.
   - **c.** Discharge the patient to home with oral antibiotics.
   - **d.** Obtain magnetic resonance imaging (MRI) for further evaluation.

Answer: B. The clinical presentation and results of the fluid analysis highly suggest a nonseptic bursitis. Cases of nonseptic bursitis can be managed with a compressive dressing, nonsteroidal antiinflammatory drugs (NSAIDs), avoidance of local trauma, and close follow-up.

104

Musculoskeletal Back Pain

Susan E. Farrell and Zheng Ben Ma

KEY CONCEPTS

- Most patients presenting to the emergency department (ED) with back pain have uncomplicated musculoskeletal pain that is self-resolving with conservative therapy and does not require imaging.
- Indications for emergent imaging include "red flags" such as an acute neurologic deficit, bowel or bladder dysfunction, or saddle anesthesia.
- Risk factors for compressive myelopathy include immunocompromised patients with a history of malignancy, injection drug use, fever, chronic steroid or anticoagulant use.
- Back pain due to metastatic disease is more common than primary tumors in the spine, and thoracic metastases are more common than lumbar metastases.
- Epidural abscess or hematoma, cauda equina syndrome (CES), spinal malignancy with compressive symptoms, and spinal osteomyelitis are all indications for emergent surgical consultation or transfer to a center where surgical spine consultation is available.
- Empirical parenteral antibiotics active against staphylococci, streptococci, and gram-negative bacilli should be administered for suspected epidural abscess. Specific antibiotics should be directed against the known pathogen if the culture or Gram stain of the aspirate is positive.
- Corticosteroids given as a single dose in the ED (10 mg dexamethasone) or as a 15-day tapering course after discharge (prednisone 60 mg, 40 mg, 20 mg daily for 5 days each) may improve functional ability but does not improve nerve root pain secondary to disc herniation.

FOUNDATIONS

Background

Back pain is one of the most common patient complaints encountered in emergency departments (EDs). Most cases of musculoskeletal back pain are related to physical motion of the vertebrae, intervertebral discs, or musculature of the back; however, a precise pathoanatomic etiology and diagnosis is identified in only 10% of cases.[1] As a result, the symptom of back pain can present the emergency clinician with a challenging diagnostic dilemma. Although most cases of acute or acute-on-chronic back pain are due to uncomplicated musculoskeletal causes, certain types of back pain are true emergencies requiring timely diagnosis and intervention. It is critical to distinguish between the large number of benign presentations of self-limited pain versus less common, high-morbidity causes of back pain that require immediate intervention.

Epidemiology

Back pain occurs in children and adults, females and males, with a lifetime prevalence in adults of 60% to 80%.[2] Total direct health care costs and indirect economic expenses associated with back pain are estimated to be in the tens of billions of dollars annually in the United States.[1-2] Risk factors associated with the development of back pain are numerous and include repetitive lifting and twisting movements, prolonged static (seated) postures, obesity, smoking, and psychosocial factors, such as anxiety and depression.[3]

Anatomy and Physiology

The spine consists of seven cervical, twelve thoracic, five lumbar, and five fused sacral and coccygeal vertebrae. The vertebrae articulate with each other superiorly and inferiorly at bilateral facet joints, creating four facet joints at each vertebral level. The thoracic vertebral bodies also have bilateral rib facets, which articulate with twelve pairs of ribs. Each vertebral body has bilateral transverse processes and a spinous process. Between the spinous process and the transverse processes are the lamina, and between the transverse processes and the posterior aspect of the vertebral body are the pedicles. Together, the pedicles and lamina form the neural arch, which, along with the posterior aspect of the vertebral body, forms the confines of the vertebral canal that contains the spinal cord and nerve roots. At each level, there are intervertebral (neural) foramina, where the spinal nerves exit.

Between the vertebral bodies are the intervertebral discs, which provide elasticity and stability to the spine. Each disc is comprised of the outer annulus fibrosis, a ring of fibrous tissue, and the collagenous inner nucleus pulposus. The spinal column is connected and stabilized by a network of spinal ligaments including anterior longitudinal ligament (ALL), the posterior longitudinal ligament (PLL), and the ligamentum flavum.

The spinal cord runs superiorly from the foramen magnum, inferiorly to the L1 to L2 interspace, but may extend as low as L3, where it then divides into the cauda equina. The cord is surrounded by three membranes: the tough dura mater, and the delicate arachnoid and pia mater (referred to as the leptomeninges). Cerebrospinal fluid bathes the spinal cord between the arachnoid and pia mater. The epidural space, between the bony vertebral canal and the dura, contains connective tissue padding and the spinal venous plexus. The dural sac ends between S1 and S3. The dura also protects the spinal nerve roots as the nerves exit the spine at each level, just below the correspondingly numbered vertebral body. The movements of the spine are governed by four groups of muscles: posterior extensor muscles of the back; forward flexors of the abdominal wall and the psoas and iliacus; lateral flexors, consisting of the quadratus lumborum, assisted by abdominal wall muscles; and rotators, which are a combination of the extensors and lateral flexors used with unilateral movements.

Pathophysiology

Nonspecific or Uncomplicated Back Pain

In as many as 90% of patients with back pain, no pathologic cause for the symptom can be identified.[1] Research indicates that in many instances

of nonspecific pain, factors that increase spinal loading pressure such as obesity and musculoskeletal dysfunction, also reduce spinal stability. Static postures that reduce lateral flexor flexibility and restrict hamstring range of motion contribute to reduced core muscle strength and inadequate support of the spinal column. Weakened core muscles, including those of the anterior abdominal wall, threaten the stability of the remaining muscular and ligamentous spinal support structures, placing patients at risk for activity-related strain.[3] Patients with nonspecific muscular back pain typically have localized pain without radicular symptoms.

Nerve Root Syndromes

Nerve root syndromes comprise a heterogenous group of disease processes that can present with similar clinical symptoms and signs. These syndromes result when there is compression or irritation of a nerve root, causing pain or paresthesias that often radiate into an extremity. Nerve root irritation may occur as the result of muscle tightness or intervertebral disc herniation; however, it can also be caused by pathologies that require urgent diagnosis and management. Therefore, nerve root syndromes should be carefully evaluated to avoid misdiagnoses of etiologies that require emergent intervention. There are multiple possible etiologies for nerve root syndromes. Three major etiologies are discussed in detail here.

With age, intervertebral discs desiccate and degenerate and the nucleus pulposus can herniate through the annulus fibrosis, compressing the nerve root at the neural foramen. Conversely, the annulus fibrosis itself can tear without a true herniation of the nucleus pulposus, also resulting in nerve root irritation. Herniations tend to occur at the L4 to L5 and L5 to S1 levels. This is because most flexion and extension of the spine occurs at the lumbosacral joint and to a lesser degree at L4 to L5, and the supporting PLL is relatively weak at this level of the spine. Although most disc herniations are posterolateral, causing unilateral symptoms, intervertebral discs sometimes herniate centrally, at the level of the cauda equina, causing severe compression of multiple nerve roots, resulting in cauda equina syndrome (CES), as discussed in the following.

Nerve root compression can also be caused by spinal stenosis. Aging causes intervertebral disc space narrowing and deterioration of spine joints. Osteophytes can form at the facet joints, and the ligamentum flavum calcifies over time. These degenerative changes can narrow both the neural foramina and the central canal, causing nerve root compression from osteophytes and increased intrathecal pressure in the narrowed canal. The subsequent pain is often bilateral, unlike that caused by disc herniation. Spinal stenosis also results in leg pain that is typically worse while walking and relieved with forward flexion (thus reducing pressure on the nerve root). This historical information is referred to as the *pseudoclaudication sign*.

Epidural space occupying lesions can also cause compression to nerve roots or to the cauda equina. Spinal epidural abscesses or hematomas causing nerve compression are true emergencies. Spinal epidural abscesses can result from hematogenous spread of bacteria (often staphylococcal species), in the setting of injection drug use, or from direct inoculation after epidural steroid injection or spinal surgery. Epidural hematomas can result from instrumentation of the epidural space or spinal surgery, although they can also develop spontaneously or following trauma in anticoagulated patients. Regardless of the cause, epidural space lesions causing nerve root compression requires emergent imaging and consultation.

Skeletal Causes of Back Pain

Common bony causes of back pain include fractures, infection, and malignancy.

Fractures may occur in any part of the spine secondary to trauma (see Chapter 35). Although a significant amount of force is required to fracture the bones of a normal spine, patients with osteopenia can incur bony fractures with minor trauma. Age-related osteopenia can result in vertebral compression fractures, causing sudden acute back pain with or without trauma. Spontaneous compression fractures occur most commonly within the thoracic or lumbar vertebral bodies. Vertebral fractures may cause radicular symptoms, depending on the location of the injury and impingement on the spinal canal or nerve roots.

Osteomyelitis of the spine is generally caused by hematogenous spread and seeding of the bone by bacteria, resulting in inflammation of the bone and periosteum, and subsequent pain. Injection drug use, spinal surgery, and tuberculosis of the spine (Pott disease), can all cause vertebral osteomyelitis.

Cancer of the vertebral bones is due to primary or metastatic lesions. Primary tumors, such as Ewing sarcoma, multiple myeloma, and osteosarcoma, are less common and usually occur in patients younger than 30 years old, often involving the posterior vertebral elements. Metastatic tumors typically involve the vertebral body and are most common in the thoracic spine, but multiple levels can be affected. Lung and breast cancers make up over 50% of metastatic spinal lesions. Lymphoma, melanoma, cancers of the gastrointestinal (GI) tract, prostate, and kidney, and multiple myeloma may also present as metastatic spinal lesions.

Skeletal back pain can also be caused by nontraumatic congenital or acquired abnormalities of the spine. Spondylolisthesis, or slippage of one vertebral body on another, results from degenerative changes but can also occur after trauma. Retrolisthesis occurs with the posterior slippage of one vertebral body on another. Facet arthropathy is an age-related degenerative cause of skeletal back pain. Inflammatory arthropathies, such as ankylosing spondylitis, rheumatoid and osteoarthritis, can cause similar spinal changes, including pathologic fractures.

CLINICAL FEATURES

History

A thorough history and a directed physical examination is essential in evaluating patients with back pain. Although nonspecific uncomplicated back pain is common, it is critical that emergency clinicians elicit historical information that indicates a higher risk of compressive myelopathy, including history of cancer, unexpected weight loss, trauma, chronic steroid use, anticoagulation, fever, an impaired immune system, injection drug use, or spinal surgery. It is important to assess for "red flag" findings that require emergent evaluation and intervention, such as bowel or bladder dysfunction, saddle anesthesia, and acute neurologic deficits such as bilateral extremity weakness. Important historical data concerning the pain includes: the onset, location, character, severity, duration and radiation of the pain (such as to the abdomen, chest or extremities).

Aggravating and alleviating factors are also important to elicit. Pain that is exacerbated by coughing, sneezing, or bearing down with bowel movements, all of which increase intrathecal pressure, may be associated with a radicular or spinal cause. Pain that is worse with walking or prolonged standing, particularly if relieved by bending forward, suggests spinal stenosis. Pain associated with stiffness that is worse in the mornings and improves through the day suggests a rheumatic etiology. In contrast, pain that is improved with rest is more likely to be muscular or skeletal in nature.

Prior history of back pain, medical or surgical history, and any traumatic events should be documented. Any history of malignancy, or systemic symptoms such as fever, chills, or malaise may indicate metastatic or infectious causes. A history of spinal procedures or surgery should be elicited. Medications such as anticoagulants (associated with epidural hematoma) or chronic corticosteroids (associated

with osteopenia) should be reviewed. A family history of autoimmune inflammatory diseases or malignancy may be contributory.

The patient should be asked about any neurologic findings that indicate serious pathology of the spine or nerve roots. These symptoms include sensations of numbness or paresthesias, pain in other locations of the spine, bowel or bladder dysfunction, or weakness in the extremities.

Physical Examination

A directed physical examination with the patient undressed is important in evaluating patients with back pain. The examination should include inspection, observation of the patient's normal movements, palpation, strength and sensory testing, specific maneuvers to assess for serious pathology, and an assessment of deep tendon reflexes. Inspect the overlying skin for erythema, warmth, or areas of swelling, noting any evidence of prior spine surgery or scoliosis. Observe the patient's general appearance including the presence of jaundice, rashes or contusions, and the patient's degree of discomfort. Observe the patient's gait and balance while ambulating. Because core and postural muscle dysfunction contributes to back pain through muscle inflexibility and tightness, range of motion should be tested in several planes.[3] Assess range of motion through flexion and extension at the waist, lateral flexion, and rotation. Palpate the spine to identify areas of maximal tenderness or the presence of muscle spasm.

Perform thorough neurologic testing for strength and sensation. Strength testing of the lower extremities is best done with the patient standing. Instruct the patient to flex both hips and knees, assuming a partial sitting or squatting position. Ask the patient to lift one leg briefly, then the other. Assess heel and toe walking (while holding the examiner's hands). Performing this activity requires full plantar and dorsiflexion strength, because the entire body weight is carried on a single extremity. If the patient is unable to comply with this approach to strength testing because of pain, this assessment can be performed with the patient reclining, although it is less reliable. Sensory testing is done with the patient reclining or sitting. Testing should include both upper and lower extremities, since some conditions, such as spinal stenosis, may occur at multiple spinal levels, including the cervical spine.

Straight leg and contralateral straight leg raise maneuvers are important in identifying radicular pain. The straight leg raise test is more sensitive but less specific than the contralateral straight leg raise test for the diagnosis of radiculopathy due to disc herniation.[4] The straight leg raise test is performed as follows:

- Position the patient supine with legs passively extended, without engaging the quadricep muscles. (This can be determined by noting that the patella can move freely side to side.)
- Raise each leg, flexing at the hip with the knee in extension.
- A positive test is elicited when pain is reproduced, radiating from the back to a point *below* the knee of the raised leg at 30 to 40 degrees of elevation. A positive result predicts lumbosacral radiculopathy with a high sensitivity though a relatively low specificity.[5]

Because L5 or S1 discs are implicated in the majority of disc herniations, a negative straight leg raise test is reassuring in ruling out disc pathology. Of note, radiation of pain from the back to the area of the posterior knee or above is a nonspecific finding and of less clinical value.

The contralateral straight leg raise test is performed in an identical manner. A positive test is elicited when pain is reproduced that radiates below the knee of the *contralateral* leg (the leg that is not being raised). Converse to the standard straight leg raise test, the sensitivity of the contralateral test for disc herniation is low, but the specificity is high. A positive contralateral straight leg raise test strongly suggests disc pathology at the L5 or S1 levels. In summary, if the straight leg raise test is positive, a positive contralateral straight leg raise test can be considered confirmatory of the presence of disc impingement. If the straight leg raise test is negative, but the contralateral straight leg raise is positive, disc herniation or impingement is still highly likely.

Further assessment can provide additional information. Assess the patellar and Achilles deep tendon reflexes, and the plantar reflex. Hyperreflexia, clonus, or a Babinski sign (positive plantar reflex) suggests upper motor neuron pathology, such as a cord impingement. Perineal sensation and anal sphincter tone should be assessed in patients with bilateral symptoms or findings, gait disturbance, severe pain, complaints consistent with saddle anesthesia, or bowel or bladder dysfunction. The cauda equina syndrome is a spinal cord compression below the termination at the conus medullaris (L1–L2) and loss of function of the lumbar plexus. The S3, S4, and S5 dermatomal nerves innervate the "saddle" region and compression causes numbness or tingling to the perineum, anus, and genitalia. Decreased rectal muscle tone may cause loss of bowel function. Bladder dysfunction due to an inability to urinate generally presents as overflow incontinence as a result of urinary retention.

Finally, because pain from abdominal or pelvic pathology often radiates to the back, a thorough abdominal examination, including an assessment of costovertebral angle tenderness and, when indicated, a prostate or gynecologic examination should be performed to exonerate non-musculoskeletal causes of low back pain.

DIFFERENTIAL DIAGNOSES

Table 104.1 lists various causes of low back pain and historical findings that are suggestive of specific etiologies. In constructing the differential

TABLE 104.1 Historical Clues to the Cause of Low Back Pain

Questions for Patient	Potential Diagnosis
Does the back pain radiate down past the knees?	Radiculopathy and possible herniated disk
Is the pain worse with walking and better with bending forward and sitting?	Spinal stenosis
Do you have morning back stiffness that improves with exercise?	Ankylosing spondylitis
Are you older than 50 years old?	Osteoporotic fracture, spinal malignancy
Has there been any recent history of blunt trauma?	Fracture
Do you take long-term corticosteroids?	Fracture, spinal infection
Do you have a history of cancer?	Spinal metastatic malignancy
Does your pain persist at rest?	Spinal malignancy, spinal infection
Has there been persistent pain for longer than 6 weeks?	Spinal malignancy
Has there been unexplained weight loss?	Spinal malignancy
Is the pain worse at night?	Spinal malignancy, spinal infection
Are you immunocompromised?	Spinal infection
Have you had fevers or chills?	Spinal infection
Do you have pain, weakness, or numbness in both legs?	CES
Do you have bladder or bowel control problems?	CES

CES, Cauda equina syndrome.

diagnoses of musculoskeletal back pain, the emergency clinician should incorporate key findings of the history and physical examination to assess the likelihood of common, nonspecific uncomplicated back pain, while determining the presence of serious findings that are associated with specific pathoanatomic etiologies that require urgent evaluation and intervention (Table 104.2).

Other nonmuscular life-threatening pathologies which cause back pain should be considered. As an example, patients with vascular disease can present with seemingly innocuous back pain, but this may be an early warning symptom of an abdominal aortic aneurysm or thoracic aortic dissection. Gastrointestinal, pelvic, and genitourinary causes of back pain should also be assessed and excluded.

DIAGNOSTIC TESTING

Most patients presenting with back pain have nonspecific uncomplicated musculoskeletal back pain that does not require diagnostic testing. When clinical suspicion exists for a concerning etiology, or red flags are noted on either history or physical examination, diagnostic testing is warranted to identify causes of back pain that require urgent or emergent intervention.

Laboratory Testing

Laboratory testing is generally not indicated for low back pain and when performed is often adjunctive to specific diagnostic imaging. An abnormal white blood cell count (WBC), erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) may suggest an infectious or inflammatory etiology. For example, while the presence of an elevated ESR is not specific, it should increase the suspicion of spinal epidural abscess, osteomyelitis, or discitis. Marked elevations in the ESR and CRP are often due to infection, but noninfectious disorders such as malignancy, chronic or inflammatory disease, trauma, and tissue ischemia should also be considered. The presence of elevated inflammatory markers should prompt diagnostic imaging.

Coagulation testing is indicated for patients on long-term warfarin; however, the value of coagulation studies has diminished with the increasing prevalence of direct oral anticoagulant (DOAC) use. If coagulation studies are abnormal in the setting of low back pain, epidural or retroperitoneal bleeding should be explored. Urinalysis, and urine pregnancy testing in female patients, can be useful in establishing nonmusculoskeletal causes of back pain, such as nephrolithiasis, pyelonephritis or pelvic etiologies.

Imaging Studies

The vast majority of patients with self-limited, nonspecific back pain do not require emergent diagnostic imaging.[6] Routine imaging for low back pain is not associated with improved patient outcomes and abnormalities, if found, are often incidental and not necessarily the cause of the presenting symptoms.[7] Therefore, emergent imaging in the setting of acute back pain should be reserved for patients with suspected diagnoses that would necessitate emergent intervention. Signs, symptoms, and historical features that should lead the clinician to consider imaging studies are provided in Box 104.1.

Point-of-Care Ultrasound

Bladder dysfunction as a result of cauda equina syndrome can be evaluated by post-void ultrasonographic measurement of bladder volume. A completely normal bladder should have about 20 mL of residual urine after voiding. In adults, 100 mL of residual urine is considered to be an abnormal level; in children, a residual urine volume in excess of 10 per cent of bladder capacity is also considered abnormal.

Plain Radiographs

Clinicians may obtain plain radiographs when there is concern for spontaneous compression fractures in patients with osteopenia and nontraumatic back pain. The sensitivity of plain radiographs is inadequate to safely exclude traumatic injuries, whether in elderly patients with minor trauma, in patients with major trauma, or in presentations that are suggestive of pathoanatomic etiologies. In these scenarios, more accurate, advanced diagnostic imaging should be performed.

Computed Tomography

Computed tomography (CT) is superior to plain radiographs in delineating the nature and extent of acute fractures. As compared to MRI, CT also has superior sensitivity in detecting cortical bone abnormalities and is preferable to MRI for the evaluation of acute bony injuries. Therefore, when there is a high pretest probability of vertebral fracture, CT imaging is warranted. In a multitrauma patient undergoing CT scans of the head, neck, chest, abdomen, and pelvis (or whole-body CT "pan-scans"), CT images can be reconstructed to facilitate the evaluation of the spine.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the test of choice for evaluating the spinal cord and surrounding structures, including the canal, intervertebral discs, soft-tissue ligaments, and the epidural space. MRI defines the bony anatomy but is more sensitive and specific than CT in defining soft tissues and neural structures, such as the conus medullaris and spinal nerve roots within the canal and neural foramina. MRI can delineate epidural hematoma or abscess, herniated disc, ligamentous

TABLE 104.2 Physical Findings Corresponding to Herniated Disc Location

Level	Pain Location	Motor Loss	Sensory Loss	Reflex Loss
L3	Front of leg	Hip flexion and knee extension	Anterior thigh, medial calf	Loss of patellar
L4	Front of leg	Leg extension at knee	Around knee	Loss of patellar
L5	Side of leg	Foot dorsiflexion	Web of big toe	None
S1	Back of leg	Foot plantar flexion	Lateral foot	Loss of Achilles

BOX 104.1 Possible Indications for Advanced Imaging in the Setting of Back Pain

History
- History of malignancy or unexplained weight loss
- Fever with localized back pain
- Immunocompromised status
- History of injection drug use or bacteremia
- History of anticoagulant use
- Trauma of high force relative to patient
- History of recent spinal procedure or surgery

Physical Examination
- New weakness of extremities
- Sensory level or saddle anesthesia
- Abnormal reflexes, including positive Babinski sign
- Urinary retention or incontinence with post-void residual volume >100 mL
- Sphincter dysfunction: loss of sphincter tone or bowel incontinence

injury, and spinal stenosis, and it is the test of choice for diagnosing osteomyelitis. MRI is also the imaging study of choice in evaluating spinal infection and malignancy. Emergent MRI is indicated for suspected CES, epidural hemorrhage, or back pain accompanied by new neurologic findings in oncology patients. MRI is superior to plain radiographs or CT when determining the acuity or chronicity of a fracture. Contrast administration provides little additional information to MRI imaging except in the evaluation of possible intraspinal infection or metastasis.

When imaging to evaluate spinal cord lesions, it is important to clarify the possible level of the lesion. A thorough neurologic examination that includes the upper extremities may be used to exclude the need for cervical spine imaging. However, it is important to remember that spinal processes, such as malignancy or stenosis, can occur simultaneously in several levels, and the region of pain may not always correspond to the lesion causing a neurologic deficit, requiring imaging of the spine above or below the suspected affected area.

Computed Tomography Myelogram

Myelography is rarely performed in the emergency department setting and is generally indicated for patients who require advanced imaging but are unable to undergo MRI. Emergency clinicians should discuss the indications with their consulting radiologist and spine specialist before ordering this diagnostic study.

MANAGEMENT

Figure 104.1 presents a detailed algorithmic approach to ED management of patients with low back pain based on physical or ancillary test findings.

Nonspecific or Uncomplicated Back Pain

Emergency department management of acute or exacerbations of chronic back pain consists of supportive care, including patient reassurance and education and symptomatic relief. Current management guidelines for the treatment of patients with acute nonspecific back pain include attention to patient self-care and behavior modification, physical activity, and oral and topical analgesia.[8,9] Patients whose evaluations do not reveal red flags in history or physical examination should be given reassurance about the likely recovery from muscular back pain. Patients should be given advice and education about an early return to normal activities as tolerated, while avoiding heavy lifting or repetitive strenuous twisting movements. Physical activity, whether gentle exercise therapy or postural rehabilitation, has been shown to ease pain and facilitate recovery in both acute and chronic back pain. This approach also offers additional benefits of improving disability and mental health in those with nonspecific lower back pain.[8-11] Furthermore, those who use exercise to facilitate recovery are predicted to have better functional outcomes over time than those who do not exercise or use bedrest to help recovery.[11]

Topical therapies are a reasonable initial approach alone or in combination with pharmacologic treatment to offer symptomatic relief in uncomplicated back pain. Application of heat has been weakly recommended for short-term improvements in pain.[11,12] Topical capsicum or its derivative capsaicin has also demonstrated some relief in neuropathic pain, including neuropathic back pain due to lumbosacral radiculopathies.[13,14] Alternatively, transdermal application of lidocaine, whether in medicated gels, ointments, or more often in patches or plaster, has also gained increasingly widespread use. Despite the popularity of these topical agents, relatively little high-quality evidence exists for their definitive recommended use in low back pain.[11] Nonetheless, its

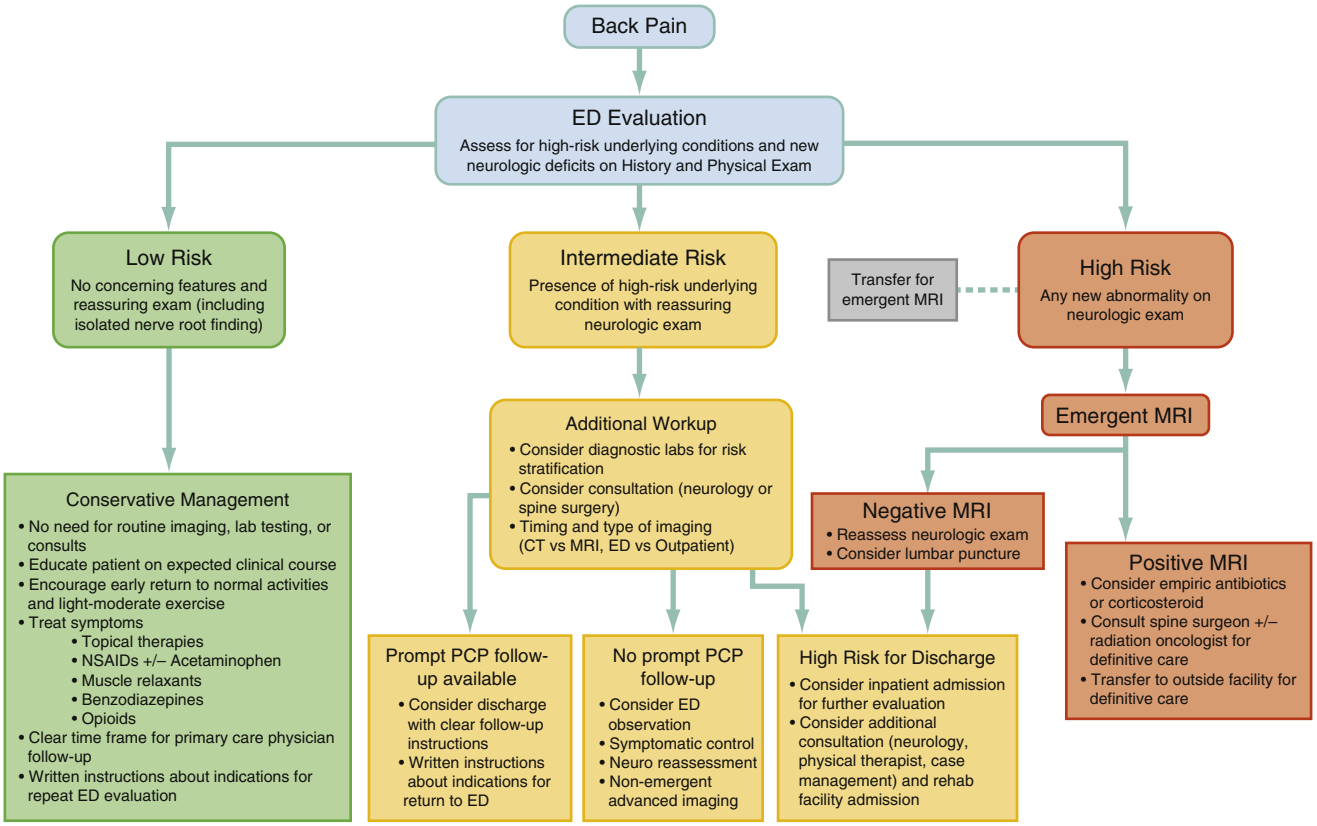

Fig. 104.1 Algorithmic approach to emergency department (ED) management of low back pain. *MRI,* Magnetic resonance imaging; *NSAID,* nonsteroidal antiinflammatory drug; *PCP,* primary care physician.

low incidence of serious adverse effects confers a clinical benefit, particularly among the elderly and medically complex.[15]

We recommend oral analgesia consisting of nonsteroidal antiinflammatory drugs (NSAIDs) alternating with or without acetaminophen. A very short course of opioid therapy may be warranted for the treatment of severe acute back pain that limits the patient's normal activity.[16] However, the use of opioid pain medications in treatment of back pain should be cautiously limited.[11-12,16] Combination therapy with NSAIDs and opioids, as compared to NSAIDs alone, does not appear to improve functional outcomes or pain at one-week follow-up.[17] A benzodiazepine may be considered to supplement analgesia when the patient has failed an NSAID regimen or when the pain is causing substantial anxiety or sleep disturbance. However, the available evidence has not demonstrated substantial effects in pain, function, or long-term outcomes.[18,19]

Early return to work, with or without activity restrictions, is associated with better long-term outcomes. Physical therapy, spinal manipulation, and multimodal rehabilitation including acupuncture have not been consistently demonstrated to be superior therapies to the above recommendations.[11,18] Approximately 10% of patients develop long-term chronic pain, often because of contributing psychosocial factors, such as anxiety or depression. Chronic back pain is more likely to develop in patients with psychiatric disorders, obesity, poor overall health status, and nonorganic signs. Development is not associated with demographic variables, prior episodes of back pain, or chronic baseline pain.[20]

In summary, nonspecific uncomplicated etiologies will account for the vast majority of patients who present to the emergency department for back pain. For these patients, the emergency clinician should focus treatment on supportive care including moderate careful exercise, low-risk topical therapies, and educating the patient regarding the self-limited nature of the disease. In those who require pharmacologic therapy, nonsteroidal antiinflammatories and acetaminophen are considered first-line. Abbreviated courses of opioids and benzodiazepines are reserved for those who have failed initial therapy after consideration of the individual's benefits and risks. There is no role for invasive procedures, such as lumbar epidural injections, or certain classes of medications, such as anticonvulsants or antidepressants, for treatment of back pain in the emergency department.

Disc Herniation and Nerve Root Pain

Herniated disks and nerve root pain (often caused by intervertebral disc disease) without neurologic deficits on examination are initially managed similarly to nonspecific uncomplicated back pain. Signs and symptoms that indicate the need for advanced imaging and emergent spine service consultation include acute bowel or bladder dysfunction, new localized motor weakness or progressive leg weakness, and acute worsening of symptoms or findings in patients with known herniated discs and chronic back problems.

Although oral steroids do not have proven efficacy in general acute back pain, there is evidence that a subset of patients with nerve root pain and acute radiculopathy benefit from a single pulse dose of 6 to 10 mg of IV dexamethasone in the ED.[21] Alternatively, a 15-day course of a tapering dose of prednisone (60 mg, 40 mg, 20 mg daily for 5 days each) improves functional ability, but not pain.[20]

Epidural Abscess and Spinal Osteomyelitis

An epidural abscess is a surgical emergency. Emergent spine surgery consultation should be obtained at the treating hospital, or if unavailable, the patient should be transferred to a facility equipped for emergent spine surgery. Empiric antibiotics should be administered to cover suspected pathogens, usually *Staphylococcus, Streptococcus,* and gram-negative organisms. Vancomycin should be included to treat methicillin-resistant *Staphylococcus aureus* (MRSA) infection and pseudomonal coverage should be considered if hematogenous spread is suspected, particularly in immunocompromised patients with diabetes or sickle cell disease. As summarized in Box 104.2, appropriate empiric parenteral antibiotic regimens include:

BOX 104.2 Antibiotic Recommendations for Epidural Abscess and Spinal Osteomyelitis

Recommended Empiric Antibiotics Spinal and Epidural Infections	Regimen	Coverage
Epidural abscess	Vancomycin (loading dose: 20–35 mg/kg actual body weight [not to exceed 3000 mg] or 20–25 mg/kg actual body weight [not to exceed 3000 mg] in patients with obesity, then 15–20 mg/kg actual body weight every 8–12 hours)	Methicillin-resistant *Staphylococcus aureus* (MRSA), methicillin-sensitive *Staphylococcus aureus* (MSSA), and *Streptococcus* species
	PLUS	Anaerobic species
	Metronidazole (500 mg IV every 6 hours)	Methicillin-sensitive *Staphylococcus aureus* (MSSA), *Streptococcus* species, and gram-negative species
	PLUS	Preferred for additional coverage of *Pseudomonas peruginosa*
	Cefotaxime (2 g IV every 4 hours)	
	OR	
	Ceftriaxone (2 g IV every 12 hours)	
	OR	
	Ceftazidime (2 g IV every 8 hours)	
Spinal osteomyelitis	Inpatient Treatment:	Methicillin-sensitive *Staphylococcus aureus* (MSSA)
	Nafcillin (2 g every 4 hours)	Methicillin-resistant *Staphylococcus aureus* (MRSA)
	OR	
	Vancomycin (30–60 mg/kg IV per day in two equally divided doses adjusted for renal function)	
	Outpatient Treatment:	Aerobic gram-negative organisms including *Pseudomonas aeruginosa* and *Salmonella* species
	Ciprofloxacin (750 mg PO two times a day)	Second-line for aerobic gram-negative organisms
	OR	
	Trimethoprim-sulfamethoxazole (1–2 DS twice a day)	

- Vancomycin (30 to 60 mg/kg IV per day in two equally divided doses adjusted for renal function) for empirical coverage of MRSA

plus

- Metronidazole (500 mg IV every 8 hours)

plus

- Either cefotaxime (2 g IV every 6 hours), ceftriaxone (2 g IV every 12 hours), or ceftazidime (2 g IV every 8 hours); ceftazidime is preferable when *Pseudomonas aeruginosa* is considered a possible or likely pathogen.

Spinal osteomyelitis is treated with antibiotics (with similar broad-spectrum coverage to that of epidural abscess) in conjunction with spine surgery consultation. Surgical intervention may be less emergent than in the case of epidural abscess as long as there is no compression on the spinal cord or a purulent fluid collection. Whenever possible, antibiotic therapy should be delayed in stable patients until tissue cultures can be obtained. If tissue culture is not obtainable and in advance of tissue culture results, broad-spectrum empiric therapy should be administered (see Box 104.2). These empiric antibiotics commonly include:

- Inpatient treatment:
  - Nafcillin (2 g every 4 hours) for methicillin-sensitive *Staphylococcus aureus* (MSSA) coverage *or*
  - Vancomycin (30 to 60 mg/kg IV per day in two equally divided doses adjusted for renal function) for empirical coverage of MRSA *or*
  - Cefepime (2 g IV every 8 hours) for gram-negative and *Pseudomonas* coverage
- Outpatient treatment:
  - Ciprofloxacin (750 mg by mouth BID) *or*
  - Trimethoprim-sulfamethoxazole (1 double-strength tablet twice daily)

Epidural Hematoma

An epidural hematoma is a surgical emergency. Emergent spine surgery consultation should be obtained at the treating hospital, or if unavailable, the patient should be transferred to a facility equipped for emergent spine surgery. Patients who are anticoagulated should have their anticoagulation reversed as described in Chapter 111.

Cauda Equina Syndrome

CES, when suspected, requires rapid confirmation by emergent MRI and emergent surgical decompression. Whenever possible, spine surgery consultation should be obtained in parallel with imaging to facilitate definitive treatment. Although prompt surgery provides the best opportunity for a good outcome, some patients may not recover function after decompressive surgery. In consultation with the spine specialist, surgical intervention may be deferred in patients with long-standing or chronic symptoms of CES. Emergent administration of intravenous corticosteroids should also be determined by the treating spine surgeon.

Malignancy

Patients who are diagnosed with a compressive malignant lesion of the spine or spinal cord may benefit from emergent corticosteroids to reduce the severity of any mass effect. Once this diagnosis is made, patients with neurologic deficits should receive a single dose of 10 mg intravenous dexamethasone in the ED.[22] The ameliorative effects of corticosteroids are transient, however, and prompt consultation with spine surgery and radiation oncology specialists is imperative to consider surgical decompression or directed radiation therapy.

Fracture

The management of acute traumatic spinal fractures is extensively discussed in Chapter 35.

DISPOSITION

Most patients presenting to the ED with acute back pain will be discharged with symptomatic treatment and an appropriate outpatient follow-up plan. As mentioned previously, patient reassurance and education about muscular back pain, in conjunction with oral and topical analgesics, are foundations of care. Patients with back pain thought to be secondary to a herniated disc with no neurologic findings should have prompt follow-up with a primary care physician or a spine surgeon.

Patients with suspected radiculopathy should be given clear return precautions, including the development of weakness, inability to stand or ambulate, saddle anesthesia, or bowel or bladder dysfunction. Patients who require emergent surgical intervention for spinal epidural abscess, compressive neoplasm, osteomyelitis, fracture, or other compressive spine lesions should be emergently transferred to the care of a spine surgeon, which may involve transfer to a tertiary or quaternary care center.

Patient transfer may be necessary if emergent spine surgery is not present at the treating facility or if emergent MRI is not available to image patients with suspected emergent infectious or compressive pathologies. Patients believed to have an epidural abscess or osteomyelitis should receive empiric parenteral antibiotics prior to transfer. Patients with findings consistent with CES or other compressive lesions due to malignancy should receive parenteral steroids prior to transfer if ordered by the receiving physician or the onsite consultant.

CHAPTER 104: QUESTIONS AND ANSWERS

1. A 55-year-old man presents with low back pain for one month. The pain is worse at night and is associated with a 10-pound weight loss. He denies any radicular symptoms. Which of the following is the most likely cause of the back pain?

a. Discitis
b. Muscle spasm
c. Osteosarcoma
d. Prostate cancer
e. Sciatica

Answer: D. The patient's subacute time course of back pain and worrisome finding of weight loss suggest a malignancy. Primary and metastatic bone neoplasms can cause back pain from tumor infiltration into the bone. Primary bone tumors, such as multiple myeloma, chordoma, Ewing sarcoma, and osteosarcoma, are 25 times less frequent than metastatic disease. Of the neoplasms, breast, lung, prostate, thyroid, lymphoma, and kidney are the most likely to metastasize to bone.

2. Which one of the following findings, in conjunction with low back pain, indicates a benign cause of pain?

a. Age of six years
b. Fever and night sweats
c. Negative sitting but positive supine straight leg raise test
d. Post-void residual of 500 mL
e. Saddle anesthesia

Answer: C. A positive supine SLR test but a negative sitting SLR test suggests a nonphysiologic cause for the pain. Low back pain and fever suggest an epidural abscess or osteomyelitis. Saddle anesthesia and post-void residual greater than 100 mL are indicative of cauda equina syndrome (CES). Children complaining of back pain must be investigated. They may have spondylolysis with varying degrees of spondylolisthesis, Scheuermann disease (kyphosis and osteochondritis of the vertebral end plates), infectious diseases, or neoplastic etiologies.

3. To avoid injuring the adult spinal cord, at what level should a lumbar puncture be performed?

a. L1 to L2
b. L3 to L4
c. L5 to S1
d. S2 to S3
e. Coccyx

Answer: B. The spinal cord ends at around L2 in adults, lower in children. When performing a lumbar puncture, to avoid injuring the spinal cord, insert the needle below the conus medullaris at level L3 to L4. Remember that between individuals, there may be significant anatomic variance.

4. A 55-year-old man complains of low back pain when walking downhill that is relieved with walking uphill. His neurovascular examination is unremarkable except for decreased bilateral Achilles reflexes. In addition to analgesia, what is the appropriate management of this patient?

a. Bedrest
b. Emergent spine surgery consultation
c. Lumbosacral plain radiographs
d. Magnetic resonance imaging
e. Surgical referral for pseudoclaudication

Answer: E. This patient presents with typical complaints of spinal stenosis. Patients with spinal stenosis should be managed conservatively with pain medications. In the absence of alarming red flag findings, these patients do not require emergent laboratory or radiographic studies. These patients may be candidates for surgery if they show any

CHAPTER 104: QUESTIONS AND ANSWERS—cont'd

of the following conditions: progressive neurologic deficit, progressive reduction in ability to walk secondary to pseudoclaudication, evidence of cauda equina syndrome (CES), or intractable pain.

5. Which of the following findings is most consistent with cauda equina syndrome (CES)?
   a. Absent patellar reflexes
   b. Bilateral buttock pain
   c. Decreased rectal tone
   d. Saddle anesthesia
   e. Urinary retention

Answer: E. The most consistent examination finding in CES is urinary retention. With a high sensitivity of 90%, the patient is unlikely to have this disease process if his or her post-void residual urine volume is less than 100 to 200 mL. Saddle anesthesia (sensory deficit over the buttocks, upper posterior thighs, and perineal area) is frequently an associated finding, with a sensitivity of 75%. In 60% to 80% of cases, the rectal examination reveals a decreased sphincter tone.

6. A 42-year-old man presents to the emergency department (ED) with a four-day history of low back pain after an episode of heavy lifting at work. He reports bilateral low back pain at the level of the iliac crests. He denies sensory or motor symptoms. He also denies bowel or bladder dysfunction. His neurologic examination is normal. What management is indicated?
   a. Erythrocyte sedimentation rate (ESR)
   b. Lumbar spine MRI
   c. NSAIDs and gentle stretching
   d. Oxycodone for three weeks
   e. Strict bedrest for two weeks

Answer: C. The patient most likely suffers from uncomplicated musculoskeletal low back pain. This is also commonly called *acute lumbosacral strain.* Most patients with this injury should not be placed on bed rest and should be allowed to return to normal activity, possibly with some restrictions. The patient has a relatively short history of low back pain with clear onset around an episode of lifting. Given a lack of concerning historical or examination findings, the patient does not require imaging at this time. Blood work would not be of help in evaluating the patient, because he lacks history or examination findings consistent with spinal infection.

7. A 35-year-old woman presents with a 3-day history of severe right lower extremity pain associated with mild low back pain. Her neurologic examination is normal except for a positive straight leg raise (SLR) test on the right and a negative contralateral straight leg raise (CSLR) test on the left. What therapy is indicated?
   a. Anxiolytic medication
   b. High-dose corticosteroids
   c. NSAIDs and gentle stretching
   d. Oxycodone for three weeks
   e. Strict bedrest for two weeks

Answer: C. Patients with herniated lumbar disks often present with radicular leg pain that overshadows the complaint of back pain. The treatment of radicular pain syndromes without neurologic deficit is similar to that of nonspecific uncomplicated back pain: NSAIDs and gentle stretching. It is very common for a patient with lumbar radiculopathy to have no clear motor or sensory deficit but have exacerbation of leg pain with SLR testing. The SLR has high sensitivity but low specificity. In contrast, the CSLR test has high specificity but low sensitivity. Given this, it is common for the patient with lumbar disk herniation to have a positive SLR but negative CSLR. The reverse is very uncommon. Diagnoses (such as spinal epidural abscess and spinal malignancy) usually present with prominent low back pain that is more significant than extremity pain.

8. A 68-year-old man presents with a 5-week history of worsening low back pain. He reports mostly midline spinal pain with occasional radiation into both lower extremities. Two weeks before the onset of his pain, he was discharged from the hospital after an inpatient admission for pneumonia. On examination, he has intact lower extremity motor and sensory function but tenderness to percussion over the lumbar spine. What diagnostic evaluation will confirm the diagnosis?
   a. Complete blood count
   b. Contralateral straight leg raise test
   c. Erythrocyte sedimentation rate (ESR)
   d. Lumbar computed tomography (CT)
   e. Lumbar magnetic resonance imaging (MRI)

Answer: E. The patient's history is suspicious for spinal epidural abscess. He is at higher risk because of his age and recent infection. In addition, the patient has tenderness with percussion of his spine. The optimal diagnostic evaluation to confirm this diagnosis is MRI. Patients with epidural abscess usually have an ESR elevated above 20 mm/hr. However, it is not uncommon for them to have a normal or only mildly elevated WBC count.

9. A 63-year-old man presents with a 9-month history of progressive low back pain with ambulation. He reports significant pain in his buttocks and posterior thighs when he walks distances greater than 25 meters. He says the pain is partially relieved when he flexes forward and completely relieved by recumbency. He reports the pain is not relieved if he stops walking but remains standing. On neurologic examination, he has intact lower extremity strength but diminished Achilles reflexes bilaterally. What is the expected finding on diagnostic imaging?
   a. Diminished Doppler flow in the tibial arteries
   b. Lumbar disc herniation at L5 to S1
   c. Normal lumbar MRI
   d. Post-void bladder volume of 500 mL
   e. Spinal stenosis at L4 through S1

Answer: E. The patient presents with classic findings of spinal stenosis and neurogenic claudication or "pseudoclaudication," including relief with flexing forward and recumbency. Persistence of pain with standing despite having stopped ambulating is also indicative of neurogenic claudication, as are diminished Achilles reflexes. Diminished pulses are indicative of vascular claudication. Pain from vascular claudication is generally relieved if a patient stops walking but remains standing. Unilateral disk herniation does not usually present with bilateral lower extremity symptoms.

Systemic Lupus Erythematosus and the Vasculitides

Eric Shappell and Eli M. Miloslavsky

SYSTEMIC LUPUS ERYTHEMATOSUS

KEY CONCEPTS

- Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder that can affect any organ system. A general approach to determine whether SLE is the cause of a nonspecific or single-organ symptom is to search for evidence of other organ involvement or systemic inflammation, which is expected in SLE-mediated presentations.
- Patients with SLE are at significantly higher risk of coronary artery or thromboembolic disease, which should prompt more thorough evaluation for these etiologies even in otherwise low-risk patients, such as young women.
- SLE itself, as well as its treatment, may lead to immunosuppression; thus, it is important to remain vigilant for the possibility of infection in patients with SLE.
- Glucocorticoids are the mainstay for the initial management of the majority of conditions that are associated with increased SLE disease activity, including musculoskeletal, cutaneous, renal, pleural, or pericardial disease.
- Antiphospholipid antibody syndrome (APS) is common in patients with SLE and carries with it an increased risk of venous and arterial thromboembolic disease.
- Rheumatology input may be helpful in diagnostic, management, or disposition decisions for select patients with SLE.

FOUNDATIONS

Background and Importance

Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder with complex pathophysiology that can affect nearly any organ system in the body. The prevalence of SLE varies by age, gender, geography, and race. Women are the most commonly affected group worldwide, representing approximately 90% of cases. The disease is more common in young people with more than two-thirds of cases diagnosed before the age of 50. In the United States, the prevalence of SLE is higher in African, Asian, and Hispanic Americans compared to Caucasians.

Patients with SLE have an increased risk of mortality (2.6-fold) as compared to the general population.[1] Morbidity and mortality for patients with SLE derive from four processes: (1) organ damage secondary to disease-mediated inflammation (e.g., nephritis, cerebritis, coronary artery disease), (2) hypercoagulability (e.g., stroke, pulmonary embolism), (3) complications of treatment (e.g., infection related to immunosuppression), and (4) increased risk of cardiovascular events. Care for the patient with SLE in the emergency department (ED) hinges on the recognition and treatment of these processes.

Etiology and Pathophysiology

The etiology of SLE is complex and incompletely understood. It appears to be related to multiple factors; genetics, hormones, and environmental factors such as smoking have all been implicated to varying degrees. With women representing 90% of SLE cases, a strong role for estrogen in disease development has been well supported in large cohort studies. The disease also has a strong genetic link, with high rates of monozygotic twin concordance.

The pathophysiology of SLE is mediated by the creation of autoantibodies with a multitude of downstream impacts. These effects include the formation and deposition of immune complexes leading to inflammation and tissue destruction (largely via complement activation) as well as autoantibodies directly targeting cell surface antigens and phospholipids, which may lead to tissue cell death, hemolysis, and hypercoagulability. The pathophysiologic mechanism of SLE may differ for each organ system. The organ systems involved in any given patient's disease may be different and relate to antigen expression in those tissues, among other factors.

CLINICAL FEATURES

Overview

SLE activity follows a relapsing and remitting pattern: acute episodes of increased disease activity ("flares") are separated by periods of stable disease or relative quiescence. The frequency and severity of flares can vary significantly between patients and over time, as can the baseline level of disease activity. While SLE is a chronic condition, it is not necessarily progressive. Whether additional organs become involved and the degree to which previously involved organs are affected is variable.

Recognition of SLE-mediated morbidity can be challenging, as SLE can affect nearly any organ system in the body, and many symptoms of the disease lack specificity. In general, ED presentations for SLE are related to one or more of the following: (1) flares of increased SLE disease activity (e.g., nephritis, arthritis), (2) SLE-mediated hypercoagulability (e.g., stroke, pulmonary embolism), and (3) complications of treatment for SLE (e.g., opportunistic infection due to immunosuppression).

Even with good medication adherence, patients with SLE are prone to flares. SLE flares are typified by worsening physical symptoms from increased organ inflammation and destruction. Flares commonly involve organ systems previously affected by SLE, though new organ systems may also become affected. As a systemic disease, worsening symptoms in one organ system are often associated with evidence of systemic inflammation and, commonly, evidence of disease activity in other organs.

As a general approach, when evaluating whether a symptom is due to SLE, providers should look for other SLE manifestations and biomarkers that can point to active disease, such as those in the Systemic Lupus International Collaborating Clinics (SLICC) Criteria for Systemic Lupus Erythematosus (Table 105.1). Single-organ symptoms without systemic inflammation should prompt consideration of

TABLE 105.1 Systemic Lupus International Collaborating Clinics Criteria for Systemic Lupus Erythematosus[a]

Criteria	Description
Clinical Criteria	
Acute cutaneous lupus	May include acute cutaneous lupus (lupus malar rash, bullous lupus, toxic epidermal necrolysis variant of SLE, maculopapular lupus rash, photosensitive lupus rash) or subacute cutaneous lupus
Chronic cutaneous lupus	Classic discoid rash, generalized hypertrophic (verrucous) lupus, lupus panniculitis, mucosal lupus, others
Oral ulcers	Palate (buccal, tongue) or nasal ulcers
Non-scarring alopecia	Diffuse thinning or hair fragility
Synovitis	Involving two or more joints (swelling, effusion, or tenderness and ≥30 minutes of morning stiffness)
Serositis	Pleural (pleuritis, effusion, rub) or pericardial (pericarditis, effusion, rub)
Renal disorder	500 mg protein/24 h or red blood cell casts
Neurologic disorder	Seizures, psychosis, mononeuritis multiplex, myelitis, peripheral and cranial neuropathies, acute confusional state
Hemolytic anemia	
Leukopenia	<4000/mm^3 at least once
Thrombocytopenia	<100,000/mm^3 at least once
Immunological Criteria	
Anti-nuclear antibody	Any level above the laboratory reference range
Anti-dsDNA	Level above the laboratory reference range (or twofold the reference range if tested by ELISA)
Anti-Sm	Presence of antibody to Sm nuclear antigen
aPL antibody	As determined by a positive test for lupus anticoagulant or anti-2-glycoprotein, false-positive result for rapid plasma regain, medium- or high-titer anticardiolipin antibody level
Low complement	May include C3, C4, or CH50
Direct Coombs test	In the absence of hemolytic anemia

[a]Fulfillment of at least four criteria, with at least one clinical and one laboratory criterion, is required to establish the diagnosis of systemic lupus erythematosus.

pathology other than SLE. It is important to identify when overall disease activity is increased as this signals the need to initiate or escalate systemic therapy. In many cases, patients themselves are able to provide direction about the predictable course of their exacerbations and can be helpful in decision-making for therapy and disposition.

Specific Symptoms

Fever

Fever in a patient with SLE can be related to systemic disease activity, infection (including opportunistic infection related to immunosuppression), or pathology unrelated to SLE. Recurrent fevers without evidence of infection may be the presenting symptom that leads to an initial diagnosis of SLE. Similarly, patients with diagnosed SLE may present with fever as a symptom attributable to a disease flare. Before attributing fever to SLE disease activity, however, care should be taken to exclude acute infection. This is particularly important for patients taking immunosuppressive medications. Most infections in SLE are caused by typical organisms. However, largely because of the immunomodulating therapies that are the cornerstone of SLE management, opportunistic diseases are possible; *Pneumocystis (carinii) jiroveci* pneumonia, cryptococcal meningitis, *Listeria* infection, and herpes zoster have all been described.

Cardiopulmonary Presentations

There is a broad range of cardiac and pulmonary pathology associated with SLE that may present with chest pain or shortness of breath. Given the lengthy differential for this spectrum of presentations and the significant degree of overlapping symptoms for the varied underlying disease processes, an anatomic approach may be useful when working through the differential.

Coronary Artery Disease. As with other systemic inflammatory conditions, there is a significantly increased risk of coronary artery disease (CAD) in patients with SLE. While SLE is associated with higher incidences of traditional risk factors such as hypertension and hypercholesterolemia, the increased risk of CAD persists even after controlling for these factors.[4] Thus, whereas there are many considerations for the cause of chest pain in patients with SLE, acute coronary syndromes (ACS) should be considered highly in these cases, including in patients who would otherwise be deemed low risk (e.g., young women). Coronary disease should also be considered in patients with SLE presenting with atypical symptoms of ACS, such as shortness of breath, epigastric pain, or fatigue.

Pericardial and Myocardial Disease. Pericarditis and effusions of the pericardium occur commonly in patients with SLE and are among the classification criteria for the disease (see Table 105.1). An estimated 25% of patients with SLE will experience symptomatic pericarditis during the course of their lives, and pericardial effusion (often asymptomatic) occurs even more frequently. In patients with pericarditis, dyspnea and chest pain that is sharp, pleuritic, and positional (improved with leaning forward) are classic features of the disease. Auscultation may reveal a friction rub. Electrocardiography may reveal classic findings of diffuse ST elevation and PR depression (Fig. 105.1); however, patients with pericarditis may also have normal or nonspecific ECG findings. Given the increased risk of CAD in patients with SLE, obtaining cardiac biomarkers in patients with ST elevation that would otherwise be diagnosed as pericarditis is generally encouraged. If there is diagnostic uncertainty as to whether ST elevation is related to pericarditis or an ST elevation myocardial infarction (STEMI), urgent cardiology consultation for consideration of cardiac catheterization is warranted. There are no specific signs of pericarditis on echocardiography. Visualization of pericardial effusion is supportive of the diagnosis of pericarditis; however, this finding may also be present in patients with SLE that do not have symptomatic pericarditis. Echocardiography is also useful to assess for associated cardiac tamponade, which is a rare but life-threatening complication of SLE. The presentation and diagnosis of cardiac tamponade are the same for patients with SLE as the general population. SLE myocarditis may present with chest discomfort and symptoms of heart failure, though acute symptomatic presentations are rare.

Valvular Disease. SLE is associated with a type of noninfectious endocarditis known as *Libman-Sacks endocarditis* (Fig. 105.2). Mitral valve disease is most common, though other valves may also be affected. While the lesions formed on heart valves in this condition are more often associated with embolization than valvular dysfunction, some patients may develop valvular insufficiency that may present with shortness of breath, fatigue, or, in rare severe cases, pulmonary edema.

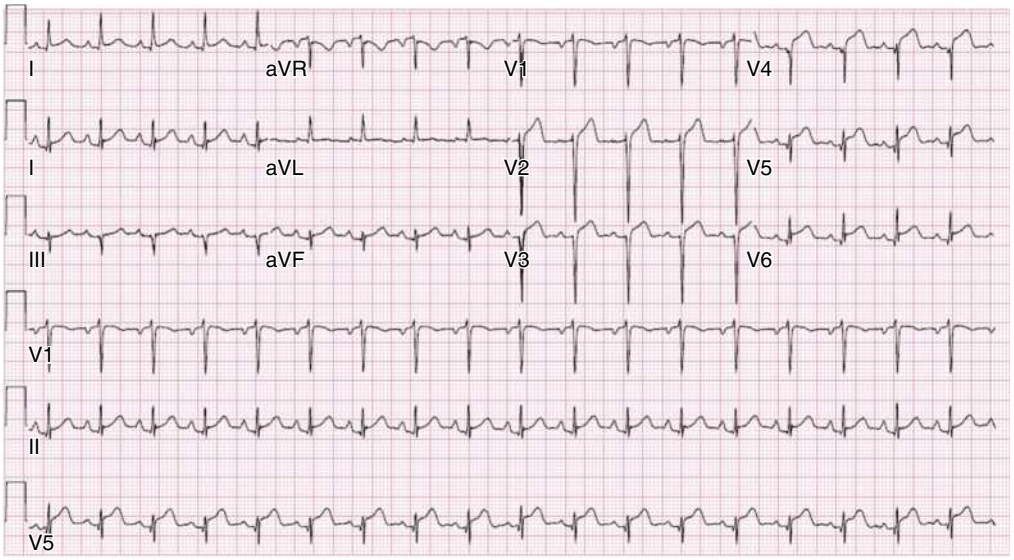

Fig. 105.1 Electrocardiogram of a 38-year-old woman with systemic lupus erythematosus (SLE) who presented to the emergency department (ED) with seizures and had chest pain while in the ED. Note diffuse ST elevation (with the absence of any reciprocal changes) and PR depression (particularly evident in lead II). Q waves anteriorly are related to prior myocardial infarct.

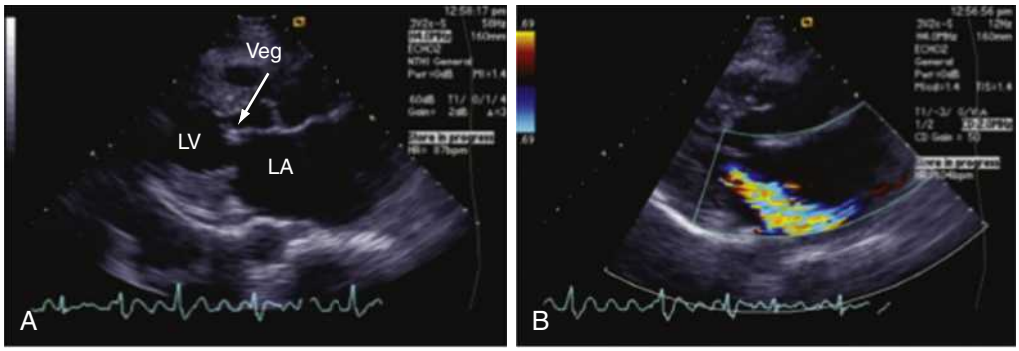

Fig. 105.2 Noninfectious endocarditis, known as a *Libman-Sacks lesion,* in a 56-year-old woman with systemic lupus erythematosus (SLE), a heart murmur, and dyspnea on exertion. (A) A parasternal long-axis view of the heart; a vegetation *(Veg)* is identified *(arrow)* on the mitral valve. (B) When color flow is superimposed on the valve, moderate to severe mitral regurgitation can be seen as a color jet entering the left atrium during systole. *LA,* Left atrium; *LV,* left ventricle. (Courtesy Martin Goldman, MD, Mount Sinai School of Medicine.)

Pulmonary Vascular Disease. Due to disease-associated hypercoagulability, deep venous thrombosis (DVT) and pulmonary embolism (PE) are more frequent in patients with SLE when compared to the general population. The degree of hypercoagulability in patients with concomitant **antiphospholipid syndrome** (APS) is even higher. Outside of the context of increased thromboembolic risk lowering the threshold for further testing, the evaluation for thrombosis and embolism in a patient with SLE does not differ from that of patients in the general population.

Though uncommon, patients with SLE may also develop pulmonary hypertension, which can present with shortness of breath, chest discomfort, and fatigue. Evaluation, in this case, may reveal a history of pathology known to lead to pulmonary hypertension (e.g., chronic thromboembolism, interstitial lung disease), physical exam findings of right heart failure, or evidence of right ventricular hypertrophy on electrocardiography or echocardiography. A definitive diagnosis is made via right heart catheterization.

Pleural Disease. Pleuritis is the most common respiratory condition occurring in SLE. Characterized by pleuritic chest pain with or without a pleural effusion or pleural rub, it has symptoms that overlap with those of other more serious conditions. A diagnosis of pleuritis should be arrived at only after other causes of pleuritic chest pain (e.g., PE) have been excluded.

Parenchymal Disease. Diseases of the lung parenchyma associated with SLE include infectious pneumonia, acute and chronic pneumonitis, interstitial lung disease, and, rarely, diffuse alveolar hemorrhage (DAH). The symptoms associated with infectious pneumonia, pneumonitis, and DAH have significant overlap; each of these entities may present with fever, cough, shortness of breath, and hemoptysis, and chest radiography may reveal nonspecific opacifications. Differentiating between these entities is difficult in the ED setting and may require further evaluation with bronchoscopy for bronchoalveolar lavage.

Mechanical Respiratory Disease. Shrinking lung syndrome is a rare condition associated with SLE that is characterized by symptoms of shortness of breath and pleurisy with low lung volumes and a restrictive pattern on pulmonary function testing. Patients may also have the elevation of one or both hemidiaphragms and pleural effusions. The

etiology of this syndrome is unclear but appears to involve some degree of restriction of chest wall expansion with or without diaphragmatic dysfunction.

Renal Disease

Renal disease is a common complication of SLE occurring in approximately one-half of patients.[5,6] Renal disease related to SLE may cause a nephrotic-type disease, primarily characterized by significant proteinuria or nephritic disease with hematuria and increased creatinine concentration. Diagnosis based on clinical criteria alone is not possible as many patients with renal impairment are asymptomatic. Patients that do have symptoms may report hematuria, foamy urine, generalized edema, or an elevated blood pressure from baseline. Given the high prevalence and morbidity of renal disease and its tendency to carry few if any symptoms, a screening urinalysis and basic metabolic panel are prudent in all but the most straightforward presentations concerning SLE-mediated disease. Renal biopsy is indicated for all patients with new-onset lupus nephritis and can be considered in those with relapsing or refractory disease.

Gastrointestinal Presentations

The most common gastrointestinal (GI) manifestation of SLE is oral ulceration. Esophageal dysmotility and reflux are also more common in patients with SLE and may present with dysphagia or pain in the epigastric region or chest. In patients with SLE, most causes of abdominal symptoms (e.g., pain, nausea, diarrhea, constipation) are the same as in the general population. Accordingly, the ED evaluation should be largely similar for each of the two groups. Special considerations for patients with SLE, however, include an increased risk of pancreatitis due to medications, mesenteric vasculitis (also known as lupus enteritis), peritonitis due to serositis, or the side effects of medications including chronic NSAIDs (e.g., peptic ulcer disease), glucocorticoids (e.g., peptic ulcer disease, perforation, infection), or immunosuppressive agents (infection).

Patients taking glucocorticoids or other immunosuppressive medications may also have masking of traditional symptoms, so a lower threshold for further testing (e.g., computed tomography [CT] imaging) should be used for this population.

Dermatologic Presentations

The most characteristic cutaneous manifestation of SLE is the malar rash. The rash has a "butterfly" distribution of raised erythema over the bridge of the nose and malar eminences while sparing the chin, forehead, and nasal-labial folds (Fig. 105.3). This sparing of the nasal-labial folds can help distinguish the classic malar rash from mimics such as rosacea or seborrheic dermatitis. Other common skin findings in patients with SLE include discoid lupus erythematosus (DLE) and subacute cutaneous lupus erythematosus (SCLE). Each of these skin findings can present years before systemic manifestations of SLE occur, and while the characteristic malar rash is highly specific for SLE, DLE and SCLE more commonly present in isolation, without progression to SLE. DLE lesions are circular and raised, scaly lesions that may be commonly found on the face, scalp, and ears, often in association with pigment change, alopecia, and scarring (Fig. 105.4). SCLE lesions are annular with an erythematous border, scaling, and central clearing. At times, these areas may coalesce to form more complex linear patterns of erythema. These lesions can be triggered by sunlight and are most commonly found in sun-exposed areas of the upper extremities, torso, and neck. The face is not usually affected by SCLE.

Musculoskeletal Presentations

Arthritis commonly afflicts those with SLE, and increasing severity of joint pain may be a marker of increasing disease activity or an SLE flare. Arthritis or arthralgias are typically symmetrical and nonerosive (unlike rheumatoid arthritis, which is erosive) and always involve multiple joints. Arthritis most commonly presents in the hands (metacarpophalangeal and proximal interphalangeal joints), wrists, feet, and knees but may be manifested in any joint. While swelling may be present, often, the joint pain of lupus presents with arthralgia alone. Uncommonly, septic arthritis may complicate SLE. An isolated swollen joint is not typical of SLE and should prompt consideration for infectious arthritis. If septic arthritis is suspected, diagnostic arthrocentesis is recommended.

Myalgias are common in SLE and may be an early marker of increasing disease activity for some patients. It should be kept in mind that fibromyalgia may also coexist with SLE and chronic myalgia not associated with other disease activity or elevated inflammatory markers may point to this diagnosis. While generalized muscle pain is sometimes seen, muscle weakness is uncharacteristic. If muscle weakness is present, an underlying myositis or myopathy, potentially related to steroid or hydroxychloroquine use, should be considered. Musculoskeletal chest pain, related to underlying pectoral, intercostal muscle,

Fig. 105.3 The Malar or Butterfly Rash Is the Hallmark of Systemic Lupus Erythematosus (SLE). (From Habif TP. *Clinical Dermatology*. 5th ed. New York: Mosby; 2009:592–606.)

Fig. 105.4 Right Ear of a Patient Suffering From Chronic Discoid Lupus. Note pigment change and tissue destruction. (Courtesy Professor Gregory Raugi, University of Washington.)

or costochondral joint inflammation may also occur and should be treated the same as in patients without SLE. Similar to pleuritis, the threat of a more malicious underlying cause of the pain should prompt the clinician first to seek other causes before arriving at this more benign diagnosis.

Hematologic Disease

Anemia, present in up to 50% of patients with SLE, may present with a chief complaint of dyspnea or weakness. Iron deficiency anemia, anemia of chronic disease, autoimmune hemolytic anemia, or medication-induced bone marrow suppression can all contribute to anemia in a patient with SLE. SLE also shares a strong association with APS, which is associated with a significantly increased risk of thromboembolic disease.

Complications Due To Medications

Chronic NSAID use for the musculoskeletal consequences of SLE may contribute to peptic ulcer disease, especially if they are coadministered with glucocorticoids. Chronic glucocorticoids are associated with an increased risk of multiple conditions including CAD, osteoporosis, avascular necrosis, psychosis, hyperglycemia, hypertension, and weight gain, among many others. Therapy with antimalarials, such as hydroxychloroquine, is common and generally well tolerated; however, retinopathy has been associated with prolonged use. Medications that interfere with DNA synthesis such as cyclophosphamide, methotrexate, mycophenolate mofetil, and azathioprine suppress the immune response, leaving patients vulnerable to both conventional and opportunistic infections. These medications are also frequent causes of cytopenias and liver function test elevations. Cyclophosphamide is one of the most potent immunosuppressants and particular care should be given to assessing for infection in patients receiving this agent. Biologic agents such as rituximab and belimumab are also associated with an increased risk of infection or cytopenias.

DIFFERENTIAL DIAGNOSIS

In keeping with its highly varied presentations and permutations of disease activity, a number of other diseases may be confused with SLE before diagnosis. These include infection, thrombotic thrombocytopenic purpura (TTP), APS, vasculitis, rheumatoid arthritis, mixed connective tissue disease, undifferentiated connective tissue disease, Sjögren syndrome, fibromyalgia, and drug-induced lupus, among others. In the ED setting, the priority should be identifying severe illness with an acute threat to organ function or risk of death. Mild, subacute, and nonspecific disease processes generally do not require definitive diagnosis in the ED setting if not associated with evidence of near-term risk to organ function. Chief complaint-driven considerations for acute presentations of SLE are listed in Table 105.2.

DIAGNOSTIC TESTING

Patients carrying a diagnosis of SLE presenting with symptoms concerning SLE-related pathology will typically require evaluation for evidence of systemic disease activity in addition to symptom-specific testing. In general, patients will not undergo testing for an initial diagnosis of SLE in the ED.

The general approach to assessing whether a symptom is caused by overall SLE disease activity is to look for signs and symptoms of the disease in other organs or systemically. For example, a patient presenting with pleurisy, arthralgias, and fever that has laboratory testing consistent with increased disease activity and chest radiography that is negative for evidence of infection may be diagnosed with a lupus flare. A patient with isolated pleurisy in the absence of other symptoms, laboratory tests, or imaging studies consistent with active SLE, however, is less likely to be suffering from an SLE flare and therefore warrants further evaluation for non-SLE pathology.

Symptom-specific testing will be the same for patients with and without SLE, with the caveat that certain testing thresholds may be lowered for patients with SLE given the increased risks associated with this disease and its treatment (e.g., cardiovascular disease, thromboembolic disease, infection).

Laboratory Tests

While patients will not typically undergo laboratory testing for an initial diagnosis of SLE in the ED, special circumstances such as low resource settings, poor outpatient follow-up, or severe illness requiring expedited diagnosis may prompt emergency physicians to begin this evaluation.

TABLE 105.2 Common or Specific Differential Considerations for Patients With Systemic Lupus Erythematosus Based on Common Presentations, Comorbidities, or Complications

Chief Complaint	Condition
Altered Mental Status	Neuropsychiatric lupus Medication effect (e.g., steroid psychosis) Seizure Infection
Fever	Infection Increased disease activity (SLE flare)
Chest pain	Acute coronary syndrome Pulmonary embolism Pericarditis/pericardial effusion Pleuritis/pleural effusion Musculoskeletal chest wall pain (diagnosis of exclusion)
Shortness of breath	Acute coronary syndrome Pulmonary embolism Pulmonary hypertension/right heart failure Pneumonia Pericarditis/pericardial effusion Pleuritis/pleural effusion Interstitial lung disease Shrinking lung syndrome Anemia
Abdominal pain	Pancreatitis Peptic ulcer disease Pseudo-obstruction Lupus enteritis
Leg swelling	Deep venous thrombosis Nephrotic syndrome Renal failure Heart failure (left- or right-sided)
Pruritic or painful rash	Discoid SLE Drug reaction Sun exposure
Arthritis	Increased disease activity (SLE flare) Osteoarthritis Septic arthritis

SLE, Systemic lupus erythematosus.

For patients carrying a diagnosis of SLE with all but the most trivial presentations of potential SLE-mediated disease, laboratory studies are indicated to assess for increased disease activity as the etiology of the patient's symptoms.

Initial Diagnosis

The diagnosis of SLE can be difficult. The broad, heterogeneous, waxing and waning nature of the disease, lack of specificity of many presenting symptoms, multitude of diseases with overlapping symptoms, and lack of uniform diagnostic criteria all contribute to this difficulty. While classification criteria for SLE have been published by the European League Against Rheumatism/American College of Rheumatology and Systemic Lupus Collaborating Clinics, these are not set forth as diagnostic criteria.[7,8] However, clinicians may find these criteria helpful in remembering salient elements for the evaluation of a patient with possible SLE, including relevant laboratory studies. Laboratory testing relevant to SLE diagnosis includes a complete blood count to assess for leukopenia, lymphopenia, and thrombocytopenia; hemolysis testing if anemia is present; complement levels; urinalysis for hematuria, proteinuria, and casts; and immunologic assays including anti-nuclear antibody (ANA), anti-double-stranded DNA (dsDNA) antibody, anti-Smith (Sm) antibody, and aPL antibodies. The Ro, La, and ribonucleoprotein (RNP) antibodies may also be seen in lupus but are less specific for SLE and are also associated with Sjögren's and mixed connective tissue disease, respectively. A positive ANA is present in nearly all patients with SLE but is also present in more than 10% of the general population. The ANA titer is important to consider as the majority of patients with SLE have high-titer ANAs. In general, the temptation to pursue a new diagnosis of SLE in the ED should be avoided due to the lack of uniform diagnostic criteria, reliance on laboratory investigations that are uncommonly carried out in the ED, and rarity that a diagnosis made emergently will significantly change patient outcomes.

Disease Activity

Routine laboratory tests with correlation to increased SLE disease activity include a complete blood count (leukopenia, anemia, thrombocytopenia), basic metabolic panel (creatinine elevation), erythrocyte sedimentation rate (ESR, elevated), and urinalysis (hematuria, proteinuria). Patients found to have new or worsening anemia should be evaluated for hemolysis, which is associated with increased SLE disease activity. This evaluation may include a direct Coombs test, peripheral blood smear, LDH, and haptoglobin. It should be noted that the ESR is not always elevated in active disease; therefore, patients with compelling symptoms without an alternative explanation can be diagnosed with SLE flare despite normal inflammatory markers. C-reactive protein (CRP) is frequently normal in active lupus. Therefore, an elevated CRP should prompt strong consideration of infection. Other more specialized laboratory markers of SLE disease activity include low complement levels (C3, C4) and elevated anti-dsDNA.

Evaluation for Infection

Leukocytosis may suggest infection in some cases; however, it has poor specificity. This finding may be even less useful in SLE patients taking glucocorticoids, as these medications are associated with baseline leukocytosis. Leukopenia may also suggest infection in some cases; however, this is also a sign of active SLE and therefore cannot be relied upon as a marker specific for infection in patients with SLE. Immature cells (e.g., band cells) on a differential are relatively specific for infection and are not routinely associated with SLE disease activity. CRP may also be a useful marker as it can be normal despite increased disease activity in SLE but typically rises in the case of infection. ESR is nonspecific and will rise in both cases of infection and SLE flares.

Imaging Studies

While SLE is also associated with a wide variety of other pathology routinely diagnosed on imaging studies (e.g., stroke, pneumonia, PE), the imaging studies of choice for these entities do not differ between patients with and without SLE. Lupus cerebritis, a blanket term for organic SLE-related CNS pathology with neuropsychiatric manifestations and no alternate diagnosis, is typically evaluated with magnetic resonance imaging (MRI) of the brain in addition to lumbar puncture. MRI of the brain in patients with lupus cerebritis may be normal or reveal nonspecific findings such as hyperintense white matter lesions, and should assist in excluding alternate diagnoses (e.g., stroke).

MANAGEMENT

Emergent Stabilization

Emergent stabilization of patients with SLE does not differ from that of patients without the disease. Management of life-threatening presentations associated with SLE such as myocardial infarction, stroke, PE, seizure, and infection should all proceed as usual. For patients with SLE in refractory shock, stress dose glucocorticoids (hydrocortisone 100 mg IV q8h) should be considered given the high incidence of chronic steroid therapy and related adrenal suppression in this population. Advanced SLE therapies (e.g., immunosuppressive agents, plasma exchange) can be coordinated with the appropriate consulting services (e.g., rheumatology, nephrology) for patients with a critical illness.

General Systemic Disease Activity

Nearly all manifestations of active SLE are managed with the introduction or escalation of immunomodulatory therapy.

Patients Diagnosed With Systemic Lupus Erythematosus

For patients that carry a diagnosis of SLE and evidence of active disease, treatment and disposition will be guided by the severity of symptoms. Mild to moderate disease with manifestations such as joint pain, serositis, or cutaneous disease typically respond to prednisone 15 to 20 mg PO daily or NSAIDs in the case of joint pain and serositis. For pericardial and pleural effusions in the absence of hemodynamic compromise or respiratory distress, respectively, drainage in the ED setting is rarely required. For patients with severe disease and end-organ dysfunction (e.g., seizures, transverse myelitis, cardiac tamponade, nephritis), either pulse glucocorticoids (e.g., methylprednisolone 1 g/day IV) or prednisone 1 mg/kg/day PO and admission are generally appropriate. If worsening renal dysfunction is discovered, admission should be considered for hydration, escalation of therapy, and consideration of renal biopsy to help classify the disease and guide treatment. In each of the presented scenarios, management and disposition decisions can be made in consultation with a patient's rheumatologist, if available.

Patients Not Diagnosed With Systemic Lupus Erythematosus

For patients who do not carry a diagnosis of SLE and who have only mild evidence of disease (e.g., rash, arthralgias, uncomplicated pleurisy), symptomatic treatment and referral to a rheumatologist or primary care physician are appropriate provided that end-organ disease such as nephritis has been considered. In patients with evidence of severe systemic SLE-related disease (e.g., seizures, transverse myelitis, cardiac tamponade), empiric pulsed glucocorticoids should be considered while a formal diagnosis of SLE is pending.

Specific Presentations

Infection

Management of infection in patients with SLE includes appropriate antimicrobial coverage based on the suspected source, prior culture

data (as available), and the patient's degree of immunosuppression, as well as source control. Patients on chronic steroid therapy with refractory hypotension associated with infection should typically be treated with stress dose glucocorticoids (e.g., hydrocortisone 100 mg IV every 8 hours). Generally, nonglucocorticoid immunosuppression should be stopped while infection is treated, with the exception of hydroxychloroquine, which has not been associated with an increased risk of infection.

Musculoskeletal Pain

Much of the pain associated with SLE is related to inflammation that is amenable to treatment with NSAIDs or low-dose glucocorticoids. Ibuprofen 600–800 mg three times daily a day or naproxen 500 mg orally twice daily is useful for conditions such as pericarditis, pleuritis, arthralgias, myalgias, and fever. It is important to distinguish inflammatory joint pain from fibromyalgia, which does not typically respond to NSAIDs or glucocorticoids. Use of NSAIDs in patients with chronic kidney disease or a history of peptic ulcer disease is discouraged. In such patients, acetaminophen is used for mild to moderate pain. Adjunctive therapies such as lidocaine patches and heating or cooling packs may also be useful in controlling musculoskeletal pain related to SLE. The use of opioid medications is discouraged in the management of chronic rheumatologic diseases, including SLE.

Cutaneous Manifestations

In cases of isolated cutaneous findings, treatment with topical corticosteroids is preferable to systemic therapy. Topical therapy may be initiated with a medium potency steroid such as triamcinolone 1% cream to the affected area. In cases in which higher potency topical corticosteroids are necessary, preparation of 0.05% betamethasone dipropionate applied once daily to the affected area for 2 weeks is appropriate. Moderate to severe cases may be treated with topical calcineurin inhibitors or systemic therapy in consultation with the patient's internist, dermatologist, or rheumatologist. In nearly all cases of SLE, avoidance of sun exposure is advisable and will help minimize cutaneous disease.

SPECIAL CONSIDERATIONS

Antiphospholipid Syndrome

Foundations

Present in approximately 15% of patients with SLE, APS is considered when patients both have a clinical history of thrombosis and test positive for one or more antiphospholipid (aPL) antibodies. These antibodies include those corresponding to anticardiolipin, lupus anticoagulant, and β_2-glycoprotein I. The thrombotic risk profile varies based on which antibody or combination of antibodies are present. In addition to its role as a strong risk factor for both venous and arterial thrombosis, the presence of APS in SLE has been shown to be an independent predictor of more severe disease. Whether it is present in the context of SLE or independently, APS is an important cause of morbidity and mortality due to thrombosis.

Clinical Features

APS may present with a number of clinical features (Box 105.1), typically related to thrombosis or thromboembolism. A small subset of those with APS may present with multiple thrombotic sites or multiorgan failure due to microvascular thrombosis. Catastrophic APS (CAPS) is diagnosed when three or more sites or organs are affected.[9,10]

Diagnostic Testing

Similar to the workup for other hypercoagulable conditions, diagnostic testing for APS is unlikely to be indicated in the ED setting. Assays detecting the presence of aPL antibodies (anticardiolipin, lupus anticoagulant, and β_2-glycoprotein I), at two timepoints 12 weeks apart, are necessary for the laboratory component of the diagnosis of APS. Two additional laboratory findings that are supportive of APS (though not diagnostic) are a spuriously elevated PTT in the setting of a normal PT/INR, due to interference of the coagulation study by aPL antibodies, or a falsely positive Venereal Disease Research Laboratory (VDRL) assay to test for syphilis, as the antigen in the VDRL test contains cardiolipin.

Management

For acute thrombotic events, anticoagulation with heparin (unfractionated or low–molecular-weight) is generally indicated. After an initial thrombotic event, anticoagulation with a low–molecular-weight heparin or vitamin K antagonists such as warfarin is recommended indefinitely. Direct oral anticoagulants carry an increased risk of thrombosis compared to vitamin K antagonists and therefore are not recommended for first-line treatment. For patients with catastrophic APS, in addition to anticoagulation and glucocorticoids, intravenous immune globulin (IVIG), immunosuppressive agents, and plasma exchange may all be indicated. Arrangement of these therapies can be considered in discussion with the relevant consultants (e.g., rheumatology, hematology, nephrology). Despite treatment, mortality for catastrophic APS approaches 50%.

Drug-Induced Lupus

Drug-induced lupus is an SLE-like, self-resolving illness characterized by arthralgias, myalgias, rash, and serositis. It may be brought on by as many as 80 different medications, including hydralazine, isoniazid, and tumor-necrosis factor (TNF) alpha inhibitors. Notably, the malar rash and major organ involvement are rare in this condition. In drug-induced lupus, antibodies against the body's own histone proteins are common and purported to be a major mechanism of disease. Although the list of potentially implicated medications is long, those agents with the most evidence for causing drug-induced lupus are summarized in Box 105.2. The diagnosis is typically clinical and confirmed by resolution of symptoms with the withdrawal of the offending medication. In addition to cessation of the culprit drug, NSAIDs or glucocorticoids may be prescribed for control of symptoms in the interim.

DISPOSITION

Disposition for the patient with SLE will vary significantly by clinical presentation. For patients with mild presentations, such as increased musculoskeletal symptom burden, uncomplicated pleurisy, or cutaneous disease, discharge with symptomatic care, return precautions, and follow-up is usually appropriate. However, patients with more acute pathology, poor insight into their disease, significant comorbidities, or weak home support may require hospitalization.

Disorders characteristic of moderate SLE flares (e.g., nephritis, pneumonitis), thrombotic events, or infectious complications in the setting of immunosuppression usually require admission for initiation or escalation of systemic therapy (e.g., glucocorticoids, anticoagulation, antibiotics) and monitoring for response to treatment. Select

Venous thrombosis
Arterial thrombosis (including stroke or transient ischemic attack)
Recurrent miscarriage
Livedo reticularis (rash)
Thrombocytopenia

patients with milder forms of illness may still be appropriate for discharge, particularly if in collaboration with the patient's rheumatologist. Admission to the intensive care unit should be considered for those who, despite initial resuscitation, suffer persistent severe circulatory or respiratory derangement.

Finally, the complexity of SLE is challenging for physicians not specialized in its many nuances and intricate pathophysiologic changes. General reasons for rheumatologic consultation or referral of patients with SLE are presented in Box 105.3.

VASCULITIS

KEY CONCEPTS

- Giant cell arteritis should be considered in patients with new onset headache, visual changes, or jaw claudication combined with elevated inflammatory markers. Large-vessel vasculitides also affect the aorta and the great vessels leading to stenosis, claudication, and aneurysm formation.
- Small- and medium-vessel vasculitis syndromes should be considered in the presence of constitutional symptoms, glomerulonephritis, diffuse alveolar hemorrhage, mononeuritis multiplex, or cutaneous vasculitis.
- Many patients with established vasculitis are receiving high-intensity immunosuppression, making them vulnerable to opportunistic infections and sepsis.

FOUNDATIONS

The vasculitides are a heterogeneous group of disorders characterized by inflammation of blood vessel walls. Arteries and veins of all sizes can be affected to varying degrees. Presentations can range from benign and self-limited to serious and life-threatening. Diagnosis can be challenging, as early vasculitis syndromes are nonspecific and can mimic infectious, inflammatory, or neoplastic conditions. Approximately 1 in 2000 adults are affected by some form of vasculitis, with a higher incidence in adults in their sixth to eight decades of life.

Most vasculitis syndromes are idiopathic, although infection, medications, or recreational drugs can be causative. The pathophysiology of vasculitic conditions is complex and heterogenous; however, two overarching mechanisms play a role. Inflammation in blood vessel walls results in wall damage and necrosis, leading to stenosis, occlusion, and subsequent end-organ ischemia. In addition, a number of symptoms such as fever, fatigue, and joint pain are caused by a generalized systemic inflammatory process. Serologic testing, imaging, and biopsy all have a role in the diagnostic workup that at times can begin in the ED setting. In addition, empiric treatment is sometimes necessary to avoid end-organ damage.

Early recognition of vasculitis is critical, as these conditions can lead to irreversible end-organ damage and, if untreated, have a high mortality rate. While vasculitis can affect almost any organ system, the recognition of cardinal features that are common across multiple vasculitic conditions is critical to diagnosis. Constitutional symptoms such as fever, night sweats, weight loss, joint pain, and fatigue are common to all vasculitic syndromes. However, other manifestations vary considerably by the size of the blood vessel involved; therefore, large-vessel vasculitides differ markedly in their presentation from medium- and small-vessel vasculitides, which have overlapping features.[11] Table 105.3 summarizes the common and unique features of different vasculitides.

LARGE-VESSEL VASCULITIS

Large-vessel vasculitis involves the aorta and its immediate branches and is generally caused by giant cell arteritis (GCA) and Takayasu arteritis (TAK). These two vasculitides have a similar distribution of large-vessel involvement but differ in two important respects. GCA typically presents with cranial symptoms caused by involvement of the branches of the external carotid artery and affects patients older than 50 years of age. TAK in contrast does not have the same cranial features and generally affects younger patients.

Giant Cell Arteritis

Background

GCA, also known as temporal arteritis, is a systemic vasculitis that affects the aorta and its branches as well as the branches of the external carotid artery, which are medium and small arteries.[12] The disease typically occurs in patients over 50 with the highest incidence in the eighth decade of life. It is the most common vasculitis in older patients. Women are affected more commonly than men. GCA is most common in patients of Scandinavian descent, and the disease is relatively rare in black patients. The most feared complication of GCA is irreversible vision loss, occurring in up to one-third of patients. Early treatment can help prevent this complication, and thus the diagnosis is an important consideration in patients older than 50 years old presenting with any combination of constitutional symptoms, headache, visual changes, jaw claudication, or symptoms of polymyalgia rheumatica,

TABLE 105.3 Common and Unique Features of Vasculitides

Vasculitis	Common Clinical Features	Unique Clinical Features
LARGE-VESSEL VASCULITIS		
Takayasu arteritis	Aortitis Vasculitis of great vessels Diminished pulses Claudication	Carotidynia
Giant cell arteritis		Headache, visual changes, jaw claudication, scalp tenderness, polymyalgia rheumatica
MEDIUM-VESSEL VASCULITIS		
Polyarteritis nodosa	Mononeuritis multiplex Mesenteric ischemia	Cutaneous ulcers, nodules, renal infarcts, testicular involvement Does not cause glomerulonephritis or lung involvement
SMALL-VESSEL VASCULITIS		
ANCA-Associated Vasculitis		
Granulomatosis with polyangiitis	Glomerulonephritis Diffuse alveolar hemorrhage	Granulomatous manifestations such as destructive sinusitis, nasal crusting, pulmonary nodules, retroorbital mass
Microscopic polyangiitis	Mononeuritis multiplex Mesenteric ischemia	Similar to GPA but without granulomatous manifestations
Eosinophilic granulomatosis with polyangiitis	Purpura	Eosinophilia, asthma, nasal polyps, cardiac involvement
Immune Complex Mediated Vasculitis		
Cryoglobulinemic vasculitis	Glomerulonephritis Palpable purpura Mononeuritis multiplex GI involvement	Associated with hepatitis B and C, lupus, Sjögren syndrome
IgA vasculitis		Rare in the absence of skin lesions Does not typically cause mononeuritis multiplex or pulmonary involvement Intussusception is unique

which is characterized by the subacute onset of symmetric shoulder and pelvic girdle pain and prominent morning stiffness.

Clinical Features

GCA symptoms typically develop over weeks. Headache, the most common presenting symptom, occurs in three-quarters of patients with GCA. Although it is classically described as temporal, the headache of GCA can occur in any location. The most salient historical feature is that the headache is new or markedly different from prior headaches. Temporal artery tenderness or other abnormalities on examination increase the probability of GCA but are not sensitive for the diagnosis. Constitutional symptoms are present in more than half the patients. Visual symptoms are also common and importantly can herald visual loss. GCA can present with a variety of visual symptoms; however, the presence of unexplained amaurosis fugax or double vision should raise particular concern in the appropriate clinical setting. Jaw claudication is a particularly important symptom because, when present, it is the most specific GCA feature. Importantly, jaw claudication should be distinguished from temporomandibular joint (TMJ) disorder, which is much more common. Jaw claudication only occurs with chewing, resolves completely with rest, and tends to be reproducible over time. In contrast to TMJ disorder, it does not occur with mouth opening or other specific motions of the jaw not associated with chewing. Scalp tenderness occurs in up to a third of patients and is typically described as superficial discomfort with pressure such as lying on a pillow. Finally, polymyalgia rheumatica (PMR), which manifests as the subacute onset of symmetric shoulder and pelvic girdle pain and prominent morning stiffness, is present in nearly half of GCA patients and represents another important clue to the diagnosis. It should be kept in mind that PMR is relatively common and, in up to 90% of cases, exists without GCA.

The large-vessel manifestations of GCA are similar to those of TAK. Involvement of the subclavian, axillary, or iliac arteries can lead to extremity claudication. Aortitis can lead to aneurysm formation and rupture. Thoracic aortic aneurysms are up to 17 times more likely to occur in patients with GCA compared with age-matched controls, and abdominal aortic aneurysm formation is twice as common. Involvement of vertebral-basilar arteries can lead to posterior circulation stroke. Other intracranial circulation is typically spared.

Diagnostic Testing

Inflammatory markers (ESR and CRP) should be evaluated when GCA is suspected. Normal inflammatory markers argue strongly against GCA, as more than 95% of patients have elevated markers at diagnosis. Temporal artery biopsy is the gold standard for diagnosis with sensitivity ranging from approximately 50% to 90%. Therefore, the diagnosis should be suspected even with a negative biopsy if suggestive clinical features are present in the setting of markedly elevated inflammatory markers without an alternative explanation. Increasingly, temporal artery ultrasound is being used in centers with experienced operators prior to biopsy. Demonstration of the halo sign around involved vessels is specific and can potentially eliminate the need for a biopsy. However, in patients with moderate to high suspicion of the disease and a negative ultrasound, biopsy should be pursued. Ophthalmologic evaluation is indicated for patients with acute visual symptoms. Fundoscopic examination can detect arteritic ischemic optic neuropathy, which is highly suggestive of GCA. The role of large-vessel imaging with CTA, MRA, or PET-CT is evolving.

Management

Patients with a moderate to high suspicion for GCA and no contraindication should be treated empirically with glucocorticoids, while simultaneously undergoing the diagnostic workup, to prevent visual loss. A typical initial regimen is oral prednisone 1 mg/kg. For patients with severe visual symptoms such as double vision or amaurosis fugax, admission for intravenous glucocorticoids (typically methylprednisolone 1 g daily for 3 days) can be considered. Tocilizumab (an IL-6 inhibitor) has recently been approved for the treatment of GCA in combination with glucocorticoids.[13] Initiation of tocilizumab should be made in consultation with rheumatology.

Takayasu Arteritis

Background

TAK is a systemic large-vessel vasculitis of unknown etiology.[14] It is eight times more common in women and is most prevalent in Asia, although it occurs worldwide. TAK typically affects a much younger population than GCA, with most patients diagnosed before the age of 40.

Clinical Features

TAK affects a similar distribution of arteries as GCA with the aorta and its branches being typically involved. However, in contrast to GCA, TAK typically presents with symptoms of more advanced vascular occlusion. This may be due to the absence of cranial symptoms as a heralding feature which leads to earlier diagnosis in GCA. The most common presenting symptoms include claudication (most commonly of the upper extremity, 35%), reduced or absent pulse (25%), hypertension (20%), or asymmetrical arm blood pressures (15%). Internal carotid artery involvement commonly causes carotidynia, lightheadedness, or headaches in approximately 20% of patients. In contrast to GCA, other cranial symptoms such as visual changes, scalp tenderness, and jaw claudication are absent. Aortitis can lead to aneurysm formation and aortic insufficiency. Constitutional symptoms are common in the early phase of the disease but are frequently absent in the stenotic phase when the disease is often diagnosed.

Diagnostic Testing

The diagnosis is made on the basis of clinical assessment and diagnostic imaging. Patients who present with symptoms of large-vessel occlusive disease (bruit, absent pulse, claudication) are candidates for imaging of the aorta and its major branches with CTA, MRA, or PET-CT.[15] Inflammatory markers are elevated in approximately 70% of patients with active disease. It should be noted that large-vessel vasculitis on imaging must be distinguished from atherosclerotic disease and noninflammatory vasculopathies, such as fibromuscular dysplasia or Ehlers Danlos syndrome, among others. Vasculitis typically causes long smooth stenoses and vessel wall thickening. In contrast, noncalcified atherosclerotic lesions cause focal stenoses. Noninflammatory vasculopathies generally cause beading, dissection, and aneurysm formation, rather than stenotic lesions and vessel wall thickening.

Management

TAK is managed with glucocorticoids in combination with steroid-sparing agents such as methotrexate, tumor-necrosis alpha inhibitors, or IL-6 inhibitors. Glucocorticoids are typically started at 60 mg and tapered over 6 to 12 months. Choice of steroid-sparing agent should be discussed with rheumatology. Surgical revascularization is reserved for patients with refractory stenotic lesions whose inflammatory disease is well controlled.

SMALL AND MEDIUM VESSEL VASCULITIS

Background

Small-vessel vasculitides as a group are the most common vasculitis syndromes. Polyarteritis nodosa, the only medium-vessel vasculitis affecting adults, is relatively rare but shares some common features with small-vessel diseases. Therefore, we will consider small- and medium-vessel vasculitis together.

Clinical Features

While each vasculitis causes multiple manifestations, it is important to recognize that there are common features shared by most small-vessel vasculitides which should alert the provider to consider this set of conditions. Specifically, the presence of DAH, glomerulonephritis, mononeuritis multiplex, mesenteric ischemia not due to atherosclerosis, or palpable purpura should prompt consideration of a small- or medium-vessel vasculitis. Joint pain and constitutional symptoms are also common to all forms of vasculitis.

DAH typically manifests with dyspnea and hemoptysis. Respiratory symptoms and signs of impaired gas exchange may develop before a drop in the hemoglobin level, which may be seen in cases of severe or persistent bleeding. It should be noted that hemoptysis is absent in approximately one-third of patients with DAH. CT imaging typically reveals diffuse ground-glass or consolidative opacities that must be differentiated from pulmonary edema or infection. The diagnosis is made on bronchoscopy with serial bronchoalveolar lavages returning increasingly bloody fluid. It should be noted that infection can also cause DAH.

Glomerulonephritis is typically asymptomatic although rarely patients will notice macroscopic hematuria. The key to diagnosis is an active urinary sediment with proteinuria and hematuria with red blood cell casts and dysmorphic RBCs. Pulmonary-renal syndrome, with both DAH and glomerulonephritis, is a classic presentation of small-vessel systemic vasculitis and anti-glomerular basement membrane (anti-GBM) disease.

While vasculitis can cause any type of peripheral neuropathy, the most common is mononeuritis multiplex, which is uncommon in other diseases. This condition generally affects large sensorimotor nerves in an asymmetric distribution. Patients may present with a combination of foot or wrist drop associated with sensory deficits, or less commonly cranial neuropathy occurring in an asymmetric manner over time.

Gastrointestinal manifestations are less common and can be nonspecific. However, symptoms of chronic mesenteric ischemia in the setting of elevated inflammatory markers or other systemic features without an alternative explanation, such as atherosclerotic disease, should prompt consideration of a small- or medium-vessel vasculitis.

The most common cutaneous manifestation of vasculitis is palpable purpura. Palpable purpura typically involves the lower extremities, is nonblanching, and is not painful or pruritic. A biopsy may be needed to distinguish the lesions of vasculitis from other causes of purpura.

Differential Diagnosis

A useful approach to vasculitis is to first recognize the common features of small- and medium-vessel vasculitis. Second, when evaluating patients with suspected vasculitis, it is important to confirm the scope of the disease by evaluating organs that may be asymptomatic such as the lung and kidneys. Finally, because these vasculitic features should prompt a workup for vasculitis but do not differentiate well between the various types of small- and medium-vessel vasculitis, it is important to focus on the differentiating features of each vasculitic condition to make a specific diagnosis. The differentiating

features include clinical symptoms, laboratory testing, and biopsy results.

Small-vessel vasculitides can be broadly divided into anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis and vasculitis caused primarily by immune-complex deposition. There are three ANCA-associated vasculitides: granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome).[16] Immune complex vasculitides include cryoglobulinemic vasculitis, IgA vasculitis (IgAV, formerly Henoch–Schonlein purpura), drug-induced vasculitis, and connective tissue disease-associated vasculitis. Anti-GBM (Goodpasture disease) is not a true vasculitis but should be considered in the setting of either glomerulonephritis or pulmonary hemorrhage. Polyarteritis nodosa (PAN) is a medium-vessel vasculitis that shares some features with small-vessel diseases.

Specific Disorders

ANCA-Associated Vasculitis

Granulomatosis With Polyangiitis. GPA is a granulomatous vasculitis affecting small- and medium-sized vessels. It affects individuals in their fifth and sixth decade of life most commonly and has a slight male predominance. In addition to the vasculitic manifestations such as glomerulonephritis, DAH, mononeuritis multiplex, and palpable purpura, GPA is unique in that it causes "granulomatous" manifestations, mainly sinusitis and mass lesions. Sinusitis is one of the most common manifestations of GPA. The presence of significant nasal crusting may alert the physician to the presence of an inflammatory process because crusting is typically absent in allergic and bacterial sinusitis. Bony destruction and nasal septal perforation are other distinguishing features that may be present. In addition, GPA can cause pulmonary nodules (Fig. 105.5), bronchial lesions, retroorbital mass, or subglottic stenosis. Sensorineural hearing loss or otitis media can also be seen. Limited GPA is a well-recognized subset of disease and can present only with chronic sinusitis or other granulomatous features without vasculitic features.

The presence of ANCA in the appropriate clinical setting is highly suggestive of the diagnosis. It should be noted that when renal involvement is present, ANCA sensitivity is approximately 90% but drops to approximately 60% in nonsevere diseases without renal involvement. GPA is typically associated with proteinase 3 (PR3)-ANCA (c-ANCA immunofluorescence pattern). If the diagnosis is uncertain, biopsy of the affected organ should be performed. Pathology generally demonstrates vasculitis without significant immune complex deposition. Granulomatous inflammation may also be present.

Treatment of GPA requires the combination of glucocorticoids and another immunosuppressant (typically rituximab or cyclophosphamide).[17] In patients with glomerulonephritis or pulmonary hemorrhage, pulse dose glucocorticoids (methylprednisolone 1 g IV for 3 days) are often used. Plasma exchange has been used previously in severe cases, but recent studies have questioned the utility of this modality, except when ANCA-associated vasculitis occurs with anti-GBM disease.

Microscopic Polyangiitis. MPA is a non-granulomatous vasculitis affecting small- and medium-sized vessels. MPA most commonly affects patients in their sixth and seventh decades and has a relatively equal sex distribution. It shares the same vasculitic features as GPA but lacks the "granulomatous" manifestations. Therefore, sinusitis and mass lesions are not seen in MPA, and the most common presenting features include glomerulonephritis, pulmonary hemorrhage, mononeuritis multiplex, and palpable purpura. Diagnosis relies on the presence of myeloperoxidase (MPO)-ANCA (p-ANCA immunofluorescence pattern) that is present in approximately 70% of patients. If ANCA is negative or the diagnosis is uncertain, biopsy typically demonstrates findings of vasculitis lacking both immune complex deposition and granulomatous inflammation. Treatment is identical to that of GPA with a combination of glucocorticoids and rituximab or cyclophosphamide.

Eosinophilic Granulomatosis With Polyangiitis. EGPA is an eosinophilic vasculitis of small and medium vessels.[18] Mean age of the diagnosis is in the fourth and fifth decade with men and women equally affected. While it shares vasculitic features with GPA and MPA, it has a number of unique features related to the eosinophilic infiltration of organs. Over 90% of patients develop asthma as one of the first manifestations, typically preceding vasculitic features. The asthma is often severe, requiring treatment with agents such as prednisone. Migratory ground-glass opacities on CT chest imaging are common and may help differentiate EGPA from severe asthma. Allergic rhinitis and nasal polyps are also frequent. Eosinophilic myocarditis, which can present with arrhythmia or heart failure, is another unique feature, present in 10% to 20% of patients. Notably, cardiac involvement has been suggested to account for nearly half of the deaths due to EGPA.

All patients with EGPA have prominent peripheral eosinophilia, typically above 1000 cells/μL, which is not a feature of other vasculitides. It should be kept in mind that treatment with glucocorticoids markedly

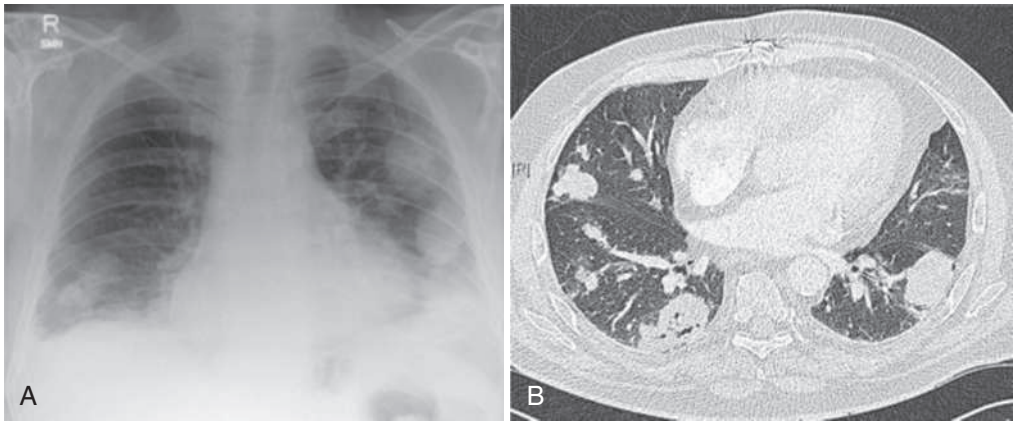

Fig. 105.5 (A) Multiple intrapulmonary nodules on a chest radiograph of a patient with granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis). (B) Pulmonary nodules seen on computed tomography (CT) imaging. (From Adam A, Dixon AK. *Grainger & Allison's Diagnostic Radiology*. 5th ed. Philadelphia: Churchill Livingstone; 2008.)

reduces peripheral eosinophilia; therefore, it may be absent in patients already receiving glucocorticoids. Differentiating EGPA from severe atopic disease or hypereosinophilic syndrome can be challenging. Generally, atopic disease lacks end-organ involvement outside of the lung, while hypereosinophilic syndromes lack asthma and vasculitic features. The diagnosis relies on the presence of MPO-ANCA, which is only seen in 50% of patients, or eosinophilic vasculitis on biopsy. Treatment of EGPA is dictated by disease severity. Severe vasculitic manifestations are generally treated similarly to GPA and MPA with a combination of pulse intravenous glucocorticoids and rituximab or cyclophosphamide. Patients without severe vasculitis may be treated with glucocorticoids alone or in combination with mepolizumab (anti-IL-5), methotrexate, azathioprine, or mycophenolate mofetil.

Anti-Glomerular Basement Membrane Disease (Goodpasture Disease)

Anti-GBM disease is caused by disruption of the basement membrane by circulating anti-GBM antibodies causing glomerulonephritis with or without alveolar hemorrhage.[19] The disease can affect individuals of all ages, with white patients more commonly affected. The incidence is bimodal; one peak occurs in 20- to 30-year-old men, and a second in 50- to 70-year-olds of both sexes. Because it is not a vasculitis per se, other vasculitic features are generally absent. The diagnosis is made by the presence of anti-GBM antibodies and demonstration of crescentic glomerulonephritis with linear staining along the basement membrane on immunofluorescence. Treatment requires the addition of plasma exchange to a combination of prednisone and cyclophosphamide. Of note, ANCA-associated vasculitis and anti-GBM disease can coexist; treatment of this syndrome is similar to that of anti-GBM disease alone.

Immune Complex Mediated Vasculitis

IgA Vasculitis. IgAV, formerly known as Henoch-Schonlein purpura, is a small- and medium-vessel vasculitis that is characterized by IgA deposition in vessel walls.[20] It is more common in children than adults at an approximately 3:1 ratio. IgAV has a strong association with infection, with 50% of cases occurring after an upper respiratory tract illness. It can also occur as a manifestation of a drug reaction. In contrast to other vasculitides, it does not typically involve the lung or the peripheral nervous system. The three organ systems typically affected are the skin, kidneys, and gastrointestinal tract. Joint pain and constitutional symptoms are also frequent. Skin manifestations, most commonly palpable purpura, are present in essentially all adults and the majority of children as the initial manifestation (Fig. 105.6). This is in contrast to other systemic vasculitides, where any of the manifestations can be the presenting feature. Gastrointestinal symptoms are nonspecific; intussusception is the most common finding, in contrast to other vasculitides where mesenteric ischemia tends to be the most common gastrointestinal presentation. Renal involvement manifests as hematuria most commonly but can be more severe with nephritic syndrome, particularly in adults, who have a worse renal prognosis. In children, the diagnosis is commonly made clinically, as it is much more common than other vasculitides. The diagnosis in adults typically requires a biopsy. Biopsy of an affected organ will demonstrate IgA deposition in vessel walls. IgAV is typically a self-limited illness. NSAIDs (e.g., naproxen 500 mg BID or ibuprofen 800 mg TID) can be helpful for fever and joint pain. Treatment with glucocorticoids should be considered in patients with severe renal or gastrointestinal manifestations. Similar to other vasculitides, prednisone should be started at 1 mg/kg or pulse intravenous dosing 1 g/day for 3 days in cases of severe end-organ involvement.

Cryoglobulinemic Vasculitis. Cryoglobulinemic vasculitis is characterized by a primarily small-vessel vasculitis in association with cryoglobulins in the peripheral blood, which are proteins that precipitate at temperatures below 37°C.[21] There are three types of cryoglobulins. Type I is typically associated with Waldenstrom macroglobulinemia and causes a hyperviscosity syndrome rather than a vasculitis. In contrast, types II and III cause vasculitis and are associated with chronic hepatitis C infection, malignancy, or autoimmune diseases (SLE, Sjögren's). Cryoglobulinemia can also be idiopathic. Cryoglobulinemic vasculitis generally causes vasculitic features such as glomerulonephritis, mononeuritis multiplex. palpable purpura, nonspecific myalgias, and arthralgias, or weakness are particularly common, while DAH is relatively uncommon. Diagnosis is made by demonstrating the presence of cryoglobulins in the bloodstream. Biopsy of an affected organ can be helpful if the diagnosis remains uncertain. Treatment includes immunosuppression if end-organ involvement is present, similarly to other vasculitides, and treating the precipitating illness (e.g., HCV).

Fig. 105.6 Purpuric Lesions Associated with IgA Vasculitis, Some of Which Have Coalesced and Undergone Central Necrosis. (From Habif TP. *Clinical Dermatology*. 5th ed. New York: Mosby; 2009.)

Polyarteritis Nodosa

Polyarteritis nodosa is a necrotizing vasculitis primarily affecting medium-sized arteries.[22] It affects patients in their fifth and sixth decade of life and has a slight male predominance. A small percentage of cases are associated with hepatitis B infection. In contrast to the small-vessel vasculitides, it does not typically involve the lung and does not cause glomerulonephritis, as both of these manifestations are due to small-vessel involvement. The renal manifestations of PAN are typically reno-vascular hypertension or renal infarcts. Similarly, cutaneous features of PAN are typically ulcers or nodules rather than palpable purpura. However, similarly to the small-vessel vasculitides, PAN can cause mononeuritis multiplex, mesenteric ischemia, joint pain, or constitutional symptoms. A unique manifestation is testicular involvement. There are no antibodies associated

with PAN. Diagnosis is made by either biopsy of the involved organ demonstrating a medium-vessel vasculitis or abdominal imaging demonstrating characteristic microaneurysms in the splanchnic vasculature. Treatment includes glucocorticoids and another immunosuppressant, most commonly cyclophosphamide. Glucocorticoid dosing is similar to other vasculitides with pulse dosing for severe end-organ involvement and prednisone 1 mg/kg for less severe end-organ involvement.

Other Vasculitides

Behçet Disease. Behçet disease (BD) is a vasculitis that affects all blood vessel sizes and is characterized by the presence of recurrent oral aphthous ulcers.[23] It affects populations living along the Silk Road most commonly, such as Turkey, Saudi Arabia, Iraq, Iran, and China, but can occur in any part of the world. In contrast to other vasculitides, the typical manifestations of vasculitis such as glomerulonephritis, DAH, mesenteric ischemia, peripheral neuropathy, or palpable purpura are rare. The most common manifestations include inflammatory eye disease such as uveitis, genital ulcers, and various skin manifestations including erythema nodosum (Fig. 105.7), among others. Gastrointestinal manifestations mimic those of Crohn's disease. Importantly, because BD can involve large vessels, it can cause aneurysmal arterial lesions with resultant rupture as well as DVT, including Budd-Chiari syndrome or cavernous sinus thrombosis. Uniquely, BD can also cause central nervous system disease, with a predilection for the brainstem.

Diagnosis is made on clinical grounds. BD should be considered in patients with recurrent oral ulcers (Fig. 105.8) and the presence of genital ulcers, inflammatory eye disease, or other systemic features. In the evaluation for BD, it is important to exclude other causes of oral and genital ulceration, in particular, herpes simplex virus infection. Treatment is guided by disease severity. Mucocutaneous manifestations are generally treated with colchicine. Internal organ involvement requires glucocorticoids 1 mg/kg or pulse dosing in severe end-organ involvement. Another immunosuppressant such as azathioprine, cyclophosphamide, or TNF alpha inhibitors should be considered with end-organ involvement in consultation with rheumatology. Notably, DVT associated with BD generally requires treatment with immunosuppression, which has been shown to decrease the rate of recurrence. Anticoagulation should be considered on an individualized basis.

Cutaneous Vasculitis. Cutaneous small-vessel vasculitis (CSVV) is the most common single-organ vasculitis.[24] It has been previously known as hypersensitivity vasculitis or leukocytoclastic vasculitis, among others. CSVV can occur as a manifestation of a drug reaction or be idiopathic. It is only distinguished clinically from the systemic vasculitides such as ANCA-associated vasculitis, IgAV, and cryoglobulinemia due to the absence of other systemic symptoms, negative serology, and absence of IgA deposition on skin biopsy. Diagnosis is made on tissue biopsy with histology generally demonstrating leukocytoclastic vasculitis. It is critical to exclude systemic involvement; therefore, a urinalysis should be obtained in patients with CSVV to investigate for glomerulonephritis. Treatment may include topical corticosteroids, NSAIDs (e.g., naproxen 500 mg BID or ibuprofen 800 mg TID), colchicine (0.6 mg BID), dapsone (50 mg daily: dapsone requires lab monitoring and should be started in consultation with dermatology or rheumatology), or glucocorticoids (ranging from 20 to 60 mg daily depending on severity), among others.

CHAPTER 105: QUESTIONS AND ANSWERS

1. Which of the following findings would decrease the likelihood that a patient's pleurisy is related to a lupus flare?
- **a.** Elevated erythrocyte sedimentation rate
- **b.** Low complement levels
- **c.** Negative review of systems
- **d.** Polyarthritis
- **e.** PR depression on electrocardiogram

Answer: c. The general approach to assessing whether a symptom is caused by SLE disease activity is to look for signs and symptoms of the disease in other organs or systemically. Patients experiencing an SLE flare are likely to have other signs or symptoms of disease (e.g., arthralgias, fever, malaise, elevated ESR, low complement levels) beyond an isolated chief complaint (in this case, pleurisy). PR depression can be suggestive of pericarditis, which may occur during flares of SLE.

2. A patient with a history of SLE presents actively seizing. In addition to respiratory support, what is the most appropriate initial step in management?
- **a.** Intravenous ceftriaxone and vancomycin
- **b.** Intravenous cyclophosphamide
- **c.** Intravenous lorazepam
- **d.** Intravenous methylprednisolone
- **e.** Intravenous tissue plasminogen activator

Answer: c. In nearly all cases (including seizure), the initial resuscitation and stabilization of the patient with SLE are the same as for patients without SLE. While this patient could have meningitis, lupus cerebritis, or a stroke, which could warrant some of the other treatments listed, the patient should be stabilized by treatment of the seizure first.

3. Which of the following symptoms is least likely to be seen in a patient presenting with giant cell arteritis?
- **a.** Amaurosis fugax
- **b.** Constitutional symptoms
- **c.** Dysphagia
- **d.** Jaw claudication
- **e.** Scalp tenderness

Answer: c. Patients presenting with giant cell arteritis (GCA) commonly have constitutional symptoms. Other presenting symptoms include headache and scalp tenderness. Jaw claudication is relatively specific for GCA, and visual symptoms (e.g., amaurosis fugax) may herald impending blindness from the disease if not treated. Dysphagia is not a presenting feature of GCA.

4. A patient with a history of SLE presents with acute bilateral arm weakness and decreased sensation below the clavicles starting 90 minutes prior to arrival. A CT of the head is normal, and an MRI of the brain and spine reveals T2 hyperintensity in the cervical spine. Which of the following is the most appropriate next step in management for this patient?
- **a.** Intravenous ceftriaxone and vancomycin
- **b.** Intravenous lorazepam
- **c.** Intravenous methotrexate
- **d.** Intravenous methylprednisolone
- **e.** Intravenous tissue plasminogen activator

Answer: d. This patient is presenting with transverse myelitis. The first line of treatment for this condition is high-dose glucocorticoids, such as methylprednisolone, and since this patient has a history of SLE, cyclophosphamide. Refractory cases may be treated with plasma exchange and additional immunosuppressive agents.

Continued

CHAPTER 105: QUESTIONS AND ANSWERS—cont'd

5. A patient with a history of SLE presents with shortness of breath. CT angiography reveals two segmental pulmonary emboli. Laboratory testing and bedside echocardiography are unremarkable. Chart review reveals positive anticardiolipin and β2-glycoprotein I titers. Which of the following is the most appropriate next step in therapy for this patient?

a. Aspirin
b. Enoxaparin
c. Rivaroxaban
d. Tissue plasminogen activator
e. Warfarin

Answer: b. This patient has SLE and antiphospholipid syndrome (APS) based on the history of thromboembolic disease and positive antiphospholipid (aPL) antibodies. The most appropriate anticoagulation for patients with APS is a vitamin K antagonist (e.g., warfarin) or a heparin analog (e.g., enoxaparin). In the acute setting, however, a heparin analog should be used due to the delayed therapeutic effect of vitamin K antagonists. Aspirin is insufficient to treat acute thromboembolic disease in APS, and direct oral anticoagulants have decreased efficacy when compared to vitamin K antagonists and heparin analogs. This patient does not have an indication for tissue plasminogen activator.

106

Allergy, Anaphylaxis, and Angioedema

Aaron N. Barksdale and Weston Ross

KEY CONCEPTS

- Anaphylaxis is a life-threatening systemic allergic (or nonallergic) reaction of acute onset and multiorgan involvement in which timely recognition and treatment remain essential.
- A history of sudden urticarial rash accompanied by respiratory difficulty, abdominal pain, or hypotension, strongly favors the diagnosis of anaphylaxis.
- The recommended treatment algorithm for anaphylaxis is shown in Box 106.7.
- Epinephrine is the first-line treatment in patients with anaphylaxis and should be given immediately. There are no absolute contraindications to the use of epinephrine in the setting of anaphylaxis.
- Antihistamines and corticosteroids are second- and third-line agents in the management of anaphylaxis and should not replace or precede epinephrine.
- Consider prolonged observation or admission for patients who (1) experience protracted anaphylaxis, hypotension, airway involvement, or unknown trigger; (2) receive IV epinephrine or more than one dose of IM epinephrine; or (3) have poor outpatient social support.
- Patients discharged after an anaphylactic event should be prescribed self-injectable epinephrine devices and instructed on use, encouraged to develop an emergency action plan, and referred to an allergist/immunologist.
- Patients with refractory hypotension may require a continuous IV epinephrine infusion or glucagon in patients with coexisting beta-adrenergic blockade).
- Non-histaminergic angioedema (nonallergic angioedema) does not typically respond to epinephrine and antihistamines, though they should be considered at initial presentation. Newer drugs, including icatibant, ecallantide, and human or recombinant C1 esterase inhibitor, have been approved for use in hereditary angioedema (HAE). Fresh frozen plasma (FFP) has been used with varying success in HAE, acquired C1 esterase inhibitor deficiency (ACID), and angiotensin-converting enzyme (ACE) inhibitor-induced angioedema.

ALLERGY

FOUNDATIONS

Background and Terminology

The prevalence of allergic disease has significantly increased over the past several decades, particularly in developed societies. It is currently estimated that 30% of the worldwide population suffer from some component of allergy, including 5% to 8% with food allergies. This has contributed to increased financial burdens on our health care systems and morbidity in affected individuals.[1–4] This is largely attributed to changes in lifestyle, diet, antibiotic use, smaller families, and the "hygiene hypothesis," which centers around decreased microbial exposure in developed countries.[1,3]

The human immune system comprises cellular and humoral components working together in a highly complex and coordinated fashion to achieve the primary goal of protecting the human host from potentially harmful offenders. The immune system, however, can overreact to otherwise harmless agents, producing an inappropriate response that may be harmful to the host, thereby giving rise to allergy or allergic diseases. These hypersensitivity reactions are manifested in clinical symptoms ranging from nuisance-level to fatal. For practical purposes, the term *allergy* is used in this chapter to refer to mast cell–mediated hypersensitivity reactions. For most allergic diseases to occur, predisposed individuals require exposure to allergens through *sensitization.* Substances that elicit an allergic reaction are referred to as *allergens,* and those that elicit an antibody response are termed *antigens.*

On the allergic continuum, there are several important allergic syndromes (Fig. 106.1). *Urticaria* (wheels, hives) is a common allergic reaction to foods, drugs, temperature changes, or physical stimuli. It is clinically characterized by a raised central swelling of variable size with surrounding reflex erythema, combined with an itching or burning sensation, with the skin typically returning to its baseline appearance within 30 minutes to 24 hours.[5]

Angioedema is characterized by sudden swelling of the subcutaneous or mucous membranes and tends to be more painful than pruritic. In general, it is slower to resolve compared to urticaria, and if the tongue or larynx is involved, it can result in airway compromise.[5] Angioedema can occur through one of two different mechanisms. Allergic (histaminergic) angioedema occurs in response to exposure to foods, drugs, or physical stimuli. Nonallergic (non-histaminergic) angioedema may be hereditary (termed hereditary angioedema [HAE]) or medication-induced (e.g., angiotensin-converting enzyme [ACE] inhibitor angioedema).

At the other extreme of this allergic continuum is *anaphylaxis,* a life-threatening systemic reaction, characterized by acute onset and multiorgan involvement.[6–8] It is a type I hypersensitivity reaction (allergic), mediated by immunoglobulin E (IgE). In its most common form, anaphylaxis is precipitated by exposure to allergens in previously sensitized individuals (immunologic). Previously, the term *anaphylactoid reaction* referred to a syndrome clinically similar to anaphylaxis that is not mediated by IgE (non-immunologic). Its clinical presentation and treatment are identical to that of anaphylaxis. Non-IgE (non-immunologic) reactions appear to result from direct degranulation of mast cells (and basophils) and may follow a single, first-time exposure to certain inciting agents (e.g., NSAIDs, monoclonal antibodies, local anesthetics, chemotherapeutic drugs). The World Allergy Organization (WAO) guidelines use the term *anaphylaxis* to refer to both IgE- and

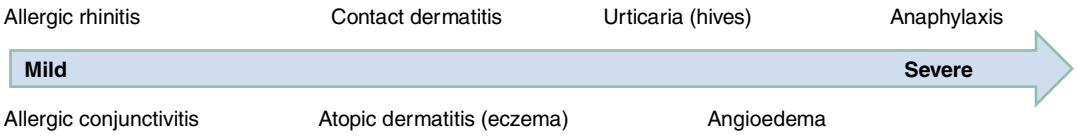

Fig. 106.1 Severity Spectrum of Allergic Disease.

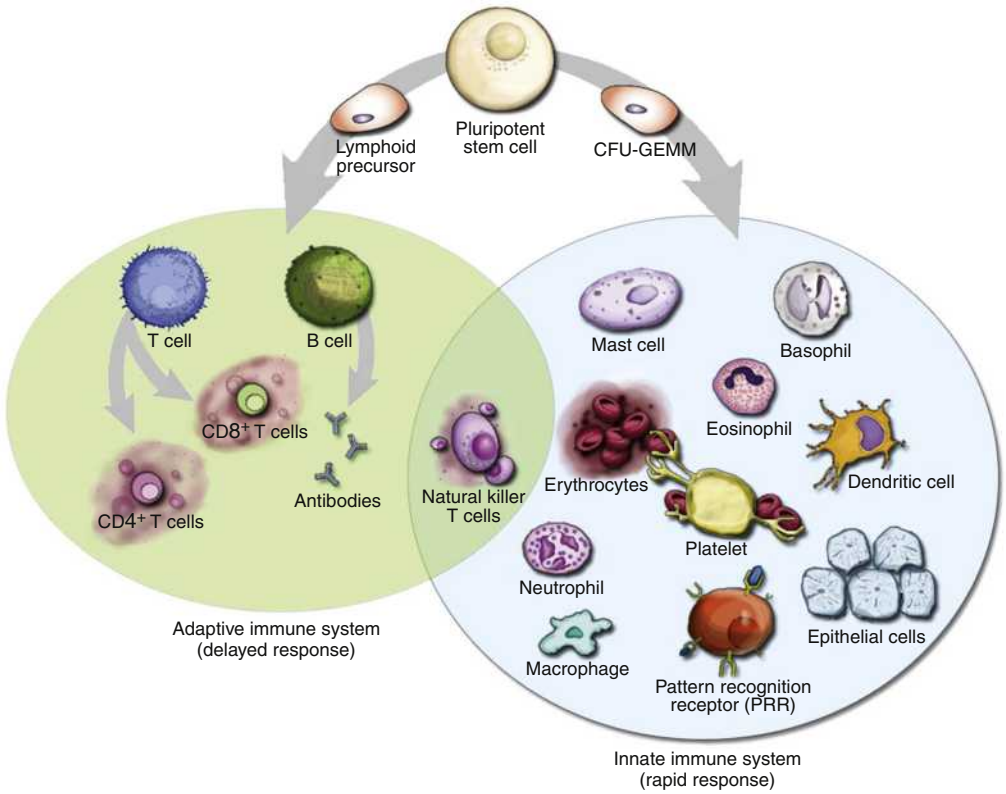

Fig. 106.2 Developmental Pathways of the Immune and Hematopoietic Systems. *CFU-GEMM,* Colony-forming unit for granulocyte, erythroid, myeloid, and megakaryocyte.

non-IgE-mediated reactions, obviating the need for the term *anaphylactoid reaction,* although this term is still often used.[6,9]

Pathophysiology

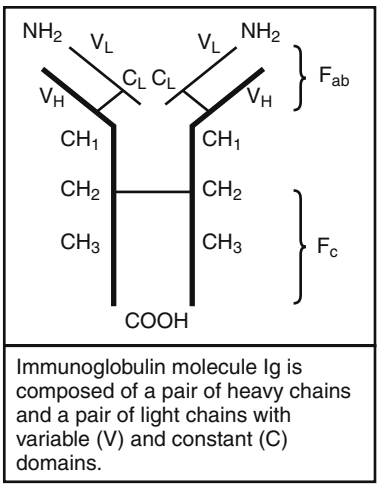
Immunologic responses to *antigens* are coordinated by two systems: the *innate* immune system, and the more recently evolved *adaptive* immune system (Fig. 106.2). The innate immune system is considered the first line of defense and is characterized by its nonspecific but rapid responses to offending agents or microbes. Its effector components include resident cells (epithelial cells, mast cells, macrophages, dendritic cells, antimicrobial proteins), infiltrative cells (natural killer cells, neutrophils, monocytes, dendritic cells), and various proteins (antimicrobial peptides, complements, cytokines, and the pathogenic pattern recognition receptor [PRR] system). The innate system responds to danger signals rapidly and nonspecifically, whereas the adaptive immune system takes time for antigen-specific cells (B and T cells) to amplify through a process known as *clonal expansion* to mount a specific immune response. The T and B lymphocytes are capable of recognizing a myriad of antigens through a vast library of antibodies and receptors (up to 10^{15}).[1,3,4]

The adaptive and innate immune systems originate from the common pluripotential hematopoietic stem cells. When the host encounters a foreign antigen, the cellular components of the adaptive immune system interact with the cellular and protein components of the innate immune system to mount a coordinated defense aimed at neutralization of the antigen.

Mast cells, basophils, and their mediators are the central effectors in allergy and anaphylaxis. Exposure of a genetically predisposed individual to an allergen leads to the synthesis and release of allergen-specific IgE by plasma cells into the circulation. Fixation of this allergen-specific IgE to surface receptors on mast cells completes the process known as *sensitization.* These IgE-bearing mast cells usually reside in the mucosal surfaces, submucosal tissue (around venules), and cutaneous surfaces, where they are capable of becoming activated on re-exposure to a specific allergen. Cross-linking of the mast cell receptors by a specific multivalent allergen sets off a cascade of conformational and biochemical events, causing the degranulation of preformed mediators, subsequent generation and release of arachidonic acid metabolites, elaboration of cytokines and chemokines, and activation of the cellular components by the innate and adaptive systems. This series of events ultimately leads to the clinical syndromes of allergy and anaphylaxis (Fig 106.3).[1,3,4]

Classification of Reactions

The term *allergy* is commonly used to describe clinical illnesses produced by excessive immune responses by a normal immune system to otherwise innocuous allergens. The classic Coombs and Gell



Immunoglobulin molecule Ig is composed of a pair of heavy chains and a pair of light chains with variable (V) and constant (C) domains.

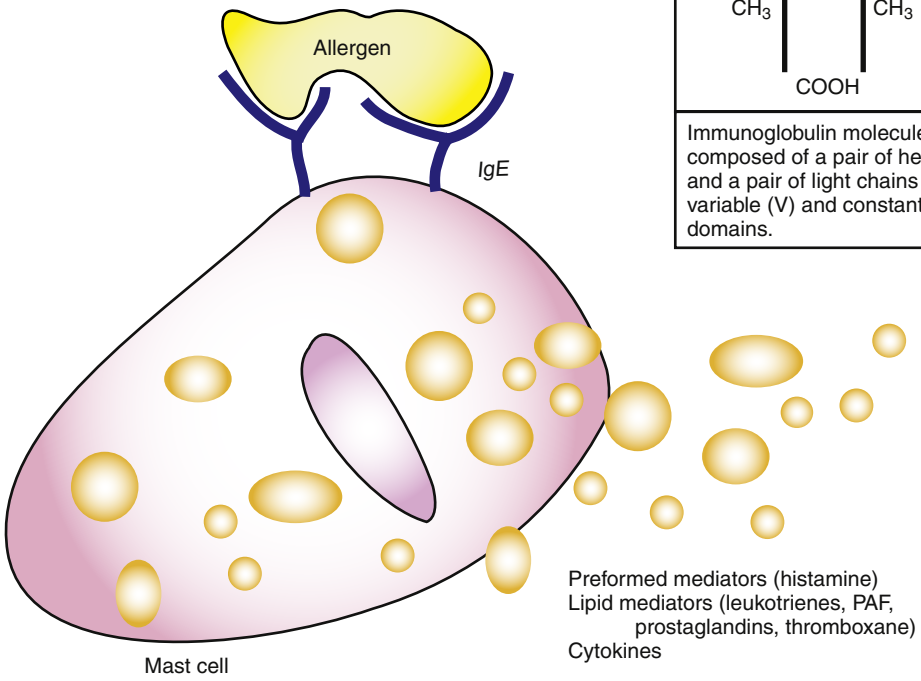


Fig. 106.3 Activation of mast cells with degranulation of mast cell mediators by antigen cross-linking of adjacent immunoglobulin E *(IgE)* on the cell surface. *PAF,* Platelet-activating factor.

BOX 106.1 Gell and Coombs Classification of Immune Reactions

Type I: Immediate Hypersensitivity
Binding of multivalent antigens to IgE on the surface of mast cells and basophils leads to degranulation of mediators. In previously sensitized individuals, the reaction develops quickly (minutes). This type of hypersensitivity reaction is seen in allergic diseases (e.g., hay fever, allergic asthma, urticaria, angioedema, and anaphylaxis). *Non-immunologic* (previously termed anaphylactoid) *reaction* refers to the direct release of preformed mediators of mast cells independent of IgE.

Type II: Cytotoxic Antibody Reaction
Antibody (IgM, IgG) binding of membrane-bound antigens leads to cytotoxicity and cell lysis of cells through the complement or mononuclear cell system (macrophages, neutrophils, and eosinophils). This type of reaction is seen in transfusion reaction and Rh incompatibility.

Type III: Immune Complex–Mediated Reaction
Binding of antibody (IgM, IgG) to antigens forms soluble immune complexes, which are deposited on vessel walls, causing a local inflammatory reaction (Arthus reaction) leading to inflammation and tissue injury. This type of reaction is seen in systemic lupus erythematosus and serum sickness (after antithymocyte globulin administration).

Type IV: Cell-Mediated Delayed Hypersensitivity
Sensitized lymphocytes (T_H1 cells) recognize the antigen, recruit additional lymphocytes and mononuclear cells to the site, and start the inflammatory reaction. No antibodies are involved. This type of reaction is seen in contact dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

IgE, Immunoglobulin E; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *T_H1,* type 1 helper.

classification can be adapted to categorize these hypersensitivity reactions (Box 106.1).

Type I reactions (immediate hypersensitivity) are IgE mediated and account for most allergic and anaphylactic reactions. Exposure to sensitizing allergens causes mediators from mast cells and basophils to be released through both IgE-dependent and IgE-independent (direct mast cell degranulation) mechanisms. Rhinitis caused by ragweed pollen and anaphylaxis caused by foods are examples of the IgE-dependent mechanism.

ANAPHYLAXIS

FOUNDATIONS

Epidemiology and Risk Factors

The prevalence of anaphylaxis and related hospital admissions has increased over the past two decades. The incidence is difficult to determine, but anaphylaxis is estimated to occur in roughly 2% of the

BOX 106.2 Risk Factors for Anaphylaxis and Increased Anaphylaxis Severity and Mortality

Risk Factors for Having Anaphylaxis
Age and sex
- Pregnant women, infants, teenagers, elderly

Route of administration
- Parenteral > oral

Higher social economic status
Time of the year
- Summer and fall (the outdoor seasons)

History of atopy
Emotional stress
Acute infection
Physical exertion
History of mastocytosis
Risk Factors for Increased Anaphylaxis Severity and Mortality
Extremes of age
- Very young (under-recognition)
- Elderly (decreased physiologic reserves)

Comorbid conditions
- Cardiovascular disease (heart failure, ischemic heart disease, hypertension)
- Pulmonary disease (asthma, obstructive airway disease)

Others
- Concurrent use of anti-hypertensive agents, specifically beta-blockers and angiotensin-converting enzyme (ACE) inhibitors
- Concurrent use of cognition-impairing drugs (e.g., alcohol, recreational drugs, sedatives, tranquilizers)
- Recent anaphylaxis episode
- Upright posture at the onset of symptoms

BOX 106.3 Etiologic Agents Causing Anaphylaxis by Immunologic Mechanisms

Immunologic Mechanisms (IgE-Dependent)
Foods: Peanut, tree nut, milk, egg, shellfish, soybean, cow milk, mammalian meats (after sensitization to alpha-gal protein following tick bite)
Medications: Antibiotics, NSAIDs, chemotherapeutic agents, immunomodulators
Insect stings: *Hymenoptera* venoms, fire ant stings
Natural rubber latex
Hormones: Insulin, methylprednisolone, parathormone, estradiol, progesterone, corticotropin
Local anesthetics: Mostly ester family (procaine, tetracaine, benzocaine)
RCM
Occupational allergens: Enzymes, animal protein, plant protein
Aeroallergens: Pollen, dust, spores, pet dander

Immunologic Mechanisms (Ige-Independent)
RCM
NSAIDs
Dextrans
Biologic agents: Monoclonal antibodies, immunomodulators

Non-Immunologic Mechanisms (Direct Mast Cell Activations)
Physical factors: Exercise, cold, heat, sunlight
Ethanol
Medications: Some opioids
Idiopathic (no apparent trigger)

IgE, Immunoglobulin E; *NSAID,* nonsteroidal antiinflammatory drug; *RCM,* radiocontrast media.

worldwide population and as high as 5% in the United States.[6–8,10] While fatal anaphylaxis is rare, representing less than 1% of cases, there is evidence that medication-induced fatalities are increasing in North America and that food-induced fatalities are increasing in Australia.[11]

The severity of anaphylaxis varies between different age groups depending on the specific trigger and cofactors, but in general, pregnant women, infants, teenagers, and elders have been shown to have an increased incidence of anaphylaxis.[6] Additional risk factors include atopy (genetic predisposition to develop allergic disease), peanut and tree nut allergy, emotional stress, seasonal occurrence in summer to fall months, higher socioeconomic status, premenstrual age, and the presence of acute infection. Severe anaphylaxis has been associated with poorly controlled asthma, history of mastocytosis, heavy physical exertion, exposure to a trigger during the concomitant use of certain medications (ACE inhibitors, beta-blockers, and nonsteroidal antiinflammatory drugs [NSAIDs]), history of a previous anaphylactic reaction, delayed epinephrine administration, and upright position at the onset of symptoms (Box 106.2).[6,8,10,12,13]

In general, the more rapid an anaphylaxis reaction occurs after an exposure, the more likely it is to be severe and potentially fatal. The dose, frequency, duration, and route of administration of a drug can also affect the tendency to develop an anaphylactic reaction (e.g., the parenteral route is more likely to lead to an anaphylactic reaction than the oral route).[6,7,10] One interesting aspect of drug-related anaphylaxis is the constancy of administration. An anaphylactic reaction may not occur in an otherwise susceptible patient as long as a drug is administered at regular intervals. The same patient, however, may experience an anaphylactic reaction if the drug is resumed after an interruption of therapy.

ACE-inhibitor use can cause an accumulation of kinins and bradykinin and thus can exacerbate the angioedema component of anaphylaxis. Beta-adrenergic blockers may oppose the actions of adrenergic agents used in anaphylaxis treatment. Recent evidence suggests that taking an ACE inhibitor or a beta-blocker increases the risk of severe anaphylaxis (and even more so when taken concurrently) but does not necessarily increase the incidence of initial anaphylactic reactions.[6,14]

Common Triggers for Anaphylaxis

Virtually any agent that is capable of activating mast cells or basophils can potentially precipitate an anaphylactic reaction. However, in up to 60% of adults and 10% of children, an inciting agent cannot be identified, which is classified as *idiopathic anaphylaxis*.[15] When a trigger can be determined, foods, insect stings, and medications are the most common causes. Box 106.3 lists many of the common agents by their proposed immunologic mechanism.[6,9,10,12]

Foods

Food allergens are the most common identifiable agents and represent up to a third of reported anaphylactic cases. The incidence has significantly increased over the past decade, especially among children. Symptoms typically occur within 5 to 30 minutes of ingestion with fatalities reported within 30 minutes of exposure, though in some cases onset can be significantly delayed. In particular, reactions to mammalian foods (e.g., beef and pork) can be delayed 3 to 6 hours following exposure; recent research strongly suggests sensitization to the alpha-gal protein following a tick bite in this circumstance.[16–19] The most commonly implicated foods include peanuts, shellfish, tree nuts, fish, soy, cow's milk, and eggs. Fatal outcomes have been more commonly

reported in adolescents and young adults, as well as those with a history of asthma, tree nut or peanut allergy, anaphylactic cases presenting without skin manifestations, or when epinephrine administration was delayed.[6,9–11] The majority of reactions occur after ingestion, but may also occur following inhalation of food particles or even after skin contact with vomit containing the instigating agent. In the setting of a known allergy, it may be difficult to avoid certain allergens, as their identity may be obscured during processing (e.g., consuming wine contaminated with *Hymenoptera* venom).

Drugs

Medications represent the second most frequent cause of anaphylactic reactions but are the most common trigger in adult subjects and result in the highest incidence of fatalities across all age groups. NSAIDs, antibiotics (specifically beta lactams), and neuromuscular blocking agents (NMBAs) are the most commonly reported triggers, but over the past decade, there has been a significant rise in chemotherapeutic or immunomodulator agent–related reactions.[6,10,20,21] Fatal drug-induced anaphylaxis has been associated with hypertension, obesity, male gender, beta-blocker use, and old age.[6,10,11]

Penicillin is the most common antibiotic cause of anaphylaxis. Although many report a history of penicillin allergy, studies have shown that less than 10% of individuals with a reported history of penicillin are truly allergic via skin testing. These individuals are often mislabeled as penicillin allergic at some point, or their allergy senesces after years of avoidance. Parenterally administered penicillin is responsible for the majority of anaphylactic reactions.[20,21]

Cephalosporins share the β-lactam ring structure and side chains of the penicillins, but allergic cross-reactivity appears to be low, in 1% to 8% of patients. Patients who have experienced urticaria or anaphylactic reactions after taking penicillin are more likely to have an adverse reaction to cephalosporins, but even in this setting, the risk of an anaphylactic reaction is low. There have been rare reports of cross-reactivity to aztreonam and carbapenems in penicillin-allergic patients, but these antibiotics should not be withheld when clinically indicated.[6,21]

NSAIDs are the most common trigger of drug-induced anaphylaxis and are believed to occur through interruption of the arachidonic acid metabolism, a non-IgE (non-immunologic) mediated process. The incidence of anaphylaxis to NSAIDs varies widely, and these reactions appear to be drug specific and without cross-reactivity to other NSAIDs. Aspirin exacerbated respiratory distress (AERD) and NSAID-induced respiratory distress syndromes are unique in individuals with a history of asthma or allergic rhinitis and are not considered anaphylactic reactions.[6,9,20,21]

Insect Stings

Anaphylactic reactions occur in up to 3% of adults and 1% of children who suffer an insect sting. The majority are associated with hymenoptera venoms (wasps, bees, ants, and sawflies) and fire ant stings. These reactions typically require a sensitizing exposure, but there have been numerous reports of anaphylactic reactions following first known stings or bites. Increased risk of fatal venom anaphylaxis has been associated with middle-aged white males, preexisting cardiovascular disease, and upright posture at the time of exposure.[9–11]

Natural Rubber Latex

Natural rubber latex (NRL) allergy is the result of sensitivity to the proteins or chemicals contained in the latex products. This sensitivity reaction can be delayed (type IV) contact dermatitis or an immediate hypersensitivity (type I) reaction (see Box 106.1). In addition to rubber gloves, NRL can be found in an array of other medical supplies, including endotracheal tubes, blood pressure cuffs, stethoscope tubing, airway masks, tourniquets, and catheters. In the United States, most health care settings have incorporated the use of non-NRL gloves and products, but in many countries, it is still a common anaphylactic trigger.[6] NRL can also found in balloons, condoms, pacifiers, sports equipment, and toys.

BOX 106.4 A Standard Treatment Protocol for Patients With a History of Radiocontrast-Induced Anaphylaxis

Prednisone 50 mg by mouth given 13, 7, and 1 h before the procedure
Diphenhydramine 50 mg PO given 1 hour before the procedure
Consider ephedrine 25 mg by mouth given 1 hour before the procedure
Consider an H_2 antagonist, such as famotidine 20 mg by mouth given 3 h before the procedure

Radiocontrast Media

Approximately 38 million computerized tomography (CT) scans, and 17 million magnetic resonance imaging (MRI) examinations using radiocontrast media (RCM) are performed in the United States annually.[22] CT scans use iodinated contrast media (ICM). ICM reactions can be divided into two types based on timing: immediate reactions occur within the first hour of administration, and delayed reactions occur from 1 hour to several days after administration. Anaphylactic reactions to ICM are largely idiosyncratic and occur within minutes of infusion. Delayed reactions are generally mild to moderate and typically limited to the integumentary system manifesting as maculopapular rash, urticaria, and angioedema. Delayed reactions rarely escalate to the levels of toxic epidermal necrolysis or Stevens-Johnson syndrome. The pathophysiologic mechanism of anaphylactic reactions to ICM is unknown, but it is believed to be non-immunologic (non-IgE). Risk factors for an anaphylactic reaction include a previous adverse reaction to ICM, a history of atopy or allergic disease, asthma, and certain medications including ACE inhibitors, β-blockers, or proton pump inhibitors.[23] A history of allergy to fish or shellfish is not a contraindication to the use of the currently available ICM, nor does it increase the risk of an adverse reaction to ICM. Clinically, the risk for severe adverse reaction to ICM is less than 1%. The death rate from ICM reactions is estimated at 1 per 170,000 administrations and accounts for 27% of drug-induced anaphylactic fatalities.[22,23] Protocols using pretest administration of antihistamines and/or glucocorticoids have been developed to minimize the risks of serious allergic reactions in patients who have had a previous adverse reaction to ICM (Box 106.4). However, there is currently little evidence to support the use of these agents to prevent anaphylaxis in patients receiving low or iso-osmolar RCM for emergently needed tests. We do not recommend delaying necessary tests for ED patients requiring emergent imaging with RCM to administer these medications as a prophylactic measure.[8]

Gadolinium-based contrast agents (GBCAs) are another type of RCM used in MRI. There is no cross-reactivity in allergies to ICM and GBCA, as they are unique structurally. Risk factors for reactions to GBCA include a history of asthma, food allergies, allergies to medications, and female gender. Reactions to GBCA are exceedingly rare, with an incidence of 0.004% to 0.01%, and typically occur within minutes of administration.[23] Like ICM, the pathophysiology of these reactions is poorly understood. Finally, adverse reactions to RCM are not related to iodine and these individuals should not be labeled as having an "iodine allergy."[8]

Exercise-Induced Anaphylaxis

Exercise-induced anaphylaxis (EIA) is a clinical syndrome in which anaphylactic-like reactions occur in relation to physical exertion.

TABLE 106.1 Mediators in Anaphylaxis and Their Physiologic Actions and Clinical Manifestations

Mediators	Physiologic Activity	Clinical Manifestation
Histamine, leukotrienes, thromboxane, prostaglandins, platelet-activating factor, nitric oxide	Vascular permeability, vasodilation, smooth muscle spasm, mucous gland secretion, nociceptor stimulation, myocardial depression	Generalized urticaria and angioedema, pruritus, wheezing, bronchoconstriction, rhinorrhea and bronchorrhea, coryza, conjunctivitis, syncope, tachycardia, hypotension, shock, abdominal pain, nausea, vomiting, diarrhea
Tryptase, carboxypeptidase, chymase, cathepsin G	Activation of the complement system, chemoattraction, activation, and degranulation of mast cells	Anaphylaxis response is amplified by recruitment and activation of the complement system and further degranulation of mast cell mediators
TNF-α, cytokines, chemokines, eosinophil chemotactic factors	Induction of anti-platelet-activating factor production, control migration of eosinophils and other inflammatory cells	May be responsible for the intensity, protracted symptoms, and multiphasic reaction of anaphylaxis

TNF-α, Tumor necrosis factor alpha.

There are two subtypes: Exercise-induced anaphylaxis (EIA), and food-dependent exercise-induced anaphylaxis (FDEIA). EIA can be dependent on other various cofactors including alcohol, environmental temperatures, pollen levels, medications such as NSAIDs (especially aspirin), or endogenous progesterone during female menstrual cycles. EIA can occur with varying levels of exertion or types of activity. While it is more commonly seen with moderate to intense physical activity, it has also been described during less strenuous activities like walking and raking leaves. Reactions can occur inconsistently with physical activities, thus increasing the difficulty of diagnosis. FDEIA only occurs if specific foods have been ingested prior to initiating exercise that would otherwise not cause symptoms without associated physical exertion. Wheat has been identified as the most common food to cause FDEIA. Avoidance of the offending food agent minimizes the risk of symptom development. Ingestion of triggering food 4 to 6 hours, or NSAIDs up to 24 hours, prior to physical activity may precipitate a reaction in susceptible individuals.[9,24–26]

Patients should be instructed to discontinue exercise at the first sign of symptoms, as continued activity can lead to clinical deterioration. Patients with suspected EIA should be prescribed epinephrine autoinjectors. They should be counseled to avoid exercising alone and preferably only exercise with a partner who is aware of their condition and able to administer an epinephrine autoinjector if necessary.[9,24]

Idiopathic Anaphylaxis

Thirty percent to 60% of adults, and up to 10% of children, have no identifiable trigger for an anaphylactic episode. The diagnosis of idiopathic anaphylaxis is often made after evaluation and testing by an allergist. In an attempt to prevent recurrent episodes, these patients may be treated with daily prophylactic medications, such as oral antihistamines with or without oral corticosteroids. A newer treatment option is omalizumab, which has been shown to reduce episodes of idiopathic anaphylactic reactions.[15] The prevalence of idiopathic anaphylaxis is unknown and difficult to estimate. Newly identifiable causes of anaphylaxis, such as alpha-gal, and other allergens have reframed prior idiopathic anaphylaxis diagnoses in some individuals.[27]

Pathophysiology

Anaphylaxis is the result of a variable intracellular signaling process, and severity depends on the specific allergen, route of exposure, and amount of effector cell activation. Mast cells and basophils appear to be the primary effector cells, but research has demonstrated other blood cell and platelet involvement as well.[28] Numerous mediators released by mast cells and basophils exert overlapping physiologic effects on target organs and tissues, making it difficult to ascribe specific clinical manifestations to any single mediator. Histamine and typtase are the two most abundant, with histamine serving as the predominant contributor to immediate hypersensitivity and inflammation.[28–30] Table 106.1 lists the primary mediators in anaphylaxis and their physiologic actions and associated clinical manifestations.

CLINICAL FEATURES

Anaphylactic reactions vary in duration and severity but typically are rapid in onset with most occurring within 2 hours of allergen exposure. Clinical presentations depend on the degree of hypersensitivity, the quantity, route, and rate of antigen exposure, as well as the target organ sensitivity and responsiveness. Presentations include a combination of clinical characteristics, affecting an array of organ systems including the skin (80% to 90%), respiratory tract (70% to 80%), gastrointestinal tract (25% to 30%), cardiovascular (30% to 50%), or the central nervous system (20% to 30%).[9,12,13,20] The National Institute of Allergy and Infectious Diseases/Food Allergy and Anaphylaxis Network (NIAID/FAAN) and WAO adopted specific diagnostic guidelines to help clinicians recognize and develop consistency in the diagnosis of anaphylaxis (Box 106.5). The criteria were initially validated with a sensitivity and specificity of 97% and 82%, respectively. A subsequent prospective validation study demonstrated a sensitivity and specificity of 95% and 71%, respectively.[31,32]

The majority of anaphylactic reactions (80% to 90%) involve the skin. This may present as isolated warmth and tingling, generalized flushing, pruritus, diffuse urticarial eruption, or any combination of these findings. Nasal congestion, sneezing, ocular itching, or tearing are also common. Patients presenting with angioedema complain of swelling and a burning sensation in the affected area. Respiratory symptoms (70% to 80%) are not always as severe as stridor or audible wheeze and may consist of cough, sense of chest tightness, subjective dyspnea, or throat tightness.[9,12,13] Hypotension or dysrhythmias may be manifested as lightheadedness or syncope. Seizure activity due to decreased cerebral perfusion is infrequently seen. Gastrointestinal symptoms are more common in elders or when triggered by a food allergen. This may include crampy abdominal pain, associated nausea and vomiting, diarrhea, or tenesmus.[9,12] Anaphylactic reactions vary a great deal from one individual to another and even among different episodes in the same individual. It should be noted that hypotension or shock are rarely presenting features in infants and children, and remain much more common in adults.[9,33] A summary of the clinical

BOX 106.5 Clinical Criteria for Diagnosis of Anaphylaxis

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Sudden onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, itching or flushing, swollen lips-tongue-uvula) *and at least one of the following:*
   a. Respiratory compromise (e.g., shortness of breath, wheeze, cough stridor, hypoxemia)
   b. Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. Two or more of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen or other triggers for that patient:
   a. Involvement of the skin-mucosal tissue (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula)
   b. Sudden respiratory compromise (e.g., shortness of breath, wheeze, cough, stridor, hypoxemia)
   c. Sudden reduced BP or symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
   d. Sudden gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP after exposure to known allergen for that patient (minutes to several hours):
   a. Infants and children: Low systolic BP (age specific) or greater than 30% decrease in systolic BP*
   b. Adults: Systolic BP of <90 mm Hg or greater than 30% decrease from that person's baseline

* Low systolic blood pressure for children is defined as <70 mm Hg from 1 month to 1 year old, <70 mm Hg + (2 × age) from 1 to 10 years old, and <90 mm Hg from 11 to 17 years old.
Modified from Simons ER, Ardusso LRF, Bilò MB, et al. 2012 Update: World Allergy Organization Guidelines for the assessment and management of anaphylaxis. *Curr Opin Allergy Clin Immunol.* 2012:12:389–399.
BP, Blood pressure.

manifestations of anaphylaxis, along with related pathophysiologic changes, is presented in Table 106.2.

DIFFERENTIAL DIAGNOSES

The diagnosis of anaphylaxis is readily apparent in a patient presenting with acute rash, respiratory difficulty, and hypotension after allergen exposure. Common anaphylaxis mimics include syncope, panic attack, or acute asthma exacerbation. A history of asthma is commonly seen in patients experiencing anaphylaxis.[6,9] Flush syndromes may occur related to certain ingestions such as scrombroidosis, sulfites, or monosodium glutamate (MSG) but typically lack the hypotension, urticaria, or airway involvement that may be seen with anaphylaxis. Vasovagal syncope often presents with bradycardia, hypotension, and pallor, rather than the tachycardia, urticaria, and respiratory distress more commonly associated with anaphylaxis.[9,12] Differential diagnostic considerations for suspected anaphylaxis are found in Box 106.6.

DIAGNOSTIC TESTING

Anaphylaxis is primarily a clinical diagnosis. Box 106.5 lists the NIAID/FAAN and WAO diagnostic criteria for anaphylaxis. Elevated serum histamine levels acquired within 1 hour and tryptase levels (specifically in hymenoptera venom-induced anaphylaxis) within 3 hours of the onset of symptoms have been shown to correlate with anaphylaxis. In addition, there is now a commercially available serum-specific test for IgE anti-alpha-gal to help identify sensitivity to mammalian meats following tick exposure. These laboratory tests are rarely helpful in the acute setting as they take time to perform. In addition, tryptase levels may not be elevated in food-induced anaphylaxis.[6,9] Diagnostic studies should be aimed at excluding other emergency conditions that could potentially be confused with anaphylaxis (Box 106.6).

MANAGEMENT

Overview

Prompt recognition and initiation of the appropriate interventions remain key in avoiding adverse outcomes. Treatment delays, even by a few minutes, could potentially lead to hypoxia, circulatory collapse, and even death.[10]

Epinephrine should be immediately administered in the distal and lateral thigh once anaphylaxis is identified, followed by a quick effort to remove any triggering agent (e.g., insect stinger and infusing medication). Initial interventions should include continuous cardiac and pulse oximetry monitoring, intravenous (IV) access, and supplemental oxygen.[6,9,12] Most of the morbidity and mortality associated with anaphylaxis is caused by acute respiratory failure or cardiovascular collapse. Therefore, the next steps in management should focus on the triad of repeat epinephrine administration as necessary, maintenance of airway patency, and expansion of intravascular volume. Antihistamines (H_1 and H_2 blockers) and corticosteroids are commonly given for anaphylaxis, but there is no objective evidence that they improve the overall outcome and should not be considered first-line medications.[6,9,12] Box 106.7 summarizes the recommended treatment algorithm in anaphylaxis.

Positioning

Hypotensive patients should be placed in the supine position with their lower extremities elevated. If they are experiencing airway difficulties or vomiting, allow the patients to place themselves in a comfortable position and attempt to elevate their legs if possible. Pregnant women should be placed in the left lateral decubitus position to prevent vena cava compression and to promote the venous return of blood to the heart.[9,12]

Epinephrine

Epinephrine is the sole first-line medication and should be given immediately whenever anaphylaxis is suspected. Delay in administering epinephrine has been associated with increased ED length of stay, hospitalization, hypoxic encephalopathy, and death. Conversely, there is a strong correlation between early epinephrine administration and decreased hospitalization or fatality.[34,35] Despite NIAID/FAAN guidelines for diagnosis and treatment of anaphylaxis being established in 2006, studies have shown that only about 30% of patients receive epinephrine in the prehospital setting, and only 50% to 70% of those ultimately diagnosed with anaphylaxis receive epinephrine in the ED.[16,33–36]

The dose of aqueous epinephrine is 0.3 to 0.5 mg of 1 mg/mL intramuscularly (IM) for adults, and 0.01 mg/kg of 1:1000 concentration IM for pediatric patients. It can be repeated every 5 to 10 minutes, as up to 30% will require more than one dose and should optimally be administered IM in the lateral, distal thigh (vastus lateralis). This provides more rapid peak plasma concentrations (8 minutes) when compared to the previously suggested subcutaneous route (34 minutes). Subcutaneous or inhalation administration of epinephrine is no longer routinely recommended.[9,12,34,37]

TABLE 106.2 Clinical Manifestations of Anaphylaxis and Related Pathophysiologic Changes

Organ System	Reaction	Symptoms	Signs	Pathophysiologic Changes
Respiratory tract				
Upper	Rhinitis	Nasal congestion	Nasal mucosal edema	Increased vascular permeability
		Nasal itching	Rhinorrhea	Vasodilation
		Sneezing		Stimulation of nerve endings
	Laryngeal edema	Dyspnea Hoarseness Throat tightness Hypersalivation	Laryngeal stridor Supraglottic and glottic edema	As above, plus increased exocrine gland secretions
Lower	Bronchospasm	Cough Wheezing	Cough Wheeze, rhonchi	As above, plus bronchiole smooth muscle contraction
		Retrosternal tightness	Tachypnea	
		Dyspnea	Respiratory distress	
			Cyanosis	
Cardiovascular system	Circulatory collapse	Lightheadedness Generalized weakness Syncope Ischemic chest pain	Tachycardia Hypotension Shock	Increased vascular permeability Vasodilation Loss of vasomotor tone Increased venous capacitance
	Dysrhythmias	As above, plus palpitations	ECG changes: Tachycardia Nonspecific and ischemic ST-T wave changes Right ventricular strain Premature atrial and ventricular contractions Nodal rhythm Atrial fibrillation	Decreased cardiac output Decreased mediator-induced myocardial suppression Decreased effective plasma volume Decreased preload Decreased afterload Hypoxia and ischemia Dysrhythmias Iatrogenic effects of drugs used in treatment Preexisting heart disease
	Cardiac arrest		Pulseless	
			ECG changes:	
			Ventricular fibrillation	
			Asystole	
Skin	Urticaria	Pruritus	Urticaria	Increased vascular permeability
		Tingling and warmth	Diffuse erythema	Vasodilation
		Flushing		
		Hives		
	Angioedema	Nonpruritic extremity, periorbital, and perioral swelling	Nonpitting edema, frequently asymmetrical	Increased vascular permeability
Eye	Conjunctivitis	Ocular itching Increased lacrimation Red eye	Conjunctival inflammation	Stimulation of nerve endings
Gastrointestinal tract		Dysphagia Cramping, abdominal pain Nausea and vomiting Diarrhea (rarely bloody) Tenesmus	Nonspecific	Increased secretion of mucus Gastrointestinal smooth muscle contraction
Miscellaneous central nervous system		Apprehension Sense of impending doom Headache Confusion	Anxiety Seizures (rarely) Coma (late)	Secondary to cerebral hypoxia and hypoperfusion Vasodilation
Hematologic	Fibrinolysis and disseminated intravascular coagulation	Abnormal bleeding and bruising	Mucous membrane bleeding, disseminated intravascular coagulation Increased uterine tone Vaginal bleeding	Mediator recruitment and activation Uterine smooth muscle contraction Bladder smooth muscle contraction
Genitourinary		Pelvic pain	Urinary incontinence	
		Urinary incontinence		

ECG, Electrocardiographic.

BOX 106.6 Differential Diagnosis of Anaphylaxis

Acute generalized urticaria
Asthma exacerbation
Myocardial infarction
Pulmonary embolus
Syncope
Adverse cutaneous drug reaction
Anxiety/panic attacks

Flush Syndrome

Flushing associated with food
Alcohol
MSG
Sulfites
Scombroidosis
Carcinoid tumor
Peri-menopause
Thyrotoxicosis

Basophilic leukemia
Mastocytosis (systemic mastocytosis and urticaria pigmentosa)
Vasointestinal peptide tumors

Shock Syndromes

Septic shock
Hypovolemic shock
Cardiogenic shock
Distributive shock

Miscellaneous

Hypoglycemia
Acquired and HAE
ACE-inhibitor-associated angioedema
Red man syndrome (Vancomycin)
Neurologic disorders (seizure, stroke, autonomic epilepsy)
Vocal cord dysfunction syndrome
Pheochromocytoma

ACE, Angiotensin-converting enzyme; *HAE,* hereditary angioedema; *MSG,* monosodium glutamate.

BOX 106.7 Treatment Algorithm for Anaphylaxis

Emergency Measures (Taken Simultaneously)

Remove any triggering agent.
Place the patient in the supine position.
Begin cardiac monitoring, pulse oximetry, and blood pressure monitoring.
Begin supplemental oxygen if indicated.
Establish large-bore IV lines (e.g., 16 or 18 gauge preferred).
Ensure a patent airway.
Be prepared for endotracheal intubation with or without rapid sequence intubation.
Be prepared to use an adjunct airway technique (e.g., awake fiberoptic intubation, surgical airway).
Start a rapid infusion of isotonic crystalloid (normal saline):
- Adults: 1000 mL IV in the first 5 min in the adult (several liters of normal saline may be required), titrated to response
- Pediatrics: 20–30 mL/kg IV increments

Anaphylaxis Treatment Medications

First-Line Agent

Epinephrine is the first-line medication and should be given immediately at the first suspicion of an anaphylactic reaction.
- Adult: 0.3–0.5 mg IM (1 mg/mL concentration) in anterolateral thigh every 5–10 minutes as necessary
- Pediatric: 0.01 mg/kg IM (1:1000 concentration) in anterolateral thigh every 5–10 minutes as necessary

Alternatively, epinephrine (EpiPen, 0.3 mL; or EpiPen Jr, 0.15 mL) can be administered into the anterolateral thigh

Second-Line Agents (Should Not Precede the Administration of Epinephrine)

Antihistamines

Diphenhydramine:
- Adults: 50 mg IV or 50 mg oral
- Pediatric: 1 mg/kg IV or oral

Famotidine:
- Adult: 40 mg IV (40 mg oral)
- Pediatric: 0.5 mg/kg IV or oral

Aerosolized Beta-Agonists (if Bronchospasm Is Present)

Adult:
- Albuterol: 2.5 mg, diluted to 3 mL of normal saline; may be repeated as needed or continuous
- Ipratropium: 0.5 mg in 3 mL of normal saline; may be repeated as necessary

Pediatric:
- Albuterol: 2.5 mg, diluted to 3 mL of normal saline; may be repeated as needed or continuous
- Ipratropium: 0.25 mg in 3 mL of normal saline; may be repeated as necessary

Glucocorticoids (No Benefit in the Acute Management)

Methylprednisolone:
- Adult: 125–250 mg IV
- Pediatric: 1–2 mg/kg IV

Prednisone/prednisolone:
- Adult: 40–60 mg oral
- Pediatrics: 1–2 mg/kg oral

Refractory Hypotension

Consider continuous IV epinephrine drip (dilute 1 mg (1 mg/mL concentration) in 1000 mL of normal saline or D_5W to yield a concentration of 1 μg/mL)
Adults: 1–10 μg/min IV (titrated to desired effect)
Pediatrics: 0.1–1.5 μg/kg/min IV (titrated to desired effect)

Other Adjunctive Vasopressors to Consider

Dopamine: 5–20 μg/kg/min continuous IV infusion (titrated to the desired effect)
Norepinephrine: 0.05–0.5 μg/kg/min (titrated to desired effect)
Phenylephrine: 1–5 μg/kg/min (titrated to desired effect)
Vasopressin: 0.01–0.4 units/min (titrated between 0.01–0.04 units/min)

Patients Receiving Beta-Blockade

Glucagon: 1–5 mg IV over 5 min, followed by 5–15 μg/min continuous IV infusion

D_5W, 5% dextrose in water; *IM,* intramuscular; *IV,* intravenous.

For patients who remain hypotensive after multiple doses of IM epinephrine and adequate volume expansion aimed at increasing blood pressure, IV epinephrine should be considered. IV epinephrine increases the risks of cardiac dysrhythmias, thus requiring cautious cardiac and hemodynamic monitoring. Dilution and slow administration are recommended to reduce untoward effects.[12,38] In adults, we suggest preparing a concentration of 1.0 μg/mL and initially infusing at a rate of 1 μg/min. The rate should be increased until hemodynamic stability is achieved, or a maximum dose of 10 μg/min. This can be prepared by mixing 1 mg (1 mL) of 1:1000 concentration of epinephrine with 1000 mL of 5% dextrose in water or normal saline; this provides an infusion of 1 mL/min equaling 1 μg/minute. In children and infants, an infusion rate of 0.1 μg/kg/min is advised, increasing in increments of 0.1 μg/kg/min to a maximum of 1.5 μg/kg/min.[37] Central venous access is encouraged when administering IV epinephrine because of the risk of tissue necrosis from extravasation.

Epinephrine derives its therapeutic value from its combined alpha-adrenergic and beta-adrenergic actions that work directly to improve the most commonly observed clinical features.

Alpha$_1$-adrenergic stimulation increases vasoconstriction, increases peripheral vascular resistance, and decreases mucosal edema. Through beta$_1$-adrenergic stimulation, inotropic and chronotropic cardiac activity is enhanced. Beta$_2$-adrenergic stimulation also provides stabilization of mast cells and basophils, and it induces bronchodilation. These combined effects result in decreased mediator release from mast cells and basophils, which improves bronchospasm, decreases mucosal edema and swelling, and reverses systemic hypotension.[12,34]

Epinephrine can produce a number of undesirable side effects, though there is no absolute contraindication in the setting of anaphylaxis. Common side effects include palpitations, anxiety, tremor, pallor, dizziness, or headache. There is a common misconception that epinephrine should be avoided in patients with a history of cardiovascular disease due to the concern of inducing life-threatening arrhythmias and other adverse cardiovascular events. These events are rare, and the majority are associated with improper dosing or administration. The benefits of the early administration of epinephrine in anaphylaxis far outweigh the risks.[34,36,37]

Airway

Patients in respiratory distress and receiving multiple doses of epinephrine should be placed on supplemental oxygen and prepared for possible advanced airway management. Patients with bronchospasm may benefit from bronchodilators, but this should not preclude the administration of epinephrine. Upper airway obstruction from laryngeal angioedema can progress rapidly, so preparations for a difficult airway should be made early. This may include an awake intubation with assistance fiberoptic laryngoscopy or the equipment to convert to a surgical airway procedure if needed.[6,9,12]

Volume Expansion

Along with airway assessment, fluid resuscitation should be initiated. For adults, infuse 1 to 2 L of normal saline rapidly through large-bore (e.g., 16-gauge) IV lines. Pediatric patients should be given boluses in 20 to 30 mL/kg increments. When IV access cannot be established, intraosseous catheter placement is an alternative. The assistance of an infusion pump or pressure bag should be considered when administering fluids in this manner. Large volumes of normal saline (2 to 7 L) may be required to reverse the effects of fluid extravasation into the extravascular space and the circulatory collapse sometimes seen in anaphylaxis. Patients with heart or renal failure should be monitored closely for signs of volume overload.[6,9,12]

Antihistamines

H_1 and H_2-antihistamines should never be used as the sole or initial treatment in anaphylaxis. They may be considered as second- or third-line treatments and can be helpful in relieving cutaneous symptoms, such as urticaria, pruritus, flushing, eye, or nasal symptoms.[6,12,34] See Box 106.7 for suggested dosing.

Glucocorticoids

While glucocorticoids are frequently administered, they have no immediate effect on the management of anaphylaxis and thus should be considered a second- or third-line intervention. Their onset of action typically takes several hours. In theory, they may provide benefit by preventing protracted symptoms or a biphasic reaction, but there is no strong evidence to support their use for those purposes.[8,39–41] With these limitations in mind, glucocorticoids are an optional adjunct in the treatment of anaphylaxis but should never precede the administration of epinephrine. See Box 106.7 for suggested dosing.

Patients Receiving Beta-Blockade

Glucagon, with positive inotropic and chronotropic cardiac effects mediated independently of alpha and beta receptors, may be helpful in patients with anaphylactic reactions who are receiving beta-blockers and fail to respond to epinephrine or other standard treatments. The initial IV dose is 1 to 5 mg for adults or 20 to 30 μg/kg (maximum dose 1 mg) for children and may be followed by an infusion of 5 to 15 μg/min. Nausea and vomiting are common side effects, so the clinician should be prepared to administer an antiemetic when indicated.[9,12]

DISPOSITION

Up to 20% of patients with anaphylaxis may experience a biphasic reaction defined as a reoccurrence of anaphylactic symptoms without re-exposure to the triggering agent. Most of these reactions occur within 8 hours but have been reported as far out as 72 hours.[8] The majority respond to the appropriate treatment, and recent literature suggests that clinically important biphasic reactions and fatalities are actually much rarer than previously reported.[41,42] Many clinicians administer corticosteroids in hopes of preventing a biphasic reaction, but recent studies have failed to show significant effect.[8,39,40] Patients at increased risk for biphasic reactions include those presenting with hypotension, wide pulse pressure, unknown trigger, greater than 1 dose of epinephrine, cutaneous signs and symptoms, prior anaphylaxis, and delayed epinephrine administration.[8,43,44]

Consensus guidelines suggest that patients who respond to initial treatments and experience complete resolution of symptoms can generally be discharged home after an observation period of 4 to 6 hours. Recent literature suggested a 95% NPV of a biphasic reaction in those observed for 1 hour and 97.3% after 6 hours of observation. Therefore, we suggest a minimum of 1 hour of asymptomatic observation and 6 hours or longer in those with increased risk of biphasic reactions (as previously mentioned).[8,45] Hospitalization should be strongly considered for patients who present with protracted anaphylaxis, hypotension, or airway involvement; receive more than two doses of IM epinephrine; or have poor outpatient social support, or inability to acquire an auto-injectable epinephrine device.[8,9]

Prior to discharge, the clinician should take an active role in educating the patient or caretakers about their allergy and anaphylaxis. It is also important to explain and demonstrate how to use the auto-injectable epinephrine device. Patients should be encouraged to develop an individualized anaphylaxis emergency action plan and to consider acquiring a medical identification device (e.g., bracelet, wallet

Fig. 106.4 Acute Urticaria. (©2001–2003, Johns Hopkins University School of Medicine. http://dermatlas.med.jhmi.edu/derm.)

card). Emphasis should be placed on timely follow-up, preferably with an allergist-immunologist.[9,34,46]

URTICARIA AND ANGIOEDEMA

PATHOPHYSIOLOGY AND CLINICAL FEATURES

Urticaria is commonly encountered in the ED. It is estimated that 25% of the population will experience an episode of urticaria in their lifetime. Urticaria is characterized by the presence of wheals (hives), angioedema, or both. It should be distinguished from other conditions, such as autoinflammatory syndromes or other causes of non-histaminergic angioedema. Urticaria appears as papules or wheals that consist of central swelling with surrounding reflex erythema and is associated with itching or a burning type sensation (Fig. 106.4).[5] These lesions are a result of mediators (predominately histamine) released from mast cells. They tend to occur on the extremities and are usually transient, with skin often returning to its normal appearance within 24 hours. Urticaria can be classified based on its duration, with acute urticaria lasting less than 6 weeks and chronic episodes lasting longer than 6 weeks. There are also several types of inducible urticaria including cold contact, delayed pressure, heat contact, solar, aquagenic, or cholinergic.[5]

Angioedema is characterized by edema of the subcutaneous or submucosal tissues, commonly involving the face, mouth, lips, tongue, extremities, or genitalia. It is a result of abrupt vasodilation and increased vascular permeability, allowing fluid to move from the vascular to the interstitial space. As the swelling is located in the deeper layers of the skin, the appearance is often normal in color and patients often complain of pain or a pressure sensation, rather than an itch. Of particular concern is when the tongue, posterior pharynx, or larynx is involved, which could progress to airway obstruction and compromise. Angioedema can be mediated by an allergic mechanism in response to exposure to foods, drugs, or physical stimuli or by a nonallergic mechanism such as HAE, acquired angioedema, or ACE-inhibitor-induced angioedema.[47]

Non-histaminergic (nonallergic) angioedema is typically a result of elevated bradykinin levels. This classification includes four subtypes: Hereditary angioedema (HAE) with or without C1 esterase inhibitor deficiency, acquired C1 esterase inhibitor deficiency (ACID), ACE-inhibitor-induced, and idiopathic angioedema. HAE is an autosomal dominant condition, with an estimated frequency of 1:50,000 globally.[48] The median age at which patients develop symptoms is 12 years.[47] ACID onset usually occurs later in life and may be associated with an underlying lymphoproliferative disorder such as lymphoma, or benign monoclonal gammopathy.[47,49] ACID is a rare condition with limited epidemiologic data. Other than familial history and age of onset, HAE and ACID are clinically indistinguishable. HAE with C1 inhibitor deficiency and ACID share the same mechanism: The lack of C1 inhibitor causes activation of the kallikrein-kinin system, increasing the consumption of kininogen, resulting in increased production of bradykinin. In the case of ACE-inhibitor-induced angioedema, bradykinin levels accumulate due to the inhibition of the angiotensin-converting enzyme, which is one of two main enzymes responsible for the breakdown of bradykinin. Bradykinin binds the bradykinin 2 receptor (β2), inducing vasodilation and vascular permeability, ultimately resulting in angioedema.[49–51]

Recent literature suggests that in the United States, non-histaminergic angioedema is responsible for approximately 110,000 ED visits annually, with 30% resulting from ACE-inhibitor-induced angioedema. ACE-inhibitor-induced angioedema has an overall incidence of 0.3% to 0.7% and is 3 to 4 times more likely in African Americans, and women are at a 50% higher risk than men. ACE-inhibitor-induced angioedema has a predilection for the face, often involving the lips, eyelids, tongue, larynx, or pharynx. The highest incidence occurs in the first month of therapy but has also been reported to occur years after initiation of therapy.[49–51]

DIAGNOSTIC TESTING

Similar to anaphylaxis, angioedema is a clinical diagnosis. Laboratory tests are not helpful in the acute setting. If a hypersensitivity reaction is suspected, a detailed history should focus on identifying any recent exposures to foods, drugs, physical stimuli, infection (especially viral hepatitis), occupational elements, or insect stings. Patients should also be questioned about prior history of similar symptoms as well as any family history of non-histaminergic angioedema.

MANAGEMENT

Angioedema With Urticaria

Angioedema that occurs in conjunction with urticaria is typically histaminergic (allergic) in nature. In cases that do not meet the criteria for anaphylaxis, antihistamines are considered the first-line treatment. Second-generation H_1-antihistamines, such as cetirizine, loratadine, and fexofenadine, are the preferred agents, and up to fourfold the conventional dose may be considered. Because 15% of dermal histamine receptors are H_2, the addition of an oral H_2-antihistamine may also be beneficial. A short course of oral corticosteroids (e.g., prednisone) may be considered as a second-line therapy.[5] In patients with severe symptoms and no cardiac risk factors, epinephrine should be given (anaphylactic dosing). In an effort to prevent reoccurrence, patients should be educated to avoid exposure to potential triggering agents.

Angioedema Without Urticaria

Acute attacks of non-histaminergic (bradykinin-related) angioedema do not typically respond to treatment with epinephrine, antihistamines, or steroids. In patients presenting with airway-threatening angioedema and no prior history, we suggest initially administering epinephrine and antihistamines at anaphylactic doses. In situations requiring intubation, awake fiberoptic intubation when available is the preferred method and paralytics should be utilized with caution. The clinician must be prepared to rapidly work through a difficult airway algorithm using alternative measures (e.g., fiberoptic laryngoscopy, surgical airway), as discussed in Chapter 1. When available, early

TABLE 106.3 Treatment Options for Hereditary Angioedema

Drug	Age Approved Use	Mechanism of Action	Dose/Route	Median Time to Symptom Relief
Berinert	Adult and pediatric patients	C1-INH protein replacement, human	20 units/kg IV	48 min
Ruconest	Adults and pediatric patients >11 years of age	C1-INH protein replacement, recombinant	50 units/kg IV (max 4200 units IV)	90 min
Ecallantide	Adults and pediatric patients >12 years of age	Plasma-Kallikrein inhibitor	30 mg SC	67 min
Icatibant	Adult patients >18 years of age	Bradykinin-2 receptor antagonist	30 mg SC	2 h

C1-INH, C1 esterase inhibitor; *IV,* intravenous; *SC,* subcutaneous.
Modified from Bernstein JA, Cremonesi P, Hoffmann TK, et al. Angioedema in the emergency department: a practical guide to differential diagnosis and management. *Int J Emerg Med.* 2017;10(15):1–11.

mobilization of ENT, anesthesiology, or another emergency physician colleague may be beneficial. In cases with suspected laryngeal or supraglottic angioedema, evaluation with nasopharyngoscopy may assist in formulating treatment plans, interventions, and disposition.

Fresh frozen plasma (FFP), which contains a C1 inhibitor, has been reported to be effective in acute attacks; however, there are rare reports of exacerbation of the angioedema by FFP. The FDA has approved four medications for use in the United States for patients with acute HAE (see Table 106.3).[49]

For ACE-inhibitor-induced angioedema, treatment is mainly supportive. Theoretically, the medications described for the treatment of HAE would be effective in ACE-inhibitor-induced angioedema, but none are FDA-approved for use at this time. There are multiple case reports of FFP being used with success in the treatment of ACE-inhibitor angioedema. Early treatment (within several hours of symptom onset) may be necessary to be successful.[52] Initial studies looking at ecallantide and icatibant have yielded mixed results, and there is no strong recommendation for their use at the time of this publication. We suggest administering one of these agents if available at your institution and the patient is showing signs of progressing airway involvement.[53–56]

Special Considerations

Thrombolytic induced angioedema is a well-recognized, yet rare complication following administration of recombinant tissue plasminogen activator (tPA). While usually transient in nature, it can be rapidly progressive and potentially life-threatening. The reported incidence is 1% to %5.[49] It is classically described as asymmetric orolingual angioedema. Increased risk is associated with ACE-inhibitor use. The mechanism of angioedema development is thought to be multifactorial. Also, tPA can increase bradykinin levels through its production of plasmin, which can also activate the complement cascade, triggering mast cell degranulation and histamine release. Recommended treatment includes antihistamines and corticosteroids. There are reports of successful treatment with epinephrine, although blood pressure control is a potential concern.[57,58]

DISPOSITION

There is a lack of data to provide concrete guidelines for disposition. Most will agree that patients who experience a complete resolution of angioedema or have only extra-oral facial involvement can be discharged home after a period of observation in the ED. Individuals suspected of HAE or ACID should be referred to an allergist, as further evaluation and potential preventative medications may be warranted. We suggest hospitalization for patients with persistent angioedema of the sublingual area, tongue, soft palate, pharynx, or larynx.

CHAPTER 106: QUESTIONS AND ANSWERS

1. Which of the following statements regarding the use of H_2-antihistamines in patients presenting with urticaria and pruritis is true?
- **a.** A portion of histamine receptors on the skin are H_2 receptors.
- **b.** Patients with skin manifestations often have concomitant reflux.
- **c.** H_2-antihistamines have synergistic properties when used with steroids.
- **d.** Use of H_2-antihistamines can effectively replace H_1-antihistamines and have fewer side effects.
- **e.** H_2-antihistamines are effective in preventing recurrence of pruritis and urticaria.

Answer: a. Because 15% of the histamine receptors in skin are H_2 receptors, the addition of an H_2-antihistamine (e.g., ranitidine) may be beneficial in the treatment of pruritis and urticaria. There is no proven synergistic effect when used with steroids. Second-generation H_1-antihistamines, such as cetirizine, loratadine, and fexofenadine, are the preferred agents in the treatment of urticaria and pruritis.

2. A 16-year-old female with a known history of hereditary angioedema (HAE) presents with facial swelling. Which HAE medication is not approved for patients in this age group?
- **a.** Ecallantide
- **b.** Icatibant
- **c.** Bertinert
- **d.** Reconest
- **e.** Cinryze

Answer: b. Icatibant is approved for treatment in adults aged 18 years or older. Berinert is approved for the treatment of HAE in adult and pediatric patients (no lower age limits). Ruconest approved for use in adults and pediatric patients ages 11 and older. Ecallantide is approved for adult patients and pediatric patients 12 years and older. Cinryze is a prophylactic HAE medication not approved for use in acute attacks.

3. Concomitant use of which of the following classes of medications is associated with increased risk of mortality in patients with drug-induced anaphylaxis?
- **a.** Penicillins
- **b.** ACE inhibitors
- **c.** NSAIDs
- **d.** Beta-blockers
- **e.** Fluoroquinolones

Answer: d. Fatal drug-induced anaphylaxis has been associated with hypertension, obesity, male gender, beta-blocker use, and advanced age. Beta-blockers may oppose the actions of adrenergic agents used in anaphylaxis treatment. These patients may require additional treatment with glucagon to counter the effects of beta-blockade.

4. What is the appropriate initial dose and route for a pediatric patient in the treatment of acute anaphylaxis?
- **a.** 0.3 to 0.5 mg of 1 mg/mL concentration epinephrine concentration, IM in anterolateral thigh
- **b.** 1 mL of 1:1000 epinephrine IV
- **c.** 0.01 mg/kg of 1:1000 epinephrine, IM in anterolateral thigh
- **d.** 2 mL of 1:10,000 epinephrine IV every 5 minutes
- **e.** 0.01 mg/kg of 1:10,000 epinephrine IV

Answer: c. 0.01 mg/kg (1:1000 concentration) given IM in the anterolateral thigh every 5 to 10 minutes as necessary is recommended for pediatric patients. Alternatively, an EpiPen Jr 0.15 mL can be considered in patients weighing 10 to 25 kg.

5. The majority of the clinical features of anaphylaxis syndrome are produced by which of the following mediators?
- **a.** Acetylcholine
- **b.** Histamine
- **c.** Leukotrienes
- **d.** Prostaglandins
- **e.** Tumor necrosis factor

Answer: b. All of the listed mediators contribute, but histamine is the predominant chemomediator.

107

Dermatologic Presentations

Catherine Anna Marco

KEY CONCEPTS

- Accurate descriptions of dermatologic lesions are essential for diagnosis and management. Primary and secondary lesions are described in Tables 107.1 and 107.2.
- Systemic illnesses with cutaneous findings include systemic infections, autoimmune or connective tissue disorders, malignancies, diabetes mellitus, endocrine disorders, and immunodeficiency states.
- Cutaneous signs of systemic disease include pruritus, urticaria, erythema multiforme, erythema nodosum, pyoderma gangrenosum, or others.
- Most skin and soft tissue infections should be treated with antibiotics to cover methicillin-resistant *Staphylococcus aureus*.
- Cutaneous abscesses are treated with incision and drainage plus antibiotics.
- Tinea capitis requires 4–8 weeks of systemic antifungal treatment.
- Onychomycosis requires long-term systemic treatment.
- Allergic reactions are treated with antihistamines and discontinuation of exposure to the allergen. Nonsedating antihistamines are the preferred agents to control pruritus and histamine-mediated rashes because they allow patients to remain active.
- Suspected infestations should be diagnosed clinically and treated expeditiously, even without definitive proof of the infestation.
- Medication reactions are common and may result from any agent, typically within 4–28 days after use.
- Rashes that are associated with mucosal lesions, blisters, or desquamating skin are often caused by significant soft tissue infections, drug eruptions, or immune disorders.
- Patients with Stevens-Johnson syndrome or toxic epidermal necrolysis require inpatient treatment, preferably in a burn unit.
- Clinicians should be familiar with one or two topical steroid preparations of low, medium, and high potency, and their appropriate therapeutic use.
- The majority of patients with dermatologic complaints are managed as outpatients. Indications for hospitalization include significant fluid and electrolyte abnormalities, disordered thermoregulation, systemic infection or other underlying disorder requiring inpatient management, and inability to care for self or maintain appropriate oral intake.

OVERVIEW

Foundations

Background and Importance

Diseases of the skin and subcutaneous tissue account for over 5 million emergency department (ED) visits annually, approximately 3.5% of all ED visits.[1] Dermatologic conditions often have a significant impact on quality of life.[2] Common diagnoses among ED patients include infections, inflammatory conditions, allergic reactions, or drug reactions.

Anatomy, Physiology, and Pathophysiology

The skin is composed of three layers: the epidermis, dermis, and subcutaneous layer (Fig. 107.1). The epidermis is a thin layer of stratified squamous epithelium, consisting mainly of keratinocytes, which progress through stages of differentiation as they migrate from the basal to the superficial layer. These layers are the stratum basale (base of the epithelium), stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum (superficial layer). The epidermis also includes other cells, such as melanocytes and Langerhans cells. Melanocytes produce melanin, which functions to add pigment to the skin and also to absorb ultraviolet radiation. Langerhans cells are a component of the immune system and function to ingest and process foreign antigens. The epidermis lacks direct blood supply and is dependent on the dermis for nutrients by diffusion through the dermal-epidermal junction. This junction is the site of immunologic injury resulting in separation of these layers, which appears as bullae.

The dermis consists of connective tissue, blood vessels, lymphatic vessels, nerve endings, and immune cells. The main function of the dermis is to support the epidermis and contribute to the protective functions of the skin. Fibroblasts produce procollagen and elastic fibers used to form the connective tissues that give support and elasticity to the skin. Sweat glands and the network of blood vessels in the dermis assist with thermoregulation.

The subcutaneous layer is composed of connective tissue and adipose tissue, functions to cushion the overlying skin, and contains lymph and neurovascular structures.

The skin serves several important physiologic functions. It serves as a barrier between the internal and external environment. The skin protects from external toxic and infectious materials, and assures homeostatic balance of fluids and electrolytes. The skin serves an integral role in temperature homeostasis through its barrier function, sweating mechanism, and blood vessel dilation or constriction; it functions in the absorption of ultraviolet radiation and production of vitamin D; sensory nerve endings in skin serve important functions of sensation; and finally, certain cells within the skin serve important immunologic functions, including Langerhans cells, lymphocytes, mast cells, and keratinocytes.

Clinical Features and Differential Diagnoses

A step-by-step approach to evaluating an unknown rash is listed in Box 107.1.

Important historical factors include the time of onset, duration of symptoms, and exposure to potential allergens, such as foods, medications, soaps, pets, or jewelry. Information about changes over time should be sought, including whether the rash has progressed, improved, or waxed and waned. Associated pain, pruritus, fever, sexual history, occupation, and hobbies should be identified. Relevant past medical history includes medical conditions, skin conditions,

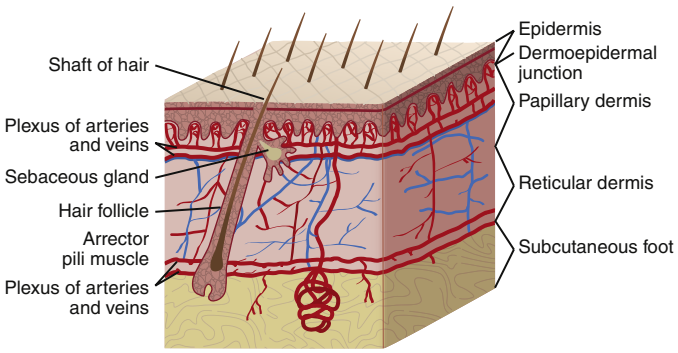

Fig. 107.1 Skin Anatomy.

   b. Immune
   c. Vascular
   d. Allergic
   e. Malignancy
10. Treatment

medications, illicit drug use, allergies, recent travel, sunlight exposure, and family history.

The physical examination is essential to identifying the diagnosis. The examination should be performed with adequate lighting. Primary and secondary lesions, as well as characteristics and patterns of lesions, should be identified. Lesions may be palpated wearing gloves to identify texture, blanching, or sloughing characteristics. Nikolsky sign may be tested, and when positive, gentle rubbing of the skin results in sloughing of the top layer of the epidermis. For patients with systemic complaints, a thorough visual examination from head to soles of feet should be performed, including skin, mucosa, and genitalia.

Identification and description of lesions is essential. Lesions may be classified as primary or secondary lesions. Primary lesions arise directly from the disease process. Secondary lesions result from factors such as scratching, treatment, healing, or complicating infections. Primary and secondary lesions and descriptions are listed in Tables 107.1 and 107.2. The significance of distribution of lesions is outlined in Table 107.3.

Diagnostic Testing

Laboratory testing is unnecessary for most patients with a rash. Specific tests for clinically suspected diseases may be indicated, such as a blood test for secondary syphilis, heterophile antibody (Monospot) for mononucleosis, or throat swab for rapid testing and culture of group A streptococcus for scarlet fever. Adjunctive skin tests may be considered, including potassium hydroxide (KOH) prep, Tzanck smear, gram stain, erythrocyte sedimentation rate (ESR), or biopsy. For the patient with severe systemic illness, a complete blood count, blood cultures, lumbar puncture studies, electrolytes, blood urea nitrogen (BUN), creatinine, glucose, and liver function tests may be considered. Ultrasound may be helpful in identifying features such as fluid collection, blood flow, septations, inflammation, and to determine the extent of soft tissue lesions.[3]

TABLE 107.1 Primary Lesions

Lesion	Description	Size
Macule	Flat circumscribed pigmented area	<0.5 cm in diameter
Patch	Flat circumscribed pigmented area	>0.5 cm in diameter
Papule	Elevated, solid, palpable lesion, variable color	<0.5 cm in diameter
Plaque	Elevated, solid, palpable lesion, variable color	>0.5 cm in diameter
Nodule	Solid, palpable, subcutaneous lesion	<0.5 cm in diameter
Abscess	Erythematous, fluctuant, tender, fluid-filled nodule	Any
Tumor	Solid, palpable, subcutaneous lesion	>0.5 cm in diameter
Vesicle	Elevated, thin walled, circumscribed, clear fluid-filled lesion	<0.5 cm in diameter
Bulla	Elevated, thin walled, circumscribed, clear fluid-filled lesion	>0.5 cm in diameter
Pustule	Elevated, circumscribed, purulent fluid-filled lesion	Any
Petechiae	Flat, erythematous or violaceous non-blanching lesions	<0.5 cm in diameter
Purpura	Erythematous or violaceous non-blanching lesions, may be palpable	>0.5 cm in diameter

TABLE 107.2 Secondary Lesions

Secondary Lesion	Description
Scale	Thickened area of keratinized epithelium
Crust	Dried area of plasma proteins, resulting from inflammation
Fissures	Deep cracks in skin surfaces, extending into dermis
Erosions	Disruption of surface epithelium, usually linear, traumatic
Ulcer	Deep erosion extending into dermis
Scar	Dense collection of collagen, a result of healing after trauma or procedures
Excoriation	Linear erosions typically secondary to scratching or rubbing
Infections	Bacterial, viral, fungal, or protozoal infection, caused by breaks in dermal-epidermal junction, often erythematous
Hyperpigmentation	Increase in melanin containing epidermal cells
Lichenification	Abnormally dense layer of keratinized epidermal cells

Management

The treatment of specific dermatologic conditions is addressed in the following sections of this chapter covering infectious, allergic, inflammatory, autoimmune, and malignant disorders. More detailed discussions of the systemic manifestations and overall management of many

TABLE 107.3 Distribution and Patterns of Selected Disease States

Dermatologic Diagnosis	Distribution and Patterns of Lesions
Atopic dermatitis, infantile	Face, scalp, flexor surfaces of extremities
Atopic eczema, adult	Face, neck, flexor surfaces of extremities
Dermatomyositis	Dorsal MCP joints, periorbital area
Disseminated gonorrhea	Distal extremities, near joints
Erythema nodosum	Anterior shins, ulnar surfaces
Herpes zoster infection	Dermatomal distribution, common on trunk
Lichen planus	Wrists, ankles, flexor surfaces
Nummular eczema	Distal extremities
Neurotic excoriations	Extremities, face, upper back, neck
Pityriasis rosea	Trunk, extremities, "Christmas tree" pattern
Porphyria cutanea tarda	Sun-exposed areas, hands, forearms, feet
Psoriasis	Extensor surfaces of extremities, sacral area
Rosacea	Face, neck
Sarcoidosis	Face, extremities, back
Seborrheic dermatitis	Chest, nasolabial folds
Secondary syphilis	Torso, palms, soles
Systemic lupus erythematosus	Nose and cheeks, head and neck, photosensitivity, alopecia
Tinea versicolor	Upper back and chest

MCP, Metacarpophalangeal.

of the conditions can be found elsewhere in this textbook. Soft tissue, bacterial, viral, tick-borne, and sexually transmitted infections are covered in Chapters 126, 118, 122, 123, and 84, respectively. Urticaria is discussed in Chapter 106.

Disposition

Most patients with dermatologic complaints are managed as outpatients. Indications for hospitalization include significant fluid and electrolyte abnormalities, disordered thermoregulation, systemic infection, underlying disorders requiring inpatient management, and inability to care for self or maintain appropriate oral intake. Dermatologic outpatient follow-up or inpatient consultation may be appropriate.

INFECTIOUS DISORDERS

Bacterial Infections

Impetigo

Impetigo is typically caused by *Staphylococcus aureus* or β-hemolytic *Streptococcus.* Pediatric patients are commonly affected. Streptococcal impetigo (ecthyma) is found most often on the face and other exposed areas. The eruption often begins as a single pustule and later progresses to multiple lesions, often with a golden yellow crust (Fig. 107.2). Lesions may be pruritic but usually are not painful. Regional lymphadenopathy is commonly present. Lesions are contagious among infants and young children and less so in older children and adults. Postpyodermal acute glomerulonephritis is a recognized complication of streptococcal impetigo.

Staphylococcal impetigo is differentiated from streptococcal impetigo in that it is more superficial, and there is little surrounding erythema. Other diagnostic considerations include herpes simplex virus (HSV) or inflammatory fungal infections. Methicillin-resistant

Fig. 107.2 Impetigo. (Courtesy Jonathan Singer, MD.)

Fig. 107.3 Bullous Impetigo. (Courtesy David Effron, MD.)

Streptococcus aureus (MRSA) impetigo is increasingly common. Bullous impetigo is caused by the toxin released by staphylococcus. It is seen primarily in infants and young children. The initial skin lesions are thin-walled, 1- to 2-cm bullae (Fig. 107.3). When these rupture, they leave a thin serous crust and collarette-like remnant of the blister roof at the rim of the crust. The face, neck, and extremities are most often affected. The differential diagnosis includes contact dermatitis, HSV infection, superficial fungal infections, and pemphigus vulgaris.

Empirical therapy should be instituted with oral or topical antibiotics. Topical therapy is initiated with bacitracin, mupirocin, retapamulin, minocycline, or ozenoxacin.[4-7] Oral antibiotics are indicated for severe or multiple lesions. Oral therapies include an agent active against *S. aureus,* such as dicloxacillin or cephalexin. If MRSA is suspected, doxycycline, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMX) is recommended. Therapy for bullous impetigo consists of a systemic oral antibiotic, such as dicloxacillin, erythromycin, or azithromycin. Even without treatment, impetigo generally resolves within 3 to 6 weeks (see Chapter 126).

Folliculitis

Folliculitis is an inflammation in the hair follicle, usually caused by *S. aureus.* It appears as pustules with a central hair. The lesions are commonly on the buttocks and thighs, in the beard or scalp, and may cause mild discomfort. The differential diagnosis includes acne, keratosis pilaris, or fungal infection. Gram-negative folliculitis with

Fig. 107.4 Cellulitis. (Courtesy Jonathan Singer, MD.)

Fig. 107.5 Methicillin-Resistant *Staphylococcus aureus* (MRSA) Abscess With Cellulitis.

Pseudomonas aeruginosa can occur after exposure to infected hot tubs and swimming pools, or in individuals taking antibiotics for acne.

Local treatment with an antiseptic cleanser such as povidone-iodine or chlorhexidine every day or every other day for several weeks is usually adequate. For patients with extensive involvement, a course of systemic oral antibiotics may be added, such as doxycycline or dicloxacillin (see Chapter 126).

Cellulitis

Cellulitis presents with localized erythema, swelling, and pain of the soft tissues (Fig. 107.4). Erysipelas is a streptococcal infection of the skin and subcutaneous tissue and typically has an erythematous appearance with a well demarcated border, often with fever, malaise, or myalgias. Cellulitis may be a cause of sepsis. Ultrasound may be helpful in differentiating from abscess.

Mild cases of cellulitis may be treated with an oral antibiotic, such as a cephalosporin, dicloxacillin, or clindamycin. Moderate cases requiring IV therapy should be treated with a penicillin, ceftriaxone, cefazolin, or clindamycin. Severe cases should be treated with IV vancomycin plus piperacillin/tazobactam. Chapter 126 provides detailed management recommendations.

Abscess

Abscesses are accumulations of pus within body tissues. *Furuncles* are skin abscesses caused by staphylococcal infection involving hair follicles and surrounding tissue. They may present with localized soft tissue swelling, erythema, and fluctuance (Fig. 107.5). Ultrasound may be helpful in differentiating abscess, which appears as a fluid-filled cavity from cellulitis, which appears as cobblestoning, with fine reticular (net-like) areas of hypoechoic stranding.[8-10]

Carbuncles are large abscesses that develop in the thick, inelastic skin of the back of the neck, back, or thighs and usually involve multiple hair follicles. They may produce severe pain and fever. Septicemia may be a complication.

Abscesses should be treated with incision and drainage. Recent literature suggests higher cure rate for antibiotic treatment with TMP-SMX in addition to incision and drainage.[11-15] TMP-SMX and clindamycin have demonstrated efficacy in cure rates following incision and drainage.[16] Moderate or severe abscesses should ideally have culture and sensitivity performed. If IV antibiotics are indicated, agents may include vancomycin, daptomycin, linezolid, telavancin, or ceftaroline. Chapter 126 provides detailed management recommendations.

Hidradenitis suppurativa affects the apocrine sweat glands. Recurrent abscess formation in the axillae and groin resembles localized furunculosis. The condition tends to be recurrent and may be resistant to therapy. Ultrasound will help differentiate abscesses from vascular or lymphoid structures. Hidradenitis suppurativa may be treated with drainage of abscesses if they are fluctuant, painful, and large. Antistaphylococcal antibiotics are useful if they are administered early and for a prolonged period. Begin treatment for mild disease with topical clindamycin for 3 months. In patients with more severe or nonresponsive disease, oral clindamycin combined with rifampin for 3 to 6 months is indicated. Antiandrogen therapy may be considered if antibiotics fail to produce improvement. Recurrent cases should be referred for surgical management.

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

The incidence of community-associated MRSA has risen steadily since the first report in 1993. In many major cities in the United States, MRSA is now the most common pathogen cultured from ED patients presenting with skin and soft tissue infections. Hospital-acquired MRSA isolates can survive on a variety of inanimate surfaces, sometimes for weeks. Pets (including dogs and cats), livestock, and birds have been identified as MRSA carriers; their role in MRSA transmission to humans is unclear.

MRSA infections are most often manifested as skin and soft tissue suppuration, such as an abscess, furuncle, or cellulitis. Lesions frequently exhibit central necrosis and are often confused with spider bites by patients. Clinical features cannot distinguish with certainty skin and soft tissue infections caused by MRSA from those caused by methicillin-susceptible *S. aureus*. Although rare, MRSA infection can present as necrotizing fasciitis. Recurrences of MRSA cellulitis are common. Contagion among the close household contacts of patients as well as correctional facility, school, or sports team contacts is well recognized.

Local resistance patterns should guide therapy. Agents typically effective against MRSA include TMP-SMX, clindamycin, minocycline, or doxycycline. Cephalosporins and macrolides are typically ineffective against MRSA. Fluoroquinolones should be avoided as *S. aureus* resistance develops readily.

Patients with large abscesses, abscesses in high-risk locations, fever, signs of systemic infection, young age, or immunodeficiency should be considered for inpatient treatment. Vancomycin is considered the parenteral drug of choice for patients with invasive *S. aureus* infection, although clinical failures have been reported. It is reasonable to combine vancomycin with another effective

Fig. 107.6 Tick.

Fig. 107.7 Erythema Migrans.

anti-staphylococcal agent as many antibiotics have better bactericidal activity. In severely ill patients, carbapenems such as meropenem, panipenem, and ertapenem are recommended, because they are active against MRSA and synergistic with vancomycin. Other effective parenteral agents may include clindamycin, linezolid, daptomycin, tigecycline, or telavancin. Chapter 126 provides detailed management recommendations.

Although decolonization strategies have been recommended by some, neither the indications for their use nor their effectiveness in reducing the risk of recurrences has been established. Common antiseptics appear to retain reasonable activity against MRSA, although the results of studies are somewhat conflicting. Good personal hygiene, including appropriate handwashing techniques, separation of infected patients, and routine cleaning of shared equipment, remain essential to limiting MRSA spread.

Erythema Migrans

Lyme disease is caused by the organism *Borrelia burgdorferi* and is transmitted by the deer tick bite (Fig. 107.6). Most cases occur in the spring and early summer. Endemic areas in the U.S. include the Northeast, Midwest, West, and scattered other areas. Although 36 to 48 hours of tick attachment is necessary to transmit disease, less than 33% of patients recall a tick bite. The incubation period is 3 to 30 days.

Clinical presentations include three disease stages. Stage I occurs early and is manifested by malaise, headache, fever, lymphadenopathy, and arthralgias. Stage I typically resolves in 4 weeks. Erythema migrans occurs in 60% to 80% of cases and manifests as erythematous annular, non-scaling lesion with central clearing (Fig. 107.7). Stage II presents with secondary annular lesions, fever, lymphadenopathy, neurologic manifestations, or cardiac conduction abnormalities that may last weeks to months. Stage III manifests as chronic arthritis, dermatitis, or central nervous system (CNS) disease.

Diagnostic tests may include a nonspecific elevated ESR and serologic tests, which are helpful in establishing the definitive diagnosis but are not typically available acutely. Serologic testing includes a two-tiered serologic analysis consisting of an enzyme-linked immunoassay or immunofluorescence assay, followed by reflexive immunoblotting.[17]

Management should include appropriate antibiotic administration. The antibiotic regimen may include doxycycline or amoxicillin, for 10 to 21 days, or as alternates, cefuroxime, clarithromycin, erythromycin, or azithromycin.[18,19] Chapter 123 provides detailed management recommendations.

Fig. 107.8 Necrotizing Fasciitis.

Necrotizing Fasciitis

Necrotizing fasciitis should be considered with skin and soft tissue infection with signs of systemic toxicity, or severe infection (Figs. 107.8, 107.9, and 107.10). The etiology is often polymicrobial (mixed aerobic/anaerobic microbes) or monomicrobial (group A streptococci, community-acquired MRSA). Radiographic tests may demonstrate soft tissue air. Prompt surgical consultation is indicated.

Empirical antibiotic treatment should be instituted with broad coverage, such as vancomycin or linezolid plus one of the following: piperacillin-tazobactam, carbapenem, or a combination of ceftriaxone and metronidazole. Chapter 126 provides detailed management recommendations.

Meningococcal Infection

Meningococcal infection is caused by the organism *Neisseria meningitides,* typically transmitted by respiratory secretions. Meningococcal disease may manifest as one of three syndromes: meningitis, bacteremia, or pneumonia. Meningococcal disease typically affects healthy children and adolescents, and it may result in significant morbidity and mortality. Infection is fatal in approximately 10% of cases.

Fig. 107.9 Necrotizing Fasciitis. Note air in subcutaneous tissues.

Fig. 107.10 Necrotizing Fasciitis.

Clinical presentation may include fever, malaise, arthralgias, nausea, and vomiting. Cutaneous findings of macules, papules, vesicles, or petechiae and purpura may be present.

Ten percent of cases may present with Waterhouse-Friderichsen syndrome characterized by shock with intracutaneous hemorrhage.

The diagnosis should be suspected clinically and treated promptly. Confirmatory tests may include blood cultures, cerebrospinal fluid (CSF) cultures, or skin scrapings.

Empirical therapy should be instituted with agents, such as a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) plus vancomycin. Alternative antibiotics may include penicillin G, chloramphenicol, a fluoroquinolone, or aztreonam. Dexamethasone should also be considered for suspected or proven meningitis.[20,21] Immunization against meningococcal infection is recommended for groups at increased risk for infection, including adolescents. Chapter 118 provides detailed management recommendations.

Scarlet Fever

Scarlet fever results from group A strep infection. The illness presents with fever, chills, malaise, and sore throat, followed within 12 to 48 hours by a distinctive rash that begins on the chest and spreads rapidly, usually within 24 hours. Circumoral pallor may be noted. The skin has a rough sandpaper-like texture due to a multitude of tiny papules. The pharynx is typically injected, and there may be erythematous lesions or petechiae on the palate. After the resolution of symptoms, desquamation of the involved areas may occur. Erythema marginatum may be seen in 10% of cases and presents with annular erythematous lesions that may be transient and reappear over days, weeks, or months (Fig. 107.11).

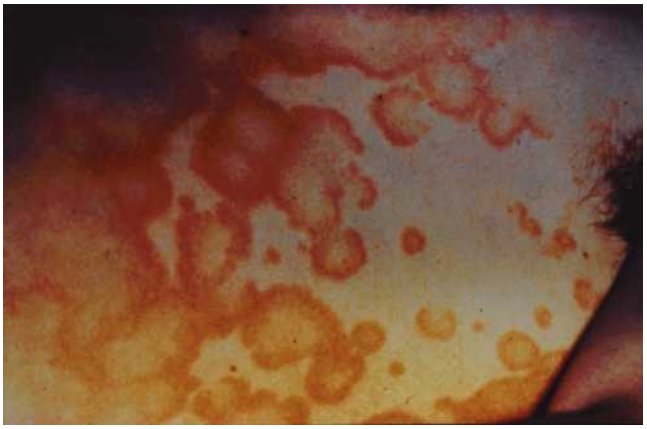

Fig. 107.11 Erythema Marginatum Associated With Rheumatic Fever. (Courtesy David Effron, MD.)

Complications include the development of a streptococcal infection of lymph nodes, tonsils, middle ear, or respiratory tract. Late complications include rheumatic fever or glomerulonephritis.

Treatment should be initiated with oral penicillin VK (children <27 kg: 250 mg twice daily or three times daily for 10 days; adolescents and adults: 250 mg four times daily or 500 mg twice daily for 10 days) or IM benzathine penicillin (given as Bicillin C-R (<27 kg: 600,000 units as a one-time dose; ≥27 kg: 1,200,000 units as a one time dose). In patients allergic to penicillin, treatment may be initiated with erythromycin, other macrolides, or a cephalosporin.

Syphilis

Syphilis is the third most common sexually transmitted infection in the United States (following chlamydia and gonorrhea) and is transmitted by direct contact with an infectious lesion. The incidence of reported cases has risen steadily since 2001. The causative organism is the spirochete *Treponema pallidum.* After an incubation period of 10 to 90 days, the primary lesion appears, which lasts 3 to 12 weeks and heals spontaneously. If untreated, in 6 weeks to 6 months after exposure, the secondary stage may be manifest. These lesions also heal spontaneously in 2 to 6 weeks as the disease enters the latent phase. Tertiary syphilis or latent syphilis may occur in months to years after untreated secondary syphilis.

The chancre is the dermatologic manifestation of primary syphilis. Chancres usually appear as single lesions but may be multiple. They appear at the site of spirochete inoculation, usually the mucous membranes of the mouth or genitalia. The chancre begins as a papule and characteristically develops into an ulcer approximately 1 cm in diameter with a central base and raised borders (Fig. 107.12). The chancre is typically painless unless it is secondarily infected, and it may be accompanied by painless lymphadenopathy. Many patients do not recall the primary chancre.

The secondary stage usually follows the primary stage by 6 weeks or more. There are a number of cutaneous manifestations of secondary syphilis. Lesions may be erythematous or pink macules or papules, usually with a generalized symmetric distribution. Secondary syphilis should be considered in the differential diagnosis of any maculopapular

Fig. 107.12 Primary Syphilis (Courtesy David Effron, MD.)

Fig. 107.13 Secondary Syphilis. (Courtesy David Effron, MD.)

rash. Pigmented macules and papules may appear on the palms and soles (Fig. 107.13). Generalized lymphadenopathy and malaise accompany the skin lesions. Moist, flat, verrucous condyloma latum may appear in the genital area. These lesions are highly contagious.

The diagnosis of primary or secondary syphilis should be made in the ED based on clinical presentation. Definitive diagnosis is made by the identification of spirochetes with darkfield microscopy and by serologic testing. The result of the Venereal Disease Research Laboratory (VDRL) test, the most commonly used diagnostic nontreponemal serologic test, is positive in approximately three-fourths of patients with primary syphilis but may be negative early in the course of the disease. The VDRL test result is positive in cases of secondary syphilis. Rapid plasma reagin (RPR) is an alternative nontreponemal test. The most specific and sensitive serologic test is the fluorescent treponemal antibody absorption (FTA-ABS) test.

Current guidelines for syphilis treatment, including in penicillin allergic individuals, are available at www.cdc.gov.[22] Treatment should be initiated in the ED based on clinical diagnosis. Primary and secondary syphilis is treated with benzathine penicillin G in a dose of 2.4 million units IM.[23] Pregnant women should be treated with the regimen appropriate for their disease state. Doxycycline or azithromycin are alternatives in patients with penicillin allergy. Patients with early latent syphilis are treated the same as patients with primary disease, whereas late latent syphilis and tertiary syphilis are treated with benzathine penicillin G, three doses of 2.4 million units IM at weekly intervals for a total of 7.2 million units. Treatment of neurosyphilis requires infusion of aqueous crystalline penicillin, 3 to 4 million units IV every 4 hours for 10 to 14 days. Following antibiotic therapy, patients may experience a *Jarisch-Herxheimer reaction,* with symptoms of fever, headache, and myalgia.

Fig. 107.14 Disseminated Gonococcal Infection. (Courtesy David Effron, MD.)

Disseminated Gonococcal Infection

Gonococcal infections are the second most common notifiable condition in the U.S., following *Chlamydia trachomatis* infections.[24] The incidence of reported gonococcal infection has risen consistently since 2009. Disseminated gonococcal infection (DGI) occurs in less than 2% of patients with gonorrhea, affecting women primarily. Symptoms typically include fever and migratory asymmetric polyarthralgias, tenosynovitis, or skin lesions. The lesions have a predilection for periarticular regions of the distal extremities. The lesions typically begin as erythematous or hemorrhagic papules that evolve into pustules and vesicles with an erythematous halo (Fig. 107.14). They may be tender and may have a gray necrotic or hemorrhagic center. Healing with crust formation usually occurs within 4 or 5 days, although recurrent crops of lesions may appear even after antibiotics have been started. Rare complications may include perihepatitis, endocarditis, or meningitis.

The organism may be cultured from the cutaneous lesions. A more reliable diagnostic technique is immunofluorescent antibody staining of direct smears from pustules.

Treatment should be initiated with ceftriaxone, 1 g IV q 24 hours, and treatment for chlamydia with doxycycline 100 mg bid for 7 days. Alternatives include cefotaxime or ceftizoxime, plus doxycycline. Patients allergic to β-lactam antibiotics or those with severe penicillin allergies may be treated with spectinomycin. Ciprofloxacin and ofloxacin are not recommended owing to increasing resistance patterns. Hospitalization is recommended for patients with DGI. Chapter 84 provides detailed management recommendations.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) typically occurs in children 6 years old or younger. It is caused by an infection with phage group 2 exotoxin-producing staphylococci. The illness begins with erythema and crusting around the mouth. The erythema then spreads

down the body, followed by bulla formation and desquamation. Mucous membranes are typically spared. After desquamation occurs, the lesions dry up quickly, with clinical resolution in 3 to 7 days.

Treatment should be initiated promptly with intravenous antibiotics, such as nafcillin, oxacillin, or vancomycin. For patients allergic to penicillin, alternatives may include clarithromycin or cefuroxime.[25] Chapter 126 provides detailed management recommendations.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute febrile illness characterized by a diffuse desquamating erythroderma. Clinical presentation may include high fever, hypotension, constitutional symptoms, multiorgan involvement, and rash. The syndrome gained notoriety in the early 1980s because of association with tampon use. However, it is also well known in men and children. Its appearance has often been linked to exotoxin-producing *S. aureus*. Approximately 50% of cases are associated with menstruation. Other cases occur in the postoperative setting, or related to burns, postpartum infection, osteomyelitis, arthritis, empyema, fasciitis, septic abortion, pharyngitis, peritonsillar abscess, sinusitis, or subcutaneous abscess.[26]

TSS is typically caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. It has been reported in previously healthy patients, immunocompromised patients, and elders. Fatigue, localized pain, and nonspecific symptoms herald the onset of this disease, followed by septic shock and multisystem organ failure.

Diagnosis of TSS requires the presence of (1) temperature of at least 38.9°C; (2) hypotension, with a systolic blood pressure of 90 mm Hg or less; (3) rash; and (4) involvement of at least three organ systems. Systemic involvement may include the gastrointestinal tract, muscular system, or CNS and laboratory evidence of renal, hepatic, or hematologic dysfunction. Headache, myalgias, arthralgias, alteration of consciousness, nausea, vomiting, or diarrhea may be present.

The rash is typically a diffuse, blanching, macular erythroderma. Accompanying nonexudative mucous membrane inflammation is common. Pharyngitis, sometimes accompanied by a "strawberry tongue," conjunctivitis, or vaginitis, may be seen. As a general rule, the rash fades within 3 days of its appearance. This is followed by a full-thickness desquamation, most commonly involving the hands and feet.

Initial treatment of TSS consists of IV fluid replacement, ventilatory support, pressor agents, antibiotics covering *S. aureus* (including MRSA) and *S. pyogenes*. Initial empirical antibiotic regimens may include clindamycin, vancomycin, linezolid, imipenem, meropenem, ticarcillin-clavulanate, or piperacillin-tazobactam. Chapter 126 provides detailed management recommendations.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii,* an organism harbored by a variety of ticks. The organism is transmitted to humans through tick saliva at the time of a tick bite, or when the tick is crushed while in contact with the host. Many patients do not report tick exposure. Although originally described in the Rocky Mountain region, this disease occurs in other areas of North, South, and Central America. Most reported cases are from the southeastern United States.

The onset of the illness is usually abrupt, with headache, nausea and vomiting, myalgias, chills, and fever. On occasion, the onset is more gradual, with progressive anorexia, malaise, and fever. The disease may last 3 weeks and may be severe with prominent involvement of the CNS, cardiac, pulmonary, gastrointestinal, and renal systems, disseminated intravascular coagulation, or shock.

The rash develops on the second to sixth day. It begins with erythematous macules that blanch on pressure, appearing first on the wrists and ankles. These macules spread up the extremities and to the trunk and face. They may become petechial or hemorrhagic (Fig. 107.15). Lesions on the palms and soles are characteristic. Increased capillary fragility and splenomegaly may be present.

Fig. 107.15 Rocky Mountain Spotted Fever. (Courtesy Jonathan Singer, MD.)

The diagnosis of Rocky Mountain spotted fever should be made based on clinical presentation in the ED. Definitive testing is not available in the ED and may include the Weil-Felix reaction and more specific immunofluorescent procedures.

Treatment should be initiated promptly based on a clinical diagnosis (see Chapter 126). Failure to administer antibiotics in a timely fashion dramatically increases morbidity and mortality. Treatment should be initiated with doxycycline.[27] Chloramphenicol may be used for patients allergic to tetracyclines, or in children younger than 9 years old. Sulfa drugs should be avoided, as they may exacerbate the illness. Rickettsiae are routinely resistant to penicillins, cephalosporins, aminoglycosides, and erythromycin. Ehrlichiosis may be difficult to differentiate from Rocky Mountain spotted fever clinically, though it is also reliably treated with doxycycline.

Viral Infections

Herpes Simplex Virus

Two known variants of HSV routinely cause human infection: HSV-1 and HSV-2. HSV-1 primarily affects nongenital sites, whereas lesions caused by HSV-2 are found predominantly in the genital area and are transmitted primarily by sexual contact. There is significant variation in viral type and anatomic site of infection.

The characteristic presentation is painful, grouped vesicles on an erythematous base (Fig. 107.16). The lesions are usually localized in a clustered, nondermatomal distribution. The skin distribution may become more generalized in patients with atopic dermatitis or other dermatoses. Adults with HSV infection should avoid contact with children with atopic dermatitis, especially in the first 3 to 5 days of infection.

The mouth is the most common site of HSV-1 infections. Children are affected more commonly than adults. Small clusters of vesicles appear but are soon denuded, leaving irregularly shaped, crusted erosions. The severity of gingivostomatitis varies from the presence of small ulcers to extensive ulceration of the mouth, tongue, and gums accompanied by fever and cervical lymphadenopathy (Fig. 107.17). The infection may be so severe that oral fluid intake is difficult, and dehydration may result. Healing typically occurs in 7 to 14 days unless a secondary bacterial infection occurs.

Herpetic whitlow is a herpes infection of the hand, typically affecting the distal phalanx (Fig. 107.18). It may be caused by HSV-1 (60%) or HSV-2 (40%).

Fig. 107.16 Herpes Simplex Virus 1 (HSV-1) Infection. (Courtesy David Effron, MD.)

Fig. 107.17 Herpes Simplex. (Courtesy Centers for Disease Control and Prevention [CDC] Public Health Image Library, Robert E. Sumpter.)

Fig. 107.18 Herpetic Whitlow. (Courtesy Jonathan Singer, MD.)

HSV-2 infections in men present with either single or multiple vesicles or erosions on the penile shaft or glans penis. Fever, malaise, and regional adenopathy may be present. A prodrome of local pain and hyperesthesia may precede the appearance of the cutaneous lesions. The vesicles erode after several days, become crusted, and heal in 10 to 14 days. Infections in women involve the introitus, cervix, or vagina.

Fig. 107.19 Varicella Zoster. (Courtesy Jonathan Singer, MD.)

Vesicles may be grouped or confluent, and may be denuded, leaving erosions and ulcerations. Herpetic cervicitis or vaginitis may be the cause of pelvic pain, dysuria, or vaginal discharge. Recurrence is common, and recurrent episodes tend to be less severe.

Recommended treatment for a first clinical episode of genital herpes is with acyclovir, famciclovir, or valacyclovir. These agents reduce the duration of viral shedding, accelerate healing, and shorten the duration of symptoms, but they do not prevent recurrent episodes. Prophylactic administration of acyclovir may be effective in ameliorating the severity of recurrent genital herpes.

IV therapy should be considered for immunocompromised patients. A mucocutaneous herpes infection in such patients is potentially fatal, as it has a propensity for generalization and dissemination to the internal organs.

Any vesicular eruption on skin or mucous membranes in a neonate should prompt concern for HSV infection, as there is a high likelihood of dissemination in this group. Unless an alternative diagnosis is established, testing of the vesicle fluid for HSV and acyclovir therapy are indicated.

Supportive care and pain control are important components of treatment. Systemic analgesics or topical anesthetic agents may be useful. Education of the patient about the prevention or spread of the disease during sexual contact and the birth process is imperative. Chapter 119 provides detailed management recommendations.

Varicella-Zoster Virus

Varicella. Varicella, or chickenpox, is an infection caused by the varicella-zoster virus. After an incubation period of 14 to 21 days, the illness begins with a low-grade fever, headache, and malaise. The exanthem coincides with these symptoms in children and follows them by several days in adults.

The skin lesions rapidly progress from macules to papules to vesicles to crusting, sometimes within 6 to 8 hours. The vesicle of varicella is 2 or 3 mm in diameter and surrounded by an erythematous border (Fig. 107.19). An unusual form of varicella has larger bullae. The drying of the vesicle begins centrally, producing umbilication. The dried scabs typically disappear in 5 to 20 days.

Fig. 107.20 Herpes Zoster. (Courtesy David Effron, MD.)

Lesions appear in crops on the trunk, where they are seen in the highest concentration, and on the scalp, face, or extremities. The hallmark of varicella is the appearance of lesions in all three stages of development in one region of the body. Extensive eruptions are often associated with a high and prolonged fever.

Complications include encephalitis or meningitis, pneumonia, secondary staphylococcal or streptococcal cellulitis, thrombocytopenia, arthritis, hepatitis, or glomerulonephritis. Varicella pneumonia occurs more commonly in adults than in children.

The illness is typically self-limited, and treatment is symptomatic. Salicylates should be avoided to minimize the risk of subsequent Reye syndrome. Oral acyclovir may be effective if it can be started within 24 hours of development of rash for patients with chronic respiratory or skin disease. Chapter 119 provides detailed management recommendations.

The disease has the potential to be contagious until all vesicles are crusted and dried, thus infected persons should be kept at home until this stage is reached. Isolation of infected patients is often futile as the disease may be transmitted before the diagnosis is clinically evident.

Varicella zoster immune globulin (VariZIG) is indicated for administration to high-risk individuals within 10 days (ideally within 4 days) of varicella zoster virus exposure.[28]

The varicella vaccine is a live attenuated virus; it is highly efficacious and very safe. A single dose is effective in children between the ages of 1 and 13 years. For older children, two doses separated by 4 to 8 weeks are recommended. In addition, the incidence of zoster occurring after vaccination appears to be lower than that of naturally acquired disease.

Herpes zoster. Herpes zoster, or "shingles," is an infection caused by the varicella-zoster virus. It occurs in individuals who have previously had chickenpox and is caused by reactivation of the latent virus from the dorsal root ganglion. At risk populations include female sex, Caucasian race, family history, or comorbidities including autoimmune diseases, asthma, diabetes mellitus, or chronic obstructive pulmonary disease.[29] Dermatomal pain may precede the eruption by 1 to 10 days and is variable in intensity; it may be described as sharp, dull, or burning in quality. The typical rash consists of grouped vesicles on an erythematous base involving one or several adjacent dermatomes. The thorax is involved in most cases, and the trigeminal distribution is the next most commonly involved region.

The vesicles initially appear clear and then become cloudy and progress to scab and crust formation. This process takes 10 to 12 days, and the crusts fall off in 2 or 3 weeks (Fig. 107.20). Herpes zoster has a peak incidence in patients 50 to 70 years old and is unusual in children. Complications may include CNS involvement, ocular infection, stroke, meningoencephalitis, myelitis, peripheral neuropathy, or myocardial infarction.[30] Ocular complications occur in 20% to 70% of cases involving the ophthalmic division of the trigeminal nerve. The severity varies from mild conjunctivitis to panophthalmitis, which threatens vision. Corneal dendritic lesions may be visible on fluorescein examination. Eye involvement may produce anterior uveitis, secondary glaucoma, optic neuritis, or corneal scarring. There is a close correlation between vesicles located at the tip of the nose and eye involvement (Hutchinson sign).

Herpes zoster generally tends to be more severe in immunosuppressed patients, especially those with acquired immunodeficiency syndrome (AIDS), Hodgkin disease, or other lymphomas. Individuals with immunosuppression or stress are at higher risk for disseminated herpes zoster infection.[31]

Herpes zoster infection is a clinical diagnosis, and treatment should be initiated based on clinical findings. If the diagnosis is in question, definitive diagnosis may be made by VZV DNA PCR or skin biopsy.

Antiviral medications are usually indicated, especially within 48 hours of onset of rash, to decrease the duration of symptoms and associated pain (see Chapter 119). Antiviral therapy may be initiated with first-line therapy with acyclovir, famciclovir, or valacyclovir. Intravenous acyclovir is indicated for treatment of disseminated HZV infection. Supportive care is important for pain and pruritus control. Burow's solution compresses (over-the-counter solution of aluminum triacetate) may be applied to hasten drying of lesions. Steroids have not been shown to reduce the incidence of postherpetic neuralgia.

IV administration of acyclovir may be of benefit in the treatment of severe ocular herpes zoster. Treatment includes mydriasis and the application of topical corticosteroids at the direction of an ophthalmologist. Eye involvement caused by herpes zoster does not appear to be exacerbated by corticosteroids, which differs from herpes simplex conjunctivitis.

Postherpetic neuralgia may occur in 15% of patients and is more common in the elderly. Treatments may include opioids, topical capsaicin, topical lidocaine, topical or oral gabapentin, or tricyclic antidepressants.[32-34] The varicella vaccine has been shown to reduce the incidence and severity of herpes zoster virus infection and is recommended for patients 60 years old and older.[35-37]

Viral Exanthems

An exanthem is defined as a skin eruption that occurs as a symptom of a general disease. In the pediatric population, an estimated 72% of cases of fever and rash are caused by viruses. Approximately 30 enteroviruses, predominantly the coxsackievirus and echovirus groups, and four types of adenoviruses are known to produce exanthems (Fig. 107.21). Most viral exanthems are maculopapular, although scarlatiniform, erythematous, vesicular, or petechial rashes are occasionally seen. The eruptions are variable in their extent, are typically nonpruritic, and do not desquamate. Oropharyngeal lesions may be present.

The classic viral exanthems are rubeola (measles), rubella (German measles), herpesvirus 6 (roseola), parvovirus B19 (erythema infectiosum or fifth disease), and the enteroviruses (echovirus and coxsackievirus).

Roseola infantum. Roseola infantum, otherwise known as *exanthem subitum* or *sixth disease,* is a benign illness caused by human herpesvirus 6 and human herpesvirus 7 and is typically spread by saliva. It is characterized by fever and a skin eruption. Ninety-five percent of cases are seen in children 6 months to 3 years old. The fever typically has an abrupt onset, with temperature rising rapidly to 39°C to 41°C, and is present consistently or intermittently for 3 or 4 days, at which time the temperature drops to normal. The rash typically appears with fever defervescence. The lesions are discrete pink or rose-colored macules

Fig. 107.21 Enterovirus. (Courtesy Jonathan Singer, MD.)

Fig. 107.22 Roseola.

or maculopapules, 2 or 3 mm in diameter, that blanch on pressure and rarely coalesce (Fig. 107.22). The trunk is involved initially, with the eruption typically spreading to the neck and extremities. The rash clears in 1 or 2 days.

Despite the presence of a high fever, the infant usually appears well. A febrile seizure may occur. Encephalitis is a very rare complication of the disease. The prognosis is excellent, and no treatment is necessary.

Measles. Measles, or rubeola, is a highly contagious viral illness spread by contact with infectious droplets, with an incubation period of 10 to 14 days. Although measles was declared eradicated in the US in 2000, the incidence has risen since that time.[38] Measles is most likely to infect unvaccinated individuals. Patients are considered to be contagious from 5 days prior to onset of symptoms until 5 to 6 days after the onset of dermatologic involvement.

Symptoms begin with fever and malaise. Symptoms include the "three C's": cough, coryza, and conjunctivitis. On the second day of the illness, Koplik spots, which are pathognomonic of the disease, may appear on the buccal mucosa as small, irregular, bright red spots with bluish white centers. Beginning opposite the molars, Koplik spots may spread to involve a variable extent of the oropharynx.

The cutaneous eruption of measles typically begins on the third to fifth day of the illness. Maculopapular erythematous lesions involve the forehead and upper neck and spread to involve the face, trunk, arms, and finally the legs and feet. Koplik spots begin to disappear coincident with the appearance of the rash. By the third day of its presence, the rash begins to fade, doing so in the order of its appearance, and the fever subsides.

Complications may include otitis media, encephalitis, or pneumonitis. Otitis media is the most common complication. Encephalitis or pneumonia may be life-threatening.

Treatment is primarily supportive and should include antipyretics, hydration, and treatment of pruritus (see Chapter 119). Vitamin A should be administered to hospitalized patients at the time of diagnosis and repeated the second day, to help prevent eye damage and blindness.[39] If bacterial invasion occurs with otitis media or pneumonia, antibiotics are indicated. Isolation of infected children is of limited value as exposure usually occurs before the appearance of the rash. Infection typically confers lifelong immunity. Postexposure prophylaxis may be administered with the measles virus vaccine or human immunoglobulin.

Rubella. Rubella, or German measles, is a viral illness characterized by fever, skin eruption, and generalized lymphadenopathy. It is spread by droplet contact, and peak incidence is in the winter and early spring. The incubation period is typically 14 to 21 days, and the rash heralds the onset of the illness in children. The maximum time of communicability is in the few days before and 5 to 7 days after the onset of the rash. Infants with congenital rubella may shed virus for more than 1 year. In adults, a 1- to 6-day prodrome of headache, malaise, sore throat, coryza, and low-grade fever precedes the rash. These symptoms generally disappear within 24 hours after the appearance of the skin eruption.

The rash of pink to red maculopapules appears first on the face and spreads rapidly to the neck, trunk, and extremities. Those on the trunk may coalesce, but lesions on the extremities typically do not. The rash remains for 1 to 5 days, and often disappears at the end of 3 days. Although clearing may be accompanied by fine desquamation, this sign is usually absent.

The major complications of rubella include encephalitis, arthritis, or thrombocytopenia. Rubella during pregnancy may result in congenital defects. No treatment is required in most cases of rubella. Antipyretics may be administered to treat headache, arthralgias, and painful lymphadenopathy.

Erythema infectiosum. Erythema infectiosum, or "fifth disease," is caused by parvovirus B19 infection and typically affects pediatric patients. It is characterized by mild systemic symptoms, fever in 10% to 15% of patients, and a characteristic rash. Arthralgia and arthritis occur commonly in adults but rarely in children. The rash is intensely red on the face and gives a "slapped-cheek" appearance with circumoral pallor. A reticular (netlike) maculopapular eruption, which may be noted on the arms, moves caudally to the trunk, buttocks, and thighs. The rash may recur with changes in temperature and exposure to sunlight. The incubation period is usually between 4 and 14 days. The infection is benign and management is supportive.

Fungal Infections

Fungal infections may affect the skin, scalp, or mucous membranes. The dermatophytoses are superficial fungal infections that are limited to the skin. Dermatophytes generally grow best in warm, moist environments,

Fig. 107.23 Tinea Corporis. (Courtesy David Effron, MD.)

Fig. 107.24 Kerion of Tinea Capitis. (Courtesy David Effron, MD.)

and grow only in the keratin or outer layer of the skin, nails, or hair. Any potential dermatophyte infection can be examined under the microscope in a KOH preparation if available. The specimen is examined for the characteristic branching hyphae of the dermatophytes or the short, thick hyphae and clustered spores of tinea versicolor.

Tinea Corporis

Tinea refers to superficial dermatophytic infection of the skin, hair, or nails, usually by the *Trichophyton* organism. Tinea corporis, commonly referred to as "ringworm" infection, presents as a sharply marginated, annular lesion with raised or vesicular margins and central clearing (Fig. 107.23). Lesions may be single or multiple. Other related forms of tinea may be seen, including tinea cruris involving the groin, tinea manuum affecting the hands, and tinea pedis of the feet.

The differential diagnosis of tinea corporis includes erythema migrans (associated with Lyme disease, with annular lesions with central clearing without scale), granuloma annulare (idiopathic skin condition that causes raised annual lesions without scale), psoriasis (erythematous plaques with silvery scale), cellulitis (erythema without central clearing or scale), or erythrasma (superficial bacterial infection that presents with hyperpigmented patches).

Infections of the body, groin, or extremities usually respond to topical antifungal agents, such as clotrimazole, miconazole, tolnaftate, terbinafine, or naftifine. Two or three daily applications of the cream form of any of these preparations result in healing of most superficial lesions in 1 to 3 weeks.

Tinea Capitis

Tinea capitis is a fungal infection of the scalp, and it is the most common cutaneous fungal infection in children. Common organisms include *Microsporum* and *Trichophyton* species. Although it is often seen in pediatric patients 6 to 10 years old, tinea capitis may also occur in adults. Nosocomial transmission of dermatophyte infections, such as *Trichophyton tonsurans,* has also been reported. Alopecia may be seen, typically with thickened, scaly scalp. Broken hairs resembling black dots near the scalp may be seen. Hair loss is the result of hyphae growing within the hair shaft, rendering it fragile, so that the hair strands break off 1 to 2 mm from the scalp. The disease may be transmitted by close child-to-child contact, or contact with household pets, hats, combs, barber's shears, or similar items. Complications may include kerion formation, lymphadenitis, bacterial cellulitis or abscess, or scarring alopecia.

The differential diagnosis of tinea capitis includes alopecia areata (alopecia without scalp changes), atopic dermatitis (patches of thickened skin with scale), nummular eczema (eczema in small circular patterns), bacterial infection (such as cellulitis or abscess), psoriasis (erythematous patches with silvery scale), seborrheic dermatitis (pruritic yellow or white patches), or trichotillomania (hair pulling).

The diagnosis is made based on clinical presentation. If in question, a fungal culture specimen may be obtained.

Systemic therapy is required for tinea capitis, due to fungal invasion of the hair follicles. Treatment should be with a systemic antifungal agent, such as terbinafine (<25 kg: 125 mg/day PO for 6 weeks; 25 to 35 kg: 187.5 mg/day PO for 6 weeks; >35 kg: 250 mg/day PO for 6 weeks). Alternatives include itraconazole, fluconazole, or griseofulvin.[40] Therapy should be given for 4 to 8 weeks. Topical treatments such as selenium sulfide, ketoconazole, or ciclopirox shampoo in addition to systemic antifungal therapy may increase cure rates.[41] Patients should be referred for outpatient follow-up with primary care or dermatology within 4 weeks. Family members should be evaluated for possible infection.

Kerion

A kerion is a fungal infection affecting hair follicles that is characterized by intense inflammation, and a boggy, erythematous mass, typically affecting the scalp (Fig. 107.24). The lesion may contain frank pus. It usually affects the scalp and is more common in children and in African Americans. Local alopecia and scarring can result. Lymphadenopathy may be present. Accurate differentiation of a kerion with or without superinfection can be challenging. Wood's lamp examination can be helpful in confirming the diagnosis.

Kerions are treated the same as tinea capitis, with systemic antifungal agents for 6 to 8 weeks. If bacterial superinfection exists, an antibiotic is added. Antibiotic options include oral cephalexin, dicloxacillin, or clindamycin. Clindamycin is recommended when community-acquired MRSA is a concern. Surgical drainage of kerions is rarely helpful and should be avoided.

Tinea Pedis

Tinea pedis, commonly referred to as *athlete's foot,* presents with scaling, maceration, vesiculation, and fissuring between the toes and on the plantar surface of the foot. Common etiologies include *Trichophyton rubrum, Trichophyton interdigitale,* and *Epidermophyton floccosum.* Secondary bacterial infection may occur. The vesicular pustular form of tinea pedis should be considered when vesicles and pustules on the instep are noted. Interdigital lesions may cause minimal symptoms and serve as a portal of entry for bacterial cellulitis. The differential diagnosis includes contact dermatitis, and dyshidrotic eczema which usually presents as pruritic vesicles on the lateral aspects of fingers. A KOH preparation is helpful to differentiate among these processes.

Fig. 107.25 Tinea Versicolor.

Treatment options include topical antifungal agents, such as terbinafine 1% cream, applied BID for 1 to 2 weeks. Alternatives include miconazole cream, powder, or spray, and clotrimazole cream, solution, or ointment. For severe disease or if topical treatment has failed, systemic therapy may be instituted with terbinafine, fluconazole, or griseofulvin.

Tinea Versicolor

Tinea versicolor, or pityriasis versicolor, is a superficial fungal infection caused by genus *Malassezia*. Superficial hypopigmented or hyperpigmented patches occur mainly on the chest and trunk, but may extend to the head and limbs. As the name implies, lesions can be a variety of colors, including pink, tan, or white. The disease may be associated with pruritus. On examination, a fine subtle scale is noted that may appear hypopigmented (Fig. 107.25). Pale yellow or orange fluorescence under Wood's light may be seen. The differential diagnosis includes vitiligo and seborrheic dermatitis. A KOH preparation reveals short hyphae mixed with spores ("chopped spaghetti and meatballs").

Tinea versicolor may be treated with topical antifungal agents, such as 2.5% selenium sulfide shampoo, applied daily for 1 weeks. Alternative therapies include imidazole creams, and ketoconazole cream or foam. For topical treatment failures, systemic therapy may be indicated, such as fluconazole, as a single 150- to 300-mg weekly dose for 2 to 4 weeks. Recurrence is common. Pigmentation may not return to normal for months.

Tinea Unguium (Onychomycosis)

Tinea unguium may be caused by dermatophytes, candida, or other fungal species. Paronychia or untreated tinea pedis may be predisposing factors. Onychomycosis presents with toenails or fingernails that are thickened, opaque, cracked, or destroyed. Subungual debris is present, and the nail may contain yellowish longitudinal streaks (Fig. 107.26). The nail of the great toe is most commonly involved. Differential diagnosis includes tinea pedis, psoriasis, or warts.

Fig. 107.26 Onychomycosis.

Topical therapy of the nails may be initiated if less than 25% of the nail bed is involved, but often may not result in cure due to poor penetration into the nail keratin.[42] Fingernails typically respond more rapidly to therapy than toenails. Involvement of one or two nails may be treated with topical antifungal agents. More extensive infection or risk factors (including advanced age, diabetes, immunosuppression, or widespread infection) requires systemic therapy with an antifungal agent, such as terbinafine (250 mg PO daily for 6 weeks [fingernail]) or 12 weeks [toenail]) or itraconazole (200 mg bid for 1 week, repeated q4wk for 2 mo [fingernail] or 200 mg/day PO for 12 weeks [toenail]).[43] Third-line agents may include griseofulvin or ketoconazole, which require prolonged courses, with high relapse rates and numerous side effects. Treatment failures or relapses are common, and they may be attributed to poor patient compliance, low bioavailability, lack of drug penetration into the nail, drug resistance, or drug interactions. Additional therapies may include surgical removal of the nail, photodynamic therapy, or laser therapy.

Candidiasis

Infection by *Candida albicans* may occur in patients of all ages. Many conditions predispose to infection, including diabetes mellitus, HIV infection, pregnancy, obesity, smoking, malnutrition, malignancy, or treatment with corticosteroids, antibiotics, or immunosuppressive agents.

Oral candidiasis. Oral candidiasis ("thrush") is the most common clinical expressions of *Candida* infection. It is common in newborns with one-third being affected by the first week of life, and also in elder persons, immunosuppressed individuals, or persons wearing dentures. It appears as patches of white or gray friable material covering an erythematous base on the buccal mucosa, gingiva, tongue, palate, or tonsils. Fissures or crust at the corners of the mouth may be present. The differential diagnosis of oral candidiasis includes lichen planus (which unlike *C. albicans* is not easily scraped off), or hairy leukoplakia (villous white patches on the lateral tongue). Oral mucous membrane infection with *C. albicans* is an AIDS-defining illness. If the patient does not use dentures and has not taken antibiotics recently, underlying immunosuppression should be considered.

Fig. 107.27 Candida Intertrigo.

Treatment of oral candidiasis includes topical antifungal agents, such as clotrimazole troches five times daily, or oral nystatin suspension four times daily, or nystatin pastilles four times daily. Treatment is continued for 5 to 7 days after the lesions disappear. For esophageal candidiasis, systemic antifungal therapy is typically required, with oral fluconazole, IV fluconazole, or IV amphotericin B. Chapter 121 provides detailed management recommendations.

Cutaneous candidiasis. Cutaneous candidiasis affects intertriginous areas, including the interdigital web spaces, groin, axilla, and intergluteal or inframammary folds. Lesions appear as moist, bright red macules rimmed with a collarette of scale, with small satellite papules or pustules just peripheral to the main body of the rash (Fig. 107.27). These satellite lesions are typical indicators of a *Candida* infection. Intertriginous lesions are prone to bacterial superinfection.

The differential diagnosis of cutaneous candidiasis includes contact dermatitis, tinea cruris, intertrigo, herpes simplex such as herpetic whitlow, and folliculitis. Candidiasis, however, is less sharply demarcated than tinea cruris and brighter red than intertrigo. A KOH preparation of a specimen taken from a pustule and roof of the lesion will reveal hyphae and pseudohyphae.

Intertriginous lesions should be treated with topical imidazole creams, such as clotrimazole, 1% cream BID for 4 weeks. Alternative topical therapies include miconazole, ketoconazole, or sulconazole. Extensive infection may be treated with fluconazole (100 mg PO daily for 2 weeks) or itraconazole (100 mg PO daily for 2 weeks). The area should be kept dry.

Vulvovaginal candidiasis. Vaginal candidiasis accounts for 20% to 25% of vaginitis. It has been estimated that 75% of women will experience vaginal candidiasis at least once. Predisposing factors include diabetes, pregnancy, immunosuppression, or hormone replacement therapy. Pruritus is a common presenting complaint. Other symptoms may include dyspareunia, dysuria, or vaginal burning. Differential diagnosis includes sexually transmitted infection, bacterial vaginosis, or urinary tract infection. A KOH preparation will reveal hyphae and budding yeast forms.

Treatment should be initiated with over-the-counter intravaginal imidazoles, such as clotrimazole or miconazole, or a single 150-mg dose of oral fluconazole.

Sporotrichosis. Sporotrichosis, caused by a variety of *Sporothrix* species, is a fungal infection that may be transmitted by contact with soil, or by zoonotic transmission from animals such as snakes, birds, or cats. Most cases present with lymphocutaneous findings, such as papules, nodules, or ulcerations (Fig. 107.28). Rarely, systemic involvement may be seen with joint, pulmonary, or neurologic complications. Definitive diagnosis may be made with serologic testing. Treatment should be initiated with an oral antifungal agent such as itraconazole, 200 mg PO daily until 2 weeks after lesions have resolved, usually 3 to 6 months. Alternative oral agents include terbinafine, or intravenous amphotericin B in the setting of systemic sporotrichosis or treatment failure.[44] Dermatologic follow-up is essential to ensure adequate resolution.

Infestations

Scabies

Scabies is a skin infestation caused by the penetration of the parasitic mite *Sarcoptes scabiei-var hominis* into the epidermis. It is an infestation of worldwide impact; over 100 million persons are affected annually. It occurs more commonly in winter months. It is transmitted mostly through close personal contacts. It may also be spread by exposure to fomites, as the scabies mite can live off the human skin for 3 days. The average number of mites harbored by a host is usually less than 20. Scabies presents with intense pruritus and rash, which usually develop after 1 to 8 weeks following exposure. The pruritus is typically worst at night. Clinical findings include small (<5 mm) papules or pustules, often with excoriations due to scratching. Burrows are uncommonly seen. Classically scabies affects several skin sites, including interdigital folds of the upper extremities and abdomen, genitalia, breasts, buttocks, or subungual skin of fingers (Figs. 107.29 and 107.30).[45] Scabies in infants and young children often

Fig. 107.30 Scabies.

Fig. 107.31 Nits as Seen in Head Lice. (Courtesy David Effron, MD.)

may present with generalized involvement of the skin, including the face, scalp, palms, and soles. In infants, the most common presenting lesions are papules and vesicopustules.

In *crusted scabies* (previously known as *Norwegian scabies*), hyperkeratotic plaques develop diffusely, often on the palmar and plantar regions, with thickening and dystrophy of the toenails and fingernails. Crusted scabies is highly contagious, as a host may harbor thousands or millions of mites. Individuals with immunosuppression, including human immunodeficiency virus infection, elders, and patients with dementia or neuropathy are at risk of developing crusted scabies.[46,47]

Scabies is a clinical diagnosis that is based primarily on the history and examination. The definitive diagnosis is made by the microscopic identification of the scabies mites, eggs, or fecal pellets *(Scybala)*. As these techniques may be impractical in the ED, treatment should be instituted based on a clinical suspicion of the diagnosis.

The differential diagnosis of scabies includes pityriasis rosea (symmetric maculopapular rash), papular urticaria, secondary syphilis (symmetric maculopapular rash), folliculitis, contact dermatitis, atopic dermatitis, seborrhea, dermatitis herpetiformis (autoimmune blistering disorder associated with celiac disease), lichen planus (pruritic violaceous polygonal lesions on the extremities), and psoriasis (erythematous patches with silvery scale).

Scabies should be treated with topical permethrin 5% cream or oral ivermectin.[48,49] Permethrin cream should be applied from the neck down, covering all areas of the body including under the nails, in the umbilicus, around the nipples, and genitals. Face and scalp should be treated in affected infants and young children. Preferably, it should be applied prior to bedtime, left on overnight, and then washed off 8 to 12 hours later. It is vital to treat not only the patient but family members and close contacts as well. A second treatment should be administered in 1 to 2 weeks. Alternative therapy may be initiated with oral ivermectin, although the cure rate may be lower than permethrin.[50] For heavily infested or immunocompromised patients, it is recommended that ivermectin be given once a week for 2 to 3 weeks. Lindane, a previously utilized agent, is not recommended, due to potential neurotoxicity as well as resistance. Emollients and antihistamines may provide symptomatic relief of pruritus.[51]

Equally important in the treatment is the decontamination of clothing, bed linens, and towels by washing them in hot water and hot machine drying. Items that cannot be washed or dry-cleaned can be decontaminated by sealing the items in an airtight container for at least 72 hours.

Pediculosis

Pediculosis may affect the scalp hair (pediculosis capitis, caused by the mite *Pediculus humanus capitis*), body (pediculosis corporis, caused by *Pediculus humanus corporis*), or genitalia (pubic lice, caused by *Pthirus pubis*). Infestation is typically associated with significant pruritus. Lesions may be erythematous macules, papules, or wheals.

Pediculosis capitis is the most common form of lice infestation in the United States and is frequently seen in children 3 to 12 years old. An estimated 10% to 40% of school children in the United States have been infected with pediculosis capitis. It can be transmitted by sharing hairbrushes, combs, or hats, and through contact with infested furniture, clothing, or linens. Lice can live on fomites for up to 4 days. Hygiene and hair length are unrelated to infection. Incidence is greatest during autumn. Scalp, occipital, or postauricular pruritus are common in patients with pediculosis capitis. Neck and auricular erythema, papules, vesicles, or lymphadenopathy may be seen.

Pediculosis corporis can present with intense pruritus and erythematous macules or wheals. Pediculosis corporis typically occurs in patients with poor hygiene or living in crowded conditions.

Pediculosis pubic ("crabs") is a sexually transmitted disease and is most commonly seen among young adults. Other concurrent sexually transmitted diseases should also be considered.

The differential diagnosis includes conditions such as tinea capitis, seborrheic dermatitis, atopic dermatitis, eczema, scabies, folliculitis, or contact dermatitis.

The diagnosis of pediculosis is made by identification of lice or nits on the hair shaft (Fig. 107.31). Nits (eggs), which appear as white dots or grains, are more easily identified than the louse itself. Nits fluoresce with the Wood's lamp. Examination with a louse comb improves the diagnostic accuracy and is faster than direct visualization.

Therapy for pediculosis should be initiated with a pediculicide, such as pyrethrin shampoo or permethrin 1% lotion, with retreatment on day 9.[52,53] Spinosad 0.9% suspension (Natroba) is a newer agent with demonstrated pediculicidal efficacy. Spinosad 0.9% is approved for use in patients older than 4 years of age and is also effective against permethrin-resistant populations of lice. Spinosad is ovicidal, killing both nits and lice; thus extensive nit combing is not necessary. However, the cost may be prohibitive. Oral ivermectin has a high cure rate and may be used as alternate therapy (200 mcg/kg PO once).[54] Other treatments may be considered, including malathion, albendazole or

thiabendazole, benzyl alcohol lotion, or levamisole. Lindane, an older therapy, should be avoided, because of neurotoxicity and poor pediculicidal activity. Over-the-counter products have variable success rates, in part due to resistance. Nits should be removed with a special fine-toothed comb. The environment should also be treated. Hats, hairbrushes and combs, and linens as well as clothing should be treated. Items should be boiled or washed and dried at high temperatures. Floors and furniture should be vacuumed. Family members should be examined and treated if infested. Sexual partners of patients with pediculosis pubis should be treated. The American Academy of Pediatrics recommends that children do not miss school simply because of head lice.

Bed Bugs

Bed bugs *(Cimex lectularius)* appear brown and are approximately 5 to 6 mm in length. Bed bugs may be potential vectors for many fungi, viruses, and bacteria, including MRSA and vancomycin-resistant *Enterococcus faecium*, although disease transmission to humans has not been documented.[55] Bed bugs are found not only in linens, but on furniture, luggage, and in walls, baseboards, and buildings, including hotels, hospitals, or apartments.[56,57] They often feed on humans at night with a painless bite.

Clinical presentation may appear as erythematous welts, macules, papules, urticaria, purpura, vesicles, or bullae, with intense pruritus. The distribution is often over uncovered areas, such as arms, legs, or shoulders. Lesions resolve spontaneously in 1 to 2 weeks.

Symptomatic treatment should be undertaken with antihistamines and topical corticosteroids. If there is suspicion for scabies, empiric treatment should be initiated with permethrin 5% cream, ivermectin, or crotamiton. Eradication from the environment is challenging, due in part to increasing resistance to insecticides. Eradication methods may include insecticides, heat, steam, freezing, or vacuuming. The hazards of widespread insecticide use, including potential for malignancy or CNS adverse effects, have created a dilemma of eradication.

ALLERGIC REACTIONS

Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to a chemical, physical, or biologic agent, which acts as an irritant or allergic sensitizer. Allergic contact dermatitis is a form of delayed hypersensitivity mediated by lymphocytes sensitized by the contact of the allergen to the skin. It is less common than irritant contact dermatitis. Caustics, industrial solvents, or detergents are common causes of irritant dermatitis. Clothing, jewelry, soaps, cosmetics, latex, plants, and medications contain allergens that commonly cause allergic contact dermatitis. The most common allergens include rubber compounds; plants of the *Toxicodendron* species, including poison ivy, oak, and sumac; nickel, often used in jewelry alloys; paraphenylenediamine, an ingredient in hair dyes and industrial chemicals; and ethylenediamine, a stabilizer in topical medications.

The primary lesions of contact dermatitis are papules, vesicles, or bullae on an erythematous base. Streaky, linear, intensely pruritic lesions are characteristic. A pattern in the dermatologic region in contact with the allergen is typical (Fig. 107.32). Eruptions associated with contact dermatitis can appear as soon as several hours after the exposure or may be delayed for days.

Treatment of contact dermatitis includes avoidance of the irritant or allergen, and treatment of the resulting inflammation. Low-potency topical steroid creams may be applied to inflamed areas around orifices, and medium-potency creams can be used elsewhere, for example triamcinolone 1% cream bid for 1 week, or other options as listed in Table 107.4). Topical steroids are ineffectual on blistered areas. Oozing or vesiculated lesions should be treated with cool wet compresses of Domeboro or Burow's solutions (aluminum acetate). Topical baths, available over the counter, may also be comforting. Systemic antihistamines, such as hydroxyzine and diphenhydramine, may help control pruritus; nonsedating antihistamines are preferred for use during the day. If present, secondary bacterial infection should also be treated.

Fig. 107.32 Neomycin Allergy. (Courtesy Joanna Marco, MD.)

Urticaria

Urticaria may occur in isolation or as part of a systemic anaphylactic reaction. Approximately 15% to 20% of the population experiences urticaria during their lifetime. Acute urticaria is seen in both sexes. Chronic urticaria is more common in women in their 40s and 50s. Half of all patients with chronic urticaria have the disease for 5 years or more.

Various mediators, including histamine, bradykinin, kallikrein, and acetylcholine, are thought to play a role in urticaria production. Urticaria may be initiated by immunologic or nonimmunologic mechanisms. Nonimmunologic urticaria may be produced by degranulation of mast cells, which may be caused by foods and drugs, including aspirin and narcotics.

Almost any medication may produce urticaria, although penicillin and aspirin are the most common. Traces of penicillin may be present in dairy products, as well as in other medications. The mechanism of production of urticaria by aspirin is unclear, but is probably nonimmunologic, and the effects of aspirin may persist for weeks after ingestion. Substances that can cause urticaria by contact with the skin include foods, textiles, animal dander and saliva, plants, topical medications, chemicals, or cosmetics. Food allergies, such as seafood, tree nuts, peanuts, or eggs, may result in urticaria. In addition, foods such as lobster or strawberries can release histamine through a nonimmunologic mechanism.

Infection is a common cause of urticaria. Viral infections that produce urticaria include rhinovirus, rotavirus, hepatitis, mononucleosis, and coxsackievirus infections. Occult infections with *Candida,* the dermatophytes, bacteria, viruses, or parasites may also cause urticaria.

TABLE 107.4 Potency of Topical Steroids

Brand Name	Generic name
Class 1: Superpotent	
Clobex lotion, spray, or shampoo, 0.05%	Clobetasol propionate
Cormax solution, 0.05%	Clobetasol propionate
Diprolene ointment, 0.05%	Betamethasone dipropionate
Olux E foam, 0.05%	Clobetasol propionate
Olux foam, 0.05%	Clobetasol propionate
Temovate cream, 0.05%	Clobetasol propionate
Ultravate cream or ointment, 0.05%	Halobetasol propionate
Vanos cream, 0.1%	Fluocinonide
Class 2: Potent	
ApexiCon E ointment, 0.05%	Diflorasone diacetate
Diprolene cream AF, 0.05%	Betamethasone dipropionate
Halog ointment, solution, or cream, 0.1%	Halcinonide
Lidex cream, gel, or ointment, 0.05%	Fluocinonide
Psorcon ointment, 0.05%	Diflorasone diacetate
Topicort cream, spray, or ointment, 0.25%	Desoximetasone
Topicort gel, 0.05%	Desoximetasone
Class 3: Upper Midstrength	
Cutivate ointment, 0.005%	Fluticasone propionate
Elocon ointment, 0.1%	Mometasone furoate
Lidex-E cream, 0.05%	Fluocinonide
Luxiq foam, 0.12%	Betamethasone valerate
Class 4: Midstrength	
Cordran ointment, 0.05%	Flurandrenolide
Elocon cream, lotion, solution, 0.1%	Mometasone furoate
Kenalog cream, 0.1%, or spray, 0.2 mg/2 second spray	Triamcinolone acetonide
Synalar ointment, 0.025%	Fluocinolone acetonide
Westcort ointment, 0.2%	Hydrocortisone valerate
Class 5: Lower Midstrength	
Cordran cream, lotion, or tape, 0.05%	Flurandrenolide
Cutivate cream or lotion, 0.05%	Fluticasone propionate
Dermatop cream, ointment, 0.1%	Prednicarbate
Desonate gel, 0.05%	Desonide
Locoid cream, lotion, ointment, or solution, 0.1%	Hydrocortisone butyrate
Pandel cream, 0.1%	Hydrocortisone probutate
Synalar cream, 0.03%, 0.025%	Fluocinolone acetonide
Westcort cream, 0.2%	Hydrocortisone valerate
Class 6: Mild	
Aclovate cream or ointment, 0.05%	Alclometasone dipropionate
Capex shampoo, 0.01%	Fluocinolone acetonide
Derma-Smoothe/FS oil, 0.01%	Fluocinolone acetonide
DesOwen lotion, 0.05%	Desonide
Synalar cream or solution, 0.01%	Fluocinolone acetonide
Verdeso foam, 0.05%	Desonide
Class 7: Least Potent	
Aquanil HC, 1%	Hydrocortisone
Cortaid cream, spray, or ointment, 1%	Hydrocortisone
Hytone cream, 1%, 2.5%; lotion, 2%	Hydrocortisone
MiCort-HC cream, 2.5%	Hydrocortisone
Nutracort cream, 2.5%	Hydrocortisone
Synacort cream, 1%	

Modified with permission from National Psoriasis Foundation: Topical steroids potency chart. Available at www.psoriasis.org/page.aspx?pid=469.

Inhalation of pollens, mold, animal dander, dust, plant products, or aerosols may produce urticaria. Respiratory symptoms may accompany the dermatosis, and a seasonal pattern of occurrence may be present. Stings and bites of insects, arthropods, or various marine animals may also produce an urticarial eruption.

Systemic diseases such as systemic lupus erythematosus, lymphoma, carcinoma, hyperthyroidism, rheumatic fever, or juvenile rheumatoid arthritis may induce an urticarial eruption.

Physical agents may produce urticaria. Dermatographism is present when firm stroking of the skin produces an urticarial wheal within 30 minutes and is the most common form of physical urticaria. Pressure urticaria is distinct from dermatographism in that the onset of urticaria is delayed by 4 to 8 hours after the application of physical pressure.

Cold urticaria may be either familial or, more commonly, acquired. Cold urticaria may also be associated with underlying illness, such as cryoglobulinemia, cryofibrinogenemia, syphilis, or connective tissue disease. Antihistamines taken 30 to 60 minutes before cold exposure may be helpful. Cholinergic urticaria is induced by exercise, heat, or emotional stress. It may be associated with pruritus, nausea, abdominal pain, or headache. The lesions of cholinergic urticaria are wheals, 1 to 3 mm in diameter, surrounded by extensive erythematous flares and, occasionally, satellite wheals. Nonsedating antihistamines are generally used to treat cholinergic urticaria.

Heat is a rare cause of hives. Solar urticaria, also uncommon, is confined to sun-exposed areas of skin and clears rapidly when the light stimulus is removed. Extensive sun exposure may cause wheezing, dizziness, or syncope in a susceptible individual. Sunscreens have not been proven to be effective for the prevention of solar urticaria. Phototherapy may be used in an attempt to induce tolerance.

Urticaria appears as edematous plaques with pale centers and red borders and is easily recognizable (Fig. 107.33). Individual hives are typically transient, lasting less than 24 hours, although new lesions may continuously develop, which represents localized dermal edema produced by transvascular fluid extravasation.

The differential diagnosis of urticaria includes drug eruption, exanthems, erythema multiforme, erythema marginatum, and juvenile rheumatoid arthritis.

Treatment of urticaria involves the removal of the inciting factor, when applicable, and the administration of antihistamines or other antipruritics. Hydroxyzine can treat pruritus for symptomatic relief. For chronic urticaria, long-term therapy with antihistamines may be needed. Nonsedating antihistamines are preferred. Cetirizine, fexofenadine, or loratadine can be used. An H_2 blocker may be added.

Steroids may be a useful adjunctive therapy. Patients with moderate or severe urticaria may benefit from prednisone or dexamethasone. Patients with recurrent urticaria may benefit from longer courses of

Fig. 107.33 Urticaria. (Courtesy David Effron, MD.)

oral steroids (14 to 21 days with a taper). Chronic administration of steroids is not recommended.

Patients with chronic urticaria may be treated with a prescription for a combination of an H_1 and H_2 antihistamine.

Poison Ivy

Exposure to *Toxicodendron* species may cause vesicular or bullous eruptions. Oozing, crusting, scaling, and fissuring may be found, with lichenification in chronic lesions. The distribution of the eruption depends on the specific contact and may be localized, asymmetric, linear, unilateral, or disseminated (Fig. 107.34). Mucous membranes are usually spared unless they are directly exposed to the inciting agent. Sensitization to poison ivy may result in sensitization to other plants in this family, including cashew, mango, lacquer, and ginkgo trees, thus patients may present with a dermatologic reaction to these exposures as well.

In addition to treatment regimens for contact dermatitis, a course of systemic corticosteroids may be indicated to treat *Toxicodendron*-associated dermatitis. Patients should be counseled to wash all clothes or items that might have contacted the plant as the irritant plant oil can remain on inanimate objects. Once the offending agent is reliably removed from the skin and clothes, ongoing outbreak is attributable to the initial contact, not spread from the serous fluid from the bullae. The patient is not contagious to others unless there is direct contact with the plant oil in those who are sensitized.

DRUG REACTIONS

Reactions to medications are common and are estimated to occur in 1% to 5% of patients. Cutaneous reactions are the most common type of reaction. Immediate reactions, occurring within 1 hour, may include urticaria, anaphylaxis, or angioedema.[58] Delayed hypersensitivity reactions often appear within 4 to 28 days after the drug is taken. Many medications have the potential to produce a drug reaction. Patients at higher risk of drug reactions include those with immunodeficiency, certain infections, or genetic predisposition. The most common eruptions are a morbilliform rash (Fig. 107.35), urticaria, or fixed drug eruption. More severe reactions may include vasculitis, erythema nodosum, angioedema, anaphylaxis, Stevens-Johnson syndrome, toxic epidermal necrolysis, blistering dermatoses, drug-induced lupus, lichenoid drug eruptions, psoriasiform drug eruptions, drug-induced neutrophilic dermatoses (i.e., Sweet's

Fig. 107.34 Toxicodendron (Poison Ivy).

Fig. 107.35 Morbilliform Drug Eruption. (Courtesy David Effron, MD.)

syndrome, erythema nodosum, and pyoderma gangrenosum), and cutaneous lymphoma-like drug reactions.

Treatment of drug eruptions includes discontinuation of the inciting agent.[59] Most cutaneous drug reactions fade within 1 week of discontinuation. Antihistamines, H_2-antagonists, and topical or systemic steroids may be indicated for symptomatic treatment.

Toxic Epidermal Necrolysis

Stevens-Johnson syndrome and toxic epidermal necrolysis are considered a continuous spectrum of the same disease, an immune-complex–mediated hypersensitivity reaction. Stevens-Johnson syndrome is considered a minor form of toxic epidermal necrolysis with less than 10% body surface area (BSA) involved. Toxic epidermal necrolysis includes patients with more than 30% BSA involved. There is overlap with patients with 10% to 30% BSA involved.[60] The main feature of non–staphylococcal-induced toxic epidermal necrolysis, or Lyell's disease, is the separation of large sheets of epidermis from underlying dermis. Toxic epidermal necrolysis may be caused by medications, infection, malignancy, or idiopathic (30% to 50% of cases). Medications that can cause toxic epidermal necrolysis include sulfa drugs, nonsteroidal antiinflammatory drugs (NSAIDs), penicillin, aspirin, barbiturates, phenytoin, carbamazepine, or allopurinol.

Mortality may be up to 30% with toxic epidermal necrolysis. Risk factors for poor prognosis include age older than 40 years, underlying malignancy, heart rate greater than 120 beats/min, initial percentage

Fig. 107.36 Toxic Epidermal Necrolysis. (Courtesy David Effron, MD.)

of epidermal detachment more than 10%, BUN level more than 10 mmol/L, serum glucose level more than 252 mg/dL, and bicarbonate level less than 20 mmol/L.

Toxic epidermal necrolysis commonly begins with prodromal symptoms, such as fever, malaise, rhinitis, sore throat, or myalgias. These are followed by the abrupt development of a macular rash that may appear as target lesions. The extremities are commonly involved, although any area may be affected. The exanthem becomes confluent, and dermal-epidermal dissociation ensues; Nikolsky sign (denudation with shear stress) is present, and the skin is commonly painful to the touch (Fig. 107.36). Mucous membrane involvement may occur with erythema, blistering, sloughing, or necrosis (Fig. 107.37). Involvement of the conjunctivae and cornea may lead to permanent scarring and blindness. Systemic involvement may occur, with renal, gastrointestinal, or respiratory tract lesions, resulting in hematuria, diarrhea, bronchitis, or pneumonia. Morbidity and mortality are often related to infection and dehydration.

The treatment of Stevens-Johnson syndrome and toxic epidermal necrolysis includes discontinuation of the offending agent and supportive care, including hydration, prevention of secondary infection, pain control, and wound management.[61,62] This is usually best accomplished in a center with burn care expertise. Treatment may also include systemic steroids, intravenous immune globulin (IVIG), or cyclosporin A.[61] Plasmapheresis may be considered in consultation with a specialist with experience in treating these serious skin disorders.[63]

DRESS syndrome. Drug reaction with eosinophilia and systemic symptoms (DRESS syndrome) is a severe drug reaction characterized by a morbilliform skin eruption, fever, lymphadenopathy, hematologic abnormalities (eosinophilia, atypical lymphocytosis), and internal organ involvement (hepatic, renal, pulmonary, cardiac, gastrointestinal, neurologic, or endocrine abnormalities).[64,65] Mortality may be as high as 10%. Common inciting medications include anticonvulsants, antibiotics, or allopurinol. Onset may be 2 to 8 weeks after beginning the medication. Treatment includes withdrawal of the inciting agent and treatment with systemic steroids.

Fig. 107.37 Toxic Epidermal Necrolysis. (Courtesy David Effron, MD.)

INFLAMMATORY CONDITIONS

Atopic Dermatitis

Atopic dermatitis is a common dermatologic condition often referred to as *eczema* or *chronic dermatitis.* Atopic dermatitis is the cutaneous manifestation of an atopic state, and it is associated with allergic diseases, such as asthma and allergic rhinitis. Patients with atopic dermatitis are known to have abnormalities of both humeral and cell-mediated immunity. The exact mechanism is unclear, but eosinophil, mast cell, and lymphocyte activation triggered by increased production of interleukin-4 by specific T helper cells seems to be involved. The course of atopic dermatitis includes remissions and exacerbations. More than 90% of patients have the onset of atopic dermatitis before 5 years of age.

Atopic dermatitis is an inflammatory skin condition. Diagnostic criteria include itchy skin plus three or more of the following: generalized dry skin in the past year, history of asthma or hay fever, onset of rash before 2 years old, and flexural dermatitis.

Skin lesions generally appear as inflammatory thickened, papular, or papulovesicular lesions. The skin is typically dry and may be scaly, but in the acute phase, it may also be vesicular, weeping, or oozing. In the chronic stage, lesions are thickened and lichenified.

The distribution of lesions varies with the age. In infants, inflammatory exudative plaques are seen on the cheeks, on the extensor surfaces, or in the diaper area. Older children and adults have lesions in the antecubital and popliteal flexion areas, neck, face, or upper chest. Infantile atopic dermatitis usually begins in the fourth to sixth month of life and improves by the third to fifth year of life. The childhood form occurs between 3 and 6 years of age, and it resolves spontaneously or continues into the adult form.

Intense pruritus is a hallmark of atopic dermatitis. During flares, patients may present with complaints of intense itching and failure of routine treatments to control their symptoms. Patients may also present with secondary infections. The itching may be focal or generalized, is worse during the winter, and is triggered by increased body temperature or emotional stress. It may be particularly challenging at night. Excoriations may be prominent, and secondary bacterial infection of excoriated lesions is common. Repeated scratching and rubbing produce lichenification, a condition of hyperpigmentation, thickening of the skin, and accentuation of skin furrows. Lichenification is a common feature of chronic atopic dermatitis.

Treatment should be aimed at control of inflammation, dryness, and itching. Topical emollients and topical corticosteroids are the cornerstone of therapy.

Skin dryness is treated with topical emollients, such as oils, ointments, lotions, and creams. In some cases, emollients are as effective as topical steroids.[66] The choice of agent should be based on patient preference and may be applied several times daily. Pruritis may be treated with topical emollients and systemic antihistamines.

Approximately 80% of patients have improvement of symptoms with topical steroid treatment. When the dermatitis is severe, the application of a fluorinated corticosteroid ointment (such as betamethasone valerate) is recommended (Table 107.4). Fluorinated corticosteroids should not be used on the face, as they can produce cutaneous atrophy. Milder corticosteroid preparations, such as 0.025% triamcinolone ointment, may be used on the face or intertriginous areas. Patients with severe disease may require systemic steroids. Other treatment modalities include calcineurin inhibitors, topical phosphodiesterase inhibitors, or UV radiation.[67]

Patients with atopic dermatitis are susceptible to infection and colonization by a variety of organisms because of their defective skin barrier functions and local skin immunodeficiency. Widespread disseminated viral infections, such as eczema molluscum (molluscum contagiosum in the setting of eczema), eczema herpeticum (herpes virus infection in the setting of eczema), or recurrent staphylococcal pustulosis may complicate atopic dermatitis.

Inpatient admission is a consideration in rare cases, for those patients who have generalized erythema and exfoliation (erythroderma) or intractable itching with skin breakdown and heightened risk for severe secondary bacterial or viral skin infections.

Pityriasis Rosea

Pityriasis rosea is a mild skin eruption predominantly found in children and young adults. The etiology is unknown, although viral, bacterial, and fungal etiologies have been suggested. Patients aged 10 to 35 years are commonly affected. Clinical presentation includes multiple pink or pigmented oval papules or plaques 1 to 2 cm in diameter on the trunk and proximal extremities. A history may reveal an initial larger patch ("herald patch") that precedes the widespread eruption (Figs. 107.38 and 107.39). Mild scaling may be present. The lesions are parallel to the ribs, forming a Christmas tree–like distribution on the trunk and extremities. Oral lesions are rare. In children, papular or vesicular variants of the disease may occur. The eruption is usually asymptomatic, although pruritus may be present. The differential diagnosis includes tinea corporis (erythematous lesions with scale and central clearing), guttate psoriasis (small psoriatic lesions over trunk and proximal extremities), lichen planus (pruritic violaceous polygonal lesions), drug eruption, Lyme disease, or secondary syphilis (erythematous maculopapular lesions).

Fig. 107.38 Herald Patch of Pityriasis Rosea.

Fig. 107.39 Pityriasis Rosea.

Pityriasis rosea is self-limited, resolving in 8 to 12 weeks. Recurrences are rare. Treatment should include supportive care, including alleviation of pruritus. Topical zinc oxide or calamine lotion are useful for pruritus. Typically steroids are not indicated. If the disease is severe or widespread (e.g., vesicular pityriasis rosea), topical or oral steroids may be used (Table 107.4). No restriction of activity or isolation is indicated.

Kawasaki Disease

Kawasaki disease (mucocutaneous lymph node syndrome) is one of the most common vasculitides of childhood. The peak age is between 1 and 2 years old. The disease is very uncommon in children older than 14 years old or in adults. It is more common in boys. Although cases of Kawasaki disease have been reported in children of all ethnic origins, the highest incidence is among children of Asian descent. The disease typically occurs in winter and spring and is usually self-limiting, resolving spontaneously without treatment within 2 to 4 weeks. However, 15% to 20% of patients will develop complications, such as damage to coronary arteries, leading to myocardial infarction and heart failure. Kawasaki disease is the leading cause of pediatric acquired heart disease in the U.S.

Clinical features are characterized by three phases. The acute febrile period (phase I) is manifested by the abrupt onset of fever, lasting approximately 12 days. During phase I, cutaneous findings include erythematous lesions on the palms and soles. Within 2 days, the blotchy, erythematous, macular lesions spread to the extremities and trunk. Nonexudative injected conjunctivae, seen in approximately 90% of patients, may be present for 1 to 3 weeks. Diffuse oropharyngeal erythema with a "strawberry" tongue appearance is often present. Symptoms of diarrhea, arthritis, or photophobia may be present. In the subacute phase (phase II), desquamation, thrombocytosis, arthritis, arthralgias, or carditis may be present. This phase may last 30 days. There is a high risk for sudden death during this phase of the illness if it has gone untreated. During the convalescent phase (phase III), which occurs within 8 to 10 weeks after the onset of the illness, most signs of the illness have resolved. Coronary aneurysms present in 25% of cases and may be diagnosed by echocardiography or coronary angiography.

For epidemiologic surveillance, the Centers for Disease Control and Prevention (CDC) defines a case of Kawasaki disease as illness in

a patient with fever of 5 or more days duration, and the presence of at least four of the following five clinical signs[68]

- Rash
- Cervical lymphadenopathy (at least 1.5 cm in diameter)
- Bilateral conjunctival injection
- Oral mucosal changes
- Peripheral extremity changes.

The diagnosis is made based on clinical findings. Laboratory tests that support the diagnosis include elevated liver function tests, leukocytosis, thrombocytosis, and an elevated C-reactive protein (CRP). The ESR is elevated during phase II and returns to normal in phase III. Pyuria may be seen on urinalysis. Electrocardiography (ECG) may show PR and QT prolongation or acute ST/T wave changes.

Management of Kawasaki disease includes hospital admission, and treatment with high-dose IVIG and aspirin during hospitalization.[69] Treatment with IVIG within the first 10 days of illness reduces the incidence of coronary artery aneurysms fivefold, compared with children not treated with IVIG. Early cardiology evaluation is important to identify and treat possible coronary artery involvement.

Erythema Multiforme

Erythema multiforme is considered to be a hypersensitivity reaction. Potential etiologies include drug reaction; HSV infection or other viral infections; fungal diseases, such as dermatophytosis, histoplasmosis, or coccidioidomycosis; and bacterial infections, especially streptococcal infections or tuberculosis. Collagen vascular disorders have been known to precipitate erythema multiforme, including rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, or periarteritis nodosa. Pregnancy and various malignant neoplasms have also been associated with erythema multiforme. The etiology is unknown in approximately 50% of cases. The differential diagnosis includes urticaria, scalded skin syndrome, pemphigus, and pemphigoid or viral exanthems.

Erythema multiforme is an acute, usually self-limited disease. It is characterized by skin lesions that are erythematous or violaceous macules, papules, vesicles, or bullae. Their distribution is often symmetric, most commonly involving the soles and palms, the backs of the hands or feet, and the extensor surfaces of the extremities. The presence of lesions of the palms and soles is particularly characteristic. The target lesion with three zones of color is the hallmark of erythema multiforme (Fig. 107.40).

Fig. 107.40 Erythema Multiforme.

Treatment should include treatment of the underlying cause. Mild forms with no systemic symptoms, lesions limited to extremities, and no mucous membrane involvement typically resolve spontaneously in 2 or 3 weeks. Patients with lesions on the trunk or patients who are immunocompromised, especially those with multiple lesions, should receive a course of systemic steroids for 14 to 21 days with a taper and urgent dermatology referral.

Erythema Nodosum

Erythema nodosum is an inflammatory reaction of the dermis and adipose tissue that presents with painful, palpable erythematous or violaceous subcutaneous nodules. These painful nodules occur most commonly over the anterior tibia but may also be seen on the arms or body (Fig. 107.41). Fever and arthralgia of the ankles or knees may precede the rash. As the lesions evolve, they may turn yellow-purple and resemble bruises. Women are affected more often than men, with the highest incidence in the third to fifth decades of life.

A number of diseases are associated with erythema nodosum; these include drug reactions, sarcoidosis, coccidioidomycosis, histoplasmosis, tuberculosis, ulcerative colitis, regional enteritis, pregnancy, malignancy, or infections. Approximately 50% of erythema nodosum cases are idiopathic.[70]

Management includes treatment of the underlying etiology. Chest radiography may be considered to exclude findings characteristic of sarcoidosis, tuberculosis, or pulmonary fungal infection. Bed rest, elevation of the legs, and elastic stockings reduce pain and edema. Aspirin or other NSAIDs may provide pain relief. Erythema nodosum is a self-limited process that usually resolves in 3 to 8 weeks. Patients

Fig. 107.41 Erythema Nodosum. (Courtesy David Effron, MD.)

Fig. 107.42 Lichen Planus. (Courtesy Centers for Disease Control and Prevention [CDC] Public Health Image Library, Susan Lindsley.)

with severe pain may be treated with potassium iodide daily for 3 or 4 weeks.[71]

Lichen Planus

Lichen planus (LP) is an autoimmune condition that results in inflammation. LP typically presents with lesions that are flat-topped violaceous papules with pruritus (also known as the five "Ps": purple, planar, polygonal, pruritic, papules). Lesions typically appear on the wrists and ankles (Fig. 107.42). The lesions may occur in an area of trauma (Koebner phenomenon). Other areas may be affected, such as oral mucosa, anogenital region, scalp, or other areas.

Medium- to high-potency topical steroids are the treatment of choice (Table 107.4). Pruritus may be treated with systemic agents, such as diphenhydramine or hydroxyzine. Systemic steroids may be indicated if greater than 15% BSA is involved, or for topical treatment failures. Alternate therapies include topical calcineurin inhibitors, methotrexate, topical or systemic retinoids, or phototherapy.[72,73]

AUTOIMMUNE DISORDERS

Bullous Pemphigoid

Bullous pemphigoid is an autoimmune blistering disorder that most commonly affects geriatric patients. Clinical manifestations are often pruritus and generalized blistering of the skin (Fig. 107.43). Nikolsky sign is negative. It often has a waxing and waning clinical course. It has been associated with numerous systemic conditions, including malignancy, diabetes, stroke, Parkinson disease, or cardiovascular disease.

Topical steroids may be prescribed as initial therapy.[74] For example, clobetasol propionate cream, 0.05% may be applied BID for 1 to 3 weeks. Systemic steroids or doxycycline may be necessary to treat widespread lesions. Patients with topical treatment failure may be treated with a systemic agent, such as doxycycline (100 mg BID for 1 to 3 weeks) or prednisone (40 mg daily for 1 to 3 weeks).

Fig. 107.43 Bullous Pemphigus. (Courtesy David Effron, MD.)

Pemphigus Vulgaris

Pemphigus vulgaris is an uncommon but important dermatologic disorder to identify. The mortality rate before the use of steroids was approximately 95%. The current mortality rate is 10% to 15%, with appropriate treatment. Pemphigus is a bullous disease, affecting both sexes equally, and is most common in patients 40 to 60 years old. The disease is mostly prevalent in people of Jewish, Mediterranean, or south Asian descent.

The typical skin lesions are small, flaccid bullae that break easily, forming superficial erosions and crusted ulcerations. Any area of the body may be involved. Nikolsky sign is positive and characteristic of the disease.

Many patients also have oral lesions (50% to 60%). The oral lesions typically antedate the cutaneous lesions by several months. The most common site is in the mouth, especially the gums and vermilion borders of the lips. Oral lesions are bullous but commonly break, leaving painful, denuded areas of superficial ulceration.

Pain control and local wound care are essential components of therapy. Treatment with oral glucocorticoids should be instituted. Other treatments may include immunosuppressive agents, intravenous immunoglobulins, immunoadsorption, or rituximab.[75] Morbidity and mortality may ensue, related to an uncontrolled spread of the disease, secondary infection, dehydration, side effects of steroid therapy, or thromboembolism.

CUTANEOUS MALIGNANCIES

The most common cutaneous malignancies are basal cell carcinoma, squamous cell carcinoma, and melanoma.[76]

Basal cell carcinoma is the most common skin cancer in the United States.[77] Basal cell carcinomas are commonly seen in patients with fair skin, sun exposure, outdoor occupation, and older age. Clinical presentation is typically on sun exposed areas, commonly on the head or neck. Clinical presentations include nodular, superficial, and morpheaform subtypes. The typical nodular appearance is a pearly papule with well-defined borders and telangiectasias. Suspicious lesions should be referred to a dermatologist for biopsy and management.

Squamous cell carcinoma is the second most common skin cancer in the United States. It is more common in men than in women. The risk of developing squamous cell carcinoma of the skin is increased with advancing age and sun exposure. Squamous cell carcinomas are typically found in sun-exposed areas, most commonly on the head or neck. The appearance is typically an irregular growth with erythema, induration, inflammation, crusting, or oozing. Suspicious lesions should be referred to a dermatologist for biopsy.

Melanoma is less common, and accounts for only 4% to 5% of skin cancers. However, it is responsible for most deaths from cutaneous malignancies. Risk factors include fair skin, dysplastic nevi, multiple (>50) nevi, prior history of melanoma, family history of melanoma, immunocompromised state, or xeroderma pigmentosum (an inherited condition resulting in UV light sensitivity). Melanoma may occur in any area of the skin, though tends to appear more often on lower extremities in women, and on the head, neck, or trunk in men. The typical appearance is an asymmetric lesion with irregular pigmentation, border, and texture, and diameter greater than 6 mm or increasing in size. Suspicious lesions should be referred to a dermatologist for biopsy.

Kaposi sarcoma appears more often in patients with underlying immunosuppression. Clinically, it presents with painless, raised, brown-black or purple papules and nodules that do not blanch. Common sites are the face, chest, genitals, and oral cavity, but widespread

TABLE 107.5 Cutaneous Signs of Systemic Disease

Anatomic Site	Sign	Systemic Disease
Generalized	Urticaria	Drug reaction SLE Infection

dissemination involving internal organs may occur. Because cutaneous Kaposi sarcoma is not generally associated with morbidity or mortality, therapy is indicated only for extensive, painful, or cosmetically disfiguring lesions.

Although the ED does not provide definitive management for cutaneous malignancies, recognition of possible malignant lesions may facilitate prompt and expeditious referral for definitive management. Any lesion with irregular pigmentation, irregular borders or texture, easy bleeding, or recent change in lesion should be referred to a dermatologist.

SKIN CONDITIONS ASSOCIATED WITH SYSTEMIC DISEASE

Systemic illness should be considered with generalized dermatologic presentations. Systemic illness should be suspected in patients with systemic symptoms, such as fever, fatigue, weight loss or gain, weakness, immunosuppression, or other generalized symptoms. Systemic illnesses with cutaneous findings may include systemic infections, autoimmune or connective tissue disorders, malignancies, diabetes mellitus, endocrine disorders, or immunodeficiency states (Table 107.5).

Cutaneous lesions most directly indicative of an internal malignant disease arise from the extension of the tumor to the skin, or by hematogenous or lymphatic metastasis. The neoplasms that most commonly produce cutaneous extension are lymphomas, leukemias, and carcinomas of the breast, gastrointestinal tract, lung, ovary, prostate, uterus, or bladder. Skin metastases generally signify a poor prognosis.

Pruritus may be a sign of systemic disease, such as liver disease, renal disease, endocrine disorder, rheumatologic disorder, malignancy, or neurodegenerative disease.[78] Malignancies associated with pruritus include Hodgkin disease, leukemia, adenocarcinoma or squamous cell carcinoma of various organs, carcinoid syndrome, multiple myeloma, or polycythemia vera. Pruritis may be present years before the underlying malignant disease is identified. It may be intractable and associated with urticaria, erythroderma, excoriation, or lichenification.

Purpura may be a manifestation of acute granulocytic and monocytic leukemia, myeloma, lymphoma, or polycythemia vera. Purpura is caused by vascular abnormalities, thrombocytopenia, or other coagulation defects. A variety of diseases and conditions may be the underlying cause, and the treatment should be directed toward this cause

whenever possible. Thrombocytopenic and nonthrombocytopenic forms are differentiated by the platelet count.

Petechiae are manifestations of intradermal hemorrhage. Petechiae may be associated with thrombocytopenia, allergic reactions, endocarditis, Rocky Mountain spotted fever, viral hepatitis, infections, trauma, or malignancy (Fig. 107.44).[79]

Generalized erythroderma may indicate systemic condition, such as drug reaction, SSSS, erythema multiforme, toxic epidermal necrolysis, malignancy, exacerbation of underlying skin condition, or collagen vascular disorder.[80]

CHAPTER 107: QUESTIONS AND ANSWERS

1. Which of the following statements regarding tinea capitis is TRUE?
- **a.** It is contagious.
- **b.** It is not transmitted by household pets.
- **c.** Tinea capitis presents with alopecia with normal underlying scalp.
- **d.** Topical treatment is effective.
- **e.** Treatment should be instituted for 1 to 2 weeks.

Answer: a. Tinea capitis is the dermatophytosis that is contagious. Systemic treatment for 4 to 6 weeks is the minimum. It may be transmitted by pets. The underlying scalp is typically inflamed.

2. A 16-year-old boy presents with cellulitis of his left forearm. What is the appropriate initial antibiotic?
- **a.** Azithromycin
- **b.** Ceftriaxone
- **c.** Clindamycin
- **d.** Linezolid
- **e.** Penicillin VK

Answer: c. Clindamycin or trimethoprim-sulfamethoxazole are recommended first-line treatment choices for suspected methicillin-resistant *Streptococcus aureus* (MRSA) infection. Macrolides and penicillins are often ineffective against MRSA. Linezolid, although effective, is expensive and is generally not recommended as a first-line treatment.

3. What is the causative organism of erythema migrans?
- **a.** *Borrelia burgdorferi*
- **b.** Group A Streptococcus
- **c.** Methicillin-resistant *Staphylococcus aureus*
- **d.** *Neisseria meningitides*
- **e.** Parvovirus B-19

Answer: a. *Borrelia burgdorferi* is the causative agent of erythema migrans, or Lyme disease. Treatment should be instituted with doxycycline for 10 to 21 days, or as alternates, cefuroxime, ceftriaxone, or penicillin G. Group A *Streptococcus* is the causative organism of scarlet fever. *Neisseria meningitides* is the causative agent of Meningococcemia. *Parvovirus B-19* is the causative agent of erythema infectiosum.

CHAPTER 107: QUESTIONS AND ANSWERS—cont'd

4. A 26-year-old man presents with an erythematous maculopapular eruption of his torso, palms, and soles. He had a painless lesion on his penis 1 month earlier. What is the treatment of choice?
   a. Azithromycin
   b. Benzathine penicillin G
   c. Ceftriaxone
   d. Doxycycline
   e. Trimethoprim-sulfamethoxazole

Answer: b. Secondary syphilis is treated with benzathine penicillin G in a dose of 2.4 million units IM.

5. A 25-year-old female presents with fever, migratory polyarthralgias, and hemorrhagic papules on her fingers and wrists. What is the best treatment?
   a. Ceftriaxone
   b. Ciprofloxacin
   c. Doxycycline
   d. Ofloxacin
   e. Vancomycin

Answer: a. Treatment of disseminated gonococcal infection is with parenteral ceftriaxone, or ceftizoxime or cefotaxime. Patients allergic to β-lactam antibiotics or those with severe penicillin allergies may be treated with spectinomycin. Ciprofloxacin and ofloxacin are not recommended because of increasing resistance patterns. Hospitalization is recommended for patients with disseminated gonococcal infection.

6. Which of the following statements regarding gonococcal dermatitis is TRUE?
   a. Gonococci can usually be seen on gram stain from the lesions.
   b. It affects primarily men.
   c. It occurs in 1% or 2% of patients with gonorrhea.
   d. The lesions have a predilection for the knees and elbows.
   e. The skin lesions are not tender.

Answer: c. Women are affected primarily. The lesions have a predilection for distal joint skin. The lesions are often multiple and have a predilection for periarticular regions of the distal extremities. The lesions begin as erythematous or hemorrhagic papules that evolve into pustules and vesicles with an erythematous halo. They may be tender and may have a gray necrotic or hemorrhagic center. The organism may be cultured from the cutaneous lesions. Gram stain only occasionally reveals the organisms.

7. A 30-year-old man presents with headache, nausea and vomiting, myalgias, fever, and a petechial rash on his extremities and trunk. Lesions are clustered on the palms and soles. What is the best treatment?
   a. Cephalexin.
   b. Doxycycline.
   c. Erythromycin.
   d. Penicillin VK.
   e. Trimethoprim-sulfamethoxazole.

Answer: b. Patients with Rocky Mountain spotted fever present with headache, nausea and vomiting, myalgias, chills, and fever. The disease may last 3 weeks and may be severe with prominent involvement of the central nervous system, cardiac, pulmonary, gastrointestinal and renal systems, disseminated intravascular coagulation, or shock. The rash begins with erythematous macules that blanch on pressure, appearing first on the wrists and ankles. These macules spread up the extremities and to the trunk and face. They may become petechial or hemorrhagic. Lesions on the palms and soles are particularly characteristic. Doxycycline is the antibiotic of choice. Chloramphenicol may be used for patients allergic to tetracyclines and in children younger than 9 years of age. Sulfa drugs should be avoided because they may exacerbate the illness. Rickettsiae are routinely resistant to penicillins, cephalosporins, aminoglycosides, and erythromycin.

108

Blood and Blood Components

Christopher E. San Miguel and Colin G. Kaide

KEY CONCEPTS

- Red blood cell transfusion is indicated only to increase oxygen delivery at the tissue level.
- One unit of packed red blood cells (PRBCs) can be expected to raise an adult's hemoglobin level by 1 g/dL. A similar increase is expected in children following the transfusion of 10 mL/kg of PRBCs.
- Controlled trials have supported newer, restrictive, red cell transfusion strategies. Pending further trials, a transfusion trigger of a hemoglobin level below 7 to 8 g/dL is appropriate for most stable hospitalized patients.
- Platelet transfusions are typically used prophylactically for counts less than 10 K/μL in adults without bleeding. For patients undergoing central venous catheter placement, a level of 20 K/μL is recommended. Patients undergoing lumbar puncture and non-neuroaxial surgery should be prophylactically transfused to a level of 50 K/μL.
- Prospective and retrospective reports have suggested a benefit to massive transfusion protocols, with most advocating a 1 : 1 : 1 ratio of fresh frozen plasma (FFP) to platelets to PRBCs.
- When available, low-titer whole blood is safe and effective for transfusion and provides a physiologic mix of blood products.
- When available, prothrombin complex concentrate (PCC) should be given over FFP for reversal of vitamin K antagonism in the setting of a life-threatening bleeding. When PCC is not available, FFP can be used for this purpose, but is considered a second-line therapy.
- Transfusion reactions can vary from minor symptoms to fatal systemic reactions. If any transfusion reaction is suspected, the transfusion should be stopped while the cause and extent of the reaction is investigated.
- An intravascular hemolytic transfusion reaction is usually the result of ABO incompatibility and typically results in immediate symptoms that can include fever, chills, headache, nausea, vomiting, sensation of chest restriction, severe joint or low back pain, burning sensation at the site of the infusion, and feeling of impending doom. Treatment involves stopping the transfusion, fluid resuscitation, and monitoring for the development of renal failure and disseminated intravascular coagulation (DIC).
- Transfusion-related acute lung injury (TRALI) is now the leading cause of reported transfusion-related mortality. Treatment involves stopping the transfusion and providing supportive respiratory care, which may include noninvasive positive-pressure ventilation (NIPPV) or intubation and mechanical ventilation.
- Improved techniques for selecting and testing blood donors has dramatically reduced the risk of viral transmission of disease by transfusion.

FOUNDATIONS

Background and Importance

The modern blood transfusion era began with identification of the ABO red cell antigen system in the early 1900s. The subsequent discovery that adding citrate enabled the storage of anticoagulated blood led to the establishment of the first blood banks in the United States in the 1930s, and blood banking expanded rapidly after World War II. In subsequent decades, transfusion research focused primarily on critical issues such as developing component therapy, prolonging the storage life of blood products, and reducing the risk of transfusion reactions and transfusion-related infections. In 2015, approximately 11.4 million red blood cell units, 2.7 million plasma units, and 2 million platelet units were transfused in US acute care hospitals.[1]

Anatomy, Physiology, and Pathophysiology

Sound transfusion decision making is informed by a thorough working knowledge of the underlying physiology and pathophysiology, as well as familiarity with the key clinical trials that support up-to-date, evidence-based guidelines. This knowledge facilitates the effective ordering and interpretation of laboratory tests, delivery of blood products, and management of common or serious complications.

Blood Banking

Red blood cell (RBC) storage methods aim to ensure viability of at least 75% of the cells 24 hours after infusion. Blood collection bags contain an anticoagulant that ensures a shelf life of 35 days and a hematocrit of 70% to 80% for packed RBCs (PRBCs). Additive solutions provide additional nutrients and extend maximum storage to 42 days.

A number of biochemical and structural changes have been documented to occur during red cell storage, including loss of deformability, leakage of potassium, irreversible membrane changes, and biochemical alterations that have the potential to affect the ability of RBCs to unload oxygen in the microcirculation.[2] These changes worsen with increased storage duration and have been collectively referred to as the storage lesion. A number of observational studies and a few randomized prospective trials have reported conflicting results as to whether these changes are clinically relevant. The most recent four, large randomized trials have found no statistically significant difference in patient outcomes based on the age of the transfused blood product. Due to methodological limitations however, these results are not yet universally considered definitive.[3]

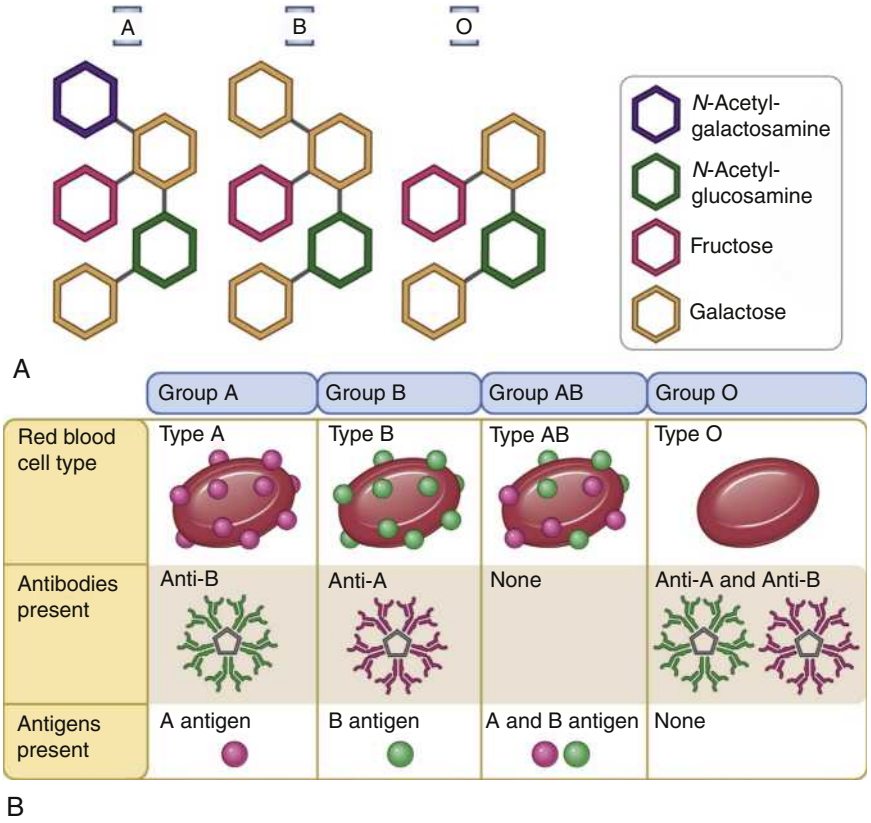

Fig. 108.1 Overview of red blood cell ABO grouping. (From: Abbas AK, Lichtman AH, Pillai S, eds. Transplantation immunology. In: *Cellular and Molecular Immunology*, 9th ed. Philadelphia: Elsevier; 2018.)

Blood Typing

Blood typing refers to the process by which blood is categorized by the antigens expressed on the red blood cells and the antibodies contained in the serum. There are currently over 30 known blood type systems, with the most important systems being the ABO and Rh systems. Kell, Duffy, and Kidd are examples of other blood type systems which generally have less of an impact on clinical practice.

Within the ABO system, there are type A and type B antigens. Red blood cells can express either, both, or neither of these antigens on their cell membranes. Throughout the first year of life, antibodies are formed against whichever antigens are not expressed on an individual's red blood cells. Type O blood, for instance, describes red blood cells that express neither type A nor type B antigens and thus is associated with anti-A and anti-B antibodies in the serum (Fig. 108.1). This seemingly spontaneous production of antibodies is theorized to be triggered by natural exposure to similar antigens in food, bacteria, or the environment and is unique to the ABO blood type system. Conversely, if type A, B, or both antigens are expressed on an individual's red blood cells (as is the case for type A, type B, and type AB blood respectively), the immune system recognizes these naturally occurring antigens as self-antigens and antibodies are not produced. Antibodies against antigens from other blood type systems can certainly be formed, but they generally require an exposure to red blood cells that express those antigens, for instance through blood transfusions or pregnancy. The "natural" production of ABO antibodies combined with the fact that ABO antigens and antibodies cause agglutination and hemolysis when mixed, means that patients can suffer from severe or even fatal transfusion reactions the first time they receive a PRBC transfusion from an ABO incompatible donor.

The second most clinically important blood type system is the Rh system. There are numerous known antigens in this system, but the D antigen is the most immunogenic. When a blood type is described as positive or negative (as in AB+), the report is referring to the presence or absence of the RhD antigen. Unlike in the ABO system, the mixing of Rh antigens and antibodies from a single transfusion is unlikely to result in a severe hemolytic reaction. This blood type system is most clinically relevant in the setting of pregnancy (or potential future pregnancies). If through a previous blood transfusion or pregnancy, an RhD negative mother has been exposed to RhD and subsequently developed anti-RhD antibodies, these antibodies can cross the placenta and into the fetal circulation. If the fetus is RhD positive, prolonged mixture of antigen and antibody can result in hemolytic disease of the newborn. Therefore, unstable hemorrhaging female patients who are not post-menopausal should receive O– blood, while male patients and postmenopausal female patients can receive O+ blood. Of note, hemolytic disease of the newborn is not seen with an ABO incompatible mother and fetus, as the vast majority of anti-ABO antibodies are IgM, which do not cross the placenta.

Type and Screen. An individual blood type and screen test includes ABO grouping, Rh typing, and antibody screen for unexpected, non-ABO/Rh antibodies. ABO grouping tests patient red cells with anti-A and anti-B serum and also with A and B red cells. Rh typing is accomplished by adding a commercial anti-D reagent to patient RBCs. To complete the antibody screen, the patient's serum is combined with commercially prepared mixtures of red cells expressing clinically significant antigens. The incidence of unexpected antibodies in the general population is low (<1%–2%), but a positive screen prompts further compatibility testing. In ideal circumstances, type-specific,

yet uncrossmatched, blood can generally be made available within 15 minutes of receiving a sample of the patient's blood.

Type and Crossmatch. When a unit of blood is ordered for transfusion, a crossmatch follows the initial type and screen. In an ideal situation, blood identical to the patient's own ABO and Rh group is utilized. Local blood supplies, however, might dictate that a nonidentical but compatible unit be used. Patients with blood group AB are known as universal recipients—they can receive packed red blood cells from any of the ABO groups, given their lack of anti-A and anti-B antibodies. Type O is commonly referred to as the universal donor of packed red blood cells, given the lack of A and B antigens.

A crossmatch procedure involves mixing the recipient's serum with donor RBCs and observing for agglutination as a final compatibility test before transfusion. If the antibody screen is negative, an abbreviated crossmatch at room temperature serves as a final check for ABO incompatibility. An antibody screen and abbreviated crossmatch requires at least 45 to 60 minutes to complete. If the antibody screen is positive, a complete crossmatch is generally required before transfusion. This requires the mixture of donor RBCs and recipient serum be incubated to 37°C (98.6°F) with the addition of antihuman globulin (Coombs reagent) to promote agglutination. Many blood banks also substitute a computer crossmatch for patients whose blood has been tested at least twice in their system. Complete crossmatch testing can take up to several hours, or even days, leading to delays in many urgent or emergent situations. If complete compatibility testing following a positive antibody screen would substantially delay transfusion of blood products to a critically ill patient, the emergency clinician may choose to bypass this step. Direct communication with the blood bank will facilitate determination of the best course of action.

Titer Testing for Whole Blood Donation. Although patients with type O blood are considered to be universal donors of packed red cells (PRBCs), whole blood from type O donors contains plasma and therefore may contain a concentration of anti-A and anti-B antibodies that can cause destruction of the recipient's type A or B RBCs. A strategy to mitigate this issue is either to transfuse only type-specific whole blood or to test donors or, more commonly, donor blood in advance to identify those with a "low titer" for anti-A and anti-B antibodies. Donors with a titer less than 256 saline dilution (immediate spin method) are designated low titer O universal whole blood (LTOWB) donors. A recent study showed LTOWB does not cause hemolysis when used in resuscitation of non–group O civilian trauma patients when up to 4 units are given.[4] LTOWB may be fresh (fresh whole blood, FWB) or stored (stored whole blood, SWB).

The use of LTOWB was standard practice in wartime settings for decades. In civilian practice in the United States, however, it has generally been unavailable and rarely used, comprising less than 1% of transfusions. More recently, interest in the use of whole blood has been growing, including the use of banked and fresh warm whole blood, despite the associated logistic hurdles.[5] In wartime settings, individuals designated as low-titer could be called upon to donate FWB acutely if needed. In the civilian setting, SWB is used on an as needed basis.

MANAGEMENT

Decision Making

Considerations in patient selection for blood product transfusion in the emergency care setting include the cause of the deficit, severity of symptoms, likelihood of ongoing hemorrhage, tissue oxygen requirements, and the patient's ability to compensate for decreased oxygen-carrying capacity. These considerations are influenced by the patient's age, underlying medical conditions, and hemodynamic stability. Clinical evaluation, including appearance (pallor, diaphoresis), mentation, heart rate, blood pressure, and nature of the bleeding (active, controlled, uncontrolled), as well as laboratory evaluation all inform transfusion decision making.

Pharmacology

PRBCs are administered through a filter and an intravenous (IV) line or intraosseous (IO) line, along with normal saline. No other in-line solutions should be utilized, unless approved for this purpose. For example, combining calcium containing fluids, such as lactated Ringers solution, with PRBCs can cause clotting in the line as the calcium binds with the citrate which is added to the PRBCs to act as an anticoagulant. Of note, this concern for clotting was mostly established in laboratory studies, and over the last 20 years there is anesthesiology literature that suggests that this clotting is not seen in clinical practice given the rapidity of administration and the PRBC to lactated Ringers ratios used. Nonetheless, no large study has demonstrated the safety of this practice, and therefore it is not routinely recommended. Dextrose containing fluids should also be avoided because the PRBCs may take up the dextrose, which causes osmotic shifts that can lead to cell lysis. Likewise, medications should not be added or pushed through the blood component transfusion line. There is growing literature demonstrating that some medications may be compatible with PRBC administration, and local guidelines or clinical pharmacist input is prudent if medication administration is necessary through the same line as a PRBC transfusion.

Devices and Techniques

Urgent or emergent transfusion requires flow rates faster than gravity can provide. An administration set with an in-line pump that is squeezed by hand is the simplest method to speed infusion. Pressure bags and rapid infusion devices are commercially available for clinical scenarios that require infusion of units of PRBCs within a matter a minutes. With high-pressure infusion, large-bore catheters are recommended so that hemolysis is prevented, however the literature supporting this recommendation is sparse.

Whole Blood

Reports on the successful use of FWB in military field hospitals have been published. In civilian practice in the United States, however, it has generally been unavailable and rarely used. The military experience with using whole blood dates back to World War I where type-specific, crossmatched blood was used in combat. This was almost 25 years before Rh typing was developed.[5] The use of citrate phosphate dextrose (CPD) or citrate phosphate double dextrose (CP2D) can allow for safe preservation of SWB for 21 days at 1°C to 6°C. The use of citrate phosphate dextrose adenine (CPDA-1) at 1°C to 6°C can increase storage time to 35 days. Owing to time dependent degradation of clotting factors and platelets, whole blood older than 2 weeks may require the addition of fresher whole blood or supplemental platelets to avoid contributing to coagulopathy.[5]

When PRBCs, plasma, and platelet transfusions in the 1 : 1 : 1 ratio are used, the mixture is significantly more diluted than when SWB is transfused. Average hematocrit and platelet count in 1 : 1 : 1 mixtures were 29% and 90 K/μl, respectively, when compared to 35% to 38% and 150 to 200 K/μl with SWB. Coagulation factors were also higher in SWB transfusions.

Current studies show that the use of SWB results in outcomes at least as good as component (RBC + plasma + platelet) therapy in hemorrhaging patients. We recommend the use of whole blood when available. Although the shelf-life of whole blood is shorter than component therapy, it can still be cost-effective owing to the higher cost of separating blood into components. The argument for using SWB early in the resuscitation process can be summarized as follows:[4,6-9]

- SWB provides a physiologic balance of blood components that are simultaneously transfused.
- A smaller volume of anticoagulant/preservative solution is transfused with SWB.
- Platelet function in SWB may be significantly enhanced compared to component therapy.
- Higher levels of hemostatic factors are delivered with SWB.
- Fibrinogen delivery is higher when utilizing SWB, as FFP does not deliver significant amounts of fibrinogen.
- Hemolytic transfusion reaction rate in SWB is low (about 1 : 120,000), therefore transfusions are generally safe and confer fewer donor exposures compared with component therapy, such as 1 : 1 : 1 protocols.
- Administration of all components together in one unit can improve the time to complete a transfusion.
- Errors associated with transfusion of type-specific blood can be minimized.

One potential complication from the lack of Rh typing in LTOWB, is the possibility of isoimmunization causing hemolytic disease of the newborn. Premenopausal women who receive LTOWB are potential candidates for anti-D immunoglobulin (Rhogam) and consultation with obstetrics.[9]

Autotransfusion may also be used in the emergency setting in the event of severe chest trauma. A large retrospective trial showed it to be both safe and effective. Autotransfusion is the process of giving a patient back his or her own blood that has been collected from an uncontaminated active bleeding site. This is most frequently done using blood from the thorax after trauma. This strategy has numerous advantages—immediate availability, blood compatibility, elimination of donor to patient disease transmission, lower risk of circulatory overload, and fewer direct complications related to the transfusion itself, such as hyperkalemia, hypothermia, hypocalcemia, or metabolic acidosis. It is also more acceptable to patients whose religious convictions prohibit non-autologous transfusions. It is impractical in some settings owing to a relatively limited number of appropriate trauma patients, specific training required to operate the equipment, and time required for equipment setup.

Packed Red Blood Cells

PRBCs are indicated only to improve oxygen delivery to tissues at the microvascular level and thus improve intracellular oxygen consumption, yet definitive demonstration of the efficacy of red cells for this purpose (or improved clinical outcomes) has proven elusive. A definitive randomized prospective study in which RBCs are withheld completely from one treatment group is unlikely to be conducted given ethical considerations.

In 2016, the AABB (formerly, the American Association of Blood Banks), published a clinical practice guideline regarding red blood cell transfusion after reviewing trials published between 1950 and May 2016. This review found strong support for using a restrictive transfusion strategy and a hemoglobin treatment threshold of 7 g/dL for most stable hospitalized patients. In those patients undergoing orthopedic surgery, cardiac surgery, or with preexisting cardiovascular disease, they recommend a hemoglobin treatment threshold of 8 g/dL. Of note, these recommendations are less universal to patients with a history of acute coronary syndrome, severe thrombocytopenia, or chronic transfusion–dependent anemia.[10]

For many patients, the decision to transfuse RBCs requires clinical judgment. The appropriate trigger for patients with active hemorrhage, for example, is not well-established, despite numerous trials.[11] With increasing support for permissive hypotension treatment strategies, clinicians must balance adequate tissue perfusion and hemostasis. We recommend transfusion with ongoing signs of inadequate perfusion, such as elevated serum lactate level, altered mental status, or decreased urinary output. Transfusions may be stopped once a patient has a stable blood pressure, even if hypotensive, combined with signs of adequate perfusion without overt ongoing hemorrhage. Of note, the hemoglobin level in acute hemorrhage can be misleading and should not exclusively be used to guide acute management. Because the hemoglobin level is a concentration, and individuals bleed whole blood and not just red cells, it takes time for fluid to shift into the intravascular space and cause the hemoglobin level to drop. Unfortunately, the amount of time required for this equilibration to occur has not been clearly established. A recent study of trauma patients demonstrated that a hemoglobin level of 11.8 g/dL or below on arrival to the hospital was only 88% sensitive for predicting significant hemorrhage.[12]

Special Preparations of PRBCs

Washed RBCs. PRBCs can be washed to remove residual plasma and any remaining leukocytes, platelets, microaggregates, plasma proteins, and free hemoglobin. Washing reduces the titer of anti-A and anti-B antibodies, thereby permitting safer transfusion of type O PRBCs into non–type O recipients. Washed cells are used in patients who have had recurrent allergic reactions to transfusion, as most of these reactions are a response to donor proteins in the plasma. Patients with IGA deficiency from circulating anti-IGA antibodies can react to IGA in the donor plasma and may also benefit from washed cells. Washing takes about an hour and reduces the viability of the unit to 24 hours.

Leukocyte-Reduced RBCs. A typical unit of whole blood or packed red cells can contain from 1 to 3 billion white blood cells (WBC), which can cause a variety of problems in the recipient including febrile (non-hemolytic) reactions, immune sensitization, or transmission of disease. Non-leukocyte-reduced products can be a major source of viral transmission, including human T-lymphotropic virus 1 and 2, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). Additionally, increased rates of bacterial contamination and postoperative or vascular line infections have been associated with the use of non-leukocyte-reduced products.

By passing the blood through a leukocyte filter, the number of WBCs can be reduced by 99.99%. This can lead to a significant reduction in complications in vulnerable populations. Leukoreduction is not effective enough, however, to prevent transfusion-associated graft-versus-host disease (TA-GvHD), thus blood transfused to susceptible patients must be irradiated. Leukocyte-reduced red cell products are now used for more than 95% of patients in the United States.

Irradiated RBCs. Blood products can be irradiated to reduce the risk for TA-GvHD in susceptible patients, which occurs in about 1 per 1 million transfusions but is associated with 90% mortality.[13] Irradiation can be performed either directly before transfusion on an individual unit or batches of irradiated PRBCs may be maintained in locations for use in the care of immunosuppressed patients. Irradiation destroys donor lymphocytes. This prevents WBCs in donor blood from recognizing the host's cells as foreign and attacking them, potentially leading to severe illness or death. Susceptible patients are those who are unable to mount an immune response to the donor lymphocytes. Although there is some variation in the literature as to who should receive irradiated PRBCs, generally the categories center on those who are immunocompromised or who have a close human leukocyte antigen (HLA) match to the donor, as occurs in the case of a directed donation. The latter group may not be able to recognize the donor cells as foreign. As a result of irradiation, post-transfusion red cell recovery is decreased and the rate of intracellular potassium release increases. PRBCs irradiated within 14 days of collection expire 28 days after

TABLE 108.1 Indications for Special Preparations of PRBCs

Special Preparation	Process	Use
Irradiated PRBCs	Irradiation of the donor blood destroys WBCs thereby decreasing the risk of transfusion-associated graft-versus-host disease.	• Neonatal or intrauterine transfusion • Hematologic malignancy • Stem cell transplant patients or donors within a week prior to cell harvesting • Hodgkin lymphoma • Directed donations from family members (biological) • Congenital cellular immune deficiency • Transfusions from HLA-matched donors • Patients treated with antithymocyte globulin or chemotherapy with purine analogs (e.g., fludarabine, bendamustine, etc.)
Washed PRBCs[14]	PRBCs are washed with saline to remove residual plasma and protein. Reduces allergic reactions to foreign proteins.	• History of severe allergic transfusion reactions • IgA-deficiency • Paroxysmal nocturnal hemoglobinuria
Leukocyte Reduced PRBCs	PRBCs are filtered to remove 99.99% of the leukocytes	• Patients undergoing chemotherapy • Multiparous females • Patients receiving multiple transfusions
CMV Negative PRBCs[15]	CMV testing is performed on units of PRBCs	• Seronegative patients who are currently pregnant • Fetal or intrauterine transfusion • Solid organ, stem cell, or bone marrow transplant recipients who are CMV negative

collection, and PRBCs irradiated more than 14 days after collection expire either 5 days after irradiation or at the original expiration date, whichever comes first.

CMV Negative Blood. Because CMV is endemic worldwide and seropositivity rates in the United States are reported at 30% to 97%, most donated blood is CMV positive. Even after an acute infection with CMV is cleared, it remains present in leukocytes. CMV testing can identify units of PRBCs that are free of the virus and safe to transfuse in at-risk populations. Leukocyte-reduced PRBCs are typically an acceptable alternative if CMV negative products are not available. Indications for CMV negative PRBCs and other special preparations are summarized in Table 108.1.

Fresh Frozen Plasma

A unit of fresh frozen plasma (FFP) contains all the clotting factors and typically has a volume of 200 to 250 mL. It must be ABO compatible and is administered through blood tubing. Triggers for FFP are not clearly defined; indications for FFP are based primarily on observational trials and expert opinion. The following indications seem reasonable based on current evidence: massive hemorrhage, as a component of a plasma exchange procedure, emergency reversal of a vitamin K antagonist in the presence of clinically significant hemorrhage or in the treatment of ace inhibitor–induced angioedema. It is worth noting, however, that the therapeutic effect is difficult to predict, and the international normalized ratio (INR) level of FFP itself is around 1.5, thus FFP can't lower an INR level below 1.5. A large volume of FFP is needed to reverse coagulopathy caused by vitamin K antagonism (at least 10 mL/kg, and perhaps as much as 30 mL/kg), which can place patients at risk for volume overload. This, in part, justifies the recommendation for prothrombin complex concentrate (PCC) over FFP when available for reversal of vitamin K antagonism in the setting of life-threatening bleeding.

Evidence from retrospective trials has supported increased use of FFP in patients anticipated to require more than 10 units of PRBCs (massive transfusion). This should not be generalized to all patients receiving a transfusion, however, as limited benefit and increased complications have been observed in patients with mild or moderate active blood loss who receive FFP.

Likewise, limited available evidence has failed to support the use of FFP in patients with an elevated INR before invasive procedures such as central line placement or lumbar puncture. The INR level itself often proves to be a poor predictor of risk for clinical bleeding. If a specific factor deficiency is identified, as in hemophilia, targeted factor replacement, if available, is preferred over FFP.

The use of FFP has also recently been described in the treatment of ace inhibitor–induced angioedema, as FFP contains c1-inhibitor and kininase II enzymes. Case reports and series suggest that the administration of 2 units of FFP may lead to significant reduction of edema within 2 to 4 hours.[16]

Platelets

The decision to transfuse platelets is multifactorial. The underlying cause of the thrombocytopenia and the age of the patient are just two factors that greatly affect transfusion recommendations. In 2015, the AABB published a clinical practice guideline concerning the general transfusion of platelets. They recommended, in most cases, transfusing adults below 10 K/μL given the risk of spontaneous hemorrhage. For patients undergoing central venous catheter placement, consideration of transfusion is recommended below 20 K/μL. Patients undergoing lumbar puncture and non-neuroaxial surgery should be considered for transfusion below 50 K/μL.[17]

Other than in the setting of massive transfusion, pediatric platelet transfusion should be discussed with a hematologist. Children with immune thrombocytopenic purpura (ITP) and no signs of active bleeding can often be managed without transfusion, even at levels below 10 K/μL.[18] If thrombotic thrombocytopenic purpura (TTP) is suspected as the cause of thrombocytopenia, platelet transfusion should be avoided. Platelet transfusion in this case may serve to exacerbate the underlying problem by adding platelet substrate for unbalanced thrombotic reactions within the vasculature. Administration of platelets in TTP is associated with increased arterial thrombosis and mortality.[19] Similarly, platelet administration is not routinely

recommended in heparin-induced thrombocytopenia (HIT), though it may be beneficial in patients with significant active bleeding.[20]

Crossmatching is generally unnecessary for platelet transfusions, but Rh-negative, premenopausal women should be transfused with Rh-negative platelets because there may be enough red cells in the platelet concentrate to cause Rh sensitization. The use of leukocyte-reduced platelets has been shown to reduce the risk of HLA sensitization and is therefore beneficial in patients receiving frequent platelet transfusions. Once sensitization has occurred and patients have developed immune-mediated platelet refractoriness, various management strategies may be considered in consultation with a hematologist, including HLA-based donor selection or platelet crossmatching.

Cryoprecipitate

Cryoprecipitate is prepared from single-donor plasma by gradually thawing rapidly frozen plasma. The result of this process is the precipitation of fibrinogen, factor VIII, factor XIII, von Willebrand factor, and fibronectin. Per AABB standards, each unit (5–20 ml) of cryoprecipitate should contain at least 150 mg of fibrinogen and 80 IU of factor VIII. Because cryoprecipitate is a plasma product, ABO compatibility is necessary. Like FFP, cryoprecipitate has similar risks for both allergic and febrile reactions. It has also been associated with the development of TRALI.

Cryoprecipitate is indicated for patients with fibrinogen deficiency, congenital afibrinogenemia, or dysfibrinogenemia. Clinically, low fibrinogen levels are most often encountered in the setting of massive hemorrhage and DIC. Although not recommended as a primary treatment, cryoprecipitate can also be given to patients with hemophilia A or von Willebrand disease when recombinant factor VIII preparations are not readily available. As cryoprecipitate does not contain factor IX, it is of no value in the treatment of factor IX deficiency (hemophilia B).

Prothrombin Complex Concentrate

Both three- and four-factor PCC products are now FDA-approved in the United States, with four-factor products containing all the vitamin K–dependent clotting factors (factor II, VII, IX, and X), whereas three-factor products lack any significant amounts of factor VII. Guidelines published by the American College of Chest Physicians recommend that PCC be used for the reversal of an elevated INR level in patients with life-threatening bleeding or intracranial hemorrhage, and available evidence has shown that a more rapid normalization of the INR in these patients occurs with the administration of PCC rather than FFP. Studies comparing three- and four-factor PCCs in patients with serious warfarin-associated bleeding have found that the four-factor product is more reliable in reducing the INR to below 1.5 within 1 hour, and we recommend its use, when available.[21,22]

OUTCOMES

Safety and Effectiveness

In an average adult, 1 unit (≈450 mL) of PRBCs increases the hemoglobin level by about 1 g/dL or the hematocrit by about 3%. A similar increase in pediatric patients is observed with administration of 10 mL/kg of PRBCs. Most transfusions are given over 60 to 90 minutes. Owing to an increased risk of bacterial growth when PRBCs are exposed to room temperature, transfusion of a single unit should not last longer than 4 hours. Unused blood should be returned promptly to the blood bank. Any units unrefrigerated for more than 30 minutes should be discarded.

One unit of activity for any coagulation factor is equal to the clotting activity found in 1 mL of FFP. Appropriate dosing of FFP has not been well grounded in evidence from clinical trials. In massive transfusion, many centers now incorporate FFP in proportion with red cells and platelets. For other indications, it seems reasonable to start with an infusion of 10 to 30 mL/kg, recognizing that results will be variable and follow-up laboratory and clinical assessment is necessary to guide further management.

Platelets are often given to adults in a dose of 6 units of platelet concentrate ("six-pack" of platelets) and in children at a dose of 1 unit per 10 kg of body weight, an amount expected to raise the platelet count by about 40 to 60 K/μl in adults or children. Administering additional platelets does not generally improve hemorrhage outcomes.[17] The AABB recommends giving either a six-pack or three-pack of platelets. Alternatively, a single apheresis unit (derived from a single donor) provides roughly the same amount of platelets as a six-pack. The advantage of apheresis platelets is that they expose the recipient to the plasma proteins of only one donor as opposed to 6 donors in a pooled unit. This, in turn, decreases the risk of allergic reactions.

Cryoprecipitate is used to correct significant hypofibrinogenemia (<100 mg/dL). A typical adult dose of around 10 bags of cryoprecipitate raises the fibrinogen level by up to 1 g/L (100 mg/dL). Cryoprecipitate can also be used in cases of post-tPA (tissue plasminogen activator) bleeding. A consensus on dosing has not been reached, though many sources recommend between 10 and 12 bags.[23]

PCC dosing is based upon the concentration of factor IX, which varies between different specific formulations. Some products also have variable dosing based upon the pretreatment INR. Consequently, emergency clinicians should consult their local protocols and pharmacists to ensure proper dosing of PCC. We also recommend that all patients with life-threatening warfarin-associated hemorrhage also receive 10 mg of vitamin K by slow IV infusion, administered at 1 mg/min or slower.

Massive Transfusion Protocols

Massive transfusion was traditionally defined as the administration of more than 10 units of PRBCs over 24 hours, but a more practical and efficacious application of the concept is the transfusion of 3 units of PRBCs over an hour or the use of 4 components over 30 minutes. The concept of utilizing a massive transfusion protocol (MTP) that called for the use of plasma and platelets along with PRBCs was born from the understanding that acute blood loss involves more than just the loss of red cells. Physiologically it makes sense to replace all components of blood after more than a few units of PRBCs have been transfused. Although protocols for MTP are variable and often predicated on institutional protocol, most now use a ratio of 1 : 1 : 1 (PRBCs : FFP : platelets) when transfusion needs exceed 3 units of PRBCs. When large and ongoing blood loss is anticipated, the initiation of a MTP should be considered.

A systematic review concluded that the available evidence could not support any definite recommendations regarding specific ratios of blood components in massive transfusion.[24] A large, multicenter randomized clinical trial compared the use in massively transfused trauma patients of a 2 : 1 : 1 ratio (PRBCs : FFP : platelets) with a 1 : 1 : 1 ratio and found no difference in mortality at 24 hours or 30 days, although fewer patients in the 1 : 1 : 1 group died of exsanguination at 24 hours.[25] Until evidence supports otherwise, we recommend a 1 : 1 : 1 ratio of blood products when a MTP is initiated.

The use of thromboelastography (TEG) or rotational thromboelastometry (ROTEM) has been studied as a way to better predict which blood components may be helpful in normalizing coagulation. While TEG/ROTEM does alter transfusion patterns, a 2015 systematic review was unable to show that TEG/ROTEM was superior to standard coagulation studies, such as prothrombin time ratio and/or the INR.[26] A subsequent study in trauma patients compared goal-directed transfusion

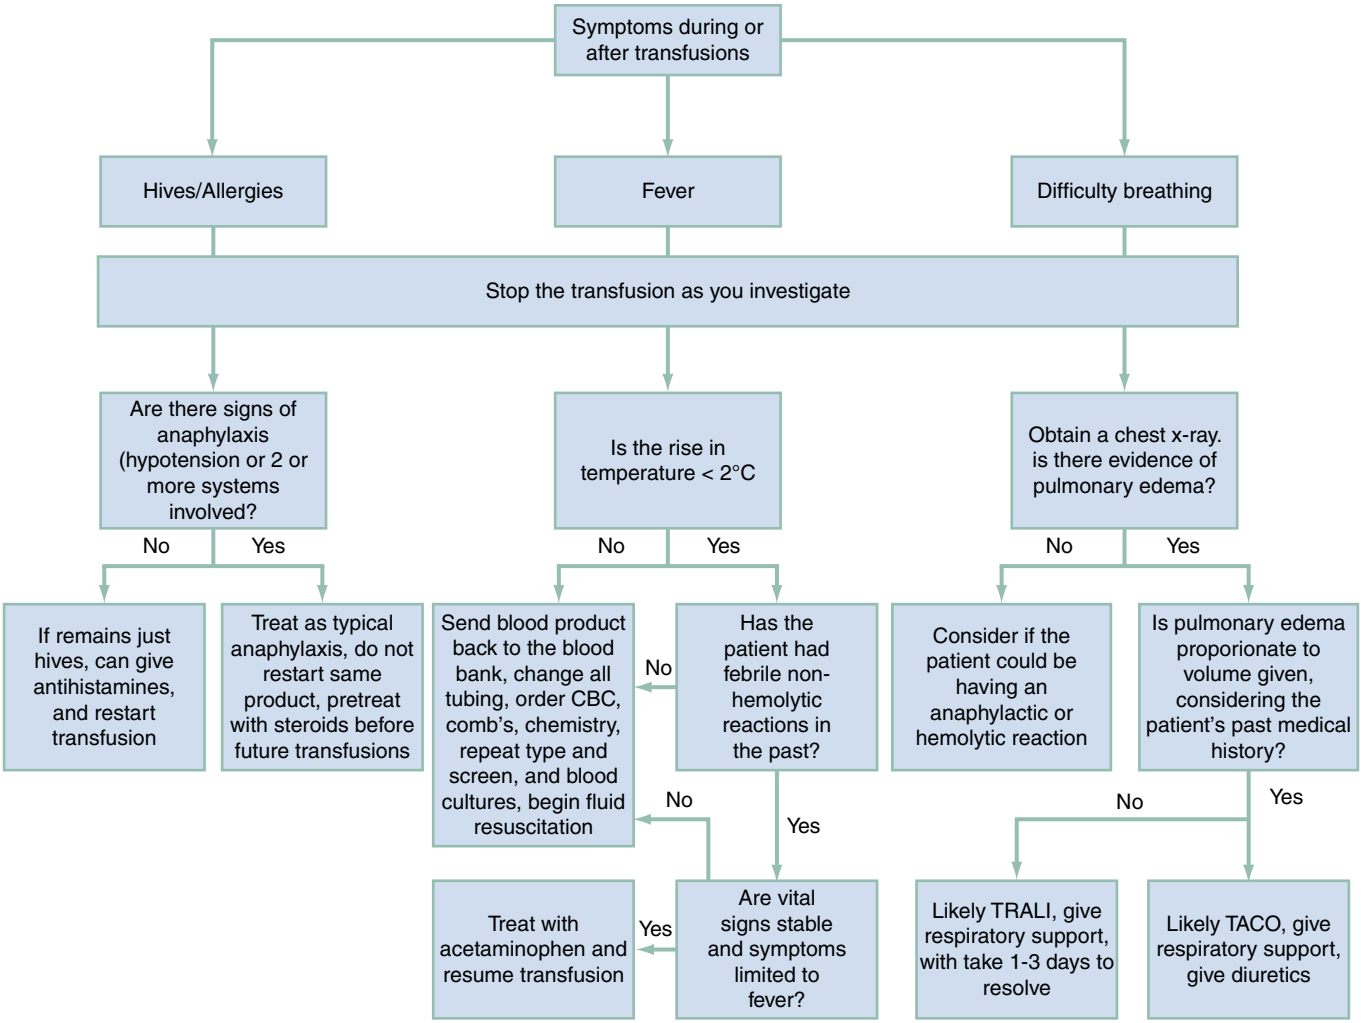

Fig. 108.2 Algorithm for treatment of transfusion reactions.

based on TEG to transfusion based on conventional coagulation parameters. In this study, the risk of death was higher in the conventional coagulation group.[27] While promising, further study is needed to clarify the role of routine TEG/ROTEM in trauma care.

Complications of massive transfusion are well-understood and many can be managed anticipatorily. Hypothermia is common and can reduce clotting factor activity. Warmed IV fluids, blood warmers, and warming lights or blankets are often needed. Frequent laboratory testing will identify electrolyte disturbances, including low magnesium and calcium levels and low or high potassium levels, which are generally treated in a standard fashion. Acidosis is a common finding with massive hemorrhage and can also be caused by hypoperfusion with or without contributions from transfused blood. Citrate from banked blood is metabolized in the liver to bicarbonate, which can result in metabolic alkalosis at times. With rapid infusion or reduced hepatic function, however, this pathway can be overwhelmed and the net effect of infusing large amounts of citrate can be worsening metabolic acidosis. A rational response to metabolic acidosis is to optimize oxygen delivery and ventilation. The benefit of administering sodium bicarbonate in this setting remains unproven and, as such, is not routinely recommended.

Complications and Adverse Effects of Nonmassive RBC Transfusion

Transfusion reactions are complications developing during or after transfusion of whole blood or individual blood components. Reactions can range from mild to life-threatening, with most acute reactions classified as mild and with upwards of 90% occurring rapidly after transfusion initiation. Delayed reactions tend to occur days to weeks after the transfusion is completed. See Figure 108.2 for a generalized and algorithmic approach to managing transfusion reactions.

Acute Transfusion Reactions

Minor Allergic. The most common manifestation of a minor allergic transfusion reaction is urticaria. In some cases, however, wheezing and angioedema can also be observed. Minor allergic reactions develop in 1% to 3% of transfusions and are generally attributed to an allergic, antibody-mediated response to donor plasma proteins. If a patient develops allergy symptoms, the transfusion should be stopped. The reaction can be treated like any other allergic reactions using antihistamines and steroids. If the reaction remains mild and is limited to the skin, the transfusion can be resumed after symptomatic treatment.

Anaphylactic. The reported incidence of transfusion-associated anaphylaxis is 1 in 20,000 to 50,000 transfusions, with most cases being idiopathic in nature. There are case reports of patients with IgA deficiency and anti-IgA antibodies developing anaphylactic reactions to IgA in donor blood, but this is not generalizable to most cases of transfusion-related anaphylaxis.

The presentation is similar to anaphylactic reactions from other causes and may include hypotension, angioedema, dyspnea,

bronchospasm, or laryngospasm. The symptoms are typically rapid in onset and begin within seconds to minutes of transfusion initiation. The transfusion should be stopped immediately, with symptoms treated in the same way as other forms of anaphylaxis. If a transfusion is still required, pretreatment with steroids and antihistamines 30 to 60 minutes before the transfusion is prudent, and the patient should be given a new transfusion product, rather than restarting the original product. In addition, transfusion of washed cellular products may further decrease risk.

Febrile (Nonhemolytic) Transfusion Reaction. A febrile, nonhemolytic transfusion reaction (FNHTR) is defined as a temperature elevation of 1°C (1.8°F) or higher that occurs with transfusion and for which no other medical explanation is identified. It is often associated with rigors and chills. Reactions are believed to result from both recipient anti-leukocyte antibodies that react with donor WBCs and from cytokines released during a storage lesion (damage to and loss of some RBCs over time during storage) of the transfused unit, the latter of which increases with the duration of blood storage.[28] The use of leuko-reduction has been shown to decrease the risk of FNHTR by around 50% for RBCs and up to 93% for platelets.

If a febrile reaction occurs in a first-time transfusion, it should be treated as an acute hemolytic reaction until proven otherwise. Similarly, any vital sign instability, rise in temperature greater than 2°C, or symptoms other than fever and chills should prompt the reaction to be treated as an acute hemolytic reaction, regardless of a history of FNHTR. The transfusion should be stopped, and testing should be done to prove the reaction is non-hemolytic (see the next section for details). When a hemolytic reaction is ruled out and the event is considered to be a simple FNHTR, treatment with acetaminophen is appropriate and the unit in question should be discarded with a fresh unit transfused in its place. Many institutions routinely utilize leukocyte-reduced blood, however if this is not the case, leukocyte-reduced blood may decrease the likelihood of a recurrent reaction. If the original unit was already leukocyte-reduced, switching to a different unit may also decrease the chance of another reaction.

Pretreatment, or treatment for symptoms, with antipyretics is appropriate for patients with recurrent reactions. If a patient has a history of FNHTR, no vital sign instability, no symptoms other than fever and chills, and the rise in temperature is less than 2°C, the transfusion may be continued as normal. Antihistamines are usually not helpful in either treatment or prophylaxis for FNHTR. Patients with severe chills and rigors may also benefit from other analgesics in addition to acetaminophen, such as ibuprofen or an opiate medication. The now infrequently used opiate pain medication meperidine has been recommended for the prevention and treatment of rigors at the dose of 0.5 to 0.75 mg/kg over 4 minutes. When meperidine is not available, other opiates such as hydromorphone (0.015 mg/kg IV) or fentanyl (0.5 to 0.75 mcg/kg IV) can be used.

Acute Hemolytic Transfusion Reaction. Intravascular hemolytic transfusion reaction is the most serious transfusion reaction. It generally results from ABO incompatibility, usually caused by a clerical or laboratory error. The incidence of acute hemolytic transfusion reactions ranges from 2 to 8 per 100,000 units transfused with a fatality rate of 1 per 100,000 units transfused. When incompatible blood is given, the impact may range widely from asymptomatic to death. While mortality from hemolytic reactions increases in proportion to the amount of blood transfused, as little as 30 ml can be fatal.

In an ABO incompatibility, the recipient's serum has preformed antibodies directed against the donor RBCs. The donor cells will begin to hemolyze within seconds or minutes. In most cases, donor blood is agglutinated (clumped and stuck together) and then hemolyzed. Vasoactive substances released by responding macrophages may cause fever, chills, hypotension, and shock.

BOX 108.1 Laboratory Abnormalities in Acute Hemolytic Transfusion Reactions

- Decrease in hemoglobin or hematocrit
- Hemoglobinemia
- Hemoglobinuria
- Increased serum lactate dehydrogenase (LDH)
- Increased serum indirect bilirubin
- Decreased serum haptoglobin
- Evidence of DIC, including: prolonged PT, PTT, decreased fibrinogen level, increased D-dimer
- Schistocytes or spherocytes on peripheral smear

BOX 108.2 The National Healthcare Safety Network Hemovigilance Surveillance Protocol Definition of TRALI

- No evidence of acute lung injury before transfusion, AND
- Acute lung injury onset during or within 6 hours of cessation of transfusion, AND
- Hypoxemia defined as either Pa_{O_2}/Fi_{O_2} less than or equal to 300 mm Hg or oxygen saturation less than 90% on room air, AND
- Radiographic evidence of bilateral infiltrates, AND
- No evidence of left atrial hypertension (i.e., circulatory overload).

(Adapted from Centers for Disease Control and Prevention (CDC). National Healthcare Safety Network Biovigilance Component Hemovigilance Module Surveillance Protocol. Available at: https://www.cdc.gov/nhsn/pdfs/biovigilance/bv-hv-protocol-current.pdf. Accessed May 10 2021.)

The onset of symptoms is usually immediate but can take up to 24 hours to fully manifest. Fevers and rigors are an early indication of an AHTR. Patients may also complain of headache, nausea, vomiting, sensation of chest restriction, severe joint or low back pain, burning sensation at the site of the infusion, or a feeling of impending doom.

Treatment includes immediate cessation of the transfusion, replacement of all blood administration tubing, and initiation of vigorous crystalloid fluid therapy. The use of vasopressors or diuretics may also be considered in order to maintain a urine output of 1 to 2 mL/kg/hr. Blood and urine specimens, as well as the remainder of the transfusion and blood tubing, should be sent for laboratory testing. The diagnosis can be confirmed by detection of free hemoglobin in blood or urine and a positive result of Coombs test on posttransfusion, but not pretransfusion, specimens. See Box 108.1 for associated laboratory abnormalities in AHTR.

Recipient blood should be sent for a direct antiglobulin test (DAT), plasma-free hemoglobin level, CBC, chemistry, haptoglobin, LDH, bilirubin, PT/PTT, D-dimer, fibrinogen, and a repeat type and crossmatch. Urine should be tested for free hemoglobin. In cases of severe intravascular hemolysis, the urine and/or plasma can become pink or dark brown in color from the free hemoglobin. Dialysis is occasionally required for either severe hyperkalemia as a direct result of the hemolysis or renal failure as a result of DIC.

Transfusion-Related Acute Lung Injury. TRALI refers to noncardiogenic pulmonary edema occurring during or shortly after the transfusion of virtually any blood products. See Box 108.2 for the definition and diagnostic criteria of TRALI. Although TRALI has been traditionally associated more with platelet and plasma transfusion, the increased use of PRBCs relative to other components seems to have

TABLE 108.2 Acute Transfusion Reactions

Condition	Notes	Clinical Findings	Laboratory Findings
TACO	Proportional to volume transfused. Onset 6–12 hours after transfusion started.	Evidence of volume overload with dyspnea, edema, rales, tachycardia, hypertension	Elevated BNP level, pulmonary edema on chest x-ray
TRALI	Not associated with volume of transfusion	Hypotension, fever, hypoxia	pulmonary edema on chest x-ray
Anaphylaxis	Not associated with volume of transfusion	Hypotension, tachycardia, urticaria, wheezing	None specific
Hemolysis	Not necessarily associated with volume transfused though generally worse with increased amounts of incompatible blood	Fever, chills, hypotension, bleeding (DIC), back pain, discoloration of urine	Evidence of hemolysis (increased LDH, decreased haptoglobin, schistocytes) Evidence of DIC (prolonged PT/PTT, low platelets, decreased fibrinogen, elevated D-dimer, schistocytes)
FNHTR	Associated with fever	Fever	None specific, lack of evidence of hemolysis

TACO, Transfusion-associated circulatory overload; *TRALI*, transfusion-related acute lung injury; *FNHTR*, febrile non-hemolytic transfusion reaction; *DIC*, disseminated intravascular coagulation.

balanced the risk as similar across different blood products. Owing to strategies designed to mitigate TRALI, the incidence has decreased significantly in recent years. Nonfatal TRALI occurs in about 1 in 60,000 transfusions, but it still accounts for 29% of transfusion-related deaths.

A proposed mechanism for the development of TRALI includes a reaction between transfused antibodies and leukocytes in the recipient, as well as the effects of biologically active factors that accumulate in stored blood, including cytokines and lipids. Another proposed mechanism involves the alloimmunization of plasma from female donors. During a prior pregnancy the donor may have produced IgG antibodies against the paternally inherited antigens in the fetus. These antibodies can persist and be transfused into the recipient contributing to the TRALI reaction. This issue seems to become relevant when high-volume plasma transfusion is used. The ultimate effect is an increase in pulmonary capillary permeability leading to leakage of high protein fluid into the alveoli. Clinical effects can include noncardiogenic pulmonary edema, with dyspnea, hypoxemia, or bilateral infiltrates on the chest radiograph. Fever, hypotension, and transient leukopenia may also be seen.

If TRALI is suspected, the transfusion should be stopped, and the blood bank notified. Respiratory support should be provided, which may include noninvasive positive-pressure ventilation (NIPPV) or intubation and mechanical ventilation. It is safe to continue transfusion of blood products from a different donor. Complete resolution is usually seen within 48 to 96 hours. The overall prognosis is better than would be expected with many other causes of acute lung injury, with a reported mortality rate of 6% in one series. One strategy suggested for reducing TRALI has been to use only male donors for plasma to avoid allotypic leukocyte antibodies or to screen for these antibodies and exclude donors when the antibodies are found.

Transfusion Associated Circulatory Overload. Transfusion associated circulatory overload (TACO) is volume overload after transfusion that is proportional to the volume transfused. Smaller volume transfusions, such as cryoprecipitate, are less likely to produce an overload state than FFP or PRBCs. Risk factors for developing TACO include preexisting heart disease (e.g., CHF), significant renal insufficiency, and extremes of age. A recent animal model suggested a two-hit hypothesis for the development of TACO. The first hit is volume incompliance and the second hit is the composition of the fluid given (PRBCs versus crystalloid solutions). A preexisting volume incompliance (myocardial infarction [MI] or acute kidney injury) confers a significant and clinically relevant difference in left ventricular end-diastolic pressure (LVEDP), heart rate, and blood pressure in animals receiving PRBCs (the second hit) as opposed to equal volumes of lactated Ringers solution. This difference was not noted in animals without the first hit in whom equal volumes of PRBCs and lactated Ringers solution were given.[30] This appears to explain similar findings in humans with heart and kidney disease.

TACO appears to develop in about 1% of transfused patients, however this number may underestimate the true incidence since many cases spontaneously resolve with diuresis.[31] There is no specific test or single criteria to definitively diagnose TACO. It should be considered in patients who develop shortness of breath, hypertension, tachycardia, and other signs of volume overload. It is also important to distinguish TACO from immune-mediated conditions such as TRALI, allergic reactions or other conditions causing shortness of breath (e.g., pulmonary embolism, MI). Some clinical clues to help differentiate TACO from other causes can be seen in Table 108.2.

Management of TACO is similar to other causes of volume overload. The transfusion (if ongoing) should be stopped. Diuretics should be given. Theoretically, nitroglycerine would have similar effect in TACO as in any other volume overload situation and can be started at 50 to 100 mcg/min IV and titrated to effect. NIPPV can be initiated early to improve oxygenation and the work of breathing. If the patient develops intractable symptoms, intubation and mechanical ventilation may be required. In future transfusions, the rate of transfusion may be slowed, and prophylactic diuretics can be given to decrease the risk of another episode of TACO.

Infectious Complications of Transfusions

Though rare, transmission of infectious diseases is the transfusion-related complication most feared by the lay public. Transmission of a wide variety of infectious diseases has been reported, but modern screening methods, of both donors and the blood itself, have sharply reduced the frequency of transmission. The risks of transmission of viral infections such as HIV, hepatitis B, and hepatitis C are all well below 1 in a million. Concerns for bacterial infections prompted the practice of completing transfusions within 4 hours and returning unused blood products to the blood bank only if they have been unrefrigerated for less than 30 minutes.

In a recent study, bacterial culture positive transfusion reactions (BCPTRs) were defined as a positive bacterial culture result from the transfused blood product, from the recipient, or from both the blood product and the recipient. A septic transfusion reaction (STR) was further distinguished as a BCPTR that met definitive CDC hemovigilance criteria with absolute "imputability" and matching culture results from both the donor unit and the patient's blood culture.[32] Over an 8-year

period the study recorded 688,514 transfusions (52%, PRBCs, 23% apheresis platelets, 18% plasma, and 8% cryoprecipitate) and identified a total of 15 BCPTRs (0.002%). Further, only half of these met the more strict STR definition. A majority of the infectious cases resulted from platelet transfusions.[32]

Although a relatively rare occurrence, STR should be at least considered in any patient who develops a fever during a transfusion when it does not improve after cessation of the transfusion and the use of antipyretics.[33] The AABB developed criteria for consideration of STR which included a temperature of 38°C or higher and a 1°C rise above pretransfusion temperature in conjunction with associated symptoms such as rigors, nausea/vomiting, dyspnea, hypotension, or shock. They also used isolated hypotension or shock (and/or cardiovascular collapse) irrespective of fever as reasons to investigate for STR.

The Biomedical Excellence for Safer Transfusion (BEST) Collaborative found an increased sensitivity for detecting an STR with modification of the AABB criteria to include isolated high fever (>39°C) and a greater than 1°C rise above pretransfusion temperature irrespective of the presence of associated symptoms. In addition, they used predefined vital sign criteria to indicate hypotension (SBP < 90 mm Hg/DBP < 60 mm Hg or a 15% decrease from baseline) and tachycardia (HR > 100 or a 15% increase from pretransfusion baseline). Finally, they took into account the use of pretransfusion use of antipyretics which could blunt fever response.[34]

When an STR is suspected the transfusion should be paused and a culture of the transfusion unit and a blood culture from the patient are indicated.

Delayed Transfusion Reactions

Delayed Hemolytic Transfusion Reaction. A delayed hemolytic transfusion reaction (DHTR) typically occurs 3 to 10 days following transfusion with blood that initially appeared to be compatible. This can result from a non–ABO-mediated immune response, usually caused by an anamnestic response in a patient previously sensitized to red cell minor antigens through transfusion, pregnancy, or transplantation. Decreased survival of transfused red cells develops as a result of extravascular hemolysis. A related phenomenon termed delayed serologic transfusion reaction (DSTR) can develop when anamnestic antibodies are detected but there is no evidence of hemolysis. Together DSTR and DHTR occur in about 1 in 1500 transfusions, with the former occurring about four times more frequently than the latter.

Clinical effects can include fever, anemia, or jaundice. Symptoms are usually mild, though rarely significant complications such as oliguria or DIC can occur. Hemoglobinemia and hemoglobinuria are generally absent. Treatment is primarily supportive and the blood bank should be notified.

Transfusion-Associated Graft-versus-Host Disease. This rare but typically fatal complication results when transfused lymphocytes proliferate and attack a recipient who is incapable of mounting an immune response to the transfused cells.

Cell-mediated immunodeficiency places patients at risk, as does having an HLA type that is similar (sharing some but not all of the HLA antigens) between donor and recipient (most often seen among first-degree relatives).

Symptoms begin 3 to 30 days after transfusion and include fever, erythematous skin rash, diarrhea, elevated liver enzyme levels, and pancytopenia. Mortality is greater than 95%.

Efforts are directed at prevention through the use of gamma irradiation of cellular components, which renders the donor lymphocytes incapable of proliferating. The use of leukocyte-reduced components is not sufficient to prevent TA-GvHD. This condition should be kept in mind when transfusion is being considered for high-risk patients, including:

- Congenital immunodeficiency
- Hematologic malignancy (Hodgkin disease)
- Stem cell transplantation
- Treatment with purine analogues (e.g., fludarabine)
- Directed donor products from a close relative

Discussion with a hematologist is prudent when deciding whether to use irradiated cellular components in these high-risk groups.

Treatment is palliative and aims to restore the recipient's immune function. It is largely unsuccessful.[35]

Post-transfusion Purpura. Rarely, profound thrombocytopenia can develop 1 to 3 weeks after a transfusion associated with an antibody response to a platelet antigen. Eventually, this low-affinity antibody is eliminated, and the thrombocytopenia resolves spontaneously. Patients at risk for bleeding or with active hemorrhage are considered for treatment with high-dose immune globulin, plasmapheresis, or platelet transfusion.

CHAPTER 108: QUESTIONS AND ANSWERS

1. A 60-year-old man on warfarin presents to the emergency department after a fall. His non-contrast head CT shows a subdural hematoma, and his INR is 4. Which of the following is the recommended agent to reverse his coagulopathy?

a. Cryoprecipitate
b. Fresh frozen plasma
c. Prothrombin complex concentrate
d. Oral vitamin K

Answer: C. Prothrombin complex concentrate (PCC) is the recommended agent for reversal of elevated INR in life-threatening bleeding, including intracranial bleeding. 4 Factor PCC contains clotting factors II, VII, IX, and X making it the ideal agent for patients with elevated INR from warfarin as this medication inhibits synthesis of these vitamin K–dependent clotting factors. Cryoprecipitate contains fibrinogen, factor VIII, factor XII, von Willebrand factors, and fibronectin and is used most often clinically in cases of low fibrinogen

CHAPTER 108: QUESTIONS AND ANSWERS—cont'd

such as massive hemorrhage and DIC. Fresh frozen plasma can be used to reverse warfarin-induced coagulopathy; however, it often requires the administration of significantly more fluid volume and PCC more reliably lowers the INR in a shorter time frame. For these reasons PCC is the preferred treatment. Vitamin K will take hours to days to reverse the coagulopathy, as it relies on the bodies metabolic processes to synthesize clotting factors. It is, however, generally recommended to give IV vitamin K along with PCC, so that once the transfused factors have been consumed the body will have started to produce its own factors again.

2. A 36-year-old female patient is receiving a unit of packed red blood cells to treat her chronic anemia from end-stage renal disease when she develops a temperature of 38.2°C. The rest of her vital signs are normal. Which of the following is the best next step in management?
   - **a.** Administer acetaminophen
   - **b.** Given a bolus of 1 L of NS
   - **c.** Start broad spectrum antibiotics
   - **d.** Stop the blood transfusion

Answer: D. The first step in any suspected transfusion reaction is to stop the blood transfusion. If after investigation and brief observation this appears to be a non-hemolytic febrile transfusion reaction, you may administer acetaminophen and resume the transaction. Fluids resuscitation is the mainstay of treatment for hemolytic transfusion reactions, which can present as a fever. However, as is the case with any transfusion reaction, the first step is stopping the blood transfusion. Antibiotics are indicated in bacterial culture positive transfusion reactions. Typically patients will experience other vital signs abnormalities, such as tachycardia and hypotension, when having one of these reactions.

3. A 76-year-old female is receiving a unit of packed red blood cells, when she suddenly develops shortness of breath. On examination, she has crackles on auscultation of her lungs bilaterally. Which of the following is true regarding transfusion-associated circulatory overload (TACO) and transfusion-related acute lung injury (TRALI)?
   - **a.** Chest x-ray can often distinguish between TACO and TRALI.
   - **b.** Only TACO should be treated with noninvasive positive-pressure ventilation.
   - **c.** TACO typically requires the presence of a significant comorbidity.
   - **d.** TRALI can be treated with aggressive diuresis.

Answer: C. While it is possible to receive enough blood products for a healthy person to become volume overloaded, TACO is much more commonly seen in patients with underlying heart or renal failure. Both TACO and TRALI result in pulmonary edema, meaning they can present with similar chest x-ray findings and physical exam findings. Both entities can be treated with noninvasive positive-pressure ventilation or intubation and mechanical ventilation, as both treatments are effective in treating pulmonary edema. TRALI, however, will not respond to diuretics, because the cause of the pulmonary edema is an inflammatory response within the lungs rather than systemic volume overload.

4. A 15-year-old male is receiving a transfusion of packed red blood cells after a traumatic injury when he complains of itching. On examination, hives are found, and soon the patient develops difficulty breathing, tachypnea, tachycardia, and hypotension. The transfusion is stopped. Which of the following medications should be administered first?
   - **a.** Diphenhydramine
   - **b.** Epinephrine
   - **c.** Furosemide
   - **d.** RhoGAM

Answer: B. Occasionally, anaphylaxis may be caused by an anti-immunoglobulin A (IgA) reaction to IgA found in the donor blood component. The patient is likely to have a congenital IgA deficiency. The presentation is similar to anaphylactic reactions from other causes. Washed red blood cells (RBCs) and plasma products from IgA-deficient individuals can be used to avoid recurrence with subsequent transfusions. As the patient is having an allergic reaction involving more than one organ system, this reaction should be treated as anaphylaxis with epinephrine; while the patient may also receive diphenhydramine, epinephrine is the critical life-saving treatment. Furosemide is indicated to treat transfusion-associated volume overload, which would not present with hives. RhoGAM is a purified anti-D antibody that can be given to Rh− individuals who have received Rh+ PRBC blood transfusions to prevent the patient from developing their own anti-D antibodies. Clinically this is most relevant for female patients to prevent hemolytic disease of the newborn in future pregnancies.

5. A 24-year-old female patient presents with cellulitis. A complete blood count demonstrates a hemoglobin level of 7.5 g/dL. On further questioning, it is discovered that her Ob/Gyn is treating her for menorrhagia, but she has no other comorbidities. She denies any lightheadedness, chest pain, dyspnea, or recent increase in bleeding. Her heart rate is 85 and her blood pressure is 136/84 mm Hg. Which of the following is the most appropriate next step in management of her anemia?
   - **a.** Discharge the patient to follow up with her outpatient provider.
   - **b.** Obtain a type and crossmatch and transfuse 1 unit of type specific packed red blood cells.
   - **c.** Order a STAT hematology consult.
   - **d.** Transfuse 1 unit of O− packed red blood cells.

Answer A. This patient is clinically stable, has a chronic source of blood loss, and her hemoglobin level is above the recommended treatment threshold of 7 g/dL, therefore it is safe to discharge her to follow up with her outpatient provider. Depending on the level of comfort, some physicians might offer a pelvic exam to characterize the degree of bleeding and/or obtain a second hemoglobin level after a brief period of observation. The patient does not warrant an emergent transfusion of either type specific or O− packed red blood cells. O− transfusions should be reserved for those patients with hemodynamic instability who are unlikely to tolerate the 60 to 90 minutes it takes to obtain a type and crossmatch. Similarly, while the patient may benefit from a hematology consult (in particular to be evaluated for von Willebrand disease) it is inappropriate to obtain this in the emergency department for a stable patient.

109

Anemia and Polycythemia

Meagan B. Verbillion and Alan A. Dupré

KEY CONCEPTS

- Anemia is caused by three basic mechanisms: loss of red blood cells (RBCs) through bleeding, destruction of RBCs, or decrease in production of RBCs.
- RBC indices along with a peripheral blood smear can help determine the mechanism of anemia.
- Anemia in the elderly often occurs as an exacerbation of pre-existing comorbid diseases.
- Anemia of uncertain etiology should be thoroughly evaluated. If the patient has no adverse hemodynamic consequences, the evaluation can proceed on an outpatient basis or management initiated in an observation setting until the patient is stable.
- Patients with sickle cell disease should be considered to have an acute pain crisis and treated appropriately until proven otherwise.
- Acute chest syndrome is one of the most common causes of death in sickle cell disease and presents with fever, dyspnea, cough, and a new infiltrate on chest radiograph.
- Transfusion therapy is most useful in sickle cell disease associated with acute stroke, acute chest syndrome, or splenic sequestration.
- Primary polycythemia vera is treated with serial phlebotomy to a goal hematocrit of less than 45%.

ANEMIA

Foundations

Background and Importance

Anemia affects a third of the global population and accounted for the primary hospital discharge diagnosis in approximately 188,000 emergency department (ED) visits in 2014 as reported by the Centers for Disease Control (CDC).[1] Anemia is an absolute decrease in the number of circulating red blood cells (RBCs). The diagnosis is made when laboratory measurements fall below accepted normal values (Table 109.1).

Anemia is divided into two broad categories: emergent, having immediate life-threatening complications, and typically secondary to acute blood loss; and non-emergent, with less imminent danger to the patient and many times can be further evaluated on an outpatient basis. Factors other than the absolute number of circulating RBCs may place the patient in one category or another (e.g., rate of onset and underlying hemodynamic reserve of the patient). Both groups necessitate a sound diagnostic approach, though emergent anemia may require immediate supportive therapy concomitant with or in advance of the definitive diagnosis. Although patients with non-emergent anemia are usually referred to a specialist, the urgency of consultation depends predominantly on the patient's hemodynamic tolerance of the anemia.

Anatomy, Physiology, and Pathophysiology

Understanding anemia starts with the structure and function of the RBC. RBCs are primarily composed of hemoglobin, which has a quaternary structure containing 4 heme polypeptide subunits bound to an iron molecule that is contained in the center of a porphyrin ring. The major function of the RBC is oxygen transport from the lung to the tissue, and carbon dioxide transport in the reverse direction. Oxygen transport is influenced by the amount of hemoglobin and its oxygen affinity, as well as blood flow. An alteration in any of these major components usually results in compensatory changes in the other two. For example, a decrease in hemoglobin is compensated for by both inotropic and chronotropic cardiac changes that result in increased blood flow and decreased hemoglobin affinity at the tissue level, thereby allowing more oxygen release. Due to disease severity or underlying pathologic conditions, these compensatory responses may fail, resulting in tissue hypoxia and cell death.

Anemia stimulates the compensatory mechanism of erythropoiesis controlled by the hormone erythropoietin, which is a glycoprotein produced in the kidney (90%) and liver (10%). It regulates the production of RBCs by controlling differentiation of committed erythroid stem cells and is stimulated by tissue hypoxia or products of RBC destruction during hemolysis. Elevated in many types of anemia, erythropoietin enhances the growth and differentiation of erythroid progenitors.

Bone marrow contains pluripotent stem cells that can differentiate into erythroid, myeloid, megakaryocytic, or lymphoid progenitors. When the late normoblast extrudes its nucleus, it still contains a ribosomal network, which identifies the reticulocyte. The reticulocyte retains its ribosomal network for approximately 4 days, 3 days of which are spent in bone marrow and 1 day in the peripheral circulation. The RBC matures as the reticulocyte loses its ribosomal network and becomes an erythrocyte which circulates for 110 to 120 days in the peripheral circulation. Erythrocytes are anucleate, flexible, biconcave discs. The erythrocyte is scavenged and removed by macrophages that detect senescent signals. Under steady-state conditions, RBC mass remains constant as an equal number of reticulocytes replace the destroyed, senescent erythrocytes.[2]

The most common cause of emergent anemia is acute blood loss. Common sites of blood loss in the trauma patient include pleural, peritoneal, pelvic, long bone (e.g., thigh), and retroperitoneal spaces. In non-traumatic circumstances, especially in patients receiving anticoagulants, the gastrointestinal tract, retroperitoneal space, uterus, or adnexa need to be considered. Certain hemolytic conditions, such as disseminated intravascular coagulopathy (DIC), can also cause rapid intravascular destruction of RBCs leading to emergent anemia (Box 109.1).

Non-emergent anemias can be subdivided into microcytic, normocytic, and macrocytic based on the mean corpuscular volume (MCV), which measures size and volume of the RBC. Microcytic anemias are caused by low iron production, gene mutations, toxins (e.g., lead poisoning), or defective heme synthesis. Normocytic anemias can be caused by primary or secondary bone marrow failure and can

TABLE 109.1 Hemogram Normal Values

Age	Hemoglobin (g/dL)	Hematocrit (%)	Red Blood Cell Count ($\times 10^6$)
3 Months	10.4–12.2	30–36	3.4–4.0
3–7 years	11.7–13.5	34–40	4.4–5.0
Adult man	14.0–18.0	40–52	4.4–5.9
Adult woman	12.0–16.0	35–47	3.8–5.2

BOX 109.1 Causes of Rapid Intravascular Red Blood Cell Destruction

Mechanical hemolysis associated with disseminated intravascular coagulation
Massive burns
Toxins (e.g., some poisonous venoms: brown recluse spider, cobra)
Infections such as malaria or *Clostridium* sepsis
Severe glucose-6-phosphate dehydrogenase (G6PD) deficiency with exposure to oxidant stress
ABO incompatibility transfusion reaction
Cold agglutinin hemolysis (e.g., *Mycoplasma* organisms, infectious mononucleosis)
Paroxysmal nocturnal hemoglobinuria exacerbated by transfusion
Immune complex hemolysis (e.g., quinidine)

be further subdivided into hemolytic and non-hemolytic. Anemia of chronic disease is the most common non-hemolytic anemia, caused by an inflammatory response to underlying disease states. Hemolytic anemias are either intrinsic or extrinsic in nature. Intrinsic hemolytic anemias are typically caused by underlying genetic mutations or enzyme deficiencies (e.g., sickle cell disease) that lead to abnormal RBC production. Extrinsic hemolytic anemias result from defects outside of the RBC (e.g., DIC). Macrocytic anemias are caused primarily by nutritional deficiencies such as folate or vitamin B_{12}, as well as various disease states (e.g., alcoholism) that retard the maturation of the RBC.

Clinical Features

The clinical manifestation of anemia depends on how rapidly the hematocrit falls and on the patient's ability to compensate for the loss. Clinical signs and symptoms of acute blood loss include tachycardia, hypotension, orthostasis, lightheadedness, dyspnea, pallor, or tachypnea. Complaints of thirst, altered mental status, or decreased urine output may also be present. The patient's age, concomitant illness, and underlying comorbidities can tremendously influence the presenting clinical findings. Children and young adults may tolerate significant blood loss with largely unaltered vital signs, preceding a precipitant hypotensive episode. Elderly patients commonly have underlying disease states that compromise their ability to compensate for blood loss, which can lead to the earlier vital sign alterations and a higher potential for rapid clinical deterioration.[3] Pertinent elements of the history and physical examination of patients with acute anemia are listed in Box 109.2.

In contrast, nonemergent anemias are usually seen in ambulatory patients complaining of fatigue and weakness, irritability, headache, postural dizziness, angina, decreased exercise tolerance, shortness of breath, or decreased libido. The history and physical examination is typically paramount in helping to identify the cause of anemia (Box 109.3). The rate of loss of hemoglobin also dictates symptom onset. When anemia is slow in onset, the patient may compensate well until the hemoglobin is very low, at which point symptoms worsen or vital sign changes occur. Most of these patients do not need immediate stabilization and can be further evaluated in the outpatient setting.

BOX 109.2 History and Physical Examination for Clinically Severe Anemia

History
General
Out-of-hospital status, therapy, response to therapy
Bleeding diathesis
Previous blood transfusion
Underlying diseases, including allergies
Current medications, especially those causing platelet inhibition
Trauma: Nature and Time of Injury, Blood Loss at Scene
Nontrauma
Skin: Petechiae, ecchymoses
Gastrointestinal: Hematemesis, hematochezia, melena, peptic ulcer
Genitourinary: Last menstruation, menorrhagia, metrorrhagia, hematuria

Physical Examination
Vital Signs Measured Serially
Blood pressure, pulse, respiratory rate, oxygen saturation
Level and content of consciousness
Skin: pallor, diaphoresis, jaundice, cyanosis, purpura, ecchymoses, petechiae
Cardiovascular: Murmurs, S_3, S_4, quality of femoral and carotid pulses
Abdomen: Hepatosplenomegaly, pain, guarding, rebound on palpation, stool hemoglobin testing

BOX 109.3 History and Physical Examination for Nonemergent Anemia

History
Symptoms of Anemia
Chest pain, decreased exercise tolerance, dyspnea
Weakness, fatigue, dizziness, syncope

Bleeding Diathesis
Bleeding after trauma, injections, tooth extractions
Spontaneous bleeding, such as epistaxis, menorrhagia
Spontaneous purpura and petechiae

Sites of Blood Loss
Respiratory: Epistaxis, hemoptysis
Gastrointestinal: Hematemesis, hematochezia, melena
Genitourinary: Abnormal menses, pregnancies, hematuria
Skin: Petechiae, ecchymoses
Intermittent jaundice, dark urine
Dietary history: Vegetarianism, poor nutrition
Drug use and toxin exposure, including alcohol
Racial background, family history
Underlying disease
- Uremia, liver disease, hypothyroidism
- Chronic disease states, such as cancer, rheumatic or renal disease
- Previous surgery

Physical Examination
Skin: Pallor, Purpura, petechiae, angiomas, ulcerations
Eye: Conjunctival jaundice, pallor
Oral: tongue atrophy, papillary soreness
Cardiopulmonary: Heart size, murmurs, extra cardiac sounds, rales indicating pulmonary edema
Abdomen: Hepatomegaly, splenomegaly, ascites, masses
Lymph nodes
Neurologic: Altered positions or vibratory sense, ataxia, peripheral neuritis
Rectal and pelvic: masses

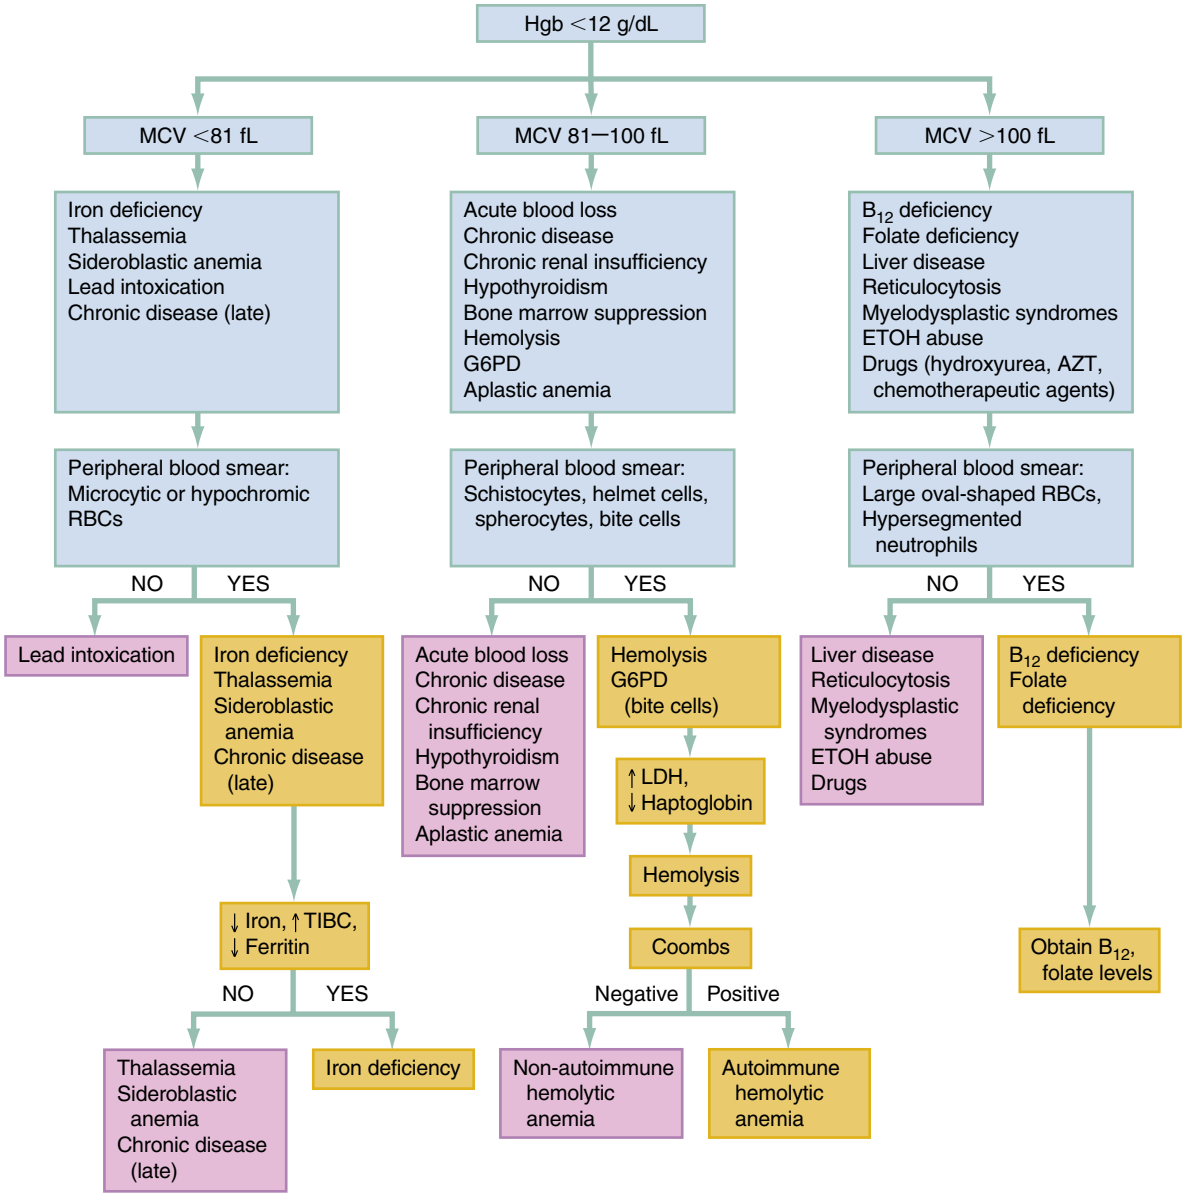

Fig. 109.1 Algorithm for the Evaluation of Anemia. *AZT,* Azathioprine; *ETOH,* ethanol; *fL,* femtoliter; *G6PD,* glucose-6-phosphate dehydrogenase; *Hgb,* hemoglobin; *LDH,* lactate dehydrogenase; *MCV,* mean corpuscular volume; *RBCs,* red blood cells; *TIBC,* total iron-binding capacity.

Differential Diagnoses

The differential diagnosis of anemia is facilitated by classification of the anemia into one of three groups: decreased RBC production, increased RBC destruction, and blood loss. A complementary approach uses RBC morphology and indices. Fig. 109.1 presents an algorithm for the evaluation of anemia.

Diagnostic Testing

In a patient suspected of acute blood loss, the following initial laboratory tests may be helpful, depending on clinical circumstances:

- Complete blood count and peripheral smear
- Blood sample for type and crossmatch
- Prothrombin time and international normalized ratio
- Partial thromboplastin time
- Serum electrolyte levels
- Glucose level (particularly if the patient has altered consciousness)
- Creatinine level
- Urinalysis for free hemoglobin

Obtaining a hemoglobin and hematocrit in the emergency department (ED) is useful for determining a baseline even though it may not be reflective of the true degree of blood loss for many hours. Depending on severity, a blood sample should be sent for type and crossmatch.

The initial laboratory evaluation for a patient with non-emergent anemia also includes a complete blood count with leukocyte differential, reticulocyte count, peripheral smear (Fig. 109.2), as well as RBC indices, including MCV, mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). RBC indices are useful in classifying anemias caused by a production deficit (Table 109.2). MCV is a measure of RBC size and volume; decreases or increases reflect microcytosis and macrocytosis, respectively. MCH incorporates both RBC size and hemoglobin concentration. It is influenced by both and is rarely helpful in the ED setting. The MCHC index

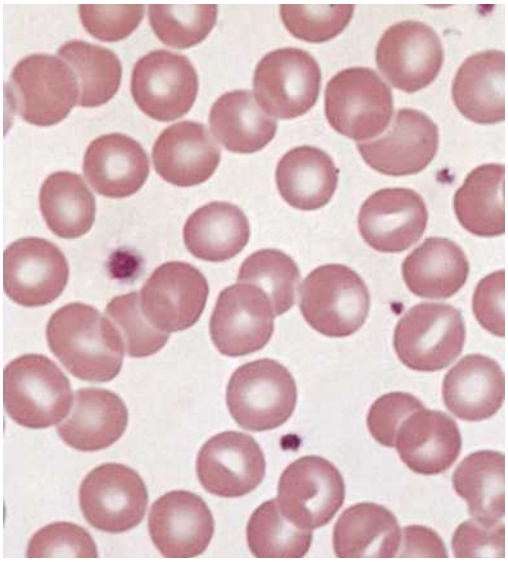

Fig. 109.2 Normal Smear. (From Hoffbrand AV, Pettite JE. *Color Atlas of Clinical Hematology*. 3rd ed. London: Mosby; 2000:22.)

TABLE 109.2 Calculation of Red Blood Cell Indices and Normal Values

Index	Formula for Calculation	Normal
Mean corpuscular volume	Hematocrit (%) divided by RBC count (10^6/μL)	81–100 fL
Mean corpuscular hemoglobin	Hemoglobin (g/dL) divided by RBC count (10^6/μL)	26–34 pg
Mean corpuscular hemoglobin concentration	Hemoglobin (g/dL) divided by hematocrit (%)	31%–36%

fL, Femtoliter; *RBC,* red blood cell; *pg,* picograms.

is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted in patients with decreased cell membrane relative to cell volume, such as in the case of spherocytosis. An additional index is the RBC distribution width (RDW), a measure of RBC homogenicity. RDW is automatically calculated as the standard deviation of MCV divided by MCV multiplied by 100. A normal RDW is 13.5 ± 1.5%. The RDW is elevated in anemias caused by nutritional deficiencies; however, it is not specific for any abnormality.

Measurements of coagulation status, serum electrolytes, glucose, blood urea nitrogen, and creatinine are useful in the diagnosis of underlying disease processes that may relate to the patient's anemia. When the cause of anemia is unknown and the patient requires transfusion, consider ordering folate, vitamin B_{12}, iron, total iron-binding capacity (TIBC), reticulocytes, and direct antiglobulin (Coombs test) pretreatment. Post-transfusion, these levels will be unreliable and could mask an underlying diagnosis.

Management

Stabilization of emergent anemia commonly runs in parallel with assessment. If the signs and symptoms suggest potential life-threatening conditions, multiple large bore intravenous lines are placed in preparation for resuscitation and transfusion.

Disposition

Criteria for the admission of patients with non-emergent anemia are shown in Box 109.4.

BOX 109.4 General Admission Criteria for Nonemergent Anemia

- Cardiac symptoms, such as dyspnea or chest pain, or neurologic symptoms, such as syncope.
- Initial unexplained hemoglobin value <8–10 g/dL or hematocrit <25%–30% in selected patients
- Difficulty in obtaining outpatient care for patients whose hemoglobin levels are significantly low or when comorbidity is present

BOX 109.5 Differential Diagnosis of Anemias Caused by Decreased Red Blood Cell Production Subclassification by Red Blood Cell Indices

Hypochromic Microcytic Anemias (Decreased MCV and Hemoglobin Concentration)
- Iron deficiency
- Thalassemia
- Sideroblastic anemia or lead poisoning
- Chronic disease (e.g., cancer, renal disease); can also be normochromic and normocytic

Macrocytic (Elevated MCV)
- Vitamin B_{12} deficiency
- Folate deficiency
- Liver disease
- Hypothyroidism

Normocytic (Normal MCV and Hemoglobin Concentration)
- Primary bone marrow involvement: Aplastic anemia, myeloid metaplasia with myelofibrosis, myelophthisic anemia
- Resulting from underlying disease: Hypoendocrine state (thyroid, adrenal, pituitary), uremia, chronic inflammation, liver disease

MCV, Mean corpuscular volume.

ANEMIAS DUE TO DECREASED RED BLOOD CELL PRODUCTION

Foundations

Anemias caused by decreased RBC production are insidious in onset and are associated with a decreased reticulocyte count. A subclassification by indices of anemias caused by decreased RBC production is listed in Box 109.5. RBC indices and a peripheral smear are useful in securing the diagnosis, although a definitive diagnosis may require more extensive outpatient work up including a bone marrow examination. Replacement of iron, vitamin B_{12}, or folate by the emergency clinician without proof of cause is generally unnecessary and not routinely recommended.

Hypochromic microcytic anemias are subdivided into deficiencies of the three building blocks of hemoglobin: iron (iron deficiency anemia; Fig. 109.3), globin (thalassemia), and porphyrin (sideroblastic anemia and lead poisoning). Anemia of chronic disease, a secondary iron abnormality, is also included on the differential and can be microcytic or normocytic.[2]

Iron Deficiency Anemia

Foundations

Iron deficiency is a frequent cause of chronic anemia seen in the ED. It is the most common cause of anemia globally.[4] It is defined by microcytic,

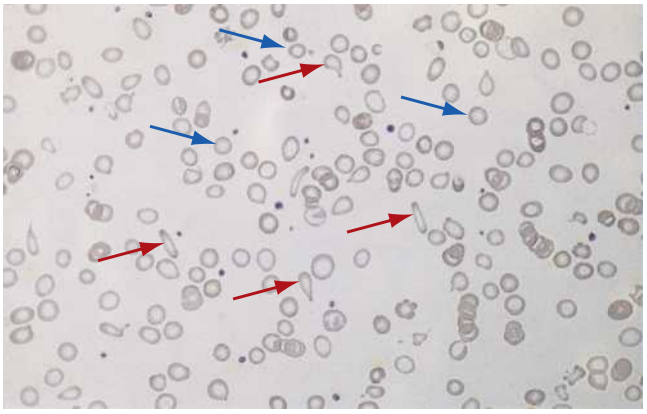

Fig. 109.3 Iron Deficiency Anemia With Hypochromic, Microcytic Cells and Poikilocytes (Abnormally Shaped Cells). (From Hoffbrand AV, Pettite JE. *Color Atlas of Clinical Hematology*. 3rd ed. London: Mosby; 2000:44.)

hypochromic RBC. Iron deficiency can either be absolute or functional. Absolute iron deficiency reflects low or exhausted total body iron stores, while functional iron deficiency is caused by inadequate iron supply to the bone marrow.[5] Iron is a critical component needed for effective erythropoiesis, and also essential for mitochondrial function, DNA synthesis, and cellular enzymatic reactions. Dietary iron is absorbed in the duodenum, thus nutritional deficiency or malabsorption syndromes can be a cause of iron deficiency anemia.[2] Occult blood loss should always be excluded in the setting of iron deficiency anemia. This is common in older patients, especially with gastrointestinal blood loss, as well as in menstruating women. Changes in RBC size, number, and hemoglobin content occur only after bone marrow and cytochrome iron stores are depleted; therefore, a patient may have early symptoms of iron deficiency (e.g., fatigue) without anemia. These non-hematologic symptoms are the result of impaired muscle-tissue oxidative capacity and decreased activity of iron-containing enzymes in the setting of iron deficiency.

Clinical Features

Most anemias secondary to iron deficiency are non-emergent in nature. The symptoms related to anemia are secondary to the body's ability to adapt to the low hemoglobin levels over time, and the eventual inability of the tissues to receive adequate oxygen for metabolic demands.

Diagnostic Testing

The diagnosis is made by laboratory evaluation of the fasting level of serum iron, serum ferritin, and TIBC. The laboratory interpretation and pitfalls are outlined in Table 109.3. A concentrated search for occult blood loss remains an important component of the evaluation.

Management

Therapy consists of oral iron replacement. A cost-effective form is ferrous sulfate. The dosage is 325 mg PO for adults (65 mg of elemental iron) three times daily, or 2 mg/kg/day of elemental iron orally for children.[5] This medication is generally well tolerated, although it may cause nausea, vomiting, or constipation. Ascorbic acid can improve the bioavailability of iron and is recommended in conjunction with iron replacement, although it can increase the frequency of side effects. Patients should be warned that iron frequently leads to black stools, and that bleeding from the digestive tract can also be manifested as black stool. In patients with poor oral tolerance or absorption, parenteral iron therapy may be necessary. Parenteral iron replenishes iron stores more effectively than oral replacement in CKD, inflammatory bowel disease, and in the post-partum period.[5,6]

The patient may experience a sense of improvement in as few as 24 hours after initiating replacement therapy. Reticulocytosis appears during a 3- to 4-day period in children, but may take more than 1 week in adults, with complete repletion of iron stores in approximately 3 to 6 months.[4] The hemoglobin concentration rises on a similar schedule. Failures of iron replacement therapy can occur due to a variety of causes, including patient noncompliance with iron supplementation, insufficient replacement, incorrect diagnosis, or presence of an additional process complicating the iron deficiency, such as anemia of chronic disease.

Thalassemia

Foundations

The hemoglobin molecule is present as two-paired globin chains. Each type of hemoglobin is made up of different globins. Normal adult hemoglobin (HbA) is made up of two alpha chains and two beta chains ($\alpha_2\beta_2$). HbA_2 is a variant of hemoglobin A that contains two alpha and two delta chains ($\alpha_2\delta_2$). Fetal hemoglobin (HbF) contains two alpha and two gamma chains ($\alpha_2\gamma_2$). A separate autosomal gene controls each globin chain.

Pathophysiology

Thalassemia is a genetic autosomal recessive disorder reflected by the decreased synthesis of and abnormal structure of globin chains. Deletions in these globin genes result in an absence or decreased function of the messenger RNA that codes for particular globins. The various globins (α, β, δ, and γ) may be affected by a number of genetic combinations. Decreased globin production in thalassemia precipitates the formation of reactive oxygen species leading to apoptosis of erythroblasts, decreased hemoglobin synthesis, and ineffective erythropoiesis, leading to hemolytic anemia.[7] Beta thalassemia is associated with reduced or absent beta-globin synthesis and an excess of alpha-globins, leading to the formation of alpha-globin tetramers. Alpha thalassemia results in an excess of β-globins and the formation of β-globin tetramers termed *hemoglobin H*. The abnormal formation of hemoglobin at various concentrations results in complications, including red cell membrane breakage and hemolysis. A common method of classification is by phenotype. Beta thalassemias are broken down into silent (carrier), minor, intermedia, and major variants. Alpha thalassemias include silent (carrier), alpha thalassemia trait, HbH, and Hb Barts. This historical classification method is now being replaced by a simpler system: transfusion-dependent thalassemia (TDT) or non-transfusion-dependent thalassemia (NTDT), with patients often shifting clinically between the two categories depending on their transfusion needs. NTDT includes thalassemia minor, mild HbE, HbH disease, and alpha-thalassemia trait. Despite its name, NTDT treatments can range from no transfusion requirement to intermittent transfusions required. Transfusion is also offered to some NTDT patients to prevent or manage disease complications. TDT includes thalassemia major, severe HbE/Beta-thalassemia, and Hb Barts hydrops. Hb Barts is almost always fatal at birth. TDT, as reflected in its name, typically requires regular, lifelong transfusions for survival, usually starting before the age of 2 years.[7]

CLINICAL FEATURES

Homozygous β-chain thalassemia (thalassemia major or Cooley anemia) occurs predominantly in Mediterranean populations. It is one of the most common single-gene disorders, resulting in no functional beta chains. The disease is characterized by severe anemia, hepatosplenomegaly, jaundice, abnormal development, and premature death. Symptoms are typically evident by the age of 2 years. Patients are transfusion dependent and die as a result of iron deposition in tissues, particularly in the myocardium, or infection.

TABLE 109.3 Diagnostic Tests for Iron Deficiency Anemia

Test	Normal	Iron Deficiency	Interpretation
Fasting serum iron	60–180 μg/dL	<60 μg/dL	Diurnal variation (draw in morning); increased by hepatitis, hemochromatosis, hemolytic anemia, or aplastic anemia; decreased in infection
Total iron-binding capacity	250–400 μg/dL	>400 μg/dL	Increased in late pregnancy or hepatitis; decreased in infection
Percentage of saturation (serum iron) of total iron-binding capacity	15%–45%	<15%	
Serum ferritin	10–10,000 mg/mL	<10 mg/mL	Reflects iron stores; may increase as an acute-phase reactant in infection
Bone marrow stainable iron	Hemosiderin granules in reticuloendothelial cells	Absent	Standard for assessment of iron stores

Heterozygous β-chain thalassemia (thalassemia minor or intermedia) results in some functional beta chains and is manifested as a mild to moderate anemia. Thalassemia minor patients are typically asymptomatic and rarely, if ever, require transfusion. Thalassemia intermedia patients usually have a moderate anemia and require occasional transfusions. Heterozygous beta thalassemia is most prevalent in Asia, the Middle East, and Mediterranean countries. This widespread distribution is attributed to a natural selection toward heterozygote carriers, as this offers protection against falciparum malaria.[7] This same protection is also offered in sickle cell trait carriers.

Alpha-thalassemia varies in spectrum from an asymptomatic carrier state to prenatal death. Four gene loci are responsible, and disease severity increases as the number of gene deletions increase. The tolerated forms are more commonly seen in Asians and African Americans. One missing gene results in a silent carrier state while two missing genes, commonly referred to as alpha thalassemia trait, results in a minor anemia. Three missing genes, also called hemoglobin H disease, can lead to a mild to moderate anemia, but most affected lead normal lives. Four defective genes result in Hb Barts, which causes hydrops fetalis and fetal death.[8]

Diagnostic Testing

Thalassemia is a microcytic, hypochromic anemia. Hypochromia, target cells, and basophilic stippling are noted on the peripheral smear. The MCV is commonly lower than seen with iron deficiency, and serum iron levels are typically normal. The diagnosis is made with hemoglobin electrophoresis and genetic testing. Screening for carriers is performed by measurement of RBC indices and estimation of the HbA_2 concentration. Prenatal diagnosis can be made by analysis of fetal blood or by fetal DNA obtained by chorionic villus sampling.[7]

Management

Usually, no treatment is necessary for silent carriers, beta thalassemia minor, and alpha thalassemia trait. Therapy for the remaining types of thalassemia consists of blood transfusions, where the goals of transfusion therapy include correction of anemia, suppression of ineffective erythropoiesis, and inhibition of increased gastrointestinal iron absorption. TDT requires transfusions every 2 to 5 weeks to maintain a pre-transfusion hemoglobin between 9 and 10.5g/dL. Transfusion is usually started when patients are young to ensure normal growth and physical activity capacity. Recurrent transfusion does increase risk of blood-borne infection, alloimmunization, and iron overload, the latter of which may lead to multi-organ dysfunction and is a common cause of death. Guidelines for transfusion are not well established in patients with NTDT, but transfusion should be considered during times of significant stress such as pregnancy, surgery, or infection, or when hemoglobin levels are low. More frequent transfusion may be used in children with NTDT if they develop signs of growth failure or reduced exercise tolerance.

Transfusion therapy improves long-term survival in patients with TDT when combined with iron chelation therapy. Iron chelation therapy can also reduce systemic and hepatic iron burden in NTDT, but it is not effective in all patients. Deferoxamine can be administered parenterally or subcutaneously. It was the first commercially available chelator. Its demanding treatment regimen, however, often leads to poor adherence. Dosages are weight based, with treatments required for 8 to 12 hours, 5 to 7 nights per week.[7] Two oral chelators are available, deferiprone and deferasirox. Deferiprone is administered two or three times daily, and deferasirox is a once-daily medication.[9,10]

Hydroxyurea, a cytotoxic anti-metabolite that induces fetal hemoglobin, is also used in some cases of NTDT. Hydroxyurea is hypothesized to improve chronic anemia and reduce the need for transfusion by reducing alpha and beta chain imbalance through the production of fetal hemoglobin. It is well tolerated by patients and has no major long-term adverse effects. Commonly reported side effects included mild transaminitis, nausea or vomiting, and transient bone marrow suppression. It is associated with a decrease in the need for recurrent transfusions. In patients with mild NTDT, it can raise baseline Hb by at least 1 g/dL and in some patients with severe NTDT (>3 transfusions per year) it can lead to a complete cessation of transfusion requirement.[11]

Splenectomy is considered in some patients and can improve hemoglobin concentration, decreasing the need for recurrent transfusions. Hematopoietic stem cell transplantation (HSCT) is another therapy in use and is potentially curative in patients with TDT with disease-free survival rates greater than 80% at 2 years. It is, however, only appropriate for a subset of patients due to age restrictions and the need for sibling donor compatibility. HSCT carries with it a 5% to 10% risk of mortality, as well as potential permanent fertility impairment.[7]

Gene therapy and gene editing are becoming more promising as possible future treatment modalities for thalassemia; data from clinical trials is in progress.

Sideroblastic Anemia

Foundations

Sideroblastic anemia involves a defect in porphyrin synthesis and can be congenital, idiopathic, or acquired. The resultant impaired hemoglobin production causes excess iron to be deposited in the mitochondria of the RBC precursor as well as increased serum iron, ferritin, and transferrin saturation levels. The defective heme synthesis results in ineffective erythropoiesis, mild to moderate anemia, and a dimorphic peripheral smear with hypochromic microcytes along with normal and macrocytic cells, as well as characteristic ringed sideroblasts.[12] A

ringed sideroblast is an erythroid precursor with a minimum of five siderotic granules covering the nucleus after Prussian blue staining.[13]

Clinical Features

Congenital sideroblastic anemia is a relatively rare disease resulting from iron metabolism related gene mutations.[14] The most common congenital cause is X-linked sideroblastic anemia (XLSA) which occurs secondary to missense substitutions in 5′-Aminolevulinste Synthase 2 (ALAS2) genes.[13] Idiopathic sideroblastic anemia is a common type of refractory anemia in elderly patients. Pallor and splenomegaly may be noted, and iron staining of the peripheral smear may demonstrate iron-containing inclusion bodies in RBCs. Idiopathic sideroblastic anemia is considered a pre-leukemic state, with acute myelogenous leukemia developing in approximately 5% of patients.

Differential Diagnoses

Acquired causes of sideroblastic anemia include drugs, alcoholism, copper deficiency, lead poisoning, zinc toxicity, myelodysplastic syndrome, or myeloproliferative disorders. Chloramphenicol, isoniazid, linezolid, and penicillamine are known causes of drug-induced sideroblastic anemia.[13] Lead poisoning, one reversible cause of sideroblastic anemia, may be suggested by basophilic stippling on the peripheral smear and the presence of metaphyseal lead lines on imaging. Elevated blood lead levels are diagnostic. Alcohol abuse may also result in disordered heme synthesis, which can be corrected by alcohol cessation or by parenteral pyridoxal phosphate (active form of vitamin B6) in cases of continued abuse. Oral pyridoxine (vitamin B6) may be ineffective because of impaired conversion to the active form in alcoholic patients.

Management

Management varies based on underlying cause. Most congenital or acquired sideroblastic anemia is treated with pyridoxine (vitamin B_6) and responds to treatment with 100 mg PO three times a day. Although a trial of treatment with pyridoxine is advised, most patients remain anemic and will require transfusion. If long-term transfusion therapy is necessary, iron overload will need to be managed and usually responds well to chelation therapy. Stem cell transplantation can be curative in some patients with congenital or myelodysplastic sideroblastic anemias.[13,14]

Anemia of Chronic Disease

Foundations. Anemia of chronic disease (ACD) is secondary to reduced erythropoiesis and reduced RBC survival time in the peripheral circulation in chronic inflammatory states, which result in decreased iron release from macrophages secondary to increased cytokines and hepcidin. It is a multifactorial, acquired disorder of iron homeostasis. Common causes include malignancy, arthritis, renal insufficiency, chronic heart failure, chronic obstructive lung disease, or chronic infections (e.g., tuberculosis or osteomyelitis).[2] ACD is commonly found in older adults and is associated with increased morbidity and mortality, largely due to the effects of anemia on comorbid disease processes and the underlying etiology of the ACD.[3]

Clinical Features

Symptoms are usually those related to the underlying disease and not from the anemia itself.

Diagnostic Testing

Anemia of chronic disease is common and typically normochromic, normocytic, though can be microcytic. It is characterized by low serum iron levels, low TIBC, and normal or elevated ferritin levels.[3] Bone marrow is typically normal, but staining reveals an abnormality in the mobilization of iron from reticuloendothelial cells. This anemia can be differentiated from iron deficiency by TIBC, ferritin, bone marrow examination, and non-responsiveness to a trial of iron therapy. A complete search for occult blood loss is prudent during evaluation. It should be recognized that true iron deficiency may also be superimposed on anemia of chronic disease.

TABLE 109.4 Clinicopathologic Correlation of Manifestations of Megaloblastic Anemia

Clinical Features	Pathologic Condition
Lemon yellow skin	Combination of pallor with low-grade icterus from ineffective erythropoiesis
Petechiae, mucosal bleeding	Thrombocytopenia
Infection	Leukopenia
Fatigue, dyspnea, orthostasis	Anemia
Sore mouth or tongue	Megaloblastosis of mucosal surfaces
Diarrhea and weight loss	Malabsorption from mucosal surface change
Paresthesias and ataxia	Related to myelin abnormality in vitamin B_{12} deficiency only

Management

Acute or emergent therapy is not usually required, as the hemoglobin and hematocrit is typically modest. Treatment should be directed at the underlying cause.

Macrocytic and Megaloblastic Anemias

Foundations

Macrocytic anemia is the hematologic manifestation of a total-body alteration in DNA synthesis caused primarily by vitamin B_{12} or folic acid deficiency, which appears clinically in tissues with rapid cell turnover, including hematopoietic cells or those of mucosal surfaces, particularly in the gastrointestinal tract. This deficiency is characterized by ineffective erythropoiesis and pancytopenia. Vitamin B_{12} and folate deficiencies have different developmental histories, but the clinical result is similar. Differentiation of folate and vitamin B_{12} deficiencies usually depends on laboratory measurements.

Clinical Features

Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic categories. Megaloblastic macrocytic anemia is the most common cause of macrocytic anemia and pancytopenia. Table 109.4 lists a number of the problems associated with megaloblastic anemia and their underlying pathologic states. Nonmegaloblastic macrocytic anemia is caused by disease states such as alcoholism, liver dysfunction, hypothyroidism, myelodysplastic syndromes, and certain drugs (e.g., hydroxyurea, methotrexate, zidovudine, valproic acid).[15] Like other causes of anemia, easy fatigability is the most common symptom reported in patients with macrocytic anemia. Additional symptoms include anorexia, dyspnea on exertion, palpitations, oral ulcers, or weight loss.[16] A unique feature of vitamin B_{12} deficiency is its neurologic involvement. Patients may have paresthesias of their hands or feet, decreased proprioception, or decreased vibratory sense; weakness and spasticity of the lower extremities with altered reflexes; and variable mental changes, such as depression, paranoid ideation, irritability, or forgetfulness. The neurologic manifestations of folic acid deficiency overlap with those of vitamin B_{12} deficiency, but the neuropsychiatric manifestations (e.g., depression and forgetfulness) predominate in folic acid deficiency. A devastating consequence of vitamin B_{12} deficiency

BOX 109.6 Causes of Folate Deficiency

- Inadequate dietary intake
  - Poor diet or overcooked or processed food diet
  - Alcoholism
- Inadequate uptake
  - Malabsorption with sprue and other chronic upper intestinal tract disorders, drugs such as phenytoin and barbiturates, or blind loop syndrome
- Inadequate use
  - Metabolic block caused by drugs, such as methotrexate or trimethoprim
  - Enzymatic deficiency, congenital or acquired
- Increased requirement
  - Pregnancy
  - Increased red blood cell (RBC) turnover: Ineffective erythropoiesis, hemolytic anemia, chronic blood loss
  - Malignant disease: Lymphoproliferative disorders
- Increased excretion or destruction or dialysis

BOX 109.7 Causes of Vitamin B_{12} Deficiency

- Inadequate dietary intake
  - Total vegetarianism: No eggs, milk, or cheese
  - Chronic alcoholism (rare)
- Inadequate absorption
  - Absent, inadequate, or abnormal intrinsic factor, as seen in patients with pernicious anemia and gastrectomy; in pernicious, autoimmune antibodies act against gastric parietal cells and intrinsic factor
  - Abnormal ileum, as can occur in sprue and inflammatory bowel disease
- Inadequate use
  - Enzyme deficiency
  - Abnormal vitamin B_{12}–binding protein
- Increased requirement by increased body metabolism
- Increased excretion or destruction

is the development of subacute combined degeneration of the spinal cord resulting from loss of myelin in the dorsal and lateral columns. The syndrome has a gradual and uniform onset of progressive weakness, spastic paresis, ataxia, and loss of proprioception. Vitamin B_{12} deficiency can also cause elevated homocysteine levels which can lead to thrombosis.[15,16]

Differential Diagnoses

Folic acid, absorbed in the upper jejunum, is commonly found in green vegetables, cereals, and fruit. It may be destroyed completely by cooking. The recommended daily intake is approximately 240 µg/day in adults and 400 µg/day if pregnant or lactating. The body stores 6 to 20 mg.[15] Therefore, a 2- to 4-month body store is available for consumption before megaloblastic changes occur. Causes of folate deficiency are listed in Box 109.6. Most patients with folate deficiency have either an inadequate dietary intake, such as alcoholic patients, or increased use, as in pregnancy.

Vitamin B_{12} is found in foods of animal origin and is absorbed in the terminal ileum after binding to intrinsic factor, which is a glycoprotein secreted by gastric parietal cells. Once absorbed, B_{12} acts as a coenzyme to produce methionine from homocysteine which assists in folic acid conversion to its active form. Therefore, a deficiency in B_{12} can also contribute to folic acid deficiency. The adult requirement of vitamin B_{12} is 1 or 3 µg/day, with a body store of 5 mg. Therefore, megaloblastic changes and clinical problems may take 5 to 10 years to develop after cessation of vitamin B_{12} uptake. The various causes of vitamin B_{12} deficiency are listed in Box 109.7. The most common cause is chronic malabsorption resulting from pernicious anemia.[15]

Megaloblastic anemia that is not responsive to folate or vitamin B_{12} is commonly related to antimetabolites used in chemotherapy or rare inherited disorders of DNA synthesis.

Liver disease, often associated with alcoholism, is the most common cause of non-megaloblastic macrocytic anemia. However, alcoholism can also cause concomitant megaloblastic anemia secondary to poor dietary intake. Thyroid hormone stimulates erythropoietin; thus hypothyroidism is commonly associated with nonmegaloblastic macrocytic anemia as well as normocytic anemia. Drugs can also cause macrocytosis and anemia. Commonly implicated agents include antiretrovirals, phenytoin, chemotherapeutic agents, valproic acid, or azathioprine. Macrocytic target cells may be seen on the peripheral smear in conjunction with this disorder.[15]

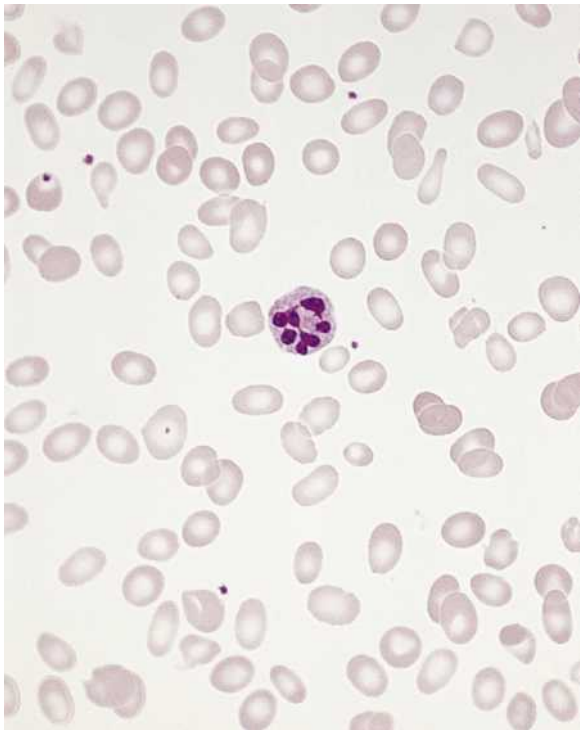

Fig. 109.4 Megaloblastic Anemia With Macrocytic Red Cells and Hypersegmented Polymorphonuclear Neutrophils. (From Hoffbrand AV, Pettite JE. *Color Atlas of Clinical Hematology*. 3rd ed. London: Mosby; 2000:61.)

Diagnostic Testing

Macrocytic anemia is suggested when the MCV is greater than 100 fL, but other criteria need to be met for megaloblastosis to be considered the cause of the macrocytic anemia. On the peripheral smear, large oval red cells (macro-ovalocytes), anisocytosis, hypersegmented polymorphonuclear neutrophils, as well as an elevated serum LDH level are diagnostic (Fig. 109.4). A bone marrow aspirate may reveal morphologic changes consistent with megaloblastic erythropoiesis. Other useful laboratory tests include vitamin B_{12}, folate level, and homocysteine levels. Laboratory techniques, values, and interpretations are listed in Table 109.5.

Management

As one form of deficiency may cause gastrointestinal absorption changes that beget other deficiencies, the clinician may need to initiate

TABLE 109.5 Serum Tests for Diagnosis and Differentiation of Megaloblastic Anemia

Test	Technique	Value	Interpretation
Vitamin B_{12}	Microbiologic or radioisotope	Normal: 300–900 μg/L Deficient: <200 μg/L	Vitamin B_{12} level is usually normal in folate deficiency.
Folate	Microbiologic or radioisotope	Deficient: <3 μg/L	Vitamin B_{12} deficiency may elevate folate levels by blocking transfer of serum folate to RBCs; hemolysis may elevate folate levels.
Lactate dehydrogenase	Spectrophotometric	Normal: 95–200 IU Megaloblastic anemia: 4–50 times normal	Normal in other macrocytic anemias; elevated two to four times normal in hemolytic anemias

RBC, Red blood cell.

therapy before the final diagnosis is made. However, it is important to obtain baseline laboratory specimens.

The usual dosage for patients with megaloblastic anemia secondary to folate deficiency is 1 mg of oral folic acid per day, and it is recommended to follow RBC folate levels to determine effectiveness as well as improvement in clinical symptoms. Parenteral administration is generally unnecessary as most cases are due to dietary deficiency.[15] In contrast, malabsorption is the most common cause of vitamin B_{12} deficiency, and parenteral therapy is initiated at 1000 mcg IM daily for 7 to 10 days, then monthly 1000 mcg IM injections. Weekly 1000 mcg IM doses for 4 weeks in between daily and monthly injections may be considered. If neurologic symptoms are present, therapy is initiated at 1 mg IM every other day for up to three weeks, followed by 1 mg IM weekly for up to twelve weeks. Thereafter, monthly 1 mg IM doses are necessary as needed to maintain B_{12} levels if the underlying cause of deficiency is not treatable. The response is often dramatic with levels of RBC, WBC, and platelets returning to normal within 4 weeks. During hematopoietic recovery, an iron deficiency may develop and should be treated in the usual manner.[15] We do not recommend vitamin B_{12} or folate supplements in patients with undiagnosed anemia. Unfortunately, the routine injection of vitamin B_{12} in the elderly is still a common practice.

Normochromic and Normocytic Anemias

Foundations

A hematologic parameter that can aid in the diagnosis of normocytic anemia associated with hypoproduction is the reticulocyte count, which reflects new RBC bone marrow production. Reticulocytes are released from bone marrow every 1 to 3 days and contain residual RNA that can be detected by supravital staining. With an average MCV of 160 fL, sufficient numbers of reticulocytes can increase the overall MCV of the total erythrocyte count. The reticulocyte count is expressed as a percentage of the total RBC population and needs to be related ("corrected") to the RBC count of the patient. The corrected reticulocyte count is equal to the measured percentage of reticulocytes multiplied by the patient's hematocrit (%), divided by the patient's normal hematocrit for age and gender.[17] The normal range is 1% to 3%.

Normocytic anemias may be classified as hemolytic or nonhemolytic. Nonhemolytic anemias are typically caused by chronic disease states or bone marrow failure, that is, decreased RBC production. Hemolytic anemia is defined by the premature destruction of RBCs.

Clinical Features

Non-hemolytic normocytic anemias include anemia of chronic disease, hypoendocrinism, aplastic anemia, and myelodysplastic or myeloproliferative syndromes.

Anemia of chronic disease may have microcytic or normocytic indices, and is associated with chronic inflammation (e.g., rheumatoid arthritis, chronic infections, or malignancy). The anemia of chronic renal failure is thought to be caused by a number of factors including decreased erythropoietin production, hemolysis, suppression by dialyzable factors, and increased blood loss caused by platelet abnormalities. Correction is with erythropoietin replacement therapy, as necessary.

BOX 109.8 Aplastic Anemia Caused by Drugs or Chemicals

- Chloramphenicol
- Phenylbutazone
- Anticonvulsants
- Insecticides
- Solvents
- Solvents
- Sulfonamides
- Gold
- Benzene

Hypoendocrinism caused by hypothyroidism, hypoadrenalism, or hypopituitarism results in a hypometabolic state in which the bone marrow responds poorly to erythropoietin, and erythropoietin levels may be low resulting in normocytic normochromic anemia.

Aplastic anemia results from destruction of myeloid stem cells leading to pancytopenia. It is suspected in anemic patients with normal indices, a low reticulocyte count, neutropenia, thrombocytopenia, or a history of exposure to certain drugs or chemicals (Box 109.8) which is the cause in 50% of cases. Autoimmune disease, viral hepatitis, radiation exposure, viral illness (Parvovirus B19, HIV, Epstein-Barr virus), and pregnancy have also been associated with aplastic anemia. Infection with Parvovirus B19 can precipitate an aplastic crisis in sickle cell patients and can lead to severe anemia requiring emergent transfusion. Patients can present with symptoms of anemia, however more commonly they present with infections secondary to neutropenia or mucosal bleeding from the accompanying thrombocytopenia. Diagnosis is suspected based on CBC findings, and can be confirmed with bone marrow evaluation. Treatment involves removal of any known causative factor as well as supportive care measures with avoidance of aspirin, effective oral hygiene, and pharmacologic suppression of menses if necessary. Transfusions of RBC or platelets are given in life-threatening circumstances. Bone marrow or peripheral blood stem cell transplantation from a histocompatible sibling can prove to be curative. In patients not amenable to transplantation, immunosuppression with antithymocyte globulin, antilymphocyte globulin, or other cytotoxic chemotherapy may be used. The disease has a wide range of severity, and the overall 5-year survival rate is 30% to 40%. Even with supportive therapy, severe aplastic anemia may prove fatal in up to 80% of patients.

Myelodysplastic syndromes are a class of hematopoietic stem cell disorders that are characterized by cytopenia, myelodysplasia, and ineffective hematopoiesis. It is caused by an accumulation of oncogenic mutations and is associated with an increased risk of progression to leukemic states. It is the cause of anemia in up to 5% of elderly patients. Laboratory evaluation can present with normocytic anemia, thrombocytopenia, and neutropenia. A definitive diagnosis is made by bone marrow examination with evidence of dysplastic cell lines and blast cells.

Treatment is selected based on MDS subtype and age and can range from supportive care to allogeneic hematopoietic stem cell transplantation.[15]

Myeloproliferative neoplasms, specifically primary myelofibrosis, results in primary bone marrow fibrosis and splenomegaly due to extramedullary hematopoiesis, that may ultimately transform to an acute leukemia. The diagnosis is made by bone marrow examination. Treatment is supportive, although a splenectomy or alkylating agents may help treat complications of extramedullary blood cell production, such as hepatosplenomegaly.[18]

Diagnostic Testing

Diagnostic testing in nonhemolytic normocytic anemias consists of a CBC with differential, and additional testing based on presumed underlying cause.

Management

Treatment is based on underlying cause, and in the ED is directed at resuscitation in the event of life-threatening anemia and appropriate admission or outpatient referrals.

Increased Red Blood Cell Destruction

Foundations

Hemolytic anemias are caused by premature RBC destruction. In the appropriate clinical context, this can be defined by evidence of anemia with elevated LDH and decreased Haptoglobin on laboratory evaluation. They can be acute or chronic, with acute hemolytic anemias requiring prompt intervention and management. There are multiple classification systems for describing hemolytic anemias based on Coombs test reactivity, intrinsic versus extrinsic defects, intravascular versus extravascular hemolysis, and congenital or acquired forms.

Pathophysiology

Defined by a shortened life span of the erythrocyte, acute hemolytic anemias can be devastating and require rapid diagnosis and intervention (see Box 109.1). Fortunately, they are relatively rare in comparison to the chronic hemolytic conditions. Chronic disorders may be related to primary blood disorders (e.g., sickle cell anemia) or may be a result of other disease states (e.g., chronic renal failure). These disorders may be manifested as acute hemolytic anemia if the tenuous balance between RBC production and destruction is upset. If the patient can be simultaneously demonstrated to have a normal hematocrit and reticulocyte count, differentiation between acquired and inherited hemolytic anemia is particularly challenging.

Clinical Features

The clinical signs and symptoms of hemolytic anemia are, in general, caused by either intravascular or extravascular processes, and this division assists in the differential diagnostic approach. Emergency physicians should consider hemolysis as a cause of anemia in patients presenting with the typical symptoms of anemia in addition to new-onset jaundice, hematuria, fever, hepatosplenomegaly, abdominal or back pain, or altered mental status.[17,19] A thorough past medical and family history is also critical in the evaluation of hemolytic anemias.

Intravascular hemolysis presents acutely and dramatically due to an acute decrease in oxygen-carrying capacity as the hemolytic process releases free hemoglobin into circulation. Free hemoglobin initially binds to haptoglobin and hemopexin. This complex is transported to the liver, conjugated to bilirubin, then excreted. Once the degree of hemolysis overwhelms the ability of the binding and transport system, free hemoglobin will start to appear in the bloodstream and urine leading to hemoglobinemia and hemoglobinuria, respectively.[17] Jaundice occurs due to excessive bilirubin production, and hemoglobin complexes can cause acute renal failure due to plugging of the microtubules.

The clinical appearance of intravascular hemolysis may vary from mild chronic anemia to severe acute anemia requiring emergent intervention. Mild anemia is commonly caused by mechanical hemolysis from prosthetic valves, or from chronic diseases such as paroxysmal nocturnal hemoglobinuria. Acute severe anemia can be seen with ABO incompatibility, autoimmune hemolytic anemias, infections, DIC, or toxins.

Extravascular hemolysis usually causes mild to moderate anemia, intermittent jaundice, and enlargement of the spleen. It occurs when RBCs are prematurely removed by macrophages in the liver, spleen, or bone marrow due to an abnormality in their shape or the binding of an antibody.[17] Hereditary spherocytosis, glucose-6-phosphate dehydrogenase deficiency (G6PD), sickle cell disease, and some autoimmune hemolytic anemias represent the most common causes of extravascular hemolysis. The signs and symptoms vary with the severity and chronicity of the hemolysis. Splenic blood flow slows as RBCs travel in the sinusoids close to the reticuloendothelial system, which is uniquely designed for removal of older or damaged cells. Once disassembled in the reticuloendothelial cell, hemoglobin is recycled and ultimately converted to bilirubin and subsequently conjugated by the liver. Primary splenic overactivity, antibody-mediated changes, or RBC membrane abnormalities may cause this normal splenic function to increase to a pathologic degree.

Differential Diagnoses

Hemolytic anemias may be classified as (1) congenital or acquired, (2) Coombs positive or Coombs negative, or (3) caused by processes intrinsic or extrinsic to the cell membrane, and the latter classification provides a useful differential diagnosis of hemolysis (Box 109.9).

Intrinsic enzyme defects. Of the membrane-sustaining energy production of the erythrocyte, 85% to 90% is through the anaerobic glycolytic pathway. At least eight known enzyme deficiencies are associated with this pathway. The most common is pyruvate kinase deficiency, which is manifested with hemolytic jaundice that is usually diagnosed in infancy.

The remaining 10% to 15% of RBC glycolysis occurs by way of the hexose monophosphate shunt. This bypass mechanism occurs in the early stages of the glycolytic pathway and generates reduced nicotinamide adenine dinucleotide phosphate (NADPH), which is important in maintaining reduced glutathione. Glutathione is essential in the protection of hemoglobin from oxidant injury. A deficiency of the first enzyme in this pathway, G6PD, is X linked and most common in African Americans or those of Mediterranean descent.[19] G6PD has a wide range of severity which is dependent on the degree of deficiency and the ability of the body to overcome oxidant stress. Clinical

BOX 109.9 Classification of Hemolytic Anemia

Intrinsic

Enzyme defect: Pyruvate kinase deficiency, G6PD deficiency
Membrane abnormality: Spherocytosis, Paroxysmal nocturnal hemoglobinuria
Hemoglobin abnormality: Hemoglobinopathies, Thalassemias (anemias)

Extrinsic

Immunologic: Alloantibodies, autoantibodies
Mechanical: Microangiopathic hemolytic anemia, prosthetic heart valve disease
Environmental: Drugs, toxins, infections, thermal
Abnormal sequestrations

BOX 109.10 Drugs Associated With Hemolysis in G6PD

Analgesics and antipyretics: acetanilid, aspirin, phenacetin
Antimalarials: Primaquine, quinacrine, quinine
Nitrofurantoin
Sulfa drugs: Sulfamethoxazole, sulfacetamide, sulfones
Miscellaneous: Naphthalene, fava beans, methylene blue, phenylhydrazine, nalidixic acid

symptoms present when oxidative hemolysis occurs typically as an acute hemolytic episode that may be both intravascular and extravascular. It occurs 24 to 48 hours after the ingestion of an oxidant drug (Box 109.10) or after acute infections, such as viral hepatitis. The anemia induced by oxidant drugs is dose related. The oxidant creates forms of activated oxygen, such as peroxide, that either denature the hemoglobin or destroy cell membranes. The former process produces Heinz bodies, which are clumps of denatured hemoglobin found in RBCs that are removed by the spleen. The diagnosis is made by enzymatic screening for G6PD, but this test cannot be performed immediately after the hemolytic episode. A 3-week delay avoids a false-negative result caused by a predominance of young cells. Treatment includes supportive care and discontinuation of oxidant drugs.[19]

Intrinsic Membrane Abnormality

These abnormalities are manifested in a number of ways. An altered shape is the main feature of autosomal dominant hereditary spherocytosis. It is caused by mutations in genes encoding the cytoskeleton of the RBC membrane resulting in spherically shaped, rigid RBCs that are susceptible to premature destruction by the spleen.[20] Clinical sequelae range from compensated asymptomatic anemia to severe life-threatening acquired aplastic crises. The diagnosis is made by reviewing the family history, RBC indices (increased MCHC and RDW), blood smear, and osmotic fragility testing. Treatment is supportive in mild cases. Splenectomy is the treatment of choice for patients with severe disease requiring therapeutic intervention, and usually results in disappearance of anemia with a median increase in hemoglobin by 3g/dL.[20] Due to the complications associated with splenectomy, if possible, it is delayed until the age of 6 years or older.

Paroxysmal nocturnal hemoglobinemia is a stem cell defect causing abnormal erythrocyte, neutrophil, and platelet sensitivity to complement. It is most often seen clinically as chronic hemolysis, hemosiderinuria, leukopenia, and thrombocytopenia. The peripheral smear is normal, and the direct Coombs test result is negative. Its major complication is thrombosis, with a predilection for the hepatic vein. Normal activation of complement with the use of sucrose or acid hemolysis (the Ham test) is diagnostic. Treatment is with supportive care and Eculizumab, a complement inhibitor that has been shown to improve RBC indices and clinical symptoms.[21] Transfusion can be life-threatening in patients with this disease as RBC lysis is caused by donor complement. Thus, only washed packed cells should be utilized. Treatment varies based on disease severity.

Intrinsic Hemoglobin Abnormality

More than 350 types of abnormal hemoglobin have been documented. Problems that may be seen include unstable hemoglobins that appear as Heinz body–positive anemia, M hemoglobins that fix iron in its ferric or methemoglobin state, or hemoglobins with increased oxygen affinity that result in tissue hypoxia and erythrocytosis.

BOX 109.11 Diseases Associated With Autoimmune Hemolytic Anemia

Neoplasms
Malignant: Chronic lymphocytic leukemia, lymphoma, myeloma, thymoma, chronic myeloid leukemia
Benign: Ovarian teratoma, dermoid cyst

Collagen Vascular Disease
Systemic lupus erythematosus
Periarteritis nodosa
Rheumatoid arthritis

Infections
Mycoplasma
Syphilis
Malaria
Bartonella
Virus: Mononucleosis, hepatitis, influenza, coxsackievirus, cytomegalovirus

Miscellaneous
Thyroid disorders, ulcerative colitis
Drug immune reactions

Extrinsic Alloantibodies

Alloantibodies are formed in response to foreign RBC antigens. In the case of the ABO system, these antibodies are preformed and ABO incompatibility resulting in donor cell destruction by the recipient's alloantibodies can be life-threatening. These immunoglobulin M (IgM) antibodies can act as a hemolysin, both agglutinating RBCs, fixing complement, and consequently causing intravascular hemolysis.

The Rh system is another set of antigens on the RBC. Individuals do not have antibodies that correspond to antigens in the Rh system unless they have been sensitized by previous exposure to antigens that they lack. The antibodies produced are IgG in nature, and they accelerate extravascular destruction of RBCs by the spleen and liver. Most autoimmune antibodies are directed toward antigens in the Rh system.

Extrinsic Autoantibodies

Evaluation of autoimmune hemolytic anemia (AIHA) is as complex as its origin, caused by autoantibody-mediated destruction against RBC surface antigens. Autoimmune hemolytic anemias are acquired disorders, with 40% to 50% remaining idiopathic. The remainder are associated with a number of diseases (Box 109.11). A sub-classification of autoimmune hemolytic anemias is based on the optimal temperature at which the antibody reacts with the RBC membrane. Therefore, there are warm-reacting (>37°C) and cold-reacting (<37°C) antibodies. The direct antiglobulin test (DAT) or Coombs test is useful in revealing cells coated with antibody or complement and can aid in diagnosis. A positive DAT alone, however, does not define AIHA and must be supported by clinical context and evidence of hemolysis on laboratory evaluation.[22] AIHA can have a varied presentation from compensated hemolysis with mild anemia and no symptoms to severe symptomatic anemia requiring immediate intervention. Splenomegaly, pallor, or jaundice are common exam findings.

Warm-reacting antibodies are characterized by a higher incidence in younger patients, predominance in women, variable complement fixation, and positive direct antiglobulin test result for IgG. IgG binds to either Rh proteins or glycophorins A-D. IgG-coated RBCs are then removed by reticuloendothelial macrophages and sequestered in the spleen for extravascular destruction. Warm agglutinins are common in

systemic lupus erythematosus, common variable immunodeficiency, myasthenia gravis, autoimmune hepatitis, myelodysplastic syndromes, or lymphoma. First-line treatment is supportive with management of the underlying condition, in conjunction with glucocorticoids and rituximab. Second- or third-line treatments include intravenous immunoglobulin (IVIG), plasma exchange, hematopoietic stem cell transplantation, azathioprine, cyclosporine, or mycophenolate. Transfusion of blood products should be used in severe cases as needed. Splenectomy is an alternative treatment option for some patients, and up to 40% achieve complete remission post-operatively.[19,22] Disease course can be relapsing and remitting.

Cold-reacting antibodies, or cold agglutinins, are seen predominantly in men and older patients and with IgM complement fixation. IgM antibodies react with surface antigens at low temperatures and cause intravascular or extravascular hemolysis due to complement fixation and activation upon rewarming. Due to the high density of IgM-antigen complexes on RBC, RBC aggregates can be seen on peripheral blood smear. They may also be found in patients with infectious mononucleosis, *Mycoplasma* infection, or lymphoma. The DAT result is positive for complement. Treatment is largely supportive with folic acid and vitamin B_{12} supplementation if deficient, avoidance of triggers, and underlying disease control.[19,22] Blood transfusions should be utilized when anemia is severe. Thrombosis is a common complication of cold agglutinin disease due to agglutinating RBCs, thus thromboprophylaxis should be considered in patients with acute exacerbations or for chronic disease in high-risk situations (i.e., immobilization, long-flights, etc.).

Drug-induced hemolytic anemia may be difficult to diagnose. It is helpful to recognize the drugs most often associated with this Coombs-positive phenomenon, and realize that the result of this test is sometimes positive only in the drug's presence. Removal of the offending agent is the mainstay of treatment. Common drugs are listed in Box 109.12.[19,22]

Extrinsic Mechanical Causes

Hemolysis may be caused by trauma to RBCs. The peripheral smear may demonstrate schistocytes or fragmented cells (Fig. 109.5). Microangiopathic hemolytic anemia, cardiac trauma, and exercise-induced hemoglobinemia are the most commonly encountered forms of traumatic hemolysis.

Microangiopathic hemolytic anemia is a form of microcirculatory fragmentation by threads of fibrin deposited in the arterioles. An underlying disease may be found in renal lesions, such as malignant hypertension or preeclampsia, vasculitis, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, or vascular anomalies. Signs and symptoms are those of intravascular hemolysis and thrombosis; treatment is supportive and directed at the underlying cause.[17]

Cardiac trauma to RBCs results from increased turbulence. This may be found in patients with prosthetic valves, arteriovenous fistula, aortic stenosis, or other left-sided heart lesions. Surgical correction may be necessary. Supportive therapy with iron is usually required.

March hemoglobinemia is a form of trauma caused by breaking of intravascular RBCs by repetitive pounding. Soldiers, marathon runners, or anyone with repetitive striking against a hard surface may incur this problem. Reassurance and a change in the patient's pattern of activity are the recommended therapies.

Environmental Causes

Hemolysis may be seen in cases of severe burns, freshwater drowning, or hyperthermia. Toxic causes of hemolysis have been documented to be of animal origin, such as brown recluse spider or some venomous snake bites; vegetable origin, such as castor beans or certain mushrooms; and of mineral origin, such as copper. Certain infections are associated with hemolytic states, including malaria, *Bartonella* infection, or *Clostridium* sepsis.

Abnormal Sequestration

Hypersplenism may be caused by any disease that enlarges the spleen or stimulates the reticuloendothelial system. An unfortunate cycle can be established in which the enlarged spleen traps more blood components and grows larger. It is usually apparent clinically as splenomegaly with pancytopenia and marrow hyperactivity. Therapy for symptomatic or severe disease is splenectomy. Adults usually tolerate splenectomy well, though children should be approached conservatively because the risk of postsplenectomy life-threatening sepsis is increased significantly.

Diagnostic Testing

Once hemolysis is suspected, the history and laboratory testing have diagnostic precedence over physical examination. Important historical and physical examination points are listed in Box 109.13. Important diagnostic tests for hemolysis are included in Box 109.14, and the interpretations of the laboratory evaluation of hemolytic anemias is included in Table 109.6. Reticulocyte count should be obtained to evaluate bone marrow response. An elevated reticulocyte count indicates the bone marrow's attempt to increase RBC production and is usually seen in hemolytic anemias due to premature destruction of RBCs.[17] Examination of spun whole blood demonstrates clear serum in myoglobinemia, pink serum with free hemoglobin in the setting of intravascular hemolysis, and yellow serum from increased bilirubin production in the case of extravascular hemolysis. The blood smear is often more diagnostic than bone marrow examination. The typical cell seen in intravascular hemolysis is the schistocyte (see Fig. 109.5). The classic cell of extravascular hemolysis is the spherocyte. It may be seen in congenital spherocytosis, but more commonly indicates splenic activity against an

Fractionated bilirubin level
Direct and indirect Coombs test
Red blood cell (RBC) membrane stability (osmotic fragility)

antibody-coated RBC membrane. An increase in macrocytes reflects the presence of younger cells associated with reticulocytosis. The specific diagnosis may be made by a blood smear, as with sickled cells in sickle cell disease or Heinz bodies in G6PD deficiency.

Haptoglobin binds free hemoglobin on a molecule-for-molecule basis. Its absence implies saturation and degradation after binding with hemoglobin and is an early finding in hemolysis. A haptoglobin of less than 25mg/dL is 95% specific for hemolysis.[22] Haptoglobin is decreased in hepatic failure and increases as an acute-phase reactant. After haptoglobin is bound, hemoglobin binds with hemopexin, transferrin, and albumin before circulating in its free form. Plasma free hemoglobin levels are determined in suspected cases of intravascular hemolysis. The result is considered positive if the level is greater than 40 to 50 mg/dL. Hemoglobin is excreted by the kidney and may appear as a smoky red pigment that is orthotoluidine positive with no associated RBCs. Prussian blue–staining granules of hemosiderin may be found intracellularly in renal tubule cells excreted in urine during chronic hemolytic states.

LDH is released when the RBC is broken down peripherally or in the marrow. It is elevated in hemolytic, thalassemic, sideroblastic, or megaloblastic anemias but may also be seen in cases of uremia, heart failure, polycythemia vera, or erythroleukemia.

In extravascular hemolysis, bilirubin is often delivered to the liver faster than the conjugating mechanism can handle it, leading to an indirect or unconjugated hyperbilirubinemia. Normal total levels are less than 1.5 mg/dL, with an indirect component less than 0.5 mg/dL. Indirect bilirubin may rise as high as 4 or 5 mg/dL even with normal liver function. Higher levels connote some degree of underlying hepatic insufficiency.[17]

The DAT (Coombs) test detects antibody or complement on human RBC membranes by adding a polyspecific antihuman globulin reagent which will detect IgG, IgA, IgM, and complement. It is used in the evaluation of AIHA. The reaction causes an agglutination of RBCs that

TABLE 109.6 Laboratory Evaluation of Hemolytic Anemias

Extravascular Destruction	Lactate Dehydrogenase	Haptoglobin	Reticulocyte Count	Coombs Test	Peripheral Smear
Congenital Red Blood Cell Defects					
Enzyme defects (e.g., G6PD)	↑	↓	↑	Negative	"Bite" cells
Hemoglobinopathies (sickle cell disease)	↑	↓	↑	Negative	Sickle cells

DIC, Disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *HUS,* hemolytic uremia syndrome; *RBC,* red blood cell; *TTP,* thrombotic thrombocytopenic purpura.

is graded 0 to 4. Agglutinating properties depend on the size of the immunoglobulin. It can have false negative results if the RBC-bound antibodies are below the threshold of the test or in the presence of low affinity autoantibodies. A false positive DAT can occur after administration of intravenous immunoglobulins or Rh immunoglobulins. It is also important to recognize that a positive DAT can occur without AIHA and can be present in patients that have been recently transfused or have delayed hemolytic transfusion reactions.[22] The indirect test measures antibody titers in serum (cold agglutinin autoimmune hemolytic anemia). The indirect antiglobulin test (IAT) assumes that IgG or C3 is in the serum and tests for serum antibody activity against RBCs. Test RBCs are first mixed with patient serum, washed, and then incubated with polyspecific antihuman globulin reagent. Agglutination will occur if serum antibodies directed toward RBCs are present. Positive tests for immunologic markers do not correlate agglutination activity with the severity of hemolysis.[22]

Management. In patients with newly diagnosed reticulocytopenia or severe hemolytic anemia, the emergency clinician may need to institute rapid transfusion therapy. Compatible blood may be almost impossible to find as the antibody can react with almost all donors. The most compatible donor cells in terms of the ABO and Rh systems should be transfused with the knowledge that they will be no more compatible than the patient's own blood cells. If emergency blood transfusion is required, type-specific or type O blood (Rh-positive for men; Rh-negative for women of childbearing age) is indicated, as well as prednisone or its equivalent in a dose of 1 mg/kg to assist with slowing the rate of hemolysis. During transfusion, patients should be closely monitored for signs of hemolytic transfusion reactions. Death commonly results from uncontrolled hemolysis, infection, the underlying primary disorder, or pulmonary embolism.[17]

Sickle Cell Disease

Foundations

Sickle cell disease is an inherited autosomal recessive mutation that produces an abnormal hemoglobin known as HbS. It affects approximately 100,000 people in the United States, and an estimated 2 million Americans carry the sickle cell trait.[23,24] It is predominantly found in the African American population, however up to 10% of patients with various sickling disorders are not ethnically African American, includes people of Mediterranean, Indian, or Middle Eastern descent.[23,25]

The globin in hemoglobin is made up of two pairs of identical polypeptide globin chains. Each person has two non–sex-linked gene foci for β-globin chains, one from each parent. Six different types of hemoglobin from varying globin chain combinations are expressed: three embryonic hemoglobins, HbA (α2β2), HbA2 (α2δ2), and HbF (α2γ2, fetal hemoglobin). Embryonic hemoglobins are expressed only in utero, and after 6 months of age, HbA typically accounts for more than 95% of hemoglobin. The sickle syndromes result from mutations in the β-globin gene. Instead of HbA (α2β2), an abnormal hemoglobin, HbS, is produced. Embryonic and fetal hemoglobin do not contain β-globin; thus, there are no clinical manifestations in early infancy. As production declines, and normal HbA (α2β2) decreases, symptoms develop.

HbS is formed when an abnormal allele at the gene loci for the hemoglobin beta chain produces altered messenger RNA, which in turn results in replacement of glutamic acid by valine at the sixth position from the N-terminal end of the beta chain. When subjected to deoxygenation or various stressors, the RBC sickles and becomes a rigid, adhesive cell that is less deformable and prone to lysis. Sickled cells increase the viscosity and sludging tendency of blood, and ultimately undergo sequestration in the spleen and liver.[25,26] The clinical complex of vaso-occlusive events, chronic hemolysis, thrombosis, and organ injury is derived from this pathologic process.

In sickle cell trait (HbAS), the patient is heterozygous and only one parent contributes the abnormal S allele. In each cell, approximately 40% of the hemoglobin is HbS. Patients usually have a benign and asymptomatic clinical course. Sickle cell disease (HbSS) is homozygous, more than 85% of the hemoglobin is HbS, and it is associated with severe disease.[25] Because a parent may contribute alleles other than S, a wide number of variants can exist. Patients with HbSS are also subject to other causes of anemia such as iron deficiency, G6PD, or megaloblastic anemias. Two clinically important S variants are sickle cell–β-thalassemia and sickle cell–hemoglobin C disease.

The diagnosis is usually made after newborn sickle cell screening via hemoglobin electrophoresis. Most individuals with sickle cell trait are asymptomatic but can present with spontaneous hematuria, renal papillary necrosis, splenic infarction, pulmonary embolism, traumatic hyphema, exertional rhabdomyolysis, or exertional sudden death. In stark contrast to sickle cell disease, which is associated with increased maternal mortality and stillbirth, recent literature suggests that pregnancy in women with sickle cell trait is not associated with an increased risk of adverse events.[27]

Clinical Features

Sickle cell disease is characterized by two major clinical features, hemolysis and acute vaso-occlusive events. The hallmark manifestation of sickle cell disease and the most common reason for ED visits is painful vaso-occlusive crises.[25] Potential precipitating factors include antecedent infection, cold exposure, or stress such as trauma. A painful crisis is believed to have its origin in tissue ischemia which furthers irreversible sickling of cells, leading to increased viscosity, sludging, and microvascular obstruction. Sludging and vascular blockage cause stasis, deoxygenation, and local acidosis, which promotes continued sickling. Pain is caused by activation of nociceptors as inflammatory mediators are released in response to vascular damage. The pain is commonly deep and aching, and is most often found in the abdomen, chest, back, or extremities.[25,26,28] The disease may mimic an acute abdomen, pulmonary embolus, renal colic, or other painful condition. A directed history that relates this pain pattern to previous sickling episodes, a careful repeated physical examination, and specific organ-related laboratory tests can be used to differentiate "uncomplicated" crises from another serious pathologic condition. Children may be seen more often with skeletal crises, especially in the hips and lower extremities, leading to bone deformities. In these cases, osteomyelitis, avascular necrosis, and bone infarct needs to be differentiated. Acute pain crisis is treated with analgesia, including opioids and nonsteroidal anti-inflammatories, and intravenous hydration. Pain control adjuvants should be considered and include sedatives, anxiolytics, or antihistamines. If pain control is able to be achieved in the ED, patients can typically be discharged on an oral pain control regimen, otherwise, hospitalization may be required for further management.[23,28]

Neurologic complications include transient ischemic attack, cerebral infarction, intracranial hemorrhage, spinal cord infarction, or vestibular and hearing problems. Patients presenting with the sudden onset of acute neurologic abnormalities should be presumed to have a stroke until proven otherwise, typically necessitating prompt imaging. Risk factors for CVA in sickle cell patients include low hemoglobin level, history of acute chest syndrome, or history of hypertension.[23,25] Transcranial Doppler (TCD) is useful in children to identify those at highest risk of developing stroke by measuring the maximum time-averaged mean velocity of blood flow in the intracranial arteries.[25,28] TCD combined with brain MRI can be used in adults to assess stroke risk. The use of regular blood transfusions can reduce the risk of cerebrovascular events in selected patients. In the setting of an acute stroke, exchange transfusion is often recommended with the goal of

hemoglobin S of less than 30% and a total hemoglobin level of 10 g/dL.[23,25] Tissue plasminogen activator (tPA) should be considered in adult sickle cell disease patients with acute non-hemorrhagic strokes, although extreme caution is advised due to increased risk of intracranial hemorrhage.[23]

Acute chest syndrome is the most common pulmonary condition associated with sickle cell disease, and one of the most common causes of death.[23,25] Patients with acute chest syndrome often have fever, cough, hypoxia, chest pain, dyspnea, or new infiltrates on chest radiograph. The pathophysiologic mechanism of the syndrome is not well understood and is postulated to be related to pulmonary microvascular sludging, infarction of pulmonary parenchyma, and bone marrow fat embolization from infarcted bone. Macrovascular pulmonary embolism and infection may also have a pathogenic role. Acute chest syndrome is commonly associated with infection, including *Mycoplasma* or *Chlamydia* species. The differential includes pneumonia, pulmonary embolism, congestive heart failure, fat embolism, or adult respiratory distress syndrome. Management consists of hydration, analgesia, maintenance of adequate oxygenation and ventilation, and empiric antibiotics with a parenteral cephalosporin, such as ceftriaxone 1 to 2g (50 mg/kg) IV daily, and a macrolide, such as azithromycin 500 mg (10 mg/kg) IV daily.[23,25] Exchange blood transfusions should be considered in patients with multi-lobe involvement, persistent or worsening hypoxemia, neurologic abnormalities, or multi-organ failure.[28] However, there are no randomized controlled studies demonstrating an improvement in outcome with exchange transfusions. Acute chest syndrome can rapidly progress to acute respiratory distress syndrome due to pulmonary sequestration or infarct, and typically requires mechanical ventilation. Long-term complications include pulmonary fibrosis, pulmonary hypertension, and cor pulmonale.[23]

Sickle cell disease is a chronic hemolytic state, often with reasonably compensated hematocrit values in the 20% to 30% range and elevated reticulocyte counts. This compensated balance may be disrupted by iron deficiency or, more commonly, by folate deficiency. A potentially life-threatening aplastic crisis may be seen as a result of suppression of erythropoiesis by an acute post-infectious condition (e.g., Parvovirus B19) or folate deficiency. Aplastic crisis is suspected when the hemoglobin level falls 2 g/dL or more from previous stable levels and the reticulocyte count is low (<2%).

Children may have an acute splenic sequestration syndrome or can develop splenic auto-infarction. This commonly occurs between 10 and 27 months of age. Acute splenic sequestration syndrome involves acute splenic enlargement from increased intrasplenic sickling and obstruction. Rapid sequestration results in a rapidly falling RBC count and circulatory collapse.[28] A Hb drop by greater than 4 g/dL is associated with 35% mortality in the pediatric population.[23] Emergency management is aimed at restoring circulating blood volume with transfusion. Splenectomy is curative, although asplenia results in an increased risk of infection with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. Autosplenectomy occurs as a result of occlusion of the splenic artery, leading to infarction and functional asplenia.[23,25]

Bacterial infections are common due to functional asplenia, and may result in life threatening pneumonia, sepsis, or meningitis, especially in infancy or childhood. Pneumococcal vaccination has dramatically reduced the incidence of invasive pneumococcal disease in sickle cell patients and is a mainstay of preventative therapy, in addition to *H. influenza* type b and meningococcal vaccination series. Prophylactic daily antibiotics, with either amoxicillin or penicillin, are usually required for all children 2 months to 5 years old with functional asplenia.[23,25] A WBC count, blood cultures, urine cultures, and a chest radiograph should be considered in the evaluation of a febrile patient with sickle cell disease. Early institution of appropriate antibiotics, such as ceftriaxone 1 to 2 g IV or IM with consideration for vancomycin 15 mg/kg IV, is necessary in patients with a discernible source of infection or sepsis. An increased incidence of *Salmonella* osteomyelitis occurs in sickle cell patients and should be considered in the differential. The origin of immunologic deficiency in sickle cell disease is believed to be multifactorial, involving functional asplenia leading to increased infection risk with encapsulated organisms, poorly migrating neutrophils, and decreased opsonin production.

TABLE 109.7 Organ Damage Seen in Sickle Cell Disease

Organ or System	Injury
Skin	Stasis ulcer
Central nervous system	Cerebrovascular accident
Eye	Retinal hemorrhage, retinopathy
Cardiac	Congestive heart failure
Pulmonary	Intrapulmonary shunting, pulmonary hypertension, embolism, infarct, infection
Vascular	Occlusive phenomenon at any site
Liver	Hepatic infarct, hepatitis resulting from transfusion, hepatic sequestration, intrahepatic cholestasis
Gallbladder	Increased incidence of bilirubin gallstones caused by hemolysis
Spleen	Acute sequestration
Urinary	Hyposthenuria, hematuria, glomerulosclerosis, end-stage renal disease
Genital	Decreased fertility, impotence, priapism
Skeletal	Bone infarcts, osteomyelitis, aseptic necrosis
Placenta	Insufficiency with fetal wastage
Leukocytes	Relative immunodeficiency
Erythrocytes	Chronic hemolysis

Major, chronic organ damage in patients with sickle cell anemia is common (Table 109.7). Severe, life threatening multi-organ failure can also occur acutely due to sudden vaso-occlusion in the lungs, liver, or kidneys presenting as abrupt hemodynamic compromise.[23] Acute chest syndrome, sepsis, and multiorgan failure are the leading causes of death in HbSS.

Differential Diagnoses

Sickle cell–β-thalassemia disease is seen most commonly in those of Mediterranean descent. The severity of the disease is related to the concentration of HbS in RBCs, and the decrease in MCHC. It should be considered in a patient with a low MCV and a positive response on sickle preparation. The peripheral smear demonstrates a combination of sickled cells and normocytic target cells. It is generally a milder form than homozygous HbSS, though can also be severe.

HbSC accounts for 30% of the sickle cell disease in the United States and United Kingdom. HbSC results from co-inheritance of HbS and HbC beta globin gene mutations. HbC defect occurs due to a glutamic acid to lysine mutation at position six on the beta chain. Patients with HbSC disease have higher mean Hb and lower absolute reticulocyte counts. RBC lifespan is twice that of HbSS. Anemia in HbSC is mild, and both target cells and sickle cells are seen on peripheral smear. It is considered to be a milder variant, though may be associated with all of the typical HbSS complications as well as an increased incidence of retinopathy.[29]

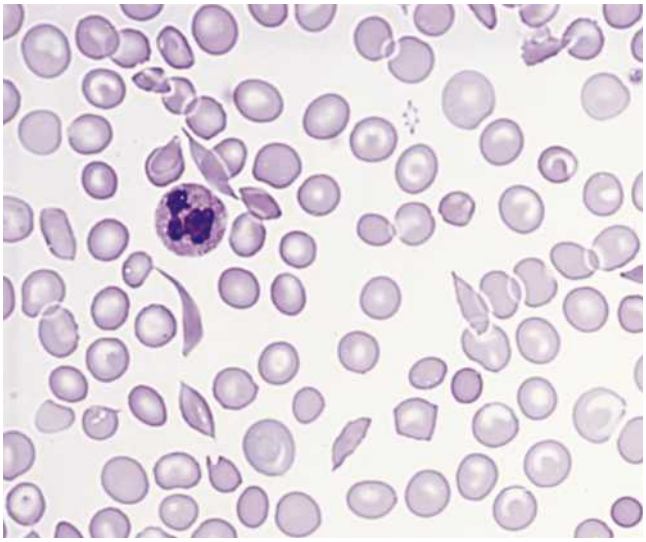

Fig. 109.6 Sickle Cells. (From Hoffbrand AV, Pettite JE. *Color Atlas of Clinical Hematology*. 3rd ed. London: Mosby; 2000:103.)

Diagnostic Testing

The initial diagnosis of sickle cell disease is usually performed via hemoglobin electrophoresis in the neonatal period as a screening test in at risk populations, or at the onset of symptoms. Patients with known or suspected sickle cell disease presenting to the ED should have a complete blood count with differential performed and compared with those of previous visits. A reticulocyte count is recommended whenever the patient's hemoglobin level has decreased by 2 g/dL from baseline. In sickle cell disease, the typical absolute reticulocyte count is three or four times the upper limit of normal. A reticulocyte count 3% or lower than the patient's usual value may suggest an aplastic crisis. A reticulocyte count greater than 12%, particularly if it is accompanied by numerous nucleated RBCs, may indicate rapid hemolysis. Unfortunately, no test is available that detects whether a patient is in a crisis, and the diagnosis is based largely on clinical presentation. In undiagnosed cases, the peripheral smear may show sickled cells (Fig. 109.6), but the definitive diagnosis of sickle cell disease is confirmed by hemoglobin electrophoresis.

Management

Current therapies, including rest, adequate nutrition, hydration, oxygenation, analgesia, transfusion, and therapy for infection, are directed toward symptomatic relief and attempts to interrupt the cycle of deoxygenated sickling and intravascular sludging. Although the use of supplemental oxygen may have some theoretical advantages, it has not been shown to reduce opioid use or hospitalization in patients that are not hypoxic.

Analgesia is a major benefit and essential early therapy for acute sickle cell vaso-occlusive crises. Many emergency clinicians caring for large populations of sickle cell patients have developed protocols to establish better physician-patient rapport, and to lessen the potential for narcotic addiction or manipulation. The following is a protocol for severe pain in adults and children weighing more than 50 kg: patients are evaluated, treated with oxygen and hydration, and given intravenous morphine sulfate, 5 to 10 mg every 2 to 4 hours, or intravenous hydromorphone, 1.5 mg every 3 to 4 hours. For children weighing less than 50 kg, intravenous bolus doses of morphine sulfate, 0.1 to 0.15 mg/kg, can be given every 2 to 4 hours, or intravenous hydromorphone, 0.015 to 0.020 mg/kg, can be given every 3 to 4 hours. At 4 to 6 hours, the patient is allowed to decide whether pain is appropriately controlled. Outpatient therapy includes 4 to 6 days of an effective oral analgesic. A 40-mg dose of oral morphine sulfate or equivalent is given 1 or 2 hours prior to discharge.[23] A major disadvantage of protocols has been a tendency to treat patients reflexively, rather than carefully considering the potential acute complications of sickle cell disease. A variety of analgesics (nonsteroidal anti-inflammatory drugs, mixed opioid agonist-antagonists, and opioids), dosages, and timing intervals may be selected. As many sickle cell disease patients can have varying degrees of hepatic or renal dysfunction, acetaminophen and nonsteroidal anti-inflammatory drugs should be used with caution. The most important aspect of pain management is a consistent, thorough, and attentive approach that offers true pain relief and helps mitigate potential under treatment.

The antisickling agent hydroxyurea reduces pain crises, the need for blood transfusions, and has reduced mortality.[28] The beneficial effects of hydroxyurea include the induction of fetal hemoglobin and mild myelosuppression. Hydroxyurea can reduce the incidence of acute painful crisis, with the potential to ameliorate chronic organ damage and prolonged survival.[26] However, the effects of hydroxyurea can take weeks to be appreciated, and it is not routinely recommended for acute episodes. Dosing of hydroxyurea should be titrated up to the maximum tolerated dose, usually ranging from 20 to 25 mg/kg/day PO.[26]

RBC transfusion is a mainstay in treatment, and more than 90% of adults with sickle cell disease have received at least one transfusion in their lifetime. Transfusion can be given acutely for severe acute exacerbation of chronic anemia with evidence of hypoxia or hypoperfusion, acute organ damage, or preoperatively as a prophylactic measure.[25] Acute chest syndrome, stroke, aplastic crisis, or acute splenic sequestration represent conditions that typically necessitate acute exchange transfusion, and the decision to initiate should be made in consultation with a hematologist. Chronic transfusions are indicated as stroke prevention in selected patients, or in those with progressive multisystem organ failure. The overall goal of transfusion therapy for symptomatic anemia is a hemoglobin level no higher than 10 g/dL, and a target HbS < 30%. Asymptomatic patients should not be transfused, regardless of hemoglobin value.

Alloimmunization, delayed hemolytic reactions, infection transmission, or iron overload are a few of the devastating complications that can result from long-term transfusion, thus transfusion needs should be carefully considered. Iron overload is treated in the usual manner with oral iron chelation therapy with deferiprone or deferasirox.[23,25]

Priapism is a painful complication of sickle cell disease that may lead to impotence. First-line therapy for priapism is aspiration of blood from the corpus cavernosum and irrigation with an α-adrenergic agent (e.g., phenylephrine). Urologic surgical management is typically reserved for patients who fail aspiration and irrigation.[23,28]

Stem cell transplantation offers the only current cure for sickle cell disease, and is associated with survival rates greater than 90% if the transplant comes from an HLA-matched, disease-free sibling. Due to the restrictive criteria for transplantation, as well as long-term conditioning regimen toxicities and transplant-related mortality, there is limited use of this modality and it remains unclear which patients will benefit most.[25]

Other agents and experimental therapies are showing promise and may have a future role in treatment, including steroids, statins, heme-oxygenase, Hb affinity modulators, antioxidants, and gene therapy.[24,28]

Disposition

If pain can be controlled, patients with painful crises can often be discharged with analgesics. Hospitalization may be warranted if pain cannot be adequately controlled. Hospitalization is also typically recommended in patients with acute chest syndrome, acute infections,

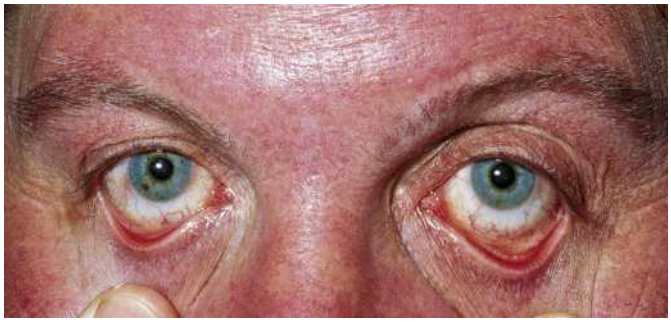

Fig. 109.7 Polycythemia Vera. Facial plethora and conjunctival suffusion in a 40-year-old woman (hemoglobin, 19.5 g/dL). (From Hoffbrand AV, Pettite JE. *Color Atlas of Clinical Hematology*. 3rd ed. London: Mosby; 2000:248.)

acute osteomyelitis, acute stroke, or other complications or disease states requiring further inpatient intervention.

POLYCYTHEMIA

Foundations

Polycythemia is a term commonly used for erythrocytosis (i.e., increased number of RBCs). This disorder is seen occasionally in EM, though rarely requires emergency intervention. An elevated RBC count, usually greater than the hematocrit, defines the disorder. It results in a low MCV, usually related to low serum iron and iron stores.

The major complications of polycythemia are related to the increase in blood viscosity associated with increased RBC numbers. As the hematocrit rises past 60%, viscosity increases in an almost exponential manner, resulting in reduced tissue flow, thrombosis, and hemorrhage.

Clinical Features

Symptoms may range from mild headaches to a fulminant syndrome of hypervolemia (vertigo, dizziness, blurred vision, or headache), hyperviscosity (arterial or venous thrombosis), and platelet dysfunction (epistaxis, spontaneous bruising, or gastrointestinal bleeding).[30]

On examination, the skin and mucous membranes may manifest plethora, engorgement, and venous congestion (Fig. 109.7). Other findings include venous congestion of the optic fundus, splenomegaly, or signs of congestive heart failure.[30] Investigation for uterine, central nervous system, renal, or hepatic tumors should be sought, as such tumors may result in secondary polycythemia.

Differential Diagnosis

Erythrocytosis can be absolute or relative (Box 109.15), and polycythemia is typically classified as primary, secondary, or apparent. Apparent polycythemia is a decrease in plasma volume, and RBC volume does not exceed the upper limit of normal. This is typically seen in the dehydrated patient and is consistent with volume contraction. Treatment is with hydration.

Primary polycythemia vera (PV) is a chronic myeloproliferative neoplasm caused by JAK2 mutations found predominantly in middle-aged or older patients. Initial symptoms are nonspecific and include headache, weakness, dizziness, excessive sweating, plethora, or pruritus after a hot water exposure.[31] The most serious complications include thrombotic episodes (cerebrovascular accident, myocardial infarction, or deep venous thrombosis), bleeding, and risk of leukemic or fibrotic transformation. Primary PV involves all cell lines—hematopoietic stem, erythroid, granulocytic, and megakaryocytic, and presents with elevated hemoglobin and RBC mass, thrombocytosis, and leukocytosis. The diagnostic criteria used by the World Health Organization and revised in 2016 are listed in Box 109.16.[31]

BOX 109.15 Causes of Absolute and Relative Polycythemia

Absolute Erythrocytosis

Right-to-left shunt
Pulmonary disease
Carboxyhemoglobinemia
High-altitude acclimatization
High affinity hemoglobins
Sleep apnea syndrome
Renal disease: focal sclerosing glomerulonephritis, renal transplantation
Tumors: hepatoma, adrenal tumors, meningioma, pheochromocytoma, hemangioblastoma
Drugs: Androgenic steroids, Recombinant erythropoietin
Polycythemia vera

Relative Erythrocytosis

Loss of fluid from vascular space: emesis, diarrhea, diuretics, burns, hypoalbuminemia
Chronic plasma volume contraction: hypoxia, hypertension, tobacco use, ethanol abuse

BOX 109.16 Diagnostic Criteria for Polycythemia Vera[a]

Major Criteria

1. Hemoglobin >16.5 g/dL in men or >16 g/dL in women or hematocrit >49% in men or >48% in women or increased red blood cell mass
2. Bone marrow tri-lineage proliferation with pleomorphic mature megakaryocytes
3. Presence of JAK2 mutation

Minor Criterion

Subnormal serum erythropoietin level

[a] Diagnosis of polycythemia vera requires all three major criteria or two major criteria and minor criterion.

The mainstay of therapy is phlebotomy to a hematocrit of less than 45% to assist in preventing thrombosis. The reduced hematocrit improves some symptoms, though neither leukocytes nor platelet counts are decreased.[30,31] In addition to phlebotomy, once-daily low-dose aspirin (40 to 100 mg PO) is recommended to prevent thrombosis. In patients with high-risk disease (history of thrombosis or >60 years of age), the addition of hydroxyurea is recommended at a dose of 500 mg PO twice daily. If there has been a prior history of arterial thrombosis, aspirin may be dosed twice daily. Venous thrombosis is typically treated with systemic anti-coagulation. In patients intolerant or resistant to hydroxyurea, interferon, busulfan, or ruxolitinib can be considered.[31] Complications necessitating additional therapy include hyperuricemia, refractory increased RBC mass, severe pruritus, excessive splenomegaly, or symptomatic thrombocytosis. Additional therapies may include paroxetine, transexamic acid, pipobroman, allopurinol, low-dose thalidomide, or prednisone. Splenectomy may be warranted in the setting of severe splenomegaly.[30] The natural history of the disease is protracted with survival less than but comparable to the general population. The most common causes of death include thrombosis, or worsening disease resulting from transformation to myelofibrosis or acute leukemia.[32]

Diagnostic Testing

Secondary polycythemia is classified according to appropriate erythropoietin response to abnormal tissue oxygen levels. This group of

disorders may be excluded by normal measured arterial oxygen saturation. Also, inappropriate autonomous erythropoietin production is considered, which can be assessed with an erythropoietin assay. Because of a strong association with renal pathologic conditions and malignancies, computed tomography should be considered to evaluate a patient with a suspected inappropriate erythropoietin response. Patients with secondary polycythemia infrequently have central nervous system symptoms or splenomegaly. As erythropoietin stimulates only the red cell pathway, WBC and platelet counts should be unchanged.

Management

The emergency treatment of symptomatic polycythemia is phlebotomy. A commonly employed approach is to remove approximately 500 mL of blood and replace it with a comparable amount of saline. Hemodynamic compromise should be averted if this procedure is performed slowly. In true emergencies, 1 to 1.5 L of blood may be removed during a 24-hour period. The initial goal is to lower the hematocrit toward 60%; the ultimate goal is a level less than 45%.

Disposition

Selected patients with known polycythemia may be managed by serial outpatient phlebotomies. Newly diagnosed or symptomatic patients should be considered for admission for further diagnostic evaluation.

CHAPTER 109: QUESTIONS AND ANSWERS

1. Anemia with an elevated mean corpuscular volume (MCV) is *not* typically seen with which of the following conditions?
- **a.** Folate deficiency
- **b.** Hypothyroidism
- **c.** Iron deficiency
- **d.** Vitamin B_{12} deficiency

Answer: c. Iron deficiency anemia typically presents as a microcytic anemia. Liver disease may present with either a macrocytic anemia or a normocytic anemia reflecting an anemia caused by multiple mechanisms.

2. An elevated mean corpuscular hemoglobin concentration (MCHC) is expected in which of the following conditions?
- **a.** Anemia of chronic disease
- **b.** Iron-deficiency anemia
- **c.** Sideroblastic anemia
- **d.** Spherocytosis

Answer: d. The MCHC index is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted only in patients with decreased cell membrane area relative to volume, such as spherocytosis.

CHAPTER 109: QUESTIONS AND ANSWERS—cont'd.

3. A 21-year-old man presents with easy fatigue and lack of energy. During a recent clinic visit, he was found to be anemic with a hemoglobin of 8 g/dL, mean corpuscular hemoglobin concentration (MCHC) of 25%, mean corpuscular volume (MCV) of 61 fL, and a peripheral smear remarkable for target cells and basophilic stippling. Serum iron levels were normal. What is the most likely explanation for his anemia?
   a. Iron deficiency
   b. Porphyria
   c. Sideroblastic anemia
   d. Thalassemia

Answer: d. Hypochromic, microcytic anemias with normal serum iron imply thalassemia (a defect in globin chain production). Both alpha- and beta-thalassemia manifest as a hypochromic microcytic anemia with target cells and basophilic stippling. The microcytosis is generally more severe than with iron-deficiency anemia. Sideroblastic anemia generally presents with elevated serum iron.

4. A 73-year-old woman presents with progressive fatigue. Her only past medical history is rheumatoid arthritis for which she takes methotrexate. She has no cardiopulmonary history and does not smoke. Physical examination is remarkable only for bilateral metacarpophalangeal, chronic swelling, and mild splenomegaly. Recent blood tests from the clinic are remarkable for a high normal serum iron, hemoglobin of 10 g/dL, and mean corpuscular volume (MCV) of 69 fL, with peripheral smear showing both microcytes and macrocytes. Which of the following is the most appropriate intervention?
   a. A trial of pyridoxine
   b. Hematology consultation for bone marrow biopsy
   c. Hematology consultation for iron chelation
   d. Send blood for vitamin B_{12} and folate levels

Answer: a. Sideroblastic anemia may be acquired or inherited. It is typically a refractory anemia in the elderly characterized by hypochromia and microcytosis but a dimorphic smear also showing normal cells and macrocytes. Some of these patients are pyridoxine deficient and may respond to a course of vitamin B_6. This anemia is a defect in porphyrin synthesis and is associated with rheumatoid arthritis, cancer, and infections. Lead poisoning is a subset. Elevated iron and ferritin levels are seen because the porphyrin defect does not allow iron incorporation and cells hemolyze in the bone marrow.

5. A 43-year-old woman presents with difficulty walking and complaints of depression that have progressively worsened over several weeks. She has no past medical history, takes no medications, and does not drink alcohol or smoke. Physical examination is remarkable for clinical depression, a spastic gait, decreased extremity proprioception, and lower extremity hyporeflexia. What test should be obtained next in this patient's evaluation?
   a. Complete blood count with differential diagnosis and RBC indices
   b. Lumbar puncture
   c. Magnetic resonance imaging (MRI) of the spine
   d. Serum potassium and calcium levels

Answer: a. Vitamin B_{12} deficiency presents classically with very low hemoglobin levels, a macrocytic picture, decreased proprioception or vibration, lower extremity spasticity/weakness with hyporeflexia, and often mental status changes, such as depression, forgetfulness, or even paranoia. Irritability and forgetfulness are also seen with folate deficiency.

110

White Blood Cell Disorders

Brian L. Springer and Alan A. Dupré

KEY CONCEPTS

- Chronic lymphocytic leukemia (CLL) is the most common leukemia in the elderly, and acute lymphocytic leukemia (ALL) is the most common leukemia in children.
- Splenomegaly is a common finding in leukemias.
- Leukostasis is usually not accompanied by clinical sequelae until the white blood cell (WBC) count is more than 500,000.
- Neutropenia plus a fever should be treated as a potentially life-threatening infection until proven otherwise.
- Infection is the most common cause of neutropenia in children.
- WBC count determination in the emergency department (ED) has poor sensitivity and specificity for any specific disease process.
- Inflammatory markers, absolute neutrophil count, bandemia, or immature granulocyte count may be more useful for identifying infection than the absolute WBC count.

FOUNDATIONS

Background and Importance

The white blood cell (WBC) and accompanying differential count are among the most common laboratory tests ordered in the emergency department (ED) setting. Unfortunately, the WBC count has not proved to be a highly sensitive or specific test, and the absence of leukocytosis does not exclude the presence of significant infection or disease. Acute infection remains the most common nonmalignant cause of leukocytosis. In evaluation of the bacterial infectious potential in febrile children and adults, the WBC and differential counts have demonstrated limited usefulness as stand-alone biomarkers. Other tests, such as procalcitonin and C-reactive protein (CRP), may have more predictive value.[1,2] Thus, the WBC count should be viewed as having limited screening value in the acute care setting. However, when combined with history and physical examination findings, the WBC and differential counts can be of utility in helping determine the presence of acute infection or other processes.[1,3]

Anatomy and Physiology

The WBC (leukocyte) series can be divided into three basic cell types: granulocytes (neutrophils, eosinophils, and basophils), monocytes (nongranulated cells that mature into macrophages), and lymphocytes. WBCs reach their site of action through the circulation. The rate at which new cells enter the circulation is usually in equilibrium with the rate of loss in tissues. The granulocytic series is primarily involved in phagocytic activity. Its origin is the pluripotential stem cells located in the bone marrow. A subset of these cells differentiates and matures into the phagocytic cell lines, which include neutrophils, basophils, and eosinophils. Nongranulated phagocytic monocytes also develop from this same lineage. Granulocytes originate, mature, and are stored in the bone marrow, with a lifespan of days once released into the peripheral circulation. The postmitotic storage pool for neutrophils, which represents 15 to 20 times the circulating population, contains metamyelocytes, band neutrophils, and mature neutrophils (polymorphonuclear neutrophils). The pool can be drawn on as a ready reserve during rapid consumption of granulocytes. Circulating neutrophils are subdivided equally into the circulating neutrophil pool and the marginal pool, consisting of mature cells adherent to the blood vessel walls. During times of physiological stress, the marginal pool can rapidly enter the circulating pool and cause a substantial increase, even doubling, of the WBC count with neutrophilic predominance. This typically resolves within 24 to 48 hours; persistent elevation may be an indicator of leukemia or other malignancy. These patients should be referred to a primary care physician or hematologist for further evaluation.

The lymphocytic series matures in lymphoid tissues located in the bone marrow, thymus, spleen, lymph nodes, or elsewhere. They are involved in the immune response against foreign substances. There are two morphologically indistinguishable lymphocyte cell types: B cells (humoral immunity) and T cells (cellular immunity). Because lymphocytes can freely leave and return to the circulation, the storage pools are less well defined. Only a relatively small number of total body lymphocytes are in circulation at any point in time.

One unique problem in WBC disorders is the wide variability in normal values and the multiple factors influencing them. WBC counts are generally performed automatically by electrical impedance or optical diffraction techniques. Although differential counts are commonly performed by direct examination of 100 to 500 cells with the oil immersion lens of the microscope, automated techniques are becoming more popular. Normal values for the WBC count are listed in Table 110.1. The "normal" count is age dependent and may be shifted upward by exercise, female gender, smoking, or pregnancy. Similarly, certain ethnic populations such as Blacks have a lower total WBC count and neutrophil, with a higher percentage of monocytes and lymphocytes.[4] Laboratory errors may be due to improper sample preparation, nucleated red blood cells (RBCs), or platelet clumping. The blood smear differential count may also be influenced by small sample size, improper cell identification, and age group (children). Differential ranges are listed in Table 110.2. One

common yet easily corrected error in laboratory analysis is reporting of results in terms of the percentage of cell types. Absolute counts for each cell type are more accurate and useful in assessing the risk for infection.

Pathophysiology

Alterations in cell counts are due to changes in production, the marginal pool, or the rate of tissue destruction. The differential diagnosis of increased or decreased WBC counts can be organized by processes impacting production, destruction, loss, or sequestration. Decreased production is caused by suppression of the bone marrow secondary to chemotherapy, radiation therapy, or viral infections. Beta-lactam antibiotics, rheumatoid arthritis, and other autoimmune diseases can destroy neutrophils and reduce the WBC count. Overwhelming bacterial infections can deplete the supply of WBCs faster than the bone marrow can increase production, resulting in net loss. Finally, sequestration may occur secondary to ischemic reperfusion injury, major trauma, or other tissue insults.

Given the spectrum of anticipated values, WBC count determinations should be interpreted in the context of the overall clinical picture. A careful history and physical examination, absolute cell counts, and review of the peripheral smear differential counts are valuable in determining the origins of quantitative WBC disorders.

Leukocytosis, or elevation in WBC count, is most frequently caused by increases in the neutrophil or lymphocyte cell lines. Neutrophilic leukocytosis (neutrophilia) is defined as an absolute neutrophil count greater than 7500 cells/mm^3 and is commonly associated with infection or inflammation (Box 110.1). This is manifested as a "left shift" in the differential count and represents movement of immature neutrophils from the postmitotic pool into the circulation. Because infection or inflammation is also associated with heightened peripheral neutrophil destruction, the proportion of immature (band) to mature neutrophils may increase beyond the baseline ratio of 1 band to 10 mature neutrophils.

WBC counts can also increase through demargination of neutrophils from the vessel walls, which often occurs in response to physiologic stress, endogenous or administered epinephrine, and exercise.[5,6]

Leukopenia is a broad definition that indicates any reduction in the circulating WBCs. The term *leukopenia* is often used interchangeably with *neutropenia*, which specifically refers to a reduction of the neutrophil cell line. Neutropenia is the most clinically significant leukopenia.

By definition, adult neutropenia is defined as an abnormally low absolute neutrophil count (ANC), calculated by multiplying the WBC count by the combined percentage of segmented and band neutrophils. An ANC below 1500 cells/mm^3 is considered mild neutropenia, less than 1000 cells/mm^3 is moderate, and less than 500

TABLE 110.1 Normal Ranges for the Blood Leukocyte Count (cells/mm^3)[a]

Age	Average	95% Range (Average Value ±2 Standard Deviation)
1 week	12,200	5000–21,000
6 months	11,900	6000–17,500
12 months	11,400	6000–17,500
4 years	9100	5500–15,500
8 years	8300	4500–13,500
Adults	7400	4500–11,000

[a]Normal leukocyte count varies with ethnicity, age, gender, smoking, pregnancy, and aerobic exercise.

BOX 110.1 Common Causes of Leukocytosis

Leukocytosis

Primary

Myeloproliferative disorders: Chronic myeloid leukemia (CML), polycythemia vera
Hereditary neutrophilia
Familial myeloproliferative disease
Chronic idiopathic neutrophilia
Leukemoid reaction

Secondary

Infection
Tissue necrosis: Cancer, burns, infarctions
Metabolic disorders: Diabetic ketoacidosis, thyrotoxicosis, uremia
Non-hematologic malignant disease
Physiologic stress: Exercise, pain, surgery, hypoxia, seizures, trauma
Drugs: Epinephrine, corticosteroids, lithium, cocaine
Laboratory error: Automated counters, platelet clumping, precipitated cryoglobulin

Lymphocytosis

Viral infection: Mononucleosis, rubeola, rubella, varicella, toxoplasmosis
Lymphoproliferative: Acute or chronic lymphocytic leukemia (ALL, CLL)
Immunologic response: Immunization, autoimmune diseases, graft rejection

TABLE 110.2 Normal Percentages for the Leukocyte Differential Count in Blood[a]

Age	Segmented Neutrophils	Lymphocytes	Monocytes	Eosinophils
1 week	45% (5500)	41% (5000)	9% (1100)	4% (500)
6 months	32% (3800)	61% (7300)	5% (600)	3% (300)
12 months	31% (3500)	61% (7000)	5% (600)	3% (300)
4 years	42% (3800)	50% (4500)	5% (500)	3% (300)
8 years	53% (4400)	39% (3300)	4% (400)	2% (200)
Adult	59% (4400)	34% (2500)	4% (300)	3% (200)

[a]Numbers in parentheses indicate the average number of cells per cubic millimeter.
Modified from: Lanzkowsky P, Lipton JM, Fish JD. *Lanzkowsky's Manual of Pediatric Hematology and Oncology*. Sixth ed. London: Academic Press; 2016.

cells/mm^3 is severe. Severe neutropenia is a well-known risk factor for increased susceptibility to bacterial infection.

Clinical Features

WBC disorders often present with clinical features characteristic of the underlying cause of the WBC disorder (e.g., characteristics of inciting infection in the setting of leukocytosis). The exception is hyperleukocytosis (WBC >100,000/mm^3) which can result in leukostasis, a syndrome characterized by metabolic abnormalities, coagulopathy, and multiorgan failure.[7] Although any organ system may be affected, symptoms most often arise from involvement of the cerebral, pulmonary, or renal microvasculature. Central nervous system (CNS) signs and symptoms may include headache, confusion, lethargy, dizziness, blurred vision, ataxia, papilledema, and retinal or intracranial hemorrhage. Pulmonary signs and symptoms may include dyspnea, tachypnea, hypoxia, pulmonary infiltrates, or respiratory failure. Mechanical obstruction of the capillaries also commonly results in peripheral vascular occlusion, acute renal failure, or myocardial infarction.

Differential Diagnoses

Leukocytosis can be caused by primary WBC disorders, including myeloproliferative disorders, hereditary leukocytosis, congenital anomalies, or a leukemoid reaction, which is a pronounced leukocytosis associated with acute inflammation or infection that may be mistaken for leukemia. Secondary forms of leukocytosis are more common. Box 110.1 lists common causes of primary or secondary leukocytosis, as well as lymphocytosis.

Diagnostic Testing

A complete blood count (CBC) often identifies the WBC disorder. Coexisting anemia, thrombocytopenia, or thrombocytosis may also have diagnostic significance. For example, the presence of pancytopenia may indicate aplastic anemia and bone marrow failure due to bone marrow neoplastic disease, toxins, chemotherapy or radiation therapy, or an autoimmune disorder. Additional laboratory tests that may aid in the evaluation of a WBC disorder include a peripheral blood smear, sedimentation rate, or CRP. Peripheral blood smears allow the clinician to examine the cells and identify abnormal cell morphology. Elevation of the ESR or CRP may indicate occult infection and guide the emergency physician to initiate antimicrobial treatment. In the setting of hyperleukocytosis, a chest radiograph or neurologic imaging are often indicated, particularly if pulmonary or CNS signs or symptoms are present, respectively.

Automated hematology counters are increasingly able to quantify the number of immature granulocytes (IG) in the peripheral blood stream. IG measurements include granulocyte precursors other than band neutrophils. Elevation of IG may have a role in identifying patients with severe sepsis and other diseases associated with systemic inflammatory response syndrome.[8]

Management

The management of most WBC disorders is related to the underlying disease process. Hyperleukocytosis, however, is a hematologic emergency and efforts should be made to lower the WBC as rapidly as possible. Reduction in the WBC can be achieved with chemotherapy, often hydroxyurea, or leukapheresis. Rapid reduction with chemotherapy may induce the tumor lysis syndrome. Decisions regarding chemotherapy and leukapheresis should be made with a hematologist. Because the presence of pulmonary or CNS clinical features resulting from hyperleukocytosis is associated with a high mortality rate, leukapheresis is often the therapeutic modality of choice.[9]

Disposition

As WBC disorders are most commonly associated with an underlying disease process, patient disposition is dependent on the type and severity of the underlying cause.

SPECIFIC DISORDERS

Chronic Myeloid Leukemia

Foundations

Chronic myeloid leukemia (CML) accounts for approximately 10% to 15% of newly diagnosed adult leukemia, making it the least common of the major leukemias. The vast majority of cases arise from a genetic translocation, resulting in an aberration known as the Philadelphia chromosome. The initiating factor that triggers this somatic mutation remains unknown, but the mutation is found only in affected cells and is not inherited. The resulting peripheral blood smear in the chronic phase is characterized by myeloid cells in all stages of differentiation demonstrating a leukocytosis with immature myelocytes, metamyelocytes, band cells, and mature polymorphonuclear leukocytes (Fig. 110.1). Risk increases with age, with the median age of diagnosis between 57 and 60 years, with a slight male predominance. Overall, rates of diagnosis have remained stable over the last several decades.[10]

Clinical Features

Clinical staging of CML reflects progression through three phases in the absence of effective treatment: chronic, accelerated, and blastic. Symptom onset during the chronic phase tends to be insidious, with up to 50% of patients remaining asymptomatic at the time of diagnosis. Eventually, the abundance of immature cells begins to crowd out and impair the function of normal white and red blood cells, as well as platelets and other elements of the circulatory system. The most common presenting features in those who are symptomatic include GI features such as abdominal pain, decreased appetite, nausea, or early satiety resulting from hepatomegaly and splenomegaly. Significant left upper quadrant pain may result from splenic infarction. Hypermetabolism associated with the disease can result in fatigue, weight loss, diaphoresis, or low-grade fevers. Patients in the accelerated or blastic phase often present with abnormal bleeding and bruising, petechiae, bone pain, or fever. Fever in the late stages often results from opportunistic infection. Hyperleukocytosis and hyperviscosity are uncommon, and the more mature granulocytes seen in CML are less likely to result in leukostasis.

Late problems in the natural history of CML involve progressive loss of cell differentiation or response to therapy. The term *blastic crisis* represents the sudden appearance of an acute form of leukemia, which is rare and associated with poor outcomes.[11] The condition may occur in lymphoid or myeloid forms. Presenting signs and symptoms of blastic crisis are related to leukostasis and bone marrow infiltration and include anemia, abnormal bleeding due to thrombocytopenia, dyspnea, or neurologic symptoms. Prognosis remains poor despite intensive supportive treatment with chemotherapeutic agents.

Differential Diagnoses

The differential diagnoses include a leukemoid reaction or lymphocytic leukocytosis, including CLL or ALL. The initial presentation may be similar to that of CLL or ALL, though patients tend to be older, with WBC counts greater than 50,000 cells/mm^3 in CML. A leukemoid reaction is a nonleukemic reactive leukocytosis that resembles CML. It may be triggered by infection, including *Clostridium difficile* disease, nonhematopoietic neoplasm, or bleeding.[12]

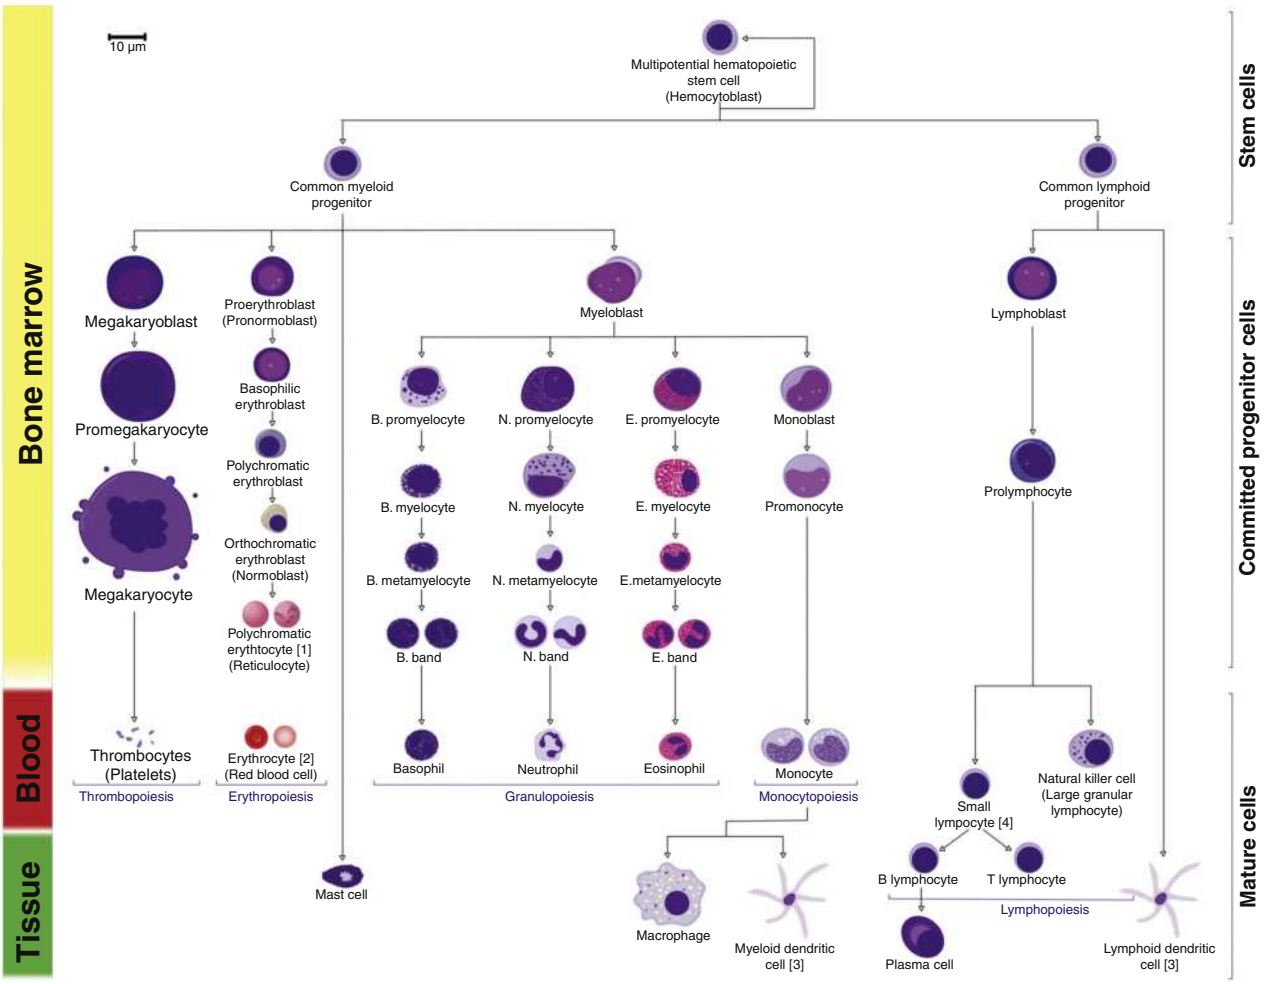

Fig. 110.1 Hematopoiesis, including myeloid and lymphoid cells in all stages of differentiation. Note immature myelocytes, metamyelocytes, band cells, as well as mature polymorphonuclear leukocytes present on the blood smear of patients with chronic myeloid leukemia. (From https://commons.wikimedia.org/wiki/Category:Mikael_Häggström/Medical_diagrams#/media/File:Hematopoiesis_(human)_diagram_en.svg.)

Diagnostic Testing

Associated laboratory abnormalities include a decreased leukocyte alkaline phosphatase and increased vitamin B_{12} levels, neither of which are associated with leukemoid reactions.

Management

Treatment for CML has evolved over the last several years to include the use of tyrosine kinase inhibitors (TKIs) that target the proteins that result from the Philadelphia chromosome genetic anomaly. Overall, survival has improved to the point where life expectancy nears that of the general population.[13] Patients in the accelerated phase may also respond to TKIs, although longer-term response to therapy tends to be limited. Patients in the blast phase may respond to chemotherapy agents targeted towards ALL, although long-term response is rare and palliative therapy may be indicated. Stem cell transplant, once a hallmark of treatment for CML, is rarely performed in the era of TKIs, though may be considered in young patients and in the setting of an accelerated or blast phase, or nonresponse to TKIs.

The need for urgent therapy in CML is usually related to hyperuricemia and renal injury, or severe anemia and subsequent angina or heart failure. Given the comparatively more mature, "less sticky" cells seen in CML, hyperleukocytosis rarely occurs unless WBC counts exceed 500,000 cells/mm^3. A higher cell count may cause leukostasis and result in deafness, visual impairment, pulmonary ventilation-perfusion abnormalities, or priapism. Treatment includes hydration, leukapheresis, allopurinol to prevent severe hyperuricemia, and specific chemotherapy. Given the risk of increased blood viscosity, red blood cell transfusion should be reserved for symptomatic anemia.[9]

Disposition

Asymptomatic patients should be promptly referred to an oncologist. Patients requiring urgent treatment for symptomatic anemia, leukostasis, or blast crisis will require hospitalization for emergent treatment, guided by oncology consultation.

Lymphocytic Leukocytosis

Foundations

The definition of lymphocytic leukocytosis (lymphocytosis) varies by age: greater than 9000 cells/mm^3 for ages 1 to 6 years, greater than 7000 cells/mm^3 for ages 7 to 16 years, and greater than 5000 cells/mm^3 for adults. It is seen in a variety of disorders, primarily infections or lymphoproliferative disease. The terms *acute* or *chronic* are currently utilized to describe the cell maturity, rapidity of onset, and aggressiveness of therapy. Chronic lymphocytic leukemia (CLL) is the most common

type of leukemia seen in individuals aged 50 years or older, and the most common leukemia seen in Western countries. The median age of diagnosis is 72 years. It is primarily a B-cell disorder, initiated by genomic alterations that impair apoptosis of clonal B cells. The disease is characterized by an accumulation of mature B lymphocytes in the peripheral circulation, bone marrow, lymph nodes, and spleen. The risk of developing CLL increases with age.[14]

Acute lymphocytic leukemia (ALL) is the most common cancer diagnosed in children. Like CLL, it is a clonal disease of the bone marrow, in this case characterized by proliferation of B-cell or T-cell precursors that ultimately crowd out and impair the development of other normal marrow elements. This results in anemia, neutropenia, and thrombocytopenia. Lymphoblasts outside the marrow result in lymphadenopathy, splenomegaly, or hepatomegaly. In pediatric ALL, an acquired or inborn genetic mutation creates susceptibility to the disease. It is theorized that a subsequent infection, toxin exposure, or other immune insult triggers further mutations that activates the disease process.[15] ALL is less common in older adults. The etiology of ALL in adults is less well understood and is related to genetic alterations that result in proliferation of lymphocyte precursors.[16]

Clinical Features

CLL is associated with a heterogenous presentation and clinical course. Patients are most often diagnosed after incidental findings such as an abnormal WBC count, enlarged lymph nodes, a palpable spleen, or an enlarged liver. Lymphadenopathy is common and seen in more than half of CLL patients at diagnosis, while splenomegaly is found in almost half. The most common symptoms are reflective of lymphocytic proliferation affecting other bone marrow cell lines and include fatigue and malaise, weight loss, decreased appetite, or decreased exercise tolerance. Signs include pallor, petechia, purpura, or other abnormal bleeding. Increased susceptibility to infection may be seen. The majority of patients follow an indolent clinical course, requiring either no treatment or delayed treatment once the disease becomes symptomatic. Rarely, patients experience aggressive early disease necessitating treatment and associated with recurrent relapses. The majority of patients have survival rates of 5 to 10 years, with increasing survival attributable to improvements in immunotherapy and chemotherapy.[17]

Although the symptoms commonly associated with ALL are nonspecific, persistence of symptoms may prompt further evaluation, particularly in the nonemergency setting. The potential for leukostasis increases in ALL when the blast count rises above 50,000 cells/mm^3.

Diagnostic Testing

The CBC may demonstrate a preponderance of B lymphocytes, with an absolute lymphocyte count greater than 5000 cells/mm^3 in adults. The diagnosis of CLL is confirmed when these B cells are determined to be monoclonal, either through flow cytometry or molecular assays.[18]

Abnormalities in ALL include anemia or thrombocytopenia. The WBC count may be normal, low or elevated, though the WBC differential will typically show diminished neutrophils at the expense of an increased percentage of lymphocytes. Definitive diagnosis is made through bone marrow aspiration and biopsy demonstrating proliferation of lymphoblasts. Immune and genetic testing help identify the disease subtype and specific cytogenetic-molecular abnormalities that may guide targeted therapy in order to improve survival.[19]

Management

Patients with CLL require treatment once they become significantly symptomatic. Progressive anemia or thrombocytopenia, symptomatic splenomegaly or lymphadenopathy, or rapid increase in lymphocytosis are indications for initiating treatment. Several treatment options exist, with multiple regimens of chemotherapy agents and monoclonal antibodies that may either be used as monotherapy or in various combinations. In patients aged 65 years or younger, combination chemoimmunotherapy is used and may have curative potential. Allogenic stem cell transplantation remains an option for high-risk patients, but is used less with the current availability of novel agents.[20] Hyperleukocytosis and leukostasis are rarely seen as complications of CLL, but when present warrant leuko-reduction via leukapheresis.

Multiagent chemotherapy regimens are effective in children, with complete remission seen in over 90% of patients. Adult ALL has a much poorer prognosis, with complete remission rates of only 20% to 40%. This is largely driven by intolerance to standard-dose chemotherapy regimens and high rates of myelosuppression-related complications and mortality.[16] The additions of tyrosine kinase inhibitors, monoclonal antibodies, and targeted immune therapies as treatment options appear to be improving remission and survival rates and are better tolerated by the elderly.[21] Adult patients who respond to initial chemotherapy were traditionally offered allogenic bone marrow transplant, though novel targeted and immune therapies lead to questions regarding the necessity of transplantation. Patient age, comorbidities, disease subtype, and genetics, as well as response to therapy all factor into decision making regarding transplant therapy.[22]

Leukopenia

Foundations

Leukopenia is a broad definition that indicates any reduction in the circulating WBCs. The term *leukopenia* is often used interchangeably with *neutropenia*, which specifically refers to a reduction of the neutrophil cell line. Neutropenia is the most clinically significant leukopenia.

By definition, adult neutropenia is defined as an abnormally low absolute neutrophil count (ANC), calculated by multiplying the WBC count by the combined percentage of segmented and band neutrophils. An ANC below 1500 cells/mm^3 is considered mild neutropenia, less than 1000 cells/mm^3 is moderate, and less than 500 cells/mm^3 is severe. Severe neutropenia is a well-known risk factor for increased susceptibility to bacterial infection.

Neutropenia may be caused by decreased production, impaired maturation, movement of circulating neutrophils into marginal or tissue pools, increased destruction, or artificially by laboratory error (Table 110.3). Neutropenia increases susceptibility to overwhelming infection. Infectious disease or drug-mediated reactions commonly cause neutropenia in adults. Common infectious etiologies include HIV, EBV, hepatitis, parasitic infections such as malaria, or bacterial sepsis.[23] Medications may cause an immune-mediated neutropenia by forming immune complexes or inducing antibody formation that destroys granulocytes, or by direct cytotoxic effects on the marrow stem cells or neutrophil precursors. Among cancer patients of all ages, treatment-associated neutropenia secondary to cytotoxic chemotherapy is the most common dose-limiting complication.[24] In children, the most common cause of acquired neutropenia is viral infection, followed by medications and autoimmune neutropenia. In healthy children, neutropenia typically resolves in step with resolution of viremia.

Clinical Features. Signs and symptoms of neutropenia are nonspecific and may include fatigue, sweats, or weight loss. Due to the body's inability to mount a substantial inflammatory or purulent response, symptoms of serious bacterial infection in neutropenic patients may be minimal or absent. The clinician should ask patients

TABLE 110.3 Linkage of Leukopenia to Phases of Neutrophil Maturation

Mechanism	Example
Proliferation in bone marrow	Aplastic anemia, leukemia, cancer chemotherapy (cyclophosphamide, azathioprine, methotrexate, chlorambucil) Drugs: Phenothiazines, phenylbutazone, indomethacin, propylthiouracil, phenytoin, cimetidine, semisynthetic penicillins, sulfonamides Infection: Viral, tuberculosis, sepsis
Maturation in bone marrow	Folate or vitamin B_{12} deficiency, chronic idiopathic neutropenia Starvation
Distribution	Hypersplenism: Sarcoidosis, portal hypertension, malaria
Increased use	Infection: Viral most common (mononucleosis, rubella, rubeola), *Rickettsia* organisms, overwhelming bacterial infection Autoimmune disease: Systemic lupus erythematosus, AIDS, Felty syndrome
Laboratory error	Leukocyte clumping, long delay in performing test

AIDS, Acquired immunodeficiency syndrome.

found to be neutropenic about their medication list, a personal or family history of neutropenia, as well as recent suspected infections or other illnesses. The physical examination is directed toward sites of infection, lymphadenopathy, hepatosplenomegaly, or underlying disease.

Diagnostic Testing and Management. Neutropenic fever, defined as a single oral temperature greater than or equal to 101°F (38.3°C) in a neutropenic patient, or greater than or equal to 100.4°F (38°C) for at least an hour, may herald a life-threatening infection and should prompt the initiation of a rapid workup and commonly the administration of broad-spectrum antibiotics. Neutropenic fever is common in those receiving chemotherapy, with up to 80% of patients developing it at least once during the course of treatment.[25] The evaluation should focus on identifying any infectious agents, with particular attention to common locations, such as the lungs, urine, or bloodstream. As such, consideration of chest radiography, urinalysis, and cultures of blood and urine remain prudent.

Disposition

The disposition for febrile neutropenic patients is evolving, and carefully selected patients may be eligible for discharge following ED evaluation. Although it remains the norm, inpatient treatment incurs significant costs and resource utilization, along with exposing the neutropenic patient to nosocomial pathogens. Select patients without significant comorbidities or signs of sepsis, and with reliable follow-up plans, may be considered for outpatient therapy. Disposition decisions should be made in conjunction with the patient's oncologist.[26] Septic patients will require hospitalization and neutropenic isolation precautions. Asymptomatic patients with incidental neutropenia can generally be referred for follow-up, which may include further investigation depending on repeat ANC or clinical course. Patients with a clear reversible source or without significant clinical findings and mild to moderate levels of neutropenia may have outpatient follow-up arranged, preferably after discussion with their physician.

CHAPTER 110: QUESTIONS AND ANSWERS

1. Which of the following statements best describes the use of the WBC count in emergency medicine decision making?
   - **a.** The absence of leukocytosis excludes the presence of significant disease.
   - **b.** The absolute neutrophil count, presence of bandemia, and immature granulocyte count may be more helpful than the total WBC count in identifying bacterial infection.
   - **c.** The total WBC count is both specific and sensitive for serious bacterial infection.
   - **d.** The WBC count is highly discerning in screening for illness in the acute care setting.

Answer: B. The WBC count and accompanying differential count are among the most common laboratory tests ordered in the ED. The WBC count has not proved to be a highly sensitive or specific test, and the absence of leukocytosis does not exclude the presence of significant disease. The WBC count has limited screening value in the acute care setting. The absolute neutrophil count or an elevated band count may be more helpful than the total WBC count in identifying bacterial infection. The immature granulocyte count can be used to help identify patients with or without sepsis.

2. Which of the following can affect the "normal" WBC count?
   - **a.** Age and ethnicity
   - **b.** Exercise
   - **c.** Gender
   - **d.** Tobacco use
   - **e.** All of the above

Answer: E. All of the statements are true. One unique problem in WBC disorders is the wide variability in normal values and the multiple factors influencing them. Normal values for the WBC count are listed in Table 110.1. The "normal" WBC count range is age-dependent and may be shifted upward by exercise, female gender, smoking, or pregnancy. Decreases in the total WBC count range by 1000 to 1200 cells/mm^3 have been noted in the Black population.

3. In evaluating a patient with severe neutropenia, which of the following is false?
   - **a.** If the patient is febrile, basic isolation techniques and specific therapies should be initiated after cultures are completed.
   - **b.** If the patient is febrile, urine and blood cultures should be obtained.
   - **c.** The clinician should ask about medications, history of neutropenia, family history, and also review information regarding recent infections.
   - **d.** The classic physical findings associated with infection will be obvious owing to the inflammatory response.
   - **e.** The review of systems focuses on bleeding problems, generalized symptoms such as fatigue, sweats, and weight loss, or autoimmune symptoms.

Answer: D. The classic physical signs of infection may be blunted in severe neutropenia, because the inflammatory or purulent response may be hampered by the limited numbers of neutrophils.

4. A patient with a known history of chronic myeloid leukemia (CML) presents with shortness of breath. The WBC count is 25,000 cells/mm^3. Which of the following conditions is LEAST likely to be the cause of the patient's dyspnea:
   - **a.** Angina
   - **b.** Heart failure
   - **c.** Hyperleukocytosis resulting in pulmonary ventilation-perfusion abnormalities
   - **d.** Renal failure and fluid overload
   - **e.** Severe anemia

Answer: C. Hyperleukocytosis can occur in CML, though the comparatively more mature, "less sticky" cells found in CML rarely cause problems unless the count exceeds 500,000 cells/mm^3. A higher cell count may cause leukostasis and result in deafness, visual impairment, pulmonary ventilation-perfusion abnormalities, or priapism. Treatment involves hydration, leukapheresis, transfusion as necessary, allopurinol to prevent severe hyperuricemia, and specific chemotherapy. The need for urgent therapy in CML is usually related to hyperuricemia and renal injury, or severe anemia and subsequent angina or heart failure.

5. When applied to lymphocytic neoplasms, the terms *acute* and *chronic* describe all of the following except:
   - **a.** Aggressiveness of therapy required in treatment
   - **b.** Cell maturity
   - **c.** Patient survival time
   - **d.** Rapidity of onset

Answer: C. Historically, *acute* and *chronic* were descriptive terms applied to lymphocytic neoplasms with respect to patient survival time. The terms *acute* and *chronic* are currently utilized to describe cell maturity, rapidity of onset, and aggressiveness of therapy required in treatment. Chronic lymphocytic leukemia (CLL) is primarily a B-cell disorder and is the most common form of leukemia in patients 50 years or older. Acute lymphocytic leukemia (ALL) is most commonly diagnosed in children younger than 10 years and is the most frequent malignant neoplasm in children younger than 15 years of age.

Disorders of Hemostasis

Jeremiah D. Gaddy and Alan A. Dupré

KEY CONCEPTS

- Although hemostatic disorders are confirmed through laboratory testing, a careful history and thorough physical examination may provide clues to the diagnosis.
- The use of antithrombotic agents remains widespread, whereas diseases such as hemophilia or disseminated intravascular coagulation (DIC) are encountered infrequently in the emergency department (ED) setting.
- Critical thrombocytopenia increases the risk of bleeding, particularly with trauma or invasive procedures. Platelet dysfunction may occur with platelet levels outside of or within the normal range. Aspirin therapy or renal disease, for instance, can cause platelet dysfunction in the setting of a normal platelet count.
- Patients with suspected new diagnosis of immune thrombocytopenic purpura (ITP) should typically be admitted for further management; glucocorticoid therapy is the mainstay of treatment.
- In patients with possible heparin-induced thrombocytopenia (HIT), clinical scoring systems are helpful in risk stratifying the possibility of HIT, prompting early cessation of heparin, alternative anticoagulation, and hematology consultation. Spontaneous HIT should be considered in patients following major surgery (typically an orthopedic procedure), or with recent serious infection.
- Thrombotic thrombocytopenic purpura (TTP) should be suspected if both thrombocytopenia and microangiopathic hemolytic anemia (MAHA) are identified. Early treatment includes plasma exchange therapy.
- Platelet transfusion is rarely indicated unless platelet counts are below 10,000/mm^3 or severe life-threatening bleeding occurs. Platelet transfusion should be avoided in the setting of thrombotic microangiopathies, such as TTP, hemolytic uremic syndrome (HUS), the "hemolysis, elevated liver function tests, and low platelets" (HELLP) syndrome complicating pregnancy, or HIT.
- Hemophiliacs are often highly informed about their disease. It is imperative that prompt intervention with replacement therapy occurs early when bleeding or the potential for bleeding is suspected. As a general rule, 1 U/kg of factor VIII will increase the circulating factor VIII level by 2%.
- Hemophilia with inhibitors creates a challenge for emergency resuscitation, and a treatment option is recombinant Factor VIIa.

FOUNDATIONS

Hemostasis is a dynamic process that is geared to preventing blood from escaping the boundaries of the vessel. This complex process occurs in phases: maintenance of vessel integrity, formation of a platelet plug, propagation of the coagulation cascade, subsequent clot development, followed by fibrinolysis and clot disintegration. Often the steps of platelet plug formation (primary hemostasis) and the coagulation process (secondary hemostasis) are utilized interchangeably, though the processes are distinctly unique yet collaborative. Common hemostatic abnormalities are acquired and result from iatrogenic causes such as medications (e.g., aspirin, warfarin, or direct thrombin inhibitor), from disease (e.g., hepatic insufficiency), and less frequently from congenital abnormalities. Disorders of hemostasis may result in hemorrhage. Identification and expeditious treatment of the underlying cause remains paramount.

Anatomy and Physiology

Vascular integrity is maintained by a lining of overlapping endothelial cells supported by a basement membrane, connective tissue, and smooth muscle. These cells are important in maintaining a barrier to macromolecules, secreting clot-preventing substances and, when injured, in contributing to the metabolic response and local vasoconstriction. The endothelium regulates clot formation by secreting substances such as tissue factor pathway inhibitor (TFPI) and heparin sulfate, preventing propagation of the coagulation pathway, as well as prostacyclin and nitric oxide, which prevent platelet aggregation and act as vasodilators. The endothelium also expresses CD39 (cluster of differentiation 39), which degrades adenosine triphosphate (ATP) and adenosine diphosphate (ADP) to adenosine monophosphate (AMP), a potent antiplatelet and antithrombotic, and adenosine, a potent locally acting platelet inhibitor that prevents platelet plug formation[1] (Fig. 111.1A). When the endothelium's physical barrier has been compromised, exposed von Willebrand factor (vWF) links to platelet glycoprotein Ib (gpIb) receptors allowing platelet adhesion to the intravascular surface. Normal inhibitory mechanisms are disrupted through damage to the endothelial cells, allowing ATP and ADP to interact with receptors to amplify platelet activation (Fig. 111.1B).

Platelets have multiple roles in hemostasis. They are complex cytoplasmic fragments released from bone marrow megakaryocytes largely regulated by thrombopoietin. After initial exposure to damaged endothelium, platelets display glycoproteins to aid in adhesion and aggregation, such as gpIb and gpIIa/IIIb. Platelets also contain lysosomes, microtubules, and granules, among other components. Granules contain over 300 metabolically active substances, including platelet factor 4, additional adhesive and aggregation glycoproteins, coagulation factors, and fibrinolytic inhibitors. Each participates in the process of coagulation and contributes to overall wound healing through the mediation of inflammation, immune response, and infection control. Platelet activity is summarized in Box 111.1. Any step in the platelet pathway may be absent, altered, or inhibited by inherited or acquired disorders. The coagulation cascade forms fibrin, and cross-linked fibrin serves to reinforce the initial platelet plug.

The coagulation pathway is a complex system of checks and balances that results in controlled formation of a fibrin clot. Coagulation factors are summarized in Box 111.2, and a simplified coagulation pathway is

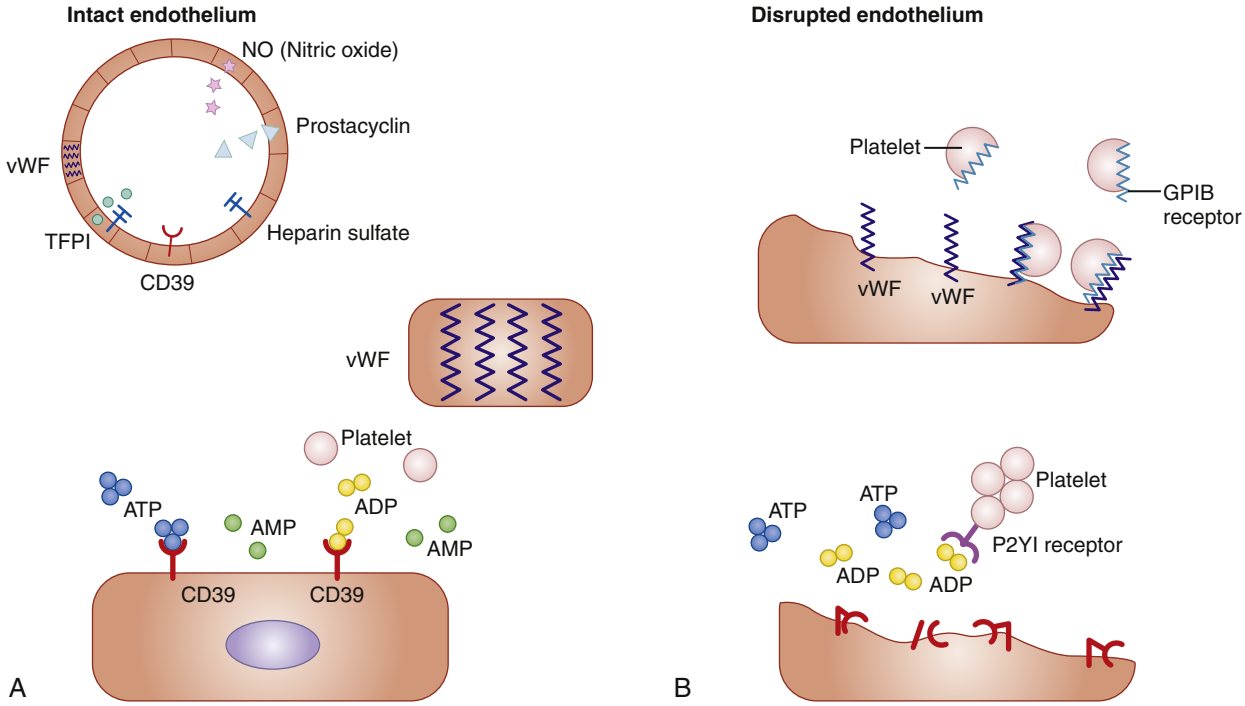

Fig. 111.1 (A) The endothelium regulates clot formation through expression of a number of substances including: CD39 (cluster of differentiation 39), which degrades adenosine triphosphate (ATP) and adenosine diphosphate (ADP) to adenosine monophosphate (AMP), a potent antiplatelet and antithrombotic, and adenosine, a potent locally acting platelet inhibitor that prevents platelet plug formation. (B) When the endothelium is injured the exposed von Willebrand factor (vWF) links to platelet glycoprotein Ib (gpIb) receptors allowing platelet adhesion to the intravascular surface and allowing ATP and ADP to interact with receptors to amplify platelet activation.

BOX 111.1 Role of Platelets in Hemostasis

1. Adhesion to subendothelial connective tissue: Collagen, basement membrane, and noncollagenous microfibrils; serum factor VIII and von Willebrand factor (vWF) permit this function; adhesion creates the initial bleeding arrest plug
2. Release of adenosine diphosphate, the primary mediator and amplifier of aggregation; release of thromboxane A, another aggregator and potent vasoconstrictor; release of calcium, serotonin, epinephrine, and trace thrombin
3. Platelet aggregation over the area of endothelial injury
4. Stabilization of the hemostatic plug by interaction with the coagulation system:
   - Platelet factor 3, a phospholipid that helps accelerate certain steps in the coagulation system
   - Platelet factor 4, a protein that neutralizes heparin
   - Pathway initiation and acceleration by thrombin production
   - Secretion of active forms of coagulation proteins
5. Stimulation of limiting reactions of platelet activity

BOX 111.2 Coagulation Factors

Factor I. Fibrinogen
Factor II. Prothrombin
Factor III. Tissue thromboplastin
Factor IV. Calcium
Factor V. Labile factor (proaccelerin)
Factor VI. Not assigned
Factor VII. Proconvertin
Factor VIII. Antihemophilic A factor
Factor IX. Antihemophilic B factor (plasma thromboplastin component, Christmas factor)
Factor X. Stuart-Prower factor
Factor XI. Plasma thromboplastin antecedent
Factor XII. Hageman factor (contact factor)
Factor XIII. Fibrin-stabilizing factor

presented in Figure 111.2. The clotting cascade is traditionally depicted as consisting of intrinsic and extrinsic pathways. A more modern approach is to view the extrinsic pathway as the initiation phase with exposed tissue factor at the site of vessel injury, and the intrinsic pathway as a parallel and amplification pathway. Both pathways converge to activate factor X, which then converts prothrombin to thrombin. Tissue factor is a critical cofactor that is required for activation of factor VII. Because of limited amounts of tissue factor and rapid inactivation by TFPI, the extrinsic pathway initiates the clot process, though sustained generation of thrombin and clot formation is dependent on the intrinsic pathway through activation of factor IX by activated factor VII. Once coagulation is initiated, controls are necessary to prevent overzealous local or generalized thrombosis (Box 111.3).

Pathophysiology

Hemostasis is dependent on normal functioning and integration of the vasculature, platelets, and coagulation pathway. The most commonly encountered disorder of hemostasis is antithrombotic drug administration, including use of antiplatelet or anticoagulant medications. Disorders of hemostasis may also be congenital, or secondary to disease states that affect the various steps of the hemostatic pathway

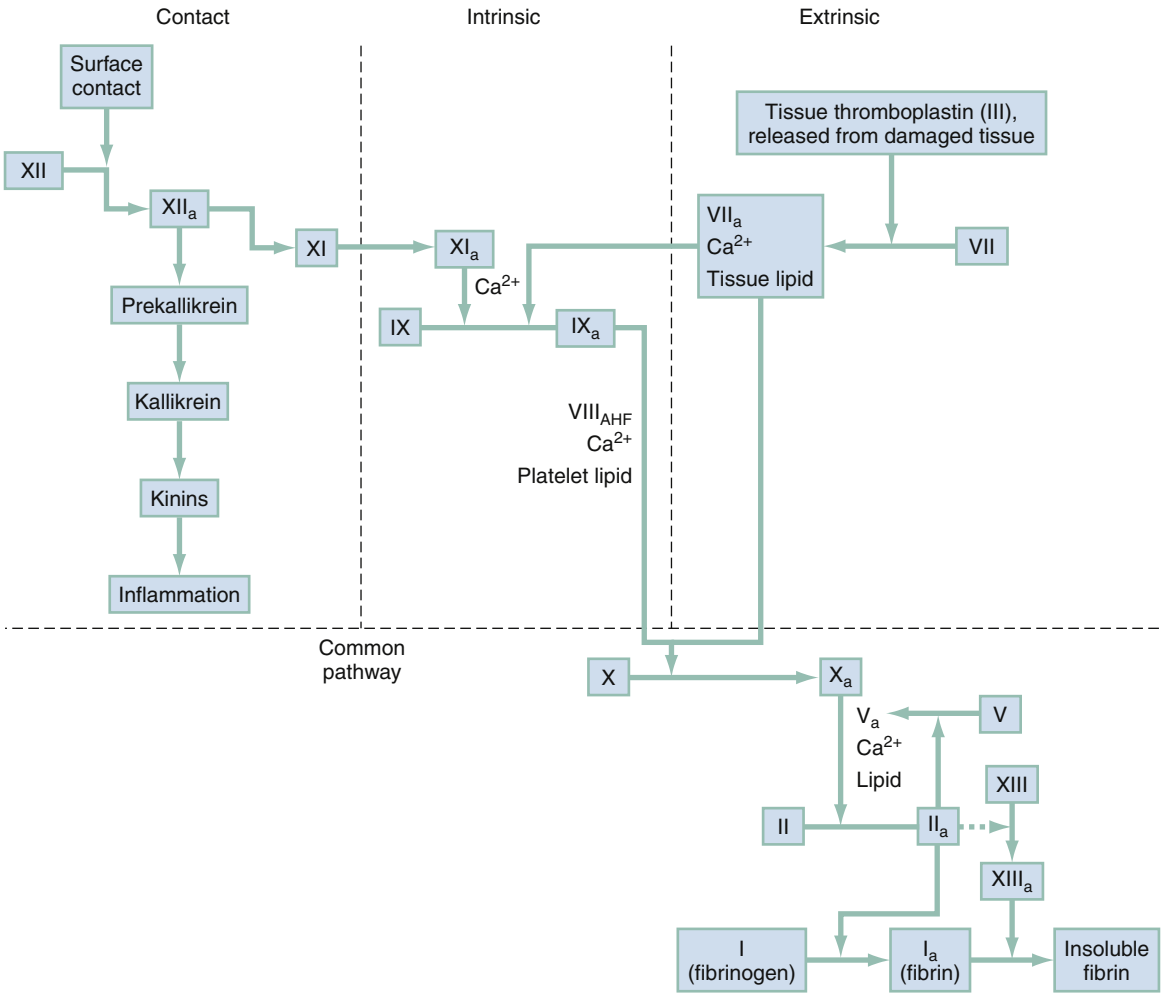

Fig. 111.2 Coagulation pathway.

BOX 111.3 Normal Controls of Coagulation

- Removal and dilution of activated clotting factors through blood flow, which also mechanically opposes growth of the hemostatic plug
- Alteration of platelet activity by endothelium-generated nitric oxide and prostacyclin
- Removal of activated coagulation components by the reticuloendothelial system
- Regulation of the clotting cascade by antithrombin III, protein C, protein S, and tissue factor pathway inhibitor (TFPI)
- Activation of the fibrinolytic system

such as malignancy or hepatic dysfunction. Due to the interconnectedness between the endothelium and platelets, vascular disorders may share similar historical or examination features with platelet disorders. Despite some overlap, disorders of hemostasis are frequently grouped into vascular disorders (often with a component of platelet dysfunction), platelet disorders, and coagulation disorders.

CLINICAL FEATURES

Disorders of hemostasis may become evident through hemorrhage that is out of proportion to what would otherwise be anticipated, excessive ecchymosis, or the presence of a petechial or purpuric rash. Hemostatic disorders may complicate any medical or traumatic problem, and platelet disorders or coagulopathy can rapidly develop in critically ill patients. Patients that fail to respond to usual hemostatic measures should be considered to have a potential bleeding disorder. When a bleeding disorder is diagnosed or suggested, the assessment initially includes stabilization, which may necessitate intravenous fluids, transfusion of red blood cells (RBC), or other blood component or factor replacement. In the setting of a known disorder, clinical complications associated with the underlying pathophysiologic condition must be considered. If the disorder is unknown, a rapid differential diagnosis should be pursued.

Key components of the history and physical examination are presented in Box 111.4. The history alone may in some cases be useful in differentiating between platelet and coagulation factor disorders.

Platelet disorders are usually manifested as acquired petechiae, purpura, or mucosal bleeding, and are more common in women. Platelet abnormalities can be caused by congenital disorders, though most are related to acquired conditions. The bleeding source is usually a capillary with resultant cutaneous and mucosal petechiae or ecchymosis. Epistaxis, menorrhagia, and gastrointestinal bleeding are common initial symptoms. The bleeding is generally mild and may occur immediately after surgery or dental extractions. The presence of petechiae or purpura may be noted on examination, and superficial ecchymoses may develop around venipuncture sites. The purpura associated with platelet disorders is typically asymptomatic and not palpable. This is

BOX 111.4 Clinical Evaluation of a Bleeding Patient

History

Nature of bleeding
- Petechiae
- Purpura
- Ecchymosis
- Significant bleeding episodes

Sites of bleeding
- Skin
- Mucosa: Oral or nasal
- Muscle
- Gastrointestinal
- Genitourinary
- Joints

Patterns of bleeding
- Recent onset or lifelong
- Frequency and severity
- Spontaneous or following injury

Challenges to hemostasis
- Dental extraction
- Operative or other invasive procedures
- Medications

Associated diseases
- Uremia: most commonly associated with platelet dysfunction
- Liver disease: most commonly associated with coagulation factor deficits
- Infection: could be associated with either platelet or coagulation deficits
- Malignant neoplasm: could be associated with either platelet or coagulation deficits

Previous transfusion history

Family history

Physical Examination

Vital signs

Skin: Nature of bleeding, signs of liver disease, petechial, purpura and distribution of skin abnormalities.

Mucosa: Oral or nasal, epistaxis

Lymphadenopathy

Abdomen: Liver size and shape, splenomegaly

Joints: Signs of previous bleeding (limited joint movement, pain mimicking osteoarthritis)

Other sites of blood loss: Pelvic, rectal, urinary tract, intramuscular or deep soft tissue

in contrast to purpura associated with vasculitis, which can burn or itch and is palpable. Vascular disorders such as vasculitis are associated with signs and symptoms similar to those of thrombocytopenic states. Inherited vascular disorders are rare, and acquired forms are usually associated with connective tissue changes or endothelial damage.

Coagulation issues may be congenital in nature, characterized by delayed deep muscle or joint bleeding, and occur more often in men. Clinically significant coagulation disorders have a number of characteristic features that help differentiate them from platelet disorders (Box 111.5).

DIFFERENTIAL DIAGNOSIS

The differential of platelet disorders is listed in Box 111.6. The differential of vascular disorders is listed in Box 111.7. The differential for coagulation disorders is listed in Box 111.8.

BOX 111.5 Features of Coagulation Disorders That Differentiate From Platelet Disorders

The bleeding source is often an intramuscular or deep soft tissue hematoma from small arterioles.

The congenital form of the disease occurs predominantly in men, often via sex-linked inheritance.

Bleeding may occur after surgery or trauma but may be delayed in onset up to 72 hours.

Epistaxis, menorrhagia, and gastrointestinal sources of bleeding are rare, whereas hematuria or hemarthrosis are common in severe cases.

The bleeding time is normal except in patients with von Willebrand disease (vWD).

BOX 111.6 Differential Diagnosis of Platelet Disorders

Decreased Platelet Count (Thrombocytopenia)

Decreased production
- Decreased megakaryocytes secondary to drugs, toxins, or infection
- Normal megakaryocytes with megaloblastic hematopoiesis or hereditary origin
- Platelet pooling and splenic sequestration

Increased destruction
- Immunologic
  - Related to collagen vascular disease, lymphoma, leukemia
  - Drug related
  - Infection
  - Post-transfusion
  - Immune thrombocytopenia
- Mechanical
  - Disseminated intravascular coagulation (DIC)
  - Thrombotic thrombocytopenic purpura (TTP)
  - Hemolytic-uremic syndrome (HUS)
  - Hemolysis elevated liver function tests & low platelets (HELLP) syndrome related to pregnancy
- Vasculitis

Dilutional secondary to massive blood transfusion

Platelet Dysfunction (Thrombocytopathy)

Adhesion defects such as von Willebrand disease (vWD)

Release defects: Acquired or drug related

Aggregation defects, such as in thrombasthenia

Elevated Platelet Count (Thrombocytosis)

Autonomous (primary thrombocythemia)

Reactive (secondary thrombocythemia)

Iron deficiency

Infection or inflammation

Trauma

Nonhematologic malignant disease

Post-splenectomy

Rebound from alcohol, cytotoxic drug therapy, folate or vitamin B_{12} deficiency

DIAGNOSTIC TESTING

A definitive diagnosis is dependent on laboratory evaluation. Tests pertinent to the ED setting are discussed in the following sections and are listed in Box 111.9.

BOX 111.7 Differential Diagnosis of Vascular Disorders

Inherited

Disorders of connective tissue
- Pseudoxanthoma elasticum
- Ehlers-Danlos syndrome
- Osteogenesis imperfecta

Disorders of blood vessels
- Hemorrhagic telangiectasia

Acquired

Scurvy (vitamin C deficiency)
Simple or senile purpura
Purpura secondary to steroid use
Vascular damage
- Infection (meningococcemia)
- Hemolytic-uremic syndrome (HUS)
- Hypoxemia
- Thrombotic thrombocytopenic purpura (TTP)
- Dysproteinemic purpura

BOX 111.8 Differential Diagnosis of Coagulation Disorders

Inherited

Von Willebrand disease
Hemophilia A (factor VIII) or hemophilia B (factor IX)
Factor XIII, factor XI, factor X, factor VII, factor V or factor II deficiency
Afibrinogenemia/hypofibrinogenemia

Acquired

Medication
Snake bite (venom-induced consumptive coagulopathy)
Liver disease
Disseminated intravascular coagulation (DIC)
Autoimmune disorders (including autoantibodies towards factors such as fibrinogen)
Acquired factor inhibitors, from treatment of congenital disorder such as hemophilia, or malignancy

BOX 111.9 Diagnostic Hemostasis Tests

Complete blood count and smear (EDTA—purple top)
Platelet count (EDTA—purple top)
Bleeding time
Prothrombin time/International normalized ratio (PT/INR; citrate—blue top)
Partial thromboplastin time (PTT; citrate—blue top)
Other coagulation studies: Fibrinogen level, anti-factor Xa assay, thrombin time, clot solubility, factor levels, inhibitor screens
As necessary: Serum electrolyte levels; serum glucose, BUN, and creatinine concentrations; type and crossmatch

BUN, Blood urea nitrogen; *EDTA,* ethylenediaminetetraacetic acid.

Complete Blood Count and Blood Smear

The complete blood count can, in some cases, assess the degree of anemia associated with a bleeding episode. Reductions in hemoglobin and hematocrit often lag behind the actual loss of RBCs in acute hemorrhage owing to the time necessary for equilibration. The peripheral blood smear may demonstrate schistocytes or fragmented RBCs in microangiopathic hemolytic anemias, such as TTP or DIC. Teardrop-shaped or nucleated RBCs may reflect myelophthisic disease where hematopoietic bone marrow is infiltrated and replaced by fibrosis, tumors, or granulomas. Characteristic white blood cell morphologies are seen with thrombocytopenia associated with infectious mononucleosis (e.g., increased WBC cytoplasm and nucleoli in the nuclei), folate or vitamin B_{12} deficiency (e.g., hypersegmented neutrophils), or leukemia (e.g., immature WBCs, hairy cell lymphocytes, and myeloblasts with Auer rods).

Platelet Count

The platelet count may be estimated from the peripheral blood smear. Normally, one platelet is present per 10 to 20 RBCs. Often, the count is automated with a normal reference range of 150,000 to 400,000/mm^3. Thrombocytopenia is defined as a platelet count of less than 100,000/mm^3. With normal platelet function, the bleeding time with platelet counts below 100,000/mm^3 increases in direct relation to the level of thrombocytopenia. Levels below 20,000/mm^3 may be associated with serious spontaneous hemorrhage. However, the platelet count provides no information regarding platelet function.

Bleeding Time and Platelet Function Assay

Historically, bleeding time was considered the best test to determine both vascular integrity and platelet function. A normal bleeding time is 8 minutes. A bleeding time of 8 to 10 minutes is borderline, and a bleeding time longer than 10 minutes is considered abnormal. However, bleeding time is insensitive in identifying medication-related platelet dysfunction, Von Willebrand disease (vWD), or in predicting surgical bleeding. Many institutions have replaced the traditional bleeding time with a platelet function analyzer instrument, which is more convenient, with improved clinical value. The platelet function assay has been found to be highly sensitive in detecting moderate to severe vWD, medication-related platelet dysfunction, or severe platelet function disorders. Although less sensitive to mild disease, the platelet function assay is useful in detecting platelet pathology relevant to the emergency clinician. Given the pervasiveness of drug-induced platelet dysfunction, it is critical to inquire about the use of medications, particularly aspirin and other antiplatelet medications (e.g., clopidogrel). Platelet function testing is independent of the coagulation pathways.

Prothrombin Time

The PT tests the factors of the extrinsic and common coagulation pathways. The patient's anticoagulated plasma is combined with calcium and tissue factor protein. Sensitivity to factor deficiencies depends on the source of the tissue factor. The PT is capable of detecting deficiencies in fibrinogen, prothrombin (factor II), factor V, factor VII, and factor X. Results are reported in seconds or as the prothrombin ratio. To generate the prothrombin ratio, the time in seconds of the sample is given over the time of a normal control, for example, 12.5/11.5. Results are also usually reported as the international normalized ratio (INR), which compensates for differences in sensitivity of various thromboplastin reagents to the effects of warfarin by calculating the prothrombin ratio raised to the power of an international sensitivity index for specific thromboplastin reagents. The test is helpful in monitoring the use of coumarin anticoagulants, and the time may be prolonged in patients with liver disease or other abnormalities of vitamin K–sensitive factors.

If all other test results are normal with an abnormal prothrombin time, the elevated PT reflects an extrinsic pathway abnormality mediated through deficiency of factor VII. The hereditary form, congenital proconvertin deficiency, is caused by a rare autosomal recessive

gene on chromosome 13. The acquired form is commonly seen and may be a result of vitamin K deficiency, warfarin use, or liver disease. Given factor VII's short half-life (3 to 5 hours), it is typically the first to manifest a deficiency when its active form is underproduced. The PT is a sensitive gauge of hepatic function and the efficacy of warfarin administration. It is recommended with routine warfarin therapy that the INR level is maintained between 2.0 and 3.0, except in the setting of cardiac valvular disease, in which the target INR level is usually in the 2.5 to 3.5 range.

Partial Thromboplastin Time

The PTT tests the components of the intrinsic and common pathways, essentially all factors but factor VII and factor XIII. In this test, a phospholipid source and a contact-activating agent (kaolin) are added to anticoagulated citrate plasma. After an incubation period that allows factor XII to become activated, calcium is added and the clotting time is recorded. A normal control sample is run simultaneously. Normal ranges may vary by laboratory. The average time is 25 to 29 seconds. The sensitivity of the test varies from factor to factor, though factor levels less than 40% are typically required before the PTT is prolonged. The test may be altered by clotting factor inhibitors of external origin (e.g., heparin) or internal origin (e.g., anti–factor VIII antibody). Spurious high values may occur in the setting of heightened plasma turbidity. The activated PTT is most sensitive to abnormalities in the sequence of the coagulation cascade preceding activation of factor X.

Two groups of inherited disorders manifest as an isolated elevation in the PTT. The first group involves deficiencies of the contact factors, including factor XII (Hageman factor), prekallikrein (Fletcher factor), and high-molecular-weight kininogen. They may cause a relatively benign disorder in which the PTT is elevated but the patient has no bleeding diathesis. These deficiencies exist as isolated laboratory abnormalities, and thus they should not be invoked as a cause of the patient's bleeding problem. They may be specifically assayed when a precise diagnosis is necessary. The second group causes significant bleeding problems resulting from deficiencies of factors within the intrinsic coagulation system. They are the most common inherited abnormalities of the clotting system. Deficiencies of factors VIII, IX, and XI account for 99% of inherited bleeding disorders. Patients with active life-threatening bleeding who are thought to have a congenital bleeding disorder can be supported with fresh frozen plasma, 15 mL/kg, while additional information is being obtained and initial diagnostic studies are being performed.

In a patient with a prolonged PTT and a lifelong history of bleeding, the most important test is an assay of factor VIII and factor IX. This test measures the ability of the patient's plasma to correct the prolonged PTT of plasma deficient in a given factor. This ability is compared with that of normal plasma, and the result is given as a percentage of normal. These tests measure the procoagulant activity of the factor, although they do not discriminate between diminished activity resulting from abnormal factor VIII versus lower levels of normal factor VIII. Factor VIII deficiency is found in both hemophilia A and vWD, and factor IX deficiency is found in hemophilia B.

Anti-Xa Assay

The anti-Xa assay is a chromogenic assay that may be available to emergency clinicians for monitoring of unfractionated and low-molecular-weight heparin levels, or drug quantification of direct factor Xa inhibitors such as rivaroxaban and apixaban. When monitoring heparin levels, the test should ideally be performed 3 to 4 hours after medication administration for peak level monitoring. Because this test is not subject to the same variability as the PTT, it has become an attractive alternative as costs of the assay have declined in recent years. The test is considered the reference standard for measurement of in vivo heparin activity, and presently represents the only reliable means of quantifying rivaroxaban and apixaban drug levels.

Fibrinogen

Fibrinogen is the final coagulation substrate, and its level reflects the balance between production and consumption. It may be decreased by low production, as in severe liver disease, or by overconsumption, as in DIC. Low levels or altered function increase the PT, PTT, and thrombin clotting time. Because fibrinogen is an acute-phase reactant, certain conditions, including malignant disease, sepsis, inflammation, or pregnancy, may impact fibrinogen levels.

Thrombin Time

Measurement of the thrombin clotting time bypasses measurement of the intrinsic and extrinsic pathways by directly analyzing conversion of soluble fibrinogen to insoluble fibrin. It is a useful screening test for both qualitative and quantitative abnormalities of fibrinogen and inhibitors, such as heparin and fibrin split products. The test is also an available means to measure drug activity of direct thrombin inhibitors, such as dabigatran.

Clot Solubility

The result of clot solubility testing may be the only abnormality in disorders involving factor XIII deficiency, which has a role in cross-linking fibrin to stabilize the fibrin clot. A washed clot is incubated in acetic acid or urea. If the fibrin clot is not properly cross-linked by factor XIII, it dissolves.

Factor Level Assays

Factor levels are determined either by bioassay, in which the ability of the sample of plasma to normalize controlled substrate-deficient plasma is evaluated, or by immunologic assay. Inhibitor screening tests reveal antibodies in plasma that prolong the normal plasma clotting time when mixed. Inhibitors may play a disruptive role in disease states such as hemophilia or when associated with certain malignancies.

MANAGEMENT

Thrombocytopenia

Thrombocytopenia can be grouped into two main causes: decreased production or increased destruction. Most experts agree that thrombocytopenia is defined as a platelet count of less than 100,000 micro/mm^3. Thrombocytopenia from decreased bone marrow production is usually caused by the effects of chemotherapeutic drugs, myelophthisic disease, or direct bone marrow effects of agents, such as alcohol or thiazides. Splenic sequestration is a rare cause of thrombocytopenia seen primarily with hypersplenism resulting from malignant hematologic disease, portal hypertension, or disorders involving increased splenic red blood cell (RBC) destruction, such as hereditary spherocytosis, autoimmune hemolytic anemia, or sickle cell disease.

Most platelet disorders are not treated by platelet transfusion, as its efficacy is questionable and alloimmunization may occur. Platelet transfusions are commonly indicated for primary bone marrow disorders (e.g., aplastic anemia or acute leukemia). Assessment of the risk for spontaneous bleeding due to thrombocytopenia is an imprecise science. In contrast to disorders with primary bone marrow involvement, less mature platelets associated with peripheral consumption or sequestration generally have more robust functionality and thus patients are less prone to spontaneous hemorrhage. An estimate of platelet functionality is combined with the platelet count for a more accurate prediction of primary hemostasis potential. At counts higher than 50,000/

BOX 111.10 Immune Thrombocytopenia Chronicity

Newly diagnosed: Up to 3 months since diagnosis
Persistent: 3 to 12 months since diagnosis
Chronic: Over 12 months since diagnosis

mm^3, hemorrhage attributed to platelet deficiency is unlikely. At counts below 40,000/mm^3 to 50,000/mm^3, a variable degree of risk exists, particularly in the setting of trauma, gastric ulcers, or invasive procedures. Spontaneous bleeding in the absence of surgery, trauma, or other risk factors is more likely when platelet counts reach below 10,000/mm^3, thus prophylactic platelet infusions should typically be reserved for this degree of thrombocytopenia; however, this threshold may be lower in stable pediatric patients but should initiate hematology consultation.[2] Patients requiring urgent central venous access or lumbar puncture may require platelet transfusion if the count is less than 20,000/ mm^3 or 50,000/mm^3, respectively.[2] Although literature is sparse, platelet transfusion is generally recommended for patients requiring neurosurgical or invasive ophthalmologic intervention if counts are less than 80,000 to 100,000/mm^3.[2]

Immune Thrombocytopenia

Immune thrombocytopenia (ITP) is a broad acquired condition that results from autoantibodies against platelet antigens. ITP includes the diseases previously termed idiopathic thrombocytopenic purpura and autoimmune thrombocytopenic purpura. ITP is further broken down into separate categories: primary ITP; secondary ITP, typically resulting from pathogens, disease states, or malignancy; and drug-induced thrombocytopenia (DITP).

Primary ITP is an acquired autoimmune thrombocytopenia that has no apparent trigger or associated condition, and can result in both increased destruction as well as decreased platelet production. Severe ITP is characterized by a platelet count of less than 20,000 micro/mm^3. ITP is further characterized as newly diagnosed, persistent, or chronic (Box 111.10). The acute form of ITP is seen most often in children aged 2 to 6 years old. A viral prodrome commonly occurs within 3 weeks preceding its onset. The platelet count decreases, usually to less than 20,000/mm^3. The course is self-limited, with a greater than 90% rate of spontaneous remission. Morbidity and mortality rates are low, although full recovery may take several weeks. The chronic form of ITP is primarily an adult disease found three times more often in women. The onset of chronic ITP is insidious, generally without a prodrome, and is manifested as easy bruising, prolonged menses, and mucosal bleeding. Petechiae or purpura are common, with platelet counts typically between 30,000/mm^3 and 100,000/mm^3.

Secondary ITP results from various infectious or other chronic disease states. Autoimmune disease, particularly systemic lupus erythematosus and rheumatoid arthritis, may cause an antiplatelet antibody-related thrombocytopenia. Similar associations have been noted with leukemia and lymphoma, particularly lymphocytic lymphoma. Postinfectious immune thrombocytopenia is usually associated with viral diseases, such as HIV, hepatitis (HBV or HCV), Epstein-Barr virus (EBV), rubella, rubeola, or varicella.

DITP is caused by drug-dependent platelet antibodies, which is a distinct mechanism from drugs that cause direct bone marrow suppression. Numerous drugs have been associated with DITP, and the resulting thrombocytopenia is expected to resolve after discontinuation of the offending drug. Owing to its relatively high frequency of use, heparin is an important cause of drug-induced thrombocytopenia in hospitalized patients.

ITP treatment is often supportive, with treatment recommendations distinguished between adult and pediatric patients. Corticosteroids are recommended for newly diagnosed adult patients with platelet counts of less than 30,000/ mm^3 who are asymptomatic or have only minor mucocutaneous bleeding. Dexamethasone, 40 mg PO or IV daily for 4 days, is the preferred glucocorticoid. Admission for further diagnostic evaluation may be considered for newly diagnosed adult patients with platelet counts of less than 20,000 mm^3.[3] IVIG in addition to corticosteroids should be considered for patients with platelet counts of less than 10,000 mm^3, significant bleeding, or when a more rapid increase in platelet count is necessary, such as the need for surgery or invasive procedure. Use of glucocorticoids with IVIG can be associated with a more sustained response than with IVIG alone.[3] If IVIG is indicated, a one-time dose of 1 g/kg should be given. A thrombopoietin receptor agonist (TPO-RA), such as eltrombopag, should be considered for life threatening bleeding in the setting of inadequate response to corticosteroids, IVIG, and platelet transfusion. Because eltrombopag takes days to weeks to normalize platelets, this will rarely be given in the emergency department and discussion with a hematologist would be prudent. Plasmapheresis and recombinant factor VIIa are no longer recommended.[4] Splenectomy is often considered a last resort for ITP that is refractory to medical management.[3]

Pediatric patients with newly diagnosed ITP and only mild bleeding (skin manifestations) can typically be managed without medication, even when platelet counts are less than 20,000 mm^3.[3] Though the overall platelet count is low, a relatively high fraction of newly minted platelets with robust functionality is seen in the circulation, thus patients remain at relatively low risk for significant spontaneous hemorrhage. Admission should be considered when there is uncertainty regarding the diagnosis or lack of close follow-up. Prednisone, IVIG, or anti-D immunoglobulin are available options for pediatric patients with newly diagnosed ITP.[3] As with adult patients, IVIG can be considered if there is a need for a more rapid correction of the platelet count. Treatment options should be discussed with the child's pediatrician or a pediatric hematologist.

Drug-Induced Thrombocytopenia

A number of drugs have been associated with thrombocytopenia of immunologic origin. Quinine and quinidine are common offenders that affect platelets through an "innocent bystander" mechanism. The platelet is coated with a drug-antibody complex, complement is fixed, and intravascular platelet lysis occurs. Beta lactams, quinolones, digoxin, sulfonamides, phenytoin, and aspirin may also be associated with thrombocytopenia, usually within 24 hours of use. Clinical trials with platelet glycoprotein IIb/IIIa antagonists show an increased risk for associated thrombocytopenia, independent of heparin therapy.[5] The platelet count may fall below 10,000/mm^3 and be complicated by serious bleeding. Laboratory testing may confirm the presence of antibody, especially with the use of quinine and quinidine.

DITP is difficult to discern from ITP, especially during the initial evaluation by the emergency clinician. In DITP, the platelet count should improve within the first 1-2 days of cessation of the offending drug, and return to normal range within a week. In the setting of active bleeding with thrombocytopenia of unclear cause, corticosteroids, IVIG, and possibly platelet transfusion in selected patients are all considerations.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is a serious immune-mediated process associated with unfractionated heparin (UFH) and other forms of heparin such as low-molecular-weight heparin (LMWH). Heparin is thought to pair with platelet factor 4 (PF4), a procoagulant substance found in platelet granules. This paired complex results in rapid generation of

TABLE 111.1 4Ts Scoring System

4Ts	2 points	1 point	0 point
Thrombocytopenia	Platelet count fall >50% and platelet nadir ≥ 20	Platelet count fall 30–50% or platelet nadir 10–19	Platelet count fall < 30% or platelet nadir < 10
Timing of Platelet Count Fall	Clear onset between days 5–10 or platelet fall ≤ 1 day (prior heparin exposure within 30 days)	Consistent with days 5–10 fall, but not clear; onset after day 10; or fall ≤ 1 day (prior heparin exposure 30–100 days ago)	Platelet count fall < 4 days without recent exposure
Thrombosis or Sequelae	New thrombosis (confirmed) or skin necrosis; acute systemic reaction post-intravenous unfractionated heparin (UFH) bolus	Progressive or recurrent thrombosis; Non-necrotizing (erythematous) skin lesions; Suspected thrombosis (not proven)	None
Other Causes of Thrombocytopenia	None Apparent	Possible	Definite

Total Points	Probability
<3 points	Low probability
4–5 points	Intermediate probability
6–8 points	High probability

antibodies, which coat platelets resulting in thrombocytopenia. The antibodies generated also activate platelets, thus creating a potential hypercoagulable state. Approximately 33% to 50% of patients with HIT will develop HIT with thrombosis (HITT).[6] A HIT-like reaction may also occur in the absence of exposure to heparin.

The overall risk for HIT ranges from 0.1% to 7.0% in patients receiving heparin.[6] The risk of HIT is related to drug and dosage factors, including duration of exposure (risk greatest following 5 days of heparin therapy), heparin type (UFH carries higher risk than LMWH), or dosage (greatest risk with higher doses). In addition, female patients are at twice the risk, and surgical or trauma patients have a higher risk for HIT than medical patients. Delayed HIT occurs a median of 14 days following the initiation of heparin, though may occur up to 40 days out.

The 4Ts Score for HIT is aimed at differentiating patients with HIT from those with alternative causes of thrombocytopenia (Tables 111.1 and 111.2).[6,7] Patients are stratified into low, intermediate or high risk based on degree of thrombocytopenia, timing of onset, presence of thrombosis, and other possible etiologies for the thrombocytopenia. For patients with intermediate or high risk for HIT based on 4Ts Score, heparin should be stopped and an immunoassay ordered. Most anti-PF4-heparin enzyme immunoassays have excellent negative predictive value, thus an unremarkable result effectively rules out HIT.[6] If the immunoassay is positive, a more specific functional test, such as a serotonin release assay, a heparin-induced platelet aggregation assay, or a solid-phase immunoassay, is indicated to confirm the diagnosis.

Current treatment recommendation for HIT is geared primarily toward management of thrombotic complications. If HIT is clinically suspected, immediate cessation of heparin is paramount. Vitamin K antagonists have been shown to increase thrombosis risk and potential for limb loss by decreasing the level of the endogenous anticoagulant protein C upon initiation.[6] Treatments for HIT include non-heparin anticoagulants, such as argatroban, bivalirudin, danaparoid, fondaparinux, or a direct oral anticoagulant (DOAC).[6] Argatroban has US Food and Drug Administration (FDA) approval for HIT, has quick onset of action, and has the most evidence supporting its use and thus is the most widely utilized anticoagulant for the treatment of HIT. Danaparoid is an alternative available outside of the United States. Recently there has been evidence supporting the safety and efficacy of DOACs for HIT or HITT. Rivaroxaban is the most well studied though favorable results have been shown with apixaban and dabigatran as well.[8] Current recommendations suggest that argatroban or bivalirudin may be preferred in the setting of increased bleeding risk, critical illness, or the need for urgent procedures.[6] For patients with normal hepatic function and who are not critically ill, the initial dose of argatroban is 2 mcg/kg/min IV. An aPTT should be drawn after 2 hours with goal to be 1.5 to 3 times the baseline aPTT. For patients with compromised hepatic function (bilirubin >1.5 mg/dL), cardiac surgery, anasarca, or who are critically ill, the recommended dosage range is 0.5 to 1.2 mcg/kg/min IV with the same aPTT. In addition to anticoagulation, evidence is increasing regarding the utility of IVIG for severe HIT.[9,10]

Post-Transfusion Purpura

Post-transfusion purpura (PTP), also known as post-transfusion thrombocytopenia, is a rare disorder that causes a precipitous fall in platelets approximately one week following transfusion. It is frequently linked to human platelet antigen 1 (HPA1) on platelets, although other antigens have also been implicated. When an HPA1 antigen–negative patient receives a platelet transfusion, the platelets with attached HPA1 antibodies provoke an anamnestic response, though the actual mechanism of platelet destruction is uncertain. Patients are usually middle-aged women with a history of prior pregnancy, during which they may have been previously sensitized to the HPA1 antigen. The platelet count often falls precipitously below 10,000/mm^3, with a significant associated risk of major bleeding.

High-dose IVIG, 1g/kg IV, is considered the first-line treatment for patients with severe thrombocytopenia or major bleeding. Glucocorticoids may be given with IVIG. Plasma exchange therapy is no longer considered a preferred therapy. Transfused platelets are often rapidly destroyed, thus platelet transfusion is generally not recommended except in the setting of severe thrombocytopenia and life-threatening bleeding, preferably with HPA1-negative blood products.

Thrombotic Microangiopathy

Thrombotic microangiopathies (TMA) represent a group of disorders that are characterized by their clinical presentation of microangiopathic hemolytic anemia (MAHA) and thrombocytopenia, and confirmed by histopathology or other specific tests. Microvascular thrombosis leads to abnormalities in the vessel wall of arterioles or capillaries, leading to consumption of platelets and destruction of RBCs. Presence or severity of clinical symptoms guide treatment decisions. There are many systemic disease states that have characteristics similar to TMA, and

TABLE 111.3 Plasmic Score

Criteria	Response	
Platelet count < 30×10^9/L	No (0 point)	Yes (1 point)
Hemolysis (Reticulocyte count > 2.5%, haptoglobin undetectable, or indirect bilirubin > 2.0 mg/dL)	No (0 point)	Yes (1 point)
Active cancer or treated for cancer within the past year	No (1 point)	Yes (0 point)
History of solid organ or stem cell transplant	No (1 point)	Yes (0 point)
MCV < 9.0×10^{-14} L (<90 fL)	No (0 point)	Yes (1 point)
INR < 1.5	No (0 point)	Yes (1 point)
Creatinine < 2.0 mg/dL	No (0 point)	Yes (1 point)

TABLE 111.4 Plasmic Risk Stratification

Total Score	Risk
0–4 points	Low risk. Consider alternative diagnosis
5 points	Intermediate risk. Consult hematology and consider plasma exchange
6–7 points	High risk. Consult hematology and immediate plasma exchange

treatment is focused on the underlying disease. The most common primary TMA disorders include thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS).

Thrombotic Thrombocytopenic Purpura. TTP is most often acquired and results from autoantibodies to ADAMTS13, an endothelial protein that cleaves large vWF multimers. Large vWF multimers increase adhesiveness to platelets, and large VWF-platelet aggregates can form microthrombi inducing tissue ischemia, platelet consumption, and MAHA.[11] TTP is rarely inherited, including disorders such as Upshaw-Schulman syndrome. HUS shares some similarities to TTP, and is generally associated with less central nervous system and more renal involvement than TTP. The first acute episode of TTP often occurs during adulthood (approximately 90%), and occurs twice as frequently in women.[12] HUS, on the other hand, frequently occurs in children, often after a gastrointestinal illness. TTP is classically, though not always, seen as a constellation of thrombocytopenia, MAHA (schistocytes seen on blood smear), and fluctuating neurologic symptoms such as mental clouding or confusion. It may be associated with cardiac (25% of the time) or mesenteric ischemia (35%), resulting in abdominal pain or diarrhea. Acute renal manifestations consist mainly of proteinuria or hematuria and rarely acute renal failure.[12] This is in contrast to HUS, where acute kidney injury is common. For patients with thrombocytopenia and MAHA, the PLASMIC score should be utilized in hospitalized patients to identify candidates for early initiation of treatment with plasma exchange (Tables 111.3 and 111.4).[13] The differential diagnosis for TTP includes HUS or other TMA syndromes associated with sepsis, malignancy, or pregnancy (HELLP).

Prior to the availability of plasma exchange, TTP followed a progressive and often fatal course, with a 90% mortality rate within a few months of diagnosis. Therapeutic plasma exchange is now the standard treatment, often with accompanying glucocorticoids.[11] Typical glucocorticoid dosage for patients without neurologic deficits or cardiac ischemia is prednisone 1 mg/kg PO daily. If patient is considered to be in severe condition, 1 g methylprednisolone intravenously for 3 days may be considered. If TTP is suspected, hematologist involvement is essential prior to initiation of therapies. Addition of rituximab may be considered in patients who are refractory to standard treatment, though its use in the acute phase of TTP is still debated. Additionally, caplacizumab (11 mg IV initial dose, followed by 11 mg subcutaneously daily for 10 days) may also be advantageous to add to the standard treatment of plasma exchange and immunosuppression.[11] With the exception of life-threatening bleeding, platelet transfusion is avoided, as platelets may cause additional thrombi in the microcirculation. Current trials are assessing the effectiveness of N-acetylcysteine, recombinant ADAMTS13, or an inhibitor of VWF-glycoprotein Ib binding.

Dilutional Thrombocytopenia

Dilutional thrombocytopenia as a complication of massive transfusion, exchange transfusion, or fluid resuscitation. Current guidelines for 1 : 1 : 1 ratio of fresh frozen plasma (FFP), platelets, and RBCs may assist in alleviating dilutional thrombocytopenia in the setting of massive transfusion.

Hereditary Thrombocytopenia and Thrombocytopathy

Hereditary thrombocytopathy and thrombocytopenic syndromes are not as rare as once thought. It has been suggested that as many as 1 in 7 patients initially diagnosed with ITP have a hereditary thrombocytopenic syndrome.[14] This may in part explain the variable success rates in the treatment of ITP. A detailed history is important, as patients diagnosed with thrombocytopathy may have at least one family member who has been treated with splenectomy for presumed ITP. Inherited thrombocytopenias are often characterized by platelet size (large, normal, or small). A blood smear is helpful in evaluating platelet size and granules. Further evaluation with light transmission aggregometry or specific tests may also be necessary.

Thrombocytopathy. Knowledge of abnormal platelet function as a clinical disorder has grown rapidly in recent years, with identified disorders of platelet adhesion, aggregation, or granule secretion.

Adhesion Defects. Bernard-Soulier Syndrome (BSS) results from an abnormality in the platelet gpIb complex, which allows platelet adhesion to vWF and thus the subendothelium.

Aggregation Defects. Glanzmann thrombasthenia (GT) is a rare autosomal-recessive disorder that results from a defect in the integrin complex glycoprotein IIb/IIIa. This protein complex is important for platelet aggregation via fibrinogen. The glycoprotein IIb/IIIa complex is the site of action for particular antiplatelet agents utilized, often employed during percutaneous coronary intervention procedures.

Secretory Defects. Secretory defects comprise two pathologic groups: defective platelet granule formation or defective secretory machinery. These include "storage pool" syndromes with decreased amounts of adenosine diphosphate, calcium, and serotonin. Congenital disorders such as Hermansky-Pudlak syndrome will often be associated with other systemic features including immune or pigmentation defects. Other secretory defects may be acquired, such as in association with systemic lupus erythematosus, alcoholism, or lymphoma. Various medications may induce secretory issues. Aspirin blocks the enzyme cyclooxygenase, which participates in thromboxane A_2 formation. Decreased release of thromboxane A_2 results in diminished platelet aggregation and reduced local vasoconstriction.

Despite the advances in the diagnosis of inherited platelet disorders, little progress has been made in targeted therapies for specific platelet disorders. There has been an increase in use of tranexamic acid (TXA) for mucocutaneous bleeding, menorrhagia, or epistaxis. Patients with severe thrombocytopenia and bleeding may benefit from platelet transfusion, though this recommendation is limited to severe bleeding due to the risk of developing antibodies or platelet alloimmunization. Platelet transfusions should preferably include human leukocyte

antigen (HLA) matching and leukocyte depletion. Desmopressin has traditionally been utilized for the theoretical benefit of increasing factor VIII and VWF in patients with a diagnosed thrombocytopathy, but with only equivocal success in BSS, no evidence for benefit in GT, and variable response rates in secretory disorders.

Thrombocytosis

Thrombocytosis is defined as a platelet count of greater than 600,000/mm^3 (Box 111.6). It is frequently secondary to infection or iron deficiency, and in these circumstances, thrombocytosis is generally not associated with other platelet-related complications. Primary (or autonomous) thrombocytosis may lead to thrombosis or bleeding, resulting from high numbers of dysfunctional platelets. Primary thrombocytosis is associated with polycythemia vera, myelofibrosis, and chronic myelogenous leukemia, or Kawasaki disease in children. Primary thrombocytosis requires a thorough hematologic evaluation.

Coagulation Disorders

Hemophilia A

Hemophilia A is caused by a deficiency of factor VIII. Most cases are sex-linked recessive in nature, as the disease is carried on the X chromosome. The prevalence of hemophilia A is approximately 17 cases per 100,000 males, with approximately 1,125,000 affected worldwide.[15] Approximately 13,500 people in the United States have hemophilia A.[16] The severity of hemophilia is categorized by factor VIII activity level. Severe hemophilia is less than 1% of normal factor activity, moderate is 1% to 5%, and mild is 5% to 40%. Approximately 42% of cases are considered severe.[16] The more severe, the more likely the patient will need replacement factor VIII. Patients with severe hemophilia require more replacement therapy and have an increased risk to develop alloantibodies, termed inhibitors, that may serve to inactivate factor VIII and may therefore limit replacement therapy. Recombinant DNA technology currently supplies most factor utilized for replacement therapy, though there is evidence that plasma-derived factor VIII has reduced immunogenicity and is associated with a lower incidence of inhibitor development.[17] Emicizumab is a recombinant immunoglobulin that substitutes for part of the function of activated factor VIII and is utilized for prophylactic treatment. It works by bridging activated factor IX and factor X to restore the function of missing activated factor VIII that is necessary for effective hemostasis. Factor VIII typically circulates in low concentrations in plasma bound to vWF. Given this close relationship, a diagnosis of vWD may present with similar symptoms.

Hemophilia is seen as a disorder of secondary hemostasis with a characteristic pattern of bleeding. Bleeding can occur anywhere, though deep muscles, joints, the urinary tract, and intracranial sites are the most common. Recurrent hemarthrosis and progressive joint destruction are major causes of morbidity. Intracranial hemorrhage (ICH) is a major cause of death in all age groups, and studies indicate probabilities for ICH of 1 in 50,000 to 1 in 140,000 male patients.[18] Mortality from ICH remains around 20% in hemophiliacs.[19] Mucosal bleeding, such as epistaxis, oral bleeding, or menorrhagia, remain rare unless associated with comorbid vWD or platelet dysfunction, such as occurs with aspirin use. Gastrointestinal bleeding is rare unless peptic ulcer disease is present. Trauma is a common initiator of bleeding irrespective of perceived severity and the bleeding may be delayed for days or weeks following initial injury. As such, a careful history of distant or seemingly negligible trauma should be included.

Comprehensive management of hemophilia involves a team effort including physicians, specialized nursing, physical therapy, social work, as well as the patient and their caregivers. ED management of hemophilia is best accomplished with advanced planning, including protocols for the administration of factor VIII developed in collaboration with a hematologist. Emergency clinicians should have rapid access to relevant information, including primary care physician, hematologist, diagnosis, factor VIII activity level, blood type, antihemophilic factor antibodies (inhibitor) status, and date of last hospitalization.

BOX 111.11 Indications for Factor Replacement in Hemophilia

- Suspected bleeding into a joint or muscle
- Any significant injury to the head, neck, mouth or eyes
- Any new or unusual headache, particularly following trauma even if seemingly minor
- Severe pain or swelling at any location
- All wounds that require surgical closure (sutures, staples), wound adhesive, or Steri-Strip placement
- History of blunt trauma that might result in bleeding
- Prior to any invasive procedure or surgery
- Suspicion of uncontrolled GI bleeding leading to anemia or signs or symptoms of hypovolemia
- Acute fractures, dislocations or sprains
- Suspicion of uncontrolled heavy menstrual bleeding, leading to anemia or signs or symptoms of hypovolemia

The severity of hemophilia, with last known factor level, as well as inhibitor status, must be considered with any bleeding in a patient with hemophilia. Many patients are well versed in their disease and often come prepared with their own treatment. The emergency clinician should institute early therapy for patients in whom bleeding is suspected. It is advisable to engage the patient's hematologist, if able, prior to initiating therapy.

Treatment decisions should be based on the *suspicion* of a bleeding related complication (Box 111.11).[20] Factor replacement therapy may need to be administered prior to diagnostic studies, particularly if ICH is suspected.

Replacement typically includes recombinant-derived factor VIII, or alternatively the patient's usual product of choice. Plasma-derived concentrate is a suitable alternative in an emergency situation. Cryoprecipitate or fresh frozen plasma are no longer generally recommended unless faced with life-threatening bleeding without alternatives.

Desmopressin can be used for patients with documented mild hemophilia A without inhibitors who are experiencing bleeding that is not life or limb threatening. Desmopressin raises factor VIII by three to six times baseline levels. This therapy should be reserved for situations when there is history of a prior favorable hemostatic response.[20] With suspicion for more significant bleeding, treatment follows as for other forms of hemophilia A.

As a general rule, 1 U/kg of factor VIII will increase the circulating factor VIII level by 2%. If the patient has a known recent factor level, this may be utilized into the calculation. In emergent therapy, however, the present factor VIII level is presumed as zero. Factor VIII activity goals are typically 40% to 50% for minor bleeding or trauma, and 80% to 100% for serious or life-threatening bleeding or trauma. Table 111.5 provides guidelines for treatment in patients without inhibitors.[21] Because the half-life of factor VIII is 8 to 12 hours, the desired level is maintained by giving half of the initial dose every 8 to 12 hours.

The response to therapy can be monitored by clinical improvement, a decreasing PTT, and, optimally, serial factor VIII activity levels. Of note, aPTT-based assays including clot-based FVIII activity assays should not be performed if patients are on emicizumab as it will artifactually shorten aPTT and elevate FVIII activity.[22] The lack of a response to factor VIII administration should raise suspicion for the presence of

TABLE 111.5 Recommended Factor VIII Therapy and Dosing for Complications Associated With Hemophilia

Type of Bleeding	Initial Dosage	Comment
Skin		
Abrasion	None	Treat with local pressure and topical tranexamic acid
Superficial laceration	Usually none; if closure is needed then then 25 U/kg	Local pressure and tranexamic acid may benefit; watch 4 hours after suturing; reexamine in 24 hours
Deep laceration	25 U/kg	May need hospitalization for observation; repeated dose may be necessary for suture removal
Superficial muscle hematoma	25 U/kg	May be complicated by local pressure on nerves or vessels; monitor for compartment syndrome
Deep muscle hematoma (e.g., iliopsoas)	50 U/kg	May be complicated by local pressure on nerves or vessels; monitor for compartment syndrome if in an extremity
Epistaxis		
Spontaneous	Usually none; but if persistent, consider 25 U/kg	Uncommon; consider platelet inhibition; treat in usual manner and consider tranexamic acid application
Traumatic	25 U/kg to 50 U/kg	Trauma-related bleeding can be significant. Consider 50 U/kg given head trauma and possible development of ICH.
Oral		
Mucosa or tongue bites or other similar minor injuries	Usually none; treat with 25 U/kg if bleeding persists	Saliva is rich in fibrinolytic activity; oral ε-aminocaproic acid (Amicar) may be given as 5 g (or 100 mg/kg) during the first hour, then 1 g per hour for 8 hours or until bleeding is controlled to block fibrinolysis; oral tranexamic acid may also be used (25 mg/kg) PO every 6 to 8 hrs, check for contraindications (patients receiving PCC or high risk of thrombosis); hospitalize patients with severe bleeding
Traumatic oral lesion (laceration) or dental extraction	25 U/kg to 50 U/kg	Saliva is rich in fibrinolytic activity; oral ε-aminocaproic acid (Amicar) may be given as 5 g (100 mg/kg) during the first hour, then 1 g per hour for 8 hours or until bleeding is controlled to block fibrinolysis; oral tranexamic acid may also be used (25 mg/kg) PO every 6 to 8 hrs, check contraindications (patients receiving PCC or high risk of thrombosis); hospitalize patients with severe bleeding
Hemarthrosis		
Early or moderate	25 U/kg	Treat at earliest symptom (pain); knee, elbow, ankle more common
Late hemarthrosis or nonresponsive to earlier treatment	40 U/kg	Arthrocentesis rarely necessary, immobilization is a critical component of therapy
Hematuria	25 U/kg	Painless hematuria should be treated with bed rest and hydration. With persistent hematuria, an anatomic cause should be excluded. Antifibrinolytics are not recommended as they prevent lysis of clots in the ureter causing serious obstructive uropathy.
Major/Life-Threatening Bleeding	50 U/kg	Administer on the suspicion of a major or life threatening bleed.

inhibitors. Up to 20% of patients develop IgG inhibitor antibodies, and usually have a severe deficiency necessitating multiple factor VIII infusions. The treatment may be complex, thus discussion with a hematologist or hospitalization may be necessary. A variety of therapies have been considered, and current treatments of choice include bypassing agents or immune tolerance induction.[23] In the emergency care setting, generally the safest immediate action is to administer recombinant factor VIIa at a dose of 90 mcg/kg IV. For patients not currently on emicizumab, an additional consideration is activated prothrombin complex concentrate at a dose of 75 to 100 units/kg IV.[20]

Hemophilia B (Christmas Disease)

Hemophilia B is a deficiency of factor IX activity. Its genetic pattern and clinical findings are indistinguishable from those of hemophilia A, but its incidence is only a fifth that of hemophilia A. Factor IX is a vitamin K–dependent glycoprotein. Its deficiency is diagnosed by a factor IX assay, usually after the factor VIII assay is found to be normal.

Clinical presentations and treatment strategies associated with hemophilia A also generally apply to hemophilia B, including those for patients who have developed inhibitors. The replacement factor therapy is similar to that for hemophilia A, with use of a recombinant factor IX preparation. Plasma-derived concentrate is a suitable alternative in an emergency situation when recombinant factor IX is unavailable. Fresh frozen plasma is not routinely recommended for hemophilia B treatment, and cryoprecipitate does not contain factor IX. Given the comparatively longer half-life of factor IX, the maintenance factor dosing schedule is every 24 hours. When bleeding is severe, the appropriate dose of factor IX is 100 to 140 units/kg IV, which should result in a factor level of 80% to 100%. For hemophilia B with inhibitors, the safest immediate action is recombinant factor VIIa at a dose of 90 mcg/

kg IV. For those not currently on emicizumab, an additional consideration is activated prothrombin complex concentrate at a dose of at 75 to 100 units/kg IV.[20] As with hemophilia A, a hematologist should be included in the decision making as soon as is feasible.

von Willebrand Disease

Von Willebrand disease is the most common hereditary bleeding disorder, with an estimated prevalence of 1%. Quantitative or qualitative deficits in vWF are associated with clinical findings. Platelet adhering properties or factor VIII activity may be altered in vWD.

Manifestations of vWD are usually milder and less debilitating than those of hemophilia. The factor VIII activity level is in the 6% to 50% range. Bleeding sites are predominantly mucosal or cutaneous. Hemarthroses are rare, and menorrhagia and gastrointestinal bleeding are common.

Desmopressin, 0.3 mcg/kg IV, is of benefit in patients with mild to moderately severe vWD. Desmopressin is the preferred treatment for patients with mild to moderately severe disease, given its low risk profile and low cost. Adjunctive antifibrinolytic agents, such as tranexamic acid, have also shown benefit in vWD. In extreme circumstances, fresh frozen plasma or cryoprecipitate may be utilized. Severe vWD, with very low or absent vWF levels, is rare (1–5%) and presents early in life.

In patients with severe vWD, or in those with mild to moderately severe vWD who do not respond to desmopressin, replacement therapy with factor VIII in the form of lyophilized concentrate of factor VIII/vWF at a dose of 50 IU/kg is indicated. A unique response to the transfusion of plasma components in patients with vWD is the stimulation of a progressive increase in factor VIII activity that lasts 12 to 40 hours. After the initial dose, fewer units are necessary, and longer dosage schedules may be followed by clinical or laboratory response.

Miscellaneous Coagulation Disorders

A number of other disorders may be caused by deficiencies in the coagulation pathway. An altered level, or abnormal function, of fibrinogen may occur, leading to an abnormal thrombin time. The inherited forms are rare, and acquired forms are associated with fibrin-blocking substances or hypofibrinogenemia, which are found most often in the setting of DIC, or dysfibrinogenemia associated with macroglobulinemia, multiple myeloma, or hepatoma.

Rare inherited deficiencies may occur with other components of the common pathway (factors II, V, and X). Acquired forms are far more common and typically relate to vitamin K deficiency or warfarin use (decreased factor II, VII, IX, and X activity), hepatic insufficiency (potentially all factors except factor VIII), or massive transfusion of stored blood (low in factors V and VIII).

Medication-Induced Anticoagulation

The use of oral anticoagulants for conditions such as atrial fibrillation or venous thromboembolic disease continues to rise. Oral anticoagulation includes vitamin K antagonists such as warfarin, as well as the increasingly utilized direct-acting oral anticoagulants (DOACs). The first to gain FDA approval, dabigatran, is a direct thrombin inhibitor. Other common DOACs include rivaroxaban and apixaban, which are selective factor Xa inhibitors. Patients with impaired renal or liver function may experience excessive anticoagulation in the setting of DOAC use. Excessive anticoagulation related to warfarin occurs from a number of causes, including interactions between warfarin and other drugs or foods, or accompanying conditions that may interfere with its absorption or metabolism. Patients may present to the ED for concerns regarding supratherapeutic dosing of anticoagulants or for hemorrhage.

BOX 111.12 Critical Sites for Hemorrhage in Anticoagulated Patients

- Intracranial
- Intraocular
- Spinal
- Pericardial tamponade
- Airway (including posterior epistaxis)
- Thorax
- Intra-abdominal bleeding
- Retroperitoneal hematoma
- Intramuscular
- Intra-articular

Bleeding related to heparin therapy is less of an issue in the ED setting, though still can occur (e.g., patient coming from a dialysis center). In addition to discontinuation of heparin, protamine sulfate can urgently reverse the effects of heparin. The full neutralizing effect of UFH is achieved with 1 mg of protamine for every 100 units of heparin. Protamine can also be utilized in an attempt to reverse the effects of LMWH, though in a less predictable or complete fashion as occurs with UFH. This is an off-label use and should be considered in life-threatening bleeding and, if possible, discussed with a hematologist. In this setting, the dose of protamine is 0.5 to 1 mg for every 1 mg of LMWH depending on timing of last administration; if ≤8 hr, use 1 mg, if >8 hr, use 0.5 mg. Administration of protamine should not exceed more than 50 mg over 10 minutes, as more rapid injection may result in adverse effects including hypotension.

In the setting of over-anticoagulation or hemorrhage related to DOAC use, management has shifted with the more recent development of drug-specific reversal agents. Careful consideration of the risk of thromboembolic events weighed with the benefits of bleeding cessation must be taken into account. If bleeding occurs in critical sites (Box 111.12) or is associated with hemodynamic compromise, then reversal should be strongly considered.[24] For dabigatran, the FDA-approved reversal agent idarucizumab, 5 g IV, can be administered. If idarucizumab is unavailable, consider activated prothrombin complex concentrate (aPCC) at a dose of 50 units/kg IV. 4F-PCC has been studied in vitro, and healthy volunteer studies but not prospectively with dabigatran-associated bleeding at this time. If aPCC is unavailable, then 4F-PCC is a reasonable alternative.[24] 4F-PCC (K-centra) includes factors II, VII, IX and X along with protein C and S whereas aPCC such as Factor Eight Inhibitor Bypass Agent (FEIBA) has inactive factors II, IX, X, and activated VII. In addition, dialysis may be considered for dabigatran, as approximately 57% of the drug is removed with 4 hours of dialysis. Caution needs to be exercised in dialysis catheter placement, however. For apixaban or rivaroxaban, the FDA-approved reversal agent for use in life-threatening bleeds is andexanet alfa.[25] An alternative to andexanet alfa is 4F-PCC at a dose of 25 to 50 units/kg IV, or a fixed dose of 2000 units IV. aPCC has been studied in vitro, and healthy volunteer studies but not prospectively with oral factor Xa–associated bleeding at this time.[26] If no andexanet alfa or 4F-PCC is unavailable, then aPCC is a reasonable alternative for life-threatening bleeding. For other DOACs, such as edoxaban or betrixaban, off-label use of andexanet alfa is a possible intervention, or use of 4F-PCC at a dose 50 units/kg or fixed dose of 2000 units IV.

Management of excessive anticoagulation from warfarin depends on the degree of elevation of the INR and whether there is accompanying bleeding (Table 111.16). If the INR is below 4.5 and not accompanied with bleeding, treatment consists of withholding additional warfarin. If the INR level is between 4.5 and 10 without bleeding, we recommend holding additional warfarin doses for 1 to 2 doses. There

TABLE 111.6 Treatment for Supratherapeutic INR

INR Level/Bleeding	Recommendation
Major, life-threatening bleeding	Cessation of warfarin Vitamin K 10 mg (IV over 30 minutes)
Any INR	4F-PCC (KCENTRA) (See dosage in Table 111.7)
INR > 10, active bleeding	Cessation of warfarin Vitamin K 10 mg (IV over 30 minutes) 4F-PCC (KCENTRA) 50 U/KG, maximum dose 5000 units.
INR > 10, no bleeding	Cessation of warfarin Vitamin K 5 mg oral
INR 4.5 < 10, no bleeding	Cessation of warfarin If higher risk of bleeding or lower chance of thromboembolism, consider vitamin K 2.5 mg oral
INR < 4.5, no bleeding	Cessation of warfarin

TABLE 111.7 4F-PCC Dosage for Warfarin Reversal in Major Bleeding

Baseline INR Level	4F-PCC Dosage
INR 2 < 4	25 U/KG, maximum dose 2500 units
INR 4 < 6	35 U/KG, maximum dose 3500 units
INR > 6	50 U/KG, maximum dose 5000 units

are differing opinions on whether or not a small dose of 1.0 to 2.5 mg of oral vitamin K is indicated. It appears reasonable to give to those patients with a higher chance of bleeding or lower risk of thromboembolism vitamin K.[27,28] Treatment for patients presenting with an INR level above 10 but not bleeding includes holding warfarin and treating with 5 mg of oral vitamin K. Patients presenting with an elevated INR and active bleeding require cessation of warfarin, 10 mg of vitamin K IV, plus the administration of 4F-PCC or fresh frozen plasma (Table 111.17).[24,27] Vitamin K can be administered orally, intravenously, or subcutaneously. Oral dosing is superior to other routes of administration, and subcutaneous dosing is the least desirable method of administration owing to erratic serum level. Intravenous vitamin K given should be administered as a slow infusion over 20 to 30 minutes rather than a rapid bolus injection.

Disseminated Intravascular Coagulation

DIC is a relatively common acquired coagulopathy reflecting dysregulated coagulation and fibrinolytic pathways. Hemostasis is normally achieved by a fine balance between procoagulants and inhibitors, and thrombus formation and lysis. This balance may be disturbed by multiple pathologic processes, most often encountered in the critical care setting, resulting in DIC. The abnormal clotting sequence observed in DIC is shown in Box 111.13. Its ubiquitous nature, multiple origins, and potentially devastating sequelae, combined with potentially effective treatment modalities, make early diagnosis critical.

The clinical consequences include the potential for a life-threatening combination of bleeding from loss of platelets and clotting factors, fibrinolysis, and fibrin degradation product interference; small-vessel obstruction and tissue ischemia from fibrin deposition; and RBC injury and anemia from microvascular hemolysis. The condition should be considered in any patient in whom purpura, a bleeding tendency, and signs of organ injury, particularly of the central nervous system or kidney, develop. This is further confounded clinically by the variable acuteness and intensity of intravascular clotting, the effectiveness of fibrinolysis, and other systemic manifestations of the precipitating disease. The clinical diagnosis of DIC is confirmed by laboratory testing (Table 111.8).

BOX 111.13 Disseminated Intravascular Coagulation Abnormal Clotting Sequence

Platelets and coagulation factors are consumed, especially fibrinogen and factors V, VIII, and XIII.
Thrombin is formed, and it overwhelms its inhibitor system and acts to accelerate the coagulation process and directly activate fibrinogen.
Fibrin is deposited in small vessels in multiple organs.
The fibrinolytic system by means of plasmin may lyse fibrin and impair thrombin formation.
Fibrin degradation products are released and affect platelet function and inhibit fibrin polymerization.
Coagulation inhibition levels (e.g., antithrombin III, protein C, and tissue factor pathway inhibitor) are decreased.

Severe liver disease or primary fibrinolysis may be confused with DIC. Liver disease of this severity is usually manifested by clinical jaundice and splenomegaly. Primary fibrinolysis is a rare disorder that affects fibrinogen and fibrin, though generally preserves other coagulation components (platelets, factor V, and factor VIII) in the low-normal range. Additional laboratory tests can be used to confirm the diagnosis of primary fibrinolysis in conjunction with a hematologist.

When planning therapy, it is critical to factor that DIC is secondary to a serious underlying pathologic process. Once the underlying diagnosis is confirmed, the initial treatment is focused on reversal of the triggering mechanism. Many episodes of DIC are self-limited, such as in a transfusion reaction, or compensated, such as in association with a tumor mass, and do not require specific intervention other than general supportive care.

If the patient demonstrates active bleeding, a significant risk of bleeding and requires an invasive procedure, arterial or venous thromboembolism, skin necrosis, or acral ischemia, specific management of DIC is warranted. In these cases of severe hemorrhagic or thromboembolic complications, in addition to treatment of the precipitating condition, specific management is based on which of the two major pathologic components of DIC predominates the clinical picture. In the setting of active bleeding, replacement therapy with platelets, fresh frozen plasma, and cryoprecipitate is recommended. Replacement therapy is instituted simultaneously with attempts to manage the primary inciting condition. The goal is to avoid depletion of clotting factors. Selective replacement therapy can be based on both laboratory and clinical response. Slowing of bleeding, a decrease in fibrin degradation products, and a rise in platelet count and fibrinogen level are useful monitors. Normalization of clotting times occurs later in the course, thus is of less value in initial monitoring.

Heparin can be selectively utilized in the treatment of DIC when fibrin deposition and thrombosis predominate the pathologic picture. Certain disease states are associated more with fibrin deposition, in which case heparin therapy should be considered. Examples include purpura fulminans, retained nonviable fetus before delivery, giant hemangioma, or acute promyelocytic leukemia. Conversely, heparin is

TABLE 111.8 Laboratory Diagnosis of Disseminated Intravascular Coagulation

Test	Finding	Pathophysiology
Peripheral smear	Low platelets, schistocytes, RBC fragments	RBC fragmentation on fibrin strands; schistocytes not always seen
Platelet count	Low (usually < 100,000/mm^3)	Consumed in clotting
Prothrombin time (PT)	Prolonged	Factors II and IV (calcium) consumed
Partial thromboplastin time (PTT)	Prolonged	Factors II, V, and VIII consumed
Thrombin time	Prolonged	Factor II consumed, decreased fibrinogen levels from the consumptive process of DIC (actual fibrinogen levels are variable as discussed below), and in vivo fibrinolysis leads to prolonged thrombin time even when fibrinogen levels are normal
Fibrinogen level	Low	Factor II consumed; may be difficult to interpret because it is an acute-phase reactant
Fibrin degradation products (including D-dimer)	Negligible to elevated	Dependent on the amount of secondary fibrinolysis
Serum creatinine or urinalysis	May be abnormal	Functional assessment of the kidney, as it is commonly impacted by microvascular fibrin deposition

RBC, Red blood cell.

generally of little benefit in the setting of meningococcemia, abruptio placentae, severe liver disease, or trauma. LMWH may also be utilized as an alternative to UFH. Continuous monitoring of the clinical response, heparin activity levels, and bleeding status is essential.

Other therapeutic agents have been evaluated, including antithrombin III, PCC, recombinant factor VIIa, and activated protein C, though none has demonstrated an improved outcome in DIC.

The goals of emergency care for patients with DIC include early recognition and close monitoring, focus on mitigation of the precipitating condition when possible, identifying potential life-threatening complications, and only rarely initiation of blood product or anticoagulation therapy.

DISPOSITION

Patients with bleeding disorders of unknown cause or of a significant degree should be considered for admission for further evaluation. Transfer may be necessary, particularly if hematologic expertise is not readily available. Owing to the potential for delayed bleeding in hemophiliacs, long-distance transports may be especially hazardous. Early notification and appropriate primary care or hematologic follow-up is prudent for other patients.

CHAPTER 111: QUESTIONS AND ANSWERS

1. What platelet count is generally recommended prior to performance of a lumbar puncture?
   a. 100,000 mm^3
   b. 50,000 mm^3
   c. 40,000 mm^3
   d. 20,000 mm^3
   e. 10,000 mm^3

Answer: B. A platelet count above 50,000 mm^3 is recommended prior to performance of invasive spinal procedures such as lumbar procedure. A platelet count above 20,000 mm^3 is recommended for central line placement. A platelet count above 100,000 mm^3 is recommended prior to neurosurgical procedures or invasive ophthalmologic interventions

2. An isolated elevation in prothrombin time (PT) or INR indicates an abnormality or deficiency in which of the following?
   a. Calcium
   b. Factor VII
   c. Factor XI
   d. Fibrinogen
   e. Platelets

Answer: B. The PT or INR tests the components of the extrinsic pathway, and abnormalities or deficiency in factor VII will cause elevation in PT and INR. Calcium derangements do not typically cause aberrations in PT, INR, or PTT. Factor XI is a component of the intrinsic pathway reflected in the PTT. Fibrinogen function is reflected in both prothrombin time (PT) and PTT values. Platelet deficiencies do not prolong the PT or INR.

3. If initial treatment of ITP with glucocorticoids fails, which of the following is most reasonable additional treatment for severe thrombocytopenia?
   a. Splenectomy
   b. Four factor-PCC
   c. IVIG
   d. Tranexamic acid
   e. Thrombopoietin receptor agonist

Answer: C. IVIG has been shown to improve platelet counts in patients with severe thrombocytopenia secondary to ITP. Splenectomy is considered the last line of treatment. Tranexamic acid prevents fibrinolysis. Thrombopoietin receptor agonists are typically reserved for patients who are not responsive to glucocorticoids and IVIG.

4. A 52 year-old-female presents to the emergency department with confusion, shortness of breath, and fatigue. Laboratory evaluation reveals a platelet count of 14,000 mm^3 and hemoglobin of 7.2. mg/dL, a low MCV, indirect bilirubinemia, and a creatinine of 1.4 mg/dL. Electrocardiogram shows non-specific T wave abnormalities in the lateral leads. She denies chest pain and vitals are normal. What would be the most reasonable next step in management?
   a. Obtain a blood smear and utilize a validated risk score for possible TTP.
   b. Immediate platelet transfusion
   c. Administer tranexamic acid
   d. Start IVIG
   e. Administer heparin

Answer: A. Early identification of TTP is imperative. This patient presents with classic signs and symptoms (neurologic symptoms, fatigue, thrombocytopenia, and microangiopathic hemolytic anemia). A validated score such as the PLASMIC score should be used to rapidly assess the likelihood of TTP, as early plasma exchange is the treatment of choice. A platelet transfusion will more than likely exacerbate symptoms. Tranexamic acid prevents fibrinolysis, and therefore would likely cause harm in the setting of microthrombi in TTP. IVIG has not been shown to be the front-line treatment for TTP. Heparin will further increase this patient's bleeding risk. The nonspecific T wave changes are likely due to TTP.

5. A 22-year-old patient with hemophilia A presents to the ED with a headache. He has a history of migraines but this feels different from his previous headaches. He denies any recent significant closed head injury, though states he fell while skateboarding 1 week prior. He is concerned about the possibility of bleeding. Neurologic examination is unremarkable. Upon further review of available records, the patient has a history of severe hemophilia A with inhibitors. His headache is worsening. What would be the best next step in management?
   a. Obtain imaging of brain and cervical spine.
   b. Consult neurosurgery for possible intracranial bleed.
   c. Administer factor VII as expeditiously as possible.
   d. Administer factor VIII as expeditiously as possible.
   e. Administer a migraine "cocktail" for his headache and reevaluate in 30 minutes.

Answer: C. Patients with known hemophilia should be treated empirically with factor replacement when intracranial bleeding is first *suspected*. An atypical headache, particularly in the setting of trauma (even seemingly minor or incidental trauma), should be treated with factor replacement as expeditiously as possible. Neurosurgery may need to be contacted, though consultation should not delay factor administration. Although this patient has hemophilia A (factor VIII deficiency), the presence of inhibitors (antibodies toward factor VIII) limit the utility of factor VIII replacement. In the setting of hemophilia with known inhibitors and bleeding, recombinant factor VIIa is recommended. Medications for treatment of routine migrainous symptoms may be considered secondary to exclusion of life- or disability-threatening intracranial hemorrhage.

Oncologic Emergencies

David A. Wacker and Michael T. McCurdy

FOUNDATIONS

As improved therapies prolong the lives of cancer patients, the prevalence of oncologic emergencies continues to increase. However, nonspecific clinical features misattributed to the underlying cancer complicate their diagnosis. In this chapter, we review febrile neutropenia, metastatic spinal cord compression (MSCC), malignant pericardial disease, hypercalcemia of malignancy, tumor lysis syndrome (TLS), leukostasis, superior vena cava (SVC) syndrome, and complications of cancer immunotherapies including monoclonal antibodies, T-lymphocyte checkpoint inhibition, and adoptive cell transfer therapy.

KEY CONCEPTS

- Patients whose absolute neutrophil count is or is expected to soon be 500 cells/mm^3 or lower are considered severely neutropenic. A single temperature of 38.3°C or sustained temperature of 38.0°C for 1 to 2 hours or longer is considered fever.
- Any neutropenic patient with fever or with infectious signs or symptoms (even in the absence of fever) should be evaluated for an infectious source, including drawing of blood cultures, and started on empirical antibiotics. Those with high-risk features (e.g., prolonged or profound neutropenia, pneumonia, hypotension, abdominal pain, neurologic changes, Multinational Association for Supportive Care in Cancer (MASCC) score < 21) should be started on an antipseudomonal beta-lactam (e.g., cefepime, piperacillin-tazobactam, antipseudomonal carbapenem). Those with low-risk features may be appropriate for oral antibiotics. Empirical gram-positive bacterial, antifungal, and antiviral coverage is unnecessary unless the clinical situation dictates otherwise.
- Neutropenic patients with fever should generally be hospitalized, including all high-risk patients. Select low-risk patients may be managed as outpatients.

FEBRILE NEUTROPENIA

Foundations

Whether due to underlying malignancy or as a cytotoxic effect of chemotherapeutics, cancer patients regularly experience depleted levels of circulating neutrophils. Risk of infection rises when a patient's absolute neutrophil count (ANC) drops below 1000 cells/mm^3. However, the increase in risk is most marked in patients with ANC less than 500 cells/mm^3. Historically, ANC of 1000 to 1500 cells/mm^3 has been considered mild, 500 to 1000 cells/mm^3 moderate, and less than 500 cells/mm^3 severe. Current guidelines do not emphasize these gradations, and neutropenia is defined as an ANC less than 500 cells/mm^3 or an ANC expected to drop below this threshold within 48 hours.[1,2] The ANC is calculated from a complete blood count (CBC) with differential count by the following formula:

$$\frac{([\%\,\text{granulocytes}] + [\%\,\text{bands}]) \times [\text{total WBC count}]}{100}$$

Neutropenic patients are particularly susceptible to infection, even from their own existing microbial flora, and such infection carries significant mortality risk. Twenty to thirty percent of patients with neutropenic fever require hospitalization, and of those patients, about 10% will not survive to discharge.[1] Most commonly, neutropenic fever is caused by pneumonia, anorectal lesion, skin infection, pharyngitis, or urinary tract infection. However, because local inflammatory responses are dampened by the absence of granulocytes, the only sign of infection may be fever, defined as a single temperature 38.3°C or greater or a sustained temperature of 38.0°C or greater for 1 hour or more. However, fever is not a requisite for infection; any neutropenic patient with signs or symptoms of infection should be treated as having neutropenic fever, whether actually febrile or not. In fact, suppressed temperature on presentation (<36.5°C) may portend higher mortality than fever or normothermia.

Clinical Features

Due to underlying immunosuppression, neutropenic patients often do not manifest infectious signs or symptoms beyond fever, making a thorough history and physical examination crucial. The interview should include a standard infectious review of systems, questioning for presence of diarrhea, nausea or vomiting, headache, neck stiffness, rashes, dysuria, cough, dyspnea, and pain at any location, including the abdomen, chest, joints, throat, sinuses, and ears.[2] Specific note should be made of indwelling venous catheters, because these increase the risk of bacteremia and skin infection.[1] To evaluate for perianal infection, the perineal region should be examined and inquiry made about pain with defecation. Although there is no hard evidence, expert opinion suggests against digital rectal examination to avoid compromise of the barrier between blood and rectal flora. Due to the chemosensitivity of the rapidly dividing epithelial cells of the mouth, mucositis is a common adverse effect of chemotherapy and provides a portal for oral flora into the bloodstream. This can be evaluated by examination and inquiry about oral pain.

Differential Diagnoses

Causes of fever in cancer patients are diverse and include infection, venous thrombus or embolus, adverse effect of chemotherapy or other medication, and direct effect of tumor burden. A clear source of infection is identified in only about one-third of neutropenic fever cases. Nonetheless, because of the potentially life-threatening effects of an infection in this population, all febrile neutropenic patients should receive empirical antibiotics and a full evaluation for an infectious source.

Diagnostic Testing

Neutropenic patients with fever should have at least two sets of blood cultures drawn before administration of antibiotics. Both may be drawn peripherally in patients without preexisting central access. In patients with a preexisting central line, one of the two blood cultures should be obtained peripherally, whereas other cultures should be simultaneously drawn off each lumen of the central catheter. Bacterial growth in the catheter-drawn samples greater than 2 hours prior to the peripheral samples may suggest a catheter-associated infection. Patients with neutropenic fever should also have a CBC with differential count performed to assess severity of neutropenia, as well as urinalysis, urine culture, chemistries, and renal and hepatic function tests. Serum lactate should be measured if sepsis is suspected. Additional cultures may be sent according to the clinical presentation (e.g., sputum culture if productive cough, stool culture, and testing for *Clostridium difficile* if diarrhea or abdominal pain).[1,2]

Initial imaging usually consists of chest x-ray, although this is often low-yield in the absence of specific respiratory symptoms.[3] If fever persists for 72 hours without identified source, empirical computed tomography (CT) scan of the chest and sinuses, and bronchoalveolar lavage may be considered to evaluate for occult fungal infection. Patients with a history of invasive aspergillosis, and those with profound or prolonged neutropenia are at higher risk of fungal pneumonia, and consideration should be given to pulmonary imaging if there is little clinical response within the first day of therapy.[1] Similarly, directed CT scans may be performed sooner in the setting of appropriate clinical signs (e.g., chest CT for a patient with coughing and bronchial breath sounds, but a clear chest x-ray, abdominal CT for a patient with unexplained abdominal tenderness).

As nucleotide sequencing becomes more reliable, assays employing this technique for pathogen identification[4-7] are being aggressively developed. Although these assays provide a useful adjunct, and may direct antibiotic therapy prior to culture growth, they are not yet sufficiently developed to stand in lieu of conventional diagnostics, and a full set of cultures should always be obtained.

Management

Febrile neutropenic patients should receive antibiotics prior to confirmation of an infectious source. Recommendations for specific regimens are based on risk of clinical decompensation. According to the Infectious Disease Society of America (IDSA), high-risk features include an expected duration of neutropenia greater than 7 days, expected nadir ANC less than 100 cells/mm^3, hypotension, pneumonia, new-onset abdominal pain, neurologic changes, or existence of other significant medical comorbidities. A current or prior infection with a resistant organism and treatment at a center with a high prevalence of resistant organisms should also be viewed as high risk. Alternatively, several scoring systems exist to assess risk of deterioration in neutropenic fever. The Multinational Association for Supportive Care in Cancer (MASCC) risk index identifies low-risk patients based on clinical features (Table 112.1). Patients scoring at least 21 points are considered low-risk, because nearly 90% of cases have uncomplicated resolution of their fever within 5 days. Similarly, the Clinical Index of Stable Febrile Neutropenia (CISNE) index (Table 112.2) has been validated to indicate patients with low (score 0), intermediate (score 1–2), and high (score ≥ 3) risk of clinical deterioration.[8-11]

High-risk patients should receive a parenteral broad-spectrum antibiotic regimen. Local antibiograms should be considered when choosing specific agents, but guidelines recommend monotherapy using a broad-spectrum beta-lactam with antipseudomonal coverage, such as ceftazidime, cefepime, piperacillin-tazobactam, or antipseudomonal carbapenem.[1,2] Among head-to-head studies of these agents in neutropenic patients, all have shown good effectiveness and none has consistently out-performed the others.[12-14] For patients with signs of sepsis or septic shock, double coverage for gram-negative bacteria with a fluoroquinolone or aminoglycoside in addition to beta-lactam therapy should be considered;[15] however, a meta-analysis of studies comparing beta-lactam monotherapy with combination beta-lactam/aminoglycoside therapy showed that patients receiving aminoglycoside had no survival benefit and were more likely to suffer adverse events, including nephrotoxicity and fungal superinfection. We therefore recommend antipseudomonal beta-lactam monotherapy for patients with neutropenia and fever but without signs of sepsis and septic shock. Regimens meeting these criteria for patients with normal renal function include piperacillin-tazobactam 4.5 g IV q6 hours or cefepime 2 g IV q8 hours; dosing adjustments must be made for patients with renal impairment. Further empirical antibiotics administered will depend on clinical presentation and consultation with oncology or infectious disease consultants.

Despite increasing rates of bacteremia with gram-positive organisms in cancer patients,[16,17] randomized controlled studies and meta-analyses have failed to demonstrate a survival benefit to immediate empirical gram-positive–specific coverage[18] and have previously suggested increased rates of adverse effects. Empirical gram-positive–specific therapy, such as with intravenous vancomycin or other glycopeptides, is not recommended except in cases of suspected cellulitis, catheter-associated infection, or pneumonia, or in the case of

TABLE 112.1 Clinical Features and Corresponding Point Values for the Multinational Association of Supportive Care in Cancer (MASCC) Risk Index[a]

Clinical Feature	Point Value
Age < 60 years	2
Onset of fever while outpatient	3
Overall moderate symptom burden	3
Absence of dehydration	3
No prior fungal infections or solid tumor type	4
No history of chronic obstructive pulmonary disease	4
Absence of hypotension	5
Asymptomatic or overall mild symptom burden	5

[a]A score of ≥ 21 suggests low risk of complication and likely resolution of fever within 5 days.

Stress-induced hyperglycemia	2
Chronic obstructive pulmonary disease	1
Chronic cardiovascular disease	1
Mucositis of grade ≥ 2	1
Monocyte count < 200 per μL	1

[a]A score of zero indicates low risk of clinical deterioration prior to resolution of the episode of neutropenic fever.

clinical instability. Similarly, randomized controlled trials have not shown a benefit in immediate, empirical antifungal therapy, and guidelines suggest against empirical antifungal agents, unless there is specific concern for a fungal source. Recent guidelines do suggest, however, that evaluation for fungal pneumonia with high-resolution chest CT scan, serum beta-galactomannan assay, and consideration of bronchoscopy with lavage is beneficial in patients with prolonged or profound neutropenia.[1] In cases requiring empirical antifungal coverage, echinocandins (e.g., micafungin 100 mg IV q24 hrs) compare well with other agents both in terms of effectiveness and safety profile.[19,20]

Neutropenic patients with community-acquired pneumonia should be covered for atypical pathogens and possibly pneumocystis pneumonia (PCP). For atypical pathogens we recommend either levofloxacin 750 mg IV q24 hrs or azithromycin 500 mg IV q24 hrs and doxycycline 100 mg q12 hrs (levofloxacin dose must be adjusted for impaired renal function). For PCP coverage, the preferred regimen is trimethoprim-sulfamethoxazole (TMP-SMX) at 15 to 20 mg of TMP per kilogram of patient's total body weight per day IV, divided into 3 or 4 doses per day (e.g., 5 mg/kg IV q6 hrs will result in a 20 mg/kg/day dose). TMP-SMX dosing must be adjusted for impaired renal function. For patients with gastrointestinal symptoms, one randomized controlled trial suggests improved 28-day survival with cefepime/metronidazole combination therapy when compared to piperacillin-tazobactam monotherapy. We recommend cefepime 2 g IV q8 hrs and metronidazole 500 mg PO q8 hrs (cefepime dose must be adjusted to renal function). Patients with a vesicular rash or other evidence of herpes infections should receive empirical acyclovir; an initial regimen of 5-10 mg/kg IV every 8 hrs is appropriate for severe cases. In the case of renal impairment, acyclovir dosing must be adjusted.

Although no specific timing of antibiotic administration is recommended in the current IDSA guidelines, evidence is mounting that delays in initiation of antibiotic therapy are correlated with worsened outcomes.[21,22] We therefore recommend that high-risk patients receive antibiotic therapy as soon as possible after obtaining blood cultures. Many process improvement efforts have been shown to reduce time to antibiotics in the ED setting, including implementation of neutropenic fever order sets and a dedicated neutropenic fever response team,[23] elevation of patients with neutropenic fever in the triage queue,[24] and establishment of a protocol for initiation of antibiotics by the bedside nurse in appropriate patients.[25]

Observational studies and a meta-analysis have demonstrated that low-risk patients may be treated with an enteral regimen, usually amoxicillin/clavulanate (875 mg PO q12 hrs) and a fluoroquinolone (e.g., ciprofloxacin 500 mg PO q12 hrs). Both amoxicillin/clavulanate and levofloxacin doses must be adjusted in the case of impaired renal clearance. Alternatively, low-risk patients may be started empirically on parenteral broad-spectrum therapy as outlined previously with transition to an enteral regimen after 24 to 48 hours if no complications arise.[26,27]

Disposition

Regardless of risk category, the majority of febrile neutropenic patients will be hospitalized for observation and initial treatment,[28,29] ideally to a unit specialized for oncology patients. Hemodynamically unstable patients and those with a deteriorating course should be admitted to an intensive care unit (ICU). A small fraction of patients may be safely treated with enteral antibiotics in the outpatient setting.[30,31] These patients should (1) meet the low-risk criteria of a MASCC score of 21 or less; (2) have no evidence of pneumonia, line infection, cellulitis, or organ failure; (3) have reliable daily follow-up with their oncologist; (4) demonstrate clinical stability during observation in the ED for 4 hours or longer; (5) carry low suspicion of infection with a drug-resistant organism.[26,27] Prior to discharge, an initial dose of parenteral antibiotics should be given in the ED, reliable follow-up and access to the outpatient antibiotic regimen must be ensured, and discharge should be coordinated with the patient's oncologist.[26,27]

METASTATIC SPINAL CORD COMPRESSION

KEY CONCEPTS

- Vertebral metastasis and spinal cord compression should be considered in any cancer patient, particularly those who have back pain, peripheral strength or sensory loss, or bowel or bladder dysfunction.
- MRI of the spine is the preferred diagnostic test when evaluating spinal cord compression. CT of the spine with myelography may be performed if MRI is contraindicated or unavailable. Plain films are not sufficiently sensitive to rule out spinal cord compression.
- Intravenous corticosteroids (dexamethasone 10 mg bolus) should be given to any patient with neurologic deficits from known or suspected MSCC. Consideration should be given to emergent surgical and radiotherapeutic intervention if compatible with goals of care.

Foundations

Malignancy-related compromise of the spinal cord most commonly occurs from an extradural neoplasm that has metastasized to the vertebral column. The lesion then typically expands locally from the marrow space through a vertebral vein foramen to invade the spinal canal. Although the resulting cord injury is termed *metastatic spinal cord compression (MSCC),* direct nerve compression by tumor is uncommon. Cord injury is more commonly caused by occlusion of the epidural venous plexus, leading to breakdown of the blood-cord barrier and vasogenic edema. If untreated, tumor expansion eventually leads to arterial obstruction, causing cord ischemia and infarct. Less commonly, direct compression of the cord over time may lead to demyelination and axonal injury.

The most common tumors causing MSCC are prostate, breast, and lung cancer, each accounting for about 15% to 20% of total cases. Renal cell cancer, non-Hodgkin lymphoma, and multiple myeloma each account for an additional 5% to 10% of all cases. Most cases of MSCC affect the thoracic spine (60%), with the lumbosacral and cervical spine each making up 25% and 15% of cases, respectively. Twenty to forty percent of patients with MSCC have multiple loci of spinal metastasis.

Clinical Features

Back pain, weakness, sensory loss, and autonomic function loss are the most frequent presenting symptoms of MSCC. Back pain occurs in more than 95% of patients with MSCC and is the most common initial symptom.[32] Extremity weakness occurs in up to 75% and generally (but not always) precedes sensory loss. Patients with MSCC may also present with autonomic nerve dysfunction, including loss of bowel or bladder function, but it is a late finding and rarely presents in isolation.

Differential Diagnoses

In addition to MSCC, patients with back pain with or without neurologic symptoms should be considered for nonmalignant musculoskeletal etiologies (e.g., muscle strain, ligamentous sprain, pathologic fracture, disc displacement, radicular stenosis, vertebral osteoarthritis) and paraspinal or vertebral infections (e.g., paraspinal abscess, vertebral osteomyelitis, discitis). In patients with known malignancy, new back pain and neurologic deficits (motor, sensory, or autonomic) carry high specificity for MSCC,[32] and this diagnosis should be presumed

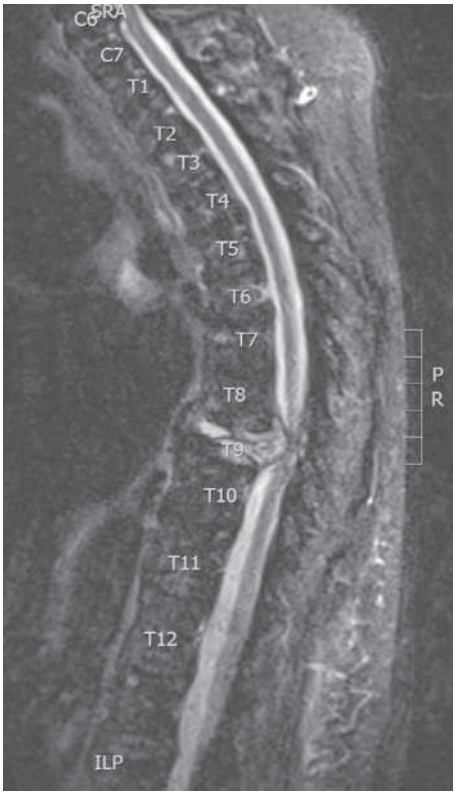

Fig. 112.1 Magnetic resonance imaging (MRI) short tau inversion recovery (STIR) image of T9 vertebral malignancy with pathologic fracture causing spinal cord compression in a patient with multiple myeloma. and investigated. In patients without known cancer, however, new back pain is the heralding symptom of cancer in 20% of cases of MSCC, which commonly takes up to two months from original presentation to diagnose.

Diagnostic Testing

A thorough physical examination should be performed, including palpation of the entire spine, as well as testing of strength, sensation, deep tendon reflexes, and rectal tone. The diagnosis is confirmed by imaging, for which magnetic resonance imaging (MRI) has become the gold standard[32] with sensitivity of 93% and specificity of 97% (Fig. 112.1). Even in patients in whom MSCC has been established by another modality, MRI should still be performed when possible, because its added resolution changes treatment strategy in approximately 50% of cases. Because multiple separate lesions can occur simultaneously, both the thoracic and lumbar spine should be imaged in any patient with MSCC. Although the incidence of a second lesion in the cervical spine is much lower, this segment should also be included when possible.

If MRI is unavailable or contraindicated (e.g., patients with incompatible pacemakers), CT scan of the spine is the next most informative study. If vertebral metastasis is seen on initial scans, presence of cord compression can be assessed by CT myelography, in which contrast is introduced into the subarachnoid space.[32] Sensitivity of this technique rivals that of MRI, but MRI offers similar information noninvasively. Thus, CT myelography is reserved for those rare patients in whom MRI is contraindicated yet radiographic confirmation of cord compression as the cause of symptoms is required prior to intervention. Plain radiographs, positron emission tomography (PET) scans, and radionuclide scans may demonstrate vertebral metastasis, but sensitivity is limited. Furthermore, these techniques provide no information about the state of the spinal cord itself or the precise location of suspected compression. These studies are therefore insufficient to rule out MSCC.[32]

Management

Treatment of MSCC in the ED entails administration of corticosteroids and initiation of definitive treatment with surgery, radiation therapy, or both.[33,34] Corticosteroids provide the most immediately available therapy for cord compression; unlike surgery or radiation, their administration does not require significant logistical planning or knowledge of the exact anatomic location of tumor. Early steroid administration has been shown to improve ambulation rates at 3- and 6-month intervals, and patients receiving corticosteroids have improved long-term pain scores. Current guidelines suggest a 10 mg intravenous bolus of dexamethasone followed by 16 mg orally per day in divided doses for any patient with neurologic deficits believed secondary to MSCC.[34] Patients with severe deficiencies, such as paraplegia, may receive a higher dose of 100 mg intravenous dexamethasone, followed by 96 mg orally per day in divided doses. Steroids are generally unnecessary in patients with vertebral metastases on imaging but without neurologic deficits.

Corticosteroids temporize vasogenic cord edema, but cord damage will ensue without definitive correction with radiation therapy, surgery, or both. For patients who can tolerate surgery and have goals of care in line with surgery, a combination of surgical decompression followed by radiation therapy provides better long-term rates of continence, ambulation, and survival than radiation therapy alone, and combined management is recommended in the most recent guidelines.[34,35] Surgical intervention is especially important in patients with spinal instability or cord compression by bony fragments.[35] Although surgery carries a high complication rate,[36] development of mini-open approaches[37,38] and use of postoperative stereotactic body radiation therapy to limit the degree of necessary resection[35] show promise to reduce complication rates and shorten recovery times. For patients unable to tolerate surgery or with incompatible goals of care, radiation alone may be pursued. Conventional fractionated radiotherapy has previously been the standard of care and continues to be an important modality for radiation therapy. Stereotactic body radiation therapy (SBRT), which employs advanced tumor mapping and beam-focusing techniques to allow safe delivery of significantly higher bolus doses of radiation to tumor cells without collateral injury to nearby tissues, is rapidly developing a central role in the management of MSCC. This is particularly true for patients with tumor histology known to be insensitive to fractionated radiotherapy, and for those with tumor in an area that has already received a maximum allowable radiation dose.[39] Neurointerventional radiology technologies such as injection of cement into spinal column fractures, or intra-arterial tumor embolization and other ablative techniques also show promise for patients whose goals of care are incompatible with major surgery.[35]

Although some recovery of lost neurologic function is possible after decompression, often the greater impact of treatment is prevention of further damage. In fact, neurologic status at initiation of treatment is the strongest indicator of functional outcome, and every effort should be made to expedite appropriate therapy to prevent further neurologic decline. No direct evidence exists to guide the exact timing of treatment, but most experts recommend definitive treatment within 24 hours whenever possible.[32]

Disposition

Following corticosteroid administration, patients with neurologic deficits (i.e., motor, sensory, or autonomic) should be hospitalized

for definitive therapy. Asymptomatic patients with incidentally noted vertebral metastasis may be managed as outpatients, provided they have reliable follow-up. Given the complexity intrinsic to management of MSCC, a multidisciplinary approach involving oncology, radiation oncology, and neurosurgery should be employed regardless of disposition.[40]

MALIGNANT PERICARDIAL DISEASE

KEY CONCEPTS

- No clinical sign or symptom is entirely sensitive for cardiac tamponade, but echocardiographic findings of a large pericardial effusion (anechoic circumferential stripe around the heart) and right atrial or ventricular collapse during diastole, combined with clinical findings of shock are highly suggestive.
- If compatible with goals of care, pericardial effusion causing tamponade should be emergently drained. Intravenous fluid or inotrope administration may be trialed as a temporizing measure, but these therapies are unreliable and should not delay definitive management.

Foundations

Pericardial manifestations of malignant disease, including pericarditis, pericardial neoplasm (usually metastatic), and pericardial effusion affect greater than 10% of cancer patients and cause about 25% of all effusive pericardial disease in the developed world.[41] Approximately two-thirds of malignancy-associated pericardial disease is clinically insignificant. However, in the remaining one-third of cases, hemodynamic compromise, organ failure, or death occurs.

Neoplastic disease is believed to cause pericardial effusion when lymphatic flow, which normally drains fluid from the pericardium, becomes obstructed or reversed by congestion in proximal malignant lymph nodes. An effusion develops both by obstruction of fluid outflow, and by metastatic spread to the pericardial lining, leading to a nonphysiologic increase in pericardial fluid production. The most common culprits in this process are lung, breast, and hematologic tumors, as well as melanoma.[41] Effusions not directly caused by malignancy may also develop in cancer patients secondary to hypoalbuminemia or as an adverse effect of radiation or chemotherapy.

Although the pericardial sac has the elastic potential for gradual expansion to greater than 1 L, it is poorly distensible in short (i.e., hours to days) time frames, and rapid accumulation of even a few hundred milliliters of fluid may precipitate cardiac tamponade. This life-threatening condition occurs when intrapericardial pressures rise to match or surpass those of the atria and then ventricles, reducing or eliminating cardiac output and leading to shock.

Clinical Features

The classic presenting symptoms of pericardial disease are dyspnea and chest pain. Weakness and fatigue are often associated, and large, slowly accumulating effusions may result in mass effect on nearby structures, causing nausea, early satiety, cough, hiccups, hoarseness, or dysphagia. Cardiac tamponade presents with shock, but other classic stigmata of the disease are unreliable. Pulsus paradoxus, defined as a 10 mm Hg systolic blood pressure gradient between inspiration and expiration in the respiratory cycle, is the most sensitive sign, present in about 80% of cases. Kussmaul sign (paradoxically increased jugular venous pressure [JVP] with inspiration) and Beck triad (hypotension, elevated JVP, and muffled heart sounds) are seen in less than half of cases. Hypotension may not even be a presenting symptom, particularly in patients with underlying hypertension.

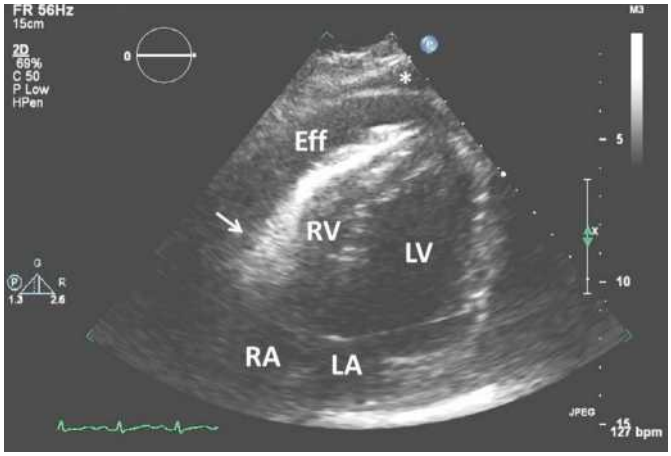

Fig. 112.2 Four-chamber apical view demonstrating pericardial effusion *(Eff)* with tamponade physiology in a patient with breast cancer. Buckling of the right ventricle wall is marked by a *white arrow*. Left ventricle *(LV)*, left atrium *(LA)*, right ventricle *(RV)*, and right atrium *(RA)* are all as marked. Incidentally noted pleural effusion is marked with an asterisk *(*)*. (Photo courtesy of the Division of Cardiology, Department of Internal Medicine, University of Maryland School of Medicine.)

Differential Diagnosis

Because of its nonspecific presentation, the differential diagnosis for malignant pericardial effusion is broad. Considerations should include acute coronary syndrome, acute heart failure or valve failure, pulmonary embolism, pleural effusion, pneumonia, and pneumothorax.

Diagnostic Testing

Evaluation for a patient with suspected malignant pericardial effusion should include chest radiography, electrocardiogram (ECG), and transthoracic echo (TTE). Electrocardiographic manifestations may include nonspecific ST or T changes, or low amplitude QRS voltage. Electrical alternans (alternating high and low QRS amplitudes) is only seen in 10% of cases. An enlarged cardiac silhouette on chest x-ray may suggest a large effusion. Echocardiography, which approaches 100% sensitivity and specificity for pericardial effusion, can also identify characteristics of tamponade physiology, such as cardiac chamber collapse and abnormal tissue imaging markers (e.g., tricuspid valve annular plane systolic excursion).[42] Emergency clinicians, who are trained in basic bedside cardiac ultrasound, can reliably identify pericardial effusion and should perform the initial examination to hasten diagnosis (Fig. 112.2).

Management

Malignant pericardial effusion generally serves as evidence of advanced cancer, and therapies should be tailored to match each patient's goals of care. If aggressive therapy is desired, cardiac tamponade is a medical emergency and warrants immediate drainage, ideally under real-time ultrasonographic guidance (Fig. 112.3). Ultrasound-guided drainage by the intercostal approach results in fewer complications and higher success rates than blind drainage by the subxiphoid approach. If ultrasound is unavailable, a subxiphoid approach should be employed by inserting the needle at a 15-degree angle to horizontal between the xyphoid process and left costal margin. After clearing the rib cage, the needle should be leveled and advanced toward the left shoulder until return of fluid is achieved. Temporizing measures such as inotropes (e.g., epinephrine in hypotensive patients, dobutamine in normotensive patients) or intravenous fluids may be attempted, but, despite

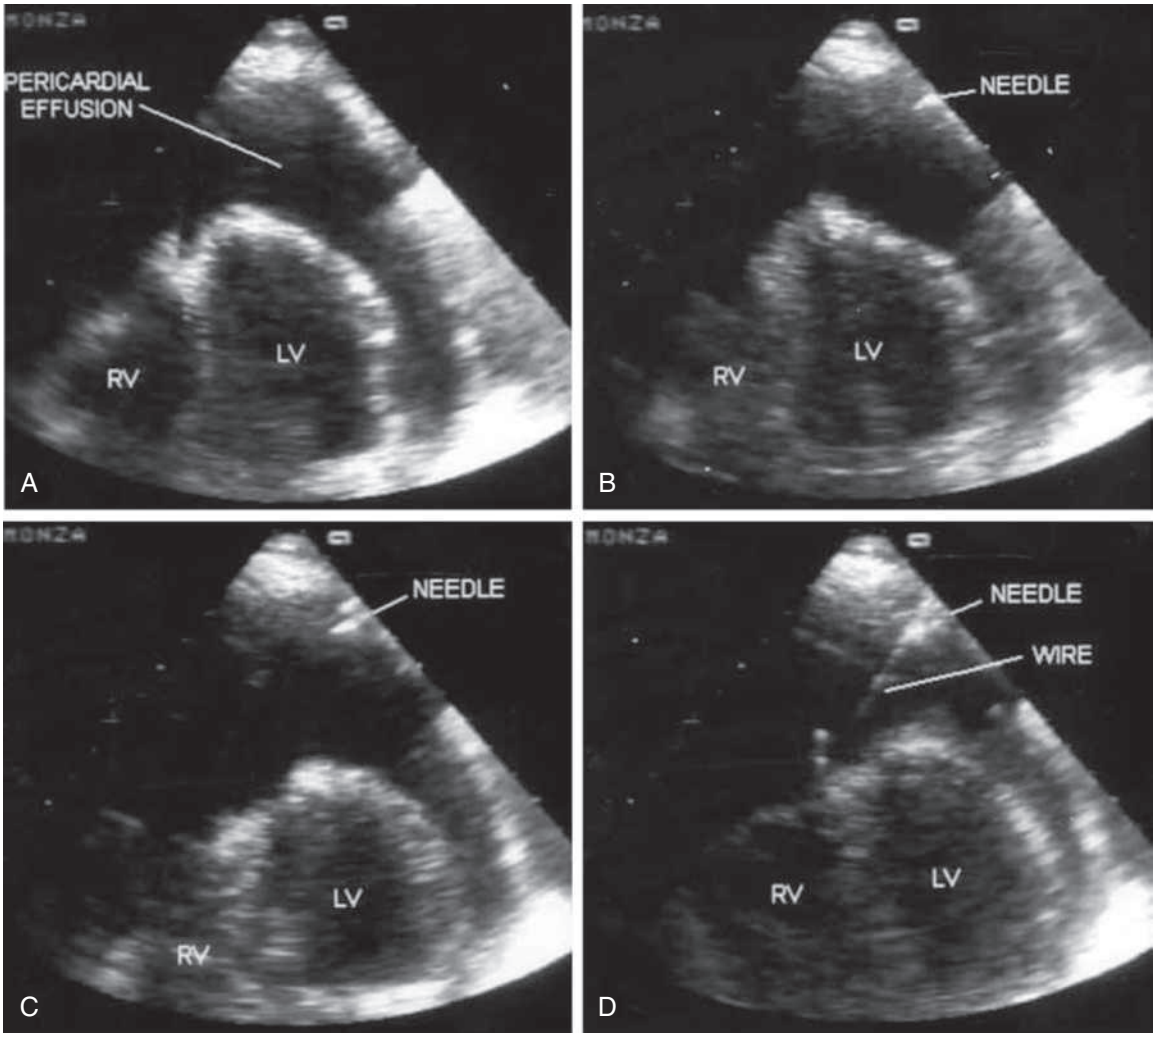

Fig. 112.3 Ultrasound-guided drainage of pericardial effusion. (A) A four-chamber apical view reveals a large pericardial effusion. (B and C) Under ultrasound guidance, a needle is advanced through an intercostal space and to the pericardial sack. (D) Upon reaching the pericardial sack fluid can be drained directly, or a wire advanced for drain placement by Seldinger technique. *LV,* Left ventricle; *RV,* right ventricle. (Reproduced from: Maggiolini S, et al. Echocardiography-guided pericardiocentesis with probe-mounted needle: report of 53 cases. *J Am Soc Echocardiogr.* 2001;14:821-824, with permission.)

early successes in trials on anesthetized animal models, these measures have not demonstrated reproducible benefit in humans and should not be viewed as a substitute for timely drainage.

Effusion without tamponade can be managed nonemergently. Fluid sampling for cytology and tumor marker analysis can help confirm etiology of effusion. This also allows intrapericardial chemotherapy or injection of sclerosing agents in a more controlled fashion. Malignant effusions tend to recur, so a long-term evacuation strategy by way of percutaneous drain,[43] surgical window,[44] or percutaneous balloon pericardiotomy[45] should be considered.

Disposition

Disposition depends on the hemodynamic effect of the pericardial effusion. Patients without tamponade or with a low likelihood of tamponade in the near future (i.e., slow evolution of symptoms) can be managed nonemergently as an outpatient. Those with tamponade or rapid development of effusion should undergo pericardiocentesis and be hospitalized to monitor for fluid reaccumulation.

HYPERCALCEMIA

KEY CONCEPTS

- Calcium levels in hypercalcemic patients should be assessed by measuring ionized calcium concentration, rather than total calcium concentration.
- First-line management of hypercalcemia includes intravenous fluids (1–2 L crystalloid bolus followed by 200–250 mL/hr), and loop diuretics only for volume management, as well as bisphosphonate therapy (pamidronate 90 mg or zoledronate 4 mg, intravenously). Calcitonin is faster acting than bisphosphonates, but tachyphylaxis may develop; consider calcitonin in hypercalcemic patients with active cardiac or neurologic symptoms (e.g., dysrhythmias, seizures).

FOUNDATIONS

Serum calcium regulation is achieved by parathyroid hormone (PTH) and calcitriol (the activated form of vitamin D), which both increase serum calcium level, and to a lesser extent by calcitonin, which

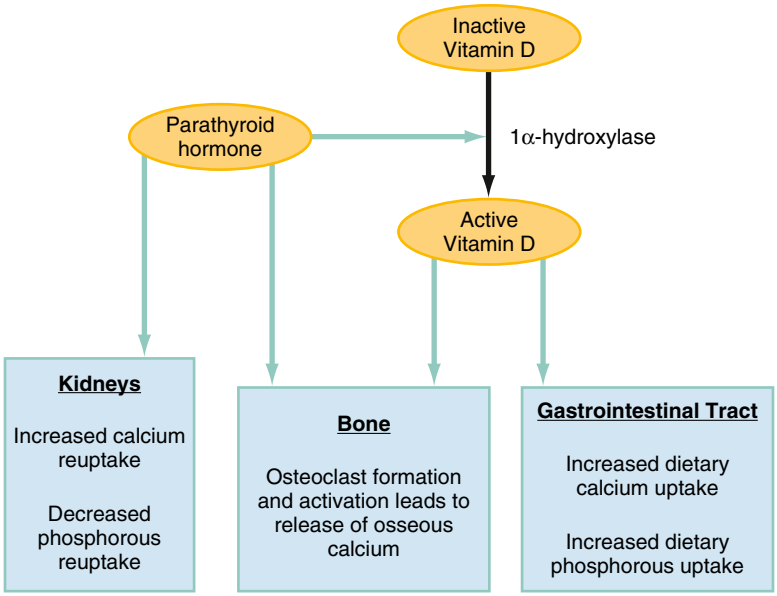

Fig. 112.4 Schematic representation of normal calcium homeostasis. Signaling molecules are represented by *circles,* targets of each signaling molecule and effects on the target are represented by *green arrows* and *boxes.* Activation of vitamin D by 1α-hydroxylase is represented by a *black arrow.*

decreases it (Fig. 112.4). Approximately a third of cancer patients will experience dysregulation of calcium homeostasis, usually caused by one or more of the following: (1) synthesis of the PTH analog PTH-related protein (PTHrP), (2) overproduction of calcitriol, (3) bone osteolysis due to direct spread of tumor, or, (4) less commonly, ectopic production of PTH.[46] In most cases, malignancy-associated hypercalcemia signifies advanced disease, with median survival of less than two months.[47-49]

Synthesis of PTHrP, classically called *humoral hypercalcemia*, causes about 80% of cases of malignancy-associated hypercalcemia, and is usually associated with squamous cancers, such as head and neck, lung, esophageal, cervical, ovarian, and endometrial carcinomas. Calcitriol overproduction is usually seen in Hodgkin and non-Hodgkin lymphomas, in which secreted cytokines inappropriately activate the vitamin D–activating enzyme 1α-hydroxylase in macrophages. Bony metastasis can cause local cytokine-induced osteolysis and, if extensive, can lead to hypercalcemia. Ectopic PTH production is a rare feature of malignancies, mainly limited to case reports. Primary hyperparathyroidism occurring coincidentally with cancer is much more common.[46]

Clinical Features

Presenting symptoms often include weakness, lethargy, confusion, abdominal pain, nausea, vomiting, constipation, polyuria, polydipsia, and kidney injury. Signs of dehydration may also be present. Manifestations depend not only on the absolute value of serum calcium but also on the patient's age and comorbidities and the rate of increase of serum calcium.[46] Acute hypercalcemia most commonly presents with neurologic abnormalities and acute kidney injury, as well as cardiac dysrhythmias if severe. Nephrolithiasis and nephrocalcinosis occur more commonly with chronic hypercalcemia, and they are infrequent manifestations of malignancy-associated hypercalcemia. Physical examination findings are often nonspecific. Electrocardiogram findings may initially exhibit QT interval shortening, progressing to dysrhythmias and heart block as hypercalcemia worsens.[50]

Differential Diagnoses

Because of its nonspecific presentation, the differential diagnosis for malignancy-associated hypercalcemia is quite broad. Consideration should be given to infection with systemic manifestations, direct neurologic injury (e.g., cerebrovascular accident or central nervous system [CNS] infection), or other metabolic derangements (e.g., hyper- or hyponatremia, acidemia, or TLS).

Diagnostic Testing

Accurate measurement of the free serum calcium level is the most important step in the evaluation of malignancy-associated hypercalcemia. Measurements of total serum calcium, which are often included in basic metabolic panels, include a large fraction of physiologically inert calcium, which is bound to albumin and other serum proteins. Approximations of the bound fraction of serum calcium can be made using serum albumin measurements, but factors affecting the avidity of calcium for serum proteins, such as pH and the presence of medications that compete for binding sites, as well as abnormal concentrations of non-albumin proteins, may lead to inaccuracies in this calculation. It is therefore recommended that free or ionized levels of calcium be obtained for any patient with suspected malignancy-associated hypercalcemia.

Testing for additional metabolic abnormalities including serum levels of sodium, potassium, bicarbonate, chloride, magnesium, and phosphorous should be performed, as should an assessment of kidney function with blood urea nitrogen and creatinine.[46] A brief review of reversible factors exacerbating hypercalcemia such as thiazide diuretic use or exogenous calcium supplementation may be helpful. Further testing to determine the etiology of malignancy-associated hypercalcemia (PTH, PTHrP, and calcitriol levels, as well as skeletal survey for bone metastasis) may eventually be undertaken but is generally unnecessary in the ED, because initial therapy is not etiology-specific.

Management

Severe hypercalcemia, especially if rapidly developing, will lead to death if untreated. First-line treatment for malignancy-associated hypercalcemia is intravenous fluid. Hypercalcemia impairs renal resorption of water and sodium, leading to hypovolemia. Hypovolemia further limits the kidneys' ability to eliminate calcium, creating a feedback loop that propagates hypercalcemia and hypovolemia. To break this loop, euvolemia must be restored, generally by

administration of intravenous fluid. An initial bolus of 1 to 2 liters of crystalloid followed by 200 to 250 mL/hr has been recommended.[46] We recommend that patients with acute oliguria or anuria be vigorously volume challenged, because poor urine output may simply be a product of hypovolemia. However, if urine output does not improve, as may be the case with heart or kidney failure, resulting hypervolemia should be treated with a combination of diuresis, dialysis, and positive-pressure ventilation. Historically, loop diuretics have been used even for euvolemic patients in an attempt to force calciuresis; however, this has led to high complication rates and the calciuretic effect is minimal.[46] We therefore recommend the use of loop diuretics only for volume overload. Thiazide diuretics enhance distal tubule calcium resorption and should be avoided in hypercalcemic patients. Hypercalcemic patients with baseline oliguria or anuria may require dialysis.

Bisphosphonates are the primary pharmacologic treatment for hypercalcemia. Analogs of pyrophosphate, which is produced in bone catabolism, bisphosphonates inhibit bone turnover by reducing osteoclast function and directly stabilizing hydroxyapatite crystals. Typical regimens consist of single doses of either 90 mg of pamidronate given over 2 to 4 hours, or 4 mg of zoledronate given over 15 to 30 minutes.[46] Both should be given intravenously, because oral availability may be limited. An average reduction of serum calcium concentration of 3 to 4 mg/dL can be expected with either regimen, but maximum effect may not be seen for 7 to 10 days. Bisphosphonates can cause an acute phase reaction in up to one-third of cases, consisting of fever, myalgia, arthralgia, and headache, usually within 36 hours. Such side effects can be managed with antipyretics and antihistamines. Bisphosphonates have also been associated with renal dysfunction and jaw osteonecrosis.

Although effective, bisphosphonates require days to lower serum calcium levels. Calcitonin has a quicker onset (12 to 24 hours) and may be useful for manifestations of hypercalcemia requiring immediate reduction of serum calcium level, such as dysrhythmias.[46] The effects of calcitonin are short-lived due to tachyphylaxis, so definitive therapy with bisphosphonates should be simultaneously given. Calcitonin should be given subcutaneously or intramuscularly 4 to 8 units/kg every 6 hours, which typically reduces the serum calcium level by 1 to 2 mg/dL.

Other pharmacologic therapies include denosumab, a human monoclonal antibody inhibiting the RANK ligand that has been used in patients with bisphosphonate-resistant hypercalcemia, as well as plicamycin (mithramycin) and gallium nitrate. Denosumab is not significantly more effective nor faster-acting than bisphosphonates but is more expensive, thus it is generally used second-line in cases of bisphosphonate failure. It may be the preferred agent in patients with renal dysfunction and CrCl <30 mL/min. Plicamycin and gallium nitrate have both fallen out of favor due to long administration times and unfavorable adverse effect profiles; we generally recommend against their use. Hemodialysis can quickly reduce serum calcium levels and should be considered in patients who are dialysis-dependent, recalcitrant to other therapies, or have life-threatening manifestations of hypercalcemia.[51,52] Regardless of other therapies, treatment of the underlying malignancy should be immediately pursued if this is compatible with goals of care, because this is the only way to reverse the underlying cause of hypercalcemia and generally does not increase serum calcium levels.

Disposition

Patients with severe hypercalcemia (>14.0 mg/dL) or an acutely increasing calcium level should be admitted to a monitored bed. Patients with a stable serum calcium concentration less than 14 mg/dL, and close, reliable follow-up may be managed on an outpatient basis in consultation with the their oncologist or primary care doctor.

TUMOR LYSIS SYNDROME

KEY CONCEPTS

- TLS is manifested by the combination of hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia, often accompanied by acute renal failure.
- Patients with TLS should have their potassium, phosphate, calcium, and uric acid levels, as well as renal indices monitored closely. Intravenous fluids should be administered, as well as therapies to reverse hyperkalemia. Hyperuricemia may be prevented with allopurinol or treated with rasburicase. Calcium should only be repleted in patients with cardiac or neurologic manifestations of hypocalcemia.

Foundations

TLS occurs when destruction of malignant cells occurs so rapidly that the body's mechanisms for regulating the unwanted products of this destruction are overwhelmed. Such cell lysis releases intracellular contents, causing hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Acute kidney injury, caused by crystal deposits of uric acid or calcium-phosphate in the renal tubules or by crystal-independent mechanisms of damage by uric acid, often accompanies TLS, further compounding the patient's ability to regulate serum electrolyte levels and eliminate products of cellular destruction. Not infrequently, kidney injury can occur to the point that renal dialysis is required.[53] TLS is most likely to occur in patients with tumors that are high-burden, rapidly growing, and highly chemosensitive, such as Burkitt lymphoma or acute lymphoblastic leukemia (ALL). TLS occurs less commonly in rapidly growing solid tumors, such as breast, testicular, and small cell lung cancers; overall the types of malignancies with potential for TLS is growing as more effective and fast-acting chemotherapeutics are developed.[54,55] Patient factors predisposing to TLS include preexisting renal failure, hypovolemia, and hyperuricemia.

Clinical Features

Although spontaneous TLS is possible, patients undergoing cytotoxic therapy are particularly at risk for TLS. Symptoms result from metabolic derangements or kidney failure and include nausea, vomiting, lethargy, confusion, edema, seizure, myalgias, and tetany; dysrhythmias may result in cardiac arrest. Release of immunoactive proteins such as cytokines from lysed cells may cause sepsis-like symptoms. Due to the immunocompromised state of these individuals, an infectious source should be presumed in patients with septic symptoms and empiric antibiotics should be administered. Electrocardiographic changes may include QT interval prolongation due to hypocalcemia and P-wave flattening, PR and QRS interval prolongation, and T-wave peaking due to hyperkalemia.

Differential Diagnoses

Differential diagnosis for patients with TLS varies with presenting symptoms. For those with nonspecific symptoms such as fatigue or myalgia, consideration should be given to other metabolic derangements such as malignancy-associated hypercalcemia, or systemic manifestations of an infectious source. Patients presenting with cardiac dysrhythmia should be considered for acute coronary syndrome, pulmonary embolism, other sources of metabolic derangements, and other causes of myocardial irritation. Seizure and other neurologic symptoms may suggest cerebrovascular accident, CNS infection or metastasis, or other metabolic abnormalities.

Diagnostic Testing

Evaluation begins with measurement of serum potassium, phosphate, ionized calcium, urea nitrogen, creatinine, uric acid, and lactate dehydrogenase (LDH). For patients who have received rasburicase, uric acid specimens should be sent on ice to prevent artificially low results.[56] If the patient is presenting with sepsis-like symptoms, investigation for a source including cultures and appropriate imaging should be undertaken. Renal imaging (e.g., ultrasound) to rule out obstructive pathology as well as urinalysis and measurement of fractional excretion of sodium (FE_{Na}) should be performed for patients presenting with acute kidney injury. Further evaluation may be indicated by specific presenting symptoms, such as head imaging for patients presenting with seizure, or abdominal imaging for patients with nausea and vomiting.

Management

Intravenous fluids to promote renal clearance of unwanted metabolites should be the initial therapy for TLS; volumes of 3 L/m^2/day are suggested, or as high as 5 to 6 L daily.[56] Acutely oliguric or anuric patients should be similarly fluid challenged because these may be the result of hypovolemia, but plans should be made for diuresis or renal replacement therapy if urine output does not improve or hypervolemia ensues. Patients with oliguria or anuria at baseline may require initial management with renal replacement therapy. Although previously recommended, treatment guidelines no longer support alkalinization of the urine, because this may instigate worse metabolic derangements, including phosphate nephropathy and xanthine crystal nephropathy.[56]

Hydration provides the primary therapy for hyperphosphatemia but limiting dietary phosphate intake and eliminating phosphate-containing supplements are also indicated. Hypocalcemia is a direct result of free calcium precipitating with excess phosphate to form the insoluble, nephrotoxic compound calcium phosphate. The extent of calcium phosphate formation is directly related to the product of serum calcium and phosphate concentrations. Products greater than 55 suggest a worsened long-term risk of calcium phosphate deposition in the viscera, although short-term outcomes are not well studied. To minimize the risk of calcium phosphate nephropathy, asymptomatic patients should go without calcium repletion. Patients with cardiac (e.g., dysrhythmia, heart blocks) or neurologic (e.g., seizure, coma) manifestations of hypocalcemia should receive intravenous calcium repletion.

Management of hyperkalemia is the same as that from any other etiology. Intravenous calcium given as a bolus can transiently (less than 1 hour) stabilize the myocardium of patients with existing or an imminent dysrhythmia (e.g., QRS widening). Efforts can then be made to shift potassium intracellularly via administration of insulin, bicarbonate, and beta-agonists. Ultimately, potassium must be removed from the body by the gastrointestinal tract with administration of potassium binders, by the kidneys with hydration and possibly loop diuretics, or by dialysis.

Uric acid is a metabolite in the degradation pathway of nucleic acids. Hyperuricemia from massive release of free nucleic acids can cause nephropathy both directly and by crystal formation in the renal tubules. In addition to hydration, hyperuricemia can be managed pharmacologically by administration of allopurinol, febuxostat or rasburicase.[56] Allopurinol, an analog of the uric acid precursor hypoxanthine, competitively inhibits enzymatic conversion of xanthine to uric acid. Although this decreases uric acid production, it does not eliminate uric acid already present in the body, and it leads to buildup of xanthine, which itself has limited solubility and potential to cause nephropathy. Febuxostat functions similarly to allopurinol, though its inhibition of the xanthine oxidase enzyme is noncompetitive. Febuxostat has been shown to be noninferior to allopurinol for prevention of tumor lysis syndrome,[57,58] however due to its high cost relative to allopurinol[59] it should only be used in patients who can't tolerate allopurinol (e.g., allopurinol allergy). Rasburicase, a recombinant form of the enzyme urate oxidase, eliminates uric acid directly by converting it into the more soluble metabolite allantoin. It is usually given as a single, intravenous dose. Significant reduction in uric acid levels within 1 day have been observed with weight-based doses of 0.05 to 0.15 mg/kg, and with fixed doses of 3 to 6 mg, with a single 6 mg dose for adults or 0.15 mg/kg dose for children reliably demonstrating effective reduction of uric acid levels.[60-62] Those with glucose-6-phosphate dehydrogenase (G6PD) deficiency should not receive rasburicase, because hydrogen peroxide is a byproduct of its activity and this may trigger hemolytic crisis. Methemoglobinemia may also result from rasburicase administration.[56]

Disposition

The Cairo-Bishop definition of TLS, a systematic classification of lab abnormalities and clinical manifestations of TLS, divides patients with only laboratory manifestations of TLS (laboratory TLS, or LTLS) from those with clinical manifestations of TLS (clinical TLS, or CTLS), such as kidney injury, dysrhythmia, or seizure. Patients with clinical TLS consisting of dysrhythmia or seizure should be admitted to an ICU; those with kidney injury may be admitted to a standard telemetry bed, but ICU care should be considered because mortality in patients with kidney injury and TLS increases relative to that with TLS alone. Patients with laboratory TLS only may be admitted to a monitored bed for observation and treatment.

LEUKOSTASIS

KEY CONCEPTS

- Leukostasis arises due to congestion of blood vessels by excessive numbers of leukocytes. This most often occurs in the lungs and CNS, and the resulting clinical picture may be difficult to differentiate from other diseases that afflict cancer patients (e.g., pneumonia, pulmonary embolism, CNS hemorrhage).
- Intravenous fluids should be administered in the ED to reduce blood viscosity, and red blood cell transfusions should generally be avoided. Therapies to lower the WBC count should be performed in consultation with an oncologist, and may include leukapheresis, administration of hydroxyurea, or initiation of chemotherapy.

Foundations

Leukostasis arises when the white blood cell (WBC) count is sufficiently high to cause vascular congestion, leading to organ dysfunction, typically in the lungs[63] or CNS. No single threshold exists for leukostasis to occur, and different types of leukemia cells cause leukostasis at widely variable cell counts. Patients with chronic lymphocytic leukemia (CLL) may tolerate WBC counts greater than 500,000 cells/μL, whereas patients with acute myeloid leukemia (AML) may develop leukostasis with WBC counts less than 100,000 cells/μL.

Two mechanisms are believed to drive leukostasis. First, blast cells are larger and less deformable than normal WBCs. As the number of blast cells in the blood increases, blood viscosity increases. Second, because certain cell types are more prone to causing leukostasis than others with similar size and physical characteristics, intrinsic features of leukemic cells, such as cytokine-induced activation of endothelial adhesion mechanisms, may also contribute.[64]

Clinical Features

Pulmonary leukostasis presents as dyspnea, tachypnea, and hypoxemia. Auscultation of pulmonary leukostasis may mimic lung infection with crackles or rhonchi, and bilateral opacities are often seen on imaging.[63] CNS leukostasis may present with confusion, audio or visual abnormalities, headache, ataxia, or coma. Intracranial hemorrhage may be seen on head imaging. Other clinical manifestations may include retinal hemorrhage, myocardial infarction, acute limb ischemia, priapism, renal vein thrombosis, and renal infarction.

Differential Diagnoses

Diagnosis of leukostasis is challenging because symptoms of leukostasis are similar to those of other problems common to leukemia patients. Pulmonary leukostasis presents with similar history, physical examination findings, and imaging as pneumonia or pulmonary edema. Patients with CNS leukostasis may present with nonspecific alteration of mental status, similar to that seen in metabolic derangement, medication side effect, or systemic manifestation of infection. Intracranial hemorrhage seen on head imaging may be related to leukostasis itself or may result from thrombocytopenia or disseminated intravascular coagulopathy (DIC), both of which often accompany hyperleukocytosis.

Diagnostic Testing

The gold standard diagnostic test for leukostasis is the presence of leukocyte-clogged blood vessels on tissue pathology. Because this is rarely available, the diagnosis must often be inferred and empirically treated based on knowledge of leukocyte count, cancer type, and clinical picture. A CBC with peripheral smear should be sent from the ED. Further evaluation is indicated to determine cancer type (if not known), including cytology and immunostaining, although results are not actionable in the ED. Symptom-specific imaging should be performed, such as chest plain films or CT for respiratory problems, and head CT or MRI for neurologic symptoms. Normal imaging findings do not exclude leukostasis, however.[63] If sent, blood gases should be processed immediately, because metabolically active leukocytes will continue to consume oxygen in the phlebotomized sample, resulting in falsely low oxygen levels.

Management

ED management of leukostasis centers on reduction of blood viscosity. Intravenous fluids should be administered to dilute the blood as much as possible. Although patients with hyperleukocytosis are often anemic, transfusion of red blood cells should be avoided in asymptomatic patients, because erythrocytes exacerbate blood viscosity. Platelets and plasma may be given as needed because these components make little or no contribution to blood viscosity.

The definitive treatment for hyperleukocytosis is reduction of leukocyte count, either by physically removing excess cells using leukapheresis or by destroying excess cells pharmacologically. Leukapheresis involves continuous removal of fractions of the patient's blood, selective extraction of leukocytes from the fractions, and return of the remaining product to the patient. Leukapheresis can reduce leukocyte count by 20% to 50% in only a few hours, but insertion of a central large-bore catheter is necessary, and leukapheresis requires specialized equipment not available at all institutions. Studies of outcomes with and without leukapheresis are small and nonrandomized, and none have shown a long-term survival benefit (>90-day survival) from the therapy. Results are conflicting as to short-term survival benefits of leukapheresis (7 to 30 days),[65,66] and expert opinion regarding use of leukapheresis for this application remains mixed overall.[67] Hydroxyurea, an inhibitor of deoxyribonucleotide synthesis, can pharmacologically reduce leukocyte burden by similar margins over 24 to 48 hours, and in studies has inconsistently shown a reduction in in-hospital mortality when used prior to induction chemotherapy.[68] Chemotherapy induction, which should only be initiated in consultation with an oncologist, can also quickly reduce leukocyte counts, but the patient should be monitored for signs of TLS.[67] Given the paucity of evidence supporting a single approach to leukoreduction, treatment varies significantly between hospitals, and should be guided by local experts. Due to the difficulty of clinically distinguishing leukostasis from other serious pathologies, treatments for other diagnoses may be simultaneously initiated. Such concomitant therapy (e.g., antibiotics) is particularly important for suspected pneumonia, because patients with hyperleukocytosis may be functionally neutropenic.

Disposition

Patents with leukostasis require hospitalization for monitoring, hydration, and leukocyte-reducing therapy. Asymptomatic patients with leukocytosis also warrant hospitalization if they have a blast count greater than 20,000 cells/μL, have a tumor type of AML, or have a new leukemia of unknown type. Patients with asymptomatic hyperleukocytosis who do not meet these criteria may be discharged with close, reliable follow-up, but this decision should be made in conjunction with the patient's oncologist.

SUPERIOR VENA CAVA SYNDROME

KEY CONCEPTS

- SVC syndrome occurs due to either external (e.g., tumor) or internal (e.g., thrombus) obstruction of the SVC.
- ED management of SVC syndrome is largely supportive. The head of the bed should be elevated, and supplemental oxygen provided if needed. If the cause of SVC syndrome is determined to be thrombus, anticoagulation may be initiated if not contraindicated.
- SVC syndrome is life-threatening only in the rare case of cerebral edema, hemodynamic collapse, or tracheal compromise. With the exception of these situations, definitive anti-cancer treatment should be postponed in order to allow for tissue diagnosis of the underlying mass if not already known.

Foundations

The superior vena cava (SVC) spans the final stretch of venous return from the upper body, spanning from the juncture of the brachiocephalic veins to the heart. The SVC is thin-walled, and blood pressures in the SVC are relatively low (≈2 to 8 mm Hg), making it particularly susceptible to external compression. When SVC flow is compromised, its internal pressure can reach 20 to 40 mm Hg, potentially resulting in symptoms or cardiac decompensation. Such clinical deterioration constitutes SVC syndrome.[69] Malignancy is the cause for more than 60% of total cases. Lung cancer and lymphoma cause over 90% of cases of malignancy-induced SVC syndrome. SVC syndrome due to an intraluminal mass, such as thrombosis, is increasing in prevalence. Cancer patients are at high risk for thrombosis due to their hypercoagulable state and indwelling venous catheters in the SVC.[69]

Clinical Features

Patients with SVC syndrome most commonly present with upper extremity, chest, or face edema or erythema, but dyspnea, dysphagia, chest pain, or cough may also be present. Physical examination

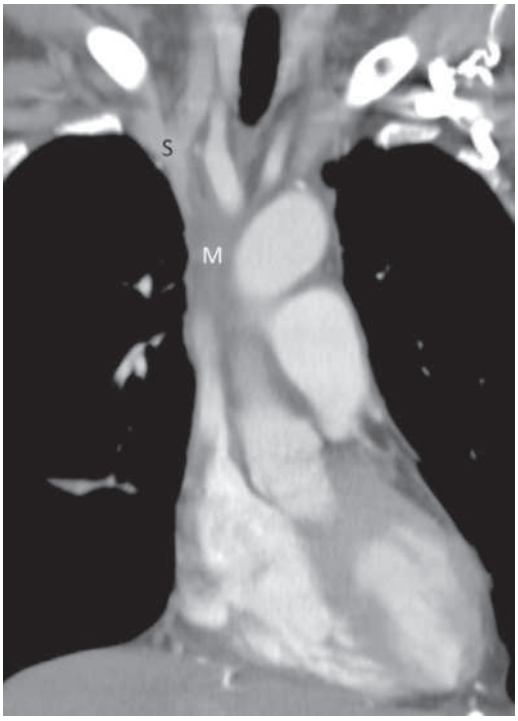

Fig. 112.5 Computed tomography (CT) scan of the chest with intravenous contrast demonstrating superior vena cava (SVC) compromise due to external mass in a patient with primary lung malignancy. *S,* SVC; *M,* intrathoracic mass. (Photo courtesy of the Department of Radiology, University of Maryland School of Medicine.)

findings often reflect elevated venous return pressures, including jugular venous distention (JVD) and edema, flushing, or cyanosis of the face, arms, and upper trunk. Distention of the SVC and compression of other nearby structures may cause vocal cord paralysis, blurred vision, and Horner syndrome.[69] Pleural effusion may be apparent on chest films or bedside sonography.[70] Overall, the type and severity of symptoms greatly depend on the acuity of SVC compression; patients with a slowly developing obstruction develop collaterals, which enable asymptomatic high-grade compression.

Differential Diagnoses

Edema and flushing isolated to the upper body is highly suspicious for SVC syndrome, particularly in a patient with known lung cancer or lymphoma. Other considerations include cellulitis or deep tissue infection (e.g., Ludwig angina), thoracic inlet syndrome, or obstruction of other deep veins (e.g., occlusive deep venous thrombosis in an internal jugular vein or subclavian vein). Other symptoms such as JVD, dyspnea, or cough are less specific and may suggest congestive heart failure, pneumonia, pericardial tamponade, or pulmonary embolism.

Diagnostic Testing

Thoracic imaging, and contrast-enhanced CT in particular, is the most important and commonly employed diagnostic modality for SVC syndrome (Fig. 112.5), but MRI is a viable alternative. In confirmed cases of SVC syndrome, a tissue diagnosis of the offending mass should be made prior to initiation of treatment.[69] This may be obtainable by sputum cytology, or by invasive means, such as bronchoscopy, lymph node biopsy, mediastinoscopy, or thoracotomy. Radiographically guided minimally invasive biopsy techniques performed by interventional radiologists have increasingly been employed for patients with SVC syndrome.[70] Moderate sedation or general anesthesia may be used safely to enable these procedures, however, in cases involving tracheal compromise, an airway should be emergently and carefully (e.g., awake fiberoptic intubation) established prior to anesthesia induction.

Management

In the ED, management of SVC syndrome is largely conservative. Elevating the head of bed to promote gravitational drainage of the upper body and administration of supplemental oxygen, when appropriate, may provide significant symptomatic relief. For patients with SVC syndrome due to obstructing thrombus, anticoagulation with or without thrombolytics should be initiated. Diuretics or steroids have historically been administered and in some practices continue to be used[70]; however, they have no proven benefit, may simply provoke complications, and we do not recommend them.

Although the symptoms of SVC syndrome are unpleasant, risk to life occurs only with the rare and extreme complications of airway obstruction, cerebral edema or hemodynamic compromise. Definitive treatment of malignant SVC syndrome can often be safely delayed until biopsy specimens are obtained because of the rare need for emergent therapy and the increasing ability to tailor anti-cancer therapy based on exact tissue diagnosis. Once a histologic diagnosis is made, the ideal combination of chemotherapy, radiation, and surgery, if indicated, is guided by specialty consultation.

In cases requiring emergent resolution of SVC syndrome, the initial steps in the ED are aimed at achieving basic medical stabilization (e.g., intubation and mechanical ventilation, hemodynamic optimization). Thereafter, endovascular stenting of SVC may be employed for rapid and effective reduction of SVC pressures.[69] Although no large randomized controlled trials have been performed, in smaller observational studies endovascular stenting for SVC syndrome has been safe and effective[71] and resulted in rapid symptomatic relief.[72] Stenting carries the additional advantages that a tissue diagnosis isn't required prior to implementation, and that stent placement doesn't interfere with later plans for radiation or chemotherapy.[69] Endovascular stenting may also be considered nonemergently in cases of failure of or contraindication to conventional therapies (e.g., radiation or chemotherapy).[69] Open surgical bypass or replacement of the SVC can be performed but is reserved for the most extreme cases, because less invasive measures are often successful.

Disposition

Although SVC syndrome is seldom life-threatening, symptomatic relief first requires diagnosis and treatment tailored to the underlying etiology. Hospitalization generally expedites this evaluation. Patients with hemodynamic compromise, cerebral edema, or tracheal compromise should be admitted to an ICU following initial stabilization.[70]

MONOCLONAL ANTIBODY THERAPIES AND COMPLICATIONS

KEY CONCEPTS

- Monoclonal antibody therapies function through various mechanisms using a range of targets. This leads to a diverse collection of known complications including infection and organ dysfunction.
- Identifying and treating infections, including opportunistic infections, is the most important element of management for the emergency physician in treating a patient with suspected complications of monoclonal antibody therapy.

Foundations

As the molecular foundations of cancer are further explored, it has become increasingly feasible to target therapeutics against

TABLE 112.3 Properties and Complications of Anti-neoplastic Monoclonal Antibody Therapies

	Target/Mechanism	Indication	Notable complications
Alemtuzumab	CD52/ADCC and CDC	CLL	Cytopenias, infusion reactions, opportunistic infections including PCP (black box warnings)
Bevacizumab	VEGF-A/direct inhibition	Glioblastoma, cancers of colon, lung, and renal cell	Bowel perforation, wound healing complications, bleeding complications (black box warnings)
Blinatumomab	CD19/BiTE	ALL	CRS, neurotoxicity (black box warnings)
Brentuximab	CD30/cytotoxic agent delivery	HL, ALCL	PML (black box warning)
Cetuximab	EGFR/direct inhibition	Cancers of colon, lung, head/neck	Anaphylactic reaction in those with alpha-gal antibodies
Ibritumomab tiuxetan	CD20/radioisotope delivery	B-cell NHL	Infusion reactions, cutaneous reactions, persistent cytopenias (black box warnings)
Inotuzumab ozogamicin	CD22/cytotoxic agent delivery	B-cell ALL	Hepatotoxicity, hepatic veno-occlusive disease (black box warnings)
Ofatumumab	CD20/ADCC and CDC	CLL, NHL	PML, hepatitis B reactivation
Panitumumab	EGFR/direct inhibition	Colon cancer	Dermatologic toxicities (black box warning), ocular keratitis
Pertuzumab	HER2/direct inhibition	Breast cancer	Embryo-fetal toxicity (black box warning), cytopenias
Rituximab	CD20/ADCC and CDC	NHL, HL, CLL	Severe infusion reactions, TLS, severe mucocutaneous reactions, PML (black box warnings)
Trastuzumab	HER2/direct inhibition, ADCC and CDC	Breast cancer	Cardiomyopathies, infusion reactions, pulmonary toxicity (black box warnings)

ADCC, antibody-dependent cell-mediated cytotoxicity; *ALCL*, anaplastic large cell lymphoma; *ALL*, acute lymphoblastic leukemia; *Alpha gal*, galactose-α-1,3-galactose; *BiTE*, bispecific T-cell engager; *CLL*, chronic lymphocytic leukemia; *CRS*, cytokine release syndrome; EGFR, epidermal growth factor receptor; *HER2*, receptor tyrosine-protein kinase erbB-2; *HL*, Hodgkin lymphoma; *NHL*, non-Hodgkin lymphoma; *PCP*, *Pneumocystis jirovecii* pneumonia; *PML*, progressive multifocal leukoencephalopathy; *TLS*, tumor lysis syndrome; *VEGF-A*, vascular endothelial growth factor A.

tumor-specific molecules. While this specificity can be achieved by small molecules such as tyrosine kinase inhibitors, the natural targeting abilities of antibodies lend themselves well to efficient development of new therapies, and this has led to steady expansion of the repertoire of anti-neoplastic monoclonal antibodies.

Monoclonal antibody therapies have been engineered to work by various mechanisms. In their simplest form, non-conjugated antibodies bind to tumor-associated targets, marking tumor cells for killing by antibody-dependent cell-mediated cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). Monoclonal antibodies tethered to cytotoxic payloads such as radioisotopes (e.g., ibritumomab) or cytotoxic medications (e.g., brentuximab) have increased the killing power of these therapeutics. Monoclonal antibodies tethered to the cytotoxic T cell–specific protein CD3, called bispecific T-cell engagers (BiTEs), are designed to amplify the efficiency of ADCC (e.g., blinatumomab). Monoclonal antibodies may also be designed to target and inhibit growth receptors on the tumor cell surface (e.g., trastuzumab) in addition to promoting cell destruction by ADCC and CDC. A list of common monoclonal antibodies along with their mechanisms of action and complications is given in Table 112.3.

Clinical Features

Because of the wide range of targets and mechanisms of action they employ, the complications of monoclonal antibody therapies are diverse, vary between therapies, and are too numerous to list here. A broad outline of the clinical features of common complications is provided in the following sections; additionally, Table 112.3 lists therapy-specific complications including black box warnings. Due to their immunomodulatory nature, patients receiving monoclonal antibody therapies are particularly susceptible to infectious complications. Clinical features will vary depending on the nature of infection, but may include fever, rigors, fatigue, malaise, and leukocytosis. Opportunistic infections have been noted (especially with use of alemtuzumab), so the emergency physician should be wary of features such as a vesicular rash which may represent reactivation of a herpetic virus, respiratory symptoms which may represent *Pneumocystis jirovecii* pneumonia (PCP) or activation of tuberculosis, or jaundice and liver function abnormalities which may represent reactivation of viral hepatitis. Monoclonal antibody therapies can also cause cytokine release syndrome (blinatumomab especially[73]) which may have presenting features very similar to infection and sepsis.

Infusion reactions can occur with all monoclonal antibody therapies but are especially common to rituximab, cetuximab, alemtuzumab, ibritumomab tiuxetan, and trastuzumab. These reactions typically occur during or shortly after infusion. Clinical features may be similar to a type I hypersensitivity reaction (anaphylaxis) or may be nonspecific. These can include rash, tachycardia, dyspnea, and hypotension.

Dysfunction of particular organ systems may also occur with monoclonal antibody therapies. Several adverse pulmonary events have been known to occur over a broad time frame, ranging from acute respiratory distress syndrome (ARDS) occurring within hours after an infusion, to organizing pneumonia developing weeks to months after completion of therapy. Various cardiac complications have been reported, including sudden cardiac death (cetuximab especially), and cardiomyopathy (trastuzumab especially). A broad range of neurologic symptoms may also occur, including progressive multifocal leukoencephalopathy (PML). Hepatotoxicity believed due to veno-occlusive disease has also been noted with inotuzumab.[74] As with all cancer therapeutics, rapid killing of cancer cells may lead to tumor lysis syndrome.

Differential Diagnoses

The differential diagnosis for patients with complications of monoclonal antibody therapies varies widely depending on presentation. Patients presenting with fever and symptoms of sepsis should be considered to have an infection until proven otherwise, though cytokine release syndrome and some infusion reactions can have a similar presentation. Opportunistic infection must also be considered. Patients with symptoms of heart or respiratory failure (e.g., dyspnea, chest pain, edema) may have primary toxicity from their therapy, but may also have pneumonia, pericardial disease, or acute coronary syndrome. For patients with neurotoxicity, other central nervous system insults such as cerebrovascular accident and meningitis should be considered.

Diagnostic Testing

Diagnostic testing must be guided by the patient's clinical picture. Patients with symptoms consistent with infection or sepsis should undergo blood and urine culturing, chest x-ray, and other workup as guided by presentation (e.g., sputum culture for productive cough). Those with symptoms of cardiac or pulmonary dysfunction should have cardiac biomarkers, electrocardiogram, chest x-ray, and echocardiogram performed. Patients with neurologic symptoms should undergo brain imaging.

Management

Aside from prompt recognition and treatment of infections, treatments for complications of monoclonal antibody therapies are largely supportive. Mild cases of cytokine release syndrome may be treated with antipyretics, and mild infusion reactions may respond to histamine blockers. However, both of these conditions may require hemodynamic support (e.g., IV fluids, vasopressors) in more severe cases. For patients experiencing infusion reactions, management with epinephrine IM and close airway monitoring should commence if there is any question of anaphylaxis. Cardiomyopathies may be managed with inotropic agents and diuresis. Pulmonary complications should be managed with appropriate respiratory support (including mechanical ventilation if needed), and corticosteroids may be considered once infectious etiology has been ruled out.

Disposition

Disposition of patients with complications of monoclonal antibody therapy depends largely on the clinical picture and severity of symptoms and should be determined in conjunction with the patient's oncologist.

T-LYMPHOCYTE CHECKPOINT INHIBITOR THERAPIES AND COMPLICATIONS

KEY CONCEPTS

- Because it involves reduction of immune self-tolerance, T-lymphocyte checkpoint inhibition therapy is marked by a wide variety of complications
- For symptoms severe enough to affect quality of life, systemic corticosteroids may be initiated. This should be done in consultation with an oncologist.

Foundations

Many cancer cells carry surface markers which are unique to tumor cells and not found on normal cells (e.g., due to mutations or fusion proteins).[75] Although these tumor-specific antigens (TSAs) can be recognized and attacked by host T cells, many are sufficiently similar to host antigens that they are protected by the same mechanisms that protect host cells from autoimmune attack, known collectively as self-tolerance.[76] The goal of T-lymphocyte checkpoint inhibitor therapy is to reduce T-cell self-tolerance, thereby allowing a T-cell immune response against TSA-bearing cancer cells.

Self-tolerance is achieved by several mechanisms, including a series of protein interactions known as checkpoints which are designed to prevent mature T cells in the peripheral tissues from attacking self-antigen bearing cells. By inhibiting these checkpoints, T-lymphocyte checkpoint inhibitor therapy enables a more vigorous antitumor immune response. Current therapies achieve this through antibody-driven inhibition of two such checkpoint pathways: the CTLA-4 pathway and the PD-1 pathway. Therapeutic antibodies targeting the PD-1 pathway exist both for PD-1 itself and its ligand PD-L1. The CTLA-4 pathway is targeted via the CTLA-4 protein (Table 112.4).[76]

Clinical Features

Inhibiting the mechanisms of the immune system that maintain self-tolerance imparts a steep price in the form of diverse complications across all organ systems. Clinical features of these complications as well as approximate rates of incidence are summarized in Table 112.5. Perhaps the most feared of these are hypophysitis, an immune-mediated pituitary disease which can cause shock due to glucocorticoid deficiency, and colitis, which can be life-threatening.[77] Additionally, patients undergoing checkpoint inhibitor therapy are susceptible to all of the other complications listed in this chapter, such as tumor lysis syndrome.[78]

TABLE 112.4 Molecular Targets for T-lymphocyte Checkpoint Inhibition Therapy, FDA-Approved Inhibitors, and Overall Complication Rates by Target

Molecular Target	Approved Inhibitors	Overall Complication Incidence
CTLA-4	Ipilimumab	60–85%[85]
PD-1	Nivolumab, Pembrolizumab	16–37%[85]
PD-L1	Atezolizumab, Avelumab, Durvalumab	12–24%[85]

TABLE 112.5 Immune-Related Adverse Events, Presenting Symptoms, Differential Diagnoses, and Initial Workup, Listed by Organ System

Organ System	Immune-Related Adverse Event and Approximate Incidence Rate (CR = case reports only)	Clinical Features	Differential Diagnosis	Diagnostic Testing
Cardiac	Pericardial effusion (CR[86-88])	See above section on Malignant Pericardial Disease.		
	Myocarditis (CR[89])	Dyspnea, fatigue, pulmonary edema[89]	ACS, pneumonia	CXR, ECG, echocardiogram
Endocrine	Hypophysitis (≈5% for all therapies; greater with anti-CTLA-4 therapy [up to 17%] than anti-PD-1 or anti-PD-L1[90])	Anorexia, fatigue, headache, nausea, diplopia, confusion, temperature intolerance, subjective fever and chills. Average onset 6–12 weeks after starting therapy.	Infection/sepsis, adrenal crisis, cerebral metastases[90]	Visual field testing; brain MRI (evaluate for pituitary stalk enlargement); pituitary function testing (e.g., thyrotrophin, gonadotrophin, and corticotrophin levels)[90]
	Thyroid dysfunction (≈10% for anti-PD-1 and anti-PD-L1 therapy; >50% for anti-CTLA-4 therapy[90])	Thyroiditis (thyroid gland pain/induration), fatigue, temperature intolerance	Hypophysitis, infection/sepsis	Thyroid function testing, antithyroglobulin and anti-thyroperoxidase antibody testing, corticotropin testing (rule out hypophysitis)
Gastrointestinal	Colitis (0–2% with anti-PD-1 therapy; 5–10% with anti-CTLA-4 therapy[90])	Abdominal pain, fever, diarrhea, hematochezia, constitutional symptoms. Average onset 6–7 weeks after therapy initiation.[90]	Infection/sepsis, bowel ischemia, cytomegalovirus colitis, *Clostridium difficile* infection, IBD, other intra-abdominal pathology[90]	CT imaging of abdomen/pelvis, testing for stool pathogens (e.g., *C. difficile* toxin), endoscopic examination of colon (e.g., colonoscopy, flexible sigmoidoscopy)[90]
	Diarrhea (12–14% with anti-PD-1 therapy; 30–35% with anti-CTLA-4 therapy[90])	Diarrhea only	Colitis, GI infection, bowel ischemia, cytomegalovirus colitis, *Clostridium difficile* infection, IBD, other intra-abdominal pathology	CT imaging of abdomen/pelvis, testing for stool pathogens (e.g., *C. difficile* toxin)
	Hepatotoxicity (5–10% for all therapies)[90]	Elevated transaminases; in severe cases abdominal pain, jaundice, coagulopathy, liver synthetic function loss	Infectious hepatitis, hepatic metastases	Liver function testing, testing of liver synthetic functions (e.g., albumin, coagulation studies), hepatic imaging (e.g., ultrasound)
Hematologic	Neutropenia (1% for anti-PD-L1 therapy[91])	Largely asymptomatic; may present with fever/infection	Neutropenia due to alternative cause (e.g., chemotherapy, primary malignancy)	Complete blood count with manual differential; workup for neutropenic fever (see separate section above) if symptoms dictate
	Anemia (10% for anti-PD-L1 therapy[91])	Largely asymptomatic; severe cases may present with fatigue or dyspnea	Anemia due to alternative cause (e.g., chemotherapy, primary malignancy, blood loss), autoimmune hemolytic anemia (incidence of 0.5% with anti-PD-1/PD-L1 therapy[92])	Complete blood count with manual differential, evaluation for hemolysis (e.g., lactate dehydrogenase, serum haptoglobin, bilirubin levels), iron studies, evaluation for sources of blood loss (e.g., inquire about history of melanotic or bloody stools)
	Immune thrombocytopenia (<0.5% for anti-PD-1/PD-L1 therapy[92])	Often asymptomatic; may present with bleeding-related complications (e.g., excessive bruising)	Immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation	Complete blood count with manual differential, evaluation for hemolysis (e.g., lactate dehydrogenase, serum haptoglobin, bilirubin levels), coagulation testing

Continued

TABLE 112.5 Immune-Related Adverse Events, Presenting Symptoms, Differential Diagnoses, and Initial Workup, Listed by Organ System—cont'd.

Organ System	Immune-Related Adverse Event and Approximate Incidence Rate (CR = case reports only)	Clinical Features	Differential Diagnosis	Diagnostic Testing
Integumentary	Skin toxicity (up to 25% with anti-CTLA-4 therapy[89])	Rash, pruritis, vitiligo. Onset usually within a few weeks of starting treatment, but can be delayed.[89]	Contact dermatitis, viral rashes, vasculitis[89]	Skin biopsy is usually feasible and yields definitive diagnosis.[89]
	Intraoral lesions (<10% for all therapies[93])	Mucositis, xerostomia, lichenoid tongue lesions[93]	Intraoral infection (e.g., herpes simplex, hand foot and mouth disease), mucositis from an alternative cause (e.g., chemotherapy)	Testing for intraoral infection (e.g., herpes serologies), consider biopsy of lesion if diagnosis is unclear
Neurologic	Myasthenia gravis (CR[89])	Weakness, ptosis, diplopia, dysarthria	Cerebrovascular accident, brain metastases, paraneoplastic syndrome, metastatic spinal cord compression	Brain imaging (CT or MRI), consideration of LP, electromyography can be helpful but often not needed in ED[89]
	Guillain-Barré syndrome (CR[89])	Weakness usually developing centrally from the extremities. Loss or attenuation of peripheral reflexes.	Cerebrovascular accident, brain metastases, paraneoplastic syndrome, metastatic spinal cord compression	Brain imaging (CT or MRI), consideration of LP, electromyography can be helpful but often not needed in ED[89]
Pulmonary	Pneumonitis (2–5% for anti-PD-1 therapy[90])	Dyspnea, hypoxemia, cough. Usual onset ≈3 months after initiation of therapy, but can occur as long as years later.[90]	Disease progression or pseudoprogression, infection, pulmonary embolus, exacerbation of coexisting lung disease[90]	Chest imaging (CXR or ideally high-resolution CT scan). Testing for underlying lung infection (sputum culture, urine legionella antigen, consideration of testing for PCP if immunocompromised, flu test if seasonally appropriate)
Renal	Acute kidney injury (≈2% for all therapies[94])	May be asymptomatic. In severe cases volume overload, uremia, acidosis, electrolyte disturbances.	AKI due to alternative cause such as sepsis, dehydration, or malignant obstruction of genitourinary tract	Measurement of serum creatinine, blood urea nitrogen, pH, and electrolytes. Renal imaging (e.g., ultrasound) to exclude obstruction. Fraction of excreted sodium testing (FENa).
Rheumatologic	Vasculitis (CR, most frequently large vessel and nervous system vasculitides[95])	Fever, fatigue, rash, numbness, weakness	Infection, paraneoplastic polyarteritis nodosa, leukocytoclastic vasculitis due to melanoma or other cancers, worsening metastatic disease, new onset of primary vasculitis[95]	Difficult to definitively diagnose from the ED; often requires biopsy of blood vessel or affected tissue[95]
	Myalgias and Arthralgias (2–12% for all therapies[89])	Morning stiffness, synovitis, proximal weakness[89]	New onset of primary rheumatologic disease (e.g., rheumatoid arthritis), drug-induced lupus or myositis	Testing for rheumatologic markers (e.g., rheumatoid factor, anti-nuclear antibody) to rule out new onset rheumatologic disease

ACS, Acute coronary syndrome; *CR*, incidence limited to case reports; *CXR*, chest x-ray; *ECG*, electrocardiogram; *LP*, lumbar puncture; *PCP*, *Pneumocystis jirovecii* pneumonia.

Differential Diagnoses

Differential diagnoses vary based on the presenting symptoms. Differentials for each complication are listed in Table 112.5.

Diagnostic Testing

Diagnostic testing varies based on the presenting symptoms. Diagnostic strategies for each complication are listed in Table 112.5.

Management

Management strategies for complications of checkpoint inhibitor therapy are laid out based on the severity of the complication. Scales to judge the grade of each type of complication have been developed[79] but are beyond the scope of this text. In general, symptoms that negatively impact daily life and are recalcitrant to targeted management (e.g., oral analgesics for myalgia, or topical prednisone for rash) are considered grade 3, and warrant initiation of prednisone 1 to 2 mg/kg/d or methylprednisolone IV 1 to 2 mg/kg/d.[79] This is particularly true of suspected hypophysitis with hemodynamic instability, for which methylprednisolone 1 to 2 mg/kg/d intravenous should immediately be initiated. Whenever possible, steroids should be initiated in consultation with an oncologist. For severe colitis, initial reports suggest that infliximab may be helpful in steroid-recalcitrant cases.[77]

Disposition

Disposition will vary based on specific complication and severity and may range from discharge with close oncology follow-up to ICU admission. Whenever possible, disposition decisions should be made in consultation with the patient's oncologist.

ADOPTIVE CELL TRANSFER THERAPIES AND COMPLICATIONS

KEY CONCEPTS

- Adoptive cell transfer therapy (CAR T-cell therapy) involves using the patient's own T-cells to attack tumor cells. Cytokine release syndrome (CRS) and immune effector cell–associated neurotoxicity syndrome (ICANS) are the most common and serious complications of this treatment.
- Expressive aphasia is a very specific and early sign of ICANS. Presence of this finding should increase clinical suspicion for ICANS, though its absence should not be used to exclude the diagnosis.
- Tocilizumab (anti-IL-6 receptor antibody) and corticosteroids may be used to treat severe CRS. ICANS is typically only responsive to corticosteroids. Because of the effects these treatments may have on the underlying antineoplastic therapy, they should only be administered in collaboration with oncology.

Foundations

Adoptive cell transfer therapies, often referred to as chimeric antigen receptor (CAR) T-cell therapies, employ the patient's own T cells, reprogrammed to attack cancer cells. Following harvest of the patient's T cells via leukapheresis or other methods, the cells are genetically modified by insertion (e.g., by lentivirus) of a chimeric antigen receptor (CAR) protein expression cassette. The CAR protein subsequently expressed by the cells is a combination of a recognition domain for a tumor-specific antigen, and an effector domain that activates the T cells to armed effector status and triggers clonal expansion when the tumor antigen is bound. Following genetic modification, the altered T cells are expanded in vitro and then transfused back to the patient.[80]

As of August 1, 2020, two FDA-approved CAR-T therapies exist: tisagenlecleucel and axicabtagene ciloleucel. Both are designed to recognize CD-19, a B cell–specific surface marker which is often overexpressed on B cell lymphoma and leukemia cells.[80]

Clinical Features

As with other immunotherapies, reprogramming the immune system comes at the cost of severe adverse effects. In the case of CAR T-cell therapy, cytokine release syndrome (CRS), and immune effector cell–associated neurotoxicity syndrome (ICANS) are particularly prevalent.[81] CRS, in which uncontrolled cytokine release leads to a potentially life-threatening inflammatory syndrome, occurs in nearly 60% of patients receiving CAR T-cell therapy.[82] Severe CRS, causing end-organ dysfunction or requiring multiple pressors to achieve hemodynamic stability, occurs in up to 25% of patients.[82,83] CRS may appear clinically similar to infection or sepsis, as symptoms include fever, malaise, myalgias, fatigue, and rash. In severe cases, hypotension, respiratory failure, and end-organ dysfunction will develop.[81] Median time from CAR T-cell therapy to onset of CRS is 3 days.[82] ICANS, in which the central nervous system undergoes immune cell–mediated damage, occurs in up to 50% of patients receiving CAR T-cell therapy.[84] Clinical features range from confusion, headache, aphasia, tremor, behavioral changes, peripheral numbness, and weakness to grand mal seizures and cerebral edema.[84] Expressive aphasia is a very specific and early sign of ICANS in at least one study, and may help differentiate ICANS from other etiologies of neurologic insult, though the absence of this finding should not be used to exclude the diagnosis.[81] Median onset of ICANS is four to seven days after CAR T-cell therapy.[84] Interestingly, while ICANS is considered a distinct entity from CRS, severe cases of ICANS are rarely seen in the absence of accompanying or preceding CRS.[84]

Differential Diagnoses

Patients presenting with symptoms of CRS should be considered to have an infection and sepsis until proven otherwise. This is especially important because lympho-depleting chemotherapy is often given prior to CAR T-cell infusion, thus imparting some degree of immunocompromise.[80] The symptoms of ICANS overlap with other CNS injuries such as cerebrovascular accident, infectious meningoencephalitis, or CNS metastasis.

Diagnostic Testing

Patients suspected to have cytokine release syndrome should undergo thorough testing for an underlying infectious source of symptoms (see earlier section on neutropenic fever). Patients with symptoms of ICANS should undergo CNS imaging by CT or MRI and consideration should be given to lumbar puncture and electroencephalography as symptoms dictate. Although brain imaging studies may be normal in ICANS, MRI imaging may show T2 hyperintensities in the white matter and thalami,[84] and appropriate imaging may be used to exclude other diagnoses. Cerebrospinal fluid of patients with ICANS may have elevated levels of protein and leukocytes,[84] so infection-specific cultures and diagnostics may be needed to rule out infectious meningitis.

Management

Due to their propensities for CRS and ICANS, FDA approval of CAR T-cell therapies to date has been contingent on provision of specific risk evaluation and mitigation strategies (REMS) for grading and management of these conditions. Due to the complexities involved, CAR T-cell therapy patients should be treated at a facility approved to administer these therapies, and the patient's oncologists should be involved in all management decisions.

Low-grade CRS (fever, malaise, and constitutional symptoms, but otherwise normal vital signs and organ function) may be treated symptomatically. For patients with more severe CRS, REMS protocols vary somewhat but generally involve escalating to therapy with the anti-IL-6 receptor antibody tocilizumab, followed by corticosteroids in the most severe cases or if there is no response to tocilizumab. Supportive therapies such as intravenous fluids, vasopressors, and respiratory support should be provided. Similarly, patients with low-grade ICANS (symptoms not affecting activities of daily life) may be treated symptomatically. Those with more severe manifestations generally receive corticosteroids, as tocilizumab generally has minimal effect on ICANS.[81] In all cases, decisions to give corticosteroids should be made in conjunction with the patient's treating oncologist because this may have a detrimental effect on the antitumor effects of CAR T-cell therapy.[80]

Disposition

Disposition decisions should be made in consultation with the patient's oncologist, but most if not all patients with suspected complications of CAR T-cell therapy should be admitted to the hospital. Because of the specialized nature of these relatively new therapies, whenever possible the patient should be transferred to the center where they received CAR T-cell therapy, or another center experienced in these treatments.

CHAPTER 112: QUESTIONS AND ANSWERS

1. Which of the following statements regarding infections in cancer patients with febrile neutropenia is *true*?
- **a.** Blood cultures should be obtained from an indwelling catheter if present.
- **b.** Empirical antifungal coverage should always be immediately initiated.
- **c.** Head computed tomography (CT) is always indicated.
- **d.** Lumbar puncture (LP) should be routinely undertaken.
- **e.** Sinus imaging should be routinely undertaken.

Answer: A. In patients with a preexisting central line, one blood culture should be obtained peripherally while other cultures should be simultaneously drawn off each lumen of the central catheter. Bacterial growth in the catheter-drawn samples more than 2 hours prior to the peripheral samples is suggestive of a catheter-associated infection. Head CT is not routinely indicated. It may be performed if the patient demonstrates focal neurologic deficits, alteration in mental status, or a lumbar puncture is planned. LP and CT scans of the sinuses are not routinely done initially unless signs or symptoms suggest these are involved.

2. A 33-year-old woman with breast cancer presents with fever and neutropenia. She is status post mastectomy and undergoing chemotherapy. She denies respiratory symptoms and chest x-ray is unremarkable. Vital signs are T 38.8°C; HR, 110 beats/min; and BP, 110/60 mm Hg. Examination is otherwise normal. She has no indwelling catheters. Which of the following is the most appropriate empirical antibiotic regimen?
- **a.** Antibiotics should be withheld pending radiographs and cultures
- **b.** Cefepime as monotherapy
- **c.** Ceftazidime and gentamicin
- **d.** Meropenem and vancomycin
- **e.** Ticarcillin and amikacin

Answer: B. Monotherapy with imipenem, meropenem, ceftazidime, or cefepime is as effective as traditional dual therapy with an antipseudomonal penicillin and aminoglycoside. However, vancomycin should be included as well if any of the following exist:
- Hypotension or evidence of cardiovascular impairment
- Clinically suspected catheter infection
- Positive blood cultures for gram-positive organisms
- Known colonization with methicillin-resistant *Staphylococcus aureus* or cephalosporin-resistant *Pneumococcus*

3. Which of the following is not a risk factor for acute tumor lysis syndrome (TLS)?
- **a.** High-burden, rapidly growing and highly chemosensitive leukemias
- **b.** Hypovolemia
- **c.** Age older than 60 years
- **d.** Preexisting renal dysfunction
- **e.** Rapidly growing solid tumors

Answer: C. TLS is most likely to occur in patients with tumors that are high burden, rapidly growing, and highly chemosensitive, such as Burkitt lymphoma or acute lymphoblastic leukemia (ALL). TLS can also occur in rapidly growing solid tumors, such as breast, testicular, and small cell lung cancers; overall, the diversity of malignancies with potential for TLS is growing as we develop more effective and fast-acting chemotherapeutics. Patient factors predisposing to TLS include preexisting renal failure, hypovolemia, and hyperuricemia. Older age is not a known risk factor for TLS.

4. A 65-year-old male with a history of a large head and neck tumor presents with symptoms of fatigue, weakness, confusion, depression and malaise, nausea, vomiting, constipation, polyuria, and palpitations. His electrocardiogram (ECG) demonstrates a shortened QT

CHAPTER 112: QUESTIONS AND ANSWERS—cont'd

interval. Which of the following electrolyte abnormalities is likely to underlie his presentation?

a. Hypercalcemia
b. Hyperkalemia
c. Hyperuricemia
d. Hypocalcemia
e. Hypokalemia

Answer: A. This patient's presentation is most consistent with malignancy-associated hypercalcemia. Malignancy-associated hypercalcemia (MAH) signifies advanced disease, with median survival of less than 2 months. Synthesis of PTHrP, classically called *humoral hypercalcemia*, causes about 80% of cases of MAH, and is usually associated with squamous cancers, such as head and neck, lung, esophageal, cervical, ovarian, and endometrial carcinomas. Presenting symptoms often include weakness, lethargy, confusion, abdominal pain, nausea, vomiting, constipation, polyuria, polydipsia, and kidney injury. Electrocardiogram findings may initially exhibit QT interval shortening, progressing to dysrhythmias and heart block as hypercalcemia worsens.

5. Which of the following monoclonal antibodies is involved in the management of severe cytokine release syndrome due to adoptive cell transfer therapy (CAR T-cell therapy)?

a. Alemtuzumab
b. Cetuximab
c. Ofatumumab
d. Tocilizumab

Answer: D. Tocilizumab (anti-IL-6 receptor antibody) has been shown to effectively mediate the pro-inflammatory effects of cytokine release syndrome. The other options listed are antitumor agents.

113

Acid-Base Disorders

Nicole S. McCoin and Wesley H. Self

KEY CONCEPTS

- Metabolic acidoses are classified into wide anion gap and normal anion gap acidoses, based on basic metabolic panel (BMP) values. A wide anion gap metabolic acidosis is present when the gap exceeds 15 mmol/L.
- Common causes of a wide anion gap metabolic acidosis are summarized with the mnemonic MUDPILES (Methanol, Uremia, DKA, Paraldehyde, Polyethylene glycol, or Paracetamol (Acetaminophen), Iron, Lactate, Ethylene Glycol, Salicylates).
- When a wide anion gap metabolic acidosis is identified on the BMP, the potential underlying causes can be determined through analysis of the delta gap and the osmolar gap.
- Common causes of a normal anion gap acidosis are summarized with the mnemonic HARDUP (Hyperalimentation/Hospital-acquired administration of saline, Acid infusion, Addison's disease, Carbonic Anhydrase Inhibitors, Renal Tubular Acidosis, Diarrhea, Ureterosigmoidostomy, and Pancreatic drainage/fistula.)
- The optimal use of sodium bicarbonate therapy for metabolic acidosis is not clear and is the subject of ongoing research. A common strategy is to use sodium bicarbonate to increase pH above 7.10 in severe metabolic acidosis or above 7.20 for patients with severe metabolic acidosis and acute kidney injury.
- Metabolic alkalosis is associated with decreased circulating volume. GI-based chloride losses can be corrected with the administration of sodium chloride–containing intravenous fluids.
- Metabolic alkalosis caused by impaired renal excretion of sodium chloride that does not respond to intravenous fluids.
- Respiratory acidosis or alkalosis relates to carbon dioxide (CO_2) clearance, and thus is dependent on minute ventilation. Respiratory acidoses are caused by etiologies that decrease the ability of the body to rid itself of CO_2, such as primary lung disease, chest wall disorders, and entities that decrease respiratory drive.
- Respiratory alkalosis results from disorders that increase CO_2 clearance such as hyperventilation and salicylate toxicity. Values from the blood gas are used primarily to identify the presence of respiratory acid-base disorders.

FOUNDATIONS

The body's homeostatic mechanisms must keep acid-base balance under tight control. Acid-base disturbances can be life-threatening, with severe acid-base disorders leading to cellular compromise and death within hours due to alterations in hydrogen bonds, protein structures, and enzyme function.

The pH of the blood summarizes the systemic acid-base balance. pH is the negative logarithm of hydrogen-ion concentration (H^+) and has a normal range of 7.35 to 7.45. This normal pH is maintained by the kidneys' regulation of plasma bicarbonate (HCO_3^-) and the lungs' regulation of the partial pressure of arterial carbon dioxide ($Paco_2$). The relationship of $[HCO_3^-]$ and $Paco_2$ to pH is described by the Henderson-Hasselbach equation: $pH = pK + \log_{10} ([HCO_3^-]/[0.03 \times Paco_2])$, where pK denotes the acid dissociation constant, $[HCO_3^-]$ is measured in millimoles per liter (mmol/L), and $Paco_2$ is measured in millimeters of mercury (mm Hg).

The terms *acidemia* and *alkalemia* describe the summary acid-base state, or the pH of the blood, while the terms *acidosis* and *alkalosis* describe discrete conditions. Blood pH less than 7.35 defines acidemia, while a pH greater than 7.45 defines alkalemia. An acidosis is an acid-base disturbance that increases $[H^+]$ and lowers the pH. An alkalosis is an acid-base disturbance that decreases $[H^+]$ and increases the pH. Multiple acidoses and alkaloses may be present at the same time; in these situations, pH describes the balance among all the acid-base disturbances.

The "metabolic system" includes cellular production and renal excretion of acids and bases. The respiratory system ventilates acid, in the form of carbon dioxide, out of the body through the lungs. The metabolic system and respiratory system are tightly coordinated to maintain acid-base hemostasis. Metabolic acid-base disorders are caused by abnormalities of cellular function, altered renal excretion of acids and bases, and exogenous gain or loss of acids and bases through the gastrointestinal tract. In clinical medicine, the principal test to evaluate for metabolic acid-base disturbances is plasma bicarbonate concentration ($[HCO_3^-]$). When a primary metabolic acid-base disturbance develops, the respiratory system compensates through increased or

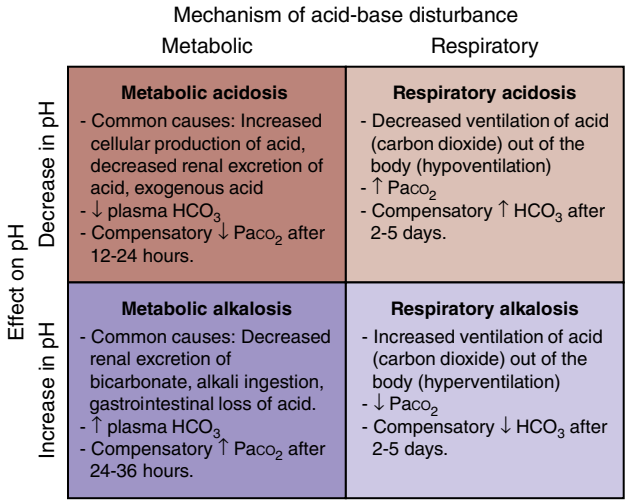

Fig. 113.1 Classification of the four major categories of acid-base disorders.

decreased ventilation of carbon dioxide to maintain acid-base hemostasis. Respiratory compensation typically takes 12 to 24 hours for a metabolic acidosis and 24 to 36 hours for a metabolic alkalosis.[1]

Respiratory acid-base disorders are caused by abnormalities in ventilating carbon dioxide out of the body through the lungs. In clinical medicine, a common method of evaluating ventilation is by measuring the partial pressure of carbon dioxide in arterial blood ($Paco_2$). After a primary respiratory acid-base disturbance develops, the metabolic system compensates by altering the excretion of acid in the kidneys to maintain acid-base hemostasis. Metabolic compensation typically takes between 2 and 5 days after a respiratory acidosis or alkalosis develops.[1]

Acid-base disorders are categorized by their pathophysiologic mechanism (metabolic or respiratory) and effect on pH (acidosis or alkalosis). Hence, the four broad categories of acid-base disorders are metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis (Fig. 113.1). A simple acid-base disturbance describes a physiologic state with a single acid-base disorder with or without compensation. A mixed-acid base disturbance describes a state with more than one primary acid-disorder, each with or without compensation.

This chapter provides an overview of the identification and classification of acid-base disorders in emergency medicine. Specific acid-base disorders are discussed in detail in other disease-focused chapters.

CLINICAL FEATURES

A variety of patient presentations may prompt a clinician to search for acid-base disorders. This typically occurs in one of the three following scenarios in the emergency department:

1. The patient presents with undifferentiated signs and symptoms and is ill-appearing with vital sign abnormalities, respiratory distress, or altered mental status.
2. The patient presents with signs, symptoms or chronic medical conditions known to potentially cause acid-base abnormalities, such as toxic ingestions, vomiting, diarrhea, pregnancy, diabetes mellitus, chronic kidney disease, chronic liver disease, chronic lung disease, or neuromuscular disease.
3. The patient is well-appearing and does not have an overt clinical presentation consistent with an acid-base disorder, but laboratory studies demonstrate an acid-base abnormality.

Once an acid-base abnormality is suspected, the clinician should initiate targeted diagnostic testing to identify the type of acid-base disorder present and its underlying cause.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTING

The initial phase of evaluating most patients with acid-base disorders is interpretation of laboratory data. These data can assist the clinician in classifying the type of acid-base disorder(s) present: metabolic acidosis, metabolic alkalosis, respiratory acidosis, or respiratory alkalosis. Once the class of acid-base disorder is identified, the clinician can develop a differential diagnosis for the cause of the disorder.

Diagnostic Testing

Acid-base disorders can be characterized by the pH, $Paco_2$, and HCO_3 concentration. Hence, interpretation of the basic metabolic panel (BMP) and blood gas is essential. Blood gas measurements can be obtained from either an arterial sample (arterial blood gas, ABG) or a venous sample (venous blood gas, VBG). Respiratory and acid-base physiology were classically described using ABG values, and ABG measurements provide a direct evaluation of oxygenation status as opposed to VBGs. However, obtaining an ABG requires arterial puncture, which is painful for patients, time-consuming for clinicians, and higher risk than venous blood sampling.

A VBG can be obtained from a routine venous blood draw with other laboratory studies and is a reasonable screening test in many settings. In the following sections, we provide a detailed discussion using ABG values; many of these concepts also apply to VBG values with the following considerations. On average, pH on a VBG is about 0.03 less than a concurrent ABG pH. The relationship between venous Pco_2 ($Pvco_2$) and $Paco_2$ is more variable, with $Pvco_2$ about 5 to 9 mm Hg higher than concurrent $Paco_2$ for many patients. $Pvco_2$ less than 45 mm Hg has nearly 100% negative predictive value for ruling out hypercapnia (defined as $Paco_2 > 50$ mm Hg). Pvo_2 does not correlate with Pao_2 and cannot be used to guide management decisions about oxygen supplementation. However, oxygenation can be adequately measured noninvasively in most patients with pulse oximetry providing saturation of peripheral oxygen (Spo_2) values. Hence, the combination of a VBG and Spo_2 is a useful screen for acid-base disturbances and hypoxemia in most patients. Patients with a complex acid-base disorder or severe respiratory illness often benefit from an ABG in addition to the initial screen with a VBG and Spo_2.

Goals for the clinician include identifying whether an acid-base disorder is present, and if so, determining the primary disturbance. Once the primary disturbance has been identified, simple formulas can be used to understand if an appropriate compensatory response has occurred and if another primary acid-base order is also present. Compensatory processes adjust the pH toward normal, but usually not completely to normal and never beyond normal.

Several methods for identifying, classifying, and understanding acid-base disorders have been described, including the physiologic, physiochemical (also known as the Stewart method), and base-excess approaches. A simplified method for acid-base classification that incorporates concepts from each approach can be rapidly applied by clinicians at the bedside and is described in detail below. This method involves a five-step approach that primarily focuses on the interpretation of the BMP to evaluate for metabolic acid-base disturbances and a three-step approach that primarily focuses on the interpretation of the ABG to evaluate for respiratory acid-base disturbances.

Basic Metabolic Panel Interpretation

The BMP is the primary test to evaluate for metabolic acid-base disturbances and includes plasma concentrations for the following: sodium (Na), chloride (Cl), potassium (K), bicarbonate (HCO_3), blood urea nitrogen (BUN), creatinine (Cr), and glucose. Normal ranges for

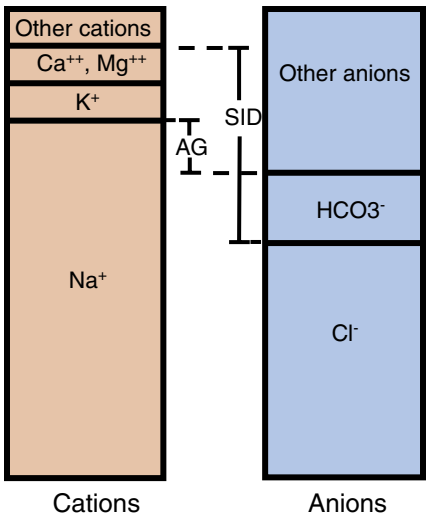

Fig. 113.2 Schematic representation of the anion gap (AG) and strong ion difference (SID). Human plasma is maintained at electroneutrality (no net charge). Thus, the sum of cations in plasma is equivalent to the sum of the anions. Calculation of the anion gap and strong ion difference can help identify the relative contribution of different cations and anions to plasma composition. An increase in anion gap indicates an increase in the contribution of "other anions," such as lactate in lactic acidosis or ketone bodies in diabetic ketoacidosis. A relative increase in chloride concentration compared to the strong cations (Na^+, K^+, Ca^{++}, Mg^{++}), such as occurs during saline infusion, leads to an increase in "other cations," including H^+, and a decrease in the SID.

laboratory tests vary, and clinicians should be familiar with the normal ranges in their institutions. Specific thresholds are shown below for illustrative purposes.

Five-Step Acid-Base Approach to the BMP

BMP Step 1. Check for Abnormal Values. Evaluate the BMP for any abnormalities. A low HCO_3 concentration (for example, <22 mmol/L) identifies a metabolic acidosis, whereas a high HCO_3 concentration (for example, >29 mmol/L) identifies a metabolic alkalosis.

BMP Step 2. Check the Anion Gap. The anion gap (AG) is calculated with the formula: $AG = [Na^+] - ([Cl^-] + [HCO_3^-])$. The anion gap is used to evaluate for the presence of a wide anion gap metabolic acidosis. A wide anion gap metabolic acidosis is present if the anion gap is elevated, regardless of values for HCO_3 and pH. The anion gap is normally between 9.0 and 15.0 mmol/L, and thresholds to signify a wide anion gap vary between 10 and 15 mmol/L due to differences in laboratory technique.[1] For illustrative purposes, a threshold of 15 mmol/L is used to define a wide anion gap in this chapter.

Plasma is electrically neutral. Hence, the sum of positive ion charges is equal to the sum of negative ion charges, as detailed in the equation: $[Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}] + [H^+]$ + unmeasured cations = $[Cl^-] + [HCO_3^-] + [CO_3^{2-}] + [OH^-]$ + albumin + phosphate + sulfate + lactate + unmeasured anions. Clinical laboratories only routinely measure plasma concentrations of the major ions, resulting in some cations and anions being "unmeasured." A greater proportion of cation charge is typically measured than the anion charge, resulting in the concept of an "anion gap"—that is, the difference between measured cations and anions (Fig. 113.2). The calculation for the anion gap accounts for the most plentiful measured cation (Na^+) and the two most plentiful measured anions (Cl^- and $HCO3^-$).

Accumulation of "unmeasured anions"—that is, any anion other than chloride and bicarbonate—results in a wide anion gap metabolic acidosis. An acidosis in which the decrease in $[HCO3^-]$ is accompanied by an increase in $[Cl^-]$ of approximately the same magnitude results in a normal anion gap acidosis, also known as hyperchloremic metabolic acidosis.

BMP Step 3. If a Metabolic Acidosis is Present, Apply the Rule of 15. The rule of 15 is used to evaluate for concomitant respiratory acid-base disturbances in addition to a metabolic acidosis. According to the rule of 15, in an isolated metabolic acidosis, HCO_3 + 15 should equal the $Paco_2$ (±2 mm Hg) and the two digits of the pH following the decimal (±0.02). If measured $Paco_2$ equals the predicted value, simple respiratory compensation for a primary metabolic acidosis exists. If measured $Paco_2$ is less than the predicted value, there is a superimposed primary respiratory alkalosis on top of metabolic acidosis. If the $Paco_2$ is higher than the predicted value, a superimposed primary respiratory acidosis is present.

The rule of 15 has an important caveat. When HCO_3 falls below 10 mmol/L, the rule of 15 loses validity because HCO_3 and $Paco_2$ have a nonlinear relationship. In cases with HCO_3 between 5 mmol/L and 10 mmol/L, the expected $Paco_2$ is about 15 mm Hg and the expected pH is about 7.15 (this is known as the corollary to the rule of 15). Alternatively, in these cases with HCO_3^- less than 10 mmol/L, Winters equation can be used to calculate a more precise expected $Paco_2$: expected $Paco_2 = [HCO_3^-] * 1.5 + 8 \pm 2$. There are examples of the interpretation of the BMP using anion gap calculations and the rule of 15 available at the end of this chapter on ExpertConsult.com

BMP Step 4. If a Wide Anion Gap Metabolic Acidosis Is Present (Anion Gap ≥15), Check the Delta Gap. Calculation of the delta gap is used to identify additional metabolic acid-base disturbances superimposed on a wide anion gap metabolic acidosis. The delta gap explores the difference between the calculated anion gap and 15 mmol/L, which is the upper limit of normal for the anion gap, as well as the change in measured bicarbonate level from 24 mmol/L, which is the upper limit of normal for the bicarbonate level. In an isolated wide anion gap metabolic acidosis, each incremental increase in the anion gap is matched by an incremental decrease in HCO_3 of approximately the same magnitude. For example, each 1 mmol/L increase in the anion gap above 15 mmol/L is expected to be accompanied by a 1 mmol/L drop in HCO_3 below 24 mmol/L. A measured bicarbonate concentration higher than predicted by the delta gap calculation indicates a concomitant metabolic alkalosis. A measured bicarbonate concentration lower than predicted by the delta gap calculation indicates a concomitant normal anion gap metabolic acidosis. There are examples of delta gap calculations available at the end of this chapter on ExpertConsult.com

BMP Step 5. If a Wide Anion Gap Metabolic Acidosis Is Present (Anion Gap ≥15), But the Cause Is Not Evident, Check the Osmolar Gap. The osmolar gap is used to screen for the presence of abnormal particles dissolved in the blood. In the evaluation of acid-base disorders, calculation of the osmolar gap is commonly used to screen for the possibility of toxic alcohol ingestion as a cause for an unexplained wide anion gap metabolic acidosis.

Osmolality is a direct measure of the number of separate particles (solute) dissolved in a unit of water (solvent) within the blood. Calculated osmolarity is a calculated value of the expected number of osmotically active solutes in blood based on measured concentrations of the most common solutes. In normal physiologic states, the major solutes are sodium, the counter anions to sodium (e.g., chloride, bicarbonate, others), glucose, and urea. In patients who have been drinking ethanol, ethanol concentration (ETOH) is easily measured and is also a major contributor. Thus, the calculated osmolarity is calculated with the equation:

$$\text{calculated osmolarity} = (2 * \text{Na}) + (\text{glucose}/18) + (\text{BUN}/2.8) + (\text{ETOH}/3.7)$$

In this equation, Na is measured in mmol/L, and glucose, BUN, and ETOH are measured in mg/dL. Units for osmolarity are mOsm/kg of

water; the equation above has built-in constants that convert mg/dL to mmol/L.

Osmolality can be measured in clinical laboratories. The measured osmolality includes the solutes in the calculated osmolarity equation and other solutes in the blood not included in the equation. The difference between measured osmolality and calculated osmolarity is the osmolar gap:

$$\text{Osmolar gap} = (\text{measured osmolality}) - (\text{calculated osmolarity})$$

$$= (\text{Measured osmolality}) - [(2 * \text{Na}) + (\text{glucose}/18) + (\text{BUN}/2.8) + (\text{ETOH}/3.7)]$$

A normal osmolar gap is 10 mOsm/kg or less. A wide osmolar gap (>10 mOsm/kg) indicates accumulation of a significant volume of solute not included in the osmolarity equation (that is, a significant volume of "unanticipated" osmotically active solutes). In the setting of a wide anion gap metabolic acidosis, a wide osmolar gap may indicate the presence of toxic alcohols, such as methanol or ethylene glycol. However, it is important to note that a normal osmolar gap does not eliminate the possibility of a toxic alcohol poisoning, because the osmolar gap decreases as toxic alcohols are metabolized. Additionally, the calculation assumes a normal baseline osmolality, which is not always true. When an elevated osmolar gap is caused exclusively by a toxic alcohol, the plasma concentration of methanol or ethylene glycol can be estimated from the osmolar gap. To estimate the concentration of methanol in mg/dL, multiply the osmolar gap by 3. To estimate the concentration of ethylene glycol in mg/dL, multiply the osmolar gap by 6. There is an example of the osmolar gap calculation in Box 113.1.

Blood Gas Interpretation

Blood gases are the primary tests to evaluate for respiratory acid-base disturbances and include measurements for pH, the partial pressure of carbon dioxide (Pco_2) and the partial pressure of oxygen (PO_2).

Three-Step Acid-Base Approach to the ABG

ABG Step 1. Determine if the Patient Is Acidemic or Alkalemic. Evaluate the pH. A pH less than 7.35 indicates acidemia; pH greater than 7.45 indicates alkalemia. pH is a summary measure that describes the overall balance of acid-base status. A pH in the normal range (7.35 to 7.45) may indicate no acid-base disturbance is present, a disturbance is present with compensation resulting in pH within the normal range, or multiple disturbances are present that, when combined, result in a pH in the normal range.

ABG Step 2. Determine if a Predominant Respiratory or Metabolic Acid-Base Disturbance Is Present. Evaluate $Paco_2$ and place it into context with the pH. In predominant respiratory acid-base disturbances, the change in $Paco_2$ is in the opposite direction of the change in pH. Using $Paco_2$ of 40 mm Hg and pH of 7.40 as idealized normal values, a $Paco_2$ greater than 40 with a pH less than 7.40 indicates a predominant respiratory acidosis. In predominant metabolic acid-base disturbances, the change in $Paco_2$ and pH are in the same direction. For example, a $Paco_2$ less than 40 mm Hg with a pH less than 7.40 indicates a predominant metabolic acidosis. There are two examples illustrating the use of ABG to determine the predominant respiratory or metabolic acid-base disturbance available at the end of this chapter on ExpertConsult.com.

ABG Step 3. If a Predominant Respiratory Acid-Base Disturbance Is Present, Determine If There Is a Concurrent Metabolic Disturbance. Compare the magnitude of changes in $Paco_2$ and pH. In a pure respiratory disturbance, a 10 mm Hg change in $Paco_2$ results in approximately a 0.08 change in pH in the opposite direction. If this delta-$Paco_2$: delta-pH ratio of 10:0.08 is not present, a concurrent metabolic disturbance is present along with the primary respiratory disturbance. The predicted pH assuming an isolated respiratory disturbance can be calculated with the equation:

$$\text{predicted pH} = \text{normal pH} + [(\text{normal } Paco_2 - \text{measured } Paco_2)/10 * 0.08]$$

$$= 7.40 + [(40 - \text{measured } Paco_2)/10 * 0.08]$$

If the measured pH is higher than predicted for the magnitude of $Paco_2$ change, a metabolic alkalosis is also present. If the pH is lower than expected for the magnitude of $Paco_2$ change, a metabolic acidosis is also present. An example highlighting the three steps in the use of the ABG to determine which acid-base disorders exist both as primary and concomitant/compensatory processes is noted in Box 113.2. Another example of this three-step approach can be found at the end of this chapter on ExpertConsult.com.

BOX 113.1 Identifying Acid-Base Disturbances With the Five-Step Focused Algorithm for Interpreting a Basic Metabolic Panel (BMP)

Clinical Concern: Acute Antifreeze (Ethylene Glycol) Ingestion

Laboratory Data

Na = 140 mmol/L
Cl = 100 mmol/L
HCO_3 = 8 mmol/L
BUN = 30 mg/dL
Cr = 2.5 mg/dL
Glucose = 80 mg/dL
ETOH = 240 mg/dL
$Paco_2$ = 17 mmHg
pH = 7.13
Measured Osmolality: 425 mOsm/kg

1. *Check the numbers*: Na = 140 mmol/L; Cl = 100 mmol/L; HCO_3 = 8 mmol/L; BUN = 30 mg/dL; Cr = 2.5 mg/dL; Glucose = 80 mg/dL. A low bicarbonate indicates a metabolic acidosis.
2. *Calculate the anion gap*: AG = 140 – (100 + 8) = 32. A high anion gap indicates wide anion gap metabolic acidosis.
3. *Apply the rule of 15*: HCO_3 is below 10 mmol/L. According to the corollary to the rule of 15, simple respiratory compensation would lead to a $Paco_2$ of approximately 15 mm Hg (±2), which is consistent with the patient's measured $Paco_2$ of 17 mm Hg. The patient's acid-base status is consistent with a primary metabolic acidosis with respiratory compensation without an additional primary respiratory acid-base disturbance.
4. *Calculate the delta gap*: Change in AG = measured AG – 15 = 32 – 15 = 17. Change in HCO_3 = 24 – measured HCO_3 = 24 – 8 = 16. The predicted change in bicarbonate concentration is 17 mmol/L, and the measured change is very similar at 16 mmol/L; this indicates the metabolic acid-base state is fully accounted for by a wide anion gap metabolic acidosis.
5. *Calculate the osmolar gap*: Calculated osmolarity = (2*Na) + (Glucose/18) + (BUN/2.8) + (ETOH/ 3.7) = (2*140) + (80/18) + (30/2.8) + (240/3.7) = 360 mOsm/kg. Osmol gap = (measured osmolality) – (calculated osmolarity) = 425 mOsm/kg – 360 mOsm/kg = 65 mOsm/kg. An osmolar gap >10 mOsm/kg indicates accumulation of a significant volume of abnormal solute in the blood. In the setting of suspected ethylene glycol ingestion, the wide osmolar gap is presumed to be due to ethylene glycol until plasma ethylene glycol concentration results are available. The estimated ethylene glycol concentration = (osmolar gap) * 6 = 65 * 6 = 390 mg/dL.

BOX 113.2 Identifying Acid-Base Disturbances With the Three-Step Focused Algorithm for Interpreting an Arterial Blood Gas (ABG)

Clinical Concern: Salicylate Toxicity

Laboratory Data

ABG: pH = 7.47/$Paco_2$ = 25 mm Hg/Pao_2 = 180 mm Hg

Determine if the patient is acidemic or alkalemic. The patient's pH is 7.47, indicating alkalemia.

Determine if a predominant respiratory or metabolic acid-base disturbance is present. The patient's $Paco_2$ is low at 25 mm Hg and pH is high at 7.47. This is consistent with a respiratory alkalosis.

Determine if there is concurrent metabolic disturbance. Change in $Paco_2$ = 40 – measured $Paco_2$ = 40 – 25 = 15. Assuming a pure respiratory alkalosis with no metabolic acid-base disturbance, predicted pH = 7.40 + [(40 – 25) / 10 * 0.08] = 7.40 + 0.12 = 7.52. The measured pH of 7.47 is lower than the predicted pH of 7.52, indicating a concurrent metabolic acidosis.

Differential Diagnosis of Acid-Base Disorders

Each of the four acid-base disorders—metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis—have multiple potential causes.

Metabolic Acidosis

As previously described, the metabolic acidoses are classified based on anion gap. Accumulation of "unmeasured" anions results in a wide anion gap metabolic acidosis. A decline in bicarbonate with a concomitant increase in chloride results in a normal anion gap metabolic acidosis.

Wide Anion Gap Metabolic Acidosis. An elevated anion gap using the threshold of 15 mmol/L, regardless of the value of the pH or [$HCO3^-$], indicates that a wide anion gap metabolic acidosis is present. The mnemonic MUDPILES can be used to recall common causes of a wide anion gap metabolic acidosis (Box 113.3). Lactic acidosis is the most common cause of a wide anion gap metabolic acidosis, accounting for approximately half of the cases. Other important causes include ketoacidosis (e.g., diabetic ketoacidosis) and toxic alcohol poisoning (e.g., methanol and ethylene glycol). A normal anion gap does not eliminate the possibility of lactic acidosis, ketoacidosis, or toxic alcohol poisoning, and these acids should be directly measured when clinical concern is high despite a normal anion gap.

Normal Anion Gap Metabolic Acidosis. The mnemonic HARDUP (see Box 113.3) can be used to recall the causes of a normal anion gap metabolic acidosis, which is also called hyperchloremic metabolic acidosis. Common causes of normal anion gap metabolic acidosis include renal tubular acidosis (failure of the kidney to properly excrete acid), diarrhea (gastrointestinal loss of bicarbonate), and saline infusion (hyperchloremia leading to the retention of acid to maintain electroneutrality).

Metabolic Alkalosis

Metabolic alkalosis can be caused by an increase in alkali or impaired renal excretion of bicarbonate. The differential for metabolic alkalosis can be divided into chloride-responsive and chloride-unresponsive conditions.

Chloride-Responsive Metabolic Alkalosis. When the circulating volume is decreased, the renin-angiotensin-aldosterone system is activated, and the kidneys reabsorb filtered sodium, bicarbonate, and chloride. This leads to metabolic alkalosis through retention of bicarbonate and decreased concentration of urine chloride (spot urine chloride concentration < 25 mmol/L). When sodium chloride–containing fluids are administered, circulating volume increases, and the metabolic alkalosis is corrected. Causes of chloride-responsive metabolic alkalosis are listed in Box 113.4.

Chloride-Unresponsive Metabolic Alkalosis. Causes of metabolic alkalosis that cannot be corrected with infusion of sodium chloride containing fluids are called chloride-unresponsive metabolic alkaloses (see Box 113.2). A common mechanism is hyperaldosteronism, which causes inappropriate renal excretion of H^+ and Cl^- and a spot urine chloride concentration greater than 40 mmol/L.

BOX 113.3 Causes of Metabolic Acidosis, Divided into Wide Anion Gap and Normal Anion Gap Metabolic Acidosis

Wide Anion Gap Metabolic Acidosis—Mnemonic: MUDPILES

Methanol
Uremia
Diabetic ketoacidosis/alcoholic ketoacidosis
Paraldehyde/**P**olyethylene glycol/**P**aracetamol (acetaminophen)
Iron
Lactic acidosis
Ethylene glycol
Salicylates

Normal Anion Gap Metabolic Acidosis—Mnemonic: HARDUP

Hyperalimentation/**H**ospital-acquired administration of saline
Acid infusion/**A**ddison disease / Carbonic **A**nhydrase Inhibitors
Renal tubular acidosis (RTA)
Diarrhea
Ureterosigmoidostomy (and ileal diversion)
Pancreatic drainage/fistula

BOX 113.4 Causes of Metabolic Alkalosis, Divided into Chloride-Responsive and Chloride-Unresponsive Metabolic Alkalosis

Chloride-Responsive Metabolic Alkalosis

Nasogastric suction
Vomiting
Chloride-wasting diarrhea
Villous adenoma
Persistent diuretic use

Chloride-Unresponsive Metabolic Alkalosis

Primary hyperaldosteronism
Secondary hyperaldosteronism (Bartter syndrome, Gitelman syndrome, congestive heart failure, liver failure, chronic renal failure)
Steroids
Cushing disease
Severe hypercalcemia
Severe hypomagnesemia
Bicarbonate ingestion
Licorice overdose (glycyrrhizic acid)

BOX 113.5 Causes of Respiratory Acidosis Based on Pathophysiologic Mechanism

Respiratory Disease (Lungs and Airways)
Airway obstruction
Obstructive pulmonary diseases (e.g., chronic obstructive pulmonary disease)
Pneumothorax
Pulmonary effusion
Pulmonary edema
Pneumonia
Mechanical ventilation (iatrogenic hypoventilation)

Chest Wall Disease
Chest wall trauma (e.g., flail chest)
Obesity hypoventilation syndrome

Respiratory Muscle Weakness
Myopathies (e.g., muscular dystrophy)
Neuropathies (e.g., Guillain-Barré)
Electrolyte abnormalities (e.g., hypokalemia, hypophosphatemia)

Decreased Respiratory Drive
Brain space-occupying lesion (e.g., intracranial mass, intracranial hemorrhage)
Drugs/toxins (e.g., sedative-hypnotics, narcotics)

BOX 113.6 Causes of Respiratory Alkalosis Based on Pathophysiologic Mechanism

Respiratory
Conditions that cause hypoxemia (e.g., pulmonary embolus)
Mechanical ventilation (iatrogenic hyperventilation)

Gastrointestinal
Hepatic encephalopathy
Neurologic
Brain lesion

Genitourinary
Pregnancy

Psychiatric
Anxiety

Toxic-Metabolic
Drugs (e.g., salicylates, catecholamines, progesterone)
Hyperthyroidism

Infectious
Fever
Sepsis

Miscellaneous
Pain

Respiratory Acidosis

Failure to adequately ventilate carbon dioxide out of the body results in increased $Paco_2$ and respiratory acidosis. Mechanisms of respiratory acidosis include hypoventilation leading to hypercapnic respiratory failure and increased production of carbon dioxide overwhelming mild to moderately impaired pulmonary function. Common causes of hypercapnic respiratory failure and respiratory acidosis include primary lung disease, chest wall disease, respiratory muscle weakness, and decreased respiratory drive from central nervous system disease or toxins. Specific causes of respiratory acidosis within these categories are listed in Box 113.5.

Respiratory Alkalosis

Respiratory alkalosis occurs when increased minute ventilation (hyperventilation) leads to decreased $Paco_2$. In the emergency department, anxiety-related hyperventilation is a common cause of respiratory alkalosis, but other medical illnesses, including salicylate toxicity, can also present with respiratory alkalosis (Box 113.6). Of note, respiratory alkalosis results in increased binding of calcium to albumin, thereby decreasing free serum calcium. Many of the classic symptoms of acute respiratory alkalosis are caused by hypocalcemia—lip and extremity paresthesia, carpal pedal spasm, muscle cramps, syncope. These symptoms quickly resolve as pH declines and free calcium concentrations return to normal.

MANAGEMENT

The management of acid-base disorders focuses on treating the specific cause of an acid-base derangement (e.g., treating diabetic ketoacidosis, managing an overdose, providing ventilatory support). Detailed discussions on the management of specific causes of acid-base disorders are included in other disease-focused chapters. Here, we discuss general principles of managing acid-base disorders.

Intravenous Fluids

Intravenous fluid administration is a common method of both causing and treating acid-base disorders. Thus, understanding the typical clinical effects of common intravenous fluid formulations is key to acid-base management. Although many intravenous fluid formulations are available, intravenous fluid use in the ED is dominated by crystalloid solutions. Three of the commonly used crystalloids are saline (0.9% sodium chloride, "normal saline"), lactated Ringers (also known as Hartmann solution), and Plasma-Lyte (Table 113.1).

One liter of saline is composed of 9 g of sodium chloride diluted in water to a total volume of 1000 ml; therefore, the mass concentration of saline is 9 g/1000 ml = 0.009 or 0.9%. The misnomer "normal saline" likely stems from in vitro red blood cell studies in the 1880s that were incorrectly interpreted as showing human blood is 0.9% salt; the actual concentration is approximately 0.6%. Saline contains 154 mmol/L of both sodium and chloride, which is supraphysiologic compared with human plasma (see Table 113.1). Thus, saline is not "normal" or physiologic. In the early 20th century, saline was adopted as a preferred intravenous fluid for patient care. The rationale behind the adoption of saline over other fluids more similar in composition to human plasma is unclear but may have been related to the ease and low cost of producing saline at the time.

The effect of intravenous crystalloid composition on acid-base status is described by the physiochemical (Stewart) model of acid-base. A key determinant of acid-base status, or the concentration of H^+ in plasma, is the relative concentrations of strong cations (Na^+, K^+, Ca^{++}, and Mg^{++}) and strong anions (Cl^-). As the concentration of strong anions increases relative to strong cations, the concentration of H^+, a weak unmeasured cation, increases to maintain electroneutrality. Thus, a relative increase in Cl^- compared with the strong cations results in acidosis.

The "strong ion difference" is a summary measure of the relative concentration of strong cations and strong anions (see Fig. 113.2). In human plasma and crystalloid solutions, the strong ion difference is approximated by the equation:

TABLE 113.1 Composition of Human Plasma and Commonly Used Intravenous Crystalloid Solutions

			BALANCED CRYSTALLOIDS	
	Human Plasma	Saline	Lactated Ringer	Plasma-Lyte
Sodium (mmol/L)	135–145	154	130	140
Potassium (mmol/L)	4.5–5.0	0	4	5
Chloride (mmol/L)	94–111	154	109	98
Calcium (mmol/L)	2.2–2.6	0	2.7	0
Magnesium (mmol/L)	0.8–1.0	0	0	1.5
Bicarbonate (mmol/L)	23–27	0	0	0
Lactate (mmol/L)	1–2	0	28	0
Acetate (mmol/L)	0	0	0	27
Gluconate (mmol/L)	0	0	0	23
pH	7.35–7.45	5.0	6.5	7.4
Osmolarity (mOsm/L)	291	308	273	294
Strong ion difference (mmol/L)	≈42	0	28	50

$$\text{Strong ion difference} = [Na^+] + [K^+] + [Ca^{++}] + [Mg^{++}] - [Cl^-]$$

Decreases in the strong ion difference indicate that unmeasured weak cations contribute more of the cation charge. At a physiologic pH of 7.40, infusion of intravenous fluids that have a strong ion difference of about 24 mmol/L has no effect on pH. Infusion of intravenous fluids with a strong ion difference of less than 24 mmol/L results in an increase in $[H^+]$ and acidosis, while fluids with a strong ion difference of greater than 24 mmol/L lead to a reduction in $[H^+]$ and alkalosis.

With a composition of 154 mmol/L of sodium and chloride, saline has a strong ion difference of 0. Therefore, infusing saline into human plasma results in a relative increase in chloride concentration compared with the strong cations, a decrease in the strong ion difference, and acidosis. Through these mechanisms, saline administration leads to a normal anion gap hyperchloremic metabolic acidosis.

"Balanced crystalloids" are crystalloids that more closely match the composition of human plasma than saline in terms of electrolyte concentrations. An idealized balanced crystalloid would contain the same electrolytes and concentrations as human plasma. However, bicarbonate-containing solutions are difficult to store in plastic containers for prolonged periods. Hence, balanced crystalloids are developed with alternative anions that serve as substitutes for bicarbonate. Historically, the primary balanced crystalloid was lactated Ringers (chloride concentration = 109 mmol/L; strong ion difference = 28 mmol/L), which is modeled after a fluid Dr. Sydney Ringer developed in the late 19th century. The primary anion in lactated Ringers is lactate, which is metabolized to bicarbonate after infusion. In terms of effects on acid-base, lactated Ringers is considered a neutral fluid that does not induce either acidosis or alkalosis.

The balanced crystalloid Plasma-Lyte (chloride concentration = 98 mmol/L) was developed with the anions acetate and gluconate and concentrations of sodium, potassium, and chloride that closely match human plasma (see Table 113.1). The calculated strong ion difference of Plasma-Lyte is 50 mmol/L, but the effective strong ion difference is likely lower because gluconate does not fully metabolize into bicarbonate. The expected effect of Plasma-Lyte on acid-base status is a mild alkalinizing effect.

Saline infusion has been known to cause hyperchloremic metabolic acidosis since the early 20th century. While physiology studies have consistently suggested that saline-associated hyperchloremic metabolic acidosis may have negative effects on renal and immune function, the clinical consequences of saline infusion in human studies have only recently begun to emerge. The administration of balanced crystalloids instead of saline in volumes typically used in clinical medicine, including in the emergency department, reduces the number of patients who experience hyperchloremia and metabolic acidosis.[2,3] Additionally, recent data suggest balanced crystalloids lead to better patient outcomes than saline, including a survival benefit in sepsis.[2-4]

Although current data do not provide definitive evidence for scenarios in which clinicians should use balanced crystalloids instead of saline, it is reasonable to preferentially use a balanced crystalloid, such as lactated Ringers or Plasma-Lyte, in patients with hyperchloremia, metabolic acidosis, renal dysfunction, sepsis, and those receiving a large volume of fluid. Potential adverse effects of balanced crystalloids include the induction of metabolic alkalosis (especially with Plasma-Lyte), low tonicity potentially increasing intracranial pressure (especially with lactated Ringers), and hyponatremia (especially with lactated Ringers).

Sodium Bicarbonate Therapy

Although bicarbonate-containing solutions cannot be conveniently stored for prolonged periods, they can be mixed for immediate use. An isotonic sodium bicarbonate solution can be prepared by adding 150 mmol sodium bicarbonate, or three 50-ml ampules of 8.4% sodium bicarbonate, to one liter of D5W. This fluid can then be infused intravenously and has a strong alkalinizing effect. The addition of sodium bicarbonate to 0.9% sodium chloride (saline) should be avoided due to the hypertonicity and high sodium concentration of this mixture.

Intravenous sodium bicarbonate therapy is recommended for the treatment of some specific poisonings, such as sodium channel blocking toxicants and salicylates, but its role in the routine treatment of severe metabolic acidosis is controversial. Identifying and reversing the underlying cause of metabolic acidosis is the primary therapy. It remains unclear whether using sodium bicarbonate to increase pH while addressing the primary cause of acidosis provides benefit. Proponents of bicarbonate therapy in this setting note that acidosis can result in decreased myocardial contractility, systemic vasodilation, and decreased responsiveness to catecholamines. Opponents note potential harms of intravenous sodium bicarbonate therapy, including a paradoxical increase in CNS acidosis (bicarbonate does not readily cross the blood-brain barrier, and decreased drive for hyperventilation leads to increased CO_2 both systemically and in the CNS), hypernatremia, hypocalcemia, hypokalemia, increased lactate production, and fluid overload.

Historically, many clinicians have argued against bicarbonate therapy for metabolic acidosis due to its potential harms and no demonstrated clinical benefit. In a recent clinical trial of adults with metabolic acidosis (pH 7.20 or less), plasma bicarbonate concentration 20 mmol/L or less, and arterial lactate concentration 2.0 mmol/L or greater, sodium bicarbonate therapy demonstrated no effect on survival among all patients but was associated with a survival benefit among patients who presented with acute kidney injury.[5] Trial exclusions included diabetic ketoacidosis, respiratory acidosis, and severe chronic kidney disease.

While no evidence-based algorithms exist, a common and reasonable practice is to use intravenous sodium bicarbonate therapy for

metabolic acidosis with a pH less than 7.10 with the goals of increasing pH above 7.10 and plasma bicarbonate concentration above 10 mmol/L. For patients with concomitant acute kidney injury, we recommend use of sodium bicarbonate therapy for a pH less than 7.20.[5] Based on current understanding, bicarbonate therapy is thought to be more beneficial for acidoses caused by loss of bicarbonate (e.g., diarrhea) or impairment of acid excretion (e.g., renal failure) than those caused by endogenous acid production (e.g., lactic acidosis, ketoacidosis).

DISPOSITION

Disposition of patients with acid-base disorders is based on treatment needs for the underlying etiology as well as the severity of the acid-base disorder. Most of the causes of acute acid-base disorders benefit from hospital admission because hours to days of monitoring and therapy are often needed to reverse the disorder. In some instances, a patient may be fully treated in the emergency department for a mild acid-base disorder or etiology that can be rapidly remedied. In these cases, repeat laboratory testing before discharge is often useful to assure that the acid-base disorder has been appropriately addressed.

ACKNOWLEDGEMENTS

We would like to recognize Corey M. Slovis, MD for helping develop many of the concepts presented in this chapter.

CHAPTER 113: QUESTIONS AND ANSWERS

1. A patient presents to the emergency department with severe metabolic acidosis. In addition to initial stabilization, what should be a priority for the clinician?

- **a.** Infuse sodium bicarbonate to normalize pH to approximately 7.40.
- **b.** Induce a respiratory alkalosis to normalize pH to approximately 7.40.
- **c.** Identify the cause of metabolic acidosis and target therapy at that cause.
- **d.** Infuse saline with the goal of decreasing the strong ion difference.

Answer: C. The key steps to managing acid-base disorders are: (1) identifying the type of acid-base disorder(s) present; (2) identifying the underlying cause of the acid-base disorder; and (3) initiating therapy to reverse the underlying cause. Optimal therapy varies based on the underlying cause. For example, in the case of metabolic acidosis, primary treatment for diabetic ketoacidosis is insulin, for lactic acidosis from sepsis is increasing tissue perfusion with vasopressors and intravenous fluids, and for severe toxic alcohol exposure is a specific reversal agent. In some scenarios with severe metabolic acidosis, sodium bicarbonate infusion is a reasonable adjunctive therapy, especially those caused by loss of bicarbonate or renal failure, while the underlying cause is being addressed.

2. What causes an increase in the anion gap?

- **a.** A decrease in plasma bicarbonate concentration accompanied by an increase in plasma chloride concentration of the same magnitude
- **b.** An increase in the concentration of unmeasured anions in the plasma
- **c.** Saline infusion
- **d.** Hypoventilation

Answer: B. Plasma is maintained as electrically neutral, meaning equal charges from plasma cations and anions. Sodium [Na^+] is the major cation routinely measured in clinical laboratories. Chloride [Cl^-] and bicarbonate [HCO_3^-] are the major anions routinely measured in clinical laboratories. The anion gap is calculated as: [Na^+] − ([Cl^-] + [HCO_3^-]). In normal physiological states, "unmeasured" anions are more plentiful than "unmeasured" cations, and hence the anion gap is positive (typically between about 9 mmol/L and 15 mmol/L). Metabolic acidosis is defined by low [HCO_3^-]. A normal anion gap metabolic acidosis occurs when a decrease in [HCO_3^-] is accompanied by an increase of [Cl^-] by the same amount to maintain electroneutrality. A wide anion gap metabolic acidosis occurs when a decrease is bicarbonate is accompanied by an increase in anions other than chloride (so called "unmeasured anions").

3. A patient in the emergency department has the following laboratory values. Select the term that best characterizes this patient's acid-base status. pH = 7.36; $Paco_2$ = 36 mm Hg; Pao_2 = 135 mm Hg; Na = 142 mmol/L; Cl = 100 mmol/L; HCO3 = 21 mmol/L.

- **a.** Acidemia
- **b.** Alkalemia
- **c.** Respiratory alkalosis with metabolic compensation
- **d.** Metabolic acidosis with respiratory compensation

Answer: D. The patient's pH is in the normal range of 7.35 to 7.45. Therefore, neither acidemia nor alkalemia is present. However, the patient may have an acid-base disorder with compensation into a normal pH range, or multiple primary acid-base disorders that when combined result in a pH in the normal range. To classify an acid-base disorder, initially interpret the basic metabolic panel findings and then the arterial blood gas findings. This patient's bicarbonate is low at 21 mmol/L, indicating a metabolic acidosis. The anion gap is 21 mmol/L, indicating a wide anion gap metabolic acidosis. According to the rule of 15, respiratory compensation for this metabolic acidosis is expected to result in a $Paco_2$ of 36 mm Hg and a pH of 7.36, consistent with the patient's measured values. Looking at the ABG results, the pH is less than 7.40, indicating a primary acidosis, and $Paco_2$ is less than 40 mm Hg, indicating the respiratory findings are a compensatory effect rather than a primary disorder.

4. How can calculation of an osmolar gap be used clinically?

- **a.** To rule out toxic alcohol ingestion
- **b.** To assist with understanding potential causes of a wide anion gap metabolic acidosis
- **c.** To differentiate primary lung pathology from respiratory muscle weakness in a patient with respiratory acidosis
- **d.** To understand if metabolic compensation has occurred after respiratory alkalosis

Answer: B. Calculation of the osmolar gap is a method to help understand the cause of a wide anion gap metabolic acidosis. It can help identify the presence of a large amount of osmotically active solutes in the blood other than the primary osmotically active solutes that are commonly measured (Na, counter anions to Na, glucose, urea, and ethanol). An elevated osmolar gap occurs when measured osmolality is higher than predicated based on a calculation accounting for the commonly measured osmotically active solutes. An important cause of wide anion gap metabolic acidosis and elevated osmolar gap is toxic alcohol poisoning (e.g., methanol or ethylene glycol). Although an elevated anion gap with an elevated osmolar gap can suggest toxic alcohol poisoning in the right clinical setting, a normal osmolar gap does not rule out toxic alcohol poisoning because the osmolar gap decreases as alcohols are metabolized and calculation of the osmolar gap assumes normal osmolality before the poisoning, which may not be true, especially in chronically ill patients.

5. A patient presents to the emergency department with shortness of breath. Plasma bicarbonate concentration is 44 mmol/L. What is a potential explanation for this laboratory value?

- **a.** Administration of a large volume of saline
- **b.** Acute respiratory failure from a spontaneous pneumothorax sustained 2 hours prior to presentation
- **c.** Chronic respiratory failure from chronic obstructive pulmonary disease
- **d.** Diabetic ketoacidosis

Answer: C. A plasma bicarbonate concentration of 44 mmol/L indicates either a primary metabolic alkalosis or metabolic compensation for a respiratory acidosis. Metabolic compensation requires alteration of renal excretion of acid, which usually takes at least 2 days to develop. Therefore, metabolic compensation is typically not present with acute respiratory failure but is present with chronic respiratory failure. Administration of a large volume of saline increases plasma chloride concentration and decreases plasma bicarbonate concentration to maintain electroneutrality. Respiratory acidosis from a pneumothorax sustained 2 hours previously would not be associated with metabolic compensation because not enough time would have elapsed for the metabolic compensatory mechanisms to have an effect. Respiratory acidosis from chronic respiratory failure is associated with metabolic compensation and thus an elevated bicarbonate concentration. Diabetic ketoacidosis results in accumulation of "unmeasured" anions (acetoacetic acid and beta-hydroxybutyric acid) and a decrease in plasma bicarbonate to maintain electroneutrality.

ACID-BASE DISORDER SAMPLE CALCULATIONS

Rule of 15 Example 1

Na = 140 mmol/L; Cl = 110 mmol/L; HCO_3 = 10 mmol/L; $PaCo_2$ = 20; pH = 7.32.

- *Check the numbers:* The HCO_3 is low, indicating a metabolic acidosis.
- *Calculate anion gap*: AG = 140 − (110 + 10) = 20
  A calculated value of 20 indicates the presence of wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3^- + 15 = 10 + 15 = 25.
  Simple respiratory compensation would lead to a $Paco_2$ of 25 mm Hg (±2) and a pH of 7.25 (±0.02). The patient's measured value for $Paco_2$ (20 mm Hg) is lower and the measured value for pH (7.32) is higher than predicted by the rule of 15. These "more alkalotic" values indicate the patient is hyperventilating more than expected to compensate for metabolic acidosis. This patient has a primary respiratory alkalosis in addition to a primary wide anion gap metabolic acidosis.

Rule of 15 Example 2

- *Check the numbers*: Na = 140 mmol/L; Cl = 100 mmol/L; HCO_3 = 20 mmol/L; $Paco_2$ = 35 mm Hg; pH = 7.35.
  A low bicarbonate value indicates metabolic acidosis.
- *Calculate anion gap*: AG = 140 − (100 + 20) = 20.
  A high anion gap indicates a wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3 + 15 = 20 + 15 = 35.
  Simple respiratory compensation would lead to a $Paco_2$ of 35 mm Hg (±2) and a pH of 7.35 (±0.02). The patient's measured values match these expected values; hence, this patient has a simple wide anion gap primary metabolic acidosis with appropriate respiratory compensation.

Rule of 15 Example 3

- *Check the numbers*: Na = 140 mmol/L; Cl 105 mmol/L; HCO_3 = 10 mmol/L; $Paco_2$ = 32 mm Hg; pH = 7.14.
  A low bicarbonate indicates a metabolic acidosis.
- *Calculate the anion gap*: AG = 140 − (105 + 10) = 25.
  A high anion gap indicates wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3^- + 15 = 10 + 15 = 25.
  Simple respiratory compensation would lead to a $Paco_2$ of 25 mm Hg (±2) and a pH of 7.25 (±0.02). The patient's measured value for $Paco_2$ (32 mm Hg) is higher and the measured value for pH (7.14) is lower than predicted by the rule of 15. These "more acidotic" values indicate the patient is hypoventilating in the context of a metabolic acidosis. This patient has a primary respiratory acidosis in addition to a primary wide anion gap metabolic acidosis.

Rule of 15 Example 4

- *Check the numbers*: Na = 140 mmol/L; Cl 105 mmol/L; HCO_3 = 10 mmol/L; $Paco_2$ = 32 mm Hg; pH = 7.14.
  A low bicarbonate indicates a metabolic acidosis.
- *Calculate the anion gap*: AG = 140 − (105 + 10) = 25.
  A high anion gap indicates wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3^- + 15 = 10 + 15 = 25.
  Simple respiratory compensation would lead to a $Paco_2$ of 25 mm Hg (±2) and a pH of 7.25 (±0.02). The patient's measured value for $Paco_2$ (32 mm Hg) is higher and the measured value for pH (7.14) is lower than predicted by the rule of 15. These "more acidotic" values indicate the patient is hypoventilating in the context of a metabolic acidosis. This patient has a primary respiratory acidosis in addition to a primary wide anion gap metabolic acidosis.

Delta Gap Example 1

- *Check the numbers*: Na = 140 mmol/L; Cl 92 mmol/L; HCO_3 = 20 mmol/L; $Paco_2$ = 37 mm Hg; pH = 7.37.
  A low bicarbonate indicates a metabolic acidosis.
- *Calculate the anion gap*: AG = 140 − (92 + 20) = 28.
  A high anion gap indicates wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3 + 15 = 20 + 15 = 35.
  Simple respiratory compensation would lead to a $Paco_2$ of 35 mm Hg (±2) and a pH of 7.35 (±0.02). The patient's measured value for $Paco_2$ (37 mm Hg) is consistent with the rule of 15, indicating no primary respiratory acid-base disturbance.
- *Calculate the delta gap*: Change in AG = measured AG − 15 = 28 − 15 = 13. Change in HCO_3 = 24 − measured HCO_3 = 24 − 20 = 4.
  The predicted change in bicarbonate concentration is 13 mmol/L, but the measured change is only 4 mmol/L. The measured bicarbonate is higher than predicted by the delta gap calculation, indicating the presence of a primary metabolic alkalosis in addition to the wide anion gap metabolic acidosis.

Delta Gap Example 2

- *Check the numbers*: Na = 140 mmol/L; Cl = 105 mmol/L; HCO_3 = 12 mmol/L; $Paco_2$ = 27 mm Hg; pH = 7.27.
  A low bicarbonate indicates a metabolic acidosis.
- *Calculate the anion gap*: AG = 140 − (105 + 12) = 23.
  A high anion gap indicates wide anion gap metabolic acidosis.
- *Apply the rule of 15*: HCO_3 + 15 = 12 + 15 = 27.
  Simple respiratory compensation would lead to a $Paco_2$ of 27 mm Hg (±2) and a pH of 7.27 (±0.02). The patient's measured value for $Paco_2$ CO_2 (27 mm Hg) is consistent with the rule of 15, indicating no primary respiratory acid-base disturbance.
- *Calculate the delta gap*: Change in AG = AG − 15 = 23 − 15 = 8. Change in HCO_3 = 24 − measured HCO_3 = 24 −12 = 12.
  The predicted change in bicarbonate concentration is 8 mmol/L, but the measured change is 12 mmol/L. The measured bicarbonate is lower than predicted by the delta gap calculation, indicating the presence of a primary normal anion gap metabolic acidosis in addition to a wide anion gap metabolic acidosis.

ABG Determination of Predominant Respiratory or Metabolic Acid-Base Disorder Example 1

ABG: pH = 7.31 / $PaCO_2$ = 53mm Hg / PaO_2 = 98mm Hg

- Determine if the patient is acidemic or alkalemic. The patient's pH is 7.31, indicating acidemia.
- Determine if a predominant respiratory or metabolic acid-base disturbance is present. The patient's $Paco_2$ is high at 53 mm Hg and pH is low at 7.31. This is consistent with a predominant respiratory acidosis.

ABG Determination of Predominant Respiratory or Metabolic Acid-Base Disorder Example 2

ABG: pH = 7.52 / $PaCO_2$ = 60mm Hg / PaO_2 = 84mm Hg

- Determine if the patient is acidemic or alkalemic.
  The patient's pH is 7.52, indicating alkalemia.
- Determine if a predominant respiratory metabolic acid-base disturbance is present. The patient's $Paco_2$ is high at 60 mm Hg and pH is high at 7.52.
  This is consistent with a predominant metabolic alkalosis. The high $Paco_2$ represents respiratory compensation via hypoventilation.

ABG Determination of Predominant and Concomitant/Compensatory Acid-Base Disorders Example 1

ABG: pH = 7.00 / $PaCO_2$ = 70mm Hg / PaO_2 = 105mm Hg

- Determine if the patient is acidemic or alkalemic.
  The patient's pH is 7.00, indicating acidemia.
- *Determine if a predominant respiratory or metabolic acid-base disturbance is present.* The patient's $PaCO_2$ is high at 70 mm Hg and pH is low at 7.00. This is consistent with a respiratory acidosis.
- Determine if there is concurrent metabolic disturbance.

Change in $PaCO_2$ = 40 − measured $PaCO_2$ = 40 − 70 = −30. Assuming a pure respiratory acidosis with no metabolic acid-base disturbance, predicted pH = 7.40 + [(40 − 70)/10 * 0.08] = 7.40 − 0.24 = 7.16. The measured pH of 7.00 is lower than the predicted pH of 7.16, indicating a concurrent metabolic acidosis.

Electrolyte Disorders

Camiron L. Pfennig and Corey M. Slovis

KEY CONCEPTS

- Electrolyte abnormalities are common in emergency medicine and can vary greatly in importance, severity, and symptoms. Asymptomatic electrolyte abnormalities can be gradually corrected, whereas those causing alterations in consciousness or life-threatening dysrhythmias require immediate therapy to avoid permanent sequelae or death. In some cases, therapy for life-threatening electrolyte disorders may precede laboratory confirmation.
- Asymptomatic electrolyte abnormalities can usually be corrected slowly, but those that cause profound mental status changes or life-threatening arrhythmias require immediate correction to avoid cardiac arrest or seizures.
- IV calcium should be used only for hyperkalemic emergencies, defined as the following: widening QRS; sine wave; bradycardias and cardiac arrest believed to be due to hyperkalemia; or rapidly evolving electrocardiographic changes, from normal to development of tall peaked T waves and loss of the P wave. Acute, rapid rises in serum potassium concentration are rare but may be seen in tumor lysis syndrome, rhabdomyolysis, or massive hemolysis.
- After the critical decision about administration of calcium has been made, a beta$_2$-agonist, insulin and glucose, normal saline, and bicarbonate (if the patient is acidotic) can be given to shift potassium intracellularly.
- When treating hypokalemia, the physician should also replace magnesium sulfate, in addition to potassium, or the patient will excrete most of the infused potassium in the urine.
- Low serum potassium levels reflect a substantial total potassium deficit; correction of large deficits can require several days.
- Hypertonic saline should be reserved for severely hyponatremic patients (typically in the 100 to 110 mEq/L range) who present with coma, seizures, or focal neurologic deficits. Central pontine myelinolysis can occur if serum sodium concentration is raised rapidly by more than 8 mEq/day.

HYPERKALEMIA

Foundations

Hyperkalemia, defined as a serum potassium level greater than 5.0 mEq/L, is the most dangerous acute electrolyte abnormality, potentially leading to life-threatening arrhythmias and death. Although hyperkalemia may have vague and varied symptoms, it is usually totally asymptomatic and can present with cardiac arrest as its first "symptom." Serum potassium concentration is normally between 3.5 and 5.0 mEq/L and is tightly regulated by the kidneys. Hyperkalemia usually develops from impaired renal excretion or intracellular release; however, in advanced chronic kidney disease or end-stage renal disease, dietary intake of potassium may be a significant factor in its development. Risk factors for hyperkalemia include impaired potassium excretion, such as dehydration and renal failure, as well as medications that cause potassium retention. Evaluation of the 12-lead electrocardiogram (ECG) of patients at risk for this electrolyte disturbance guides management decisions. Hyperkalemia can be rapidly progressive, requiring lifesaving interventions at the earliest suspicion of toxicity.

Hyperkalemia causes cardiotoxicity by increasing the resting membrane potential of the cardiac myocyte, causing "membrane excitability," and conversely, sluggish depolarization, as well as decreased duration of repolarization. At very high levels, potassium causes the depolarization threshold to rise, leading to overall depressed cardiac function. Nearly any cardiac arrhythmia can be seen with hyperkalemia, including heart blocks, bradydysrhythmias, pseudoinfarction, ST-segment elevation, Brugada pattern, and the classic "sine wave" pattern.[1] As hyperkalemia advances, the end result is cardiac arrest, usually from deterioration into ventricular fibrillation, pulseless electrical activity, or asystole. A serum potassium level of 10.0 mEq/L is usually fatal, but decompensation and death can occur at any level above 7 to 8 mEq/L.

Clinical Features

Hyperkalemia is a difficult diagnosis to make on clinical grounds alone. Hyperkalemia is classified as mild (K 5.5 to 6.0), moderate (K 6.1 to 6.9) or severe (K >7.0). Patients with mild to moderate hyperkalemia are often identified during routine blood sampling for an unrelated condition. Patients with moderate to severe hyperkalemia may have gastrointestinal effects, such as nausea, vomiting, and diarrhea, which are often associated with their underlying disease. Patients with severe hyperkalemia may present with neuromuscular findings, including muscle cramps, generalized weakness, paresthesias, tetany, and focal or global paralysis. The signs and symptoms of progressive muscle weakness, paresthesias, dyspnea, and depressed deep tendon reflexes are neither sensitive nor specific, nor do they appear reliably with a particular serum potassium level. Patients with severe hyperkalemia may present with hemodynamic instability and cardiac arrhythmias requiring immediate intervention.

Differential Diagnosis

The most common cause of hyperkalemia is spurious elevation due to hemolysis during or after the blood draw. Thus, an ECG should be used to assess for true hyperkalemia while another sample is analyzed. Box 114.1 organizes the most common causes of hyperkalemia. The presence of one of these conditions may be the lone historical clue in hyperkalemia. Physicians should not rely solely on an ECG to determine the presence or absence of hyperkalemia in an otherwise stable patient.[2]

Diagnostic Testing

The ECG is helpful in making the diagnosis of hyperkalemia and can be used in unstable patients to initiate treatment (Figs. 114.1 to 114.3). Classic electrocardiographic changes—the peaked T wave, flattened p wave with prolonged PR interval or a totally absent P wave, wide QRS, and sine wave pattern, portending imminent cardiac arrest—have been well described as appearing sequentially with rising serum potassium

BOX 114.1 Five Most Common Causes of Hyperkalemia

- Spurious elevation: Hemolysis due to drawing or storing of the laboratory sample or post–blood sampling leak from markedly elevated white blood cells, red blood cells, or platelets
- Renal failure: Acute or chronic
- Acidosis: Diabetic ketoacidosis (DKA), Addison disease, adrenal insufficiency, type 4 renal tubular acidosis
- Cell death: Rhabdomyolysis, tumor lysis syndrome, massive hemolysis or transfusion, crush injury, burn
- Drugs: Acute digitalis overdose, succinylcholine, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, nonsteroidal antiinflammatory drugs (NSAIDs), spironolactone, amiloride, potassium supplementation

levels. Peaked T waves usually appear as serum potassium levels exceed 5.5 to 6.5 mEq/L; P wave disappearance and PR prolongation are common with levels above 6.5 to 7.5 mEq/L; and levels above 7.0 to 8.0 mEq/L can result in QRS prolongation. Although these changes may occur in only half the patients, recognition of these patterns is vital to rapid diagnosis and initiation of lifesaving treatment. A serum potassium level above 5.0 mEq/L is diagnostic of hyperkalemia, but the value itself does not always predict electrocardiographic changes or the degree of cardiotoxicity. Furthermore, stable patients who are otherwise unlikely to have elevated potassium should not be presumptively treated for hyperkalemia based on subtle electrocardiographic changes alone. In addition, hyperkalemia may present as an atropine-resistant bradycardia, with or without apparent heart block.[1]

Management

Patients with suspected or known hyperkalemia should have intravenous (IV) access and continuous cardiac monitoring. Treatment of hyperkalemia should be directed by the clinical scenario combined with the ECG and laboratory potassium value, and consists of three main steps: (1) stabilization of the cardiac membrane, (2) shifting of potassium into the cells, and (3) removal of potassium from the body. A variety of treatment options are considered for the acute management of hyperkalemia, including calcium, insulin, beta$_2$-adrenergic agonists, sodium bicarbonate, resins, and dialysis (Table 114.1).

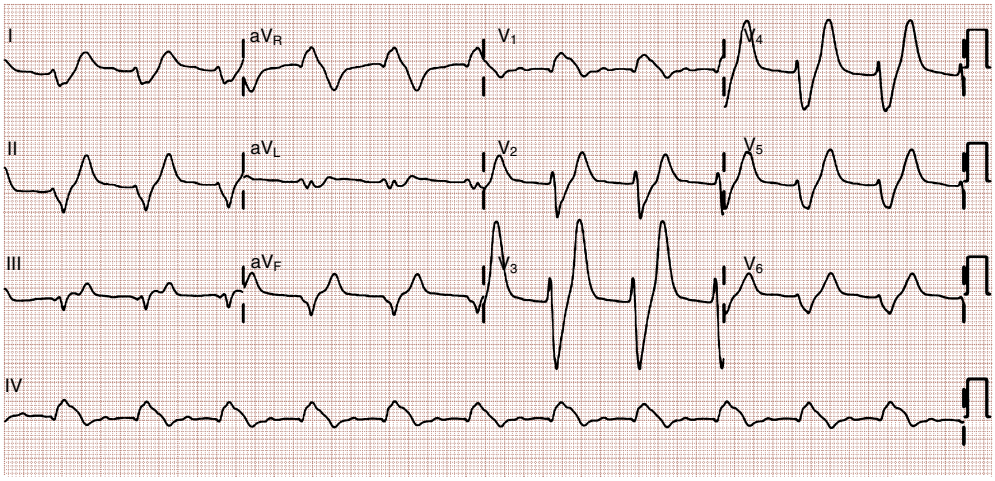

Fig. 114.1 Hyperkalemia with QRS widening merging into T wave, absent P wave.

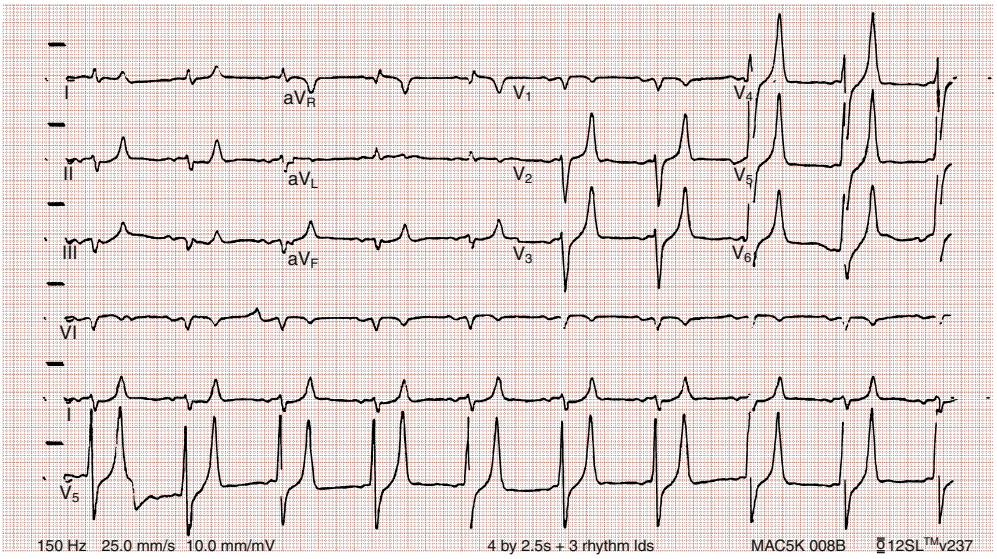

Fig. 114.2 Hyperkalemia in the same patient as in Figure 114.1 after potassium-lowering therapy has begun. Tall peaked T waves, decreased P wave.

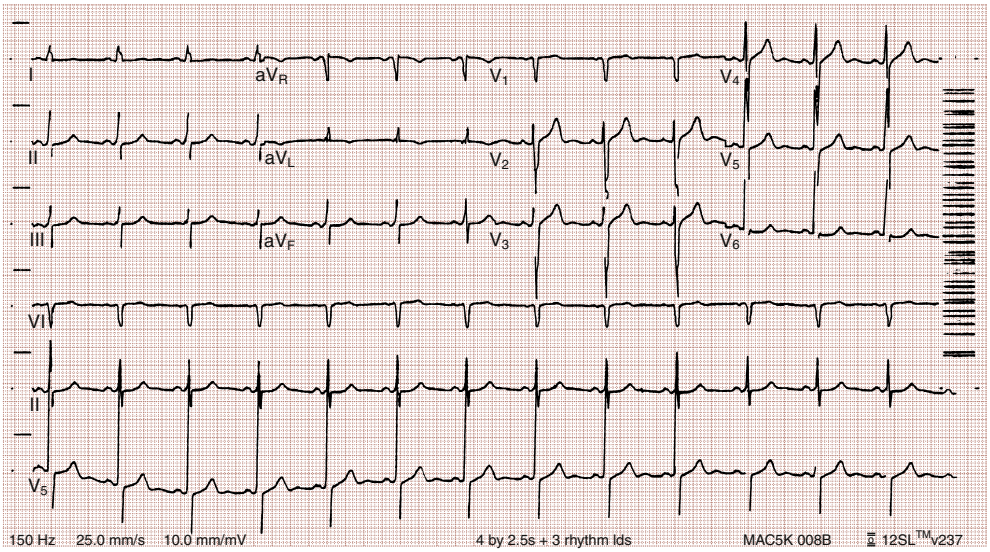

Fig. 114.3 The same patient as in Figures 114.1 and 114.2 after dialysis. The electrocardiogram (ECG) is now normal.

TABLE 114.1 Treatment of Hyperkalemia

Treatment	Medication	Features
Stabilize cardiac membrane	Calcium chloride 1 g or calcium gluconate IV 2 g	For wide QRS, restores the electrical gradient; does not decrease serum potassium Onset within minutes; lasts 30 to 60 minutes
Shift potassium into cells	Regular insulin, 10 units, IV push, combined with 100 mL of 50% dextrose, IV push; 5 units IV insulin if renal dysfunction to avoid hypolgycemia High-dose nebulized albuterol by face mask (10 to 15 mg by continuous inhalation) Bicarbonate 50 to 100 mL Normal saline 100 to 250 mL	Insulin: Onset <15 minutes; maximum effect 30 to 60 minutes (≈0.6 mEq/L decrease) Nebulized albuterol: Onset <15 minutes (0.5 to 1 mEq/L decrease) If severely acidotic In conjunction with nephrologist if dialysis dependent
Remove potassium from the body	Hemodialysis Normal saline and furosemide Ion exchange resin	Emergently in cardiac arrest, urgently in renal failure; may delay if renal function is normal In patients with rhabdomyolysis or tumor lysis syndrome with intact urine output, not effective acutely

IV, Intravenous.

IV calcium stabilizes the cardiac membrane by restoring the electrical gradient. Calcium increases the depolarization threshold and the calcium gradient across the cardiac membrane, quieting myocyte excitability and increasing cardiac conduction speed, thus narrowing the QRS. Calcium does not decrease serum potassium levels, and its effect is rapid (within 1 to 3 minutes), but transient (30 to 60 minutes or less). The dose is one ampule, or 10 mL of 10% calcium chloride solution. Calcium chloride is preferably administered through a central venous line due to the risk of tissue necrosis should it extravasate at the injection site. More than 10 mL of calcium gluconate will often be required, because it contains only one-third the calcium contained in calcium chloride. Calcium gluconate is preferred in pediatric cases, as well as in patients with less emergent (i.e., more chronic) hyperkalemic patients, when a slow infusion is desired or when only a smaller peripheral vein is available for administration.

Beta$_2$-agonists, insulin, saline, and potentially sodium bicarbonate shift potassium intracellularly. Insulin is the most reliable agent to move potassium into cells, but beta$_2$-adrenergic receptor agonists also provide benefit in some patients. Insulin, given IV in combination with glucose to prevent hypoglycemia, also shifts potassium into cells by stimulation of the sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) pump. The onset of action is less than 15 minutes, and the effect is maximal between 30 and 60 minutes, with a maximal drop of 0.6 mEq/L on average. Clinicians should follow glucose levels closely for hours post-therapy with glucose and insulin.

Nebulized albuterol is effective in shifting potassium into cells by stimulation of the Na^+, K^+-ATPase pump. Nebulized albuterol begins to take measurable effect after 15 minutes and lowers the serum potassium level by 0.5 to 1 mEq/L, depending on the dose. The effective dose is at least four times higher than that typically used for bronchodilation. The combination of nebulized albuterol and insulin with glucose appears to be additive, lowering serum potassium, on average, by 1.2 mEq/L.

Saline infusions also stimulate the Na^+, K^+-ATPase pump; only a few hundred milliliters are required for beneficial effects. Saline infusions should be given judiciously in anuric patients and in consultation

with a nephrologist. Sodium bicarbonate is effective in hyperkalemic patients who are acidotic and has no benefit when used for hyperkalemia in non-acidotic patients. Sodium bicarbonate buffers hydrogen ions extracellularly while shifting potassium intracellularly, but it should be used in combination with other treatment options and reserved for patients with confirmed acidosis.[3]

Hemodialysis effectively and reliably decreases serum potassium levels by at least 1 mEq/L in the first hour and another 1 mEq/L during the next 2 hours. It is the only reliable method of potassium removal that has been experimentally studied and should be instituted early to treat life-threatening hyperkalemia in patients with renal failure. In patients with intact renal function, medical management alone is usually sufficient, even in extreme cases, and hemodialysis may not be necessary unless multiple medical modalities fail. There are no randomized trials addressing the use of diuretics (e.g., furosemide) in the emergent management of hyperkalemia. In cases such as rhabdomyolysis or tumor lysis syndrome, it may be appropriate to use a normal saline infusion supplemented by furosemide to enhance diuresis and urinary potassium excretion. Sodium polystyrene sulfonate (Kayexalate), does not decrease the serum potassium level within the first 4 hours of treatment, is not effective in the acute management of hyperkalemia, and may cause serious adverse gastrointestinal effects.[4]

Control of hyperkalemia in patients with chronic kidney disease and in those with heart failure continues to be difficult. However, two oral medications, patiromer and sodium zirconium cyclosilicate, have shown clinical promise in ongoing trials to lower serum potassium levels.[5,6] Zirconium is a highly selective cation exchanger that entraps potassium in theintestinal tract in exchange for sodium and hydrogen. Hypokalemia is often seen in association with hypomagnesemia, and patients with low serum potassium levels should be assumed to be hypomagnesemic also.

HYPOKALEMIA

Foundations

Hypokalemia is the most common electrolyte abnormality encountered in clinical practice. More than 20% of hospitalized patients and up to 40% of outpatients on thiazide diuretics have potassium values less than 3.5 mEq/L.[7] Moderate hypokalemia is a serum level of 2.5 to 3 mEq/L; severe hypokalemia is defined as a level less than 2.5 mEq/L. Although hypokalemia is usually asymptomatic, due to potassium's effect on the heart and muscle, very low levels can result in severe cardiac dysrhythmias or rhabdomyolysis, respectively.[8,9] Hypokalemia is often seen in association with hypomagnesemia, and patients with low serum potassium levels should be assumed to be hypomagnesemic as well.[10]

Clinical Features

Hypokalemia is usually asymptomatic but can present with nonspecific complaints, primarily weakness and muscle pain.[7] Although short periods of mild potassium depletion are typically well-tolerated in healthy individuals, severe potassium depletion can result in serious cardiovascular instability, neurologic dysfunction, glucose intolerance, gastrointestinal symptoms, and renal failure, as well as affect the acid-base balance in the body. The likelihood of symptoms appears to correlate with the rapidity of the decrease in serum potassium.

In patients without underlying heart disease, abnormalities in cardiac conduction are extremely unusual, even when the serum potassium concentration is below 3.0 mEq/L. Paresthesias, depressed deep tendon reflexes, fasciculations, muscle weakness, and confusion can occur when the serum potassium level is less than 2.5 mEq/L. However, in patients with cardiac ischemia or heart failure, even mild to moderate hypokalemia increases the likelihood of cardiac arrhythmias secondary to potassium's effect on the action potential. Hypokalemia is an independent risk factor contributing to reduced survival of cardiac patients and increased incidence of arrhythmic death. Based on available evidence, serum potassium concentrations should be maintained above 4.5 mEq/L in patients having an acute myocardial infarction. Hypokalemic patients can demonstrate first- and second-degree heart block, atrial fibrillation, ventricular fibrillation, and asystole. Life-threatening cardiac arrhythmias are managed by restoration of serum potassium levels into the normal range. Thyrotoxic periodic paralysis is a rare disorder characterized by acute hypokalemia and muscle weakness. It is usually seen in patients of Asian descent and is potentially fatal when involvement includes respiratory muscles.[8]

BOX 114.2 Five Most Common Causes of Hypokalemia

- Renal losses: Diuretic use, drugs, steroid use, metabolic acidosis, hyperaldosteronism, renal tubular acidosis, diabetic ketoacidosis (DKA), alcohol consumption
- Increased nonrenal losses: Sweating, diarrhea, vomiting, laxative use
- Decreased intake: Ethanol, malnutrition
- Intracellular shift: Hyperventilation, metabolic alkalosis, drugs
- Endocrine: Cushing disease, Bartter syndrome, insulin therapy

Differential Diagnosis

The five most common causes of hypokalemia are renal losses, increased nonrenal losses, decreased potassium intake, intracellular shift, and endocrine etiologies (Box 114.2). Increased excretion of potassium, especially coupled with poor intake, is the most common cause of hypokalemia, and patients receiving diuretics represent the single most common patient group encountered in clinical practice. Thiazide diuretics are more likely than loop or osmotic diuretics to cause hypokalemia, but both the thiazide and loop diuretics block chloride-associated sodium and increase delivery of sodium to the collecting tubules. Hypokalemia is a common adverse effect of treatment with diuretics and may cause fatal arrhythmias and increase the risk of digitalis toxicity.[9] In addition to diuretics, other drugs and disorders can cause significant renal potassium losses, including hyperaldosteronism, steroid excess, metabolic acidosis, DKA, renal tubular acidosis, and alcohol consumption. When given in large doses, penicillin and its synthetic derivatives promote renal potassium excretion by increasing sodium delivery to the distal nephron. Individuals with secondary hyperaldosteronism, whether due to congestive heart failure (CHF), hepatic insufficiency, or nephrotic syndrome, may also exhibit hypokalemia. Patients with renal tubular acidosis can become hypokalemic, because a defect in the distal tubule leads to increased potassium excretion.

Administration of insulin may reduce serum potassium because of insulin's ability to stimulate the Na^+, K^+-ATPase pump and move potassium intracellularly; hypokalemia can be a dangerous complication with intentional overdoses of insulin or during treatment of DKA. Although most patients with DKA present with high-normal or mildly elevated serum potassium levels, patients are usually 2 to 3 mEq/kg deficient in total body potassium. To avoid hypokalemic arrhythmias or cardiac arrest from hypokalemia, a potassium infusion should be started once significant hyperkalemia has been ruled out and intact renal function confirmed.

Hypokalemia can also occur from gastrointestinal and dermal losses. In diarrheal states, large quantities of potassium can be lost in the stool, with consequent secondary hyperaldosteronism. Large doses of laxatives and repeated enemas also cause excessive potassium loss in the stool. Although hypokalemia is often seen after protracted vomiting or nasogastric suctions, only 5 to 10 mEq/L of potassium is lost in gastric fluid. Hypokalemia in this setting is secondary to metabolic alkalosis, chloride losses, and hyperaldosteronism. On occasion, excessive

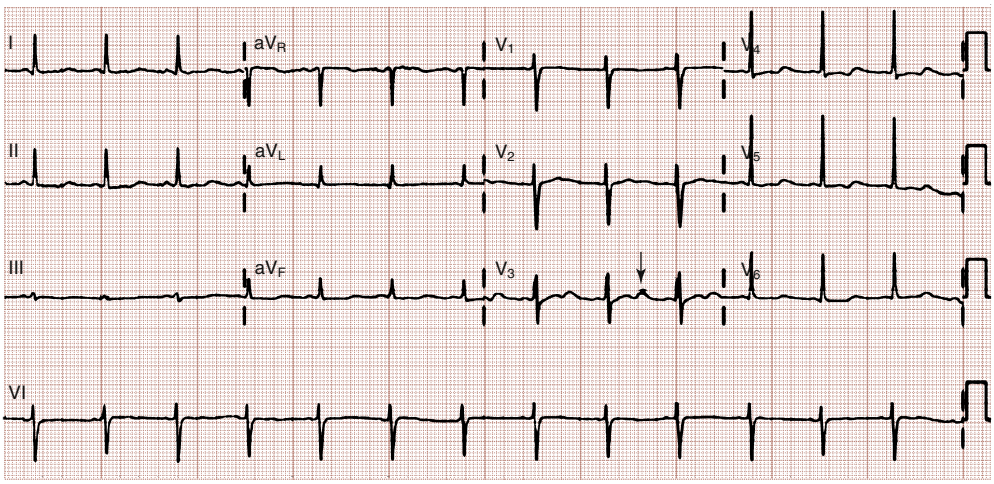

Fig. 114.4 Hypokalemic electrocardiographic changes, including flattened T wave, prolonged QT interval, nonspecific ST changes, and prominent U wave *(arrow)*.

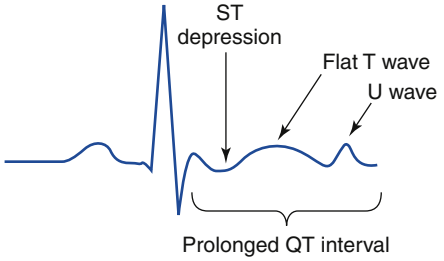

Hypokalemia

Fig. 114.5 Electrocardiographic changes in hypokalemia.

sweating can lead to hypokalemia from potassium losses through the skin. Patients with extensive burns can also suffer from hypokalemia because of significant skin losses. Dietary potassium deficiency should be considered in the severely malnourished patient or chronic alcoholic. Poor potassium intake combined with increased nonrenal losses can result in severe hypokalemia.

Hypokalemia can also result from an acute shift of potassium from the extracellular compartment into cells, most commonly in patients with metabolic alkalosis or hyperventilation, and in patients taking medications such as beta-agonists or decongestants. Stimulation of beta-receptors can lead to hypokalemia, especially in patients using repetitive and high doses of beta-agonists for chronic obstructive pulmonary disease or asthma. A standard dose of nebulized albuterol reduces serum potassium by 0.2 to 0.4 mEq/L, and a second dose taken within 1 hour can reduce it by almost 1 mEq/L. Patients with starvation or near-starvation may develop hypokalemia when fed, because insulin secretion and increased cellular uptake can cause an acute exaggerated intracellular migration of potassium.

Diagnostic Testing

Hypokalemia is rarely diagnosed on clinical presentation alone and is typically made by measurement of the serum potassium concentration during routine laboratory studies. If there is any suspicion for hypokalemia or a patient presents with generalized weakness, palpitations, or arrhythmias, an ECG should be obtained. Just as tall-peaked T waves are characteristic of hyperkalemia, flattened T waves can be seen in hypokalemia. Hypokalemia may produce U waves, which are small deflections after the T wave (Figs. 114.4 and 114.5). Hypokalemia may also cause a dangerously prolonged QT interval. Although there is no threshold of QT prolongation at which torsades de pointes is certain to occur, once the QT interval becomes longer than 500 milliseconds, the risk of torsades de pointes increases twofold to threefold.[9] Hypokalemia is also notorious for causing nonspecific ST and T wave changes. In addition, prolonged potassium depletion of even a modest proportion can provoke or exacerbate kidney injury or hypertension. A severe degree of hypokalemia with paralysis is a potentially life-threatening medical emergency and may be seen as levels drop below 2.0 mEq/L.

Management

Because potassium is an intracellular cation; a low serum potassium level almost always reflects a significant total body potassium deficit; each 0.3 mEq potassium drop below normal correlates with an approximately 100 mEq total body deficit. In the absence of nausea or vomiting as the cause of hypokalemia, patients with mild or moderate hypokalemia may only need oral potassium replacement therapy. Oral replacement is available in liquid, powder, and tablet form. Potassium chloride is the most commonly used supplementation, and 40 to 60 mEq orally every 2 to 4 hours is typically well tolerated. If the cause of hypokalemia is not clear, or the hypokalemia is severe and associated with profound weakness, obtain a spot urine potassium level before starting therapy to assess whether the patient's kidneys are inappropriately wasting potassium from a renal or endocrine cause. Although a 24-hour serum is more accurate, a urinary potassium above 13 mEq/L per gram of creatinine is indicative of inappropriate renal potassium loses.[7] Treatment of hypokalemia is essential in multiple populations of patients. Hypokalemia is arrhythmogenic, especially in the settings of acute myocardial infarction, high catecholamine states, and hypertrophied or dilated ventricles. Hypokalemia is an important independent risk factor for morbidity and mortality in patients with heart failure, requiring serum potassium levels to between 4.0 and 5.0 mEq/L in this population.

If IV infusion is necessary, potassium chloride can be safely given at a rate of 10 to 20 mEq/hr. In the rare instance when IV repletion is planned at more than 20 mEq/hr, such as for levels below 2.0 mEq/L or QT interval greater than 500 milliseconds, the patient should have continuous cardiac monitoring and central line access established.

Hypokalemia is associated with hypomagnesemia, and the severity of the hypokalemia correlates with a similar degree of hypomagnesemia. Magnesium replacement should usually accompany potassium repletion.[10] Unless the patient receives at least 0.5 g/hr of magnesium sulfate along with potassium replacement, potassium will not move intracellularly and the patient will lose potassium through excretion. Correction of large potassium deficits may require several days, with simultaneous oral and IV replacement.

Disposition

Patients with mild hypokalemia, above 3.5 mEq/dl without any ECG changes can usually be discharged home with very close outpatient follow-up for a potassium recheck in a week. Hypokalemia due to diuretic therapy requires either increased potassium intake, the addition of a potassium sparing agent or switching the patient to a combined thiazide and potassium sparing diuretic.

Once the patient is discharged, if increased potassium intake is desired, then oral potassium repletion is best accomplished by encouraging the ingestion of potassium and magnesium-rich foods such as potatoes, avocado, black beans, tomatoes, and bananas.

Patients in whom the underlying cause of their hypokalemia cannot be successfully treated such as refractory nausea and vomiting require admission. Patients cannot be discharged until their potassium level is above 3.0 mEq/dl, they can tolerate food and liquids, and they have a QT interval of less than 500 msec.

HYPERNATREMIA

Foundations

Hypernatremia is defined as a serum sodium concentration above 145 mEq/L. It is rarely seen in previously healthy patients and usually portends a poor prognosis. Most hypernatremic patients have either an impaired sense of thirst or no access to water: elders, infants, patients with mental impairment, and those who are intubated and paralyzed are at highest risk for this disorder. Hypernatremia can be divided into three physiologic pairings: (1) hypernatremia with dehydration and low total body sodium, (2) hypernatremia with low total body water and normal total body sodium, and (3) hypernatremia with increased total body sodium (Box 114.3). Diabetes insipidus, an insufficient production of (or lack of response to) antidiuretic hormone, can lead to life-threatening hypernatremia (Box 114.4).

Clinical Features

Patients often have multiple causes of severe hypernatremia. Hypernatremia in adults is almost exclusively due to a free water deficit and should be considered in any patient presenting with altered mental status, as well as in bed-ridden patients with no access to water. Patients with impaired antidiuretic hormone function may complain of polyuria or polydipsia. Others may have obvious causes of extrarenal fluid losses, while some may have no complaints at all.

Diagnostic Testing

In addition to routine serum chemistries, serum osmolarity and urine sodium concentration and osmolality should be obtained. The degree of hypernatremia almost always equals the total body water (TBW) deficit in adults. The patient's TBW deficit can be estimated by the formula

$$\text{TBW deficit} = \text{TBW} \times (\text{serum } Na^{+} - 140)/140$$

A patient's TBW is calculated by multiplying the patient's body weight in kilograms times 0.6. However, because of differences in the percentages of body fat, based on the age and sex of the patient, it is more accurate to use the correction factors listed in Table 114.2.

Management

The treatment of hypernatremia has three interdependent goals: first, to quickly correct underlying shock, hypoperfusion, or significant hypovolemia with normal saline; second, to treat the underlying cause of hypernatremia, such as fever, vomiting, or diabetes insipidus; and third, to carefully lower the serum sodium level, usually by replacement of the body's total water deficit.[11,12] Until hypoperfusion and hypovolemia are corrected, homeostatic mechanisms for sodium balance promote sodium resorption to maintain intravascular volume, even at the expense of the serum sodium concentration.

The rate of correction in hypernatremia is extremely important to minimize morbidity and mortality. Both too quick and too slow

BOX 114.3 Three Types of Hypernatremia

Hypernatremia With Dehydration and Low Total Body Sodium
Heatstroke
Increased insensible losses: Burns, sweating
Gastrointestinal loss: Diarrhea, protracted vomiting, continuous gastrointestinal suction
Osmotic diuresis: Glucose, mannitol, enteral feeding

Hypernatremia With Low Total Body Water and Normal Total Body Sodium
Diabetes insipidus
Neurogenic
Elderly with "reset" osmostat
Hypothalamic dysfunction
Suprasellar or infrasellar tumors
Renal disease
Drugs (amphotericin, phenytoin, lithium, aminoglycosides, methoxyflurane)
Sickle cell disease

Hypernatremia With Increased Total Body Sodium
Salt tablet ingestion
Salt water ingestion
Saline infusions
Saline enemas
IV sodium bicarbonate
Poorly diluted interval feedings
Primary hyperaldosteronism
Hemodialysis
Cushing syndrome
Conn syndrome

IV, Intravenous.

BOX 114.4 More Common Causes of Diabetes Insipidus

Central
Idiopathic
Familial disease
Cancer
Hypoxic encephalopathy
Infiltrative disorders
Post supraventricular tachycardia
Anorexia nervosa

Nephrogenic
Chronic renal insufficiency
Polycystic kidney disease
Lithium toxicity
Hypercalcemia
Hypokalemia
Tubulointerstitial disease
Hereditary
Sickle cell disease

TABLE 114.2 Calculation of Body Water

Population	Total Body Water
Children and adult men	Body weight (kg) × 0.6
Adult women	Body weight (kg) × 0.5
Elderly men	Body weight (kg) × 0.5
Elderly women	Body weight (kg) × 0.45

correction speeds are associated with an increased risk of death, regardless of the initial sodium level.[11,12] In adult patients who develop hypernatremia over a short time due to sodium loading, "rapid correction" at a rate of at least 1 mEq/hr decrease in serum sodium appears relatively safe.[11,12] However, most adult patients develop hypernatremia over days to weeks. In this group of patients, serum sodium concentration should be corrected slowly, at no more than 0.5 mEq/hr or 10 to 12 mEq/day.

Normal saline should be started for volume replacement until the patient is hemodynamically stable, and then changed to half-normal saline at 100 mL/hr once vital signs have normalized. The treatment of central diabetes insipidus with desmopressin (DDAVP) is an effective means of improving polyuria and hypernatremia; initial doses in the acute setting range from 1 to 2 μg.

Disposition

The disposition is based on the patient's underlying etiology and severity of the hypernatremia. Almost all hypernatremic patients require hospitalization due to their dehydrated status and underlying comorbidities. Most of the time these patients have a free water deficit with a low chance of dangerous overcorrection. In mild cases, increasing water intake at home can restore the proper sodium balance.

HYPONATREMIA

Foundations

Hyponatremia, defined as serum sodium concentration of less than 135 mEq/L, is the second most common electrolyte abnormality encountered in clinical practice and can be a marker of underlying disease. The most common causes of severe hyponatremia in adults are therapy with thiazides, the postoperative state, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), psychogenic polydipsia, exercise-associated hyponatremia, and unintentional water intoxication. Gastrointestinal fluid loss, ingestion of overly dilute formula, accidental ingestion of excessive water, and receipt of multiple tap water enemas are the main causes of severe hyponatremia in infants and children. Most patients presenting to the emergency department (ED) with hyponatremia are asymptomatic and do not require emergent therapy. If symptoms are present, they are typically based on the degree of hyponatremia and how acutely the hyponatremia developed. Symptoms range from headache, nausea, and vomiting to confusion, seizures, and coma. There are two groups of hyponatremic patients that require treatment with either normal saline or hypertonic saline: (1) severe but asymptomatic hyponatremia with a sodium level of 110 mEq/L or less and (2) acute symptomatic hyponatremia with a sodium level below 120 mEq/L.

Central nervous system (CNS) damage due to hyponatremia may be caused by cerebral edema and increased intracranial pressure, by osmotic fluid shifts during overly aggressive treatment, or by both. When neurons are subjected to a hyponatremic environment, they become depleted of sodium and potassium in an attempt to limit their own osmolarity to prevent intracellular fluid shifts that would lead to cerebral edema. If fluid therapy raises extracellular sodium levels too quickly, fluids shift out of neurons and can cause diffuse demyelination.

BOX 114.5 Causes of Hyponatremia

Pseudohyponatremia
Hyperlipidemia
Hyperproteinemia (multiple myeloma, macroglobulinemia)

Dilutional
Hyperglycemia

Hypovolemic Hyponatremia: Decreased Total Body Water and Sodium, With a Relatively Greater Decrease in Sodium
Body fluid losses: Sweating, vomiting, diarrhea, gastrointestinal suction
Third spacing: Bowel obstruction, burns, pancreatitis, rhabdomyolysis
Renal causes: Diuretics, mineralocorticoid deficiency, osmotic diuresis, renal tubular acidosis, salt-wasting nephropathies

Hypervolemic Hyponatremia: Increased Total Body Sodium With a Relatively Greater Increase in Total Body Water
Heart failure
Chronic renal failure
Hepatic failure or cirrhosis

Euvolemic Hyponatremia: Increased Total Body Water With Nearly Normal Total Body Sodium
SIADH
Drugs causing SIADH (diuretics, barbiturates, carbamazepine, chlorpropamide, clofibrate, opioids, tolbutamide, vincristine)
Psychogenic polydipsia
Beer potomania
Hypothyroidism
Adrenal insufficiency
MDMA (ecstasy)
Accidental or intentional water intoxication

MDMA, N-methyl-3,4-methylenedioxyamphetamine; *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone.

This can result in a flaccid paralysis and death due to central pontine myelinolysis, a syndrome more accurately labeled as the osmotic demyelinating syndrome (ODS).[13,14]

Causes of hyponatremia fall into four general categories: pseudohyponatremia, hyponatremia with dehydration and decreased extracellular volume, hyponatremia with increased extracellular volume, and euvolemic hyponatremia with increased TBW (Box 114.5).

Pseudohyponatremia

Pseudohyponatremia is a falsely low sodium reading caused by the presence of other osmolar particles in the serum. The phenomenon of pseudohyponatremia is explained by the increased percentage of large molecular particles that do not contribute to plasma osmolality relative to sodium. Severe hypertriglyceridemia and hyperproteinemia are two common causes of this condition. Blood draw or laboratory error should also be considered as a possible cause of hyponatremia, especially if the blood sample was drawn near an infusion site using 5% dextrose in water (D_5W) when a very abnormal sodium level is reported in an otherwise healthy patient.

Hyperglycemia is sometimes considered a cause of pseudohyponatremia; however, it causes a dilutional hyponatremia by pulling water into the vascular space through osmosis. In true pseudohyponatremia, serum osmolality is normal and no shifts of water occur. Two different formulas based on the degree of a patient's hyperglycemia are currently

used to correct serum sodium levels. The most recommended formula advocates for the addition of 1.6 mEq/L to the measured sodium for every 100 mg/dL of glucose above 100. However, another acceptable formula recommends using this 1.6 mEq/dl only for the first 400 mg rise in glucose and then using 2.4 mEqs for each additional 100 mg/dl rise in glucose. Either formula is acceptable to use, the key concept being that as glucose levels rise significantly, a "normal" and not as lowered serum sodium is distinctly abnormal.

Hypovolemic Hyponatremia

Hypovolemic hyponatremia, or hyponatremia with dehydration, occurs when there is decreased extracellular volume combined with an even greater loss of sodium. Hyponatremia secondary to body fluid losses should be differentiated from that due to renal losses. Hyponatremia with dehydration due to body fluid losses includes sweating, vomiting, diarrhea, and gastrointestinal suction. Hypovolemic hyponatremia is also seen with "third spacing" in bowel obstruction, burns, and intra-abdominal sepsis. Hypovolemic hyponatremia due to renal causes includes diuretic use, mineralocorticoid deficiency, renal tubular acidosis, and salt-wasting nephropathy. Hypovolemic hyponatremia can be further exacerbated when fluid losses are replaced with hypotonic saline.

Hypervolemic Hyponatremia

Hypervolemic hyponatremia, or hyponatremia with increased extracellular volume, occurs when sodium and water are retained, but water retention exceeds sodium retention. Most of these patients present with edema. Hyponatremia with increased total body sodium occurs in patients with heart failure, chronic renal failure, and hepatic failure.[14,15] The fluid retention in these states is secondary to renal hypoperfusion, resulting in increased aldosterone secretion and a decrease in free water excretion.

Euvolemic Hyponatremia

The final category of hyponatremia is one in which patients are euvolemic but have increased TBW. Causes of this type of hyponatremia include SIADH, psychogenic polydipsia, beer potomania, hypothyroidism, diuretic use in patients with mild CHF, and accidental or intentional water intoxication. Euvolemic hyponatremia has also been described in patients after the use of the recreational drug *N*-methyl-3,4-methylenedioxyamphetamine (MDMA; or ecstasy). MDMA-induced hyponatremia is multifactorial and related to increased free water intake to avoid dehydration and rhabdomyolysis, along with the tendency to be very active while using the drug, leading to sweating and antidiuretic hormone secretion.[14] For similar reasons, there are extensive case reports of significant exercise-associated hyponatremia in endurance athletes.

SIADH is an important cause of hyponatremia that occurs when antidiuretic hormone is secreted independent of the body's need to conserve water. The process results from excess antidiuretic hormone production that increases TBW, causing the serum sodium to decrease. Patients with SIADH inappropriately concentrate their urine, despite a low serum osmolality and normal circulating blood volume. Despite excess TBW, they have no signs of edema, ascites, or heart failure, because most of the increased water is intracellular rather than intravascular. The three most common causes of SIADH are (1) pulmonary lung masses and infections, (2) CNS disorders, and (3) drugs (Box 114.6). Lung cancers (especially small cell cancer), pneumonia, and tuberculosis can lead to SIADH. CNS infections, masses, and psychosis can also cause SIADH. A large number of medications are associated with SIADH, the most common of which are thiazide diuretics, narcotics, lithium, oral hypoglycemics, barbiturates, and antineoplastics. The mainstay of treatment of most patients with SIADH and other causes of euvolemic hyponatremia is free water restriction.

BOX 114.6 Three Most Common Causes of Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Lung Masses
Cancer (especially small cell)
Pneumonia
Tuberculosis
Abscess

Central Nervous System Disorders
Infection (meningitis, brain abscess)
Mass (subdural, postoperative, cerebrovascular accident)
Psychosis (with psychogenic polydipsia)

Drugs
Thiazide diuretics
Narcotics
Oral hypoglycemic agents
Barbiturates
Antineoplastics

Clinical Features

The signs and symptoms of hyponatremia worsen as sodium levels decline and also correlate with how rapid hyponatremia develops. Nonspecific signs of hyponatremia include anorexia, nausea, vomiting, and generalized weakness. Acutely hyponatremic patients whose sodium level drops below 120 mEq/L over 24 to 48 hours may present with severe neurologic findings, including confusion, seizures, coma, and brainstem herniation. Determination of the hydration status of the patient may help establish the etiology of the hyponatremia and direct subsequent treatment. *Hypovolemic* hyponatremia is more likely in the patient with diminished skin turgor, increased capillary refill, dry mucous membranes, and orthostasis, whereas the patient with jugular venous distention, peripheral edema, or pulmonary congestion is much more likely to have *hypervolemic* hyponatremia. Patients with SIADH have no edema and normal skin turgor. Of note, in geriatric patients, the risk of hyponatremia doubles for those presenting with large-bone fractures.

Diagnostic Testing

A spot urinary sodium or urinary chloride level can help determine if hyponatremia is renal in origin (Table 114.3). Patients with hypovolemic hyponatremia due to nonrenal causes typically have a low urinary sodium or chloride level (<20 mEq/L), because they try to retain solute. Patients with hypovolemic hyponatremia due to renal causes have elevated urine sodium and chloride levels (>20 mEq/L) because their kidneys cannot retain sodium or chloride. Patients with euvolemic hyponatremia typically have a urinary sodium concentration more than 20 mEq/L secondary to volume expansion caused by water retention. Patients with psychogenic polydipsia who are ingesting large quantities of water have dilute urine with low quantities of urinary sodium. Patients with hypervolemic hyponatremia secondary to CHF or cirrhosis have urine sodium levels of less than 20 mEq/L because of renal hypoperfusion, whereas those with renal causes of hypervolemic hyponatremia or with SIADH have sodium levels more than 20 mEq/L, because their kidneys do not retain sodium. In interpreting serum sodium levels, consider the possibility of sampling error if the

TABLE 114.3 Spot Urine Interpretation

	Hypovolemic Hyponatremia	Hypovolemic Hyponatremia	Euvolemic Hyponatremia	Euvolemic Hyponatremia	Hypervolemic Hyponatremia	Hypervolemic Hyponatremia
Underlying etiologies	Nonrenal causes	Renal causes	SIADH, endocrinopathies	Psychogenic polydipsia	Edematous disorders: e.g., CHF, cirrhosis	Renal failure
Urinary sodium	<20 mEq/L	>20 mEq/L	>20 mEq/L	<20 mEq/L	<20 mEq/L	>20 mEq/L
Mechanism	Extrarenal solute loss	Renal solute loss	Volume expansion	Normal renal response to excess volume and sodium retention	Renal hypoperfusion	Renal solute loss

CHF, Congestive heart failure; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion.

TABLE 114.4 Characteristics of Infusates

Infusate	Infusate Sodium (Mmol/L)	Extracellular Fluid Distribution (%)
3% Hypertonic saline	513	100
0.9% Normal saline solution	154	100
Lactated Ringers solution	130	97
Half-normal saline solution	77	73
0.2% Sodium chloride + D_5W	34	55
D_5W	0	45

D_5W, 5% dextrose in water.

reported value does not seem consistent with the patient's presentation and confirm that a diuretic such as furosemide, which will increase urinary sodium losses, has not been recently administered. Consider adrenal insufficiency when a dehydrated patient has both hyponatremia and hyperkalemia.

Of note, in geriatric patients, the risk of hyponatremia doubles for those presenting with large-bone fractures.

Management

Treatment of hyponatremia is guided by the patient's clinical presentation, severity of symptoms, estimated duration of illness, fluid status, and underlying cause of the sodium disturbance. Typically, sodium should be corrected during a time course of 48 to 72 hours. The neurologic changes, including flaccid paralysis, dysarthria, dysphagia, and hypotension, associated with overly rapid sodium correction are referred to as *osmotic demyelinating syndrome (ODS),* previously termed *central pontine myelinolysis.* Most ODS cases occur in the alcoholic, malnourished, and geriatric population, although this devastating side effect can occur in young, healthy patients as well. If a patient develops symptoms of ODS during therapy, all sodium-containing fluids should be stopped and D_5W administered immediately to temporarily lower sodium values. Most patients presenting to the ED with hyponatremia are stable and require no emergent therapy. However, patients who have serum sodium levels of significantly less than 120 mEq/L and those who have acute alterations in mental status, seizures, or new focal findings due to hyponatremia need immediate intervention. Table 114.4 presents the sodium concentration of various infusates, and the following equation is helpful to estimate the effect of 1 liter of any infusate on serum sodium:

$$\text{Change in serum } Na^+ - \text{serum } Na^+/TBW + 1$$

There is no consensus regarding the optimal treatment of symptomatic hyponatremia. However, there is agreement that correction should occur at a sufficient pace and magnitude to reverse the manifestations of hypotonicity but not be so rapid as to pose a risk for development of ODS.[13,14] For relatively asymptomatic patients with sodium values of 115 to 135 mEq/L, free water restriction is typically the most important treatment.

In more severe cases when the sodium value is 120 mEq/L or less and the patient has alterations in mental status, has focal findings, or is seizing, 3% hypertonic saline (513 mEq/L of sodium) is indicated.[15,16] Correction of hyponatremia by 4 to 6 mEq/L within 6 hours, with bolus infusions of 3% saline if necessary, is sufficient to manage the most severe manifestations of hyponatremia. Initially, 100 mL of 3% hypertonic saline should be infused over 10 minutes. If a second bolus is required, an additional 100 mL of the 3% solution may be administered during the next 50 minutes. To minimize the likelihood of ODS, it is essential that symptomatic patients with severe hyponatremia have serum sodium levels raised slowly. Previous guidelines endorsed the safety of raising the serum sodium by up to 10 to 12 mEq within the first 24 hours. However, in patients believed to have been hyponatremic for more than 48 hours, severe hyponatremia should be corrected by no more than 8 mEq in the first 24 hours.[13]

Potassium deficits should be replaced aggressively in the treatment of hyponatremic patients with a sodium disorder. If patients are retaining volume and diuresis is not adequate, furosemide can be used; D_5W is infused if the sodium level is rising too quickly.[16] Patients may be able to make full neurologic recoveries from ODS with the reinduction of hyponatremia in these extreme cases. Demeclocycline in a dosage of 600 to 1200 mg daily is effective in patients with refractory hyponatremia.

Hypovolemic Hyponatremia

Treatment of hypovolemic hyponatremia begins with rehydration. Hypotensive, dehydrated patients should be volume resuscitated with normal saline. Once the patient is hemodynamically stable, the infusion rate should be slowed. Typically, normal saline is started at 500 to 1000

mL/hr until the blood pressure is stable and then slowed to 200 mL/hr with frequent sodium checks. If the sodium value is below 120 mEq/L, the sodium concentration should be allowed to rise by less than an average of 0.5 mEq/hr or about 8 mEq/day until about 120 mEq.[13,15,16] The underlying cause of hyponatremia should be identified and treated.

Hypervolemic Hyponatremia

Normal saline and hypertonic saline can cause pulmonary edema in the hypervolemic hyponatremic patient. Restriction of fluid and sodium is the preferred treatment, although loop diuretics can be used in severe cases. Hemodialysis is an alternative in patients with renal impairment and should be considered for significantly hyponatremic renal failure patients with volume overload. Patients with CHF benefit from diuretics that increase water excretion and cause vasodilation to improve cardiac output.[17] In patients with liver failure, albumin is a consideration, along with diuretics and possibly paracentesis to improve the underlying pathologic process. Water restriction may make the largest impact on the long-term care of these patients.

Euvolemic Hyponatremia

The mainstay of treatment of euvolemic hyponatremia is free water restriction, as hypo-osmolality in SIADH results from a relative abundance of water in the intracellular and extracellular spaces, maintained by a reduced ability to excrete water. However, water restriction is insufficient to treat acute severe hyponatremia and is not recommended as a sole intervention for patients requiring more rapid correction based on clinical presentation. The only definitive treatment of SIADH is elimination of its underlying cause. Most cases of SIADH caused by malignant disease resolve with effective antineoplastic therapy; most due to medication resolve promptly when the offending agent is discontinued.

In patients with SIADH, normal saline may cause the serum sodium concentration to fall even more as free water is retained and hypertonic urine is excreted. If a patient is symptomatic because of a rapid decrease in serum sodium concentration, treatment with hypertonic saline is recommended. Rapid correction of hyponatremia may occur during hemodialysis. To minimize the risks of ODS, hemodialysis is reserved for patients with documented renal failure under close monitoring. Vaptans, which are oral agents that inhibit the effects of vasopressin, have been studied for treatment of patients with hyponatremia due to SIADH but need further evaluation before becoming standard of care.[15,16]

Disposition

Patients that are altered or lethargic with hyponatremia should be admitted to the ICU. Other hyponatremic patients that should be admitted to the ICU include patients on a hypertonic saline infusion and those who received a hypertonic saline bolus. In addition, nephrology should be consulted for patients with symptomatic hyponatremia or rapidly rising sodium to discuss the use of desmopressin or vaptans. Patients who have returned to neurologic baseline with stable sodium trended over 4 to 6 hours may be admitted to a monitored floor bed. Patients may be discharged once their sodium is approaching 130 mEq/L, their underlying cause has been identified and either corrected or more aggressively treated. Patients who have developed hyponatremia acutely (such as the endurance athlete) who present asymptomatically or with mild symptoms may be considered for discharge from the ED with close outpatient follow-up and a lab recheck.

HYPERCALCEMIA

Foundations

Hypercalcemia is usually defined as a serum calcium level above 10.5 mg/dL; normal levels are usually defined as between 9 and 10.5 mg/dL. Hypercalcemia is considered mild if the total serum calcium level is between 10.5 and 12 mg/dL; levels higher than 14 mg/dL can be life-threatening. Hypercalcemic crisis typically evolves from preexisting mild hypercalcemia, which develops into an acute severe hypercalcemic emergency.

Clinical Features

The clinical presentation of hypercalcemia is often vague and nonspecific. Symptoms include nonfocal abdominal pain, constipation, fatigue, body aches, anorexia, polydipsia, polyuria, nausea, and vomiting. Symptom severity depends on the degree of hypercalcemia, the rapidity of onset, and the patient's baseline neurologic and renal function. Neuropsychiatric disturbances include anxiety, depression, and hallucinations. The CNS manifestations that often predominate in more severe cases include lethargy, altered mental status, seizures, and coma. Death due to hypercalcemia is usually related to complications caused by coma, dehydration, or electrolyte disturbances. Cardiac conduction abnormalities may occur; bradydysrhythmias are the most common. Severe hypercalcemia (>14 mg/dL) has also been associated with sinus arrest, atrioventricular block, atrial fibrillation, and ventricular tachycardia.

Differential Diagnosis

There are five major causes of hypercalcemia (Box 114.7). Hyperparathyroidism is the most common cause of hypercalcemia in outpatients, whereas malignancy is the most common cause in hospitalized patients; together, these two etiologies account for the majority of hypercalcemia cases.[18] Mild hypercalcemia, in an otherwise normal person, may be due to thiazide diuretics in the setting of minimal dehydration. Other less common causes of elevated calcium concentration should be considered after malignant disease and parathyroid disease are ruled out. Malignancy-associated hypercalcemia occurs in up to 40% of all patients with advanced cancer and generally conveys a poor prognosis.[19] Other causes of hypercalcemia include granulomatous disease, such as sarcoidosis and tuberculosis; medications and pharmacologic agents; and a number of diverse conditions, such as rhabdomyolysis and prolonged immobilization.

BOX 114.7 Five Most Common Causes of Hypercalcemia

Malignant Disease
Ectopic secretions of parathyroid hormone, multiple myeloma, cancer metastatic to bone
Most common: Breast, lung, hematologic, kidney, prostate

Endocrine
Hyperparathyroidism, multiple endocrine neoplasias, hyperthyroidism, pheochromocytoma, adrenal insufficiency

Granulomatous Disease
Sarcoidosis, tuberculosis, histoplasmosis, berylliosis, coccidioidomycosis

Pharmacologic Agents
Vitamins A and D, thiazide diuretics, estrogens, milk-alkali syndrome

Miscellaneous
Dehydration, prolonged immobilization, iatrogenic, rhabdomyolysis, familial, laboratory error

Diagnostic Testing

The diagnostic evaluation of a patient with suspected hypercalcemia begins with obtaining electrolyte and renal function tests and an ECG. Calcium is measured by determination of either a total serum calcium level or an ionized calcium level. Ionized calcium is the active form of the total calcium level. Ionized calcium is more accurate in the diagnosis and treatment of hypocalcemia but does need to be routinely evaluated in hypercalcemia. The serum total calcium level represents both bound and unbound calcium and, thus, should be corrected based on the albumin concentration. A correction of the total serum calcium is made by adjusting for deviations in the serum albumin level. The adjustment is accomplished by adding or subtracting 0.08 mg/dL to the measured total serum calcium for every 1.0 g/L of albumin below or above 4 g/L albumin, respectively.

A short QT interval can be seen in hypercalcemia and is considered a classic finding. However, although the incidence and duration of QT shortening appear to be correlated with the degree of hypercalcemia, it is not a reliable finding and is not routinely seen in most patients (Fig. 114.6). ST segment elevation may be the least well documented but most consistent electrocardiographic finding, making hypercalcemia a potential cause of ST segment elevation caused by conditions other than myocardial infarction.[20,21] Some hypercalcemic patients may have U waves in the precordial leads despite normokalemia, while others may have an Osborn wave despite normothermia.[22] In severe cases of hypercalcemia, sinus bradycardia, high-degree atrioventricular block, and ventricular fibrillation may also be seen.

Management

Patients in hypercalcemic crisis are usually dehydrated, often obtunded, and also predisposed to arrhythmias as a result of concomitant electrolyte disturbances; thus, they require IV access with a normal saline infusion and close monitoring. Normal saline inhibits proximal tubule reabsorption of calcium and corrects the patient's volume depletion. Normal saline should be infused "wide open" until blood pressure and perfusion are normalized. After the initial bolus, the saline infusion should be adjusted to a rate of approximately 200 to 300 mL/hr, depending on the patient's age, renal function, cardiac and other comorbid diseases, to establish adequate urine output (2 L/day). Although the administration of higher volumes of saline may further augment calcium excretion, it is much more likely to increase morbidity and mortality from volume overload, pulmonary edema, and myocardial ischemia. The routine use of furosemide in the management of hypercalcemia is no longer recommended.[18] Furosemide was once thought to block the distal reabsorption of calcium, thus complementing saline's proximal tubule effects. However, furosemide has not been shown to have significant calcium reabsorption blocking effects. The use of furosemide should be reserved for augmenting saline diuresis to avoid volume overload during the treatment of hypercalcemia. If a loop diuretic is given to patients who are not yet volume replete, not only can the patient's hemodynamics and renal status deteriorate, but hypercalcemia may worsen. Once calcium excretion by saline infusion has begun, other electrolyte values should be carefully monitored, with particular attention to serum potassium levels.

Osteoclast-inhibiting therapies for severe hypercalcemia are generally considered in consultation with the patient's primary physician or oncologist. Drugs that inhibit osteoclast-mediated bone resorption include the bisphosphonates, mithramycin, calcitonin, and glucocorticoids. IV bisphosphonates are the most extensively studied and most efficacious agents for the treatment of malignancy-associated hypercalcemia. Their calcium-lowering effect is achieved predominantly by inhibition of osteoclast function and survival. Zoledronic acid is the bisphosphonate of choice in hypercalcemia of malignancy. The infusion takes 15 minutes; zoledronic acid may be more effective than other bisphosphonates at keeping the calcium level down over time. The use of IV bisphosphonates is restricted to the treatment of acute hypercalcemia associated with serum calcium concentrations above 15 mg/dL and rapid deterioration of CNS, cardiac, gastrointestinal, and renal function. Denosumab for the management of hypercalcemia of malignancy provides a new option for the management of patients with persistent hypercalcemia despite bisphosphonates.[23] In the rare case in which a patient has a life-threatening hypercalcemic arrhythmia or heart block, hemodialysis should be considered. In cases of hypercalcemic crisis resulting from primary hyperparathyroidism, urgent parathyroidectomy is potentially curative. Hematology, oncology, and palliative care specialists should be involved early in the care of the patient with hypercalcemia associated with malignancy to assure the appropriate targeted therapies. Isolated mild hypercalcemia rarely requires urgent treatment; however, an outpatient hypercalcemia

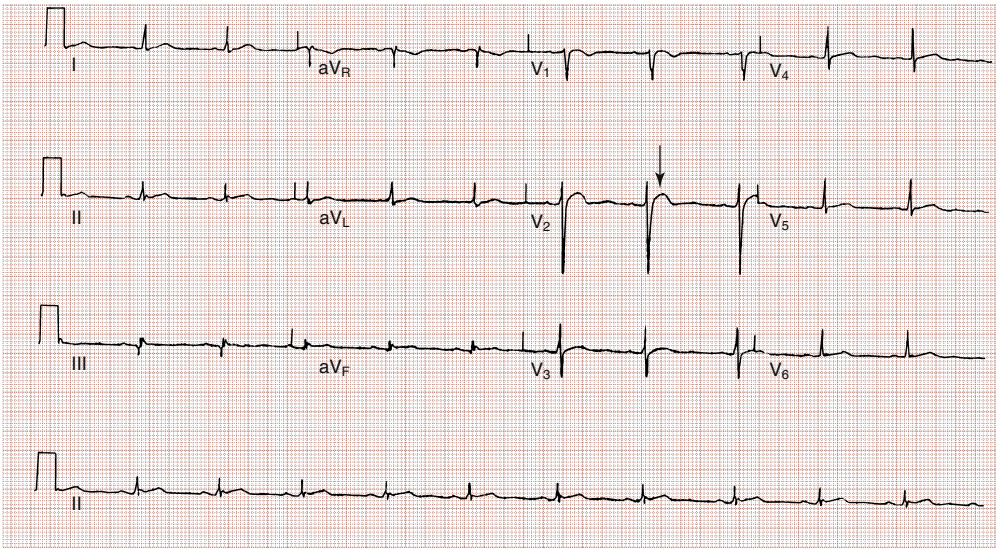

Fig. 114.6 Short QT interval *(arrow)* in a patient with multiple myeloma and a calcium level of 14.2 mg/dL. (Courtesy Dr. Barton Campbell.)

evaluation should be discussed at discharge, because many will ultimately be diagnosed with hyperparathyroidism.

Disposition

Patients with altered mental status or arrhythmias from hypercalcemia should be admitted to the intensive care unit for close monitoring, management of electrolytes, and frequent laboratory testing. In patients with symptomatic hypercalcemia, medical floor admission may be necessary for continuous fluid resuscitation and electrolyte monitoring. Patients with mild to moderate hypercalcemia may be discharged home with instructions to avoid dehydration and high calcium diets. In patients with known malignancy or suspicion for malignancy, disposition planning should be coordinated with the oncology team.

HYPOCALCEMIA

Foundations

Calcium regulation is critical for normal cell function, neural transmission, membrane stability, bone structure, blood coagulation, and intracellular signaling. Total body calcium is controlled by a feedback system in which parathyroid hormone induces the bone and the kidneys to increase serum calcium levels. Vitamin D facilitates intestinal calcium absorption. Conversely, elevated calcium levels normally inhibit parathyroid hormone release.

Clinical Features

Although there are many clinical manifestations of hypocalcemia, neuromuscular and cardiovascular findings predominate. Severity of symptoms is related to not only the absolute calcium level, but also the rate calcium rise. The patient may complain of muscle cramping, perioral or finger paresthesias, shortness of breath secondary to bronchospasm, and tetanic contractions. Symptomatic hypocalcemia may result in cardiovascular collapse, hypotension, and dysrhythmias. More severe hypocalcemia can lead to cardiovascular collapse, hypotension, syncope, dysrhythmias, CHF, angina, hypotension, and QT prolongation. Patients with a calcium level lower than 8.95 mg/dL have a 2.3-fold higher risk of sudden cardiac activity than those with calcium levels higher than 9.55 mg/dL.[24]

Chronic hypocalcemia may manifest with cataracts, poor dentition, dry skin, coarse hair, and pruritus. Chvostek sign may be present: when the examiner taps the facial nerve, facial or eye muscle twitching will be elicited. Trousseau sign may also be present; when the examiner inflates the blood pressure cuff to 20 mm Hg above the systolic blood pressure for 3 minutes, carpal spasms will be induced because of the increased excitability caused by local ulnar and median nerve ischemia. Trousseau sign is relatively specific for hypocalcemia, whereas Chvostek test is less diagnostic.

Differential Diagnosis

There are multiple causes of hypocalcemia, of which hypoalbuminemia is the most common (Box 114.8). Because calcium is bound to albumin and other serum proteins, hypoalbuminemia will cause a fall in the measured serum calcium by about 0.8 mg/dL for every 1 g/dL reduction in serum albumin. The active form of calcium is ionized calcium, which is not affected by changes in albumin.

Hypoparathyroidism is a common cause of hypocalcemia and often develops after surgery for head and neck cancers; it occurs in 1% to 2% of patients after total thyroidectomy. Patients with vitamin D deficiency, including those with malabsorption syndromes, liver disease, malnutrition, and very little sunlight exposure, are at high risk for development of hypocalcemia. Derangements in magnesium and phosphate can also lead to hypocalcemia. Hyperphosphatemic patients often have hypocalcemia because of phosphate's affinity to bind calcium, whereas hypomagnesemia causes end-organ resistance to parathyroid hormone and inhibits the hypocalcemic feedback loop. Patients with sepsis demonstrate hypocalcemia usually associated with hypoalbuminemia.

BOX 114.8 Most Common Causes of Hypocalcemia

Hypoalbuminemia
Hypoparathyroidism: inherited, postsurgical, autoimmune, infiltrative
Vitamin D deficiency and vitamin D resistance: Malabsorption syndrome, liver disease, malnutrition, sepsis, anticonvulsants, lack of sunlight exposure
Chronic renal failure
Hyperphosphatemia
Hypomagnesemia
Respiratory alkalosis
Severe pancreatitis
Drugs: Bisphosphonates, phenytoin, phosphate, calcitonin
Tumor lysis syndrome
Rhabdomyolysis

BOX 114.9 Five Most Common Symptomatic Causes of Hypocalcemia Seen in the Emergency Department

- Hyperventilation: Anxiety, sympathomimetics
- Ethanol abuse, chronic malnutrition: Hypoalbuminemia
- Massive blood transfusion
- Toxins: Hydrofluoric acid, ethylene glycol
- Severe pancreatitis

The most common causes of symptomatic hypocalcemia are massive blood transfusions, toxins, pancreatitis, tumor lysis syndrome, and chronic malnutrition (Box 114.9). Patients receiving massive blood transfusions are at risk for development of hypocalcemia because of citrate toxicity.[25] Rapid blood transfusions and radiocontrast dyes containing citrate infusions should be monitored closely in patients with hepatic failure, CHF, or other low-output states to avoid hypocalcemia. Trauma patients that have sustained blood loss are at risk of hypocalcemia and those that require blood transfusions are at even higher risk of profound hypocalcemia.[26]

Hypocalcemia in acute pancreatitis is caused primarily by precipitation of calcium soaps in the abdominal cavity, but glucagon-stimulated calcitonin release and decreased parathyroid hormone secretion may play a role. Toxic exposures to hydrofluoric acid and ethylene glycol can cause profound hypocalcemia secondary to their abilities to complex and chelate with calcium. Patients being treated for malignant neoplasms are at risk for development of tumor lysis syndrome and multiple secondary electrolyte abnormalities. Hypocalcemia has been attributed to the precipitation of calcium phosphate salts. Finally, one should expect to encounter hypocalcemia in malnourished patients and chronic alcoholics who present to the ED, especially alcoholics with hyperventilation due to alcohol withdrawal.

Diagnostic Testing

Most cases of hypocalcemia are discovered by clinical suspicion followed by appropriate laboratory testing. A serum calcium level less than 8.5 mg/dL or an ionized calcium level less than 2.0 mEq/L is considered diagnostic. Total serum calcium is approximately 50% free

(ionized) and 50% bound, primarily to albumin; thus the serum level should be "corrected" when hypoalbuminemia exists. The ionized calcium level, which is not affected by the albumin level, is more accurate. It is best to perform the whole blood ionized calcium determination rapidly to avoid changes in chelation and pH. In select cases, a parathyroid hormone level may be sent to assist the admitting or consulting physician. Electrocardiography and cardiac monitoring are recommended in suspected hypocalcemia patients to evaluate the QT interval and to provide continuous monitoring for potential dysrhythmias. The most common ECG finding in hypocalcemia is QT prolongation as a result of ST segment lengthening and can mimic acute myocardial infarct with J point elevation, absence of ST segment, and shortening of the QTc interval.[27,28]

Management

Most asymptomatic patients and those with mild symptoms can be treated with oral calcium supplementation, such as calcium carbonate. IV calcium is administered, either as calcium chloride or calcium gluconate, to patients with moderate to severe symptoms; 100 to 300 mg of elemental calcium given over 5 to 30 minutes will raise the ionized calcium level 0.5 to 1.5 mEq. Calcium chloride contains 272 mg of elemental calcium but can be caustic to veins, so it should be given via central venous access unless patients are critically ill without central access. Calcium gluconate contains 92 mg of elemental calcium. Although this is one-third the amount contained in calcium chloride, it is safer to administer and can be given peripherally. Most patients requiring IV calcium should be admitted to the hospital for monitoring and treatment of nausea, vomiting, hypertension, and bradycardia. Patients taking digoxin have increased cardiac sensitivity to fluctuations in serum calcium, so IV calcium administration should be accompanied by continuous electrocardiographic monitoring. Hypocalcemia is an independent predictor of all-cause mortality in heart failure and chronic kidney disease patients and these patients should be monitored very carefully.[29]

Disposition

Hypocalcemic patients need to be admitted to a monitored bed if ongoing calcium repletion is necessary due to the risk of bradycardia and hypertension. Other patients may be discharged home with internal medicine follow-up and the consideration of outpatient evaluation by an endocrinologist.

HYPERMAGNESEMIA

Foundations

Hypermagnesemia is a relatively rare electrolyte abnormality defined as a serum magnesium concentration above 2.2 mg/dL. Hypermagnesemia is usually iatrogenic and seen in patients who cannot optimally regulate magnesium excretion (e.g., renal insufficiency), especially as their magnesium load increases.

In patients with normal renal function, large amounts of magnesium can be excreted daily in the stool and urine. However, in patients with impaired renal function, hypermagnesemia can be seen even with therapeutic doses of magnesium-containing products. An adult dose of 10 ounces of laxative syrup results in consumption of approximately 2.0 g of elemental magnesium per single dose. A healthy adult can excrete more than 6.0 g of magnesium daily, but renally impaired patients may not be able to tolerate small doses of laxative syrup. In patients with constipation, retention of magnesium-based laxatives can serve as a reservoir for continuous magnesium absorption.[30] Thus, a patient with renal insufficiency should be cautious and minimize the use of magnesium citrate for treatment of constipation.

TABLE 114.5 Clinical Effects of Hypermagnesemia

Effect	Level (Mg/Dl)
Decreased deep tendon reflexes	4 to 5
Hypotension	5 to 7
Respiratory insufficiency	10
Heart block	10 to 15
Cardiac arrest	10 to 24

Decreased gastrointestinal elimination and increased gastrointestinal absorption of magnesium due to intestinal hypomotility can also result in toxicity. Hypermagnesemia can be seen with bowel obstruction, colitis, gastric dilation, and use of medications that decrease motility, including narcotics and anticholinergics. Other less common causes of hypermagnesemia include adrenal insufficiency, hyperparathyroidism, hypothyroidism, lithium therapy, rhabdomyolysis, and tumor lysis syndrome.

Clinical Features

Clinical manifestations of hypermagnesemia are concentration dependent, and typically symptoms begin to develop around magnesium levels of 4 mg/dL (Table 114.5). Hypermagnesemia is easily overlooked because of its nonspecific symptoms. Patients with mild hypermagnesemia (less than 7 mg/ dL) may present with headache flushing, nausea, vomiting, and weakness. As the magnesium level rises (7 mg/dL to 12 mg/dL), the patient may also be confused, constipated, and found to have diminished deep tendon reflexes. When serum magnesium levels rise above 7 mg/dL, patients can have signs and symptoms of hypotension, respiratory insufficiency, and heart block. Severe hypermagnesemia (greater than 12 mg/dL) presents as progressive loss of neuromuscular, respiratory, and cardiovascular functions and can lead to coma and cardiorespiratory arrest. Magnesium acts as a calcium channel blocker and also blocks potassium channels needed for repolarization. As magnesium levels rise, hypotension and electrocardiographic changes, including QRS widening and QT and PR prolongation, begin to occur. In addition, hypermagnesemia can interfere with blood clotting by interfering with clotting time and platelet adhesiveness. Finally, hypermagnesemia causes suppression of parathyroid hormone secretion and can be associated with hypocalcemia. If a patient taking oral magnesium, especially an elderly patient, presents with clinical symptoms including altered mental status, hypotension, bradycardia, and respiratory failure, hypermagnesemia must be included in the differential.

Differential Diagnosis

Hypermagnesemia is most commonly seen in patients receiving parenteral treatment for pre-eclampsia or eclampsia, cardiac arrhythmias, or asthma exacerbations. In addition, hypermagnesemia is also seen in people utilizing laxatives and antacids, patients receiving cathartics for drug overdoses, and patients undergoing bowel preparations prior to colonoscopies. Even though most patients at risk for hypermagnesemia have underlying renal impairment, hypermagnesemia has been reported in patients with normal renal function, especially in elders.[31] Box 114.10 lists the most common causes of increased serum magnesium levels.

Diagnostic Testing

Measured plasma magnesium levels often do not reflect total magnesium content, making it difficult to correlate symptoms to specific

BOX 114.10 Five Most Common Causes of Hypermagnesemia

- Iatrogenic: IV administration, dialysate
- Oral administration: Laxatives, antacids, vitamins, cathartics, dialysate, parental
- Impaired elimination—hypomotility: Bowel obstruction, chronic constipation
- Impaired elimination—medications: Anticholinergics, narcotics, lithium therapy
- Miscellaneous: Hypothyroidism, tumor lysis syndrome, adrenal insufficiency, milk-alkali syndrome

magnesium levels consistently. Although there is some question of the role of measuring ionized magnesium in patients with hypomagnesemia, only total body magnesium needs to be followed in hypermagnesemic patients.

Management

Management of hypermagnesemia is dictated by the neuromuscular, cardiovascular, and CNS changes that occur. Most stable or asymptomatic hypermagnesemic patients can be treated with cessation of their magnesium therapy. As symptoms become more pronounced, IV isotonic fluids are administered to dilute the extracellular magnesium. Diuretics (furosemide 1 mg/kg) can be used to promote excretion of magnesium in patients with normal kidney function and reverse mild symptoms.

In patients with higher levels of serum magnesium or more severe symptoms, renal consultation should be initiated immediately to arrange for dialysis with magnesium-free dialysate. A dialysis session of 3 to 4 hours can reduce the magnesium level up to 50%. IV calcium therapy to reverse magnesium toxicity should be reserved for patients with life-threatening symptoms while dialysis is being arranged. Calcium directly antagonizes the neuromuscular and cardiovascular effects of magnesium and is recommended in hypotensive patients with respiratory depression and cardiac instability. In treating life-threatening hypermagnesemia, initially administer 1 g calcium chloride or 2 g calcium gluconate and repeat as needed. When needed, a continuous infusion at 2 to 4 mg/kg/hr can be administered while dialysis is being arranged. Most stable or asymptomatic hypermagnesemia patients can be treated with cessation of their magnesium therapy and discharged home with close outpatient follow-up. However, patients with higher levels of serum magnesium or more severe symptoms, should be admitted to a telemetry bed with ICU level of care discussed with the inpatient team. Unfortunately, severe hypermagnesemia often ends in death despite robust attempts to lower serum magnesium levels.

Disposition

Most stable or asymptomatic hypermagnesemia patients can be treated with cessation of their magnesium therapy and discharged home with close outpatient follow-up. However, patients with higher levels of serum magnesium or severe symptoms should be admitted to a telemetry bed with ICU level of care discussed with the inpatient team. Unfortunately, severe hypermagnesemia often ends in death despite robust attempts to lower serum magnesium levels.

HYPOMAGNESEMIA

Foundations

Hypomagnesemia is a common electrolyte abnormality that often goes undetected. Normal serum magnesium levels range from 1.5 to 3.0 mEq/L. Symptoms of hypomagnesemia typically begin to be manifested at serum levels below 1.2 mEq/L, although symptoms are often not well correlated with the patient's serum level. This is because most of the body's magnesium is intracellular, and thus a single blood sample with a low serum magnesium level may not accurately reflect total body magnesium or the extent of true hypomagnesemia. The incidence of hypomagnesemia is estimated to be 2% in the general population. In hospitalized patients, the risk is highest for patient requiring ICU level care.[32]

Magnesium exists in three states: (1) ionized magnesium, (2) protein bound, and (3) complexed to serum anions. Even though studies show the importance of measuring ionized calcium, most research shows that ionized magnesium can be inferred from total magnesium. Currently, the clinical role of measurement of ionized magnesium is unclear, and measurement of ionized magnesium is not standard practice in the ED; there may be a role for measurement of ionized magnesium in the intensive care setting.[33,34]

Clinical Features

Determination of the clinical consequences of isolated hypomagnesemia is often confounded by coexisting hypokalemia, hypocalcemia, or hyponatremia. However, many signs and symptoms are reported to correlate with hypomagnesemia, including muscle cramping, diffuse weakness, palpitations, vertigo, ataxia, depression, and seizures. Women with an adequate intake of magnesium are less likely to be affected by preeclampsia. The clinical manifestations most likely seen in the ED involve the neuromuscular and cardiovascular systems. Patients may present with hyperactive deep tendon reflexes, muscle cramps, Trousseau and Chvostek signs, and dysarthria and dysphagia from esophageal dysmotility. Cardiac conduction abnormalities secondary to magnesium depletion, and often coexisting hypokalemia, can result in PR and QT interval prolongation. Dysrhythmias including atrial fibrillation, multifocal atrial tachycardia, premature ventricular complexes, ventricular tachycardia, torsades de pointes, and ventricular fibrillation are the most common cardiovascular manifestations of hypomagnesemia.

Differential Diagnosis

There are many causes of hypomagnesemia (Box 114.11). The following sections describe the five most common ED presentations of hypomagnesemia.

Patients Maintained on Diuretics

Patients using either loop or thiazide diuretics are at increased risk for hypomagnesemia. Both types of diuretics can inhibit magnesium reabsorption. Conversely, potassium-sparing diuretics are also magnesium sparing, because they enhance magnesium reabsorption and decrease magnesium excretion. The degree of hypomagnesemia induced by the loop and thiazide diuretics is generally mild, in part because the associated volume contraction will tend to increase proximal sodium, water, and magnesium reabsorption.

Malnourished and Alcoholic Patients

Healthy patients consume enough magnesium in green vegetables, legumes, fruits, shellfish, fresh meat, and cocoa on a regular basis to maintain normal total body magnesium stores. However, hypomagnesemia is common in patients with chronic protein-calorie malnutrition because of an associated lack of essential minerals and vitamins including magnesium. This is especially true in chronic alcoholics who may not eat foods rich in magnesium. Magnesium losses are further increased in chronic alcoholics because of alcohol's diuretic effects may combine with episodes of pancreatitis and diarrhea.

Hypomagnesemia may also be seen in patients with malabsorption disorders (celiac sprue and short bowel syndrome), patients with increased magnesium excretion (chronic diarrhea or inflammatory bowel conditions), and patients with severe body dysmorphic disorders.

Patients With Hypokalemia

Both potassium and magnesium are critical to help stabilize the membrane potential, to decrease cell excitability, and for function of the Na^+, K^+-ATPase pump. Approximately 50% of patients with hypokalemia also have concomitant magnesium deficiency. Increasing degrees of hypokalemia are correlated with an increasing likelihood of a magnesium deficit. Hypokalemic patients who are refractory to potassium replacement are likely to also be hypomagnesemic.

Patients With Acute Coronary Artery Disease and Ventricular Arrhythmias

There appears to be a relationship between low serum magnesium levels and the subsequent development of coronary heart disease likely because low magnesium intake is associated with higher incidence of diabetes, hypertension, and metabolic syndrome.[35] Patients who have had a myocardial infarction are more likely than controls to be hypomagnesemic.[36] Patients with acute myocardial infarction who have mild hypomagnesemia appear to have a twofold to threefold increase in the frequency of ventricular arrhythmias in the first 24 hours compared with those with normal magnesium levels

There is controversy about whether magnesium should be administered empirically after acute myocardial infarction. At present, magnesium supplementation is recommended only for those acute coronary syndrome patients who have evidence of hypokalemia, prolonged QT, or known hypomagnesemia. However, Yuksel et al. found that the serum magnesium level is an independent predictor for electrocardiographic no-reflow in patients with STEMI who underwent PCI. In addition, it was demonstrated that initial Mg level is an independent predictor for long-term mortality in patients with STEMI who underwent PCI.[37]

Dysrhythmia is the most common cardiovascular manifestation of hypomagnesemia. Magnesium affects the duration of phase 2 of the action potential, and hypomagnesemia can prolong the QT interval. Magnesium also has effects on phase 4, the resting membrane potential, where it keeps the cell more negative by stimulating the sodium-potassium pump. The exact mechanism underlying a possible association between hypomagnesemia and arrhythmias is unknown. Arrhythmias are likely to be due to concurrent hypokalemia, hypomagnesemia, or both, resulting in a prolonged QT interval and increases in spontaneous depolarization.

Patients Receiving Specific Medications

In addition to diuretics, many nephrotoxic drugs, including aminoglycosides, amphotericin B, cisplatin, digoxin, and pentamidine, can produce magnesium wasting. Solid organ transplant patients maintained on calcineurin inhibitors including tacrolimus and cyclosporine are at risk for hypomagnesemia.[38] Long-term use of proton pump inhibitors, especially when combined with diuretics, may be associated with decreased intestinal absorption of magnesium.[39,40]

Diagnostic Testing

Clinical manifestations of hypomagnesemia begin at serum levels below 1.2 mEq/L, but symptoms do not always correlate with the total serum magnesium level. Because most of the total body magnesium is intracellular, the magnesium level alone does not guide therapy. The possibility of hypomagnesemia is considered in patients with depression, malnourishment, significant or refractory hypokalemia, and ventricular arrhythmias. Electrocardiographic findings in hypomagnesemia are nonspecific and may be caused by both the hypomagnesemia and concomitant hypokalemia. Hypomagnesemia should be suspected whenever electrocardiographic findings of hypokalemia are noted, including PR and QT interval prolongation, ST segment depression, flattening and widening of the T waves, loss of voltage, and U waves.

Management

The route of magnesium repletion varies with the severity of the clinical manifestations. Patients at risk of magnesium deficiency or with symptoms consistent with hypomagnesemia should be considered for treatment even with serum magnesium levels within normal range.[41] Parenteral magnesium is recommended for life-threatening conditions. In patients with normal renal function, 1 to 2 g of IV magnesium sulfate is an appropriate loading dose. A stable patient with hypomagnesemia can be treated with a loading dose of 1 to 2 g IV of magnesium sulfate during 10 to 60 minutes, followed by a maintenance dose of 0.5 to 1 g/hr until symptoms have resolved. The administration of 1 g of IV magnesium increases the serum magnesium concentration by 0.15 mEq/L within 18 to 30 hours.[42] Patients in cardiac arrest should receive a bolus of 1 to 2 g magnesium sulfate by IV push.

Magnesium administration is strongly encouraged for patients receiving IV potassium repletion. A dose of 0.5 g/hr is safe in patients who are well hydrated and have normal renal function. There are potential adverse effects to rapid magnesium replacement at more than 1 to 2 g/hr, including decreased deep tendon reflexes, respiratory depression, and heart block. Magnesium gluconate oral supplementation can be given if the patient is only mildly hypomagnesemic and asymptomatic. Oral absorption is variable, but most commonly magnesium oxide 400 mg twice daily can be administered to patients with adequate renal function.

Disposition

Patients with cardiac arrhythmias from hypomagnesemia should be admitted to a telemetry bed or critical unit in collaboration with cardiology. Other symptomatic patients may also need to be admitted to a monitored bed for parenteral magnesium. Asymptomatic patients can often be managed with supplements and strict follow-up instructions. When preparing any patient with hypomagnesemia for discharge, physicians can encourage lifestyle changes, including adequate magnesium intake that may benefit blood pressure control, promote weight loss, and improve chronic disease risk.

HYPERPHOSPHATEMIA

Foundations

Hyperphosphatemia is defined as a serum level above 2.5 mg/dL, but it is usually clinically significant only when levels are greater than 5 mg/dL. Although rare in the general population, hyperphosphatemia is extremely common in patients with renal insufficiency or renal failure. Almost all patients with renal failure experience hyperphosphatemia at

some time during the course of their disease. Phosphate is a potential biomarker to predict mortality and disease severity in patients receiving dialysis.[43] Even in patients without renal failure, patients in the ICU with altered phosphate levels have increased morbidity and mortality.[44]

Clinical Features

Patients with hyperphosphatemia may present with multiple complaints related to electrolyte abnormalities, particularly hypocalcemia. Hyperphosphatemia causes hypocalcemia by precipitating calcium out of the blood and decreasing vitamin D production. It is this secondary hypocalcemia that can cause muscle cramping, tetany, and seizures. Chronic hyperphosphatemia can also lead to metastatic calcifications in joints, tissues, and arteries.

Differential Diagnosis

Hyperphosphatemia can occur via four major pathways: (1) decreased phosphate excretion, (2) excessive phosphate intake, (3) increased renal tubular reabsorption, and (4) shift of phosphate from intracellular to extracellular space. In addition, physicians should be aware of spurious elevations in phosphate (Box 114.12).[45]

Decreased excretion of phosphate combined with excessive intake is the most common mechanism for the development of hyperphosphatemia. Excessive phosphate intake alone is an uncommon cause of hyperphosphatemia in patients with normal renal function. When patients have glomerular filtration rates below 30 mL/min, the kidneys do not excrete the full amount of ingested phosphate to maintain homeostasis.[46] Exogenous phosphate, including IV or oral phosphate administration and phosphate enemas and laxatives can cause a large burden on the kidneys if they do not have normal baseline function. In 2014, the U.S. Food and Drug Administration (FDA) made a drug safety announcement after identifying over 50 cases of adverse events warning against utilizing a single dose of sodium phosphate larger than recommended or taking more than one dose in a day, especially in patients also taking medications that act on renal function.[47]

BOX 114.12 Five Most Common Causes of Hyperphosphatemia

Decreased Phosphate Excretion
Acute and chronic renal failure

Increased Renal Tubular Reabsorption
Hypoparathyroidism
Thyrotoxicosis
Excess vitamin D administration

Excessive Phosphate Intake
Phosphate enemas or laxatives
IV or oral phosphate administration

Shift of Phosphate From Intracellular to Extracellular Space
DKA
Tumor lysis
Rhabdomyolysis

Spurious Hyperphosphatemia
Paraproteinemia
Hyperbilirubinemia
Hemolysis
Hyperlipidemia

DKA, Diabetic ketoacidosis; *IV,* intravenous.

Hypoparathyroidism, vitamin D intoxication, and thyrotoxicosis increase renal phosphate reabsorption and may cause elevated phosphate levels. Hyperphosphatemia may also occur when there is a large shift of phosphate from the intracellular to the extracellular space and the kidneys' ability to excrete phosphate is overwhelmed. This cause of hyperphosphatemia is seen in rhabdomyolysis, tumor lysis syndrome, and DKA. Hyperphosphatemia can be a spurious finding in cases of hyperproteinemia, such as multiple myeloma, hyperlipidemia, hemolysis, or hyperbilirubinemia.

Diagnostic Testing

The diagnostic evaluation of a patient with suspected hyperphosphatemia begins with obtaining electrolyte and renal function tests with hyperphosphatemia defined as a serum level above 2.5 mg/dL. A low serum calcium level along with a high phosphate level is seen in patients with hypoparathyroidism, pseudohypoparathyroidism, and renal failure. The addition of the BUN and creatinine assist with narrowing down the differential to renal failure. Patients with hyperphosphatemia from renal failure are more likely to have elevated PTH levels when compared to those with hyperphosphatemia from hypoparathyroidism where low levels of PTH are expected.

Imaging studies are not typically indicated in the initial evaluation of hyperphosphatemia in the ED setting. However, some patients may need renal imaging studies and long-bone studies when admitted to differentiate the etiology of the hyperphosphatemia further.

Management

One of the most critical steps in management of hyperphosphatemia is the treatment of underlying causes while reducing the phosphate load in the body either by promoting urinary excretion or hemodialysis. Dietary restriction alone may suffice for control of hyperphosphatemia in persons with mild renal insufficiency, but it is inadequate for control in those with overt renal failure. Because most patients presenting with severe hyperphosphatemia also have hypocalcemia, treatment focuses on the correction of both.

In patients with normal renal function, phosphate excretion can be increased by saline infusion coupled with loop diuretics. Hyperphosphatemia usually resolves in 6 to 12 hours in patients with normal renal function. In patients with hyperphosphatemia with renal failure, hemodialysis or peritoneal dialysis should be considered early in the management. Currently, phosphate control is initiated only when hyperphosphatemia occurs, but it may be beneficial to intervene earlier in patients with chronic kidney disease. The optimal method for controlling serum phosphate in patients undergoing dialysis is unknown and may involve combinations of dietary modification, phosphate binders, and enhancement of phosphate clearance through longer dialysis sessions.[48]

Disposition

Often, hyperphosphatemic patients need to be admitted to reverse the underlying etiology of their electrolyte abnormality. All patients that require hemodialysis need to be admitted to a monitored bed on a phosphate-restricted diet. Patients should also be admitted to a monitored be if they require ongoing volume resuscitation with diuresis.

HYPOPHOSPHATEMIA

Foundations

Hypophosphatemia is defined as mild (2 to 2.5 mg/dL), moderate (1 to 2 mg/dL), or severe (<1 mg/dL). Mild to moderately severe hypophosphatemia is usually asymptomatic and, like hypomagnesemia, often goes unrecognized. Although most patients remain asymptomatic,

AIDS, Acquired immunodeficiency syndrome; *DKA,* diabetic ketoacidosis.

severe hypophosphatemia may result in potentially life-threatening complications. Major clinical sequelae usually occur only in severe hypophosphatemia. Symptoms of hypophosphatemia typically begin to be manifested at serum levels below 1.0 mg/dL.

Clinical Features

Mild to moderate hypophosphatemia is usually asymptomatic, but major clinical manifestations can occur with severe hypophosphatemia. Because phosphate is an essential component to adenosine triphosphate, hypophosphatemia can affect a variety of organ systems and a wide variety of symptoms (Box 114.13). Patients with hypophosphatemia may present with nonspecific complaints including joint pain, myalgias, irritability, and depression. Severe hypophosphatemia can be manifested as seizures, arrhythmias, cardiomyopathy, insulin resistance, acute tubular necrosis, rhabdomyolysis, and acute respiratory failure.

Differential Diagnosis

Hypophosphatemia is must commonly induced by one of the three causes: (1) Increased phosphate excretion, (2) inadequate phosphate intake, or (3) a shift in phosphate stores. Acute hypophosphatemia is most commonly due to a rapid intracellular shift. Hyperventilation, glucose, insulin, volume expansion, and resolving acidosis can lead to hypophosphatemia by rapid intracellular shift. The many causes of hypophosphatemia include decreased phosphate intake or increased absorptive states, hyperventilatory states, hormonal and endocrine effects, medications, and disease states (Box 114.14). The ED patients most likely to have hypophosphatemia are those who are malnourished with alcohol withdrawal, acute hyperventilation, or sepsis and patients with DKA or alcohol ketoacidosis in whom reintroduction of insulin and glucose causes phosphate uptake into cells.

Diagnostic Testing

The diagnostic evaluation of a patient with suspected hypophosphatemia begins with obtaining electrolyte and renal function tests with hypophosphatemia defined as a serum level below 2.5 mg/dL. Often, the etiology of hypophosphatemia can be determined by the history. However, if the etiology is unclear, the patient may need to have a renal

phosphate excretion measured or calculated upon admission. Imaging in hyperphosphatemia is rarely indicated unless there are confounding cardiac, neurologic, or respiratory factors.

Management

We recommend patients with phosphate levels below 2.0 mg/dL be given phosphate repletion; patients with levels below 1.0 mg/dL necessitate treatment. Because hypophosphatemia is often coupled with hypokalemia, patients with hypophosphatemia often require potassium repletion as well. Oral phosphorous, 250 to 500 mg twice daily, can be given to stable or asymptomatic patients. IV preparations are available as sodium phosphate (Na_2PO_4 and $NaPO_4$) or potassium phosphate (K_2PO_4 and KPO_4), and rate of infusion and choice of initial dosage should be based on severity of hypophosphatemia and presence of symptoms.

If the serum phosphorus concentration is less than 1.5 mg/dL (0.48 mmol/L), 1.3 mmol/kg of elemental phosphorous (up to a maximum of 100 mmol) can be given in three or four divided doses in a 24-hour period. For routine replacement, give 0.5 mL/hr K_2PO_4; this may be increased to 1 mL/hr in severely symptomatic patients. Each milliliter of K_2PO_4 contains 3 mmol of phosphorus and 4.4 mEq of potassium.

Typical replacement therapy provides approximately 1 g of phosphorus per day. Patients should be monitored for the development of hypocalcemia, hyperkalemia, and hyperphosphatemia while IV phosphate is administered, especially in patients with renal insufficiency. Patients with DKA are initially hypophosphatemic. However, no studies have shown significant benefit to routine phosphate therapy in DKA. Risks of routine treatment with phosphate include hyperphosphatemia, renal failure, hypocalcemia, and hypomagnesemia. In patients with severe malnutrition or significant hypophosphatemia, replacement can be considered, but more than 60 mmol/day should not be administered without reason.

Disposition

Mild asymptomatic hypophosphatemia can be treated with oral phosphate while patients with severe or symptomatic hypophosphatemia should be treated with IV phosphate therapy and admitted for monitoring and subsequent serum electrolyte testing. In general, all symptomatic patients need treatment with phosphate. The outlook for patients depends on the primary condition causing the hypophosphatemia.

CHAPTER 114: QUESTIONS AND ANSWERS

1. A patient with end-stage renal disease misses dialysis and presents feeling weak. His 12-lead electrocardiogram (ECG) shows peaked T waves, absent P waves, and a QRS duration of 240 milliseconds. Which of the following is the next step in emergency department (ED) management?
   - **a.** Calcium
   - **b.** Furosemide
   - **c.** Hemodialysis
   - **d.** Insulin with glucose
   - **e.** Nebulized albuterol

Answer: A. Calcium is the first medication that should be administered in this patient with a widened QRS. The treatment of hyperkalemia is based on the clinical scenario combined with the 12-lead ECG and the laboratory potassium value. Evaluating the ECG of patients at risk for this electrolyte disturbance is critical because results of the serum potassium level can be delayed. Hyperkalemia can be rapidly progressive, and lifesaving interventions should be instituted at the earliest suspicion of toxicity. Intravenous (IV) calcium is used to stabilize the cardiac membrane by restoring the electrical gradient. Calcium increases the depolarization threshold and the calcium gradient across the cardiac membrane, quieting myocyte excitability and increasing cardiac conduction speed, thus narrowing the QRS.

2. For which of the following patients would it be most appropriate to supplement potassium to keep serum levels above 4 mEq/L?
   - **a.** A 23-year-old woman with palpitations and no past medical history
   - **b.** A 42-year-old woman with poorly controlled diabetes mellitus
   - **c.** A 51-year-old man with hypertension, recently started on lisinopril
   - **d.** A 55-year-old man with history of coronary artery disease, chest pain, and premature ventricular complexes
   - **e.** A 68-year-old-man with chronic bronchitis and fever

Answer: D. The 55-year-old patient is at highest risk for life-threatening complications from hypokalemia secondary to his underlying comorbidities. In patients with cardiac ischemia or heart failure, even mild to moderate hypokalemia increases the likelihood of cardiac arrhythmias secondary to potassium's effect on the action potential.

3. A malnourished man with a long history of chronic obstructive pulmonary disease is brought to the emergency department (ED) in respiratory distress. He receives bronchodilators, intravenous (IV) dextrose, and thiamine. He improves significantly, but then begins to complain of severe muscle aches, diffuse weakness, and the feeling that he cannot breathe deeply. Supplementation with which of the following might have prevented his new symptoms?
   - **a.** Calcium gluconate
   - **b.** Diazepam
   - **c.** Normal saline
   - **d.** Potassium phosphate
   - **e.** Sodium bicarbonate

Answer: D. Patients with hypophosphatemia may present with nonspecific complaints, including joint pain, myalgias, irritability, and depression. Severe hypophosphatemia can be manifested as seizures, arrhythmias, cardiomyopathy, insulin resistance, acute tubular necrosis, rhabdomyolysis, and acute respiratory failure. Because hypophosphatemia often presents with hypokalemia, phosphate repletion should be considered in conjunction with potassium administration.

4. A 58-year-old man with history of small cell lung cancer is brought in for weakness and pleuritic chest pain. He is alert, with normal vital signs, nonfocal neurologic examination, and serum sodium concentration of 129 mEq/L. What is the most appropriate management of the hyponatremia?
   - **a.** Free water restriction
   - **b.** Hypertonic saline bolus
   - **c.** Intravenous (IV) furosemide
   - **d.** Normal saline bolus
   - **e.** Sodium chloride tablets

Answer: A. The patient with small cell lung cancer is demonstrating signs and symptoms of hyponatremia. Lung cancers, especially small cell cancer, can lead to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). The mainstay for treatment of euvolemic hyponatremia is free water restriction. Because the hypoosmolality in SIADH results from a relative abundance of water in the intracellular and extracellular volumes and is maintained by a reduced ability to excrete water, the restriction of free oral water intake is usually the most effective therapy. For relatively asymptomatic patients with sodium values of 115 to 135 mEq/L, a trial of free water restriction to less than 0.8 mL/day to 1.25 L/day should be attempted.

5. A runner is brought in after collapsing during a race. He has been careful to drink at each mile marker. He has altered mental status and is combative even after 10 mg of diazepam. What is the most appropriate treatment after his witnessed tonic-clonic seizure?
   - **a.** 5% Dextrose solution
   - **b.** Fosphenytoin
   - **c.** 3% Hypertonic saline
   - **d.** Lorazepam
   - **e.** Pentobarbital

Answer: C. This runner is demonstrating symptoms concerning for exercise-associated hyponatremia, the occurrence of hyponatremia during or up to 24 hours after prolonged physical activity. Hypertonic saline is indicated in severe cases of hyponatremia when a patient has alterations in mental status, focal neurologic findings, or seizures.

Diabetes Mellitus and Disorders of Glucose Homeostasis

Gerald E. Maloney Jr. and Jonathan M. Glauser

KEY CONCEPTS

- The diagnosis of diabetes can be determined by one or more of four methods—random plasma glucose level above 200 mg/dL, fasting plasma glucose concentration above 126 mg/dL, 2-hour, 75-g post-load oral glucose tolerance test (OGTT) > 200 mg/dL, or HbA_{1c} value above 6.5%.
- Diabetic ketoacidosis (DKA) is diagnosed by the presence of hyperglycemia, anion gap metabolic acidosis, and elevated ketoacid levels.
- The essential treatment of DKA includes administration of insulin, correction of dehydration, correction of potassium level, correction of acidosis, and treatment of the underlying cause.
- The use of sodium bicarbonate to correct acidosis in DKA has not demonstrated any benefit and may be associated with worse outcomes.
- A hyperglycemic hyperosmolar state is usually seen in older adults with multiple comorbid conditions and is distinguished from DKA by the absence of ketoacidosis. In addition to fluid resuscitation and correction of hyperglycemia, treatment should address the underlying cause of the state, which includes infection, myocardial infarction, and cerebrovascular accident.
- Diabetic peripheral neuropathy is common and has multiple treatment options, including gabapentin, pregabalin, and duloxetine.
- Diabetic foot ulcers and other diabetic soft-tissue infections (e.g., gas gangrene, Fournier's gangrene) are frequently polymicrobial and require broad-spectrum antibiotic therapy covering gram-positives, gram-negatives, and anaerobes.
- Hypoglycemia may be associated with significant morbidity and mortality. When the diagnosis is suggested and, if possible, confirmed by laboratory evaluation, therapy should be initiated immediately.
- Hypoglycemia caused by sulfonylurea oral hypoglycemic agents may be prolonged. Patients should be observed for an extended period or hospitalized.

DIABETES MELLITUS

Diabetes Mellitus Foundations

Background and Importance

Diabetes mellitus is the most common endocrine disease. It comprises a heterogeneous group of hyperglycemic disorders characterized by a high serum glucose concentration and disturbances of carbohydrate and lipid metabolism. Acute complications include hypoglycemia and hyperglycemia, diabetic ketoacidosis (DKA), and hyperglycemic hyperosmolar state (HHS). Long-term complications affect multiple organ systems through involvement of the microvasculature and include retinopathy, nephropathy, neuropathy, and angiopathy. As a result, complications such as coronary and cerebral vascular disease, blindness, chronic kidney disease, complicated infections, and amputations occur with a much higher incidence in patients with diabetes than in patients without. Diabetes is ranked as one of the five major chronic diseases that account for a significant proportion of our health care spending. Several trials have shown to varying degrees that tight glucose control can reduce the risk of death and severe microvascular complications. Patients with diabetes mellitus incur emergency department (ED) costs three times higher than those of nondiabetic patients and are admitted to the hospital four times more often.[1,2]

Epidemiology

The most recent data (2015) estimate that some 30 million people, or 9.4% of all Americans and 13% of adults older than 20 years have diabetes.[1] The incidence of diabetes in those younger than 20 approaches as high as 45/100,000 by the teenage years. The type of diabetes depends on age; most of those younger than 10 years have type 1, whereas type 2 predominates among the 10- to 19-year-olds.[2] Additionally, 33% of the total US population is thought to have prediabetes.

Type 1 is less common than type 2. The peak age at onset of type 1 diabetes is 10 to 14 years, and approximately 1 of every 600 schoolchildren has this disease. In the United States, the prevalence of type 1 is approximately 0.26% by the age of 20 years, and the lifetime prevalence approaches 0.4%. The annual incidence among persons from birth to 16 years of age in the United States is 12 to 14 per 1 million population. The incidence is age-dependent, increasing from near-absence during infancy to a peak occurrence at puberty and another small peak at midlife.[1,2]

The morbidity of diabetes is related primarily to its vascular complications. A mortality rate of 36.8% has been attributed to cardiovascular causes, 17.5% to cerebrovascular causes, 15.5% to diabetic comas, and 12.5% to renal failure.

Anatomy, Physiology, and Pathophysiology

Normal Physiology. Because plasma glucose is the predominant metabolic fuel used by the central nervous system (CNS), maintenance of the plasma glucose concentration is critical to survival. The CNS cannot synthesize glucose, store more than a few minutes' supply, or concentrate glucose from the circulation. Brief hypoglycemia can cause profound CNS dysfunction, and prolonged severe hypoglycemia may cause cellular death. Glucose regulatory systems have evolved to prevent and correct hypoglycemia.

The plasma glucose concentration is normally maintained within a relatively narrow range, between 60 and 150 mg/dL, despite wide variations in glucose levels after meals and exercise. Glucose is derived from three sources—intestinal absorption from the diet, the breakdown of glycogen (glycogenolysis), and the formation of glucose from precursors (gluconeogenesis), including lactate, pyruvate, amino acids, and glycerol. After glucose ingestion, the plasma glucose concentration increases as a result of glucose absorption. Endogenous glucose production is suppressed, and the plasma glucose level rapidly declines in response to insulin to a level below the baseline.

Insulin. Insulin receptors on the beta cells of the pancreas sense elevations in the blood glucose concentration and trigger insulin release. For incompletely understood reasons, glucose taken orally results in more insulin release than parenteral glucose. Certain amino acids induce insulin release and even cause hypoglycemia in some patients. Sulfonylurea oral hypoglycemic agents work, in part, by stimulating the release of insulin from the pancreas.

The number of receptors determines the sensitivity of the specific tissue to circulating insulin. The number and sensitivity of receptors are also the primary factors affecting the long-term efficacy of the sulfonylurea oral hypoglycemic agents. Receptor sites are increased in glucocorticoid deficiency and may be relatively decreased in obese patients.

Under normal circumstances, insulin is rapidly degraded through the liver and kidneys. The half-life of insulin is 3 to 10 minutes. Whereas insulin is the major anabolic hormone implicated in diabetes, glucagon is the major catabolic hormone in disorders of glucose homeostasis.

Although most tissues have the enzyme systems required to synthesize and hydrolyze glycogen, only the liver and kidneys have glucose-6-phosphatase, the enzyme necessary to release glucose into the circulation. The liver is essentially the sole source of endogenous glucose production. Renal gluconeogenesis and glucose release contribute substantially to the systemic glucose pool only during prolonged starvation.

Glucose Regulatory Mechanisms. Maintenance of the normal plasma glucose concentration requires precise matching of glucose use with endogenous glucose production and dietary glucose intake. The regulatory mechanisms that maintain systemic glucose balance involve hormonal, neurohumoral, and autoregulatory factors. Glucose regulatory hormones include insulin, glucagon, epinephrine, cortisol, and growth hormone. Insulin is the main glucose-lowering hormone. Insulin suppresses endogenous glucose production and stimulates glucose use. Insulin is secreted from the beta cells of the pancreatic islets into the hepatic portal circulation and has important actions on the liver and peripheral tissues. Insulin stimulates glucose uptake and storage, and it is used by other insulin-sensitive tissues, such as fat and muscle.

Counterregulatory hormones include glucagon, epinephrine, norepinephrine, growth hormone, and cortisol. When glucose is not transported intracellularly because of a lack of food intake or lack of insulin, the body perceives a fasting state and releases glucagon, attempting to provide the glucose necessary for brain function. Glucagon is released in response to hypoglycemia as well as to stress, trauma, infection, exercise, and starvation. It increases hepatic glucose production within minutes, although transiently.

Epinephrine both stimulates hepatic glucose production and limits glucose use through direct and indirect actions mediated by α-adrenergic and β-adrenergic mechanisms. Epinephrine also acts directly to increase hepatic glycogenolysis and gluconeogenesis. It acts within minutes and produces a transient increase in glucose production but continues to support glucose production at approximately basal levels thereafter. Norepinephrine exerts hyperglycemic actions by mechanisms similar to those of epinephrine, except that norepinephrine is released from axon terminals of sympathetic postganglionic neurons.

Cortisol is released in response to stress, and it increases blood glucose by both increasing hepatic gluconeogenesis and inhibiting skeletal muscle uptake of glucose. These mechanisms contribute to the hyperglycemia seen during physiologic stress or illness.

Pathophysiology. Type 1 diabetes results from a chronic autoimmune process that usually exists in a preclinical state for years. The classic manifestations of type 1 diabetes—hyperglycemia and ketoacidosis—occur late in the disease, an overt sign of beta-cell destruction. The most striking feature of long-standing type 1 diabetes is the nearly total lack of insulin-secreting beta cells and insulin, with the preservation of glucagon-secreting alpha cells, somatostatin-secreting delta cells, and pancreatic polypeptide–secreting cells.[3]

Although the exact cause of diabetes remains unclear, research has provided some clues. Studies of the pathogenesis of diabetes mellitus have demonstrated that the cause of the disordered glucose homeostasis varies from individual to individual. This cause may determine the presentation in each patient. Individual patients are currently not studied for the source of their disease, except on an experimental basis. The goals of ongoing research are to identify who is susceptible to the development of diabetes, prevent diabetic emergencies and sequelae, and prevent expression of the disease.

Types of Diabetes

The American Diabetes Association (ADA) defines four major types of diabetes mellitus: type 1 diabetes mellitus, type 2 diabetes mellitus, gestational diabetes, and diabetes due to secondary disease processes or drugs.[1,4] Additionally, the diagnostic criteria of prediabetes was established for patients with glucose levels above the normal fasting range of 110 mg/dL but less than 126 mg/dL; this category has received much attention for the targeting of focused interventions to reduce progression to diabetes mellitus.[1] The 1997 National Diabetes Data Group discontinued the use of the terms *insulin-dependent diabetes mellitus* and *non-insulin-dependent diabetes mellitus* because they were confusing and clinically inaccurate. The most recent update to the standards of care for diabetes was published in January 2021.[1] The diagnostic criteria for the diagnosis of diabetes were changed in 2010 from the previous standards of elevated fasting glucose concentration and an abnormal result on the 2-hour oral glucose tolerance test (OGTT) to use of the hemoglobin A_{1c} (HbA_{1c}) value as the preferred confirmatory test.[4] A HbA_{1c} value above 6.5% is diagnostic of diabetes. However, the fasting plasma glucose concentration and 2-hour OGTT are still considered valid screening tests for diabetes, as is the presence of a random glucose measurement of more than 200 mg/dL in a non-fasting patient with symptoms of diabetes. Use of the fasting plasma glucose concentration may help identify patients at risk for diabetes when the glucose concentration is elevated but does not meet the threshold for the diagnosis of diabetes.

Type 1 Diabetes Mellitus. Type 1 diabetes is characterized by an abrupt failure of insulin production with a tendency to ketosis, even in the basal state. Parenteral insulin is required to sustain life. From 85% to 90% of patients with type 1 diabetes demonstrate evidence of one or more autoantibodies implicated in the cell-mediated autoimmune destruction of the beta cells of the pancreas. The autoimmune destruction has multiple genetic predispositions and may be related to undefined environmental insults.

Type 2 Diabetes Mellitus. Patients with type 2 diabetes may remain asymptomatic for long periods and show low, normal, or elevated levels of insulin. Ketosis is rare in type 2 disease. Patients frequently have hypertriglyceridemia and a high incidence of obesity. No association exists with viral infections, islet cell autoantibodies, or human leukocyte antigen (HLA) expression. Hyperinsulinemia may be related to peripheral tissue resistance to insulin because of defects in the insulin receptor. Defects in muscle glycogen synthesis have an important role in insulin resistance.

Gestational Diabetes. Gestational diabetes mellitus is characterized by an abnormal OGTT result that occurs during pregnancy and reverts to normal during the postpartum period or remains abnormal. The clinical pathogenesis is thought to be similar to that of type 2. The clinical presentation is usually nonketotic

hyperglycemia during pregnancy. Screening is performed around the 24th to 28th week with a 75-g oral glucose load in a woman with no prior history of diabetes.[4]

Diabetes of Other Causes. Myriad causes of diabetes have been identified, including chronic pancreatitis, cystic fibrosis, genetic defects in the beta cell or in insulin receptors, and chemical-induced (e.g., Vacor; statins; chemotherapeutic, antipsychotic, or antiretroviral medications). The management of diabetes due to these conditions is cause-specific and depends on whether the underlying pathophysiologic process more closely resembles type 1 or 2 diabetes.[3]

Prediabetes. Impaired glucose tolerance (IGT) has been replaced by the term *prediabetes* to identify individuals at high risk for the development of diabetes.[4] The pathogenesis of prediabetes is thought to be related to insulin resistance. This group is composed of persons whose plasma glucose levels are between normal and diabetic; they are at increased risk for diabetes and cardiovascular disease. Prediabetes encompasses patients with both impaired fasting glucose (110 to 125 mg/dL) or IGT (level of 140 to 199 mg/dL after a 75 g oral glucose load). Presentations of prediabetes include nonketotic hyperglycemia, insulin resistance, hyperinsulinism, and often obesity. Prediabetes is not associated with the same degree of complications of diabetes mellitus, and many of these patients have normal glucose tolerance. However, each year, about 1% to 5% of patients with prediabetes will develop diabetes mellitus.[4]

Diabetes Mellitus Clinical Features

Type 1

The patient with type 1 diabetes is usually lean, younger than 40 years at diagnosis, and prone to ketosis. Plasma insulin levels are absent to low; plasma glucagon levels are high but suppressible with insulin, and patients require insulin therapy to treat their symptoms. The onset of symptoms may be abrupt, with polydipsia, polyuria, polyphagia, and weight loss developing rapidly. In some cases, the disease is heralded by ketoacidosis. Myriad problems related to type 1 diabetes may prompt an ED visit, including acute metabolic complications, such as DKA, and late complications, such as cardiovascular or circulatory abnormalities, retinopathy, nephropathy, neuropathy, foot ulcers, severe infections, and various skin lesions.

Type 2

The patient with type 2 diabetes is usually middle-aged or older and overweight, with normal to high insulin levels. Insulin levels are lower than would be predicted for glucose levels, however, leading to a relative insulin deficiency. Type 2 patients demonstrate impaired insulin function related to poor insulin production, failure of insulin to reach the site of action, or failure of an end-organ response to insulin. Although most adult patients with type 2 are obese, 20% are not.

Symptoms in type 2 diabetes tend to begin more gradually than in type 1. The diagnosis of type 2 is often made by the discovery of an elevated blood glucose level on routine laboratory examination. Hyperglycemia may be controlled by dietary therapy, oral hypoglycemic agents, or insulin administration. Decompensation of the disease usually leads to HHS rather than to ketoacidosis.

Diabetes Mellitus Differential Diagnosis

The differential diagnosis for diabetes includes hyperglycemia due to physiologic stress, catecholamine release, or certain toxins. Calcium channel blocker overdose has been known to cause insulin resistance and thus present with both significant hyperglycemia and metabolic acidosis. The rodenticide PNU (vacor), which destroys the pancreatic islet cells, can induce a diabetes-like state. Patients with prediabetes may exhibit frank hyperglycemia with a large carbohydrate load or physiologic stress.

Diabetes Mellitus Diagnostic Testing

Serum Glucose Level

The diagnosis of diabetes can be established in one or more of four ways—random plasma glucose level above 200 mg/dL, fasting plasma glucose concentration above 126 mg/dL, 2-hour, 75-g post-load OGTT higher than 200 mg/dL, or HbA_{1c} value above 6.5%.[4] In the absence of hyperglycemia with metabolic decompensation, these criteria should be confirmed by repeated testing on a different day. Confirmation can be made by the same test or two different tests (e.g., fasting plasma glucose and HbA_{1c}). A fasting value above 150 mg/dL is likely to distinguish diabetic from nondiabetic patients more accurately. Formal OGTTs are unnecessary except during pregnancy or in patients who are thought to have diabetes, but who do not meet the criteria for a particular classification. The World Health Organization and ADA have provided protocols for performing the OGTT.[4]

Glycosylated Hemoglobin

Measurement of glycosylated hemoglobin (HbA_{1c}) is one of the most important ways to assess the level of glucose control. An elevated serum glucose level binds progressively and irreversibly to the amino-terminal valine of the hemoglobin β chain. The HbA_{1c} measurement provides insight into the quality of glycemic control over time. Given the long half-life of red blood cells, the percentage of HbA_{1c} is an index of glucose concentration of the preceding 6 to 8 weeks, with normal values approximately 4% to 6% of total hemoglobin, depending on the assay used. Levels in patients with poorly controlled disease may reach 10% to 12%. The ADA has recommended at least biannual measurements of HbA_{1c} for the follow-up of all types of diabetes. The ADA currently sets an HbA_{1c} value of less than 7% as a treatment goal. Different medical societies have advocated for patient-specific A_{1c} goals, particularly in the elderly, who are more prone to adverse effects from hypoglycemia resulting from attempts at tight glucose control.[5,6] For functionally independent older adults, the HbA_{1c} goal is 7% to 7.5%, and 7% to 8% is recommended for functionally dependent, frail patients, or patients with dementia.[5]

Urine Glucose Level

Urine glucose measurement methods are of two types, reagent tests and dipstick tests. The reagent tests (e.g., Clinitest) are copper reduction tests. The reagent tests are rarely used because they are difficult to perform, and the test material is toxic for ingestion or dermal exposure. Dipstick tests generally use glucose oxidase, which may also be affected by different substances. Dipsticks are inexpensive and convenient but may vary in their sensitivity and strength of reaction to a given concentration of glucose. Dipstick interpretation can vary significantly, depending on the observer and type of lighting. Both falsely high and falsely low urine glucose readings can also occur. With the plus system, 1+, 2+, 3+, and 4+ have different implications about urine glucose concentrations, depending on the brand of the dipstick. The use of reflectance colorimeters to read dipsticks increases accuracy.

Urine Ketone Level

Urine ketone dipsticks use the nitroprusside reaction, which test for acetoacetate but does not measure β-hydroxybutyrate. Although the usual ratio of acetoacetate to β-hydroxybutyrate in DKA is 1:2.8, it may be as high as 1:30, and in which case, the urine dipstick does not reflect the true level of ketosis. When ketones are in the form of β-hydroxybutyrate, the urine ketone dipstick may infrequently yield a negative reaction in patients with significant ketosis.

Dipstick Blood Glucose Level

Dipsticks for testing the blood glucose level are clearly more accurate than urine dipsticks as a means of monitoring blood glucose concentration, but they also may be inaccurate. Hematocrits below 30% or above 55% cause inaccurately high or low readings, respectively, and a number of the strips specifically disclaim accuracy when used for neonates. The sensitivity of dipsticks to a variety of factors varies with the particular brand. The largest errors are in the hyperglycemic range. Dipstick readings rarely err more than 30 mg/dL when the actual concentration is below 90 mg/dL. Although specific glucose concentrations may not be accurately represented, blood glucose dipsticks are useful for estimating the general range of the glucose value. Reflectance meters increase the accuracy of the dipstick blood glucose level determination. The use of glucometers has supplanted the use of dipsticks in most clinical settings and tends to be fairly accurate, except, again, at the extremes of glucose levels (<30 or >600 mg/dL). If maximum accuracy is desired, a laboratory blood glucose level should be determined.

Diabetes Mellitus Management

Management of Hyperglycemia

Patients often present to the ED with typical diabetic symptoms, such as polyuria, polydipsia, and polyphagia. Many have serum glucose concentrations above 200 mg/dL but are not ketotic. Patients with newly diagnosed hyperglycemia with normal electrolyte values may be treated with intravenous (IV) hydration alone or with insulin, often reducing the glucose concentration to 150 mg/dL. In reliable patients whose initial glucose concentration is greater than 400 mg/dL, initiation of oral hypoglycemic therapy may be appropriate, with lifestyle modification and coordination with a clinician who will provide longitudinal care. An HbA_{1c} value should be obtained before initiation of therapy to confirm a diagnosis of diabetes and to establish a baseline.

Detailed descriptions of oral hypoglycemics are provided below, but considerations for ED initiation in acute hyperglycemia are listed here. Initial therapy for type 2 diabetes generally includes metformin at a dose of 500 mg daily or twice daily depending on immediate or extended-release formulation. The extended-release formulation may be better tolerated in terms of GI side effects. Sulfonylurea therapy may be considered as well, with glyburide (2.5 to 5 mg once daily) or glipizide (5 mg once daily).[5–7] Patients with kidney disease may have complications from the use of a sulfonylurea or metformin and will likely need insulin therapy with or without a glucagon-like peptide-1 receptor agonist. Patients with heart failure or less severe renal disease might benefit from a sodium/glucose cotransporter-2 inhibitor (SGLT-2).[8–10] Recent studies have shown a mortality benefit to canagliflozin and empagliflozin. If possible, diabetic testing supplies should be given and patients should be taught how to test blood glucose prior to discharge. No target blood glucose level needs to be achieved for safe discharge; observational studies showed no difference in short-term outcomes whether a specific glucose target was achieved or not. Follow-up should be stressed and warning signs of hypoglycemia discussed.

Management of Diabetes Mellitus

Although emergency clinicians do not routinely provide longitudinal care for diabetic patients, these patients frequently present to the ED, and it is helpful to understand fundamental management principles of this important disease. The basic concepts of the diabetic diet remain unchanged, although many studies emphasize foods and medications that alter glucose absorption. Various high-fiber diets have improved glycemic control. The number of supplements or low–glycemic index snacks has risen in the last decade. Exercise continues to be a cornerstone of diabetes management, although care must be taken to balance it with appropriate calorie intake and medication use.

Oral Hypoglycemic Agents. Goals of diabetic management include lowering the hemoglobin A_{1c} to less than 7% and maintenance of the fasting blood sugar level to within 90 to 130 mg/dL. When started on monotherapy, after 3 years, approximately 50% of patients need a second drug. There have been an increasing number of oral agents for hyperglycemia available in recent years. (Table 115.1) Some of these have serious side effects, requiring the emergency clinician to be familiar with these drugs. If these effects are expected to be prolonged, the patient may require observation. Categories of oral agents may be divided into those that increase the insulin supply, including sulfonylureas, secretagogues, and insulin itself. Medications that decrease insulin resistance include the biguanides and thiazolidinediones; drugs that reduce the rate of glucose absorption include α-glucosidase inhibitors. Metformin is generally used as the first-line agent for oral therapy. If the goal of lower HbA_{1c} levels is not achieved, the addition of a sulfonylurea or pioglitazone should be considered.[8]

Biguanides. The ADA and European Association for the Study of Diabetes have recommended lifestyle changes, including weight control, at the time of diabetes diagnosis. Metformin (a biguanide) is the initial drug of choice because it does not induce weight gain, has low cost and good tolerability, and does not induce hypoglycemia. However, it lowers blood glucose by only about 100 mg/dL and lowers HbA_{1c} by approximately 1.5%. Newly diagnosed diabetics frequently require additional agents to control their serum glucose and to lower their HbA1c levels.[8]

Metformin is renally excreted and should not be used with a glomerular filtration rate (GFR) < 30. The Food and Drug Administration (FDA) also recommends not starting metformin in patients with a GFR of 30 to 45, though increased rates of adverse events were not noted in this group.[8] Metabolic and lactic acidosis are a concern with biguanides. Historically, holding metformin after IV contrast and rechecking renal function before restarting has been advocated. However, evidence has failed to show the necessity of this approach for most patients. Patients with existing kidney disease, or those with dehydration or hypoperfusion, should probably have metformin held after IV contrast. There is no clear evidence to support holding metformin

TABLE 115.1 Common Oral Diabetic Medications

Medication	Function	Details
Biguanides (metformin)	Decrease hepatic glycogenolysis	500–1000 mg daily or bid
Sulfonylureas (glipizide, glimepiride)	Stimulate pancreatic insulin release	2.5–5 mg daily or bid
Thiazolidinediones (pioglitazone, rosiglitazone)	Insulin sensitizers, decrease hepatic gluconeogenesis	Increased risk of adverse cardiac events
Meglitinides (repaglinide, nateglinide)	Stimulate postprandial insulin release	Take with meals only
Dipeptidyl peptidase 4 inhibitors (sitagliptin)	Decrease insulin degradation and gluconeogenesis	Once daily; can be found in multiple combination medications
α-Glucosidase inhibitors (acarbose, miglitol)	Delay breakdown of carbohydrates in the intestines	Major side effect is diarrhea

routinely for all patients. Metformin must be used with caution in patients with hypoxemia, pregnancy, heart failure, liver compromise, and alcohol abuse. These patients may be at increased risk for developing lactic acidosis, associated with a 50% mortality rate.[11]

Sulfonylureas. Developed in the 1940s, sulfonylureas have historically been a mainstay of oral diabetes treatment. These drugs increase insulin secretion by interacting with potassium channels in the beta cell membrane. This class of drugs is especially useful for patients with early-onset, type 2 diabetes mellitus, and fasting blood glucose levels less than 300 mg/dL. This class of drugs is contraindicated in patients with a known allergy to sulfa agents. Examples of sulfonylureas include glipizide (Glucotrol, Glucotrol XL), glimepiride (Amaryl), gliclazide (Diamicron), chlorpropamide (Diabinese), and glyburide (DiaBeta, Glynase PresTab, Micronase). The risk of hypoglycemia is greater in older adults and in those with impaired renal and hepatic function. This class of medication is also associated with weight gain. They generally lower the glucose level by 20%, and HbA_{1c} levels by 1% to 2%. Glipizide is shorter acting and therefore less likely than the other sulfonylureas to induce prolonged hypoglycemia. However, for all sulfonylureas, there have been several case reports of delayed onset of hypoglycemia from 12 to 21 hours after ingestion, leading to general recommendations to observe the patient for a 24-hour period. In addition to providing glucose, hypoglycemia due to sulfonylureas may be treated with octreotide, although the data supporting this recommendation is limited.

Thiazolidinediones. Thiazolidinediones reduce insulin resistance and are especially useful in patients who require large amounts of insulin and still lack adequate glucose control. They have been associated with hepatotoxicity and require liver function monitoring for at least 1 year after initiation. Due to its hepatotoxic effects, troglitazone has been removed from the market; pioglitazone (Actos) and rosiglitazone (Avandia) remain approved for monotherapy. Cardiovascular risks, including myocardial infarction, may be higher with rosiglitazone. These agents may also be associated with weight gain, fluid retention, and heart failure. They increase insulin sensitivity and may be expected to reduce the HbA_{1c} value by 0.5 to 1.4 points. They are contraindicated for patients with New York Heart Association class III or IV heart failure.[12]

α-Glucosidase Inhibitors. The *α-glucosidase inhibitors* delay intestinal monosaccharide absorption and prevent complex carbohydrate breakdown; these agents include acarbose (Precose and generic) and miglitol (Glyset). They must be titrated to minimize gastrointestinal (GI) side effects and should not be used in patients with certain GI disorders. Liver function must be monitored because of dose-dependent hepatotoxicity. The *α-glucosidase inhibitor* should be taken with meals because they delay the absorption of glucose. Side effects include abdominal pain, diarrhea, and flatulence from unabsorbed carbohydrates. They lower the $HgbA_{1c}$ by 0.5 to 0.8 points.

Meglitinides. The nonsulfonylurea secretagogues, the meglitinides, are similar to the sulfonylureas in action and mechanism. They bind to adenosine triphosphate (ATP)–sensitive potassium channels of beta cells to increase insulin secretion. They have a rapid onset of action and should be taken before a meal, involve less risk of hypoglycemia, and are suitable for patients allergic to sulfa medications. The specific agents available are nateglinide (Starlix) and repaglinide (Prandin). These may be better for patients with impaired renal function due to their hepatic metabolism. Similar to the management of refractory hypoglycemia with sulfonylureas, hypoglycemia due to meglitinides may be treated with octreotide by bolus or infusion.

Glucagon-Like Peptide Analogs and Agonists. Glucagon-like peptide (GLP-1) analogs and agonists stimulate the release of insulin from pancreatic cells. Exenatide (Byetta) is US FDA–approved for twice-daily subcutaneous injection in patients with type 2 diabetes who have not achieved satisfactory control with metformin, a sulfonylurea, pioglitazone, or lifestyle modifications. It lowers serum glucagon concentrations and slows gastric emptying. These agents should be used with caution if gastroparesis is a concern. Exenatide lowers HbA_{1c} by 1 to 1.5 points, even when administered once weekly.

GLP itself has a half-life of only a few minutes. The GLP agonists bind to the GLP receptor on the pancreas and have a much longer half-life. This class also includes the subcutaneously administered medications Liraglutide (Victoza), semaglutide (Ozempic), and lixisenatide. Recently, an oral version of semaglutide (Rybelsus) was approved by the FDA for once daily use. GLP-1 receptor antagonists have the following potential adverse effects: nausea, vomiting, diarrhea, renal impairment, pancreatitis, and thyroid carcinoma, with a warning against use if there is a personal or family history of medullary thyroid cancer. They have been associated with weight loss and may decrease hospitalization for heart failure.[9,10,13] Clinical experience with their toxicology is limited, but there have been episodes of hypoglycemia reported. Observation recommendations for hypoglycemia are not established, but, given the long half-life of the medications, we recommend a period of at least 24 hours.

Dipeptidyl Peptidase-4 Inhibitors. Dipeptidyl peptidase-4 (DPP-4) inhibitors include sitagliptin (Januvia), saxagliptin (Onglyza), and linagliptin (Tradjenta). DPP-4 degrades endogenous GLP; by preventing this degradation, the DPP-4 inhibitors prolong the half-life of GLP and increase insulin secretion. These are generally used as second- or third-line agents. Sitagliptin is FDA approved as monotherapy, but it is also available in combination with other oral hypoglycemic medications. Patients with chronic kidney disease may be at risk for hypoglycemia and should be treated symptomatically. DPP-4 inhibitors inhibit glucagon release and delay gastric emptying, and they are associated with a possible risk of pancreatitis.[10] Agents in the DPP-4 inhibitor class have not been associated with weight gain. They may be expected to produce a decrease in the HbA_{1c} of 0.4 to 0.8 points.

Amylin Analog. Pramlintide, administered three times daily before meals, is an amylinomimetic agent, or amylin analog, and decreases gastric emptying and glucagon secretion. It has been approved for use in patients with types 1 and 2 diabetes and may promote weight loss.

Sodium-Glucose Cotransporter 2 Inhibitors. Dapagliflozin (Farxiga), canagliflozin (Invokana), and empagliflozin (Jardiance) are sodium-glucose cotransporter 2 (SGLT2) inhibitors. Canagliflozin and empagliflozin have been FDA approved for cardiovascular risk reduction in patients with type 2 diabetes and established cardiovascular disease.[14] SGLT2 is a protein that transports filtered glucose from the proximal renal tubule into tubular epithelial cells, enhancing urinary excretion levels of glucose.[9] The typical threshold for urinary glucose excretion is typically a plasma glucose level of ~180 mg/dL the SGLT2 inhibitors decrease this threshold to ~40 mg/dL, markedly increasing urinary glucose excretion. They may also lower blood pressure and induce some degree of weight loss, possibly due to the loss of calories from glycosuria.[9]

SGLT2 inhibitors have been shown to reduce hospitalization for heart failure in people with diabetes, may reduce cardiovascular events, reduce albuminuria, and slow the progression of nephropathy.[9,10] Adverse events include hypotension, volume depletion, urinary and genital mycotic infections, and diabetic ketoacidosis, including normoglycemic DKA.

Insulin. Certain principles apply to all insulins, such as their ability to enhance gluconeogenesis and lipogenesis and suppress glycogenolysis. Human insulins are available today as regular insulin and neutral protamine hagedorn (NPH). Regular insulin, used in the treatment of DKA, has an onset of action within 30 to 60 minutes and is typically dosed 30 to 45 minutes before a meal. Its duration of action is approximately 4 to 12 hours. The longer-acting NPH insulin (e.g., Humulin, Novolin) is typically dosed 4 to 6 hours before a meal. It has

a 12- to 24-hour duration of action and is administered two or three times daily. Regular and NPH insulin may be combined to reduce the number of daily injections.

The development of insulin analogs, with modification of the terminal end of the A or B chain of the insulin molecule, has resulted in rapid-acting and long-acting formulations. The rapid-acting insulins currently on the market are glulisine, insulin lispro (Humalog), and insulin aspart (NovoLog). Their onset of action is approximately 10 to 30 minutes, and their duration is 3 to 5 hours. They are typically administered 5 to 20 minutes before a meal. Ultrafast-acting insulin analogs reduce postprandial glucose fluctuations and abnormalities.[12] The intent is to match insulin absorption and action to food-related rises in the plasma glucose level.[5] These basal insulin analogs may enable the time of administration of the insulin to vary widely.[12]

Long-acting insulin analogs are detemir (Levemir), deglutec, and glargine (Lantus); their onset of action is 3 to 4 hours, and their duration of action approaches 24 hours, similar to that of NPH. Insulin deglutec has a half-life of 25 hours, with a duration of action of 42 hours. Insulin glargine and detemir, being long-acting but without a peak response, more closely mimic continuous pump infusion. Advances in basal insulin formulations have resulted in products with longer durations of activity, less inter-patient variability in plasma concentration, and "flatter," more predictable pharmacokinetic properties, including a lower frequency of severe hypoglycemia.[15]

Although treatment for type 2 diabetes has traditionally started with oral agents, analog insulin therapy has been recently advocated as initial therapy for type 2 diabetes. Type 2 diabetes is associated with a decline of beta-cell function over time, and early intensive insulin therapy has been suggested to rest the beta cells and possibly preserve their function. Emergency clinicians may, therefore, see patients who were started on insulin therapy early after their diagnosis. Starting patients on 10 units/day of glargine, or detemir, 0.1 to 0.2 units/kg once daily in the evening or 10 units once or twice daily,[13,15] with 6 units of insulin aspart at mealtime, has been used as primary treatment for type 2 diabetes.[12] Basal insulin titration algorithms from numerous societies and colleges have recommended initial starting dosages of 10 units/day, titrating upward by 1 to 3 units every 1 to 3 days, with a target HbA_{1c} level below 6.5% to 7%.[16]

While many emergency clinicians are more comfortable starting patients on oral hypoglycemic agents to manage type 2 diabetes, on occasion, patients may be started on insulin from the ED. This approach involves the development of an outpatient protocol and follow-up with a specialty consultant, such as an endocrinologist. Glargine, detemir, or NPH insulin may be initiated at 0.1 to 0.2 units/kg, or roughly 10 units/day, with follow-up within 3 to 4 days for dose adjustment.

Pancreas Transplantation. Solid organ pancreas transplantation has become more common; several centers have performed combined pancreas and kidney transplants in those with end-stage kidney disease due to diabetic nephropathy. Transplantation ameliorates many secondary complications of diabetes, such as nephropathy, neuropathy, gastroparesis, retinopathy, and microvascular changes. The percentage of grafts functioning after 1 year and 1-year survival rate of patients is greater than 75% in selected medical centers. However, rejection, post-transplantation pancreatitis, and graft thrombosis, as well as other vascular and immunosuppression problems, continue to plague transplant recipients.

New Trends in Diabetes Management. Changes in the therapy of diabetes have recently included greater use of human insulin, which has prevented some of the adverse reactions to beef and pork products.[12] Unfortunately, some patients demonstrate sensitivity reactions, even to human insulin.

The initiation of immunosuppressive therapy at the initial diagnosis of type 1 diabetes can prolong the patient's ability to secrete insulin. This beneficial effect, whether achieved by azathioprine or cyclosporine, is not usually sustainable.[16] The potential side effects of immunosuppressive agents have precluded large trials in patients early in their disease.

Glycemic control now involves improved technology and more widespread individual monitoring of daily insulin dosage adjustments. Tight glycemic control limits the progression of microvascular disease, including neuropathy, renal disease, and certain types of retinopathy. However, those achieving tight control are more likely than other diabetic patients to experience hypoglycemic episodes.

Emergency clinicians and out-of-hospital care providers often encounter patients with insulin pumps.[17] Many types of insulin pumps are available, each with a pump mechanism, reservoir for insulin, tubing, and indwelling subcutaneous needles. They are attached, usually with tape, to the patient's body and administer insulin at a regular adjustable rate. Most pumps also allow the patient to administer additional boluses of insulin, as necessary. These pumps support tight glycemic control and are preferred by some patients. However, insulin pumps are associated with a variety of problems, including hypoglycemia. More recently, a wearable, automated bionic bihormonal pancreas has been noted to improve mean glycemic levels with less frequent hypoglycemic episodes among adults with type 1 diabetes mellitus. A consensus conference of the American Association of Clinical Endocrinologists and American College of Endocrinology supported the use of continuous glucose monitoring (CGM) for use in type I diabetes in reducing hypoglycemia, improving glucose control, and possibly reducing health care costs.[18] Real-time CGM provides users with updated glucose readings every 5 minutes.[19] The bionic pancreas receives data from a continuous glucose monitor to control subcutaneous delivery of insulin and glucagon.[19]

Because glucose rotates the polarization of light waves, new fiberoptic technology has been developed to determine the blood glucose level noninvasively.[19] This technique may be applied to the insulin pumps of the future. Ultrafast-acting insulins and biosimilar insulins may also be available in the near future. An inhaled insulin (Afrezza) has recently been released but has been associated with coughing and may exacerbate symptoms of reactive airway disease.

The pharmacologic treatment of diabetes continues to improve, with newer agents offering the promise of improving glycemic control for longer periods, with fewer glycemic fluctuations, less weight gain, and less hypoglycemia. New insulin analogs, such as deglutec and U-500, improve glycemic control without contributing to hypoglycemia.[18] The U500 insulin is much more concentrated, and errors in dosing are more frequent when using this product, however. Other new areas of research have included agents that increase the urinary excretion of glucose or increase hepatic gluconeogenesis.

LATE COMPLICATIONS OF DIABETES

Late complications of diabetes develop approximately 15 to 20 years after the onset of overt hyperglycemia, resulting in significant morbidity and mortality. The Diabetes Control and Complications Trial (DCCT) has shown that tight glycemic control significantly reduces the risk of microvascular disease, such as microalbuminuria (the earliest sign of nephropathy), neuropathy, and retinopathy, but at the expense of greatly increasing the risk of recurrent hypoglycemia.[2]

Vascular Complications

Diabetes is associated with an increased risk for atherosclerosis and thromboembolic complications, a major cause of morbidity and premature death. The cause of accelerated atherosclerosis is unknown, although it is probably related to oxidated low-density lipoprotein, and

increased platelet activity. Atherosclerotic lesions are widespread, causing symptoms in many organ systems. Coronary artery disease and stroke are common. Diabetic patients have an increased incidence of so-called silent myocardial infarction, complicated myocardial infarctions, and congestive heart failure. Peripheral vascular disease is noted clinically by claudication, nonhealing ulcers, gangrene, and impotence. In addition, standard treadmill stress tests have a decreased sensitivity in the detection of coronary artery disease in diabetics. For this reason, exercise or pharmacologic stress echocardiography or a nuclear medicine imaging study should be considered when a provocative test is needed to evaluate the diabetic patient for acute coronary syndrome.[1]

Diabetic Nephropathy

Renal disease is a leading cause of death and disability in diabetic patients. Approximately 50% of cases of end-stage renal disease in the United States are caused by diabetic nephropathy. The appearance of microalbuminuria correlates with the presence of coronary artery disease and retinopathy. Azotemia generally does not begin until 10 to 15 years after the diagnosis of diabetes. The progression of renal disease is accelerated by hypertension. Meticulous control of diabetes can reverse microalbuminuria and may slow the progression of nephropathy. Blood pressure should be aggressively managed; angiotensin-converting enzyme inhibitors are effective in controlling hypertension and lowering microalbuminuria. Chronic hemodialysis and renal transplantation are unfortunate endpoints for many diabetic patients with renal disease.

Retinopathy

Diabetes is a leading cause of adult blindness in the United States. Approximately 11% to 18% of all diabetic patients have treatable diabetic retinopathy, ranging from mild to severe, and manifested in many forms. The severity of diabetic retinopathy is clearly related to the quality of glycemic control. Background retinopathy is found in most patients with prolonged diabetes and is characterized by microaneurysms, small vessel obstruction, cotton wool spots, soft or hard exudates, and macular ischemia. Proliferative retinopathy defines an entity of new vessel formation and scarring, as well as associated vitreal hemorrhage and retinal detachment. The diabetic patient may present with complaints ranging from the acute blurring of vision to sudden unilateral or even bilateral blindness. Less often, diabetic patients have more gradual vision loss caused by the common senile cataract (or snowflake cataract), which may disappear as the hyperglycemia is corrected. Diabetic patients with retinopathy should be referred to an ophthalmologist. Even in those with normal vision, ophthalmologic procedures may limit visual loss or prevent crises such as neovascular glaucoma.

Neuropathy

Autonomic and peripheral neuropathies are well-known complications of diabetes. The prevalence of peripheral neuropathy ranges from 15% to 60%. The cause of the neuropathy is not clearly understood, but studies have suggested several factors in its development, including the effects of diabetic vascular disease on the vasa nervorum. Neurologic manifestations of diabetes may regress with improved glycemic control.

Several distinct types of neuropathy have been recognized in diabetes.[20] Peripheral symmetric neuropathy is a slowly progressive, primary sensory disorder manifested bilaterally with anesthesia, hyperesthesia, or pain. The pain is often severe and worse at night. It affects the upper and lower extremities, although the lower extremities and distal most sections of the involved nerves are most often affected. There may be a motor deficit as well. The pain may be very difficult to control; opioid analgesics have been used, but nonopioid medications such as gabapentin, pregabalin, and amitriptyline are preferred. Nortriptyline has been used, but the effects seem to dissipate after about 3 months of use. Pregabalin seems to hold the most promise when used at higher dosages (up to 600 mg/day). Duloxetine at a dosage of 60 mg/day is also effective. Both pregabalin and duloxetine achieve significant pain control in at least 50% of patients. Gabapentin, 300 mg tid, has some efficacy, achieving significant pain relief in about one-third of patients; amitriptyline 25 mg daily demonstrates similar results, though if there is no improvement after 5 to 7 days, any further efficacy is unlikely. N-methyl-D-aspartate receptor (NMDAR) antagonists such as memantine and dextromethorphan have shown promise in reducing pain and hyperalgesia in diabetic neuropathy.[21] A reasonable approach for the emergency clinician is the initiation of duloxetine or pregabalin, with the understanding that it may take several days for a peak effect to be reached.[20]

Mononeuropathy, or mononeuropathy multiplex, affects motor and sensory nerves, generally one nerve at a time. The onset is rapid, with wasting and tenderness of the involved muscles. There may be a sudden onset of wrist drop, foot drop, or paralysis of cranial nerves III, IV, and VI. Diabetic mononeuropathies may be most bothersome at night and generally resolve in a few months. Diabetic truncal mononeuropathy occurs rapidly in a radicular distribution. In contrast to other mononeuropathies, it is primarily, if not exclusively sensory. If it causes pain, it may mimic that of a myocardial infarction or acute abdominal inflammation. Whereas diabetic mononeuropathy is often the first indication of diabetes, truncal mononeuropathy is more often found in known diabetic patients. Management is similar to other diabetic neuropathies, with the exception of CN III palsy, which is usually expectant management.

Autonomic neuropathy occurs in many forms. Neuropathy of the GI tract, with resultant gastroparesis, is manifested by difficulty in swallowing, delayed gastric emptying, constipation, or nocturnal diarrhea. Impotence and bladder dysfunction or paralysis may occur. Orthostatic hypotension, syncope, and even cardiac arrest have resulted from autonomic neuropathy. Diabetic diarrhea responds to diphenoxylate and atropine, loperamide, or clonidine. There are small case series that also describe success using 5HT3 receptor antagonists successfully as well. Orthostatic hypotension is treated by sleeping with the head of the bed elevated, avoidance of sudden standing or sitting, and use of full-length elastic stockings. For gastroparesis, metoclopramide is recommended for its prokinetic and antiemetic properties, though caution must be taken with prolonged use due to the risk of tardive dyskinesia. Many patients with gastroparesis present with abdominal pain; opioids are not recommended for this group due to the risk of worsening dysmotility of the GI tract. In patients with acute presentations of pain and vomiting due to gastroparesis, intravenous haloperidol has shown effectiveness in a few small trials.

The Diabetic Foot

Approximately 20% of hospitalizations in diabetic patients are related to foot problems.[17] Sensory neuropathy, ischemia, and infection are the principal contributors to diabetic foot disease. Loss of sensation leads to pressure necrosis from poorly fitting footwear and small wounds going unnoticed. The most common cause of injury is pressure on plantar bone prominences. All neuropathic foot ulcers should be assessed for infection, devitalized tissue débrided, and radiographs obtained to evaluate for the presence of foreign bodies, soft tissue gas, or bone abnormalities (see Chapter 126).[19]

Not all ulcers are infected. Infection is suggested by local inflammation or crepitation. Conversely, some uninflamed ulcers are associated with underlying osteomyelitis. Most mild infections are caused by gram-positive cocci, such as *Staphylococcus aureus* or streptococci, and may be treated with oral antibiotics with activity against gram-positive

TABLE 115.2 Common Serious Infections in Diabetics and Their Antimicrobial Therapy

Infectious Condition	Antimicrobial Therapy
Diabetic foot infection	Mild—consider trimethoprim-sulfamethoxazole, 800/160 bid or clindamycin 300 mg q6h Moderate to severe—piperacillin-tazobactam (Zosyn), 3.375 g IV q6h and vancomycin, 15 mg/kg IV q12h
Malignant otitis externa	Oral—ciprofloxacin, 500 mg PO bid for 10–14 days IV—ceftazidime, 2 g IV q8h ± gentamicin, 2 mg/kg IV q8h
Mucormycosis	Amphotericin B, 1–1.5 mg/kg/day Posaconazole, 400 mg bid
Mucocutaneous candidiasis	Ketoconazole, 200 mg PO daily; may need several weeks of therapy
Nonclostridial gas gangrene (including Fournier's)	Clindamycin, 600 mg q6h + third-generation cephalosporin + vancomycin, 15 mg/kg q12h

organisms, such as trimethoprim-sulfamethoxazole, 800/160 mg bid, a first-generation cephalosporin such as cephalexin, 500 mg qid, or clindamycin, 300 mg qid. A strict non-weight-bearing regimen, meticulous wound care, and daily follow-up are also vitally important to wound healing. This approach may not be possible when patients do not have adequate home support or do not have ready access to follow-up care.

Deeper, limb-threatening infections—as evidenced by full-thickness ulceration, cellulitis more than 2 cm in diameter, with or without lymphangitis, bone or joint involvement, or systemic toxicity—are usually polymicrobial in origin and caused by aerobic gram-positive cocci, gram-negative bacilli, and anaerobes (see Chapter 125, Bone and Joint Infections). These patients require hospitalization and, after culture, broad-spectrum IV empirical antimicrobial therapy (Table 115.2). Additional measures include strict non-weight-bearing status, tight glycemic control, early surgical intervention for débridement, and meticulous wound care. Occult osteomyelitis should be considered in all cases of neuropathic ulceration.[19] Hyperbaric oxygen has been shown to have some efficacy in treating complicated infections, especially with anaerobic organisms. Up to one-third of patients eventually undergo amputation.

Infections

Diabetic patients are more susceptible to complications of infections because of their inability to limit microbial invasion with effective polymorphonuclear leukocytes and lymphocytes. They have an increased incidence of extremity infections and pyelonephritis compared with the general population. In addition, they are particularly susceptible to certain other infections, such as tuberculosis, mucocutaneous candidiasis, intertrigo, mucormycosis, soft tissue infections, nonclostridial gas gangrene, Fournier's gangrene, osteomyelitis, and malignant *Pseudomonas* otitis externa (see Table 115.2). Glycemic control, and hospitalization are usually required.

Cutaneous Manifestations

Dermal hypersensitivity is manifested by pruritic erythematous indurations that occur at insulin injection sites. The declining prevalence of this condition has paralleled the improved purification of insulin. Similarly, insulin lipoatrophy is subcutaneous depressions at injection sites and seems to be a result of insulin impurities. Although lipoatrophy is more common than dermal hypersensitivity, its prevalence has also declined sharply because of improved insulin preparations. Insulin lipohypertrophy is manifested by raised areas of subcutaneous fat deposits at insulin injection sites. These lesions generally reflect the failure of the patient to rotate injection sites adequately. They resolve spontaneously over months if insulin injection is avoided in the affected areas and sites are properly rotated.

Insulin pumps are often associated with localized skin problems, usually a reaction to the tape securing the tubing and needles. On occasion, sensitivity to the catheters is seen. Skin infections at the site of injection are the most common complication of insulin pumps. A few patients have been noted to have hard nodules at the injection site. The cause of these nodules is uncertain.

Diabetic patients who use oral hypoglycemic agents may have rashes associated with these medications. After consumption of ethanol, approximately 38% of type 2 patients taking chlorpropamide exhibit a flush consisting of redness of the face and neck and a sense of warmness or burning. Patients may demonstrate urticaria in response to insulin and oral hypoglycemics.

Skin Conditions

Diabetic skin conditions include fungal infections, acanthosis nigricans, necrobiosis lipoidica diabeticorum, xanthoma diabeticorum, bullosis diabeticorum, and diabetic dermopathy.

Acanthosis Nigricans. This is characterized by a velvety, brown-black thickening of the keratin layer, most often in the flexor surfaces. It is the cutaneous marker for a group of endocrine disorders with insulin resistance.

Necrobiosis Lipoidica Diabeticorum. This begins as erythematous papular or nodular lesions, usually in the pretibial area but in other areas as well. The early lesions may contain telangiectasias. These lesions spread and frequently form a single pigmented area of atrophic skin, often with a yellow and sometimes ulcerated center and an erythematous margin. A history of previous trauma is sometimes found.

Xanthoma Diabeticorum. These lesions are evidence of the hyperlipidemia associated with diabetes, similar to the xanthoma found in nondiabetic hyperlipidemic patients. Xanthomas have an erythematous base and a yellowish hue.

Bullosis Diabeticorum. This is a rare occurrence. Bullae are usually filled with a clear fluid and are most often found on the extremities, especially the feet. The fluid is occasionally slightly hemorrhagic. The bullae usually heal spontaneously without scarring.

Diabetic Dermopathy. Also known as skin spots, this is the most common skin finding in diabetes. It arises as discrete, depressed, and brownish lesions generally less than 15 mm in diameter and found in the pretibial area.

Impetigo or Intertrigo. Resistant, aggressive impetigo or intertrigo may suggest diabetes.

Diabetes Disposition

The decision to admit or discharge a diabetic patient depends on multiple factors. Primary considerations include the severity of illness,

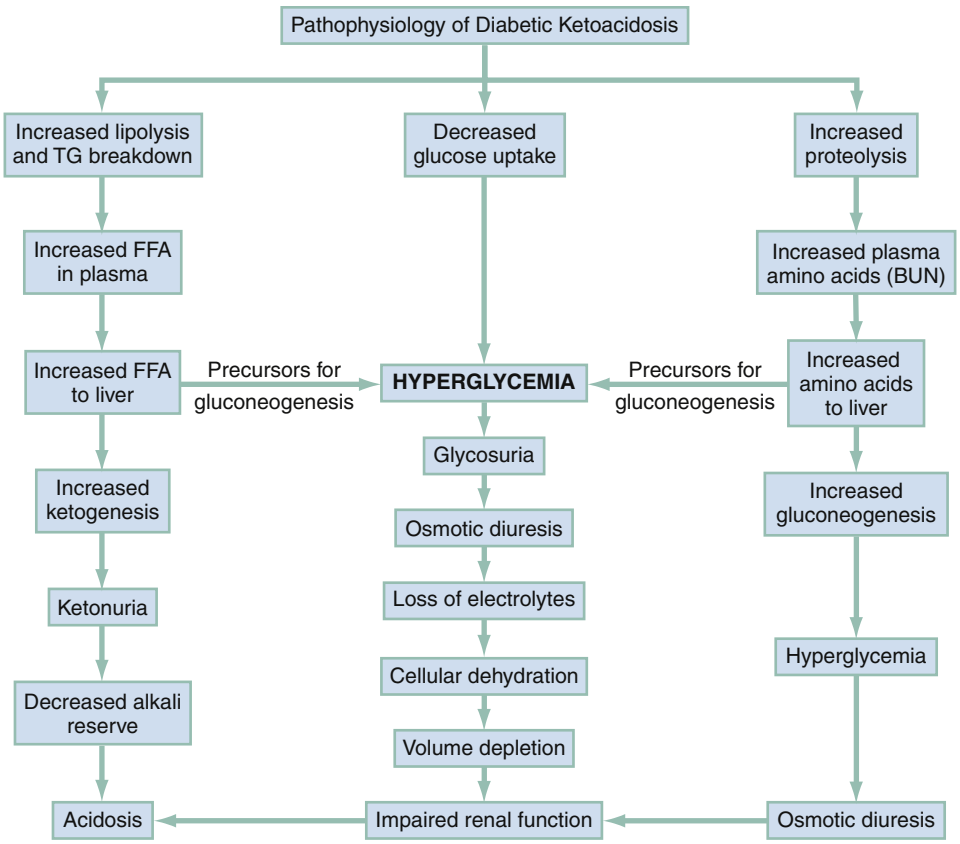

Fig. 115.1 Syndrome of Diabetic Ketoacidosis. *BUN,* Blood urea nitrogen; *FFA,* free fatty acids; *TG,* total glucose concentration.

whether this is a new diagnosis (where teaching, obtaining supplies, diabetic lifestyle education, and possibly insulin titration are needed) or an established diagnosis. Issues such as the ability to obtain medications and diabetic supplies and the ability to manage diabetes at home (particularly as relates to the measurement of blood glucose and insulin administration, which may be difficult in the elderly or those with low vision) are additional factors. Even in the absence of other complicating factors, such as DKA or infection, admission may be necessary for both achieving glycemic control and developing an appropriate outpatient plan for diabetes management. The elderly, socioeconomically disadvantaged populations, uninsured persons, and those with mental illness are at particular risk. Recent significant price increases for insulin have compelled many people with diabetes to forgo this part of their therapy. The mortality and morbidity rate from diabetes is also substantially higher in chronically underserved populations, such as African Americans; the rates of death, kidney disease, and amputations are all much higher in African-Americans as compared to Caucasians. African Americans have more than twice the incidence of diabetes compared to Caucasians (11.8 vs. 5.7) and are 2.3 times more likely to die from the disease as Caucasians.

DIABETIC KETOACIDOSIS

Foundations

Pathophysiology

DKA is a syndrome in which insulin deficiency and glucagon excess combine to produce a hyperglycemic, dehydrated, acidotic patient with profound electrolyte imbalances. All derangements producing DKA are interrelated and based on insulin deficiency (Fig. 115.1). DKA may be caused by the cessation of insulin intake or by physical or emotional stress, despite continued insulin therapy. The effects of insulin deficiency may be mimicked in peripheral tissues by a lack of insulin receptors or insulin sensitivity at receptor or post-receptor sites. When the hyperglycemia becomes sufficiently marked, the renal threshold is surpassed, and glucose is excreted in the urine. The hyperosmolarity produced by hyperglycemia and the dehydration are the most important determinants of the patient's mental status.[16]

Glucose in the renal tubules draws water, sodium, potassium, magnesium, calcium, phosphorus, and other ions from the circulation into the urine. This osmotic diuresis, combined with poor intake and vomiting, produces the profound dehydration and electrolyte imbalance associated with DKA (Table 115.3). Exocrine pancreatic dysfunction closely parallels endocrine beta-cell dysfunction, producing malabsorption that further limits the body's intake of fluid and exacerbates electrolyte loss.

In 95% of patients with DKA, the total sodium level is normal or low. Potassium, magnesium, and phosphorus deficits are also usually marked. As a result of acidosis and dehydration, however, the initially reported serum values for these electrolytes are often higher than actual body stores.

The cells, unable to receive fuel substances from the circulation, act as they do in starvation from other causes. They decrease amino acid uptake and accelerate proteolysis so that large amounts of amino acids are released to the liver and converted to two-carbon fragments.

Adipose tissue in the patient with DKA fails to clear the circulation of lipids. Insulin deficiency results in the activation of a hormone-sensitive lipase that increases circulating free fatty acid (FFA) levels. Long-chain FFAs, now circulating in abundance as a result of insulin deficiency, are partially oxidized and converted in the liver to acetoacetate and β-hydroxybutyrate. Despite the increased pathologic

TABLE 115.3 Average Fluid and Electrolyte Deficits in Severe Diabetic Ketoacidosis[a]

Weight	Water (mL/kg)	Sodium (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)	Phosphorus (mEq/L)
≤10 kg	100–120	8–10	5–7	6–8	3
10–20 kg	80–100	8–10	5–7	6–8	3
≥20 kg	70–80	8–10	5–7	6–8	3

[a]Per kilogram of body weight.

production of ketones, the body acts as it does in any form of starvation to decrease the peripheral tissue's use of ketones as fuel. The combination of increased ketone production with decreased ketone use leads to ketoacidosis.

Acidosis plays a prominent role in the clinical presentation of DKA. The acidotic patient attempts to increase lung ventilation to rid the body of excess acid with Kussmaul breathing. Bicarbonate is consumed in the process. Acidosis compounds the effects of ketosis and hyperosmolality to depress mental status directly.

Acidemia is not invariably present, even with significant ketoacidosis. Ketoalkalosis has been reported in diabetic patients vomiting for several days and in some with severe dehydration and hyperventilation. The finding of alkalemia, however, should prompt consideration of alcoholic ketoacidosis, in which alkalemia is much more common.

DKA most commonly occurs in patients with type 1 diabetes and is associated with inadequate administration of insulin, infection, or myocardial infarction. DKA can also occur in type 2 diabetics and may be associated with any type of stress, such as sepsis or GI bleeding. Approximately 25% of all episodes of DKA occur in patients whose diabetes was previously undiagnosed.

Clinical Features

Clinically, most patients with DKA complain of a recent history of polydipsia, polyuria, polyphagia, visual blurring, weakness, weight loss, nausea, vomiting, and abdominal pain. Approximately 50% of these patients, especially children, report abdominal pain. In children, this pain is usually idiopathic and probably caused by gastric distention or stretching of the liver capsule; it resolves as the metabolic abnormalities are corrected. In adults, however, abdominal pain more often signifies actual abdominal disease that may be triggering the DKA.

Physical examination may or may not demonstrate a depressed sensorium. Typical findings include tachypnea with Kussmaul breathing, tachycardia, frank hypotension or orthostatic blood pressure changes, odor of acetone on the breath, and signs of dehydration. An elevated temperature is rarely caused by DKA itself and suggests an inciting infection.

Differential Diagnosis

Alcoholics, especially those who have recently abstained from drinking, with Kussmaul's breathing, fruity odor to the breath, and acidemic blood gas values may have alcoholic ketoacidosis. These patients may be euglycemic or hypoglycemic, and a large part of their acidosis is often caused by the unmeasured β-hydroxybutyric acid. Alcoholic ketoacidosis accounts for approximately 20% of all cases of ketoacidosis. Ketoacidosis can also develop with fasting, commonly in the third trimester of pregnancy and in nursing mothers who do not eat.

The differential diagnosis for DKA is broad and includes any entity that may cause elevated anion gap acidosis, ketosis, or both. The presence of DKA should not exclude investigation for other causes of anion gap metabolic acidosis, such as sepsis, poisoning, or lactic acidosis, because physiologic stress from one of these other causes can precipitate DKA.

TABLE 115.4 Typical Laboratory Values in Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar State

	DKA	HHS
Glucose (mg/dL)	>350	>700
Sodium (mEq/L)	Low 130s	140s
Potassium (mEq/L)	≈4.5–6.0	≈5
Bicarbonate (mEq/L)	<10	>15
Blood urea nitrogen (mg/dL)	25–50	>50
Serum ketones	Present	Absent

DKA, Diabetic ketoacidosis; *HHS,* hyperglycemic hyperosmolar state.

Diagnostic Testing

Initial tests allow preliminary confirmation of the diagnosis and initiation of therapy (Table 115.4).[22] Subsequent tests are carried out to determine more precisely the degree of dehydration, acidosis, and electrolyte imbalance and reveal the precipitant of DKA.

Laboratory studies should include serum glucose, electrolyte, and venous blood pH. Although serum ketoacid levels are frequently measured, they are not necessary to diagnose DKA and may be elevated in non-DKA states (e.g., starvation ketosis from inadequate utilization of glucose stores) or dehydration. If determination of the pH is the sole concern, venous blood gas samples correlate well with arterial pH and are preferable as they are less invasive and have a lower complication rate than arterial sampling. If there is concern about the degree of respiratory compensation and better assessment of ventilation is required, then arterial samples should be obtained.

Blood gas measurement usually reveals a low pH, with the aforementioned rare exception of a concomitant alkalemia, resulting in a pseudo-normalization of the pH. Metabolic acidosis with an anion gap is primarily the result of elevated plasma levels of acetoacetate and β-hydroxybutyrate, although lactate, FFAs, phosphates, volume depletion, and several medications may also contribute. Rarely, a well-hydrated patient with DKA may have a pure hyperchloremic acidosis with no anion gap if they have been aggressively rehydrated with normal saline. Again, although rare, there have been case reports of a normal anion gap in a patient with DKA. This can occur with vomiting sufficient to cause a concomitant metabolic alkalosis, resulting in pH and bicarbonate levels in the normal range.[22]

Knowledge of the relationship between the rise in anion gap (delta AG) and the fall in bicarbonate (delta HCO_3), or delta gap (delta AG-delta HCO_3), can delineate the existence of a mixed acid-base disorder. A delta gap greater than + 6 indicates a concomitant metabolic alkalosis, and a delta gap less than -6 indicates a concomitant hyperchloremic metabolic acidosis. Winter's formula (expected $Paco_2$ = [1.5 × serum HCO_3^-] + [8 ± 2]) can be applied to determine if there is appropriate respiratory compensation or the presence of multiple acid-base disorders.

The glucose level is usually elevated above 350 mg/dL; however, euglycemic DKA (blood glucose level ≤ 300 mg/dL) has been reported in up to 18% of patients. The incidence of euglycemic DKA may be higher in patients treated with SGLT2 inhibitors.

If an immediate potassium level is not available through point-of-care testing or blood gas analysis, an electrocardiogram can reveal signs of hyperkalemia or hypokalemia. Initial serum potassium levels are typically normal or high in DKA due to intracellular potassium shifting out of cells in exchange for elevated serum hydrogen ions. However, as potassium is lost in the urine, the total body potassium usually declines by several hundred milliequivalents. This, in combination with the insulin doses administered in DKA, can result in life-threatening hypokalemia. A basic metabolic panel should be obtained to evaluate for an anion gap, potassium and glucose levels, and renal function. Because magnesium deficits are common in DKA, we recommend determining these levels as well. Urinalysis, in addition to the presence of ketones, may also help confirm a urinary tract infection as a precipitant of DKA. Whether to obtain blood or urine cultures should be determined by the clinical picture.

The serum sodium level is often misleading in DKA. It is often low in the presence of significant dehydration because it is strongly affected by hyperglycemia, hypertriglyceridemia, salt-poor fluid intake, increased GI and renal losses, and insensible loss. When hyperglycemia is marked, water flows from the cells into the vessels to decrease the osmolar gradient, thereby creating dilutional hyponatremia. Elevated lipid levels cause pseudohyponatremia by decreasing the fraction of serum that is water. Newer autoanalyzers remove triglycerides before the assay is performed, thus eliminating this artifact. The true value of the sodium level may be approximated by adding 1.6 mEq/L to the sodium value on the laboratory report for every 100-mg/dL glucose above the norm. Thus, if the laboratory reports a serum sodium level of 130 mEq/L and blood glucose level of 700 mEq/L, the corrected total serum sodium level is 139.6 mEq/L.

Acidosis and the hyperosmolarity induced by hyperglycemia shift potassium, magnesium, and phosphorus from the intracellular to extracellular space. Dehydration results in hemoconcentration, which contributes to normal or high initial serum potassium, magnesium, and phosphorus readings in DKA, even with profound total body deficits. The effect of acidosis on the serum potassium level determination can be corrected by subtracting 0.6 mEq/L from the laboratory potassium level for every 0.1-decrease in pH noted in the blood gas analysis. Thus, if the potassium level is reported as 5 mEq/L and the pH is 6.94, the corrected potassium value is 2 mEq/L, representing severe hypokalemia. As insulin is administered and the hydrogen ion concentration decreases, the patient needs considerable potassium replacement. The ADA algorithm for potassium repletion is helpful in guiding the management of potassium derangements. No conversion factor has been developed for the estimation of true magnesium levels, although initial values may be high.

All laboratory determinations must be interpreted with caution. Serum creatinine level determinations made by the autoanalyzer may be falsely elevated. Leukocytosis more closely reflects the degree of ketosis than the presence of infection. Only the elevation of band neutrophils has been demonstrated to indicate the presence of infection, with a sensitivity of 100% and specificity of 80% from a single retrospective study. Historically, the diagnosis of pancreatitis in a patient with DKA could be confounded by the elevation of amylase levels in DKA. Given the strength of the current literature demonstrating greater specificity of lipase for the diagnosis of pancreatitis, lipase (which must be three times the upper limit of normal to meet diagnostic criteria for pancreatitis) should be the blood test of choice if pancreatitis is a concern.

BOX 115.1 Summary of Treatment of Diabetic Ketoacidosis

Identify diabetic ketoacidosis—serum glucose, electrolyte, and ketone levels and arterial blood gas analysis; also obtain complete blood count with differential, urinalysis, chest radiograph, and electrocardiogram, if indicated.

Rehydrate.

- 1–2 L NS IV during 1–3 h
- Children—20 mL/kg NS during the first hour
- Correct electrolyte abnormalities.
- Sodium—correct with the administration of NS or 0.45% NS.
- Potassium—ensure adequate renal function. Add 20–40 mEq KCl to each liter (when serum potassium <5.5 mEq/L) of fluid until ketoacidosis is corrected and potassium is normalized. (Do not give insulin until potassium 3.3 mEq/L or greater.)
- Phosphorus—usually unnecessary to replenish.
- Magnesium—correct with 1–2 g $MgSO_4$. Serum magnesium levels may not correlate with body stores.

Supplement insulin.

- Insulin replacement—0.1 unit/kg/h regular insulin IV
- Change IV solution to D_5W/0.45% NS when glucose concentration is ≤300 mg/dL.

Correct acidosis.

- Administer IV fluids and insulin.

Search for and correct underlying precipitant.

Monitor progress and keep meticulous flow sheets.

- Vital signs
- Fluid intake and urine output
- Serum glucose, K^+, Cl^-, HCO_3^-, CO_2, pH
- Amount of insulin administered

Admit to hospital or intensive care unit.

Consider outpatient therapy in children with a reliable caregiver

and

- Initial pH ≥ 7.35
- Initial HCO_3^- ≥ 20 mEq/L
- Can tolerate oral fluids
- Resolution of symptoms after treatment in the emergency department
- No underlying precipitant requiring hospitalization

NS, Normal saline.

Management

When possible, intubation should be avoided in the patient with DKA. Patients often have tremendous respiratory drive, and matching this minute ventilation with the ventilator can be challenging. The comatose DKA patient, especially if vomiting, requires intubation however. Once the patient is intubated, maintenance of hyperventilation prevents worsening acidosis. The patient in hypovolemic shock requires aggressive fluid resuscitation with isotonic crystalloids before vasopressors are used, and clinicians should consider other possible causes of shock (e.g., sepsis or myocardial dysfunction secondary to myocardial infarction). Bedside ultrasonography may be of benefit in excluding other causes of hypotension and evaluating the volume status of an individual patient. Although it is not routinely used in the ED setting, in cases in which the volume status is difficult to ascertain because of complex underlying physiologic derangements (e.g., congestive heart failure, renal failure), the rapid ultrasound for shock and hypotension examination (see Chapter e5) or invasive hemodynamic monitoring may guide fluid therapy.

When hyperglycemia, ketosis, and acidosis have been established, fluid, electrolyte, and insulin therapy should be initiated (Box 115.1).

Intravenous Fluids

The severely dehydrated adult patient is likely to have a fluid deficit of 3 to 5 L. No uniformly accepted formula exists for the administration of fluid in this disorder. If the patient is in hypovolemic shock, the isotonic crystalloid solution should be given as rapidly as possible in the adult or in boluses of 20 mL/kg in the child until a systolic pressure of 80 mm Hg is obtained. There is no consensus regarding the ideal fluid to use; concerns have been raised using large amounts of normal saline exacerbating metabolic acidosis. At least one small trial has studied the use of a balanced crystalloid solution (Plasmalyte) in DKA, with reports of more rapid restoration of normal physiologic parameters.[18]

In the adult who has marked dehydration in the absence of clinical shock or heart failure, 1 L of fluid may be administered in the first hour. In general, 2 L of fluid resuscitation during the first 1 to 3 hours is followed by a slower infusion of a hypotonic solution, such as 0.45% normal saline solution. DKA patients without extreme volume depletion may be successfully treated with a lower volume of IV fluid replacement. An initial bolus of 20 mL/kg during the first hour is the usual fluid resuscitation therapy for a child. The fluid rate should be adjusted according to age, cardiac status, and degree of dehydration to achieve a urine output of 1 to 2 mL/kg/h.

Fluid resuscitation alone may help lower hyperglycemia. Because a low level of circulating insulin may be present, increased perfusion may transport insulin to previously unreached receptor sites. In addition, a large volume of glucose may be cleared by the kidneys in response to improved renal perfusion. The mean plasma glucose concentration has been noted to drop by 18% after the administration of saline solution without insulin.[18]

Acidosis also decreases after fluid infusion because increased perfusion improves tissue oxygenation and diminishes lactate formation while increasing lactate clearance. Increased renal perfusion promotes renal hydrogen ion loss, and the improved action of insulin in the better-hydrated patient inhibits ketogenesis. Although fluid administration decreases the serum glucose concentration and improves acidosis, the underlying deficiency in DKA requires administration of insulin for the correction of ketoacidosis.

Potassium

Potassium replacement is invariably needed in DKA. The initial potassium level is often normal or high, despite a large deficit because of severe acidosis. Potassium levels often plummet with correction of acidosis and administration of insulin. Once potassium levels reach 5.0 to 5.5 mEq/L and the patient is making urine, potassium should be administered while monitoring renal function (Table 115.5).[18] In patients with relatively lower serum potassium concentration at presentation (3.3 to 5.0 mEq/L), hypokalemia may become life-threatening when insulin therapy is administered; therefore, IV administration of potassium in concentrations of 20 to 40 mEq/L should be given with insulin administration. In patients with hypokalemia (<3.3 mEq/L), insulin should only be initiated once potassium has been replaced to achieve levels of 3.3 mEq/L or higher. The primary rationale for such conservative recommendations regarding potassium administration is that serum levels do not correlate with total body stores in the DKA patient, and the potassium level can drop more rapidly than anticipated with insulin administration.

TABLE 115.5 American Diabetes Association Recommendations for Potassium and Phosphorus Repletion

Potassium <3.3 mEQ/L	Replete to >3.3 mEQ/L before starting insulin
Potassium 3.3–5.5 mEQ/L	Supplement potassium to maintain these levels while starting insulin
Potassium >5.5 mEQ/L	Do not start potassium supplementation until <5.5 mEQ/L
Phosphorous <1.0 mEQ/L	Initiate supplementation with potassium phosphate

It was once believed that there was always a phosphorus deficit in DKA. However, there is no significant evidence to support this practice, and only isolated case reports have supported concerns about clinically significant hypophosphatemia in DKA. If the measured serum phosphorus level is low, it should be replaced with potassium phosphate.

Insulin

DKA cannot be reversed without insulin, and insulin therapy should be initiated as soon as the potassium level is determined to be adequate or potassium has been repleted. No randomized trials have compared insulin with placebo or other therapies for DKA. However, the mortality from DKA was 90% in historical controls before the development of exogenous insulin and 50% after insulin was introduced. With appropriate supportive therapy, mortality has reached the current levels of less than 10%.[11]

Although the dosing of insulin infusions has been established, an IV bolus before the infusion is no longer recommended. More recently, in selected patients with mild DKA, the subcutaneous or intramuscular administration of insulin has been proven safe and effective as IV administration of insulin. In selected cases with good outpatient follow-up, treatment of DKA with intermittent bolus dosing of regular insulin by the subcutaneous or intramuscular route without admission has also been shown to be safe. Such a strategy requires a well-hydrated, mildly acidemic patient, well versed in disease management, who has excellent outpatient follow-up. Poor perfusion may hamper the absorption of intramuscular or subcutaneous insulin, resulting in erratic absorption, making IV infusion the route of choice in sicker DKA patients.[5] The current initial therapy of choice, as recommended by the ADA, is regular insulin infused at 0.1 units/kg/h up to 5 to 10 units/h, mixed with IV fluids.

Children with DKA pose additional management challenges. Whereas the general principles of fluid and electrolyte repletion in concert with insulin therapy remain the same, controversy exists about the dosing and administration of fluids and insulin because of concerns related to the risk of inducing cerebral edema in children with DKA. Despite concerns about this complication, it remains rare, with an overall incidence of 1% in pediatric DKA patients. Virtually all current evidence supporting the contention that higher doses of insulin and aggressive fluid resuscitation contribute to the development of cerebral edema has come from retrospective reviews and small case studies. A recently completed large prospective study of 1255 pediatric DKA patients showed a similar risk of cerebral edema irrespective of restrictive or permissive fluid resuscitation.[15] Similarly, retrospective reviews of a large number of children with DKA did not show any significant difference in the development of cerebral edema based on insulin infusion rates. The degree of acidosis or uremia seem to be the best individual predictors of cerebral edema, as opposed to any specific fluid or insulin regimen, and earlier concerns about fluid resuscitation causing cerebral edema may have been the result of sicker patients getting more fluids (e.g., confounding by indication, since sicker patients are more likely to develop cerebral edema). Cerebral edema has a significant mortality rate, and patients should be carefully monitored and receive mannitol at the earliest suspicion of cerebral edema.

Because the half-life of IV regular insulin is 3 to 10 minutes, insulin should be administered IV by infusion rather than repeated bolus. When the blood glucose concentration has dropped to 250 to 300 mg/dL,

adding dextrose to the IV fluids reduces the risk of iatrogenic hypoglycemia and rapid shifts in osmolarity. In patients with euglycemic DKA, dextrose should be added to the IV fluids at the start of insulin therapy.

Insulin resistance rarely occurs in diabetic patients and requires an increase in dosage for a satisfactory response. Resistance may be caused by obesity or accelerated insulin degradation.

Magnesium

Magnesium deficiency is a common problem in patients with DKA without renal disease. Both the initial pathophysiologic process and therapy for DKA induce profound magnesium diuresis. Magnesium deficiency may exacerbate vomiting and mental changes, promote recalcitrant hypokalemia and hypocalcemia, or induce fatal cardiac dysrhythmia. If there is a concern for hypomagnesemia, we recommend adding magnesium to the IV fluids, with the typical adult patient requiring 1 to 3 g for repletion.

Sodium Bicarbonate

In the past, sodium bicarbonate was recommended for severely acidemic patients (pH < 7.0). However, research has demonstrated worse outcomes for patients receiving bicarbonate, including exacerbation of electrolyte deficits such as hypokalemia, delaying clearing of ketosis, paradoxical worsening of cerebrospinal fluid (CSF) acidosis due to suppression of respiratory compensations, and preferential permeability of the blood-brain barrier to CO_2. Unless needed to stave off impending cardiac arrest in a severely acidemic patient, we do not recommend routine bicarbonate administration. If a severely acidemic patient requires endotracheal intubation, the use of a bolus of bicarbonate in the immediate pre-intubation period may reduce the risk of cardiovascular collapse from a precipitous decline in pH after induction during rapid-sequence intubation; this recommendation is based on expert opinion as opposed to any specific clinical trials.[18]

Complications

The precipitating causes of DKA may have associated morbidity and mortality rates equal to or worse than those of DKA itself. These include iatrogenic causes, infection, and myocardial infarction. Morbidity in DKA is largely iatrogenic—hypokalemia from inadequate potassium replacement, hypoglycemia from inadequate glucose monitoring, failure to replenish glucose in IV solutions when the serum glucose concentration drops below 250 to 300 mg/dL, alkalosis from overaggressive bicarbonate replacement, and pulmonary edema from overaggressive hydration.

The mortality in treated DKA is approximately 5% to 7%. The primary causes of death remain infection, especially pneumonia, arterial thromboses, and shock. The decrease in the mortality rate over the last several decades has demonstrated the importance of appropriate therapy. Cerebral edema remains a rare but important cause of morbidity and mortality in children with DKA.

Cerebral edema should be considered when the patient in DKA becomes altered or lapses into a coma after the reversal of acidosis. Cerebral edema generally occurs 6 to 10 hours after the initiation of therapy, often without warning signs, and the associated mortality rate is 90%.[15] Cerebral edema is less common in adults or children older than 5 years and appears to be most strongly associated with severity of illness (acidemia and azotemia), although subclinical cerebral edema in children is probably common. Furthermore, subclinical cerebral edema may precede or follow the onset of therapy, raising the question of whether it is caused by therapy or is simply a manifestation of the basic pathophysiologic mechanisms of DKA. The treatment of cerebral edema is largely supportive. No large clinical trials have identified effective treatment, although some authors recommend mannitol. Steroids have not been shown to be effective.

Diabetic Ketoacidosis Disposition

Most patients with DKA require hospital admission, often to the intensive care unit. The use of observation units to manage uncomplicated DKA in selected patients has been shown to be effective (see Chapter e6). All pregnant diabetic patients in DKA require admission and consultation with an endocrinologist and obstetrician specializing in the care of high-risk pregnancies. Some children (initial pH ≥ 7.35; bicarbonate ≥ 20 mEq/L) who can tolerate oral fluids after 3 or 4 hours of treatment may be discharged home with a reliable caregiver. Patients who have mild DKA may be treated as an outpatient if the patient or parent can understand discharge instructions and are able to return, underlying causes do not require inpatient therapy, and close follow-up is confirmed.

HYPERGLYCEMIC HYPEROSMOLAR STATE

Foundations

HHS represents a syndrome of acute diabetic decompensation characterized by marked hyperglycemia, hyperosmolarity, dehydration, and decreased mental function that may progress to frank coma. The terminology has changed recently from the former term *hyperglycemic hyperosmolar nonketotic coma* because some patients have mild degrees of ketosis, and coma is not universally present.[4,18] Ketoacidosis is generally minimal or absent, although metabolic acidosis from another source, such as lactic acidosis from sepsis or uremia from acute renal failure, may be present. Focal neurologic signs may be present, or there may be a global encephalopathy. DKA and HHS may occur together.

Pathophysiology

As with DKA, the pathophysiologic mechanisms of HHS vary with the particular patient. Because most patients with HHS are older adults, decreased renal clearance of glucose produced by the decline of renal function with age often contributes to the illness. Decreased insulin action results in glycogenolysis, gluconeogenesis, and decreased peripheral uptake of glucose. The hyperglycemia pulls fluid from the intracellular into the extracellular space, transiently maintaining adequate perfusion. Soon, however, this fluid is lost in a profound osmotic diuresis, limited finally by hypotension, decreased renal perfusion, and a subsequent drop in the GFR. The urine is extremely hypotonic, with a urine sodium concentration between 50 and 70 mEq/L, compared with 140 mEq/L in extracellular fluid. This hypotonic diuresis produces profound dehydration, leading to hyperglycemia, hypernatremia, and associated hypertonicity. Often, the patient is unable to take in adequate fluids because of stroke, Alzheimer disease, or other diseases, greatly exacerbating the dehydration.

The reason for the absence of ketoacidosis in HHS is unknown. FFA levels are lower than in DKA, thus limiting the substrates needed to form ketones. The most likely reason for the blunted counterregulatory hormone release and lack of ketosis seems to be the continued secretion of tiny amounts of insulin that block ketogenesis.

HHS is a syndrome of severe dehydration that results from a sustained hyperglycemic diuresis in which the patient is unable to drink sufficient fluids to offset the urinary losses. The full-blown syndrome does not usually occur until volume depletion has progressed to the point of decreased urine output.

HHS is most common in geriatric patients with type 2 diabetes but has been reported in children with type 1 diabetes. HHS may occur in

patients who do not have diabetes, especially after burns, parenteral hyperalimentation, peritoneal dialysis, or hemodialysis.

Clinical Features

The prodrome of HHS is significantly longer than that of DKA. Clinically, extreme dehydration, hyperosmolarity, volume depletion, and CNS findings predominate. If they are awake, patients may complain of fever, thirst, polyuria, or oliguria. Approximately 20% of patients have no known history of type 2 diabetes. The most common associated diseases are chronic renal insufficiency, GI bleeding, gram-negative pneumonia, and gram-negative sepsis. Approximately 85% of patients have underlying renal or cardiac impairment as a predisposing factor. Arterial and venous thromboses are common and often complicate the picture.

The patient often exhibits orthostatic hypotension or frank hypotension, tachycardia, and fever, with signs of marked dehydration. The depression of the sensorium correlates directly with the degree and rate of development of hyperosmolarity. Some patients have a normal mental status. Neurologic issues are common in HHS. Although a decreased level of consciousness is the most common neurologic finding, seizures, stroke syndromes, and movement disorders have been reported in various case series. Whether HHS is the cause or result of these disorders is unclear, and there is no current evidence to recommend the prophylactic use of antiepileptics or antithrombotic agents in HHS patients.

Differential Diagnoses

The differential diagnosis of HHS is identical to that of DKA (Table 115.6). In addition, diabetic patients receiving chlorpropamide are subject to water intoxication with dilutional hyponatremia, which may be manifested as coma without acidosis that is clinically indistinguishable from HHS. The patient with HHS who has a sharply depressed sensorium may not be initially distinguishable from the patient with profound hypoglycemia. When the blood glucose concentration cannot be rapidly checked, the immediate administration of one ampule of $D_{50}W$ minimally worsens HHS and may be lifesaving for patients with hypoglycemia.

Diagnostic Testing

Laboratory findings usually reveal a blood glucose level above 600 mg/dL and serum osmolarity above 350 mOsm/L. The blood urea nitrogen concentration is invariably elevated. Although patients with HHS do not have ketoacidosis caused by diabetes, they may have a metabolic acidosis secondary to some combination of lactic acidosis, starvation ketosis, and retention of inorganic acids attributable to renal hypoperfusion.

The patient with HHS typically has a more profound electrolyte imbalance than the patient with DKA. Levels of potassium, magnesium, and phosphorus may seem initially high, even in the presence of a marked total deficit. In the absence of acidemia, however, the discrepancy between the initial electrolyte reading and body stores is less than that of DKA. Initial serum sodium readings are inaccurate because of hyperglycemia.

Management

The fluid, electrolyte, and insulin regimens for the initial resuscitation in HHS are subject to the same controversies as the therapies for DKA (see Box 115.1). There have been varying recommendations about which IV fluids to administer, generally based on calculations of water deficits. There have been no well-done randomized trials comparing isotonic versus hypotonic fluid resuscitation; isotonic crystalloid is recommended in the volume-depleted patient. Cerebral edema has been noted in isolated case reports in adults, especially with glucose levels above 700 mg/dL. An association between IV fluid resuscitation and cerebral edema has not been shown in the literature; previous reports of this association may be due to the confounder that sicker patients often receive more aggressive fluid resuscitation.

Intravenous Fluids

For patients in hypovolemic shock, an initial IV fluid infusion is given as rapidly as possible. Glucose should be added to resuscitation fluids when the blood glucose level drops below 300 mg/dL. Because many HHS patients are older adults with coexisting diseases, such as congestive heart failure and renal failure, noninvasive or invasive forms of hemodynamic monitoring may be required to guide fluid administration when there is clinical suspicion of pulmonary edema or volume overload.

Electrolytes

Measurement of serum electrolyte levels should be used to guide replacement in the HHS patient. In particular, because acidosis is generally less, potassium levels more accurately reflect total body stores than they do in DKA.

Insulin

The pathophysiologic mechanisms of HHS are different from those of DKA, and there is usually enough basal insulin function to prevent frank ketoacidosis. Therefore, a continuous IV insulin infusion is not required in these patients, as with DKA. However, there are times when

TABLE 115.6 Features Distinguishing Diabetic Ketoacidosis Versus Hyperglycemic Hyperosmolar State

DKA	HHS
• Typically type 1 diabetic patients • Metabolic acidosis present • Blood sugars typically >250 mg/dL, though occasionally can be lower (euglycemic DKA) • May have infection, trauma, myocardial ischemia as underlying triggers, or may be due to inadequate insulin administration • Associated with significant fluid deficits • Insulin and fluids required to correct • Occurs across the age spectrum (toddler to geriatric)	• Typically type 2 diabetic patients • Usually do not have metabolic acidosis as a result of glucose abnormality • Sugars typically markedly high (>500 mg/dL) • Infection most common underlying cause, but may have other etiologies (dehydration, ischemic event, etc.) • Associated with significant fluid deficits • While insulin and fluids may be given, treatment is directed at an underlying cause • Typically seen in geriatric population

DKA, Diabetic ketoacidosis; *HHS,* hyperglycemic hyperosmolar state.

the use of an IV insulin infusion may help lower the glucose concentration in a more controlled fashion, particularly in patients with very high glucose levels (>700 mg/dL) or those who are severely hypoperfused, in whom intramuscular or subcutaneous insulin absorption may be erratic. If an IV insulin infusion is used, it should be a rate similar to that for DKA (0.1 unit/kg/h).

Other Considerations

A search for the underlying precipitant of HHS should be pursued. Response to therapy should be followed in the manner described for patients in DKA. Phenytoin (Dilantin) is contraindicated for the seizures of HHS because it is often ineffective and may impair endogenous insulin release.[5] Admitted patients should be given low-dose subcutaneous heparin to lessen the risk of thrombosis, which is increased by the volume depletion, hyperviscosity, hypotension, and inactivity associated with HHS.

Acute Complications

Reasons for high morbidity and mortality rates are not always clear, but many patients with HHS are older adults who have underlying cardiac and renal disease. Pediatric HHS differs from adult HHS in that children have a much higher incidence of fatal cerebral edema. Other causes of morbidity and mortality are similar to those described for DKA. The mortality rate of treated HHS patients has been 40% to 70% in the past but now ranges from 8% to 25%.[1,22]

Hyperglycemic Hyperosmolar State Disposition

In general, patients with HHS require hospitalization for IV hydration, glucose control, and evaluation of precipitating and complicating conditions.

DIABETES IN PREGNANCY

Before the discovery of insulin in 1922, diabetes in pregnancy was associated with a fetal death rate of 60% to 72% and maternal morbidity of approximately 30%.[7] In 1977, a linear relationship between glycemic control and perinatal mortality was discovered. Strict metabolic control is now a goal in all diabetic pregnancies.[6]

Pregnant patients are at particular risk from DKA due to the impact on both maternal and fetal health. For a variety of reasons, pregnant women are predisposed to glucose intolerance and excess ketone production. Although uncommon, DKA may reduce fetal oxygen delivery and cause perinatal asphyxia. Severe ketoacidosis is associated with a 50% to 90% fetal mortality rate due to hypoperfusion of the placenta.[18] Cognitive deficits in the offspring have been associated with maternal ketonuria from any cause. Hypoglycemia is common in pregnancy, in part because of intensive insulin treatment to maintain euglycemia. The effects of hypoglycemia on the fetus are unclear.

HYPOGLYCEMIA

Foundations

Hypoglycemia is a common problem in patients with type 1 diabetes, especially if tight glycemic control is practiced; it is the most dangerous, acute complication of diabetes. The estimated incidence of hypoglycemia in diabetic patients is 9 to 120 episodes/100 patient-years. As significant efforts continue to keep fasting and postprandial glucose concentrations within the normal range, the incidence of hypoglycemia may increase. The most common cause of coma associated with diabetes is an excess of administered insulin with respect to glucose intake.[22] Severe hypoglycemia is usually associated with blood glucose levels below 40 to 50 mg/dL and impaired cognitive function.

Protection against hypoglycemia is normally provided by the cessation of insulin release and mobilization of counterregulatory hormones, which increase hepatic glucose production and decrease glucose use. Diabetic patients using insulin are vulnerable to hypoglycemia because of insulin excess and failure of the counterregulatory system.

Hypoglycemia has many causes, such as missing a meal (decreased intake), increased energy output (exercise), and increased insulin dosage. It can also occur in the absence of any precipitant. Oral hypoglycemic agents have also been implicated in causing hypoglycemia, both when taken therapeutically and as an agent of overdose.

Hypoglycemia without warning symptoms, or hypoglycemia unawareness, is a dangerous complication of type 1 diabetes and is probably caused by previous exposure to low blood glucose concentrations because even a single hypoglycemic episode can reduce neurohumoral counterregulatory responses to subsequent episodes. Other factors associated with recurrent hypoglycemic attacks include overaggressive or intensified insulin therapy, longer history of diabetes, autonomic neuropathy, and decreased epinephrine secretion or sensitivity.

The Somogyi phenomenon is a common problem associated with iatrogenic hypoglycemia in type 1 diabetic patients. Excessive insulin dosing results in an unrecognized hypoglycemic episode that usually occurs in the early morning while the patient is sleeping. The counterregulatory hormone response produces rebound hyperglycemia, evident when the patient awakens. Often, the patient and physician interpret this hyperglycemia as an indication to increase the insulin dosage, which exacerbates the problem. Instead, the insulin dosage should be lowered or the timing changed.

Clinical Features

Symptomatic hypoglycemia occurs in most adults below a blood glucose level of 40 to 50 mg/dL. The rate at which the glucose level decreases, however, and the patient's age, gender, size, overall health, and previous hypoglycemic reactions contribute to symptom development. Signs and symptoms of hypoglycemia are caused by excessive secretion of epinephrine and CNS dysfunction; these include sweating, nervousness, tremor, tachycardia, hunger, and neurologic symptoms, ranging from bizarre behavior and confusion to seizures and coma. In patients with hypoglycemia unawareness, the prodrome to marked hypoglycemia may be minimal or absent, and these individuals may rapidly become unarousable. They may have a seizure or show focal neurologic signs, which resolve with glucose administration.

Differential Diagnoses

Hypoglycemia in the nondiabetic patient may be classified as postprandial or fasting. The most common cause of postprandial hypoglycemia is alimentary hyperinsulinism, such as that seen in patients who have undergone gastrectomy, gastrojejunostomy, pyloroplasty, or vagotomy. Fasting hypoglycemia is caused when there is an imbalance between glucose production and use. The causes of inadequate glucose production include hormone deficiencies, enzyme defects, substrate deficiencies, severe liver disease, and drugs. Causes of overuse of glucose include the presence of an insulinoma, exogenous insulin, sulfonylureas, drugs, endotoxic shock, extrapancreatic tumors, and a variety of enzyme deficiencies.

Diagnostic Testing

The cardinal laboratory test for hypoglycemia determines the blood glucose concentration. It should be performed, if possible, before therapy is begun. As noted, POC fingerstick testing helpful in permitting rapid, reasonably accurate blood glucose level estimates before therapy.

Laboratory testing should address any suggested cause of the hypoglycemia, such as ethanol, other drug ingestion, sepsis, or acute kidney

injury causing decreased clearance of medications. If factitious hypoglycemia is suggested, testing for insulin antibodies or low levels of C peptide may be helpful. A patient who is surreptitiously administering exogenous insulin will have normal to low levels of C peptide and markedly elevated insulin levels.

Management

In alert patients with mild symptoms, oral consumption of sugar-containing foods or beverages is often adequate. In other patients, after blood is drawn for glucose determination, one to three ampules of $D_{50}W$ is administered IV while the patient's airway, breathing, and circulation are assessed and maintained. Augmentation of the blood glucose level by administration of an ampule of $D_{50}W$ may range from less than 40 mg/dL to more than 350 mg/dL. If alcohol use disorder is suggested, we recommend that thiamine be administered as well. In children younger than 8 years, providers should use $D_{25}W$ or $D_{10}W$. $D_{25}W$ may be prepared by diluting $D_{50}W$ 1:1 with sterile water. The dose is 0.5 to 1 g/kg body weight or 2 to 4 mL/kg when using $D_{25}W$. With recent shortages of $D_{50}W$, many emergency medical services (EMS) agencies and some hospitals have moved to the use of $D_{10}W$, giving boluses of up to 250 mL to achieve a similar glucose load to an ampule of $D_{50}W$.

If IV access cannot be rapidly obtained, 1 to 2 mg of glucagon may be given intramuscularly or subcutaneously. The onset of action is 10 to 20 minutes, and a peak response occurs in 30 to 60 minutes. It may be repeated as needed. Glucagon may also be administered IV; 1 mg has an effect similar to that of one ampule of $D_{50}W$. Glucagon is ineffective in causes of hypoglycemia resulting from absent glycogen, notably alcohol-induced hypoglycemia.

Families of type 1 diabetic patients are often taught to administer glucagon intramuscularly at home. Of the families so instructed, only 9% to 42% inject the glucagon when indicated. Intranasal glucagon has not been widely used. All patients with severe hypoglycemic reactions require aspiration and seizure precautions. Although the response to IV administration of glucose is generally rapid, older patients may require several days for complete recovery.

Treatment of hypoglycemia secondary to oral hypoglycemic agents depends on the agent. Metformin and the thiazolidinediones rarely cause significant hypoglycemia, whereas sulfonylureas, which are insulin secretagogues, can cause hypoglycemia. Sulfonylurea oral hypoglycemic agents pose particular problems because the hypoglycemia they induce tends to be prolonged and severe. Patients with an overdose of sulfonylurea hypoglycemic agents should be observed for a period of 24 hours if hypoglycemia recurs in the ED after management of the initial episode. Patients at risk for hypoglycemia from oral sulfonylureas include patients with impaired renal function, pediatric patients, and patients who are naïve to hypoglycemic agents. Although symptoms may occur after an overdose, several case reports in patients (e.g., with renal failure and pediatric patients) have described refractory hypoglycemia after ingestion of a single pill. One case series of pediatric patients presenting with sulfonylurea ingestion who were initially euglycemic demonstrated an average time to hypoglycemia of 8 hours.[22] However, in some patients, the onset of symptoms was delayed for up to 18 hours. As a result, we recommend 24 hours of observation for patients with known or suspected ingestion of hypoglycemic agents.

A patient with hypoglycemia from sulfonylureas, in addition to standard glucose replacement, frequently requires treatment with an agent to inhibit further insulin release, such as octreotide, a somatostatin analog. Several case series have described the use of octreotide in adult and pediatric patients suffering from sulfonylurea-induced hypoglycemia, frequently reporting successful results, with a significant decrease in the number of episodes of recurrent hypoglycemia. A randomized clinical trial has concluded that patients receiving octreotide had a decreased glucose supplementation requirement.[22] No single set protocol for use has been described; however, typical adult doses have ranged from 50 to 100 μg IV or subcutaneously every 12 hours, with pediatric dosages of 0.1 μg/kg IV or subcutaneously. Although experience thus far with octreotide has been positive, it does not obviate the need for prolonged observation and serial glucose level measurements.

Disposition

Type 1 diabetic patients with brief episodes of hypoglycemia uncomplicated by other conditions may be discharged from the ED if a cause of the hypoglycemia can be identified and corrected by instruction or medication. All patients should be given a meal before discharge to ensure their ability to tolerate oral feedings and to begin to replenish glycogen stores in glycogen-deficient patients. Patients who are discharged should receive short-term follow-up for ongoing evaluation. Patients with hypoglycemia caused by long-acting sulfonylurea medications should be observed in the hospital if they have recurrent hypoglycemia after a period of observation in the ED. Other agents, such as metformin, do not typically produce hypoglycemia, although they may have other issues, such as lactic acidosis, that may require admission.

The determination of inpatient (and if inpatient, type of bed, and monitoring required) versus outpatient evaluation of hypoglycemia in a nondiabetic patient should be based on the suggested cause and nature of the episode (i.e., factors such as severity, persistence, and recurrence).

CHAPTER 115: QUESTIONS AND ANSWERS

1. Which of the following statements regarding patients with impaired glucose tolerance is true?
- **a.** Spontaneous reversion to normal glucose tolerance is rare.
- **b.** The condition is associated with fewer complications than diabetes mellitus.
- **c.** The rate of decompensation to diabetes mellitus is greater than 10%/year.
- **d.** There is a predisposition to ketosis.

Answer: b. Patients with impaired glucose tolerance have a glucose level between normal and diabetic. They are at increased risk of cardiovascular disease and development of diabetes (1% to 5%/year), but it is not associated with the same degree of complications as with true diabetes. Many patients spontaneously develop normal glucose levels.

2. What percentage of adults with type 2 diabetes are obese?
- **a.** 40%
- **b.** 60%
- **c.** 80%
- **d.** 100%

Answer: d. Nonobese patients form a subgroup with a different disease, more similar to type 1 diabetes. Young people with maturity-onset diabetes often have an autosomal dominant inheritance, are nonobese, and have a relatively mild disease course.

3. A 56-year-old man with a 10-year history of type 2 diabetes and poor glucose control (HbA_{1c} = 10.7%) complains of constant burning pain in both feet. Which agent would be most appropriate to start in this patient for the initial management of his symptoms?
- **a.** Aspirin, 325 mg PO daily
- **b.** Naproxen, 500 mg bid
- **c.** Oxycodone/acetaminophen, 5/325 mg qid
- **d.** Pregabalin, 600 mg daily

Answer: d. Pregabalin in a dose of 600 mg daily gives pain relief in approximately 50% of patients with diabetic neuropathy. Duloxetine, 60 mg daily, achieves similar results. Gabapentin, 300 mg once a day up to tid, and amitriptyline, 25 mg daily, provide pain relief in approximately 33% of patients.

4. A 27-year-old juvenile-onset diabetic is brought by emergency medical services (EMS) for a hypoglycemic coma. Fingerstick glucose level is 30 mg/dL. The paramedics were not able to obtain intravenous (IV) access, and two immediate attempts at IV cannulation failed in the emergency department (ED). What should be the next step in the patient's management?
- **a.** Albuterol, 2.5 mg nebulized
- **b.** Central venous catheter placement, then $D_{50}W$ IV
- **c.** Epinephrine, 1 mg IV
- **d.** Glucagon, 2 mg intramuscularly

Answer: d. Intravenous dextrose (25 to 75 g for adults, 0.5to 1 g/kg for children) is preferable but, if unable to obtain IV access, administer glucagon, 1 or 2 mg intramuscularly (IM) or subcutaneously (SC; 0.025 to 0.1 mg/kg IM or SC in children). The onset of action is 10 to 20 minutes. It is ineffective in cases of glycogen absence, such as alcohol-induced hypoglycemia.

5. A 33-year-old juvenile-onset, insulin-dependent diabetic suddenly faints without prodrome or warning while walking through the ED. Relatives report that diabetes is his only past history. Which of the following findings is most likely?
- **a.** Autonomic neuropathy on later orthostatic testing
- **b.** Fingerstick glucose 27 mg/dL
- **c.** Hemoccult-positive stool
- **d.** Positive enzyme-linked immunosorbent assay (ELISA) D-dimer

Answer: b. Hypoglycemia without warning, or hypoglycemia unawareness, is a complication of type 1 diabetes caused by previous hypoglycemic episodes. A single hypoglycemic episode may blunt neurohormonal counterregulatory responses to later hypoglycemic episodes. Risk factors are overaggressive insulin therapy, longer history of diabetes, and autonomic neuropathy, which usually causes orthostasis on first standing or after being upright in a static position. These patients may become abruptly unarousable without warning.

CHAPTER 115: QUESTIONS AND ANSWERS—cont'd.

6. A 47-year-old man presents with hypoglycemia. He is a known type 2 diabetic on glyburide. Fingerstick glucose is 27 mg/dL. Twenty minutes after two ampules (50 g) of dextrose, his glucose level is 29 mg/dL. Which of the following agents is indicated?

a. Adenosine
b. Epinephrine
c. Hydrocortisone
d. Octreotide

Answer: d. A patient with hypoglycemia from sulfonylureas, in addition to standard glucose replacement, frequently requires treatment with an agent to inhibit further insulin release, such as octreotide (a somatostatin analog). Sulfonylureas are insulin secretagogues.

7. What is the most important determinant of mental status in a patient with diabetic ketoacidosis (DKA)?

a. Acidemia
b. Calcium level
c. Glucose level
d. Osmolarity

Answer: d. The hyperosmolarity produced by dehydration and hyperglycemia is the most important determinant of mental status during an episode of DKA.

Rhabdomyolysis

Brit Long and Alex Koyfman

KEY CONCEPTS

- Rhabdomyolysis is a process wherein striated muscle cells break down, resulting in the release of creatine kinase, potassium, calcium, phosphate, and uric acid.
- Rhabdomyolysis is associated with a variety of causes including overexertion, extreme body temperature changes, ischemia, infection, immobility, drugs, toxins, endocrine disease, autoimmune reactions, trauma, and genetic conditions.
- The classic presentation of rhabdomyolysis is myalgia, weakness, and dark-colored urine. However, the absence of this triad does not exclude the condition. Clinicians should suspect the disease in patients with risk factors, dark urine, and elevated creatine kinase.
- Diagnosis of rhabdomyolysis is based on elevated creatine kinase more than five times the upper limit of normal (CK > 1000 U/L).
- Although most patients recover without complications, severe rhabdomyolysis is associated with renal failure, electrolyte disorders such as hyperkalemia, compartment syndrome, and disseminated intravascular coagulation.
- Rhabdomyolysis management includes treating the underlying etiology and administering intravenous (IV) hydration with a goal urine output of 2 to 3 mL/kg/hour and euvolemia. Mannitol, sodium bicarbonate, and loop diuretics should not be used routinely in management.
- Although most patients require admission for further evaluation and management, patients with normal vital signs, normal laboratory assessment, normal oral intake, clear etiology, and follow-up may be appropriate for discharge.

FOUNDATIONS

Background and Importance

Rhabdomyolysis is the result of damage to striated muscle, leading to release of creatine kinase, aspartate transaminase, lactate dehydrogenase, aldolase, the heme pigment myoglobin, and electrolytes. Patients most commonly present with diffuse muscle pain, weakness, and dark urine, which is caused by renal excretion of myoglobin pigment. Although most cases follow a benign course, patients with severe disease may experience renal failure, electrolyte derangements, compartment syndrome, or disseminated intravascular coagulation.

Anatomy, Physiology, and Pathophysiology

Skeletal muscle is 80% water and 20% protein, accounting for about half of the total body protein stores. Muscle cells require a significant amount of ATP and oxygen for appropriate cellular function, both at rest and with activity. Myoglobin delivers and releases oxygen to active skeletal muscle. Potassium, sodium, and calcium are strictly regulated by ATP-dependent cellular pumps, including sodium-potassium–adenosine triphosphatase (Na^+,K^+-ATPase) and an active calcium exchanger (Ca^{2+}-ATPase pump) (Fig. 116.1). Under normal physiologic conditions, the concentration of free ionized calcium in the extracellular space is approximately 10,000 times greater than that in the intracellular space. Because extracellular calcium functions as an intracellular regulator and results in a sizeable electrochemical force on Ca^{2+}, even minor changes in the permeability of the plasma membrane to calcium will produce significant fluctuations in the cytosolic concentration, with potentially unfavorable consequences for the integrity of the cell.

Rhabdomyolysis involves four pathophysiologic processes (Fig. 116.2):

1. Impairment of the muscle's production or use of ATP at the cellular level. ATP concentrations within the cell fall; energy-dependent mechanisms falter, including Na^+,K^+-ATPase pumps, leading to disruption of chemical gradients, sarcolemma and cell membrane compromise, and cell destruction.
2. Disruption in the delivery of oxygen, glucose, and other nutrients to skeletal muscle.
3. Increased metabolic demands beyond the ability of the organism to deliver oxygen and nutrients.
4. Direct myocyte damage.

The pathogenesis of rhabdomyolysis follows a final common pathway—increased cytoplasmic calcium concentration from cell membrane damage and ATP depletion. Calcium activates proteases, phospholipases, and other proteolytic enzymes, which result in further ATP depletion, direct intracellular toxicity, and increased cellular membrane permeability. Increased intracellular calcium causes skeletal myocyte destruction and the release of toxic components into the extracellular and vascular spaces. Damage to adjacent capillaries causes local edema, increased local pressures, and tissue ischemia, resulting in further damage and energy depletion. Leukocytes adhere to damaged tissue and release radical oxygen species and enzymes that result in further cell damage. Ischemic etiologies of rhabdomyolysis may include reperfusion injury to myocytes.

Table 116.1 lists the various risk factors and causes of rhabdomyolysis.[1-4]

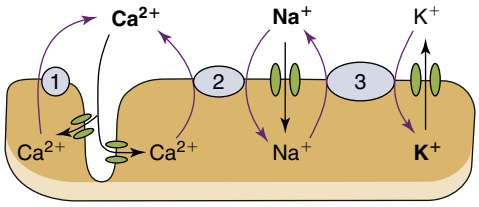
CLINICAL FEATURES

Rhabdomyolysis presents with a wide range of signs and symptoms. Patients may be asymptomatic or seriously ill with evidence of life-threatening complications, such as acute renal failure, disseminated intravascular coagulation, and dysrhythmias. In most patients, rhabdomyolysis presents in a mild form. Diagnosis in patients with a traumatic etiology is typically straightforward, but the diagnosis is often more challenging when rhabdomyolysis results from nontraumatic etiologies, or the patient is not able to provide a reliable history or cooperate with physical examination.

The classic presentation is localized muscle pain, stiffness, swelling, and tenderness, combined with dark-colored urine. However, this

combination of factors is found together in less than 10% of patients. Localized muscle pain is the most common symptom (80%), followed by localized muscle weakness and swelling. The thighs are most commonly involved, followed by the calves and back. Other symptoms may include fever, palpitations, tachycardia, nausea and vomiting, agitation, focal sensory deficits, pain with passive range of motion, skin changes, and decreased urine output. The finding of dark urine depends on the severity of the injury and the patient's muscle mass, urine concentration, and baseline renal function. The absence of visibly dark urine does not exclude the diagnosis of rhabdomyolysis.

Children are more diagnostically challenging. Most pediatric patients with rhabdomyolysis experience muscle pain, but fewer than 5% present with dark urine. Children also more commonly present with symptoms suggestive of a viral syndrome.



1 = ATP-dependent Ca^{2+} pump
2 = Na^{+}-Ca^{2+} exchanger (3:1)
3 = Na^{+}, K^{+}-ATPase pump (3:2)

Fig. 116.1 Normal Membrane Ionic Pump Function of Skeletal Muscle Cell. When the ATP supply is impaired, the intracellular sodium concentration increases, reversing the function of the Na^{+}-Ca^{2+} exchanger, with a subsequent increase in the intracellular calcium level.

A focused history provides important information regarding the symptoms of rhabdomyolysis, risk factors for the disease (see Table 116.1), prior history of the condition, or a family history consistent with rhabdomyolysis (due to inherited myopathies), which is associated with recurrent episodes of rhabdomyolysis. Other important historical points include changes in urine output and color, oral intake, and medication or illicit substance use. In patients with severe trauma or altered mental status, history from first responders, witnesses, or family members can assist.

Complications

Early Complications

Compartment Syndrome. Most skeletal muscles are encased in compartments formed by bones, fascia, and other structures. The massive influx of calcium and sodium in rhabdomyolysis leads to the accumulation of large amounts of extracellular fluid in myocytes, causing local edema and raised pressure within the compartments. Note that rhabdomyolysis can therefore be the cause and result of compartment syndrome.[5]

Electrolyte Disorders and Acidosis. Potassium released from damaged muscle may lead to hyperkalemia. Over 98% of the body's potassium is found in the intracellular space, and 60% to 70% of the total cellular mass of the human body consists of skeletal muscle. Therefore, damage to as little as 100 g of muscle may increase the serum

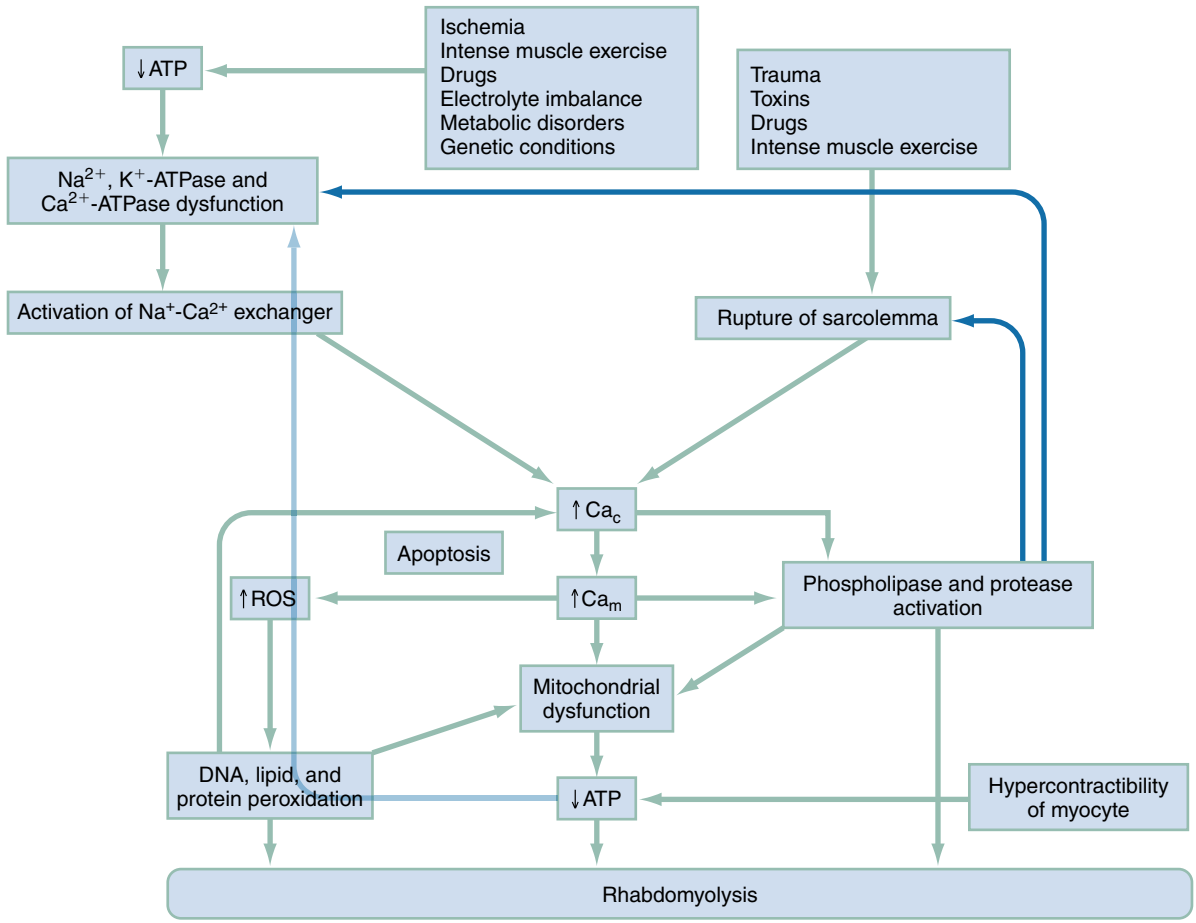


Fig. 116.2 Pathophysiology of rhabdomyolysis. Ca_c, cytosolic [Ca]; Ca_m, mitochondrial [Ca].

TABLE 116.1 Risk Factors and Etiologies of Rhabdomyolysis[1-4]

Exertion	Intense exercise, seizure, status asthmaticus, sickle cell crisis, alcohol withdrawal
Trauma or compression	Motor vehicle accidents, prolonged immobilization, crush syndrome, electrical injury, burns
Extreme changes in body temperature	Hyperthermia, hypothermia, serotonin syndrome, malignant hyperthermia, neuroleptic malignant syndrome
Electrolyte alterations	Hypokalemia, hypophosphatemia, hypocalcemia, hyponatremia, hypernatremia, hyperglycemia
Muscle ischemia/hypoxia	Arterial occlusion due to embolus, thrombus, or during vascular surgery
Infections	Sepsis, *Salmonella, Streptococcus pyogenes, Staphylococcus aureus, Clostridium* species, *Legionella*, influenza, coxsackie, Epstein-Barr virus, herpes virus, HIV
Drugs/toxins	Statins, anti-lipid agents (ezetimibe, clofibrate, gemfibrozil), proton pump inhibitors, psychiatric medications (SSRIs, SNRIs, TCAs, benzodiazepines, barbiturates, phenothiazines, lithium), alcohol, cocaine, opiates, amphetamines, LSD, phencyclidine, synthetic cannabinoids, bath salts, antihistamines, propofol, arsenic, carbon monoxide, azathioprine, quinidine, salicylates, succinylcholine, thiazides, vasopressin, pentamidine, terbutaline, theophylline
Endocrine	Thyroid abnormalities, hyperaldosteronism
Autoimmune	Dermatomyositis, polymyositis
Genetic	Krebs cycle disorders, G6PD deficiency, lipid metabolism disorders, mitochondrial chain disorders, muscular dystrophies
Foodborne	Ingestion of burbot, eel, pike, crayfish, buffalo fish, and other fish/crustacean species

HIV, Human immunodeficiency virus; *SSRI*, selective serotonin reuptake inhibitors; *SNRI*, serotonin norepinephrine reuptake inhibitors; *TCA*, tricyclic antidepressants; *LSD*, lysergic acid diethylamide; *G6PD*, glucose-6-phosphate dehydrogenase.

potassium by 1.0 mEq/L. Acidemia contributes to hyperkalemia and can be exacerbated by oliguria.

Rhabdomyolysis-related fluid sequestration or myoglobin-induced kidney injury reduces the kidney's ability to excrete acid. Metabolic acidosis is also caused by the release of organic acids (e.g., lactic acid, uric acid, and sulfur-containing proteins).

The disruption of muscle cells releases phosphoric components into circulation, and when massive, this can lead to hyperphosphatemia and ectopic calcification, typically depositing in necrotic tissue. In case of rhabdomyolysis with severe, extensive muscle damage, calcium phosphate crystal deposition in damaged muscle can lead to early-phase hypocalcemia, with potentially fatal dysrhythmias. This is rare and reported only in case reports. Hyperkalemia coupled with hypocalcemia predisposes patients to malignant dysrhythmias. Furthermore, excessively high phosphate levels shut down the 1α-hydroxylase enzyme of the kidneys, decreasing production of the active form of vitamin D, further contributing to early hypocalcemia. Late in the course of rhabdomyolysis, calcium initially deposited in the cytoplasm of necrotic muscle cells can reenter the plasma, resulting in late hypercalcemia.

Hypovolemia. In rhabdomyolysis, fluid moves from intravascular compartments into damaged muscle. In cases of massive muscle crush or electrical injury, this fluid shift may exceed 15 liters, causing profound intravascular volume depletion.

Hepatic laboratory abnormalities. Reversible elevations in aspartate transaminase (AST) levels may occur with rhabdomyolysis, possibly caused by myocyte release of proteases. The level of AST elevation is correlated with the severity of CK elevation in patients with rhabdomyolysis.[6] However, AST elevations may also be of skeletal muscle origin. Preexisting hepatic dysfunction may potentiate statin-induced rhabdomyolysis.[2] Rhabdomyolysis is not typically associated with abnormalities of other liver function tests or synthetic function such as alanine aminotransferase, prothrombin time, and albumin.

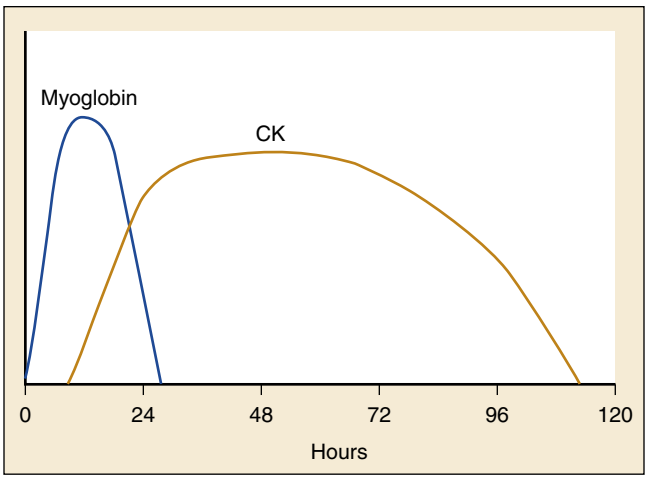

Fig. 116.3 Variations of Myoglobin and Creatine Kinase (CK) Levels During the Course of Rhabdomyolysis. Myoglobin is the first enzyme that increases but, because of its rapid clearance from the plasma, it returns to normal levels within the first 24 hours after the onset of symptoms. The CK level increases a few hours later than myoglobin, reaches its peak value within the first 24 hours, and remains at these levels for 3 days. CK is considered to be a more useful marker for the diagnosis and assessment of the severity of muscle injury because of its delayed clearance from the plasma.

Late Complications

Myoglobin-Induced Acute Kidney Injury. Experimental evidence suggests that myoglobinuric acute renal failure is caused by myoglobin cast formation in the distal convoluted tubules, the direct cytotoxic action of myoglobin on the epithelial cells of the proximal convoluted tubules, and ischemia from intrarenal vasoconstriction (Fig. 116.3).

Myoglobin concentrates along the renal tubules and precipitates in acidic urine with uric acid to form obstructive casts. This

is enhanced by volume depletion and renal vasoconstriction, which reduce blood flow and the glomerular filtration rate (GFR), promoting the accumulation of necrotic epithelial cells into tubular casts. Tubule obstruction occurs at the level of the distal tubule, whereas direct cytotoxicity occurs mainly in the proximal tubules. There remains some controversy about the exact mechanism of renal dysfunction in rhabdomyolysis; some experts believe that casts and tubular obstruction are not the cause, but rather the consequence, of poor tubular clearance.

When the concentration of myoglobin filtered at the glomerulus exceeds normal levels, tubular cells at the proximal convoluted tubule increase their resorptive capacity to limit the excretion of myoglobin into the urine, protecting the kidney from its nephrotoxic effects. At a urine pH of 5.6 or lower, myoglobin, an iron-containing heme protein, dissociates into free iron (Fe), ferrihemate (Fe-heme complex), and globin inside the proximal tubular epithelial cell. Oxidation of ferrous oxide in the Fe-heme complex in combination with free iron reaction with H_2O_2 produces free radicals which may result in nephrotoxicity. Free iron may also act as a free radical, although its role in rhabdomyolysis-induced renal injury is unclear. Myoglobin itself has been shown to exhibit peroxidase-like enzyme activity. Ferrihemate causes direct nephrotoxic effects along with the resultant increased oxidative stress within the tubular epithelial cell. More recent evidence has argued against free iron's role in oxidative stress–induced renal injury, instead emphasizing the role of ferrihemate-induced lipid peroxidation in cell injury.

Fluid shifts and renal dysfunction lead to activation of the renin-angiotensin-aldosterone system and production of vasoconstricting molecules such as endothelin 1 and vasopressin. There is also decreased production of vasodilatory prostaglandins. Nitric oxide (NO), a potent vasodilator agent, assists with the maintenance of renal blood flow. Myoglobin released from damaged muscle may act as a NO scavenger in the renal microcirculation, itself reduced by NO buffering against oxidant injury. When increased myoglobin concentrations overcome NO, the kidney is deprived of the ability to autoregulate blood flow and maintain adequate perfusion. Thus, myoglobin is free to cause damage in proximal tubular epithelial cells, specifically under acidotic conditions. Other locally stimulated vascular mediators, including thromboxane A_2, tumor necrosis factor alpha, and F_2-isoprostanes, also reduce renal blood flow and cause oxidant injury.

Disseminated Intravascular Coagulation. Extensive muscle damage may result in the release of prothrombotic substances, mainly thromboplastin, which activate the coagulation cascade. Although rare, this can lead to the formation of thrombi in the capillary tufts of the glomeruli and disseminated intravascular coagulation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of rhabdomyolysis includes conditions that may present with influenza-like symptoms, myalgias, extremity pain, or urinary changes. Such conditions include heatstroke, sepsis, infective endocarditis, myocarditis, spinal epidural abscess, pyomyositis, toxic ingestion or carbon monoxide exposure, thyroid abnormalities, compartment syndrome, vascular injury, and orthopedic injuries.

Red or dark urine can be seen with hemoglobinuria, urolithiasis, porphyria, ingestion of specific foods (blackberries, beets, rhubarb, food coloring) and numerous medications, including laxatives, rifampin, doxorubicin, chloroquine, hydroxocobalamin, and deferoxamine.

Notably, many of the conditions that mimic rhabdomyolysis can also cause rhabdomyolysis (e.g., heatstroke, bacterial or viral infection, and toxic ingestions).

DIAGNOSTIC TESTING

Serum Creatine Kinase

The definitive diagnosis of rhabdomyolysis is made by serologic testing for creatine kinase (CK). CK functions as an energy reservoir for ATP: creatine + ATP = creatine kinase + ADP (adenosine diphosphate). CK has a half-life of 1.5 days; it increases in the first 12 hours after injury, peaks during the first three days, and normalizes at approximately five days. A CK level five times the upper limit of normal (≈1000 U/L), without an alternative cause, confirms the diagnosis.

Serum and Urine Myoglobin

Myoglobin is a dark-red protein composed of globin and a molecule of heme. It supplies oxygen to skeletal and cardiac muscle in times of need and is renally excreted. It is initially filtered at the glomerulus and reabsorbed in the tubules, where it is broken down into its component parts, globin and heme. As with all other low-molecular-weight proteins, a small amount is excreted in the urine. The normal concentration of myoglobin in the urine is less than 10 μg/L. A normal serum concentration of myoglobin is less than 100 μg/L.

During rhabdomyolysis, myoglobin released by damaged muscle is increasingly filtered at the glomerulus. This leads to an initial increased resorptive capacity by glomerular and tubular epithelial cells, developed presumably as a protective response to increased filtered myoglobin. When serum myoglobin concentrations exceed 0.3 mg/L and the renal threshold of 1.0 mg/dL is met, this resorptive capacity is overwhelmed, and excess myoglobin appears in the urine. This myoglobin is detected by urine dipstick as positive for blood with microscopic urine analysis showing few, or no RBCs (Table 116.2).

In the past, the diagnosis of rhabdomyolysis was made by measuring serum myoglobin; however, myoglobin has a serum half-life of 1 to 3 hours, is completely absent after 24 hours, and normal levels depend upon the patient's muscle mass. These factors make serum myoglobin an unreliable diagnostic test. This is also true of urine myoglobin levels, which depend on the degree of muscle injury, volume status of the patient, and urinary flow rate. A well-hydrated patient with normal renal function can rapidly clear myoglobin from the body. The absence of plasma or urine myoglobin does not rule out rhabdomyolysis (Fig. 116.4).

Urine Dipstick and Urinalysis

Myoglobinuria causes a false-positive result for blood in urine dipstick testing. The drawback of this test is its inability to distinguish among heme compounds. In myoglobinuria, microscopic analysis will show few if any red blood cells, thereby distinguishing between hemoglobin and hemoglobin-rich red blood cells (from hemolysis or hematuria). Myoglobinuria, in combination with an elevated plasma CK level, confirms rhabdomyolysis. At plasma concentrations above 100 to 300 mg/L, macroscopic myoglobinuria manifests as tea-colored urine.

The urine dipstick test or urinalysis result is generally acidic in rhabdomyolysis, which plays a role in cast and uric acid crystal formation and pathologic myoglobin metabolism in tubular epithelial cells. Proteinuria may be noted because of the detection of the globin component of myoglobin. Urine sediment will show myoglobin casts and dead epithelial cells (see Table 116.2).

Other Laboratory Findings

Common electrolyte disturbances in patients with rhabdomyolysis include hyperkalemia, hyperphosphatemia, and early hypocalcemia followed by late hypercalcemia. Late hypercalcemia is postulated to be due to the mobilization of calcium that was initially sequestered in damaged muscle.

TABLE 116.2 Causes and Microscopic Features of Red and Brown Urine

Cause	Results for Blood in Urine[a]	Sediment[b]	Supernatant
Hematuria	+++	Red	Yellow
Myoglobinuria	+++	Normal	Red to brown
Hemoglobinuria	+++	Normal	Red to brown
Porphyria	–	Normal	Red
Bile pigments	–	Normal	Brown
Food and drugs[c]	–	Normal	Red to brown

[a]Urine tested with dipstick test.
[b]Normal refers to white or yellow color.
[c]Food and drugs that can cause red urine include beets, blackberries, rhubarb, food coloring, fava beans, phenolphthalein, rifampin, doxorubicin, deferoxamine, chloroquine, ibuprofen, and methyldopa. Those that cause brown urine include levodopa, metronidazole, nitrofurantoin, iron sorbitol, chloroquine, and methyldopa.

(Adapted from: Bosch X, Poch E, Grau JM. Rhabdomyolysis and acute kidney injury. *N Engl J Med.* 2009;361:62-72.)

Hyperuricemia from the release of muscle nucleic acids is especially common in patients with large muscle mass, as is elevation in serum lactate dehydrogenase (LDH). Metabolic acidosis typically occurs from the generation of organic acids from damaged muscle—namely, lactate and uric acid. Hypoalbuminemia and anemia result from capillary damage and release into the extracellular space.

Both blood urea nitrogen (BUN) and creatinine (Cr) concentrations increase, but with a characteristic decrease in the BUN/Cr ratio due to large amounts of creatinine released into the serum from damaged muscle. A normal BUN/Cr ratio is 10:1; in rhabdomyolysis, it can be 5:1 or even less. In severe cases with significant muscle necrosis and electrolyte abnormalities, disseminated intravascular coagulation (DIC) can ensue with bleeding or thrombosis and abnormal coagulation panel, thrombocytopenia, low fibrinogen, elevated D-dimer, and fragmented RBCs, triggered by the released thromboplastin from damaged tissue.

Prognostic Tests in Rhabdomyolysis

Although CK levels may correlate with the risk of developing acute kidney injury in patients with rhabdomyolysis due to traumatic injury, such as crush injury, the degree of CK level elevation is not a reliable predictor of acute kidney injury, need for dialysis, or death.[7,8]

However, patients with an estimated glomerular filtration rate (eGFR) of more than 60 mL/min/1.73 m^2 appear to have low risk for acute kidney injury or death. Based on the cumulative evidence, CK should be used as a diagnostic marker for rhabdomyolysis, but not as a prognostic indicator of acute renal injury.[9] Once the diagnosis of rhabdomyolysis is made, the eGFR can be used to predict renal injury and help determine the need for admission. The eGFR is typically reported routinely on basic metabolic panels that include creatinine.

MANAGEMENT

Management of rhabdomyolysis focuses on treatment of the cause, prevention of renal failure, and management of life- or limb-threatening complications.

Fluid Replacement

Volume expansion is critical to avoiding myoglobin-induced acute renal failure in those who are hypovolemic.[10] Fluid expansion increases renal blood flow, glomerular filtration, and urine production, while reducing the risk of renal injury. Patients with rhabdomyolysis can present with severe dehydration due to fluid sequestration in the affected skeletal muscles. Several case series, mostly from victims of natural disasters with crush injury, have shown that some degree of intravascular volume contraction is a prerequisite for developing acute renal failure. Because acute renal failure appears to develop in hypovolemic patients with a longer delay to supportive therapy, fluid resuscitation should be instituted as early as possible.[11] Victims of mass casualty events often have prolonged extrication times, so fluid resuscitation should begin before complete extrication, when possible.

Fluid resuscitation should generally be initiated at CK levels more than five times the upper limit of normal (typically, 1000 IU/L) and should be continued until levels trend down and drop below this level. Fluid boluses are recommended in patients with hypovolemia or crush injury. In euvolemic or hypervolemic patients, over-resuscitation may be harmful. In general, titration to a urinary output of 2 to 3 mL/kg/hr or more and patient euvolemia are reasonable targets for adults.[3]

Balanced crystalloids such as plasmalyte or lactated Ringers solution are recommended for initial resuscitation, though there are no studies demonstrating improved outcomes with balanced fluids in rhabdomyolysis compared to normal saline. Normal saline contains supraphysiologic concentrations of chloride ions. Massive infusion of normal saline leads to a disproportionate increase in serum chloride concentrations, inducing an iatrogenic metabolic (hyperchloremic) acidosis that may exacerbate myoglobin precipitation, tubular obstruction, and risk of hyperkalemia-related complications.

Urine alkalinization, achieved through addition of sodium bicarbonate to IV fluids, is no longer recommended. Animal data suggested potential value for alkalinization, based on: (1) decreased renal myoglobin precipitation; (2) decreased reduction-oxidation (redox) cycling of myoglobin and lipid peroxidation, and thus tubule injury; and (3) decreased myoglobin-induced renal vasoconstriction.

However, the clinical benefits of alkalinization over IV hydration were never established, and sodium bicarbonate therapy has not been proven superior to normal saline diuresis at increasing urine pH, or more importantly, improving patient outcomes such as mortality and renal failure.

We do not recommend the use of sodium bicarbonate to induce urinary alkalinization in rhabdomyolysis because there is no evidence of improved outcomes with its use. However, isotonic bicarbonate infusion may be considered for those with non-anion gap metabolic acidosis or uremic acidosis.

Mannitol and Other Diuretics

In human studies, the addition of mannitol has not demonstrated benefit over fluid expansion alone, and no randomized controlled trials have shown any beneficial effect. Accordingly, we do not recommend the use of mannitol in the treatment of rhabdomyolysis. Animal studies demonstrated that the bulk of mannitol's effect is attributable simply to its osmotic diuretic action, but large accumulated doses of mannitol may be detrimental by causing renal vasoconstriction and tubular toxicity, a condition known as osmotic nephrosis, as well as exacerbating hypovolemia.

There also is no evidence to support the use of loop diuretics or carbonic anhydrase inhibitor diuretics in the treatment of rhabdomyolysis.

Experimental Therapies

Antioxidants such as glutathione and vitamin E analogues have shown promise in experimental animal models of myoglobin-induced oxidant injury and may have a future role in management. Grape seed proanthocyanidin extract has been shown to have renoprotective effects in animal models. The xanthine oxidase inhibitor, allopurinol, is being studied as a prophylactic agent in those at risk for exertional rhabdomyolysis.[12]

Renal Replacement Therapy

Renal replacement therapy (RRT) is needed in up to 20% of patients with acute kidney injury from rhabdomyolysis. As with other causes of acute renal failure, the indications for emergent RRT remain (1) uncorrectable metabolic acidosis, (2) life-threatening hyperkalemia and other electrolyte disturbances despite medical management, and (3) manifestations of uremia, and anuria or oliguria, despite volume expansion in patients with complications related to fluid overload. The current literature does not demonstrate a mortality benefit with RRT in the setting of rhabdomyolysis, but in those with a previously mentioned indication for RRT, RRT is associated with more rapid removal of myoglobin and improvement in electrolyte, BUN, and creatinine levels. RRT should be continued until the indication for it is corrected and the patient has improved.

DISPOSITION

The majority of patients with rhabdomyolysis require hospitalization for fluid resuscitation and close monitoring of renal function. Discharge with close outpatient follow-up or observation stays can be

considered in select, milder cases. Patients with a known etiology, mild symptoms, normal vital signs, normal renal function and electrolytes, and reliable follow-up may be discharged. Hemodynamically unstable patients or those requiring RRT should be considered for ICU admission, whereas those who do not meet these criteria or are not appropriate for outpatient management should be admitted to the hospital floor.

Prognosis

Rhabdomyolysis has an excellent prognosis when recognized and treated early. The majority of cases follow a benign course and resolve without complications. With the exception of hyperkalemia-related death or the rare complication of DIC, which typically occurs in patients with extensive muscle damage or crush injury, acute kidney injury is the most serious complication of rhabdomyolysis. Most patients who have acute renal failure will recover full renal function with fluid rehydration to euvolemia. Mortality data for patients with renal failure vary widely according to the study population, underlying etiology, presence of multiple causative agents, and comorbidities with no clear data; however, long-term survival among patients with rhabdomyolysis and acute renal injury tends to be very good when timely management is provided.

CHAPTER 116: QUESTIONS AND ANSWERS

1. Which of the following statements regarding muscle cell physiology and rhabdomyolysis is true?
- **a.** Acute renal failure from rhabdomyolysis is very rare.
- **b.** Hemoglobin has a higher oxygen affinity than myoglobin.
- **c.** The final common pathway of injury in rhabdomyolysis is cell membrane damage.
- **d.** The normal intracellular Na^+ concentration is high.
- **e.** The normal intracellular Ca^{2+} concentration is low.

Answer: E. Normal intracellular concentrations of Na^+ are low, creating a negative intracellular environment. This allows more facilitated transfer of Ca^{2+} from the intracellular to extracellular space, maintaining low intracellular Ca^{2+} concentrations. The final common pathway of injury is sarcolemma damage with intracellular Ca^{2+} accumulation, proteolytic enzyme inhibition, actin-myosin coupling dysfunction, and cell damage with release of intracellular contents (e.g., myoglobin, PO_4^-, uric acid, lactate dehydrogenase). Myoglobin, which has four times the O_2 affinity of hemoglobin, overwhelms the haptoglobin-binding capacity, is filtered at the glomerulus, and precipitates in renal tubules. Approximately 5% to 15% of cases of acute renal failure in the United States are related to rhabdomyolysis. This myoglobin precipitation is markedly facilitated by acidosis.

2. Which of the following statements regarding exertion (exercise)-related rhabdomyolysis is true?
- **a.** Eccentric (lengthening) muscle work is more damaging than concentric.
- **b.** Hypocalcemia increases the risk for this syndrome.
- **c.** It is the result of voluntary muscle exertion.
- **d.** It is seen exclusively in untrained athletes.
- **e.** The mechanism is different than after a crush injury.

Answer: A. Exertional rhabdomyolysis is seen in trained and untrained individuals as well as after exercise or situations of involuntary muscle activity (e.g., psychoses, seizures, tetany, myoclonus). The mechanism (e.g., failure of energy supplies, sarcolemma breakdown, intracellular calcium accumulation, enzyme dysfunction, cellular swelling) is the same. Hypokalemia is a risk factor because a low potassium level limits microvascular dilation and muscle perfusion.

3. Which of the following statements regarding drug-induced rhabdomyolysis is true?
- **a.** Cocaine myotoxicity is not related to the degree of intoxication.
- **b.** Colchicine and cyclosporine are myotoxins.
- **c.** Ethanol myotoxicity is potentiated by high carbohydrate intake.
- **d.** Statin myotoxicity is unrelated to state of hydration.
- **e.** The use of the drug ecstasy is not associated with rhabdomyolysis.

Answer: B. Statins, ethanol, cocaine, colchicine, cyclosporine, and many other drugs are myotoxic. Illicit drugs include amphetamine, ecstasy, LSD, and other sympathomimetics. Ethanol is a direct muscle membrane toxin, and this effect is potentiated by starvation, binge drinking, and coexisting electrolyte abnormalities (low K^+, PO_4^-, and Mg^{2+}). Intravenous cocaine use is more myotoxic than inhaled cocaine, and the severity seems to parallel the degree of intoxication.

4. What is the most common viral cause for rhabdomyolysis?
- **a.** Cytomegalovirus
- **b.** Epstein-Barr virus
- **c.** Herpesvirus
- **d.** Human immunodeficiency virus
- **e.** Influenza virus

Answer: E. Influenza is the most common viral etiology followed by HIV infection and enteroviral infection.

5. What is the most common bacterial cause for rhabdomyolysis?
- **a.** *Legionella*
- **b.** *Pseudomonas*
- **c.** *Salmonella*
- **d.** *Staphylococcus*
- **e.** *Streptococcus*

Answer: A. *Legionella* is the bacterium classically associated with rhabdomyolysis in adult patients. The pathogenesis is believed to be due to direct invasion and toxic degeneration of muscle fibers.

6. Which of the following electrolyte abnormalities has not been associated with rhabdomyolysis?
- **a.** Hypermagnesemia
- **b.** Hypernatremia
- **c.** Hypocalcemia
- **d.** Hyponatremia
- **e.** Hypophosphatemia

Answer: A. There are no reported cases of hypermagnesemia-induced rhabdomyolysis to date.

7. A 53-year-old intoxicated alcoholic is brought to the ED by EMS after being found unconscious for an unknown reason. He is now awake but mildly lethargic. He has no complaints of pain or

CHAPTER 116: QUESTIONS AND ANSWERS—cont'd.

disability. The physical examination is nonfocal. Which of the following statements is true?

a. A CK-MB fraction of 5% would indicate myocardial damage.
b. A negative urine myoglobin level would exclude rhabdomyolysis.
c. His lack of pain complaints would exclude rhabdomyolysis.
d. Hypocalcemia would be expected in the presence of rhabdomyolysis.
e. If rhabdomyolysis were found, normal phosphate level would be reassuring.

Answer: D. Hypocalcemia is the most common electrolyte abnormality after rhabdomyolysis. Hypercalcemia may follow later. Only 50% of patients with serum evidence of rhabdomyolysis have complaints of muscle pain. Likewise, the presence of urine myoglobin reflects the glomerular filtration rate, plasma myoglobin concentrations, urine flow, and plasma myoglobin binding. This test result may be negative, especially late in the course of the process. Hyperphosphatemia is expected, and a normal level raises the suspicion that hypophosphatemia was the cause of the rhabdomyolysis. CK-MB levels of 3% to 5% are often seen and reflect skeletal rather than cardiac muscle damage.

8. Which of the following is a proven cornerstone of management for rhabdomyolysis, along with hydration?

a. Alkalinization
b. Chelation therapy
c. Furosemide
d. Mannitol
e. None of the above

Answer: E. Furosemide is somewhat contraindicated because of its tendency to acidify the urine. Mannitol and alkalinization are not proven, although they are often used. Chelation therapy is under investigation.

117

Thyroid and Adrenal Disorders

Molly E.W. Thiessen

KEY CONCEPTS

Hyperthyroidism

- Hyperthyroidism induces a hypermetabolic state and increases β-adrenergic activity. The resulting clinical manifestations range from vague constitutional symptoms to more organ-specific symptoms (see Box 117.1).
- Hyperthyroidism in elders may be asymptomatic or may manifest with subtle nonspecific symptoms such as weight loss, shortness of breath, and/or dementia.
- The laboratory test of choice for suspected hyperthyroidism is the thyroid stimulating hormone (TSH) concentration with free T_4 and T_3 levels.
- Thyroid storm is a life-threatening thyrotoxic crisis that often presents with fever, extreme tachycardia, and/or altered sensorium. It requires prompt recognition and therapy, as well as identification and treatment of any precipitating cause, such as infection.
- The order of medication administration in thyroid storm is critical. Iodine can precipitate thyroid storm and must be given a minimum of 1 hour after thionamide therapy (PTU or methimazole). As such, the typical order is beta blocker (propranolol), PTU or methimazole, and then iodine (SSKI, Lugol solution).

Hypothyroidism

- Hypothyroidism results from lack of stimulation of the thyroid gland (central or secondary hypothyroidism) or intrinsic gland dysfunction limiting hormone production (primary hypothyroidism).
- Signs and symptoms of hypothyroidism range from asymptomatic to overt organ failure, which can lead to death (see Box 117.5).
- Determination of an elevated TSH level is the most sensitive and single best screening test to confirm the diagnosis of primary hypothyroidism.
- Replacement with levothyroxine (T_4) remains the treatment of choice and resolves physical and psychological signs and symptoms in most patients.
- Myxedema coma is a life-threatening event that presents with altered mental status and hypothermia, along with a concomitant precipitating event (see Box 117.6). It usually occurs in patients with untreated or undertreated hypothyroidism. Treatment with thyroid hormone replacement must be initiated, often based solely on clinical findings.

Adrenal Excess States

- Adrenal excess states run the spectrum from Cushing syndrome, to primary and secondary hyperadrenalism, to pheochromocytoma.
- Symptoms of adrenal excess will vary, depending on the etiology, with chronic, nonspecific symptoms that arise from Cushing syndrome (generalized weakness, fatigue, menstrual irregularities, and weight gain), to simple refractory hypertension with hyperaldosteronism, to acute, refractory hypertension and hyperadrenergic symptoms with pheochromocytoma.
- Diagnosis of hyperaldosteronism is typically clinical, and confirmed by laboratory testing and imaging studies, depending on the etiology. In most cases, acute stabilization of the presenting complaint is paramount, and definitive diagnosis will occur outside the ED. Any adrenal incidentaloma discovered on imaging obtained in the ED, especially in the setting of hypertension, should prompt further evaluation for adrenal excess.

Adrenal Insufficiency

- Clinical manifestations of secondary adrenal insufficiency are often vague and nonspecific, including fatigue, weakness, dizziness, nausea, vomiting, and other nonspecific GI symptoms. Patients with primary adrenal insufficiency characteristically have more pronounced clinical manifestations and skin hyperpigmentation.
- The ACTH stimulation test and measurements of cortisol levels is the most convenient method and is considered the criterion standard to make the diagnosis.
- Refractory hypotension in the acutely ill patient may be the only clue to adrenal insufficiency and is readily treated with IV administration of glucocorticoids (hydrocortisone, 100 mg).

HYPERTHYROIDISM

Foundations

Background and Importance

Hyperthyroidism is a condition caused by overproduction and increased circulation of thyroid hormone. The disorder runs the spectrum from subclinical hyperthyroidism to thyrotoxicosis and thyroid storm, a life-threatening disorder. Thyrotoxicosis is a hypermetabolic condition that results from elevated levels of thyroid hormones—triiodothyronine (T_3) and thyroxine (T_4). This can occur from hormone overproduction, increased thyroid hormone release from an injured gland, or exogenous thyroid hormone. For the purpose of this discussion, the terms *hyperthyroidism* and *thyrotoxicosis* are used interchangeably.

Anatomy, Physiology, and Pathophysiology

The normal adult thyroid gland is a highly vascular bilobar organ overlying the anterior trachea (Fig. 117.1). The thyroid's function is to secrete two iodinated hormones, T_3 and T_4. Only about 20% of circulating T_3 is directly secreted by the thyroid; the remainder is produced by peripheral conversion of T_4 to the more biologically active T_3. The thyroid is the only endocrine gland that stores large quantities of hormone.

Hormone production is regulated by a negative feedback loop involving the hypothalamic-pituitary-thyroid axis (Fig. 117.2). As the serum levels of T_4 and T_3 fall, the hypothalamus releases the tripeptide thyrotropin-releasing hormone (TRH), which in turn stimulates the anterior pituitary gland's release of the polypeptide thyroid-stimulating hormone (TSH) from its thyrotroph cells. TSH then binds to epithelial

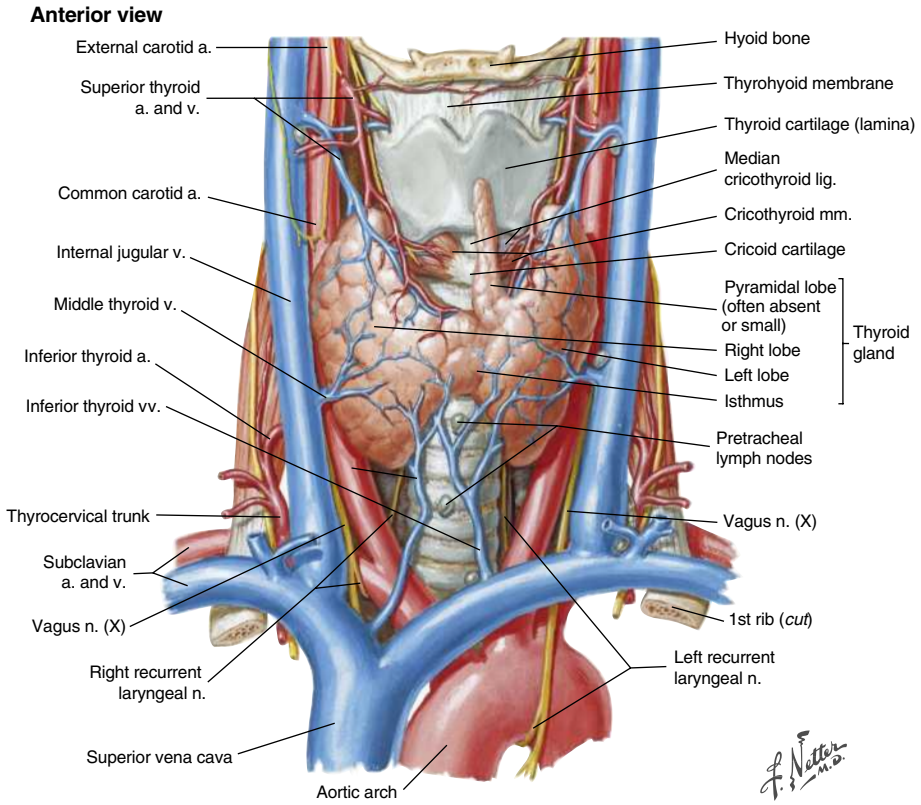

Fig. 117.1 Anatomy of the thyroid gland and related structures. (Netter illustration from www.netterimages.com. Copyright Elsevier. All rights reserved.)

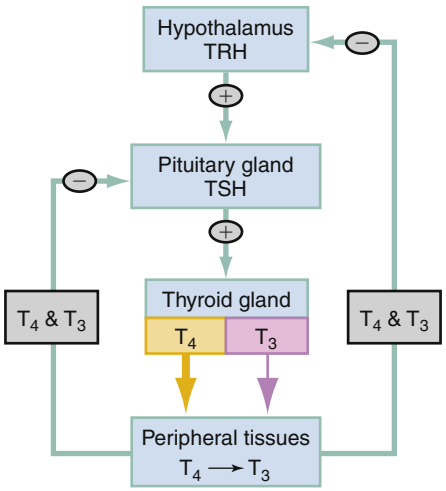

Fig. 117.2 Negative feedback loop of thyroid hormone regulation—hypothalamic-pituitary-thyroid axis. Thyroid hormone production is regulated by the hypothalamus and pituitary gland. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates pituitary thyrotropin (TSH) synthesis and secretion. In turn, TSH stimulates the production and release of thyroxine (T_4) triiodothyronine (T_3) from the thyroid gland. Once released, T_4 and T_3 exert a negative feedback mechanism on the production of TRH and TSH. T_4 is converted to T_3 in the peripheral tissues.

cells on the thyroid gland, stimulating follicular cells to synthesize and secrete the thyroid hormones T_4 and T_3. TRH release may also result from exercise, stress, malnutrition, hypoglycemia, and sleep.

The function of thyroid hormone is to influence the metabolism of cells by increasing their basal metabolic rate. It has a role in protein synthesis and functions together with other hormones necessary for normal growth and development. T_3 and T_4 increase the expression and sensitivity of β-adrenergic receptors, increasing the response to endogenous catecholamines.

T_4 is a prohormone with only mild intrinsic activity; its deiodination produces T_3, the biologically active hormone. More than 99.5% of thyroid hormones are protein-bound in the serum to thyroxine-binding globulin (TBG) and other proteins, rendering them metabolically inactive. As a result, only free T_4 and free T_3 are clinically relevant.

Although iodide is a necessary substrate for thyroid hormone production, excess iodide can have two opposing effects. In the Wolff-Chaikoff effect, excess iodine inhibits the release of thyroid hormone from the gland by blocking iodide trapping and thyroglobulin iodination. This inhibition is transient, typically lasting only a matter of days. An iodine load can induce hyperthyroidism (Jod-Basedow effect) in some patients with multinodular goiter and occult Graves disease.

Clinical Features

History and Physical Examination

Hyperthyroidism induces a hypermetabolic state and increases β-adrenergic activity. The resulting clinical manifestations range from vague constitutional symptoms to more organ-specific symptoms (Box 117.1). Altered mental status and coma typify thyroid storm, the most severe manifestation of disease.

Hyperthyroidism in older adults often manifests in more subtle ways, often asymptomatic or with nonspecific symptoms of weight loss, shortness of breath, and/or dementia. Elders are more prone to cardiac manifestations of hyperthyroidism and may present with atrial fibrillation.[1] Elders who smoke or have higher circulating thyroid hormone levels appear to have more severe symptoms. Thyrotoxic periodic paralysis is a rare manifestation that presents as a sudden and

BOX 117.1 Symptoms of Thyrotoxicosis

Constitutional: Weight loss despite hyperphagia, fatigue, generalized weakness
Hypermetabolic: Heat intolerance, cold preference, excessive perspiration
Cardiorespiratory: Palpitations, dyspnea, dyspnea on exertion, chest pains, poor exercise tolerance
Gastrointestinal: Nausea, vomiting, diarrhea, dysphagia
Neuropsychiatric: Anxiety, restlessness, hyperkinesis, emotional lability, confusion, insomnia, poor attention
Neuromuscular: Myopathy, myalgias, tremor, proximal muscle weakness (difficulty getting out of a chair or combing hair)
Ophthalmologic: Tearing, irritation, wind sensitivity, diplopia, foreign body sensation
Thyroid gland: Neck fullness, dysphagia, dysphonia
Dermatologic: Flushed feeling, hair loss, pretibial swelling
Reproductive: Oligomenorrhea, amenorrhea, menometrorrhagia, decreased libido, gynecomastia, erectile dysfunction, infertility

BOX 117.2 Physical Findings in Thyrotoxicosis

Vital signs: Tachycardia, widened pulse pressure, bounding pulses, fever
Cardiac: Hyperdynamic precordium, systolic flow murmur, prominent heart sounds, systolic rub (Means-Lerman scratch), tricuspid regurgitation, atrial fibrillation, evidence of heart failure
Ophthalmologic: Widened palpebral fissures (stare), lid lag, globe lag, conjunctival injection, periorbital edema, proptosis, limitation of superior gaze
Neurologic: Fine tremor, hyperreflexia, proximal muscle weakness
Psychiatric: Fidgety, emotionally labile, poor concentration
Dermatologic: Warm, moist, smooth skin; rosy cheeks, blushing face; fine brittle hair; alopecia, flushed facies; palmar erythema; hyperpigmented pretibial plaques, nodules, or induration that is nonpitting; onycholysis (Plummer nails, separation of the distal portion of the fingernail from the nail bed)
Neck: Diffuse symmetric thyroid enlargement, sometimes with a bruit and palpable thrill; thyroid with multiple irregular nodules or a prominent single nodule; tracheal deviation, venous prominence with arm elevation (Pemberton sign)

profound muscle weakness progressing to flaccid paralysis, similar to familial hypokalemic periodic paralysis.

Ophthalmopathy is a classic finding in Graves disease. Patients subsequently present with eyelid edema, hyperemia, conjunctival hyperemia, and chemosis. Graves ophthalmopathy is also associated with restrictive extraocular myopathy, and exophthalmos. As the disease progresses, patients may experience restriction of their upward gaze from infiltration of the inferior rectus muscle and visual loss from optic nerve involvement (compression by inflamed, enlarged orbital contents). Increased activity at the sympathetic innervation of the eyelids leads to widening of the palpebral fissures, resulting in the characteristic stare and lid lag of thyrotoxicosis.

Physical examination findings of hyperthyroidism depend largely on age (Box 117.2). Younger patients typically present with signs of sympathetic stimulation, whereas older adults often lack the same adrenergic response and present with weight loss and fatigue, more consistent with apathetic hyperthyroidism.[1] In Graves disease, patients uncommonly have classic pretibial myxedema, which are confluent, painless, reddish raised nodules and plaques over the pretibial area and dorsum of the feet, often described as orange skin. Hyperpigmentation and induration are present, but pitting is absent. Pretibial myxedema is often associated with Graves ophthalmopathy.

Tachycardia is the most common cardiac finding. Other findings include a widened pulse pressure, bounding peripheral pulses and, rarely, a friction rub heard along the left sternal border (Means-Lerman scratch). Atrial fibrillation is more common in elders, especially those over 65 years of age. Dilated cardiomyopathy may develop as a complication of a high cardiac output state. Patients can also develop primary pulmonary hypertension, as well as increased chamber size and poor right ventricular function.[2]

Most hyperthyroid patients have an enlarged thyroid gland, especially in toxic multinodular goiter or Graves disease, although many elders with Graves disease have nonpalpable thyroids. Retrosternal enlargement can occur, making detection difficult while causing the obstructive symptoms discussed earlier. Facial and neck vein engorgement can be elicited when arms are elevated above the head (known as the Pemberton sign). The absence of thyroid enlargement should suggest exogenous (factitious) thyroiditis as well as ectopic thyroid hormone production, such as a hydatidiform mole or struma ovarii, an ovarian tumor composed of some thyroid tissue.

Thyroid Storm

Thyroid storm is a rare, life-threatening form of severe thyrotoxicosis, with multiorgan dysfunction and significantly higher mortality rates than thyrotoxicosis without storm.[3] Although it can occur as the result of unrecognized or undertreated thyrotoxicosis, more often, it is an acute reaction to surgery, trauma, infection, iodine load or parturition in patients with preexisting hyperthyroidism. Other precipitants include acute myocardial infarction, pulmonary embolism, hyperemesis gravidarum, preeclampsia, and diabetic ketoacidosis. Untreated, mortality approaches 100%, but prompt recognition and therapy have lowered mortality to 10% to 30%.[3,4] Death in thyroid storm is caused by multiorgan dysfunction, congestive heart failure, respiratory failure, arrhythmias, disseminated intravascular coagulation, hypoxic brain insult, or sepsis.

The typical clinical manifestations of thyroid storm include marked pyrexia (104°–106°F [40°–41°C]), extreme tachycardia (often out of proportion to level of fever), and altered mental status. These findings, coupled with the clinical picture of a patient with hyperthyroidism, lid lag, stare, goiter, ophthalmopathy, and tremor, should alert the emergency clinician to the diagnosis. Cardiovascular collapse can result in congestive heart failure, hypotension, and cardiac arrhythmias. Hypotension can also result from volume depletion secondary to nausea, vomiting, and diarrhea. Abdominal pain is common; hepatic failure with cholestatic jaundice is less common but carries a poor prognosis. Thyroid storm is a clinical diagnosis, and no validated diagnostic criteria yet exist. However, a scoring system developed by Burch and Wartofsky in 1993 is repeatedly cited and utilized by practicing endocrinologists. Although the test characteristics (e.g., sensitivity and specificity) have not been published, it may help distinguish among thyrotoxicosis, impending thyroid storm, and frank thyroid storm (Table 117.1).[5]

Differential Diagnoses

The differential diagnosis for the thyrotoxic patient is broad. An anxious patient may be interpreted to be manic or experiencing a panic attack. The hyperadrenergic state may be confused with that seen in patients with sympathomimetic intoxication, suffering from anticholinergic crisis, or experiencing withdrawal from alcohol or sedative-hypnotics. The hyperpyrexia and altered mental status seen in thyroid storm may mimic other hyperthermic disorders such as heatstroke, neuroleptic malignant syndrome, serotonin syndrome, bacterial

TABLE 117.1 Diagnostic Criteria for Thyroid Storm

Criteria	Score[a]
Fever (°F)	
99–99.9	5
100–100.9	10
101–101.9	15
102–102.9	20
103–103.9	25
≥104	30
Tachycardia (beats/min)

[a]Tally the maximum score from each category. A score of 45 or higher suggests thyroid storm, or impending storm, and a score below 25 is unlikely to represent thyroid storm.

meningitis, and sepsis. Elders with apathetic hyperthyroidism may be mistakenly diagnosed with psychiatric illness.

Diagnostic Testing

The initial diagnosis of thyrotoxicosis is based on the clinical picture and confirmed with laboratory values. Measurement of the serum TSH level is the most sensitive test for hyperthyroidism. In thyrotoxicosis, the serum TSH concentration is depressed or undetectable (<0.01 μU/mL in third-generation assays), and a normal TSH level excludes hyperthyroidism. Accuracy of the TSH determination is improved when the free T_4 test is added. Assessment of thyroid function during acute nonthyroidal illness is difficult, especially in critically ill patients.

TABLE 117.2 Thyroid Function Test Interpretation

Tsh	Free T_4	Free T_3	Disease
Normal	Normal	Normal	None
Low	High	High	Hyperthyroidism
Low	Normal	Normal	Subclinical hyperthyroidism
Low	Normal	High	T_3 toxicosis
Low	High	Normal	Thyroiditis, T_4 ingestion, hyperthyroidism in older adults or those with comorbid illness
Low	Low	Low	Euthyroid sick syndrome; central hypothyroidism
High	Normal	Normal	Subclinical hypothyroidism; recovery from euthyroid sick syndrome

T_3, Triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone.

Severe systemic illness depresses TSH production, leading to low levels of TSH, free T_3, and free T_4.

Elevation of free T_4 and free T_3 levels in conjunction with TSH suppression is diagnostic of thyrotoxicosis. Because nearly all T_3 and T_4 is bound to TBG, assays measuring total T_3 or T_4 are influenced by changes in TBG; they are therefore unreliable and should not be used. Subclinical hyperthyroidism is likely if TSH is suppressed and the free T_4 level is normal. T_3 toxicosis occurs in about 5% of patients with thyrotoxicosis. These patients have an elevated free T_3 level and a normal free T_4 level. When the reverse pattern is present—normal free T_3 level and elevated free T_4 level—the differential includes thyroiditis, exogenous levothyroxine ingestion, and hyperthyroidism in elders, often with suppressed T_4 to T_3 conversion due to comorbid illness (Table 117.2). Since Graves is caused by autoantibodies to the TSH receptor, the presence of thyroid receptor antibodies in the serum can help distinguish it from other causes. Additionally, a radioiodine scan can help discern Graves from exogenous intake or hyperthyroidism due to struma ovarii. A magnetic resonance imaging (MRI) test of the brain and an ultrasound of the thyroid may help differentiate whether excess levels of thyroid hormone are emanating from either the pituitary or the thyroid gland.

Many thyrotoxic patients have hyperglycemia. This is likely to be the result of increased glycogenolysis and catecholamine-mediated antagonism of insulin. Mild hypercalcemia can be seen, is related to hormone-mediated bone resorption, and is associated with osteoporosis and increased fracture risk. Other frequent laboratory abnormalities include abnormal liver function tests, leukocytosis, mild anemia, and low serum cholesterol levels.

In thyroiditis, the diagnostic evaluation is more difficult. An exquisitely tender gland and elevated erythrocyte sedimentation rate (ESR) or C-reactive protein make the diagnosis of subacute thyroiditis likely. The other forms of thyroiditis lack these findings.

Factitious thyrotoxicosis can often be diagnosed by history. Laboratory testing will demonstrate low thyroglobulin levels and a low T_3/T_4 ratio (<20 ng/microgram).[5] Furthermore, radioactive iodine uptake is depressed in thyroiditis and factitious thyrotoxicosis but increased in hyperthyroidism.

Management

Management of thyrotoxicosis is based on etiology and symptom severity. For those with mild symptoms, outpatient referral and management are appropriate. Patients with moderate to severe symptoms are best managed in the emergency department (ED) setting. Treatment is divided into supportive, symptomatic, and thyroid-directed therapy.

BOX 117.3 Management of Thyrotoxicosis

β-Adrenergic Blockade

Propranolol 60–80 mg PO every 4 hours
or
Metoprolol, 25–50 mg PO every 6 hrs
If IV route is required, propranolol, 0.5–1.0 mg IV slow push test dose, then repeat 1–2 mg every 15 min as tolerated to desired effect, then 1–2 mg every 3 hr
or
Esmolol, 50–100 μg/kg/min infusion
Strict contraindication to beta blocker—reserpine 2.5–5 mg IM every 4 hr

Inhibition of Thyroid Hormone Synthesis

Propylthiouracil, 500–1000 mg loading dose, then 250 mg every 4 hr
or
Methimazole, 60–80 mg/day in divided doses
Preferred route, PO or nasogastric (NG); alternative route: PR (in rectum), enema prepared by pharmacy; same dose for all routes

Inhibition of Thyroid Hormone Release

Saturated solution of potassium iodide (SSKI, 50 mg iodide/drop), 1–2 drops PO or PR tid
or
Lugol solution (8 mg iodide/drop), 5–7 drops PO or PR tid
or
Sodium iodide, dosing as per Endocrinology recommendations
or
If allergic to iodine, lithium carbonate, 300 mg PO or NG qid

Administration of Corticosteroids

Inhibit T_4 to T_3 conversion; treat relative adrenal insufficiency.
Hydrocortisone, 300 mg IV, followed by 100 mg tid
or
Dexamethasone, 2–4 mg IV qid

Diagnosis and Treatment of Underlying Precipitant

Consider empirical antibiotics if critical.

Supportive Measures

Volume resuscitation and replacement of glycogen stores with D_5/0.9 NS (dose varies, depending on volume status and CHF)
Acetaminophen
Cooling blanket, fans, ice packs, ice lavage

Miscellaneous

Lorazepam or diazepam as anxiolytic and to decrease central sympathetic outflow
Cholestyramine (blocks enterohepatic recirculation of thyroid hormone), 1–4 g PO twice daily for severe or refractory thyrotoxicosis

CHF, Congestive heart failure; *D_5W/0.9 NS,* 5% dextrose in 0.9% normal saline; *IV,* intravenously; *NG,* by nasogastric tube; *PO,* by mouth; *PR,* by rectum; *T_3,* triiodothyronine; *T_4,* thyroxine.

Specific dosages of the drugs discussed in the following sections can be found in Box 117.3. The order of medication administration in thyroid storm is critical. Iodine can precipitate thyroid storm and must be given a minimum of 1 hour after thionamide therapy (PTU or methimazole). As such, the typical order is beta blocker (propranolol), propylthiouracil (PTU), or methimazole, and then iodine (saturated solution of potassium iodide [SSKI], Lugol solution). In addition, it is important to identify and treat the precipitating cause of thyroid storm.

Supportive Treatment

Supportive therapy for thyroid storm patients should include management of hyperthermia with cooling and acetaminophen. Aspirin should be avoided in thyrotoxic patients because it decreases the protein binding of T_4 and T_3. Agitation is controlled with benzodiazepines. Fluid resuscitation is needed to compensate for insensible and gastrointestinal (GI) losses; dextrose-containing solutions are helpful because glycogen stores are often depleted. Electrolyte replacement is guided by laboratory values.

Symptomatic Treatment

Symptomatic treatment consists primarily of beta blockade to diminish the adrenergic response. Propranolol is the beta blocker of choice because it has the added benefit of blocking conversion of T_4 to T_3; its nonselective effects also improve tremor, weakness, hyperpyrexia, restlessness, irritability, and emotional lability. The onset of action after oral dosing is about 1 hour.

For more rapid beta blockade, propranolol can be administered intravenously (IV). A short-acting agent such as esmolol may be used when concerns about beta blockade exist, due to underlying asthma or COPD, or pulmonary edema from heart failure. In asthmatics, a β_1-selective drug such as esmolol or metoprolol may be considered.

If beta blockers are contraindicated, reserpine, 2.5 to 5 mg intramuscularly (IM) every 4 hours, is also an option. Patients should be closely monitored for hypotension, regardless of the agent used, because thyrotoxicosis can lower systemic vascular resistance and cause congestive heart failure. Patients who develop clinically significant heart failure should be treated with the usual medications for heart failure, including diuretics and angiotensin-converting enzyme inhibitors. Atrial fibrillation is often refractory to rate control until antithyroid therapy is instituted.

Thyroid-Directed Treatment

Thyroid-directed therapy has three goals: reduce thyroid hormone production, prevent thyroid hormone release, and block peripheral conversion of T_4 to T_3. In conjunction with this treatment, an additional goal is the avoidance of therapeutic interventions that may worsen thyrotoxicosis. As such, certain drugs should be avoided in the thyrotoxic patient. Amiodarone and iodinated contrast material both contain iodine and can increase thyroid hormone production. Aspirin can increase free thyroid hormone concentrations through its effect on protein binding. Pseudoephedrine, ketamine, and albuterol increase sympathetic tone and can exacerbate the adrenergic effects of thyrotoxicosis; when indicated, they should be used cautiously.

Reducing Thyroid Hormone Production. Thionamides inhibit oxidation and organic binding of iodine to thyroglobulin, thereby blocking the synthesis of thyroid hormone. PTU or methimazole can be used. PTU has the additional effect of impairing the conversion of T_4 to T_3; methimazole has a longer duration of action. Both PTU and methimazole may be given by nasogastric tube or rectum as needed. PTU is preferred in the first trimester of pregnancy, and methimazole is preferred in the second and third trimesters. Methimazole is available in IV form outside the United States, but its use is not recommended by the most recent American Thyroid Association guidelines.[6]

Side effects of thionamide therapy vary from mild to life-threatening. These can range from urticarial, rash, arthralgia, GI upset, to agranulocytosis, hepatotoxicity and vasculitis.

Inhibiting Thyroid Hormone Release. Inorganic iodine blocks the release of stored thyroid hormone. Because an iodine load can increase the synthesis of thyroid hormone, these agents should not be administered until 1 hour after the initiation of PTU or methimazole therapy. Traditionally, oral iodine in the form of potassium iodide (SSKI), or Lugol solution, is administered. Like the thionamides,

these agents may be given via nasogastric tube or retention enema, as needed. Lithium may be considered an alternative therapy for iodine-allergic patients. Lithium is also the agent of choice for iodine-induced hyperthyroidism, which is usually the result of the administration of amiodarone or iodinated contrast material.

Inhibiting Conversion of T_4 to T_3. Corticosteroids are capable of inhibiting the peripheral conversion of T_4 to T_3 and blocking the release of hormone from the thyroid gland. When steroids are used in conjunction with PTU and iodide, the concentration of T_3 can return to normal within 48 hours. Hydrocortisone may be administered, and dexamethasone is an alternative.

Miscellaneous Therapies

Cholestyramine, an anion exchange resin, interrupts the enterohepatic recirculation of thyroid hormone by binding it in the bowel lumen. Because it may help to decrease the level of circulating hormone more rapidly, its use is recommended for severe or refractory thyroid storm. Although it has been shown to result in a more rapid decline in hormone levels compared with thionamides alone, it requires weeks of therapy and, as such, is reserved for outpatient management.[7] Plasmapheresis has been used in thyroid storm as an attempt to remove circulating thyroid hormone.[5,8] Extracorporeal membrane oxygenation (ECMO) has been recently described as successful in supporting patients with severe thyroid storm and "rapid clinical deterioration."[9] Neither radioactive iodine nor surgery plays a role in the management of thyroid storm or thyrotoxicosis until a sustained euthyroid state has been established because these interventions can precipitate thyroid storm.

First-line treatment of subacute thyroiditis is the use of nonsteroidal antiinflammatory drugs (NSAIDs). Corticosteroids are used in refractory cases. Symptomatic patients are treated with beta blockers. Management of drug-induced hyperthyroidism depends on the inciting agent. In the case of AIT-1, treatment typically consists of stopping amiodarone and initiating antithyroid therapy. AIT-2 is managed with corticosteroids, and the decision to stop amiodarone is made on a case-by-case basis.[10] Management of drug-induced hyperthyroidism related to lithium involves stopping lithium. When related to immunomodulator therapy, discontinuation of the offending drug is not always mandatory.[11] Treatment is based on the determination of the type of reaction present; Box 117.4).

Identification and Treatment of the Precipitating Event

Thyroid storm is often precipitated by a physiologic stressor, such as infection, myocardial ischemia, pulmonary embolism, and stroke. Management of thyroid storm with PTU, followed by iodine, beta blockers, corticosteroids, fluid resuscitation, rapid cooling, and treatment of the precipitating illness, can resolve acute thyroid storm within 24 hours.

Disposition

The disposition of patients with hyperthyroidism is guided by symptom severity, with intensive care unit (ICU) admission for patients in thyroid storm. Patients with mild thyrotoxicosis controlled with a first-line medication who are otherwise stable can be managed as outpatients. Admission to the hospital may be appropriate for patients who require more than beta blockers for symptom control or whose symptoms persist despite therapy. Patients with rapid atrial fibrillation should be admitted to a monitored setting. Patients managed as outpatients can be sent to a primary care physician or referred to an endocrinologist. Lack of insurance and other socioeconomic factors have been linked to higher admission rates in patients with thyrotoxicosis.[12]

Note: Many subtypes and varying etiologies of hyperthyroidism have been identified. Table 117.3 provides descriptions of cases distinguished from the above general description.

BOX 117.4 Thyrotoxicosis and Thyroid Storm Special Situations

Congestive Heart Failure

If rate-related, high-output failure:
- Beta blockade is first-line therapy (dose as in Box 117.3)
- ACEI, digoxin, diuretics as needed

If depressed ejection fraction:
- Avoid beta blocker or one-quarter dose
- ACEI if blood pressure adequate
- Digoxin and furosemide as needed

If pulmonary hypertension:
- Oxygen
- Sildenafil

Atrial Fibrillation

Beta blocker preferred for rate control (dose as in Box 117.3)
Calcium channel blockers prone to hypotension; diltiazem, 10-mg test dose.
- Avoid verapamil.

Digoxin less effective but may be tried
Amiodarone should be avoided because of iodine load
Refractory to conversion to sinus rhythm unless euthyroid first

Thyroiditis (Subacute)

NSAIDs for inflammation and pain control
Prednisone, 40 mg/day, if refractory to NSAIDs
Beta blockade to control thyrotoxic symptoms
No role for PTU, methimazole, or iodides

Factitious Thyrotoxicosis

Beta blockade for thyrotoxic symptoms
Cholestyramine to block absorption of ingested thyroid hormone
No role for PTU, methimazole, or iodides

ACEI, Angiotensin-converting enzyme inhibitor; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PTU,* propylthiouracil.

HYPOTHYROIDISM

Foundations

Background and Importance

Hypothyroidism is a condition in which the thyroid gland fails to produce or secrete sufficient circulating thyroid hormone to meet the needs of the peripheral tissues. The condition results from lack of stimulation of the thyroid gland (central or secondary hypothyroidism) or intrinsic gland dysfunction limiting hormone production (primary hypothyroidism). Hypothyroidism is the most common functional disorder of the thyroid gland.

Thyroid disorders are the second most common endocrine condition after diabetes mellitus. Higher incidence rates are found in women than in men, which is attributed to the higher prevalence of autoimmune disease found in women in general. In the United States (US), 1% to 2% of women are affected by hypothyroidism. Subclinical hypothyroidism affects 4% to 10% of the population. The incidence of subclinical hypothyroidism in pregnancy is 5% to 8%.[13] There is no specific race or ethnic predilection, but older age groups are at a higher risk for the development of hypothyroidism.

Pathophysiology

Intrinsic gland failure accounts for up to 99% of all cases of hypothyroidism. Factors that may result in primary hypothyroidism include autoimmune disorders, infiltrative disorders, congenital thyroid dysfunction, pregnancy, radiotherapy, medications, infection, surgery,

TABLE 117.3 Hyperthyroidism Summary

	Background and Importance	Pathophysiology	Clinical Features	Diagnostic Testing	Management
Graves Disease	Most common form of hyperthyroidism in the United States Strong genetic association, with frequent occurrence in the setting of other autoimmune disorders[1] Some environmental causes, such as smoking	Autoantibodies bind to the TSH receptor and stimulate thyroid hormone production and release. Infiltration of the inferior rectus muscles Increased activity at the sympathetic innervation of the eyelids	Enlarged thyroid gland • May be absent in the elderly Ophthalmopathy • eyelid edema • hyperemia • conjunctival hyperemia • chemosis • restrictive extraocular myopathy • exophthalmos • restriction of upward gaze • visual loss secondary to optic nerve compression • widening palpebral fissure • lid lag Pretibial Myxedema • confluent, painless, reddish raised nodules and plaques over the pretibial area and dorsum of the feet, often described as "orange skin" • hyperpigmented • indurated • nonpitting	Thyroid receptor antibody positive Radioiodide uptake increased	Patients should first be treated to stabilize their acute thyrotoxic symptoms. Patients can then be referred for: • radioactive iodine therapy • OR long-term antithyroid drug administration • OR thyroidectomy
Toxic Multinodular Goiter	Second leading cause of hyperthyroidism in the United States More common in women >50 years old	Multiple autonomously functioning nodules	Enlarged, palpable thyroid gland Milder, more gradual in onset than Graves disease May present acutely when iodine replacement is given to iodine-deficient patients.	A ^{123}I or ^{99m}Tc pertechnetate scan	Patients should first be treated to stabilize their acute thyrotoxic symptoms. Patients can then be referred for: • radioactive iodine therapy • OR thyroidectomy Treatment with antithyroid drugs may be appropriate on occasion, when specific contraindications to the above exist
Toxic Adenoma	Typically affects the same population as toxic multinodular goiter, but is less common	Single hyperfunctioning nodule within the thyroid	Typical hyperthyroid signs and symptoms	A ^{123}I or ^{99m}Tc pertechnetate scan	Patients should first be treated to stabilize their acute thyrotoxic symptoms. Patients can then be referred for: • radioactive iodine therapy • OR thyroidectomy Treatment with antithyroid drugs may be appropriate on occasion, when specific contraindications to the above exist

Thyroiditis	Hashimoto thyroiditis is most common form in the United States	Any inflammatory process that results in thyroid gland inflammation can lead to thyroiditis: • autoimmune • drug-induced • infectious • traumatic Inflammation leads to follicular cell breakdown, with resultant release of preformed thyroid hormone, resulting in thyrotoxicosis Hashimoto is the result of thyroid antibodies and lymphocytic infiltration of the thyroid gland.	Exquisitely tender thyroid gland Hashimoto patients may have transient thyrotoxicosis, followed by painless goiter and hypothyroidism secondary to the destruction of thyroid tissue.	Elevated ESR and CRP Radioiodide uptake depressed	NSAIDS Corticosteroids for refractory cases
Postpartum Thyroiditis	5% of pregnant women will develop this. 70% recurrence rate in subsequent pregnancies Some women will have permanent hypothyroidism.	Autoimmune etiology, presents as the immune system returns to its normal function following pregnancy. Triphasic course: (1) thyrotoxicosis, 2 to 6 months postpartum, although this phase may be asymptomatic; (2) a hypothyroid state lasting 2 to 3 months; and (3) a euthyroid state by the end of the first postpartum year.	20% to 30% may have only thyrotoxicosis 40% may have only hypothyroidism	Diagnostic Triad: • Lack of previous history of thyroid disorder • Abnormal TSH concentration during the first postpartum year • Absence of TSH receptor antibodies or a toxic nodule	Supportive treatment Beta blockers are recommended to control pulse and other symptoms Atenolol is contraindicated in breastfeeding because of excretion in breast milk; propranolol and metoprolol are preferred.
Subacute Thyroiditis	de Quervain thyroiditis Most common in women, ages 40–60	Thought to be caused by a viral infection of the thyroid	Viral prodrome • fever • fatigue • myalgias • pharyngitis Anterior neck pain, may radiate to ears/jaw/throat Exquisitely tender thyroid, may be enlarged About 50% of patients have mild, typical symptoms lasting 3 to 6 weeks. About one-third of patients will then have hypothyroidism for up to 6 months, followed by a return to a euthyroid state 5–15% of patients will have persistent hypothyroidism.	Clinical suspicion based on history and physical exam TSH low Free T4 *may* be elevated relative to T3 Elevation of ESR, CRP May also see mild leukocytosis and anemia Radioactive iodine uptake is low	Initial treatment with beta-adrenergic blocking agents and NSAIDs. • May substitute corticosteroids for NSAIDs if moderate to severe thyrotoxic symptoms at presentation or failure to respond to initial interventions

Continued

TABLE 117.3 Hyperthyroidism Summary—cont'd.

	Background and Importance	Pathophysiology	Clinical Features	Diagnostic Testing	Management
Painless Thyroiditis	"Silent thyroiditis" Common cause of post-partum thyroiditis Also seen in nonpregnant women and men	Likely autoimmune Medication related • lithium • cytokine therapy	Similar to subacute thyroiditis, but typically without viral prodrome, neck pain or inflammatory response Small, nontender goiter Mild symptoms Triphasic course	ESR, CRP normal No leukocytosis Anti-thyroid peroxidase antibodies present in 50% of patients Low radioactive iodine uptake in thyrotoxic phase Typical lab findings for thyrotoxicosis in this phase (low TSH and high free T4)	Beta-adrenergic blocking agents Corticosteroids for severe cases
Acute Suppurative Thyroiditis	Rare Life-threatening	Infection of the thyroid gland • bacterial • parasitic (rare) • mycobacterial (rare) • fungal (rare)In adults, most often secondary to hematogenous spread or iatrogenic In children and adolescents, can be secondary to pyriform sinus fistula	Fever Anterior neck pain Neck swelling and induration Neck erythema Dysphonia Dysphagia Patients may be euthyroid.	Ultrasound or CT may demonstrate inflammation, destruction of the thyroid, and/or abscess formation; these findings may be absent early in the course of the disease.	Beta-adrenergic blocking agents for tachycardia Antibiotics and/or surgical drainage Definitive treatment of pyriform sinus fistula, when present.

Drug Induced Thyroiditis	Amiodarone
	Lithium
	Immunomodulators
	• immune checkpoint inhibitors
	• tyrosine kinase inhibitors
		Drug induced, related to specific drugs
		Amiodarone
		• Contains a large amount of iodine, and has a significant effect on thyroid function.
		• type-1 amiodarone induced thyroiditis (AIT)
		• iodine content of amiodarone unmasks subclinical Graves disease or goiters
		• type-2 AIT
		• direct destructive effect on thyroid cells, resulting in the release of preformed hormone[2]
		Immunomodulators
		• direct destructive effect on thyroid cells
		Lithium
		• more commonly causes hypothyroidism
		• exact mechanism unknown, theories include:
		  • Increased iodide retention and stores in the thyroid resulting in increased thyroid hormone production
		  • Autoimmune mechanism
		  • Direct toxic effect.[3]
			Exacerbation of the tachyarrhythmia for which the patient is being treated or heart failure.
			Immunomodulators
			• initial hyperthyroid phase (typically within a few weeks, but can present years later), followed by hypothyroidism[4]
				Typical lab findings for thyrotoxicosis (low TSH and high free T4)	Treatment depends on the inciting agent and type of reaction
					Amiodarone
					AIT-1
					• stop amiodarone
					• Antithyroid therapy
					AIT-2
					• corticosteroids
					• may or may not stop amiodarone
					Lithium
					• stop lithium
					Immunomodulators
					• inciting agent may or may not be stopped, depending on the type of reaction

Factitious Thyroiditis		Exogenous thyroid ingestion • intentional • nutritional supplements, particularly those marketed for weight loss.[5] • accidental	Thyroid enlargement not present on physical exam	Low thyroglobulin levels Low T3/T4 ratio (<20 ng/microgram) Radioactive iodine uptake is depressed	Cessation of offending agent
Subclinical Hyperthyroidism	Risk factor for cardiovascular morbidity and mortality, as evidenced by coronary artery disease, acute coronary events and atrial fibrillation Patients older than 65 years at higher risk	Subclinical hyperthyroidism with suppressed TSH and variable levels of functional thyroid hormone in the body Over time, some patients may remit and some will progress to full hyperthyroidism.	Patients are clinically euthyroid, but there is association with cardiovascular disease, osteoporosis, and changes in mood and cognition	Low TSH • lower TSH imparts higher riskNormal free T4 and T3	Treatment is recommended in patients over 65 with TSH <0.1 mU/L over time, IF They are asymptomatic but have risk factors for cardiovascular disease, osteoporosis, or are postmenopausal women not on estrogens or bisphosphonates OR They are symptomatic

inadequate dietary iodine intake, thyroid medication noncompliance, and previous treatment of thyrotoxicosis. Worldwide, iodine deficiency is the most common cause of hypothyroidism; however, in iodine-replete regions, the primary cause is autoimmune. Hypothyroidism may also be associated with other autoimmune diseases, most commonly diabetes mellitus.

Central causes of hypothyroidism are rare and result from hypothalamic dysfunction in the secretion of TRH or pituitary dysfunction in the secretion of TSH. Pituitary adenoma is the most common cause of central hypothyroidism. Other causes include pituitary hemorrhage (Sheehan syndrome), pituitary infiltrative processes, brain injury, and space-occupying mass. Sheehan syndrome is a result of postpartum pituitary hemorrhage that leads to pituitary ischemia and necrosis. Patients often have lactation failure, amenorrhea, adrenal insufficiency, and central hypothyroidism.

Clinical Features

History and Physical Examination

Signs and symptoms of hypothyroidism range from asymptomatic to overt organ failure, which may lead to death. Patients with early hypothyroidism often present with vague complaints. As a result, thyroid dysfunction should be considered in patients with generalized arthralgias, infertility or menstrual changes, depression, and hypercholesterolemia. Typical symptoms develop insidiously and progress with the disease (Box 117.5). Patients with subclinical hypothyroidism may present with varying nonspecific signs and symptoms similar to those of patients with overt hypothyroidism, but less pronounced. Patients with Hashimoto thyroiditis present typically with an insidiously developed goiter and hypothyroidism.

The thyroid plays a fundamental role in maintaining cardiovascular homeostasis in physiologic and pathologic states; it influences cardiac contractility, heart rate, diastolic function, and systemic vascular resistance. Increased peripheral vascular resistance and low cardiac output have been suggested to be additional links between hypothyroidism and impaired blood pressure regulation and resultant hypertension. Antihypertensive medications are usually ineffective in noneuthyroid individuals. The accelerated atherosclerosis in hypothyroidism is ascribed to dyslipidemia, diastolic hypertension, and impaired endothelial function. These cardiovascular findings are linked to overt and subclinical hypothyroidism.

Overt hypothyroidism leads to significant neuropsychiatric impairments of mood and cognition. Subclinical hypothyroidism may cause subtle deficits in memory and cognition.

Pulmonary abnormalities in hypothyroidism are primarily related to hypoventilation and hypercapnia; up to 65% of patients with pulmonary hypertension have concomitant thyroid dysfunction. Although the exact relationship is unknown, pulmonary artery pressures normalize after treatment of thyroid disease.

In pregnancy, hypothyroidism may be manifested typically, but it is often subtle and difficult to distinguish from normal changes in pregnancy.

In children, hypothyroidism may affect growth, development, and cognitive ability. Declining growth velocity noticed during several years might be the first clue to evaluate for thyroid disorders. T_4 replacement will induce a rapid growth spurt, although predicted bone maturation size might not be achieved. In adults, thyroid hormone functions to regulate and maintain bone mass; patients with hypothyroidism are at increased risk for fracture, although the underlying mechanism resulting in this association is unclear.

Myxedema Coma

Myxedema coma is a life-threatening event, presenting with altered mental status, hypothermia, and a concomitant precipitating event.[14] Precipitating events are listed in Box 117.6. Diagnosis must often be made on the basis of clinical findings (Box 117.7), and can be difficult because not all patients will present with all 3 elements described mentioned previously. Treatment of myxedema coma requires potentially toxic doses of thyroid hormone and can precipitate thyroid storm. Mortality rates are high, up to nearly 30%, even with optimum therapy. Higher mortality is seen in hospitalized patients who require steroids, mechanical ventilation, or exogenous catecholamines.[4] Without treatment, the mortality approaches 100%.

BOX 117.5 Symptoms and Signs of Hypothyroidism

Vital Signs
- Systolic blood pressure, normal or low
- Diastolic blood pressure, normal or elevated
- Slow pulse to sinus bradycardia
- Respirations, normal or slow, shallow
- Temperature, normal, but prone to hypothermia with stress

Hypometabolic Complaints
- Cold intolerance
- Fatigue
- Weight gain, but decreased appetite

Cutaneous
- Coarse, brittle hair
- Alopecia
- Dry skin, decreased perspiration
- Pallor, cool hands and feet
- Coarse, rough skin
- Yellow tinge from carotenemia
- Thin, brittle nails
- Lateral thinning of the eyebrows

Neurologic
- Slow mentation and speech
- Impaired concentrating ability and attention span
- Lethargy
- Decreased short-term memory
- Agitation, psychosis
- Seizures
- Ataxia, dysmetria
- Mononeuropathy
  - Carpal tunnel syndrome
  - Sensorineural hearing loss
- Peripheral neuropathy, paresthesias

Muscular
- Proximal myopathy
- Pseudohypertrophy
- Delayed relaxation of reflexes (hung up or pseudomyotonic)

Cardiac
- Decreased exercise capacity
- Dyspnea on exertion
- Sinus bradycardia
- Long QT with increased ventricular arrhythmia
- Chest pain, accelerated coronary disease
- Diastolic heart failure (delayed ventricular relaxation)
- Pericardial effusion (asymptomatic)
- Peripheral edema

Respiratory
- Dyspnea on exertion
- Obstructive sleep apnea
- Primary pulmonary hypertension

Gastrointestinal
- Constipation
- Ileus
- Gastric atrophy

Reproductive
- Oligomenorrhea and amenorrhea
- Menorrhagia
- Decreased fertility
- Early abortions
- Decreased libido
- Erectile dysfunction

Rheumatic
- Polyarthralgias
- Joint effusions
- Acute gout or pseudogout

Head, Ear, Eyes, Nose, and Throat
- Hoarseness
- Deep husky voice
- Macroglossia
- Hearing loss
- Periorbital swelling
- Broad nose
- Swollen lips
- Goiter

Differential Diagnoses

Differential considerations include other causes of the common clinical presentations of hypothyroidism, such as congestive heart failure,

BOX 117.6 Myxedema Coma: Aggravating or Precipitating Factors

Infection, sepsis (especially pneumonia)
Exposure to cold
Cerebrovascular accident
Drug effect
- Altered sensorium: sedative-hypnotics, narcotics, anesthesia, neuroleptics
- Decreased T_4 and T_3 release: amiodarone, lithium, iodides
- Enhanced elimination of T_4 and T_3: phenytoin, rifampin
- Inadequate thyroid hormone replacement: noncompliance; interference with absorption (iron, calcium, cholestyramine)

Myocardial infarction
Gastrointestinal bleeding
Trauma, burns
Congestive heart failure
Hypoxia
Hypercapnia
Hyponatremia
Hypoglycemia
Hypercalcemia
Diabetic ketoacidosis

T_3, Triiodothyronine; *T_4*, thyroxine.

BOX 117.7 Recognition of Myxedema Coma

Patient profile—older woman in the winter
Known hypothyroidism; thyroidectomy scar
Hypothermia—temperature usually <95.9°F (36°C); <90°F (32°C) is poor prognostic sign; as low as 75°F (24°C) reported; nearly normal in presence of infection
Altered mental status—lethargy and confusion to stupor and coma, agitation, psychosis, and seizures (myxedema madness)
Hypotension—refractory to volume resuscitation and pressors unless thyroid hormone administered
Slow, shallow respirations with hypercapnia and hypoxia; high risk of respiratory failure
Bradycardia (sinus), long QT and ventricular arrhythmias
Myxedema facies—puffy eyelids and lips, large tongue, broad nose
Evidence of severe chronic hypothyroidism—skin, hair, reflexes, bradykinesis, voice
Acute precipitating illness (e.g., pneumonia)
Drug toxicity (e.g., sedative, narcotic, neuroleptic)
Hyponatremia

pulmonary edema, depression, encephalopathy, hypothermia, systemic infection, and shock.

Diagnostic Testing

Determination of an elevated TSH level is the most sensitive and single best screening test to confirm the diagnosis of primary hypothyroidism. An elevated TSH level with a low T_4 level is indicative of primary hypothyroidism. Central hypothyroidism is associated with a low or normal TSH level, with a low T_4 level. An increased TSH concentration with a normal T_4 level represents subclinical hypothyroidism.

If the TSH level is normal but the T_4 level is low, hypothyroxinemia exists; patients are often asymptomatic but can experience pathologic effects. A useful confirmatory test is the presence of thyroid antibodies (antithyroglobulin, antimicrosomal). They may help determine the cause of hypothyroidism or may serve to predict a future occurrence. Other laboratory findings may include mild anemia, hypercholesterolemia, elevated hepatic enzyme levels, elevated prolactin level, and hyponatremia. Blood glucose levels may be normal to low.

The electrocardiogram is nonspecific in hypothyroidism. It might reveal sinus bradycardia with low-voltage complexes and nonspecific ST-T wave changes.

The presence of myxedema coma carries a high mortality, and inappropriate treatment can cause thyroid storm, so appropriate identification is essential. A recent scoring system was proposed that indicates the risk of myxedema coma and recommended treatments (Table 117.4). While this scoring system requires wider validation, the elements listed are helpful in guiding the clinician to the diagnosis.[14]

TABLE 117.4 Myxedema Coma Scoring Tool

Criterion	Score
GCS 0-10	4
GCS 11-13	3
GCS 14	2
GCS 15	0
TSH > 30 mU/L	2
TSH 15–30 mU/L	1
Low FT4 (<0.6 ng/dL)	1
Hypothermia (<95 degrees F)	1
Bradycardia (<60 beats/minute)	1
Precipitating Event	1

For total scores 8–10, myxedema coma is most likely and proceeding with treatment is recommended; for total scores 5–7, myxedema coma is likely, and treatment is recommended if there are no other likely diagnoses; for total scores <5, myxedema coma is unlikely and clinicians should consider other diagnoses.
Adapted from: Chiong YV, Bammerlin E, Mariash CN. Development of an objective tool for the diagnosis of myxedema coma. *Transl Res.* 2015;166(3):233-243.

Management

Hypothyroidism

Replacement with levothyroxine (T_4) remains the treatment of choice and resolves most physical and psychological signs and symptoms of hypothyroidism in most patients. Synthetic levothyroxine is a levo isomer of thyroxine and has activity identical to that of the endogenous hormone. Approximately 70% to 80% is absorbed from the GI tract, predominantly in the small intestine. T_4 levels peak approximately 4 hours after ingestion. The T_3 concentration rises more slowly because it depends on conversion from T_4. Dose optimization is guided by monitoring of serum TSH levels and symptoms.

Levothyroxine is the drug of choice for patients with subclinical hypothyroidism and a serum TSH concentration above 10 mIU/L and for symptomatic patients with a serum TSH concentration between 5.1 and 10.0 mIU/L. The usual daily dosage is between 50 and 75 μg. The TSH concentration guides thyroid hormone dosing, and should be checked every 6 to 8 weeks after initiation of treatment until TSH levels normalize. It is recommended that levothyroxine be taken at bedtime or 60 minutes before breakfast to improve absorption.[15]

Studies comparing combination therapy of levothyroxine (T_4) and T_3 (liothyronine) with levothyroxine monotherapy included variable combinations and dosages, and have not established a significant benefit for the vast majority of patients. The most recent American Thyroid

BOX 117.8 Treatment of Myxedema Coma

- Protect airway, ventilatory support; monitor for alkalosis
- Fluid resuscitation
  - 0.9 NS or D_5/0.9 NS if hypoglycemia
  - Watch for unmasking of CHF
- Thyroid hormone replacement
  - T4 200–400 μg IV (give lower doses to patients who are smaller, have coronary artery disease or a history of arrhythmia) loading dose
  - Subsequent daily replacement of 1.6 μg/kg body weight PO, give 75% of this dose if given IV
- Hydrocortisone—100 mg IV every 8 hrs
- Hyponatremia
  - Consider fluid restriction.
  - Avoid hypotonic fluids; use only 0.9 NS or D_5/0.9 NS.
  - If <120 mEq/L, consider 3% saline, 50- to 100-mL boluses.
- Passive rewarming
  - Regular blankets; prevent heat loss
  - If heating blankets are considered, pretreat with IV fluids and monitor blood pressure closely.
  - Avoid mechanical stimulation.
- Treatment of any precipitating illness, with special attention to infectious causes

CHF, Congestive heart failure; *D_5/0.9 NS,* 5% dextrose in 0.9% normal saline; *IV,* intravenous; *PO,* by mouth; *T_3,* triiodothyronine; *T_4,* thyroxine.

Association guidelines do not recommend combination therapy for routine treatment.[15]

Myxedema Coma

The cornerstone for the treatment of myxedema coma is rapid replacement of IV thyroid hormone (Box 117.8). An initial loading dose of 200 to 400 μg IV should be given, using lower doses in patients who are smaller, older, or have a history of coronary artery disease or arrhythmia. Subsequent daily replacement dose is 1.6 μg/kg body weight, decreasing the dose to 75% of the IV dose. In very ill patients, liothyronine administration can be considered in addition to levothyroxine therapy, with extreme caution because elevated levels of T3 in the serum are associated with increased mortality. Stress doses of an IV glucocorticoid are recommended due to possible concomitant adrenal insufficiency. Hydrocortisone, 100 mg IV, is the drug of choice because it has mineralocorticoid and glucocorticoid effects.

Hypotension may respond to crystalloid infusion, but vasopressors are occasionally required. In patients with initially refractory hypotension, the mere replacement of thyroid hormone may have a beneficial effect on improvement of blood pressure. Passive rewarming with blankets and removal from the cold are generally sufficient until the administered thyroid hormone takes effect.

Hyponatremia may occur and is associated with increased mortality. As with other causes of hyponatremia, hypertonic saline should be administered for severe cases of altered mental status or seizures and then corrected more slowly to avoid osmotic demyelination syndrome. The metabolism of sedatives, narcotics, and anesthetics may be slowed, prolonging their effects; lower dosages should be considered.

Disposition

Most patients with hypothyroidism may be treated on an outpatient basis. Patients with severe hypothyroidism or patients with myxedema coma require inpatient care, often in an ICU setting.

Note: There are varying etiologies of hypothyroidism, each with unique aspects of their pathophysiology, diagnosis, and management. These are summarized in Table 117.5.

ADRENAL EXCESS STATES

Foundations

Background and Importance

Adrenal excess states can arise from a variety of causes, including Cushing syndrome, primary and secondary hyperaldosteronism, and pheochromocytoma. Regardless of the etiology, these all result in an excess of adrenal function, which can result in various symptoms that will prompt a patient to present to the ED. In particular, adrenal excess states are to be considered in any patient with resistant hypertension.[16] Left untreated, the long-term metabolic and cardiovascular effects of these diseases can be devastating.

Cushing Syndrome

Pathophysiology

Cushing syndrome results from excessive exposure to cortisol. The most common cause of this syndrome is long-term exogenous steroid administration. Endogenous Cushing syndrome is caused by excessive release of cortisol internally, usually from a corticotropin (ACTH) released from the pituitary (Cushing disease), or cortisol secretion from primary adrenal lesions (adrenal adenoma or carcinoma or adrenal hyperplasia of the adrenal cortex), or ectopic production of a corticotropin-releasing hormone (CRH) by a nonpituitary or other neuroendocrine tumor.[17,18]

Clinical Features

Because of systemic excess in cortisol, patients with Cushing syndrome will present with a variety of nonspecific symptoms given the broad downstream effects of the glucocorticoid exposure. Patients may experience multiple nonspecific symptoms, including psychiatric symptoms, generalized weakness, fatigue, menstrual irregularities and weight gain. Physical examination may reveal obesity, hirsutism, abdominal striae, an increase in adipose distribution on the back and above the clavicles (the classic "buffalo hump") and thin skin.[16,18] According to Nieman and colleagues, easy bruising, facial plethora, proximal muscle weakness and abdominal striae are the physical findings most associated with Cushing syndrome.[18] Cushing syndrome has also been linked to hypertension, diabetes, central obesity, and osteoporosis.[17]

Differential Diagnoses

Because of symptoms that are similar across the spectrum of etiologies of adrenal excess states, the differential diagnosis spans the same gamut. Resistant hypertension and glucose disorders can also be seen in hyperaldosteronism and pheochromocytoma. It can be difficult to distinguish simple obesity and metabolic syndrome from Cushing syndrome.[19] There is also significant overlap in the presenting symptoms of simple depression. Menstrual irregularities can also be associated with a variety of other etiologies, in addition to Cushing syndrome.[18]

Diagnostic Testing

The diagnostic workup of patients with suspected endogenous Cushing syndrome is complex and usually performed in the outpatient setting. Patients who should be referred for evaluation include individuals with an incidentaloma consistent with adrenal adenoma on imaging; patients who have presentations that would not be typical for their age, such as hypertension or osteoporosis at a young age; and patients with multiple clinical findings that would suggest Cushing syndrome.[18]

TABLE 117.5 Hypothyroidism Etiologies

	Background and Importance	Pathophysiology	Clinical Features	Diagnostic Testing	Management
Primary	Most common etiology of hypothyroidism[1]	Results from thyroid hormone deficiency	Typical symptoms span the spectrum from hypothyroidism to myxedema coma	An elevated TSH level with a low T_4 level indicates primary hypothyroidism.	Levothyroxine replacement
Autoimmune	Hashimoto thyroiditis, also known as chronic autoimmune lymphocytic thyroiditis One of the most common organ-specific autoimmune diseases Most common cause of primary hypothyroidism in iodine-replete areas of the world	Infiltration of the thyroid gland by lymphocytic inflammatory cells results in destruction and eventual fibrous replacement of the gland's follicular tissue and subsequent functional hypothyroidism.	Patients typically present with an insidiously developed goiter and hypothyroidism.	Elevated TSH Low T_4	Levothyroxine replacement
Infiltrative disorders[1]	Rare cause of primary hypothyroidism	Infectious Malignant Autoimmune Inflammatory	Patients will present with typical hypothyroid symptoms	Elevated TSH Low T_4	Levothyroxine replacement
Congenital thyroid dysfunction	Most preventable cause of intellectual disability	Most commonly caused by thyroid dysgenesis, resulting in decreased production of T_4. Some infants have minimal thyroid tissue but it is insufficient to sustain normal thyroid hormone production. Cognitive deficit is directly related to the amount of delay in diagnosis and treatment	Typically discovered on newborn screening tests	Elevated TSH Low T_4	Levothyroxine replacement
Pregnancy-related hypothyroidism		Thyroxine binding globulin (RBG) and Total T_4 increase and peak by 16 weeks and stay elevated throughout pregnancy.[2] Human chorionic gonadotropin (hCG) and TSH have identical subunits, which then both stimulate the release of T_4 and T_3, resulting in a decreased level of TSH throughout pregnancy. Increased peripheral metabolism of thyroid hormone occurs primarily in the second and third trimesters	In pregnancy, hypothyroidism may be manifested typically, but it is often subtle and difficult to distinguish from normal changes in pregnancy. Other obstetric complications of hypothyroidism include miscarriage, anemia, abruptio placentae, postpartum hemorrhage, low birth weight, and neonatal respiratory distress[2]	TSH will be altered, interpret based on local trimester- specific TSH ranges[3]	Women with preexisting hypothyroidism will generally require increased doses of replacement hormone in pregnancy. At this time, the evidence is not sufficient to recommend universal screening for thyroid function and subsequent treatment in pregnant women without overt symptoms or risk factors for hypothyroidism.[2]
Medication related	Lithium Lithium causes overt hypothyroidism in 14–17% of patients, and subclinical hypothyroidism in 19–35% of patients.	Lithium inhibits release of T_4 and T_3. Lithium may increase autoimmunity to the thyroid if it was preexisting.	Typical hypothyroid signs and symptoms	Elevated TSH Low T_4	Lithium: Treatment with exogenous thyroid hormone is effective, and lithium therapy need not be discontinued.

Continued

TABLE 117.5 Hypothyroidism Etiologies—cont'd

	Background and Importance	Pathophysiology	Clinical Features	Diagnostic Testing	Management
	Amiodarone[4] • Anti-thyroid peroxidase autoantibodies and female gender are linked with an increased risk of amiodarone induced hypothyroidism (AIH) • Increased incidence in iodine replete areas	Amiodarone is a class III antiarrhythmic medication Chemical structure similar to that of T_4 Contains large amounts of iodine. Inhibits the peripheral conversion of T_4 to T_3 Directly cytotoxic to the thyroid Blocks thyroid hormone entry into cells Decreases T_3 receptor binding	Typical hypothyroid signs and symptoms	Elevated TSH Low T_4	If amiodarone therapy must be continued for arrhythmia control, patients with AIH may be successfully treated with exogenous thyroid hormone replacement and amiodarone use may continue.[4] Patients should be screened with a TSH prior to starting amiodarone.[5]
Inadequate dietary intake	Uncommon in developed nations, but still a major concern in areas where the iodine content in the water is low.	Insufficient dietary iodine intake leads to reduced T4 and T3 production, with compensatory increase in TSH concentration and gland cell proliferation, goiter.	Goiter	Elevated TSH Low T_4	Dietary iodine supplementation
Prior hyperthyroid treatment		Thyroid known to be functionally absent based on prior anti-thyroid treatment	Typical hypothyroid signs and symptoms	Elevated TSH Low T_4	Levothyroxine replacement
Surgically removed		Thyroid known to be surgically absent based on prior anti-thyroid treatment	Typical hypothyroid signs and symptoms	Elevated TSH Low T_4	Levothyroxine replacement
Nonthyroidal Illness Syndrome (NTSI)[6–8]	Previously known as euthyroid sick syndrome Transient form of central hypothyroidism that occurs in critically ill patients	Its molecular basis remains unclear, but its presence in critically ill patients predicts adverse outcomes and mortality.[6–8] In acute phases, this is likely related to changes in binding and uptake of thyroid hormone by cells, as well as decreased conversion of T_4 to T_3. In chronic phases, likely results from dysregulation of the hypothalamic-pituitary-thyroid axis in the setting of critical illness	Typical hypothyroid signs and symptoms in the setting of critical illness	Initially low T_3, followed by decrease in T_4 and TSH as illness progresses.	At this time, there is no evidence that treatment of patients with NTIS improves outcomes.

Diagnosis begins with urine free cortisol, late night salivary cortisol and/or a dexamethasone suppression test, and additional imaging studies as indicated.[18] Given that these tests typically occur outside of the ED, these patients should be referred to a primary physician for definitive testing, or have workup by an inpatient team when admission is indicated.

Management

Management in the ED is directed towards treating the manifestation of Cushing syndrome that prompted the current presentation. Acute control of hypertension and glucose disorders is as per routine clinical practice. Definitive management of the underlying causes follows appropriate diagnosis via the methods described above and requires surgical resection of responsible lesions.[18]

Disposition

The need for hospitalization of patients who present with extremes of the disorders associated with Cushing syndrome (uncontrolled hypertension, glucose disorders, fractures) is determined by usual practices for these presentations. Most patients with chronic Cushing syndrome and milder symptoms can be discharged and referred for further workup as outpatients.

Hyperaldosteronism

Pathophysiology

Hyperaldosteronism is the result of excessive aldosterone production. Aldosterone acts on the kidneys, regulating sodium absorption, potassium excretion, and subsequently, hydrogen excretion. In primary hyperaldosteronism, excessive aldosterone is produced by the adrenal glands, independent of the signals from the renin-angiotensin system and sodium administration.[20,21] It is the most common cause of secondary hypertension and is significantly linked to cases of refractory hypertension.[21] Because aldosterone has toxic effects on vascular structures, it can result in cardiovascular disease and stroke, in addition to hypertension.[16] Primary hyperaldosteronism is caused by an intrinsic abnormality of the adrenal glands, such as hyperplasia or malignancy. Secondary hyperaldosteronism is caused by increased action of renin on the adrenal glands, as seen in states of renal hypoperfusion, but has the same downstream effects.

Clinical Features

Patients with hyperaldosteronism most commonly present with hypertension and its associated symptoms, as it is significantly linked with refractory hypertension. Patients may also present with a variety of other cardiovascular events, such as atrial arrhythmias, heart failure, and strokes. Primary aldosteronism is associated with the metabolic syndrome of obesity, high-density lipoprotein cholesterol and hypertriglyceridemia, and hyperglycemia. Laboratory workup may also demonstrate hypokalemia.[22]

Differential Diagnoses

Hyperaldosteronism can mimic any disease that presents with hypertension and/or disorders of potassium regulation. Its differential diagnosis includes essential hypertension, other adrenal disorders, thyroid dysfunction, and diabetes.

Diagnostic Testing

The most recent Endocrine Society clinical practice guideline recommends referral for testing for any patient with hypertension that is not controlled with three or more medications, or any patient requiring four or more medications, any patients with hypertension and hypokalemia, sleep apnea, family history of early onset hypertension or stroke, or a family history of primary aldosteronism. In the ED, significant hypertension and any incidentaloma on the adrenal should also be referred for further evaluation.[23] Workup (inpatient or outpatient) entails measurements of the plasma renin activity or plasma renin concentration and plasma aldosterone concentration, as well the plasma aldosterone/renin ratio. If the renin concentration or renin activity are suppressed, and the aldosterone level is inappropriately high, then further confirmatory testing with laboratory studies and imaging are indicated.[23]

Management

Presentations of acute cardiovascular events, refractory hypertension or severe electrolyte derangements are managed acutely in the ED according to usual practice. Further workup and treatment for underlying primary aldosteronism is initiated once the patient has been stabilized.

Disposition

Patients with severe, acute cardiovascular events or electrolyte derangements should be admitted to the hospital according to usual practice. Patients who are stable or improving and are otherwise appropriate for discharge based on their presenting symptoms and diagnosis can be discharged home with referral for further workup as described previously.

Pheochromocytoma and Paraganglioma

Pathophysiology

Emanating from adrenal medullary chromaffin cells, pheochromocytomas are rare catecholamine–secreting neuroendocrine tumors, whereas paragangliomas are catecholamine–secreting tumors arising from the thoracic and abdominal parasympathetic ganglia.[24] The excess catecholamine states result in significant downstream systemic effects, both based on the action of norepinephrine and epinephrine as vasopressors. There is also evidence that patients with pheochromocytomas and paragangliomas have increased circulating steroids, due to the interaction between the adrenal cortex and the medulla.[25] The tumors can be benign or associated with malignancy, especially in patients who are younger and have larger tumors.[26] Certain medications can potentiate the effects of catecholamines and result in an acute exacerbation of underlying pheochromocytoma. These include dopamine receptor antagonists, beta-blockers, sympathomimetics, opioid analgesics, norepinephrine reuptake inhibitors, serotonin reuptake inhibitors, monoamine oxidase inhibitors, corticosteroids, peptides, and neuromuscular blocking agents.[24]

Clinical Features

Clinical features of pheochromocytoma and paraganglioma are characteristic of catecholamine excess. Classic symptoms include paroxysms of hypertension, diaphoresis, palpitations, headache, abdominal pain, nausea, vomiting, and weight loss. In extreme cases, patients may present with hypertensive crisis.[27] With increasing use of CT and MRI imaging, a larger proportion of patients are diagnosed after a tumor is discovered incidentally (e.g., "incidentaloma").

Differential Diagnoses

Because catecholamine excess mimics any hyperadrenergic state, the differential diagnosis includes sympathomimetic toxicity, withdrawal syndromes, hyperthyroidism, serotonin syndrome, neuroleptic malignant syndrome, and presentations of typical untreated or refractory hypertension and underlying arrhythmias.

Diagnostic Testing

Definitive testing for pheochromocytoma and paraganglioma entails establishing a biochemical diagnosis via plasma free metanephrines

or urinary fractionated metanephrines. Once the diagnosis is apparent via these tests, CT imaging of the thorax, abdomen, and pelvis with contrast is recommended. MRI is reserved for patients with metastatic disease, neck and skull base lesions, or other contraindications to CT.[24] Given the significant overlap in presentation and symptomatology with multiple diseases as listed previously, providers must maintain a high index of suspicion in certain patient populations. Testing for pheochromocytoma and paraganglioma is indicated for any patient with the signs and symptoms listed previously, especially if they are paroxysmal, symptoms like this that are precipitated by the medications listed previously, or a personal or family history of pheochromocytoma, paraganglioma, multiple endocrine neoplasia type 2 (MEN2), or Von Hippel-Lindau (VHL) disease. Any patient with an adrenal incidentaloma should also be referred, regardless of symptoms.[24]

Management

Acute management of pheochromocytoma and paraganglioma focus on controlling the catecholamine surge effects. The first-line treatment is typically alpha-adrenergic blockade, such as phenoxybenzamine (final dose typically between 20–100 mg daily) or doxazosin. If resultant tachycardia ensues, providers may add calcium channel blockers or beta-adrenergic blockers. Of note, in patients with pheochromocytoma and catecholamine excess, beta-adrenergic receptor blockade in isolation can result in hypertensive crisis because of unopposed alpha-adrenergic receptor stimulation. Beta-adrenergic blockade should only be performed following alpha-adrenergic blockade in these patients. Use of calcium channel blockers alone is not recommended as initial treatment, but can be used in patients with very mild hypertension or undesirable alpha-adrenergic receptor blocker side effects.[24] Surgical removal of the offending pheochromocytoma or paraganglioma is the definitive treatment, and is typically delayed until the hyperadrenergic state is adequately controlled.

Disposition

Patients who present in hypertensive crisis or other extreme presentation who are not controlled with initial doses of the medications listed above should be admitted for continued treatment and monitoring. Patients who are stable can be discharged for continued workup and referral as outpatients.

ADRENAL INSUFFICIENCY

Foundations

Background and Importance

Adrenal insufficiency is the failure of the adrenal glands to function appropriately, and is a potentially life-threatening disease. Acute manifestations of disease may result in severe, refractory hypotension. Secondary adrenal insufficiency is more common than primary adrenal insufficiency. Its most common cause is exogenous corticosteroid administration.

Anatomy and Physiology

The adrenal glands are responsible for the release of the hormone aldosterone, corticosteroids, and catecholamines. They are paired structures that sit in the retroperitoneum, one atop each kidney. The adrenal gland has two distinct structures—the outer adrenal cortex, comprised anatomically of the zona glomerulosa, and the medulla, comprised anatomically of the zona fasciculata and reticularis. The medulla acts in concert with the central nervous system to produce and secrete epinephrine and norepinephrine in response to sympathetic stimulation. It also secretes the mineralocorticoid cortisol from the zona fasciculata and androgens from the zona reticularis. The outer cortex, which includes the zona glomerulosa, secretes the mineralocorticoid aldosterone.

ACTH, produced and secreted by the anterior pituitary, stimulates the adrenal cortex to synthesize and produce cortisol, which regulates carbohydrate, protein, and lipid metabolism, and aldosterone, which regulates fluid and electrolyte balance through sodium and potassium homeostasis. Cortisol is the primary glucocorticoid in humans, accounting for approximately 95% of all glucocorticoid activity.

Pathophysiology

Primary adrenal insufficiency, or Addison disease, is the failure of the adrenal gland to produce cortisol, aldosterone, or both, with an intact hypothalamic-pituitary-adrenal (HPA) axis (Fig. 117.3). Its most common cause in adults is autoimmune destruction of the adrenal gland. It can also be caused by infectious diseases and certain medications.[16] Adrenal insufficiency may occur alone, with other autoimmune diseases.

In primary disease, the HPA axis remains intact. Primary adrenal insufficiency is characterized by absent or low cortisol with high levels of circulating ACTH because of reduced negative feedback effects on the anterior pituitary. The increased ACTH concentration results in secretion of other hormones with similar chemical structure. One classic feature exemplifying this relationship is ACTH stimulation of melanocyte-stimulating hormone, which causes melanocytes to form a black pigment and the characteristic skin hyperpigmentation seen in those with primary adrenal insufficiency.

Secondary adrenal insufficiency is a result of impaired stimulation of the adrenals from the disruption of normal secretion of ACTH by the pituitary (see Fig. 117.3). It is characterized by a low plasma cortisol level, with low circulating ACTH levels.

Tertiary adrenal insufficiency is caused by hypothalamic disease. There is a decrease in release of corticotropin-releasing hormone, resulting in minimal ACTH and cortisol production. Aldosterone, sex hormone, and catecholamine synthesis are normal; the most common cause is long-term exogenous steroid administration.

Adrenal insufficiency may be further characterized as acute or chronic (Box 117.9). The most common cause of acute adrenal insufficiency is the exogenous administration of glucocorticoids, which results in suppression of the HPA axis. Although the time for HPA axis recovery after exogenous suppression is highly variable, adrenal insufficiency should be anticipated to occur in patients who receive corticosteroid therapy for prolonged periods, typically more than several weeks.

Adrenal crisis is usually seen in patients with Addison disease because of mineralocorticoid deficiency but can also present in patients with secondary or tertiary adrenal insufficiency who undergo severe physiologic stress, or exogenous steroid withdrawal (after suppression of the HPA axis). These stressors deplete cortisol stores and impair the ability to mount a normal stress response.

Clinical Features

The clinical manifestations of chronic adrenal insufficiency are nonspecific, as seen in Box 117.10. Primary and secondary adrenal insufficiency result in hyponatremia from different mechanisms—aldosterone deficiency and sodium wasting in primary adrenal insufficiency and a low cortisol level and free water retention in secondary adrenal insufficiency.

Primary adrenal insufficiency characteristically has more pronounced clinical manifestations than secondary adrenal insufficiency. Patients have symptoms related to a deficiency of glucocorticoids,

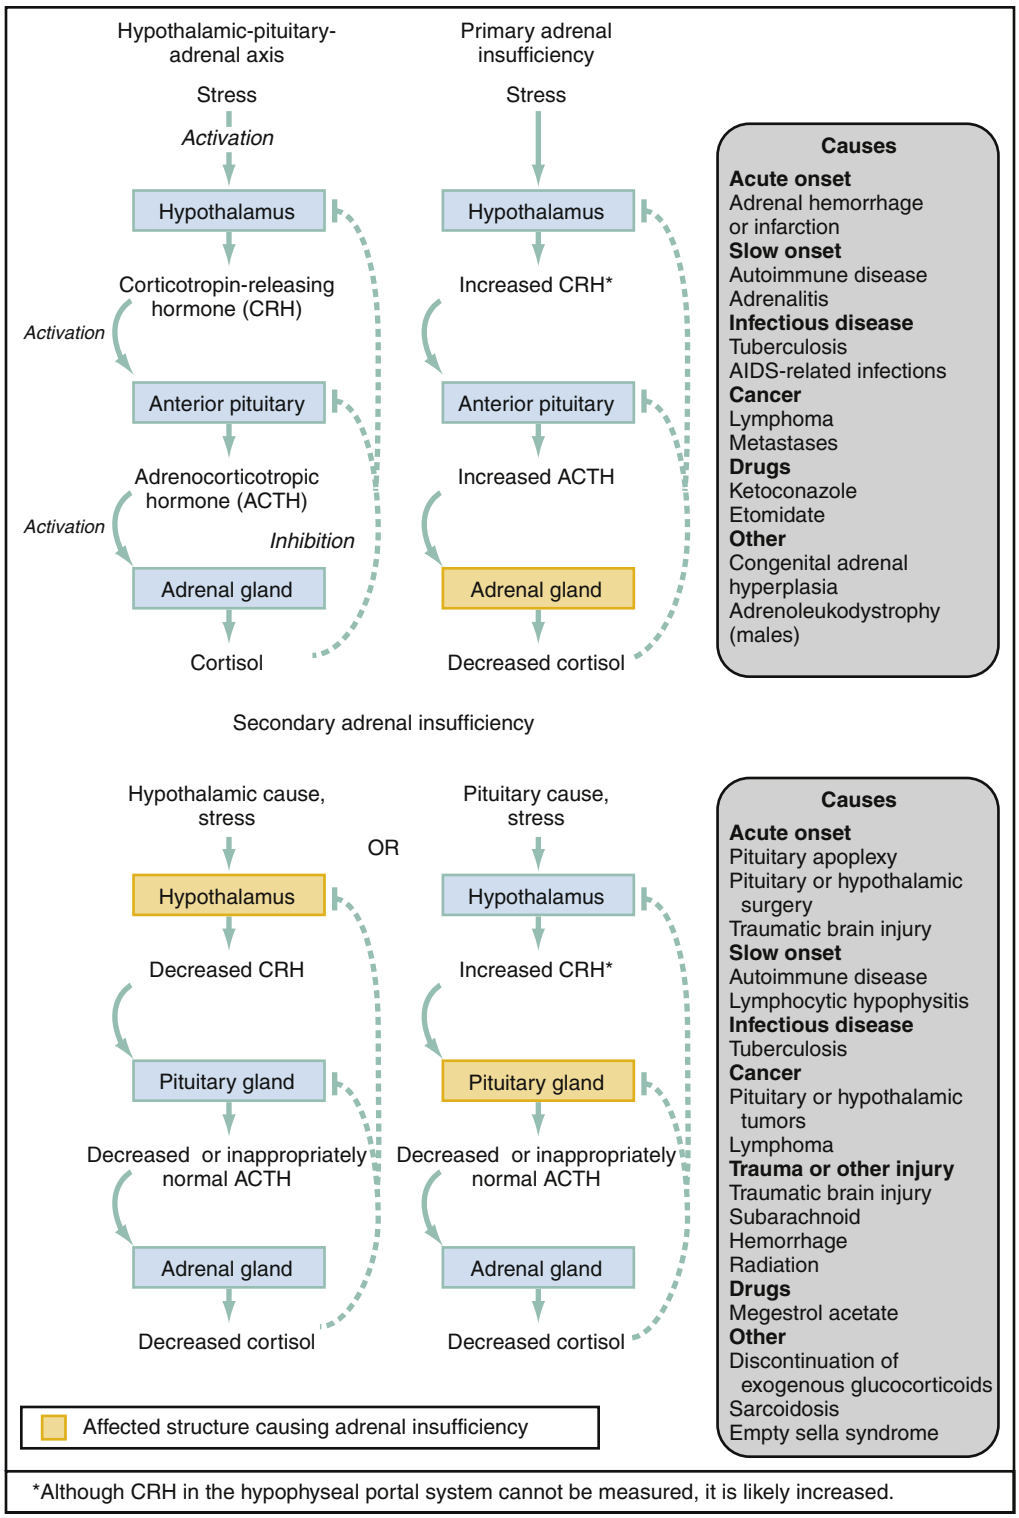

Fig. 117.3 Hypothalamic-pituitary-adrenal axis and causes of primary and secondary adrenal insufficiency. (Adapted from: Wallace I, Cunningham S, Lindsay J. The diagnosis and investigation of adrenal insufficiency in adults. *Ann Clin Biochem*. 2009;46[Pt 5]:351-367.)

mineralocorticoids, and androgens. Primary adrenal insufficiency more commonly presents with skin hyperpigmentation, particularly in areas exposed to the sun or subject to friction or pressure, salt craving, hyperkalemia, and acidosis. These patients may show signs of sodium and volume depletion (e.g., orthostatic hypotension and tachycardia). In secondary adrenal insufficiency, patients more often present with pale skin, loss of axillary and pubic hair, decreased libido, and impotence. Glucocorticoid deficiency and low ACTH concentrations may result in hypotension and hyponatremia with normal potassium levels.

BOX 117.9 Causes of Adrenal Insufficiency

Primary Adrenal Insufficiency

Chronic

Autoimmune adrenalitis (Addison disease): isolated or polyglandular deficiency, human immunodeficiency virus (HIV) infection (direct involvement or disseminated cytomegalovirus, *Mycobacterium avium-intracellulare,* tuberculosis, cryptococcosis, histoplasmosis, blastomycosis, toxoplasmosis, *Pneumocystis* pneumonia)
Tuberculosis and disseminated infections as seen with HIV
Metastatic cancer (breast, lung)
Infiltrative (sarcoid, hemochromatosis, amyloid)
Congenital (adrenal hypoplasia, adrenoleukodystrophy, ACTH resistance)
Bilateral adrenalectomy
Drug toxicity (e.g., etomidate, ketoconazole, rifampicin)

Acute

Adrenal hemorrhage
Meningococcemia and other sepsis
Anticoagulation (heparins and warfarin)
Anticardiolipin antibody syndrome
Trauma

Secondary Adrenal Failure

Chronic

Pituitary tumor (primary or metastatic)
Pituitary surgery or irradiation
Chronic steroid use with functional deficiency
Infiltrative (sarcoid, eosinophilic granuloma, tuberculosis)
Traumatic brain injury
Postpartum pituitary necrosis (Sheehan syndrome)
Empty sella syndrome

Acute

Pituitary apoplexy (hemorrhage into a pituitary tumor)
Postpartum pituitary necrosis (Sheehan syndrome)
Traumatic brain injury
Relative adrenal insufficiency (sepsis, hepatic failure, severe acute pancreatitis, trauma)

ACTH, Adrenocorticotropic hormone.

BOX 117.10 Clinical Features of Adrenal Insufficiency

General

Weakness, fatigue
Anorexia
Gastrointestinal symptoms
Weight loss
Hyponatremia
Blood pressure ≤ 110/70 mm Hg
Fevers (mild)
Depression, apathy
Myalgia, arthralgias
Auricular calcifications

Primary

Hyperpigmentation
Salt craving
Orthostasis, syncope
Vitiligo
Hyperkalemia
Hyperchloremia and acidosis
Hypoglycemia

Secondary

Hyperkalemia
Hyperpigmentation
Hypoglycemia
Orthostasis, hypotension
Amenorrhea
Axillary and pubic hair loss
Decreased libido

Crisis

Refractory hypotension

Adrenal crisis presents with hypotension and shock that does not respond to fluid resuscitation and pressors. Patients may have many other nonspecific symptoms, as listed above, but shock is the hallmark.

Differential Diagnoses

Because of the vague and nonspecific symptoms, the differential diagnosis of hypoadrenalism is extensive. The wasting associated with chronic adrenal insufficiency resembles that of anorexia nervosa or an occult carcinoma. The generalized weakness, fatigue, and myalgias can be confused with chronic fatigue syndrome, polymyalgia rheumatica, myopathy, hypothyroidism, or influenza syndromes.

Lack of recognition of acute adrenal crisis with refractory hypotension can result in evaluations for sepsis, GI bleeding, myocardial ischemia, or anaphylaxis. Abdominal pain in crisis may be clinically indistinguishable from an acute abdomen, especially if precipitated by adrenal hemorrhage. The headache and visual field cuts in pituitary apoplexy may resemble those of a hemorrhagic stroke. Finally, the constellation of symptoms seen in acute adrenal insufficiency—weakness, malaise, fatigue, nausea, dizziness, and arthralgias—is also present in steroid withdrawal syndrome. Because both can occur with the cessation of chronic glucocorticoid administration, history is critical to distinguish between the two disease processes.

Diagnostic Testing

Although there are many tests available to confirm the diagnosis of adrenal insufficiency, they require a significant amount of time or serial testing. For this reason, if there is suspicion of adrenal crisis, treatment should be initiated immediately, prior to confirmatory tests.

Mild to moderate hyponatremia, with levels typically above 120 mEq/L, are seen in primary adrenal insufficiency. Aldosterone deficiency leads to sodium wasting, and decreased cortisol levels lead to increased antidiuretic hormone, resulting in increased water absorption. Hyperkalemia may be seen in primary adrenal insufficiency secondary to a low circulating aldosterone concentration, but is not seen in secondary causes when aldosterone is not affected.

In stable patients, cortisol measurement is the mainstay for an accurate diagnosis. Measurement of the cortisol level in the ACTH stimulation test is the standard method. Random basal serum cortisol concentrations are of limited value for assessment of HPA axis reserve. In most emergent presentations, these tests are reserved for inpatient workup after initial ED stabilization.

Management

Patients with adrenal insufficiency require hormone replacement to correct a lack of circulating glucocorticoid and mineralocorticoid. Treatment of adrenal crisis should begin as soon as possible and prior

to diagnostic testing when crisis is suspected. The first-line treatment is hydrocortisone, 100 mg IV, with IV fluids, pressor support and glucose administration, as indicated (Box 117.11). An alternative is dexamethasone (4-mg IV bolus); in contrast to hydrocortisone, it does not interfere with serum cortisol assays.

Chronic management of adrenal insufficiency includes hydrocortisone (30 mg total daily in split doses; two-thirds of the daily dose is usually given in the morning and one-third in the late afternoon) and fludrocortisone, (50 to 200 μg/day) for mineralocorticoid replacement. In the setting of fever, infection, or other illness, these doses should be increased.

Whereas definitive treatment of secondary adrenal insufficiency is directed at replacement of missing hormone (ACTH or CRH) at the level of the hypothalamus or pituitary, in the ED setting, simple steroid hormone replacement is administered. Steroid tapering is necessary when gradual downregulation of the HPA axis has been provoked by exogenous glucocorticoids. There is no universally recommended method for steroid tapering.

Disposition

Severely ill patients should have the underlying disease process identified and treated; an ICU setting is indicated due to the high mortality rate. Most patients with mild symptoms of hypoadrenalism may be discharged for outpatient evaluation and treatment.

The references for this chapter can be found online at ExpertConsult.com.

BOX 117.11 Treatment of Hypoadrenalism

Maintenance

Hydrocortisone, 15–25 mg, divided into 2 or 3 doses daily
Fludrocortisone, 50–100 μg/day

Maintenance During Minor Illness

Hydrocortisone, double typical daily dosages
Fludrocortisone, 50–200 μg daily

Coverage During Procedural Stress

Hydrocortisone, 100 mg IV

Adrenal Crisis or Relative Adrenal Insufficiency of Critical Illness

Dexamethasone, 4 mg IV bolus
or
Hydrocortisone, 100 mg IV bolus, followed by additional dosing of 200 mg/24 hrs as bolus divided every 6 hrs or infusion if critically ill or major stress
0.9 NS, 2–3 L in the first few hours
Switch to D_5/NS if hypoglycemia
Treat precipitating illness

D_5/NS, 5% dextrose in normal saline; *0.9 NS,* 0.9% normal saline.

CHAPTER 117: QUESTIONS AND ANSWERS

1 What is the most common presenting sign of thyrotoxicosis?

a. Atrial fibrillation
b. Means-Lerman scratch
c. Tachycardia
d. Wide pulse pressure

Answer: C. The most common cardiac sign of thyrotoxicosis is tachycardia. Widened pulse pressure, a Means-Lerman scratch (a systolic friction rub), dilated cardiomyopathy, and pulmonary hypertension are all cardiac findings in patients with thyrotoxicosis, with atrial fibrillation being more common in patients over the age of 65.

2. In thyroid storm, which of the following is the proper sequence of drug administration?

a. All three together (antithyroid drugs, sodium or potassium iodide, steroid) at the same time
b. Antithyroid drugs, sodium or potassium iodide, steroid
c. Sodium or potassium iodide, steroid, antithyroid drugs
d. Steroid, sodium or potassium iodide, antithyroid drugs

Answer: B. Iodine can precipitate thyroid storm and must be given a minimum of 1 hour after thionamide therapy (PTU or methimazole). As such, the typical order is beta blocker (propranolol), PTU, or methimazole, and then iodine (SSKI, Lugol solution). In addition, it is important to identify and treat the precipitating cause of thyroid storm.

3. A 32-year-old female with a history of bipolar mood disorder on lithium presents with asthenia, fatigue, cold intolerance, and dry skin. A TSH test confirms your suspected diagnosis. How should you counsel the patient regarding her lithium use?

a. Instruct the patient to continue the lithium, no other intervention is necessary.
b. Instruct the patient to continue the lithium, while initiating therapy with levothyroxine.
c. Instruct the patient to stop her lithium, while initiating therapy with levothyroxine.
d. Instruct the patient to stop her lithium immediately and follow up with her primary care physician for an alternative medication.

CHAPTER 117: QUESTIONS AND ANSWERS—cont'd

Answer: B This patient presents with symptoms of overt hypothyroidism, confirmed by a high TSH on laboratory testing. Instruct the patient that she may continue her lithium for her chronic bipolar mood disorder, while initiating levothyroxine therapy. A well-known cause of hypothyroidism, lithium causes overt hypothyroidism in 14% to 17% of patients, and subclinical hypothyroidism in 19% to 35% of patients. Most of lithium's effects on the thyroid is due to the inhibition of T_4 and T_3 release. Lithium also increases thyroid autoimmunity if it is present before the initiation of lithium treatment. Treatment with exogenous thyroid hormone is effective, and lithium therapy need not be discontinued.

4. A 52-year-old man is brought in by ambulance from his home with altered mental status and hypotension. EMS reports that he became ill with an influenza-like illness 4 days ago and stopped taking all of his medications secondary to vomiting. Despite multiple fluid boluses, he remains hypotensive. Laboratory results demonstrate severe acidosis, hyponatremia and hyperkalemia. What is the most appropriate treatment for this patient?
   a. Adrenocorticotropic hormone (ACTH)
   b. Continued normal saline (0.9%) fluid boluses
   c. Hydrocortisone
   d. Norepinephrine

Answer: C. This patient presents with adrenal crisis, as evidenced by refractory hypotension and electrolyte abnormalities typical for hypoadrenalism. While refractory hypotension in the acutely ill patient may be the only clue to adrenal insufficiency, the paramedics also report that the patient has been unable to take his usual medications, presumably for primary adrenal insufficiency, and in the setting of acute illness has resulted in adrenal crisis. Additional fluids and pressors will be ineffective until appropriate glucocorticoid treatment is initiated, hydrocortisone, 100 mg IV. ACTH administration is used for evaluation of adrenal insufficiency and is not appropriate for therapeutic administration during the acute crisis.

5. A 37-year-old male presents to the ED with complaints of palpitations, abdominal pain, nausea, vomiting, and diaphoresis. He reports episodes similar to this that have been increasing in frequency and severity over several months. His vital signs are P 127, BP 174/90, RR 28, T 37.1°C, and Sao_2 96%. Once stabilized, what is the most appropriate oral treatment for this patient?
   a. Amlodipine 5 mg PO daily
   b. Metoprolol, 100 mg PO BID
   c. Phenoxybenzamine 10 mg PO BID
   d. Propranolol ER 80 mg PO daily

Answer: C. This patient presents with episodic, or paroxysmal symptoms that are consistent with pheochromocytoma. Following initial stabilization and appropriate workup, the patient will require control of his vital sign abnormalities and symptoms leading up to surgery. The first-line treatment for pheochromocytoma is alpha-blockade, so in this question, phenoxybenzamine is correct. In patients with catecholamine excess, beta blockade alone can result in hypertensive crisis because of unopposed alpha-adrenergic receptor stimulation. Beta blockers can be used, but this should only be done following alpha-blockade; as such, propranolol and metoprolol are incorrect. Calcium channel blockers may be used in mild cases or in patients with undesirable alpha-blockade side effects, but are not considered first line; as such, amlodipine is also incorrect.

118

Bacteria

Manpreet Singh and Madonna Fernández-Frackelton

KEY CONCEPTS

- All septic patients should be treated with antibiotics as soon as possible, even before a definitive diagnosis is made. Patients with pneumococcemia, meningococcemia, and aggressive soft tissue infections can decompensate rapidly.
- The source of sepsis should be identified as soon as possible, and surgical causes should be addressed. A surgeon should be consulted as soon as possible for patients with sepsis and a débridable source of infection.
- Immunity to diphtheria, tetanus, and pertussis wanes significantly in adults. Pertussis should be considered a cause of persistent cough in adults. A tetanus vaccination history should always be obtained from patients with trauma or infection. When there is doubt about the history, the age-appropriate vaccine according to CDC guidelines should be administered.
- Consider botulism in the differential diagnosis for the infant with failure to thrive, constipation, or decreased muscle tone and for the patient who injects drugs with neurologic symptoms.

DIPHTHERIA

Foundations

Background and Importance

In the fifth century BCE, Hippocrates first described what was likely diphtheria, characterized by sore throat, membrane formation, and death from suffocation. In 1821, Pierre Bretonneau named the condition *diphtherite* (Greek for leather), describing the characteristic pharyngeal membrane. In 1890, von Behring and Kitasato created the first diphtheria antitoxin (DAT) and 1 year later administered the first dose of antitoxin to a human with diphtheria. Immunization dramatically decreased the incidence of diphtheria in the United States from 206,000 cases in 1921 with 15,520 deaths to only 2 cases between 2004 and 2017.[1,2]

Humans are the only known reservoir for *Cornybacterium diphtheriae*. Spread is person-to-person through respiratory droplets or by direct contact with secretions, skin lesion exudates, or rarely fomites or food. Transmission is associated with crowded living conditions. Individuals may spread the disease when they are actively ill, in the convalescent stage, or as asymptomatic carriers.[1,3,4]

Immunization against diphtheria is highly effective (Fig. 118.1). Before widespread immunization in the United States, the incidence of diphtheria exceeded 100 cases per 100,000 population, and the disease predominantly affected children. Most people acquired natural immunity to diphtheria by age 15, and recurrent exposure to toxigenic strains of the bacteria acted as a booster. Because childhood immunization nearly eliminates toxigenic strains in a population, adult immunity wanes, so more adults in industrialized nations are susceptible to diphtheria. By the 1980s the Centers for Disease Control and Prevention (CDC) reported 0 to 5 cases per year nationwide. Currently, sporadic cases occur primarily in inadequately immunized adolescents and adults.[2] Even in industrialized nations with high childhood vaccination rates, more than 50% of adults older than 40 years old lack protective antibodies. Recent reemergence due to disruption of national vaccination programs has led to outbreaks in Yemen and Venezuela, with a recent death in Spain from a traveling passenger from that region.

Anatomy, Physiology, and Pathophysiology

Diphtheria is caused by *C. diphtheriae,* an unencapsulated, nonmotile, gram-positive bacillus named for its shape (*korynee,* for "club") and its characteristic clinical presentation (*diphtheria,* for "leather," describing the leathery pharyngeal membrane).[1]

Infection with *C. diphtheriae* can occur at various sites of the respiratory tract or the skin. Respiratory diphtheria includes faucial (pharyngeal or tonsillar), nasal, and laryngeal (tracheobronchial) types, named for the primary location of infection. Cutaneous diphtheria can occur as a primary skin infection or as a secondary infection of a preexisting wound.[1,3]

Toxigenic strains of *C. diphtheriae* bacterium are lysogenized with the bacteriophage and produce an exotoxin that inhibits cellular protein synthesis. The diphtheritic membrane, composed of leukocytes, erythrocytes, fibrin, epithelial cells, and bacteria, results from necrosis caused by local effects of the exotoxin. Initially, the pharynx appears erythematous, but as necrosis occurs, grayish white patches appear and eventually coalesce. The membrane causes surrounding edema and cervical adenitis. The initial grayish white, filmy appearance changes to a thick, grayish black membrane with sharply defined borders. This membrane adheres to the underlying tissue, and bleeding occurs if removal is attempted.[1]

Circulating exotoxin causes the systemic symptoms of diphtheria, most profoundly affecting the nervous system, heart, and kidneys.[1,3] The degree of local and systemic toxicity depends on the location and extent of membrane formation. Pharyngeal diphtheria has the greatest toxicity and cutaneous diphtheria the least. As the exotoxin disrupts cellular protein synthesis, it causes peripheral neuropathy manifested

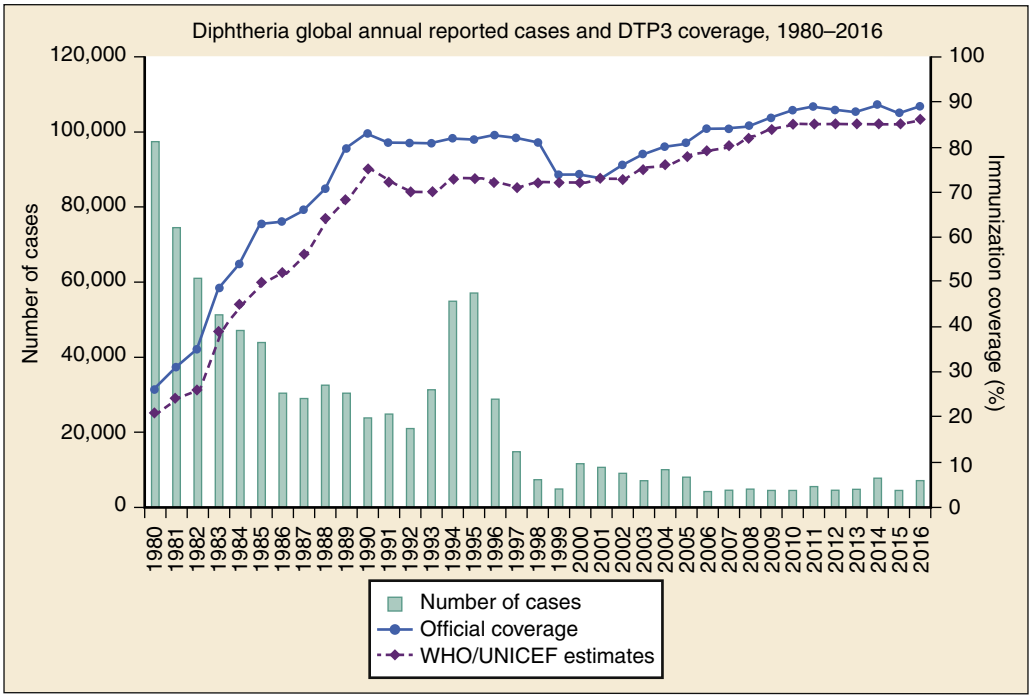

Fig. 118.1 Global annual reported cases of diphtheria compared with percentage of immunization coverage from 1980 to 2016. *DTP3,* Third dose of diphtheria-tetanus-pertussis vaccine; *UNICEF,* United Nations Children's Fund; *WHO,* World Health Organization. (From: World Health Organization, 2016 Global Summary. Geneva: WHO; 2016. World Health Organization: Immunization, vaccines and biologicals: diphtheria. Available at: www.who.int/immunization/monitoring_surveillance/burden/diphtheria/en/.)

by muscle weakness. About 5% of patients with respiratory infection develop polyneuritis; 75% of patients with severe disease have some form of neuropathy.[5] The muscles of the palate are usually affected first. Other cranial nerves, peripheral nerves, and the spinal cord may be affected. Degenerative lesions develop in dorsal root and ventral horn ganglia of the spinal cord and in cranial nerve nuclei. Cortical cells are spared. Proximal muscle groups are affected first. In severe cases, paralysis may develop in the first few days of illness. Paralysis typically does not last more than 10 days, but may last up to 3 months. Complete recovery over a longer time is the rule.[1]

The exotoxin directly damages myocardial cells. Cardiac dysfunction may appear 1 to 2 weeks after the onset of illness, but may arise earlier in severe cases. Electrocardiographic (ECG) changes suggestive of myocarditis occur in up to two-thirds of patients, but clinical manifestations of myocarditis occur in only 10% to 25% of cases.

Clinical Features

The average incubation period of respiratory tract diphtheria is 2 to 4 days (range 1–8 days). Signs and symptoms are indistinguishable from other upper respiratory tract infections, with low-grade fever and sore throat as the most frequent presenting complaints. Weakness, dysphagia, headache, voice changes, and loss of appetite are also common. Cough, shortness of breath, nasal discharge, and neck edema occur in less than 10% of patients. Cervical adenopathy occurs in approximately one-third of patients, and a membrane is observed in more than half of patients.

In patients with faucial diphtheria, the extent of the membrane parallels clinical toxicity. If the membrane is limited to the tonsils, disease may be mild; if it covers the entire pharynx, the onset of illness is usually abrupt and severe. Cervical lymphadenopathy and infiltration of neck tissues may be so extensive that the patient has a "bull-neck" appearance. Patients with this form of malignant diphtheria usually have high fever, severe muscle weakness, vomiting, diarrhea, restlessness, and delirium. Respiratory tract obstruction or cardiac failure from myocarditis can result in death.

Nasal diphtheria presents with serous or serosanguineous nasal discharge, and these patients do not usually have constitutional symptoms. A membrane may be visible. Treatment is important to prevent a persistent carrier state. Laryngeal diphtheria may begin in the larynx or spread downward. Respiratory tract edema with subsequent upper airway obstruction may develop. In cutaneous diphtheria, patients typically do not develop systemic toxicity. The skin characteristically has an ulcer with a grayish membrane; however, wounds from which *C. diphtheriae* is cultured are clinically indistinguishable from other chronic skin conditions.[1]

The most serious complications of diphtheria are airway obstruction, congestive heart failure, cardiac conduction disturbances, and muscle paralysis. Overall mortality is less than 3% but rises to 7% in patients with myocarditis and 26% in patients with the malignant form of the disease with neck swelling.[5] Although invasive disease is rare, endocarditis, mycotic aneurysms, osteomyelitis, and septic arthritis have all been described in immunocompromised hosts.[1]

Differential Diagnosis

It may be difficult to differentiate respiratory diphtheria from many other respiratory conditions, especially in the early phase of infection (Box 118.1). In general, the diphtheritic membrane is darker, grayer, more fibrous, and more firmly attached to the underlying tissues than in other conditions that have a membrane-like appearance. Acute necrotizing ulcerative gingivitis (ANUG) frequently involves the gingivae, which are unaffected in diphtheria. Acute bacterial epiglottitis has a more rapid onset than diphtheria, and laryngoscopy reveals an erythematous, edematous epiglottis without membrane formation.[1] Cutaneous diphtheria is difficult to differentiate from other acute and

BOX 118.1 Differential Diagnosis of Respiratory Diphtheria

Streptococcal pharyngitis
Viral pharyngitis (Epstein-Barr virus, adenovirus, herpes simplex)
Tonsillitis
Gonococcal pharyngitis
Acute necrotizing ulcerative gingivitis (ANUG)
Acute epiglottitis
Mononucleosis
Laryngitis
Bronchitis
Tracheitis
Candida albicans (thrush)
Rhinitis

chronic ulcerative skin lesions. *C. diphtheriae* can secondarily infect these lesions, especially in high-risk patients such as those with alcohol use disorder and unimmunized or underimmunized people.

Diagnostic Testing

The laboratory should be notified when *C. diphtheriae* is suspected, because routine cultures do not identify the organism. Throat or nasopharyngeal swabs should be obtained for respiratory diphtheria, and if present, membranous material should be examined. Samples should be obtained from skin lesions in cutaneous infections. Specimens should be collected before antibiotic therapy is initiated and transported to the laboratory for rapid inoculation onto tellurite selective culture medium.[1,3] Definitive identification is made using a combination of colony morphology, microscopic appearance, and fermentation reactions.[1] *C. diphtheriae* isolates should be tested for toxin production. The Elek test for toxin A is available at the CDC. Polymerase chain reaction (PCR), which is more reliable but not as readily available commercially, can detect the toxin structural gene. Newer methods that rapidly detect the toxin by mass spectrometry are not readily available but may be used in the future.[6] A positive culture for group A beta-hemolytic streptococcus does not exclude diphtheria, as up to 30% of patients with diphtheria test positive for streptococcal coinfection or carrier state.

Leukocytosis, mild thrombocytopenia, and proteinuria are common but neither sensitive nor specific for diphtheria. Changes on ECG are nonspecific and include ST-T wave changes, varying degrees of atrioventricular block, and dysrhythmias.[1] The ECG may be normal in the presence of myocarditis (see Chapter 68). An echocardiogram may show dilated or hypertrophic cardiomyopathy. Cardiac enzymes may be elevated; serum troponin levels correlate with the severity of myocarditis.

Management

Patients with evidence of diphtheria should be placed in respiratory isolation and treated presumptively for *C. diphtheriae*. The goals of therapy are to protect the airway, limit toxin effects, and stop future toxin production by terminating bacterial growth. Although airway obstruction from diphtheria is rare in the United States, the management is identical to that of other forms of airway obstruction. Early intubation should be considered for patients with laryngeal involvement. Patients may be dehydrated from fever and decreased oral intake related to dysphagia or neurologic impairment. In the course of resuscitation, the patient should be assessed for fluid responsiveness, as the toxin's effect on the myocardium may result in heart failure[1](see Chapter 3).

BOX 118.2 Check List for Assessing a Patient With Suspected Diphtheria

Suspect Case

- Pharyngitis, nasopharyngitis, tonsillitis, laryngitis, tracheitis (or any combination of these), absent or low-grade fever
- Grayish adherent pseudo-membrane present
- Membrane bleeds, if manipulated or dislodged

Probable Case

Suspect case above, plus one or more of the following:

- Stridor
- Bull-neck (cervical edema)
- Toxic circulatory collapse
- Acute renal insufficiency
- Submucosal or subcutaneous petechiae
- Myocarditis
- Death
- Recent return (<2 weeks) from travel to area with endemic diphtheria
- Recent contact (<2 weeks) with confirmed diphtheria case or carrier
- Recent contact (<2 weeks) with visitor from area with endemic diphtheria
- Recent contact with dairy or farm animals or domestic pets
- Immunization status: Up-to-date- any DTaP/DT/Tdap/Td shot within past 10 years?

Laboratory Confirmed Case

- Positive culture of *Corynebacterium diphtheriae* (or *Corynebacterium ulcerans*) and
  - Positive Elek test *or*
  - PCR for tox gene (positive for subunit A and B)

DT, Diphtheria-tetanus; *DTaP,* diphtheria, tetanus, and acellular pertussis; *PCR,* polymerase chain reaction; *Td,* diphtheria-tetanus; *Tdap,* tetanus, diphtheria, activated pertussis.
Available at: www.cdc.gov/diphtheria/downloads/dip-cklist-diag.pdf.

Equine serum diphtheria anti-toxin (DAT) should be administered if the diagnosis of respiratory diphtheria is deemed probable (Box 118.2) and before laboratory confirmation.[1,7] DAT is currently not licensed by the U.S. Food and Drug Administration (FDA) for use in the United States, and several countries do not currently hold DAT stockpiles.[8] The CDC can be contacted at 770-488-7100 to distribute DAT to physicians as an investigational new drug. The size and location of the membrane, duration of illness, and patient's overall degree of toxicity determine the DAT dose. Patients with probable or confirmed respiratory diphtheria are eligible to receive DAT (20,000 to 40,000 units for pharyngeal or laryngeal involvement of 2 days' duration; 40,000 to 60,000 units for nasopharyngeal lesions; 80,000 to 100,000 units for systemic disease of 3 days' duration or more or for diffuse neck swelling).[7] After conjunctival or intradermal sensitivity skin testing, the antitoxin is administered intravenously (IV). If the patient exhibits sensitivity to the antitoxin, desensitization should be performed. Active immunization against diphtheria should also be initiated because clinical infection may not confer immunity.

After DAT, antibiotics are initiated to prevent growth and spread of the organism but are no substitute for the antitoxin. Erythromycin 40 mg/kg/day (maximum of 2 g) intravenously or orally in divided doses is the preferred treatment. Procaine penicillin G 300,000 units/day q12h intramuscularly (IM) for those weighing 10 kg or less, and 600,000 units/day in q12h for those weighing more than 10 kg is an acceptable alternative.[1,3] Treatment failures are more common with penicillin than with erythromycin. Azithromycin

and clarithromycin have activity similar to erythromycin in vitro and may result in better compliance. These agents have not been adequately tested in clinical disease. Daily oral therapy may be substituted when the patient can swallow. Negative cultures should be documented after treatment.

Myocarditis and neuritis are treated with supportive care and monitoring. Patients with ECG changes consistent with myocarditis have three to four times the mortality rate of those with normal ECGs. The mortality rate for patients with left bundle branch block and atrioventricular block is 60% to 90%. Serial ECGs are recommended, and survivors may have permanent conduction abnormalities. No data support the use of steroids.

Cutaneous lesions should be débrided of necrotic tissue and cleansed vigorously. A course of antibiotics is recommended, but DAT for cutaneous lesions is of questionable value. We recommend 20,000 to 40,000 units of antitoxin, but few data support its use in this setting.[1,7]

Carriers of *C. diphtheriae* should receive oral penicillin G or erythromycin for 7 days or IM benzathine penicillin (600,000 units for those weighing less than 30 kg and 1,200,000 units for those weighing more than 30 kg). Active immunization should also be provided to unimmunized and partially immunized carriers. After 2 weeks of therapy, cultures should be obtained; if positive, erythromycin therapy should be given for 10 additional days.[1]

Individuals who have been in close contact with infected patients should have cultures taken and be kept under surveillance for 7 days. Previously immunized close contacts should receive a booster of diphtheria toxoid if the last booster was more than 5 years earlier. The vaccine should be diphtheria, tetanus, and acellular pertussis (DTaP) or diphtheria-tetanus (DT or Td) as appropriate for age. Close unimmunized contacts or those whose immunization status is unknown should receive the same antimicrobial therapy as carriers (previously described), have culture specimens taken before and after therapy, and have active immunization initiated. Close contacts who cannot be kept under surveillance should receive IM benzathine penicillin to ensure compliance and a Td booster (appropriate for age and immunization history). DAT is not recommended for this group because of the risk of horse serum allergy.[7]

A universal primary immunization program with regular boosters every 10 years is the most effective method for controlling diphtheria. Emergency clinicians should routinely administer age-appropriate tetanus and diphtheria toxoids as part of wound management.

Disposition

All patients with possible pharyngeal diphtheria should be isolated, admitted, and monitored for arrhythmias. A cardiologist should be consulted for patients with evidence of myocarditis. The CDC should be contacted for all suspected or proven cases of diphtheria.

PERTUSSIS

Foundations

Background and Importance

Pertussis is an acute respiratory disease first described in 1578 when an epidemic swept through Paris. *Pertussis* means "violent cough." It is also called *whooping cough* because the severe episodes of coughing are followed by forceful inspiration, which creates a characteristic "whoop" sound. Bordet and Gengou identified the causative organism in 1900. Pertussis was a major cause of mortality among infants and children in the United States in the prevaccination era. A vaccine was developed in the 1940s, but pertussis remains a significant cause of morbidity and mortality worldwide.[9]

Pertussis is a highly contagious respiratory illness transmitted by aerosolized droplets. It can occur at any age but is predominantly a pediatric and adolescent illness. Infection rates are greater than 80% in adults exposed more than 12 years after completing a vaccination series and up to 90% in susceptible individuals with household exposure. Half of the cases in the United States occur from June through September. The average incubation period is 7 to 10 days (range less than 1 week to 3 weeks). Neither vaccination nor prior infection confers lifelong immunity.

Pertussis is prevalent worldwide. The World Health Organization (WHO) estimated over 24.1 million cases in 2017 with 160,700 annual deaths.[10] In the United States, annual pertussis rates declined sharply after the introduction of the vaccine, reaching a nadir of 1010 cases in 1976. There has been a steady increase since, with 11,647 cases reported in 2003 and more than 28,000 cases in 2014 (Fig. 118.2A and B).[11] The incidence is highest in infants who have not received the entire vaccine series (see Fig. 118.2C). Waning immunity in the adult population and increased reporting may be contributing factors, but the emergence of the antivaccination movement is a leading factor.

A 1991 report found a possible relationship between the vaccine and acute encephalopathy. Although there appears to be no relationship between the vaccine and long-term neurologic complications, the report resulted in a decline in the use of the whole-cell pertussis vaccine. The acellular pertussis vaccine has been approved in the United States since 1991 for persons 15 months to 64 years and since 1997 for infants.

Anatomy, Physiology, and Pathophysiology

Pertussis is caused by organisms of the *Bordetella* genus, which are small, aerobic, gram-negative coccobacilli. *Bordetella pertussis* and *Bordetella parapertussis* are responsible for human disease. The organisms are fastidious and require a medium containing charcoal, blood, or starch, and an optimal temperature of 95° to 98.6°F (35° to 37°C) to grow. *Bordetella bronchiseptica,* a flagellated, motile organism, causes illness in animals, including kennel cough, and may rarely cause respiratory infection in immunocompromised humans.[12] *Bordetella* adheres preferentially to ciliated respiratory epithelial cells, but does not invade beyond the submucosa and is seldom recovered in the bloodstream. It elaborates several toxins that act locally and systemically, including pertussis toxin, dermonecrotic toxin, adenylate cyclase toxin, and tracheal cytotoxin. Local tissue damage consists of inflammatory changes in the respiratory mucosa. Secondary pneumonia and otitis media may occur. Systemic effects of pertussis toxin include sensitization to the lethal effects of histamine and increased excretion of insulin. This hyperinsulinemia can cause hypoglycemia, particularly in young infants potentially leading to seizures.[9]

Clinical Features

Pertussis has three clinical stages: the catarrhal phase, paroxysmal phase, and convalescent phase. The *catarrhal* or *prodromal phase* begins after an incubation period of approximately 7 to 10 days and lasts approximately 1 to 2 weeks. Infectivity is greatest during the catarrhal phase, when the disease is clinically indistinguishable from other upper respiratory tract infections. Signs and symptoms include rhinorrhea, low-grade fever, malaise, and conjunctival injection. A dry cough usually begins at the end of the catarrhal phase.[9,12]

The *paroxysmal phase* begins as fever subsides. Cough increases and lasts 1 to 6 weeks, but may persist for up to 10 weeks. Paroxysms of staccato coughing occur an average of 15 times per day and are followed by a sudden, forceful inhalation that produces the characteristic "whoop." One-third of adults with pertussis develop this whoop, and it is rare in young infants, who may present with apneic episodes and

(A, From: World Health Organization. WHO/IVB database 2018; 194 WHO states. Available at www.who.int/immunization/monitoring_surveillance/burden/vpd/surveillance_type/passive/pertussis/en/. B and C, From: Centers for Disease Control and Prevention: National Notifiable Diseases Surveillance System: Pertussis (whooping cough). Available at: www.cdc.gov/pertussis/surv-reporting.html.)

no other symptoms. Paroxysms may be spontaneous, occur more frequently at night, or be precipitated by noise or cold. During the paroxysm, the patient may exhibit cyanosis, diaphoresis, tongue protrusion, salivation, and lacrimation. Post-tussive vomiting, syncope, and apnea may occur. Infants may be exhausted after a typical paroxysm. Between episodes of coughing, patients do not appear acutely ill.[9,12]

In the *convalescent phase* a residual cough may last weeks to months. Paroxysms of coughing may be triggered by unrelated respiratory infection or by exposure to a respiratory irritant. This recurrence of coughing does not represent recurrence of pertussis infection.

Atypical presentations can occur in young and preterm infants. Fever is usually absent in uncomplicated neonatal pertussis. Tachypnea,

BOX 118.3 Pertussis Complications

Periorbital edema
Subconjunctival hemorrhage
Petechiae
Epistaxis
Hemoptysis
Subcutaneous emphysema
Pneumothorax
Pneumomediastinum
Diaphragmatic rupture
Umbilical and inguinal hernias
Rectal prolapse

apnea, and cyanotic and bradycardic episodes may be the predominant symptoms.[13] Older children and adults who have partial protection from vaccination or previous illness may have a long-lasting intractable dry cough that is frequently misdiagnosed as bronchitis. Post-tussive vomiting in adults is highly suggestive of pertussis.[9,14]

Physical findings are nonspecific. Tachypnea is variably present and may be related to the degree of pulmonary involvement. Low-grade fever, conjunctival injection, and rhinorrhea are common during the catarrhal phase. Fever during other stages of illness suggests secondary infection. Petechiae above the nipple line, subconjunctival hemorrhages, pneumothorax, and epistaxis may occur because of increased intrathoracic pressure during coughing paroxysms.[9,12] Chest examination may reveal rhonchi; the presence of rales suggests pneumonia.

Complications of pertussis are listed in Box 118.3. Secondary pulmonary infection may result from decreased respiratory clearance cause by the *Bordetella* organism and its toxins on bronchial and lung mucosa. Bacterial or viral pneumonia superinfection complicating pertussis is a leading cause of death, especially in infants and young children. Aspiration of gastric contents and respiratory secretions may occur during paroxysm of coughing, whooping, and vomiting. A fever during the paroxysmal phase should alert the physician to a possible superinfection.[9,10,12]

Seizures and encephalopathy occur in approximately 1% of patients but are more common in infants. This may be due to hypoxia, hypoglycemia, cerebral petechiae, toxin effect, or secondary infection by neurotropic viruses or bacteria. Central nervous system (CNS) hemorrhages may occur from increased cerebrovascular pressures during paroxysm of coughing. Sudden increases in intrathoracic and intra-abdominal pressures can result in other complications.[9,12] Bradycardia, hypotension, and cardiac arrest can occur in neonates and young infants with pertussis. Severe pulmonary hypertension has been recognized in this age group and can lead to systemic hypotension, hypoxia, and increased mortality.[13] Intensive care monitoring is recommended for these patients, regardless of how well they appear on admission.

Differential Diagnoses

The differential diagnosis includes acute viral upper respiratory tract infection, pneumonia, bronchiolitis, cystic fibrosis, tuberculosis, exacerbation of chronic obstructive pulmonary disease, and foreign body aspiration. The marked leukocytosis may suggest leukemia.

Diagnostic Testing

Pertussis should be considered in patients with cough lasting longer than 2 weeks with paroxysms, whoops, or post-tussive emesis, regardless of previous vaccination status.[13] Up to 27% of adults in the United States with a prolonged cough have serologic evidence of pertussis.

Ancillary studies are of limited value in the emergency department (ED). During the late catarrhal and early paroxysmal phases, a marked leukocytosis and a characteristic lymphocytosis are often present. A white blood cell (WBC) count of greater than 20,000/mL is common in pediatric patients.[12] Adults with pertussis frequently do not have the characteristic leukocytosis and lymphocytosis, and some infants and immunocompromised hosts may not mount this response. The chest radiograph (CXR) may show peribronchial thickening, atelectasis, or pulmonary consolidation.

BOX 118.4 Pertussis Case Definition

Clinical Case

Cough and illness for more than 2 weeks with no apparent other cause *plus* one of the following:

- Paroxysms of coughing
- Inspiratory "whoop"
- Post-tussive emesis

Probable Case

All of the following:

- Meets clinical case definition
- Not laboratory confirmed (Only PCR and culture are considered laboratory confirmation.)
- Not epidemiologically linked to a laboratory confirmed case

Confirmed Case

One of the following:

- Acute cough illness of any duration with a positive culture for *Bordetella pertussis*
- A case that meets the clinical case definition and is confirmed by PCR for *B. pertussis*
- A case that meets the clinical case definition and is epidemiologically linked directly to a case confirmed by either culture or PCR

PCR, Polymerase chain reaction.

Laboratory confirmation is important for epidemiologic purposes. Nasopharyngeal aspirate or swab (synthetic, non-cotton) should be obtained for culture and PCR, if both are available; sputum and throat swabs are inadequate because ciliated respiratory epithelial cells are required.[12] The *Bordetella* organism is fastidious, and isolation requires a medium impregnated with antibiotics to reduce overgrowth of competing bacteria. Colonies of *B. pertussis* take 3 to 7 days to appear. Pertussis cultures are 30% to 50% sensitive, and this drops to less than 3% three weeks after the onset of cough. Direct fluorescent antibody techniques are useful as a rapid screening test for pertussis but are variably specific and should not be relied upon as laboratory confirmation of *B. pertussis.* Adults generally come to medical attention late in the disease when cultures are rarely positive. PCR is more likely to identify the organism during the first 3 weeks of illness, but it has a high false-positive rate for various reasons, including asymptomatic carriers, recent vaccination, or contamination. Serologic testing is often performed as well. Most laboratories use enzyme-linked immunosorbent assay, which rises 2 to 3 weeks after infection or primary immunization. Paired serologic tests showing a twofold increase are considered positive, but they are reported as "probable" cases by the CDC unless performed at the CDC or the Massachusetts state laboratory. See Box 118.4 for the case definition.

Management

Acute Treatment

Treatment of pertussis is supportive and includes oxygen, frequent suctioning, appropriate hydration, parenteral nutrition as needed, and avoidance of respiratory irritants. Patients with suggested pertussis and

associated pneumonia, hypoxia, CNS complications, or those experiencing severe paroxysms should be hospitalized. Children younger than 1 year old should also be admitted, because they are not yet fully immunized and have the greatest risk for morbidity and mortality. Neonates with pertussis should be admitted to a neonatal intensive care unit (NICU) because apnea and significant cardiac complications can occur without warning.[9,12]

Antibiotic treatment does not reduce the severity or duration of illness at any phase. The goal of antibiotic therapy is to decrease infectivity and carriage.[14] The CDC recommends macrolides; erythromycin, clarithromycin, and azithromycin are preferred for pertussis in persons 1 month of age and older. Erythromycin estolate ester 40 to 50 mg/kg/day (maximum of 2 g/day) has previously been recommended for four divided doses for 14 days, but a 7-day course of erythromycin estolate ester at 1 g/day is just as effective at eradicating *B. pertussis* with better compliance. Azithromycin 10 mg/kg/day for 5 days is recommended in infants younger than 1-year-old because of an association between oral erythromycin and infantile hypertrophic pyloric stenosis (IHPS). Alternative treatments include azithromycin (10 mg/kg on day 1, followed by 5 mg/kg on days 2 to 5) or clarithromycin (15 mg/kg/day; maximum of 1 g/day in two divided doses). Trimethoprim-sulfamethoxazole (8 mg/kg/day of trimethoprim) is an alternative for macrolide-allergic patients two months of age or older, but efficacy is unproven. Patients should be considered infectious for 3 weeks after the onset of the paroxysmal phase or until at least 5 days after antibiotics are started.[9] Droplet isolation is recommended during this period.

Corticosteroids, especially in young critically ill infants, may reduce the severity and course of illness, but effectiveness has not been established. Inhaled beta$_2$-adrenergic agonists do not reduce the frequency or severity of paroxysmal coughing episodes but may help patients with reactive airway disease. Past trials with pertussis immune globulin are limited and do not show benefit. Standard cough suppressants and antihistamines are ineffective.[15]

Postexposure prophylaxis with an appropriate macrolide is recommended for those at high risk for developing severe pertussis, including household contacts of a pertussis case, infants and women in their third trimester of pregnancy, persons with preexisting health conditions that may be exacerbated by a pertussis infection, and close contact with any of the above-listed people. This includes but is not limited to those who work in NICUs, childcare settings, and maternity wards. Women in their third trimester of pregnancy may be a source of pertussis to their newborn infant.[16]

Vaccination

Whole-cell and acellular pertussis vaccines are distributed in combination with diphtheria and tetanus toxoids as DPT and DTaP, respectively. The whole-cell vaccine is 70% to 90% effective at preventing serious pertussis infection. Pediatric recipients have fever, irritability, behavioral changes, and local discomfort at the site of inoculation. Moderately severe reactions are uncommon but include temperature above 104°F (40°C), persistent, high-pitched crying, and seizures. Severe neurologic complications (prolonged seizures and encephalopathy) occur rarely but led to decreased use of the whole-cell form of the vaccine and the development of DTaP.[17]

The acellular pertussis vaccines contain inactivated pertussis toxin and one or more other bacterial components; they are less effective than the whole-cell vaccine but have fewer reported adverse reactions.[18,19] DTaP has replaced DPT for childhood immunizations in the United States and is approved for children ages 6 weeks to 6 years old.[12,] Current American Academy of Pediatrics (AAP) guidelines state that acellular pertussis vaccinations are as safe as whole-cell vaccines, but new data suggest the latter provide a better, longer-lasting serologic response. There has also been a correlation between acellular vaccination and food allergies. Further studies are needed to guide future recommendations.

Pertussis immunity wanes 5 to 10 years after immunization and 15 years after natural infection, resulting in an increased incidence in people older than 15 years. Tetanus, diphtheria, acellular pertussis (Tdap) (with reduced diphtheria toxoid and pertussis antigens) is indicated as a booster vaccine in persons 11 to 18 years old. It is safe and effective in adults, including pregnant women and those over 65 years of age. Persons older than 65 years old who have never received Tdap and anticipate close contact with infants younger than 12 months old should receive a single dose of Tdap, regardless of interval since last Td vaccination. A live attenuated nasal vaccine has completed phase one trials in humans showing greater than 99.9 nasopharyngeal colonization and is undergoing further clinical development.[20]

TETANUS

Foundations

Background and Importance

Tetanus is a toxin-mediated disease characterized by severe uncontrolled skeletal muscle spasms. Respiratory muscle involvement leads to hypoventilation, hypoxia, and death. Dramatic descriptions of this disease date to ancient Egypt, when physicians recognized a frequent relationship between tissue injury and subsequent fatal spasm.[21] Prophylactic injection of tetanus antitoxin provided passive immunity to wounded soldiers during World War I. In 1924, an effective vaccine was developed, and large-scale testing during World War II indicated that the tetanus toxoid confers a high degree of protection against disease.[22] Despite the availability of an effective vaccine, tetanus remains endemic worldwide. It is more common in warm, damp climates and relatively rare in cold regions. The global annual incidence of reported cases of tetanus has declined with the introduction of vaccination programs (Fig. 118.3A). The WHO reported 15,103 cases of tetanus in 2018 but estimates that thousands of unreported cases occur annually resulting in approximately 34,000 neonatal deaths. Most of these cases occur in countries with low immunization rates.[23]

Since the introduction of vaccination programs in the United States, the incidence of tetanus has steadily declined from 4 cases per million population in the 1940s to fewer than 0.01 cases per million population in 2010 (see Fig. 118.3B).[24] The highest incidence occurs in people older than 65 years old (0.23 case per million population). Half of cases occur in injection drug users. The overall case fatality rate is 18% but approaches 50% in patients over 70 years old (Fig. 118.4). Cases have been reported in fully vaccinated patients, but no deaths occurred.[24]

Tetanus classically occurs as a result of a deep penetrating wound. A history of injury is present in more than 70% of patients, but the injury may be trivial. The remainder may have another identifiable condition or no apparent source.[21] The most common portals of entry are puncture wounds, lacerations, and abrasions. Tetanus has also been reported in association with chronic skin ulcers, abscesses, otitis media, foreign bodies, corneal abrasions, childbirth, and dental procedures. Postoperative tetanus has been reported in patients who have undergone intestinal operations and abortions. In these cases, the source of bacteria is probably endogenous because up to 10% of humans harbor *Clostridium tetani* in the colon. Inadequate primary immunization and waning immunity continue to be the primary risk factors for tetanus in the United States. As tetanus vaccination of children has improved, older people have accounted for an increasing percentage of reported cases.

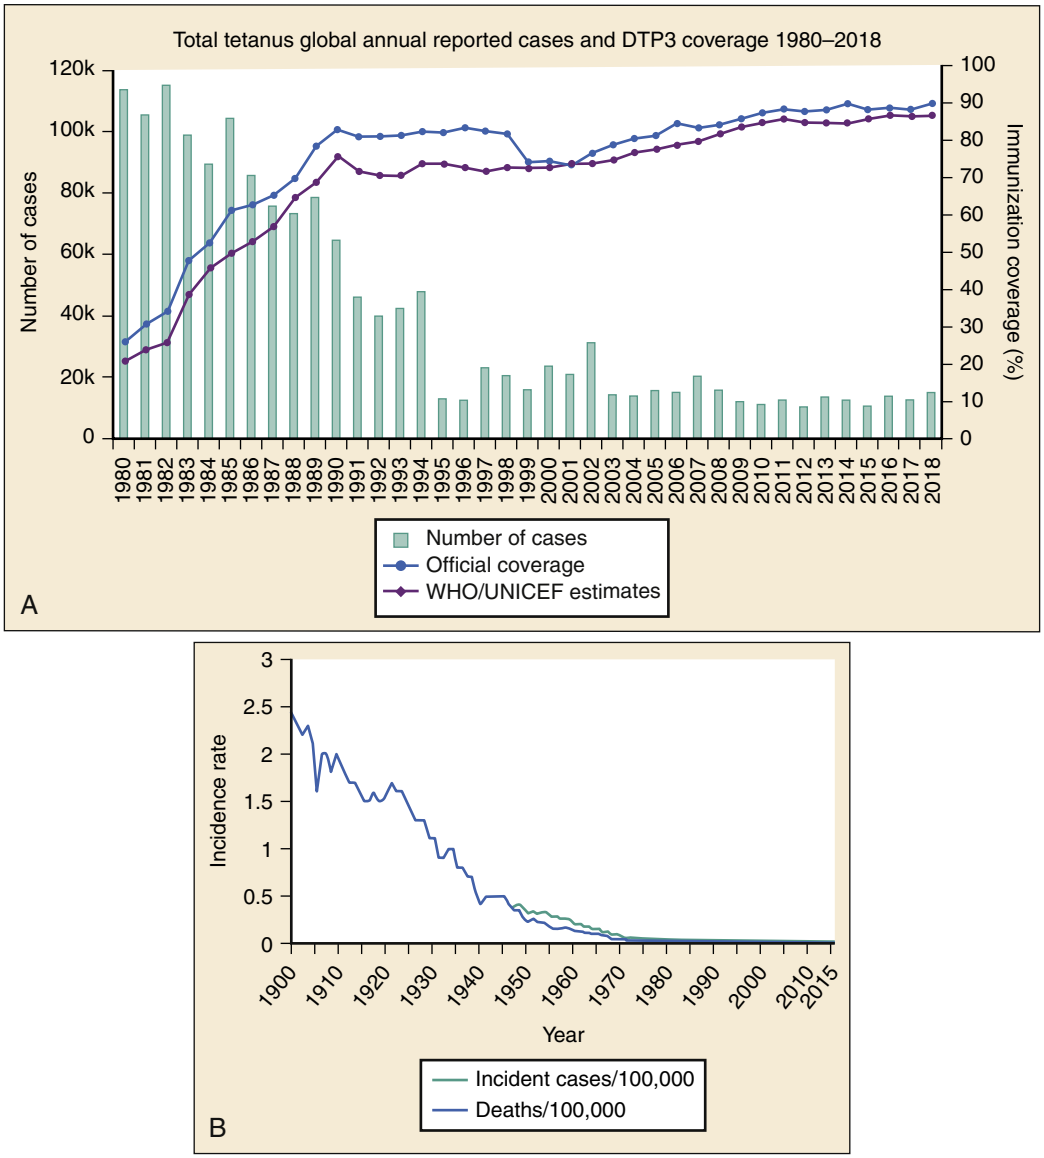

Fig. 118.3 (A) Global annual reported cases of tetanus compared with percentage of immunization coverage. (B) Incidence of reported tetanus cases in the United States by year. *DTP3,* third dose of diphtheria-tetanus-pertussis vaccine; *UNICEF,* United Nations Children's Fund; *WHO,* World Health Organization. (A, From: World Health Organization. Immunization, vaccines and biologicals: tetanus. Available at: https://www.cdc.gov/vaccines/pubs/surv-manual/chpt16-tetanus.html. B, From: Centers for Disease Control and Prevention National Notifiable Diseases Surveillance System. Available at: https://www.cdc.gov/vaccines/pubs/surv-manual/chpt16-tetanus.html.)

Anatomy, Physiology, and Pathophysiology

C. tetani is a spore-forming, motile, rod-shaped, obligate anaerobic bacillus. It stains gram-positive in fresh culture but has a variable staining pattern in culture and tissue samples. *C. tetani* is ubiquitous in soil and dust and is also found in the feces of animals and humans. Spores are resistant to heating and chemical disinfectants and can survive in the soil for months to years. When introduced into a wound, spores may not germinate for weeks because of unfavorable tissue conditions. When injury favors anaerobic growth, the spores germinate into mature bacilli, which form a single spherical terminal endospore to produce a characteristic drumstick appearance. Only these mature bacilli produce the tetanus toxin that causes clinical disease.[21]

C. tetani is a noninvasive organism. The development of clinical disease requires a portal of entry and tissue conditions that promote germination and growth in a susceptible host. Tetanus-prone wounds have damaged or devitalized tissue, foreign bodies, or other bacteria. Under these conditions, *C. tetani* produces the neurotoxin that causes clinical illness. Germination and replication of *C. tetani* can occur without clinical signs of wound infection.

C. tetani produces the neurotoxin tetanospasmin at the site of tissue injury. Tetanospasmin binds the motor nerve ending and moves by retrograde axonal transport and trans-synaptic spread to the CNS. It binds preferentially to inhibitory (GABAergic and glycinergic) neurons and blocks the presynaptic release of these neurotransmitters. Interneurons afferent to alpha motor neurons are affected first. Without inhibitory control, the motor neurons undergo sustained excitatory discharge, resulting in the muscle spasm characteristic of tetanus.[25] Tetanospasmin may also affect preganglionic sympathetic neurons and

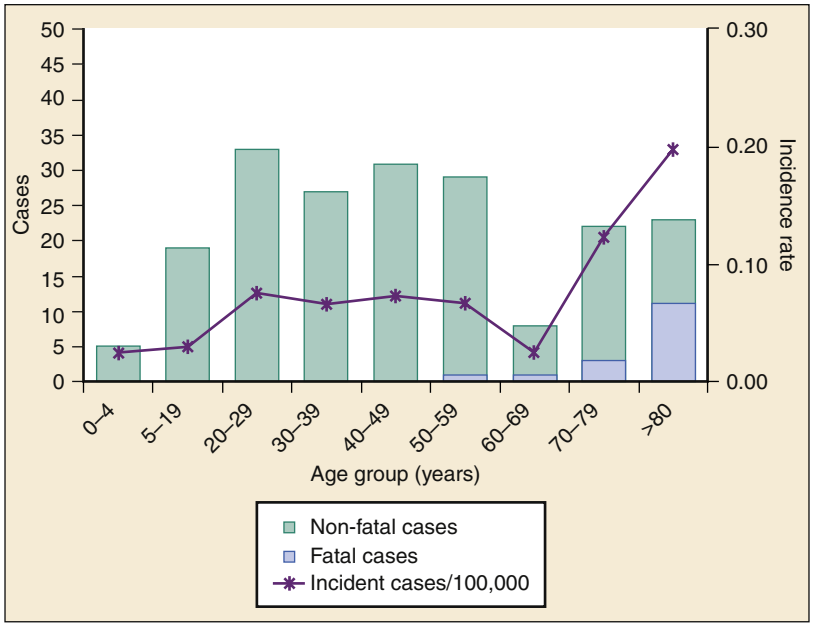

Fig. 118.4 Incidence of and mortality from tetanus by age group in the United States, 2009 to 2015. (Centers for Disease Control and Prevention. Manual for the surveillance of vaccine-preventable diseases. Available at: www.cdc.gov/vaccines/pubs/surv-manual/chpt16-tetanus.html.)

parasympathetic centers, resulting in autonomic nervous system dysfunction. The clinical manifestations include dysrhythmias and wide fluctuations in blood pressure and heart rate. The binding of tetanospasmin at the synapse is irreversible; recovery occurs only when a new axonal terminal is produced.[21]

Clinical Features

The incubation period for tetanus ranges from 1 day to several months. Shorter incubation periods portend a worse prognosis.[21] The duration of the incubation period is not useful in making the diagnosis of tetanus because many patients have no history of an antecedent wound. Four types of clinical tetanus have been described.

Generalized Tetanus

Generalized tetanus, the most common form of the disease, results in spasms of agonist and antagonist muscle groups throughout the body. The classic presenting symptom is trismus or "lockjaw," caused by masseter muscle spasm, and is present in 50% to 75% of patients. As the other facial muscles become involved, a characteristic sardonic smile (risus sardonicus) appears. Other early symptoms include irritability, weakness, myalgias, muscle cramps, dysphagia, hydrophobia, and drooling. As the disease progresses, generalized uncontrollable muscle spasms occur spontaneously or as a result of minor stimuli, such as touch or noise. Spasms can cause vertebral and long-bone fractures and tendon rupture. Opisthotonos is prolonged tonic contraction that resembles decorticate posturing. Spasms of laryngeal and respiratory muscles can cause ventilatory failure and death. Autonomic dysfunction is the major cause of death in patients who survive the acute phase and is manifested by tachycardia, hypertension, hyperpyrexia, cardiac dysrhythmias, and diaphoresis. The illness progresses over 2 weeks. If the patient survives, recovery is complete after 4 weeks or more. Throughout this illness, patients remain completely lucid unless they are chemically sedated.[21]

Localized Tetanus

Localized tetanus is a form of the disease characterized by persistent muscle spasms close to the site of injury. Symptoms may be mild or severe, but mortality is lower than with generalized tetanus. Local tetanus may progress to generalized disease. This form of illness may reflect partial immunity to tetanospasmin and may be present for weeks to months before resolution.[21]

Cephalic Tetanus

Cephalic tetanus, a rare variant of localized tetanus, results in cranial nerve palsies and muscle spasms. Palsies precede the spasm in many cases, resulting in misdiagnosis. The most commonly involved cranial nerve is the facial nerve (VII), mimicking Bell palsy. Most cases occur after facial trauma or otitis media. Patients have trismus and palsies of cranial nerve III, IV, VII, IX, X, or XII ipsilateral to the site of local infection. The clinical course is variable. In one-third of cases, resolution of symptoms is complete. The remainder progress to generalized tetanus with an overall mortality rate of 15% to 30%.[18,21]

Neonatal Tetanus

Neonatal tetanus is generalized tetanus of the newborn and occurs almost exclusively in countries where maternal immunization is inadequate and contaminated material is used to cut and dress umbilical cords. Symptoms begin during the first week of life and include irritability and poor feeding. Mortality approaches 100% because of the high toxin load for body weight and inadequate medical support. Even with limited resources, mortality can be reduced to less than 50% with medication and experienced medical personnel.

Complications

Acute respiratory failure results from respiratory muscle spasms or laryngospasms and airway obstruction. If patients survive the acute onset of illness and have adequate ventilatory support, autonomic dysfunction becomes the leading cause of death. Autonomic instability occurs several days after the onset of generalized spasms. Disinhibition of the sympathetic nervous system predominates and causes dysrhythmias, hypertension, myocarditis, and pulmonary edema. Dysrhythmias and myocardial infarction are the most common fatal events during this phase.

Forceful tetanic muscle spasms can cause vertebral subluxations and fractures, long-bone fractures, and shoulder and temporomandibular joint dislocations. Rhabdomyolysis occasionally occurs and can cause acute renal failure. Renal failure may also result from dehydration and sympathetic nervous system hyperactivity.

Secondary infection may occur in the initial inoculating wound or as a complication from invasive treatment modalities, such as mechanical ventilation. Hyperthermia may also result from muscle spasms and sympathetic hyperactivity. Prolonged immobility can lead to deep venous thrombosis and pulmonary embolism. Gastrointestinal complications include peptic ulcers, ileus, intestinal perforation, and constipation. The syndrome of inappropriate secretion of antidiuretic hormone occurs in a small number of patients. Hemolysis has also been reported.

Mortality is a function of the previous immunization status, incubation period, severity and rapidity of onset of illness, comorbid disease, age, and sophistication of medical treatment available. With appropriate intensive care treatment, older patients may fare as well as their middle-aged counterparts. Long-term physical complications in survivors are rare. The most common persistent problem is psychological trauma related to the disease and its treatment.[21]

Differential Diagnoses

Strychnine poisoning is the only clinical condition that truly mimics generalized tetanus. Strychnine, like tetanospasmin, antagonizes glycine release, but unlike tetanospasmin, it has no effect on GABA release. Patients have opisthotonos while remaining alert. The annual incidences of tetanus and strychnine poisoning are similar in the United States, and serum and urine tests for strychnine should be performed when tetanus is considered.

In patients who present with diffuse generalized spasms, the diagnosis is unlikely to be missed, but ideally the disease should be considered and diagnosed in the early stages to minimize complications and decrease mortality. Some conditions with clinical similarities to tetanus are listed in Box 118.5. Trismus is most commonly caused by intraoral infections. These can be excluded with careful history and physical examination. Mandibular dislocation can be ruled out with appropriate radiographs of the mandible and temporomandibular joints. Dystonic reactions can be differentiated from tetanus by medication history and symptoms alleviated by benztropine or diphenhydramine. Patients with encephalitis usually exhibit an altered mental status. Meningitis can be excluded by examination of the cerebrospinal fluid (CSF). Rabies should be considered when there are symptoms of brainstem dysfunction, including dysphagia and respiratory muscle dysfunction. A history of exposure to secretions of an infected animal is the most helpful historical point. In addition, rabies does not cause trismus.

Cephalic tetanus is especially difficult to diagnose when the cranial nerve palsy precedes trismus. The differential diagnosis of cephalic tetanus includes Bell palsy, botulism, cranial nerve palsies, and facial cellulitis with facial nerve compression and ophthalmoplegia.

Diagnostic Testing

The diagnosis of tetanus should be made on clinical grounds. Wound cultures are of little value and are positive in only one-third of cases. A positive culture does not indicate whether the bacterium is a toxin-producing strain. There are no laboratory tests to confirm or to exclude the diagnosis of tetanus. Lumbar puncture may be indicated to exclude meningitis in the neonate when the diagnosis of tetanus is uncertain. A computed tomography (CT) scan helps assess for intracranial disease. A serum calcium level is helpful to exclude hypocalcemia. Electromyography may be useful if the diagnosis of cephalic or localized tetanus is in doubt.

BOX 118.5 Differential Diagnosis of Tetanus

Acute abdomen
Black widow spider bite
Dental abscess/infection
Dislocated mandible
Dystonic reaction
Encephalitis
Head trauma

Status epilepticus
Strychnine poisoning
Subarachnoid hemorrhage
Temporomandibular joint syndrome

The spatula test involves touching the oropharynx with a tongue blade. With a negative test, the patient gags and expels the tongue blade. With a positive test, the patient has reflex masseter muscle spasm and bites the spatula. This test is 94% sensitive and 100% specific for tetanus.

Management

The four treatment strategies for patients with tetanus should be undertaken simultaneously: supportive care, elimination of unbound tetanospasmin, prevention of further toxin production, and active immunization.[22]

Supportive Care

Supportive care begins with controlling muscle spasms. Reflex spasms result from stimulation of the patient caused by any movement or loud noises. Unnecessary stimulation should be avoided. Benzodiazepines are the mainstay of symptomatic therapy. These drugs are GABA agonists and indirectly antagonize many of the effects of tetanospasmin, but they do not affect the glycine release inhibition by tetanospasmin. Diazepam is the most extensively studied, but lorazepam and midazolam are equally effective. Diazepam has a rapid onset of action, wide safety margin, and can be given orally, rectally, or IV. It is inexpensive and available in most parts of the world. Its long cumulative half-life and active metabolites can cause prolonged sedation and respiratory depression. The IV formulations of diazepam and lorazepam contain propylene glycol, which, at high doses, can produce lactic acidosis. Gastrointestinal delivery of these agents is limited by motility problems associated with tetanus. Midazolam has a short half-life and does not contain propylene glycol; it should be given by continuous infusion and is cost-prohibitive in many areas of the world. Propofol infusion is effective and expensive, but patients may not tolerate the lipid vehicle. Neuroleptics, barbiturates, and intrathecal baclofen have no advantage over benzodiazepines. Dantrolene is a direct muscle relaxant without CNS activity. It has been reported as an adjunctive agent for muscle spasms and may decrease the need for mechanical ventilation.[19] Magnesium sulfate infusion has been advocated as both adjuvant and first-line therapy for tetanus, with recent data showing effectiveness as first-line therapy to control spasms and muscle rigidity in mild-to-moderate tetanus.[26]

If spasms cannot be controlled with these regimens or airway compromise develops, the patient should receive neuromuscular blockade and mechanical ventilation. Succinylcholine should not be the first-line neuromuscular blockade because there is a risk of severe hyperkalemia resulting from its use in any neuromuscular disease. This effect does not begin until about 4 days after the onset of disease. Long-acting nondepolarizing agents are preferred. Vecuronium and rocuronium are shorter acting and lack significant cardiovascular side effects but require continuous infusion. Adequate sedation should be provided, and neuromuscular blockade should be withheld daily to assess the patient's status. All intubated patients should be considered for early tracheostomy to decrease reflex spasms caused by the endotracheal tube.

Autonomic instability requires monitoring and treatment. Sympathetic hyperactivity can be treated with combined alpha- and beta-adrenergic antagonists, such as labetalol and propranolol. The use of beta-antagonists alone can lead to unopposed alpha-activity, resulting in severe hypertension. If beta-antagonists are necessary, a short-acting agent such as esmolol should be used. Clonidine has variable success at modulation of sympathetic outflow in these cases. Morphine and magnesium sulfate infusions as well as spinal anesthesia and intrathecal baclofen have been shown to improve autonomic dysfunction.[21] Diuretics should be avoided for blood pressure control as volume depletion can worsen autonomic instability. Bradydysrhythmia should be treated with temporary pacing. Atropine and sympathomimetic drugs should be used with caution because the autonomic instability is essentially due to catecholamine excess.

Elimination of Unbound Toxin and Active Immunization. Passive immunization with human tetanus immune globulin (HTIG) and active immunization with Td should be initiated as soon as possible in all patients with suspected tetanus. HTIG neutralizes circulating toxin and reduces mortality. It does not neutralize toxin already present in the nervous system, nor does it treat any existing symptoms. HTIG should be administered at a site separate from the Td; 500 units is as effective as higher doses. Adult and pediatric doses are the same. Administration of a portion of the HTIG proximal to the site of inoculation is often recommended but has not been studied. The preparation of HTIG available in the United States is not licensed for intrathecal administration, which is of questionable benefit.[21]

Prevention of Further Toxin Production. Toxin production is eliminated by treatment of the *C. tetani* infection. Wound débridement and antibiotic administration can cause transient release of tetanospasmin, so these measures should be delayed until after the HTIG is administered. Metronidazole (500 mg orally or IV every 6 hours) is the antibiotic of choice for *C. tetani*. Table 118.1 lists pediatric doses of metronidazole based on age and weight.

Penicillin has good in vitro and in vivo activity against *C. tetani,* but it also has GABA antagonistic activity and may potentiate the effects of tetanospasmin. Metronidazole has better penetration into devitalized tissue and abscesses than penicillin and is superior in terms of recovery time and effect on mortality. Macrolides, doxycycline, chloramphenicol, and tetracycline are effective alternatives in metronidazole-allergic patients.[21]

Vaccination

Tetanus toxoid is an inactivated form of tetanospasmin. Vaccination confers protective antibody levels in nearly 100% of people who receive three doses. Immunity wanes between 5 and 10 years after completion of the series. In high-risk patients such as older patients, injection drug users, and immunocompromised patients, immunity wanes more quickly, and the response to the vaccine is slower.

Adults with uncertain primary immunization status should receive a primary series of three tetanus toxoid doses, followed by booster doses every 10 years. Age-specific guidelines for tetanus prophylaxis have been developed by the Advisory Committee on Immunization Practices (ACIP) and published by the CDC (Tables 118.2 and 118.3). Tetanus vaccination should be updated for all patients who present for wound management. Those younger than 7 years old should receive diphtheria-tetanus or DTaP. Patients 7 years old or older should receive Tdap.

HTIG prophylaxis (250 units IM) is recommended for unimmunized and underimmunized patients with high-risk wounds (>6 hours old, >1 cm deep, contaminated, stellate, denervated, ischemic, infected). When tetanus toxoid and HTIG are given concurrently, separate injection sites should be used. The only contraindication to tetanus and diphtheria toxoids is a history of a neurologic or severe hypersensitivity reaction to a previous dose. The most common side effects of tetanus vaccine are minor: local swelling, pain, erythema, pruritus, fever, nausea, vomiting, malaise, and nonspecific rash. Local reactions do not preclude future use of toxoid. Serious anaphylactic reactions are rare. If a patient who requires toxoid gives a history suggestive of a neurologic or severe anaphylactic reaction, HTIG should be administered alone to protect the patient from development of tetanus as a result of the present injury. HTIG does not confer active immunity, and such patients should be referred to an allergist for measurement of antibody levels, antitoxin desensitization, and immunization. No evidence exists that tetanus and diphtheria toxoids are teratogenic and HTIG is not contraindicated in pregnancy. For inadequately immunized patients of any age, referral should be made to ensure that the patient receives the remainder of the immunizations required.

TABLE 118.1 Pediatric Doses of Metronidazole Based on Age and Weight

Weight and Age	Dosage
Neonates <1200 g and 0 to 7 days	7.5 mg/kg IV or orally every 24 hours
Neonates <1200 g and 8 to 28 days	7.5 mg/kg IV or orally every 12 hours
Neonates >1200 g and 0 to 7 days	7.5 mg/kg IV or orally every 12 hours
Neonates >1200 g and 8 to 28 days	25 to 30 mg/kg/day IV or orally every 12 hours
Infants and children	30 mg/kg/day IV divided every 6 hours, maximum 4 g/day

IV, Intravenous.

BOTULISM

Foundations

Background and Importance

Botulism is a rare life-threatening paralytic illness caused by neurotoxins produced by *Clostridium botulinum*. The disease occurs in one of five forms: food-borne botulism, infant botulism, wound botulism, unclassified botulism, and inadvertent botulism.[27] Since the approval of botulinum toxins A and B by the FDA for cosmetic and therapeutic uses in the United States, cases of iatrogenic botulism have been reported.[28]

The term *botulism* comes from the Latin *botulus,* meaning "sausage," because of an association noted between sausage ingestion and the paralytic illness. Botulism first received attention in the United States during World War I when women were encouraged to preserve fruits and vegetables. The recommended heating methods for home canning did not destroy spores, leading to epidemics of botulism. Wound botulism was first described in 1943, the CDC began surveillance of this form of the disease in 1950. Infant botulism, now the most common form of the illness, was first described in 1976.

TABLE 118.2 Routine Diphtheria, Tetanus, and Pertussis Vaccination Schedule for Children and Adults—United States

Dose	Customary Age	Age/Interval	Product
Primary 1	2 months old	6 weeks or older	DTaP
Primary 2	4 months old	4 to 8 weeks after first dose[b]	DTaP
Primary 3	6 months old	4 to 8 weeks after second dose[b]	DTaP
Primary 4	15 to 18 months old	6 to 12 months after third dose[b]	DTaP
Booster	4 to 6 years old, not needed if fourth vaccination administered after birthday[a]		DTaP
Additional booster	11 to 18 years old		Tdap
Adult booster	>18 years old All pregnant women	Every 10 years	Tdap or Td[c]

[a]If primary immunizations are started after the age of 6 years, the series should begin and continue with Tdap.
[b]Prolonging the interval does not require restarting of the series.
[c]Td should be given to adult patients who have previously received Tdap. Tdap can be given regardless of interval since Td.
DTaP, Diphtheria, tetanus, and acellular pertussis; *Td,* diphtheria-tetanus; *Tdap,* tetanus, diphtheria, activated pertussis.
Modified from: Recommended childhood immunization schedule—United States, 2020. Available at www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html and *MMWR.* 2019;68(5):112.

TABLE 118.3 Summary Guide to Tetanus Prophylaxis in Routine Wound Management

History of Absorbed Tetanus Toxoid (Doses)	CLEAN MINOR WOUNDS		ALL OTHER WOUNDS[a]	
	Tdap[b] or Td	TIG	Tdap[b] or Td	TIG
Unknown or less than three	Yes	No	Yes	Yes
Three or more[c]	No[d]	No	No[e]	No

[a]Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
[b]For children younger than 7 years old, DTaP is preferred. For persons older than 7 years old, Tdap is preferred to tetanus toxoid alone. Td is preferable in adults who have previously received one dose of Tdap.
[c]If only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.
[d]Yes, if greater than 10 years old since last dose.
[e]Yes, if greater than 5 years old since last dose. (More frequent boosters are not needed and can accentuate side effects.)
HTIG, Human tetanus immune globulin; *Td,* diphtheria-tetanus; *Tdap,* tetanus, diphtheria, activated pertussis.
Modified from: Centers of Disease Control and Prevention. Pink Book. National enteric disease surveillance: botulism annual summary in 2017. Available at: www.cdc.gov/vaccines/pubs/surv-manual/chpt16-tetanus.html.

A total of 182 confirmed cases of botulism were reported to the CDC in 2017, a decrease from 205 cases in 2016. Of these, 77% were infant botulism, 10% were food-borne botulism, 10% were wound botulism, two cases were iatrogenic, and one was suspected adult intestinal colonization.[29] Despite the ubiquitous nature of botulinum spores and the variety of possible routes of toxin entry, the incidence of disease is low.

Typical food-borne botulism results from the ingestion of preformed heat-labile toxin rather than from the ingestion of spores or live bacteria. Food-borne botulism usually results from exposure to home-canned foods that are inadequately preserved and undercooked; large outbreaks occasionally occur after the ingestion of contaminated food at restaurants or from commercial sources. A variety of preserved foods have been implicated, and botulism has also been reported to result from ingestion of improperly prepared and stored fresh foods.

Infant botulism occurs in children younger than 1 year old with a peak incidence between the ages of 6 weeks and 6 months. In contrast to food-borne botulism in adults, infant botulism is caused by the ingestion of spores with in vivo production of toxin. Honey and to a lesser extent corn syrup have been implicated as sources of *C. botulinum* spores in infant botulism. Soil and vacuum cleaner dust have also been implicated, but the source of ingestion remains unknown in most cases. Types A and B botulinum toxins have been responsible for almost all infant cases. There appears to be no relationship between infant botulism and sudden infant death syndrome.

Wound botulism once accounted for approximately one botulism case per year, but the increased use of black tar heroin has resulted in a dramatic increase in cases. Most cases occur in California among injection drug users, with two confirmed cases in Los Angeles county associated with heroin injection. Toxin type A is the most frequent causative agent.[29,30]

Unclassified or adult infectious botulism is a rare illness that is analogous to infant botulism. The *Clostridium* bacterium produces toxin in vivo. Patients with compromised gastric acidity, disturbances of gastrointestinal motility, or abnormal gastrointestinal bacterial flora may be susceptible to in vivo production of botulinum toxin.

Inadvertent botulism is an iatrogenic form of the disease that occurs in patients who have been treated with botulinum toxin injections for dystonia and other movement disorders and for cosmetic purposes. Inadvertent generalized weakness as well as unintentional focal weakness may be seen.[31]

The potential exists for botulinum toxin to be used as a biologic weapon. It is highly potent and easy to produce. The Aum Shinrikyo, responsible for the 1995 sarin gas attack on the Tokyo subway,

produced and dispersed aerosolized botulinum toxin in Japan on at least three occasions between 1990 and 1995. In 1995, Iraq admitted to the United Nations that it had produced 19,000 L of concentrated botulinum toxin and loaded approximately 10,000 L into warheads. These 19,000 L are not fully accounted for and constitute three times the amount needed to kill the entire human population by inhalation.

Anatomy, Physiology, and Pathophysiology

C. botulinum is an anaerobic, gram-positive, rod-shaped organism. It forms spores that germinate under certain environmental conditions. It produces a potent exotoxin that is responsible for the disease. Each strain of *C. botulinum* produces a specific toxin type—A through G. Only types A, B, E, and F produce disease in humans.[32] Botulinum toxins are the most potent known biologic compounds. Doses as small as 0.09 to 0.15 μg IV or 0.7 to 0.9 μg inhaled can cause death in a 70-kg human.[33] Heating at 185°F (85°C) for 5 minutes destroys any botulism toxin, and heating of toxin-contaminated food just before ingestion prevents food-borne botulism. Conversely, spores are highly heat resistant and can survive a temperature of 212°F (100°C) for several hours.

Food-borne botulism results from ingestion of food that contains preformed toxin. Toxin-contaminated food may have a normal appearance and taste or exhibit signs of spoilage. Because of the potency, one bite can expose a person to enough toxin to cause illness. Digestive enzymes do not destroy preformed toxin.

Infant and adult infectious botulism results from in vivo bacterial elaboration of toxin in the gastrointestinal tract. Achlorhydria and recent antibiotic use predispose the gastrointestinal tract to colonization with *C. botulinum*. Wound botulism results from in vivo bacterial elaboration of toxin in a wound. Inadvertent or iatrogenic botulism results from injection of preformed toxin for medical purposes.[32] Primate studies indicate that aerosolized botulinum toxin can also be absorbed systemically through the respiratory tract.[33]

The botulinum neurotoxin is similar in structure and function to the tetanospasmin toxin produced by *C. tetani,* but the clinical effects differ dramatically. Tetanospasmin targets inhibitory interneurons in the CNS, causing generalized muscle spasm, whereas botulinum toxin targets peripheral neuromuscular junctions and autonomic synapses, causing flaccid paralysis. When botulinum toxin is absorbed, it circulates until it reaches the neurons. The toxin binds to the presynaptic nerve membrane, becomes internalized, and inhibits the release of acetylcholine predominantly at the cholinergic synapses of the cranial nerves, autonomic nerves, and neuromuscular junction. Clinically, this is manifested by cranial nerve palsies, parasympathetic blockade, and descending flaccid paralysis. Once affected with type A toxin, the nerve is permanently damaged, and recovery requires axonal regeneration and the formation of new synapses, which may take several months. Recovery after type F toxin is substantially faster.[27]

Clinical Features

Food-borne botulism is the prototype for understanding the clinical signs and symptoms of all forms of botulism. Symptoms begin 6 hours to 8 days after the ingestion of toxin-containing food. A shorter incubation period is associated with a more severe form of illness. Early symptoms include weakness, malaise, lightheadedness, nausea, vomiting, and constipation. These symptoms are generally not severe and occur in fewer than half of the patients.

Neurologic symptoms may begin immediately or be delayed for several days. The cranial nerves are first affected. Patients experience diplopia, blurred vision, dysphonia, dysphagia, dysarthria, and vertigo. Next, a symmetrical descending muscle weakness occurs, involving the upper and lower extremities and the muscles of respiration. Blockade of the cholinergic fibers of the autonomic nervous system leads to a variety of symptoms. Decreased salivation causes a dry mouth, which may be so severe that the patient complains of a painful tongue and sore throat. Ileus and urinary retention may occur.

The patient with botulism is usually alert and afebrile unless a secondary infection is present. Postural hypotension may be present. Ocular signs include ptosis, extraocular palsies, and markedly dilated and fixed pupils; the absence of ocular abnormalities does not exclude the diagnosis. The oropharynx may be erythematous, with dry mucous membranes. The gag reflex is depressed or absent. Muscle weakness is usually present and varies from mild to severe. Neck muscles are often weak. Upper extremity muscles are affected more than those of the lower extremity, and proximal muscles are weaker than distal muscles. Deep tendon reflexes may be normal, symmetrically decreased, or absent. The sensory examination is normal. The abdomen may be distended with hypoactive or absent bowel sounds. Bladder distention may be apparent on examination. Respirations may be tachypneic and shallow or normal. In advanced illness, signs of respiratory failure may be present. Atypical presentations of food-borne botulism have been reported, and certain serotypes produce distinct variations in the pattern of symptoms. Type A disease may be more severe and is more commonly associated with bulbar findings and upper extremity weakness. Type A and type B disease may rarely cause a decreased level of consciousness. Type E is associated with a greater incidence of gastrointestinal symptoms.[27]

The presentation of *infant botulism* is different from that of food-borne botulism. Constipation is a common presenting complaint, followed by several days to weeks of poor feeding, weak cry, loss of head control, and hypotonia. Patients have decreased muscle tone and depressed deep tendon reflexes. Cranial nerve involvement causes alterations in facial expression, ptosis, and extraocular palsies. Respiratory failure occurs in 50% of patients. Fever is absent unless a secondary infection is present.[34]

Wound botulism has notable differences from food-borne botulism. The incubation period is longer, from 4 to 14 days, because the toxin must be produced within the wound after the spores have germinated. If the wound is infected, the patient may be febrile. Gastrointestinal symptoms are absent in wound botulism. Recurrent episodes are well described.[30]

The clinical presentation of *unclassified (adult infectious) botulism* is similar to food-borne botulism, although the mortality rate is significantly greater. Recovery from botulism is slow, and survivors are hospitalized for several weeks to months.

Complications from botulism include respiratory failure and problems associated with prolonged intensive care management. Aspiration of oral secretions and gastric contents because of loss of protective airway reflexes can occur. In the past 50 years, the overall mortality rate has decreased from 50% to less than 1% with modern intensive care. Mortality rates are higher in wound botulism patients (15% to 17%) and lower in infant botulism patients (<1%). For those who recover, muscle strength and endurance may not return to normal for up to 1 year, and persistent psychological problems are common.[29]

Differential Diagnoses

The differential diagnosis of *adult botulism* includes a wide variety of illnesses. The first presenting case is often misdiagnosed because early symptoms suggest pharyngitis or gastroenteritis, both of which can affect several members of a single household. Only after one or more cases progress to classic botulism is the diagnosis usually suggested.

Botulism should be differentiated from other illnesses that cause paralysis. In Guillain-Barré syndrome, weakness usually starts distally and ascends, paresthesias may be present, and the CSF protein level may be elevated. Tick paralysis is an ascending paralysis, which

is notable for a lack of bulbar involvement and the presence of a tick. In myasthenia gravis, eye signs are also prominent, but pupillary response is preserved, no autonomic symptoms are present, and weakness responds to the administration of edrophonium or ice applied to the affected muscle group. Of note, minimal improvement in weakness after the administration of edrophonium has been reported in botulism.[35] Poliomyelitis causes fever, asymmetrical neurologic signs, and CSF abnormalities. Diphtheria can be distinguished by the prolonged interval between pharyngitis and neurologic symptoms. Eaton-Lambert syndrome does not usually involve bulbar muscles. Strokes of the brainstem have an acute onset and asymmetrical, neuroanatomically localizing signs and symptoms.

Certain toxins should be considered in the differential diagnosis of botulism. Anticholinergics (atropine, belladonna, jimson weed) cause pupillary dilation and dry, red mucous membranes but also cause delirium. Organophosphate insecticides cause hyperthermia and altered mental status. Dystonic reactions are self-limited and respond to diphenhydramine or benztropine. Neuromuscular blockade from the administration of aminoglycosides is distinguished by medication history. Heavy metal poisoning produces changes in mental status. Magnesium toxicity may mimic botulism, but history and serum magnesium levels distinguish these entities. In paralytic shellfish poisoning, paresthesias are prominent, a history of shellfish ingestion is present, and recovery occurs within 24 hours.

Infant botulism has a broader differential diagnosis. Common illnesses that can mimic infant botulism include sepsis, viral illnesses, dehydration, encephalitis, meningitis, and failure to thrive. Neurologic illnesses such as Guillain-Barré syndrome, myasthenia gravis, and poliomyelitis should also be considered.[34] Hypothyroidism, hypoglycemia, diphtheria, and toxin exposures are all part of the differential diagnosis, as are less common conditions such as inborn errors of metabolism, congenital muscular dystrophy, and cerebral degenerative diseases.

Diagnostic Testing

Botulism is a clinical diagnosis that should be considered in any patient who presents with the constellation of gastrointestinal, autonomic, and cranial nerve dysfunction. Bilateral cranial nerve involvement and the progression of neurologic findings should increase clinical suspicion. Routine laboratory studies are of no value in the diagnosis. If a lumbar puncture is performed, the CSF may show only a slight elevation of protein.[32]

The diagnosis is confirmed by detecting botulinum toxin or *C. botulinum* in gastric contents, stool, or wound of the patient, botulinum toxin in the patient's blood, or toxin or organisms in the suspected food source. Local health departments and the CDC should be notified for instruction on the handling of specimens. Ideally, the specimens should be obtained before administering antitoxin, but treatment should not await laboratory confirmation. Serial measurements of the patient's vital capacity are helpful in recognizing deteriorating ventilatory function.[27]

Electromyography (EMG) can detect abnormalities consistent with the diagnosis of botulism and may be useful in differentiating botulism from other paralytic illnesses. The EMG signature of botulism is decreased amplitude of the compound muscle action potential in response to a supramaximal stimulus and facilitation of the muscle action potential with repetitive nerve stimulation. Not all motor units are affected, and normal test results do not exclude the diagnosis.

Management

The treatment of botulism consists of supportive care and specific treatment with antitoxin and other medications to block the effects of the toxin. All patients with suspected botulism should be admitted to an intensive care unit (ICU) because respiratory failure may develop rapidly. A decrease in vital capacity to less than 30% of predicted or less than 12 mL/kg is an appropriate criterion for intubation. Ileus should be treated with nasogastric suction and urinary retention with an indwelling urinary catheter. The autonomic dysfunction of botulism is much less severe than that of tetanus and rarely requires intervention.

Saline enemas and cathartics have been recommended to cleanse the gastrointestinal tract of residual toxin, but no evidence supports these treatments. Cathartics should not be given in the presence of ileus. Magnesium-containing cathartics should be avoided because elevated serum magnesium levels can exacerbate muscle weakness. Special care should be taken with use of gastrointestinal clearance in infants with botulism. Because the source of toxin is outside the gastrointestinal tract in wound botulism, bowel decontamination is not indicated.

Equine antitoxin contains antibodies to toxin types A, B, and E. It should be administered as soon as possible after appropriate laboratory specimens have been obtained. It neutralizes circulating toxin but does not affect bound toxin. Early administration prevents illness progression, decreases hospital length of stay, prevents respiratory failure, and shortens the duration of respiratory failure in patients with severe disease. Antitoxin can be obtained from the CDC or state health department. After skin testing for hypersensitivity, one 10-mL vial should be given IV. The serum half-life is 5 to 8 days. Contrary to the information in the package insert, only one vial of antitoxin is required. Repeated doses are unnecessary and increase the risk of hypersensitivity reactions, which occur in approximately 9% of patients.[29]

Infant botulism is treated with human botulism immune globulin (BabyBIG), which is pooled plasma from immunized adults with high titers of antibodies to toxins A and B.[35] BabyBIG shortens hospital length of stay by a mean of 3.1 weeks and mechanical ventilation by a mean of 1.7 weeks. It can be obtained by calling the Infant Botulism Treatment and Prevention Program (IBTPP) on-call physician at 510-231-7600 (24/7/365).[34,35]

Antibiotics are not currently recommended for food-borne botulism and may increase cell lysis and promote toxin release. Because the source of toxin is in vivo production within an infected wound, débridement and antibiotic administration should be considered only after antitoxin has been administered. Otherwise, the use of antibiotics should be limited to treatment of secondary infections that may develop. Antibiotic treatment of both infant and wound botulism has no proven benefit. If antibiotics are used for any reason in a botulism patient, attempts should be made to avoid the aminoglycosides and tetracyclines because they can impair neuron calcium entry and worsen the effects of botulinum toxin.[27] Guanidine hydrochloride may enhance acetylcholine release from terminal nerve fibers and has been recommended as an experimental component of botulism therapy.[35]

Disposition

All patients with possible botulism should be admitted to an ICU because respiratory failure may develop rapidly and insidiously. An infectious disease specialist should be consulted for management issues. The CDC should be called for assistance in any case of suggested botulism. The CDC can be reached by calling 404-639-3311 (days) and 404-639-2540 (nights, weekends, and holidays). State and local health departments may also be helpful in investigating and preventing major epidemics. Area emergency departments should be alerted so that clinicains can be aware of possible subsequent cases.

PNEUMOCOCCEMIA

Foundations

Background

Streptococcus pneumoniae is a significant cause of morbidity and mortality worldwide. Pneumococcemia is defined as the presence of *S. pneumoniae* in the blood. The clinical presentation ranges from a mild illness to a fulminant, life-threatening, systemic syndrome. *S. pneumoniae* also causes myriad localized infections, including otitis media, pneumonia, meningitis, and, less commonly, endocarditis, septic arthritis, and peritonitis.[31,36]

S. pneumoniae was discovered in 1881 by Sternberg in the United States and simultaneously by Pasteur in France. The first pneumococcal vaccine was licensed for use in the United States in 1977, and today there are two forms available: one for infants younger than 2 years old and individuals with impaired host defenses, and one for otherwise healthy individuals older than 2 years old.[37-40] *S. pneumoniae* remains a substantial cause of serious illness despite the availability of antibiotics and vaccines. Infection appears sporadically in normal individuals and in patients with impaired host defenses. Most cases of pneumococcal infections are community acquired, with a peak incidence in winter. Invasive pneumococcal disease (IPD) is defined as isolation of *S. pneumoniae* from a normally sterile site (blood, pleural fluid, CSF). Pneumococcemia occurs in less than 2% of all hospitalized patients with community-acquired pneumonia, but up to 7.3% of those admitted to the ICU, 11.5% of those with multilobar infiltrates, 15% of those with a temperature 104°F (40°C) or higher or 95°F (35°C) or lower, 20% of those with a systolic blood pressure below 90 mm Hg, and 22% of those with HIV. Other sources include the meninges (8%) and the sinuses or middle ear (4%).

Bacteremia is primary in 18% of adults but is much higher in children. People at higher risk for pneumococcemia include those with chronic respiratory or cardiovascular disease, chronic alcohol abusers, patients with cirrhosis, diabetes mellitus, or an absent or functionally impaired spleen (postsplenectomy or sickle cell disease), those receiving immunosuppressive therapy, those with chronic renal failure, nephrotic syndrome, organ transplantation, lymphoma, Hodgkin disease, multiple myeloma, and acquired immunodeficiency syndrome (AIDS).[39] Pneumococcus is spread from person to person by close contact, and crowded living conditions are associated with epidemics. The mortality rate from pneumococcemia is 10% to 20% for young adults and much higher for older patients, those with underlying disease, and those with localized infections, such as meningitis.[40-41] The case fatality rate is significantly lower for children.

Anatomy, Physiology, and Pathophysiology

Pneumococcemia is caused by *S. pneumoniae,* an encapsulated, gram-positive, facultative anaerobic coccus. Antigenic differences in the polysaccharide capsule separate *S. pneumoniae* into 90 serotypes.[31] In the United States, seven serotypes account for most of invasive disease in children younger than 6 years old and 50% of invasive disease in people older than 6 years old. Worldwide, 10 capsular types account for two-thirds of invasive disease while in western industrialized nations, seven capsular types account for two-thirds of invasive disease.

S. pneumoniae enters the blood by one of two routes: (1) It begins as a pulmonary infection that spreads to mediastinal lymph nodes, the thoracic duct, and into the circulation; (2) it colonizes or causes infection in the upper respiratory tract and spreads to the subarachnoid space through the arachnoid villi to the venous sinus and into the blood (with or without meningeal involvement).

S. pneumoniae bacteremia causes a clinical picture that ranges from a minor febrile illness to life-threatening septic shock. Multiple virulence factors contribute to adherence to tissues, inhibition of phagocytosis, activation of complement, and stimulation of cytokines.[31] Host defenses rely heavily upon antibody and complement production, and people who have impaired humoral immunity are more susceptible to IPD. In patients with pneumococcal infections, antibodies specific to the capsule serotype develop within several days of onset of infection. This response occurs approximately 30 days after a patient receives the pneumococcal vaccine. Patients who demonstrate substantial host resistance are able to develop active immunity, and some children can spontaneously clear culture-proven pneumococcemia.

Clinical Features

The clinical presentation of pneumococcemia ranges from mild illness to fulminant disease, progressing to death within several hours. Occult bacteremia begins as a febrile illness in which the only direct indication of pneumococcemia is a positive blood culture (often at 24 to 48 hours). Sepsis is indicated by 2 or more systemic inflammatory response syndrome (SIRS) criteria or the quick SOFA (qSOFA) assessment[42] (see Chapter 127). Patients may present with lethargy, signs of poor tissue perfusion, cyanosis, and hypoventilation or hyperventilation. Either occult bacteremia or sepsis can occur in conjunction with a localized infection.

Symptoms include fever, chills, cough, shortness of breath, headache, and rash. The clinical presentation of pneumococcemia is similar to that of other common febrile illnesses. Although signs of focal infection, such as pneumonia, may be present, often the only indication of pneumococcemia is fever or other signs of bacterial toxicity. Most adult patients have fever or hypothermia. Cough, rigors, pleuritic pain, and gastrointestinal symptoms occur in about one-third of adult patients. Fever (temperature >101.3°F [38.5°C]) occurs in 90% of younger patients but in less than 60% of those older than 65 years old. Patients with signs of sepsis have an increased risk for a fulminant course with rapid deterioration. Physical examination findings vary with the site of primary infection. A focal primary source of infection is more common in adults than in children. Clinicians should evaluate for signs of otitis media, sinusitis, and meningitis. Pneumococcemia is considered primary in 18% of adults and 30% of children, so lack of localized infection as a source does not rule out IPD.

Cardiovascular collapse can occur with fulminant pneumococcal sepsis. Patients who develop severe illness from pneumococcemia may have end-organ damage from inadequate perfusion, disseminated intravascular coagulation (DIC), septic emboli, respiratory failure, meningitis, gastrointestinal bleeding, hepatic coma, renal failure, and myocardial infarction.

Pneumococcemia occasionally results in hematogenous seeding, causing peritonitis, arthritis, endocarditis, meningitis, and cellulitis. Adults and children with functional or anatomic asplenia may have fulminant pneumococcemia, or *overwhelming postsplenectomy infection (OPSI),* characterized by septic shock, adrenal hemorrhage, and DIC. Although the incidence of OPSI is unknown, studies demonstrate that it is substantial and that the risk for it does not decrease over time after splenectomy. Most invasive pneumococcal infections occur in the first 2 years postsplenectomy, and about two-thirds occur between 5 and 20 years. OPSI may arise with symptoms indistinguishable from those of common viral illnesses.[43,44] The 100-fold increased incidence of pneumococcal bacteremia and meningitis in children with sickle cell disease is likely primarily due to splenic dysfunction, but complement abnormalities may also play a role.[45]

Differential Diagnoses

Pneumococcemia is challenging to distinguish from other causes of febrile illness. The presence of fever and shock, with or without a

characteristic rash, suggests the possibility of sepsis caused by *Haemophilus influenzae, Neisseria meningitidis,* and other streptococcus types. The presence of confirmed pneumococcemia does not exclude other diagnoses, such as influenza.

Diagnostic Testing

The only test specific for pneumococcemia is a blood culture that grows *S. pneumoniae.* Ancillary testing should include a complete blood count with differential, blood and urine cultures, electrolyte values, glucose concentration, serum creatinine level, serum lactate, and blood urea nitrogen level. A CXR may demonstrate pneumonia. The results of sputum Gram stain, culture, and sensitivity testing may help direct later inpatient care. Sputum specimens should be collected before antimicrobial therapy is instituted if possible; however, therapy should not be delayed to obtain sputum. Antigen testing of urine for pneumococcal polysaccharide is up to 100% sensitive in IPD.[45]

If the patient appears toxic or has signs of respiratory compromise, an arterial blood gas, serum lactate, and coagulation profile should be obtained. If signs of meningitis or alterations in mental status are present, a lumbar puncture should be performed. Gram stain of the buffy coat may be positive in cases of overwhelming pneumococcal sepsis. The WBC count is usually elevated. A normal or low WBC count is suggestive of more serious disease, as are hypoxemia and hypercarbia. Increased mortality occurs in patients with serum creatinine levels higher than 2.0 mg/dL, bilirubin levels higher than 1.5 mg/dL, and albumin levels below 2.5 g/dL.

Management

Acute Treatment

Management of pneumococcemia consists of stabilization of life-threatening conditions, eradication of the infection, and treatment of predisposing or coexisting conditions. All septic patients should be managed with sepsis-directed therapy (see Chapter 127).[46,47] The decision to initiate antibiotic therapy is often made with limited objective data, which include the clinical findings, age of the patient, underlying conditions, and preliminary laboratory studies. Prompt initiation of antibiotics is essential to reduce the morbidity and mortality of pneumococcal infection, and should begin in the ED. To simplify selection of a treatment strategy, patients can be divided into two groups:

1. Bacteremia or sepsis suggested by clinical findings; organism not identified: Patients in this group are given antibiotics based on the most likely organism, patient's age, immune status, presence of coexisting disorders, and local patterns of antibiotic resistance. The antibiotic regimen is altered after identification of the organism and its sensitivities.
2. *S. pneumoniae* growth is reported from blood cultures (usually 1 to 2 days prior): The treatment regimen for occult bacteremia is guided by the patient's age, history, physical examination, general appearance, and ancillary test results. The antibiotic selected on initial visit may be sufficient to treat pneumococcal bacteremia subsequently identified by the laboratory. The patient should be reevaluated promptly. Repeated blood culture should be obtained if the patient has not been taking an antibiotic. For well-appearing children, a 7- to 10-day course of an appropriate oral antibiotic is reasonable. The decision to admit a child is based on the findings at the time of reevaluation.

Adult patients with laboratory-proven pneumococcemia may be treated with penicillin G if susceptibility has been documented: 2 to 4 million units IV every 4 hours if local penicillin resistance patterns are still low. Meningitis is treated with 4 million units of penicillin G every 4 hours. In children, the dosage for meningitis is 250,000 units/kg per 24 hours in divided doses every 4 hours IV up to a maximum of 20 million units.

S. pneumoniae susceptibility to penicillin in the United States continues to decline.[48] Unless penicillin susceptibility has been documented, treatment should begin with ceftriaxone (1 to 2 g IV every 12 to 24 hours; 50 to 100 mg/kg/day in children) or cefepime (1 to 2 g IV every 8 to 24 hours; 50 mg/kg every 8 hours in children). When meningitis is suspected, higher doses should be given. In areas where ceftriaxone resistance has emerged, vancomycin (weight-based loading dose 20 mg/kg, maintenance dose based on renal function in children) should be administered.

Ceftriaxone is commonly administered to children with suggested occult bacteremia treated as outpatients while blood, urine, and CSF culture results are pending. Ceftriaxone (initial dose of 50 to 100 mg/kg IM or IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours, up to a maximum of 4 g) and cefotaxime (200 mg/kg/day in divided doses every 6 hours IV, up to a maximum of 12 g) are excellent antibiotics for *N. meningitidis* and *H. influenzae*. Alternative initial treatment of pneumococcemia in penicillin- or cephalosporin-allergic patients includes vancomycin, imipenem, and chloramphenicol.

Patients with pneumococcemia may not respond to treatment for the first 24 to 48 hours of therapy. This may be attributed to the normal course of the disease, an incorrect diagnosis, the underlying illness, or an antibiotic regimen that does not treat the infection sufficiently.

Vaccination

Pneumococcal vaccine is effective in preventing infection; the 23-valent vaccine contains the purified polysaccharide antigens of the serotypes that cause 70% to 88% of pneumococcemia infections in the United States. Although it is only 60% to 70% effective at preventing invasive disease, it is safe, inexpensive, and of substantial value for well-defined groups at risk.[37,39] The 23-valent pneumococcal vaccine has limited immunogenicity in children younger than 2 years. The heptavalent conjugate vaccine PCV7, licensed in 2000, linked the polysaccharide to proteins, resulting in an improved immunogenic response in children younger than 2 years old.[49] This vaccine significantly decreased IPD caused by the included serotypes, but an increase in disease caused by non-vaccine serotypes prompted the development of a 13-valent conjugate vaccine. PCV13 was licensed in the United States in 2010 and has replaced PCV7.[37] Recommendations for the use of the PVC13 and 23-valent (PPSV23) vaccines are given in Tables 118.4, 118.5, and 118.6.[50,51]

Approximately 50% of IPD in children with comorbidities is caused by serotypes not included in either the 13-valent or 23-valent vaccine.[52] Other preventive measures for pneumococcemia include passive immunization with immunoglobulins for patients with congenital or acquired immunodeficiency diseases and daily antibiotic prophylaxis for children with functional or anatomic asplenia.[53]

Disposition

Toxic-appearing patients of any age should be treated with antibiotics and admitted to the hospital. Patients with underlying or coexisting conditions and those with an unclear course of illness should also be admitted or observed. Children who are afebrile and appear well on initial examination are unlikely to have serious sequelae. The decision to treat a febrile child with antibiotics on an outpatient basis is based on clinical findings, vaccination history, medical history, the ability of the parents to follow the discharge instructions, and availability of timely follow-up.

MENINGOCOCCEMIA

Foundations

Background

Few clinical situations in emergency medicine produce greater concern than meningococcal infection. Virtually all emergency clinicians

practicing before the meningitis vaccine have had a patient who appeared relatively well on initial presentation, only to be moribund with fulminant infection a few hours later. Vieusseux initially described "Epidemic cerebrospinal fever" in 1805, and Weichselbaum identified the causative bacterial agent in 1887. The introduction of sulfonamide therapy in 1937 dramatically improved outcomes. Sulfonamide prophylaxis was also effective at eradication of the carrier state and was used to prevent epidemics that occurred in military barracks. In the 1940s, sulfonamide resistance began to emerge. In 1963 an outbreak of resistant meningococcal disease occurred in the United States, which

spurred efforts to develop a vaccine. Subsequent worldwide resistance has resulted in continued efforts to develop safe and effective vaccines.[53]

Humans are the only reservoir for *N. meningitidis*. In 2013, 564 cases of meningococcal disease were reported in the United States. Active Bacterial Core surveillance by the CDC reports an incidence of 0.14 per 100,000 population, a marked decrease since the licensing of the first conjugated meningococcal vaccine in 2005 (Fig. 118.5). Of the more than 13 serogroups, groups A, B, C, Y, and W-135 cause most infections. Most cases occur sporadically, with occasional outbreaks, notably on college campuses in dormitories or other crowded living situations. More than half of the cases in infants are caused by serogroup B, for which there is no effective vaccine. Serogroups C, Y, and W-135 cause 75% of meningococcal disease in patients older than 11 years old.[54]

The incidence of meningococcal disease peaks in the winter. Superimposed on this annual variation are cyclic peaks of disease every 5 to 15 years. Approximately every 10 years, massive outbreaks of serogroup A occur in sub-Saharan Africa (the "meningitis belt"). The last outbreak was in 2013 with over 9000 cases and close to 900 deaths.[55] During nonepidemic periods, children younger than 5 years old have the highest incidence of infection. During epidemics, the incidence increases among children aged 5 to 9 years, an observation that may be of value in predicting the beginning of an epidemic. Crowded living conditions increase the risk for spread of meningococcal disease. The incidence of disease and the carrier state are several times higher among military recruits in the first few weeks of service than in the general public. This is also true of first-year college students, particularly those living in dormitories. Other risk factors for development of invasive meningococcal disease include close contact with an infected patient, complement deficiency, properdin deficiency, asplenia, chronic alcohol abuse, active and passive smoking, corticosteroid use, and recent respiratory illness. The mortality rate of meningococcemia is 40% in the United States. Septicemia without meningitis carries a much higher mortality rate (up to 70%) than meningitis alone (less than 10%).[53,54,56]

Anatomy, Physiology, and Pathophysiology

Meningococcal disease is caused by *N. meningitidis,* a fastidious, aerobic, gram-negative diplococcus. *N. meningitidis* is an encapsulated organism classified into at least 13 serogroups based on the capsular polysaccharides.[53] *N. meningitidis* is an obligate human pathogen. It attaches to nonciliated epithelial cells in the nasopharynx. It may remain on the epithelial surface, causing an asymptomatic carrier state or producing mild upper respiratory tract infection symptoms. The carrier state acts as an immunizing process. In certain patients, the bacteria enter the bloodstream and cause localized infection, bacteremia, sepsis, or fulminant infection. Multiple host and microorganism characteristics determine whether clinical disease develops, but the presence of bactericidal antibodies is protective. Complement deficiency plays a role in a host's inability to fight this infection. The capsule is required for *N. meningitidis* to adhere to epithelium, but only unencapsulated meningococci enter epithelial cells; capsular biosynthesis has been shown to stop as the bacteria enter the epithelial cell.[53] The release of lipo-oligosaccharide (LOS) and endotoxin by autolysis of the *N. meningitidis* cell is the initial event in the development of meningococcal sepsis. LOS stimulates a massive host mediator response.

All of the major pathophysiologic events of meningococcal sepsis are caused by the host's inflammatory response to the organism causing functional and histologic damage to the microvasculature, resulting in increased vascular permeability, pathologic vasoconstriction and vasodilation, loss of thromboresistance, DIC, and profound myocardial dysfunction.[53]

Clinical Features

Presentation of meningococcemia ranges from a mild febrile illness to fulminant disease progressing to death within hours. Most patients have fever on presentation. Other complaints include headache, irritability, lethargy, myalgias, emesis, diarrhea, cough, and rhinorrhea. Anywhere from 27% to 77% of patients present with the classic hemorrhagic skin lesions.[53] These patients can rapidly progress to purpura fulminans, with hypotension, adrenal hemorrhage, and multiorgan failure. The following categories detail the five patterns of presentation.

Occult Bacteremia

This is a febrile illness in which the only direct indication of meningococcemia is a positive blood culture. In its mildest form, meningococcal bacteremia cannot clinically be distinguished from more benign febrile illnesses. Initial diagnoses include common childhood infections, such as otitis media, acute viral upper respiratory infections, and gastroenteritis. For some patients the illness resolves after treatment with an oral regimen of antibiotics; others experience spontaneous resolution without antibiotic treatment. *N. meningitidis* accounts for less than 1% of occult bacteremia cases, but these patients are much more likely to develop meningitis (up to 58%) than are those with *S. pneumoniae*. Despite the total absence of clinical clues to meningococcal infection at initial presentation, some untreated patients subsequently deteriorate rapidly.

Meningococcal Meningitis

Patients with meningococcal meningitis present similarly to those with meningitis of other causes, with headache, photophobia, vomiting, fever, and signs of meningeal inflammation. This classic triad of fever,

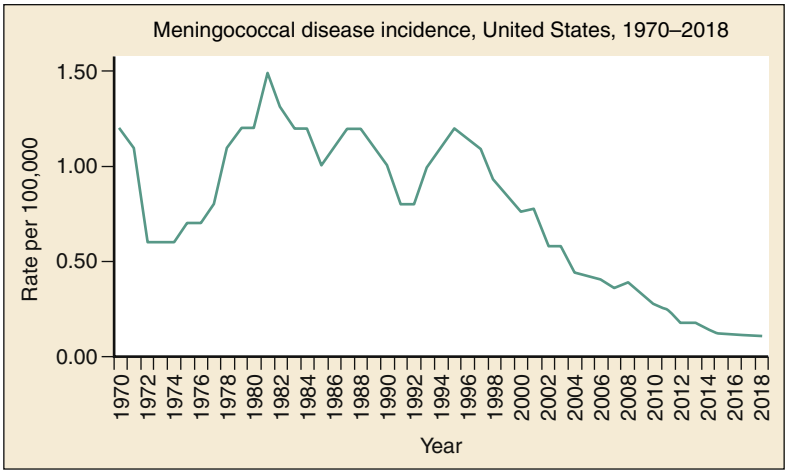

Fig. 118.5 Meningococcal disease incidence by year in the United States from 1970 to 2018. (Centers for Disease Control and Prevention. Manual for the surveillance of vaccine-preventable diseases. Available at: https://www.cdc.gov/meningococcal/surveillance/index.html)

neck stiffness, and altered mental status is present in less than 30% of patients.[57] Infants and small children may present with fever, irritability, and vomiting as the only complaints. More than half of patients with meningococcal meningitis have rash on presentation, and 20% present with seizures. Onset of symptoms is less abrupt (usually during 24 hours), and the prognosis is better for patients with meningococcal meningitis than for patients with meningococcemia without clinical signs of meningitis.

Meningococcal Septicemia

Patients with meningococcal septicemia present with lethargy, poor tissue perfusion, cyanosis, and hypoventilation or hyperventilation. Hemorrhagic skin lesions are present in 28% to 77% of patients, but a macular or maculopapular rash may occur and be mistaken for a variety of viral exanthems. Petechiae generally appear on the extremities and under pressure points, such as the elastic bands of socks and underwear. They may progress to involve almost any body surface, including the mucosa and sclera, but typically spare the palms, soles, and head. Macular lesions may progress to purpura and ecchymoses in fulminant meningococcemia.

Purpura fulminans, the most advanced form of meningococcal septicemia, occurs most often in children and is usually associated with DIC. This condition is characterized by rapidly spreading ecchymoses and gangrene of the extremities. Mucosal and gastrointestinal bleeding as well as oozing from IV sites may occur. Clinical signs of meningitis and CSF pleocytosis may not be present, even when diplococci are isolated from the CSF, likely because the systemic progression of the disease is so rapid that it precludes a host meningeal inflammatory response to the organism in the CSF. Shock can result from distributive shock, intravascular volume loss, and heart failure, probably related to myocarditis. Renal failure, coma, and bilateral adrenal hemorrhage often occur.[53]

Fever and a Nonblanching Rash

Up to 30% of patients present without signs of meningitis or septicemia. They are typically admitted for fever and a nonblanching rash and no other specific findings. If left untreated, meningitis or fulminant septicemia and shock can develop.[50,56]

Chronic Meningococcemia

This syndrome is characterized by fever, rash, and arthritis in conjunction with a positive blood culture for *N. meningitidis*. Headache and upper respiratory symptoms are often present. This is the rarest form of meningococcal disease, accounting for less than 2% of cases. It may progress to meningitis, endocarditis, or fulminant meningococcemia regardless of treatment.

Complications

Circulatory collapse is a common complication of meningococcemia and the most common cause of death. Many of the inflammatory mediators released during sepsis cause peripheral vasodilation, capillary leak, and myocardial dysfunction. Acidosis, hypoglycemia, hypokalemia, hypocalcemia, hypophosphatemia, and hypoxia also contribute to myocardial dysfunction, which may become unresponsive to inotropic medications.

Acute respiratory failure occurs from capillary leak, DIC, and large volume requirements in the setting of decreased cardiac function. Patients frequently require mechanical ventilation. Renal failure is common due to impaired renal perfusion. If meningitis accompanies meningococcemia, focal neurologic deficits and seizures may occur but are less common than with pneumococcal meningitis. Long-term neurologic sequelae include hearing loss, visual deficits, neurodevelopmental impairment, cranial nerve palsies, and hemi- and quadriparesis. Purpura fulminans may result in skin lesions and loss of digits or limbs from gangrene. Purulent or immune complex arthritis and pericarditis with tamponade may also occur.

Poor prognostic indicators include seizures, hypothermia, hyperpyrexia, total peripheral WBC count of less than 500/mm^3, platelet count of less than 100,000/mm^3, metabolic acidosis (pH <7.30), development of purpura fulminans, onset of petechiae within 12 hours of admission, absence of meningitis, presence of shock, low sedimentation rate, and extremes of age. In one study, all patients who developed organ system failure had one or more of the following at the time of initial presentation: circulatory insufficiency (hypotension or shock), peripheral WBC count of less than 10,000 cells/mm^3, or a coagulopathy.[51]

Differential Diagnoses

It is difficult to distinguish the clinical signs of meningococcemia from bacteremia caused by *S. pneumoniae,* other streptococcal groups, *H. influenzae,* and *Neisseria gonorrhoeae.* A hemorrhagic rash is more commonly associated with meningococcal disease. The differential diagnosis of meningococcemia also includes viral exanthems, Rocky Mountain spotted fever, typhus, typhoid fever, endocarditis, vasculitis

syndromes (polyarteritis nodosa and Henoch-Schönlein purpura), toxic shock syndrome (TSS), acute rheumatic fever, dengue fever, drug reactions, idiopathic thrombocytopenic purpura, and thrombotic thrombocytopenic purpura.

Diagnostic Testing

The tentative diagnosis of meningococcemia is based on clinical findings and confirmed by the isolation of *N. meningitidis* from blood cultures or any other usually sterile site, such as CSF or synovial, pleural, or pericardial fluid. Ideally, blood culture specimens should be obtained before the administration of antibiotics unless this delays the patient's treatment. Blood cultures are positive in approximately 50% to 80% of cases. A lumbar puncture should be performed in stable patients without evidence of DIC. The CSF shows either gram-negative diplococci on Gram stain or a positive culture in about 46% to 94% of cases. Even patients without clinical signs of meningitis frequently have the organism grown from the CSF. Gram stain of petechial scrapings may show gram-negative diplococci in up to two-thirds of cases, and the organism can rarely be seen in the peripheral blood buffy coat. Highly specific antigen tests for CSF are available but have a high false-negative rate. PCR of the buffy coat or CSF is more sensitive and specific than any of the preceding tests and is not affected by prior antibiotic therapy.[53,54]

Ancillary laboratory tests are of little value in establishing a specific diagnosis of meningococcal sepsis but may be useful in ruling out other disease, determining prognosis, and monitoring complications. The WBC count may be high, low, or normal, but a bandemia is typically present. The symptoms and signs of CNS infection may be nonspecific in the infant and child younger than 2 years old. If meningitis is present, the CSF opening pressure is usually elevated, the protein level is increased, and the glucose concentration is decreased. Pleocytosis is usually present, with a predominance of polymorphonuclear leukocytes. Gram-negative diplococci may be seen on microscopy. Early in the disease or with fulminant disease, the CSF may be free of inflammatory cells. Serologic evidence of DIC is frequently present.[54,55] A CXR is useful in evaluation for pneumonia and acute respiratory distress syndrome. An echocardiogram helps assess for myocardial dysfunction and pericardial effusion. Serum lactate may help direct therapy.

Management

Acute Treatment

Morbidity and mortality in meningococcemia are reduced with prompt recognition and intravenous antibiotic therapy. Patients can be divided into two general groups:

1. Bacteremia or sepsis suggested by clinical findings; no organism identified: Patients should receive empirical antibiotics based on factors that include the most likely organism, patient's age and immune status, presence of coexisting disorders, and local patterns of antibiotic resistance. A narrower-spectrum agent is selected after identification of the organism and its sensitivities.
2. *N. meningitidis* growth is reported from prior blood cultures: Treatment for occult bacteremia is guided by the patient's age, history, physical examination, general appearance, and ancillary test results. The antibiotic selected at the time of the initial visit may be sufficient to treat the meningococcal bacteremia subsequently identified by the laboratory. The decision to hospitalize the patient is based on the findings at the time of reevaluation and the risk of sequelae. We recommend repeating blood cultures, considering lumbar puncture, and admitting the patient to the hospital until results of repeated cultures are obtained.

The standard antibiotic regimen for laboratory-proven meningococcemia is penicillin G (4 million units every 4 hours IV for adults) and penicillin (250,000 to 300,000 units/kg/day in divided doses every 4 hours IV for children, up to a maximum of 20 million units). Penicillin resistance in *N. meningitidis* remains low in the United States but has been reported in Spain and the United Kingdom.[53]

Although appropriate first-line therapy, penicillin is rarely given as the initial agent in patients with suspected meningococcal sepsis or meningitis. Ceftriaxone (100 mg/kg IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours, up to a maximum of 4 g) and cefotaxime (100 mg/kg/day IV in divided doses every 6 hours, up to a maximum of 12 g) are appropriate initial antibiotics as well. The cephalosporins are safe and have rapid onset of action and excellent coverage for *S. pneumoniae* and *H. influenzae*. Chloramphenicol (100 mg/kg/day divided every 6 hours to a maximum of 4 g/day) should be considered in penicillin- and cephalosporin-allergic patients. IM ceftriaxone is occasionally administered to children with suspected bacteremia treated as outpatients while culture results are pending. Several reports have demonstrated the efficacy of ceftriaxone (80 to 100 mg/kg IV) in a single daily dose; however, twice-daily dosing remains the standard recommendation at this time. Ceftriaxone-treated patients have more rapid sterilization of the CSF and a lower incidence of hearing loss than conventionally treated patients.

Patients with fulminant meningococcemia often require airway management, IV fluid resuscitation, and vasopressor support. Fluid requirements may be high. In the setting of frequent myocardial dysfunction, intensive cardiovascular monitoring is required. Electrolyte and acid-base abnormalities should be corrected. If the patient is oliguric or anuric, hemodialysis may be necessary to correct these abnormalities. Fresh frozen plasma should be considered for patients with bleeding complications.

The role of steroids in the treatment of meningococcemia without meningitis is controversial. Although corticosteroids were once widely recommended to treat the adrenal insufficiency associated with fulminant meningococcemia, recent studies demonstrate that adrenal function is not impaired in all patients. If patients have persistent shock despite vigorous fluid resuscitation and vasopressor therapy, glucocorticoid therapy and adrenal function testing should be considered as this subgroup of patients may benefit.[57]

The use of corticosteroids in patients with bacterial meningitis is currently recommended for adults and children. Corticosteroid administration before antibiotic administration decreases long-term neurologic sequelae in adults and children. There is also a mild decrease in mortality. In neonates, there are limited data of low quality that suggest steroids decrease morbidity from hearing loss and may decrease mortality. Although these benefits are not seen in patients with meningococcal meningitis, the organism is typically not identified when steroids are initiated. Dexamethasone (0.4 to 0.6 mg/kg/day every 6 hours for 4 days) should be given to patients with bacterial meningitis. The first dose should be given before the first dose of antibiotics if possible.[58,59] Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have been described, but data are limited.

Antibiotic Prophylaxis and Vaccination

Close patient contacts (household, nursery schools, daycare centers, military recruits, college dormitories, teammates) should receive antibiotic prophylaxis. Intimate contacts and health care workers with intimate exposure (e.g., mouth-to-mouth resuscitation, intubation, or suctioning) should receive rifampin, 10 mg/kg (up to 600 mg) orally every 12 hours for four doses. The dose for neonates is 5 mg/kg. Patients should be warned that rifampin discolors the urine and secretions; contact lenses should be removed to avoid permanent staining.

IM ceftriaxone (125 mg for children younger than 15 years old and 250 mg for those older than 12 years old) is an effective alternative for pregnant women and for people in whom compliance with an oral regimen cannot be ensured. Ciprofloxacin (500 mg orally) is another alternative for adults.[56]

Meningococcal vaccine should be considered an adjunct to prophylaxis in epidemics and for close contacts in sporadic cases if one of the serotypes contained in the vaccine is identified as the causative agent. The currently available vaccines are quadrivalent vaccines for serogroups A, C, Y, and W-135. No vaccine is licensed for group B, a serogroup that causes a significant portion of meningococcal infection in the United States, but trials are currently underway.[60] The conjugate vaccines (MCV4: Menactra and Menveo) produce a superior immune response compared to the polysaccharide vaccine (MPSV4: Menomune). Routine vaccination with MPSV4 is not recommended and should be limited to patients over 55 years old, or when MCV4 is unavailable. Routine vaccination with MCV4 is recommended for persons 11 or 12 years old with a booster at 16 years old. Vaccination is also recommended for those at increased risk of meningococcal disease, including microbiologists who are routinely working with *N. meningitides*, military recruits, children with functional or anatomic asplenia, and people traveling to endemic areas of the world, such as sub-Saharan Africa.[54]

Disposition

All patients with possible or confirmed meningococcemia should be placed in respiratory isolation and hospitalized, preferably in an ICU, because they can decompensate rapidly and without warning. A possible exception is the well-appearing child who has culture-proven *N. meningitidis* and has been taking appropriate antibiotics as an outpatient. This child should have a lumbar puncture performed to determine CSF involvement if one was not performed at the initial evaluation. Antibiotics should be continued on an inpatient basis, but an ICU may not be necessary if the child appears well.

TOXIC SHOCK SYNDROME

Foundations

Background and Importance

Toxic shock syndrome (TSS) is a toxin-mediated systemic inflammatory response syndrome that was first described in 1978 in a series of seven children 8 to 17 years old who had high fever, rash, headache, confusion, conjunctival injection, edema, vomiting, diarrhea, renal failure, hepatic dysfunction, DIC, and shock. *S. aureus* was cultured from various body sites but not from the blood in five of the seven cases. The disease gained notoriety in the early 1980s when many cases were reported in association with tampon use in young, healthy menstruating women. The term *toxic shock syndrome* was coined to describe the constellation of signs and symptoms. Investigators noted positive vaginal cultures for *S. aureus,* recurrence of illness during subsequent menses, and the value of antistaphylococcal antibiotics in preventing recurrences. Nonmenstrual cases were also recognized in both men and women due to a variety of predisposing conditions, and a case definition was published in 1982 (Box 118.6).[61-64]

In the late 1980s, several reports described group A streptococcus infection (*S. pyogenes*) associated with shock and multisystem organ failure. This is called *streptococcal toxic shock syndrome* because it shares many features with staphylococcal TSS. Box 118.7 shows the case definition for streptococcal TSS.[65]

The peak incidence of TSS occurred in 1980, when 890 cases were reported, 91% of which were associated with tampon use. Since then, the reduction in cases of the menstrual form of TSS has followed an active effort to decrease the absorbency of tampons and to change their composition. Menstruation remains the most common setting for TSS, but nonmenstrual TSS accounts for just under half of the reported cases. TSS has also been reported in association with barrier contraceptives and childbirth. Nonmenstrual TSS occurs in people of all ages and both sexes. The CDC reported an average of about 300 cases a year between 2010 and 2015, with a steady increase in the incidence of streptococcal TSS and a decrease in the incidence of staphylococcal TSS. The age and sex distribution reflects the association with menses. Streptococcal TSS accounts for two-thirds of the cases.[63]

Nonmenstrual staphylococcal TSS is associated with superinfection of various skin lesions, including burns, surgical sites, dialysis catheters, and lung (influenza-associated). It may also occur in association with staphylococcal respiratory infections or even with colonization by a toxigenic strain of the organism, without an obvious infectious source. Streptococcal TSS is classically associated with more severe soft tissue infections, such as necrotizing fasciitis and myositis, as well as with pneumonia, peritonitis, myometritis, and osteomyelitis.

The mortality rate from staphylococcal TSS has declined since the disease was first described. The case fatality rate in 1980 was 10% and is

BOX 118.6 Case Definition of Toxic Shock Syndrome (Revised)

Clinical Case Definition

Fever: Temperature >102°F (38.9°C)

Rash: Diffuse macular erythroderma

Desquamation 1 to 2 weeks after onset of illness, particularly of palms and soles

Hypotension: Systolic blood pressure <90 mm Hg for adults or below fifth percentile by age for children younger than 16 years old, orthostatic drop in diastolic blood pressure >15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness

Multisystem involvement—*three* or more of the following:

- Gastrointestinal: Vomiting or diarrhea at onset of illness
- Muscular: Severe myalgia or creatine kinase level at least twice the upper limit of normal for laboratory
- Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
- Renal: BUN or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (>5 leukocytes/high-power field) in the absence of urinary tract infection
- Hepatic: Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory
- Hematologic: Platelets <100,000/mm^3
- CNS: Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Laboratory Criteria for Diagnosis

Negative results on the following tests, if obtained:

Blood, throat, or CSF cultures (blood culture may be positive for *Staphylococcus aureus*)

Rise in titer to Rocky Mountain spotted fever, leptospirosis, or rubeola

Case Classification

Probable: A case that meets the laboratory criteria and in which four of the five clinical findings are present

Confirmed: A case that meets the laboratory criteria and in which all five of the clinical findings are present, including desquamation, unless the patient dies before desquamation occurs

ALT, Alanine transaminase; *AST,* aspartate transaminase; *BUN,* blood urea nitrogen; *CNS,* central nervous system; *CSF,* cerebrospinal fluid.

BOX 118.7 Case Definition of Streptococcal Toxic Shock Syndrome

Clinical Case Definition

Hypotension: Systolic blood pressure ≤90 mm Hg for adults or below fifth percentile by age for children younger than 16 years old

Multisystem involvement—*two* or more of the following:

- Renal: Creatinine >2 mg/dL (177 μmol/L) for adults or more than twice the upper limit of normal for age or more than twofold elevation above baseline for patients with preexisting renal disease
- Hematologic: Platelets <100,000/mm^3 or DIC, defined as prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
- Hepatic: Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory, or a twofold increase in patients with preexisting liver disease
- Acute respiratory distress syndrome: Defined by acute onset of pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia
- Generalized erythematous maculopapular rash that may desquamate
- Soft tissue necrosis, including necrotizing fasciitis, myositis, or gangrene

Laboratory Criteria for Diagnosis

Isolation of group A streptococcus

Case Classification

Probable: A case that meets the clinical case definition in the absence of another identified cause of the illness and with isolation of group A streptococcus from a nonsterile site

Confirmed: A case that meets the clinical case definition and with isolation of group A streptococcus from a normally sterile site (e.g., CSF or joint, pleural, or pericardial fluid)

ALT, Alanine transaminase; *AST,* aspartate transaminase; *CSF,* cerebrospinal fluid; *DIC,* disseminated intravascular coagulation.

now 5%. Streptococcal TSS remains a highly fatal disease, with a mortality rate of 30% to 70%.

Anatomy, Physiology, and Pathophysiology

Staphylococcal TSS is caused by colonization or infection with toxigenic strains of *S. aureus*, which produce toxic shock syndrome toxin 1 (TSST-1). *S. aureus* is present in virtually all cases of both forms of the illness. Because the organism is often not invasive, the blood cultures are often negative. Streptococcal TSS is caused by invasive infection with toxigenic strains of group A streptococcus.[61,62,64]

The effects of various exotoxins produced by *S. aureus* and group A streptococcus cause the shock and multiorgan dysfunction associated with TSS. *S. aureus* produces TSST-1 and enterotoxin B. TSST-1 is identified in more than 90% of menstrual cases and 60% of nonmenstrual cases. Other toxins may play a role in nonmenstrual TSS. Antibodies to these toxins are protective against disease. Group A streptococcus produces streptococcal pyrogenic exotoxins A and B. These exotoxins are absorbed into the bloodstream through inflamed or traumatized mucous membranes or from areas of focal infection. Absorbed toxins act as superantigens, inducing mononuclear cells to synthesize and to release cytokines, tumor necrosis factor alpha (TNF-α), and interleukins at a rate and magnitude many fold greater than with the normal antigen presentation, which begin the cascade of systemic vasculitis and the multisystem manifestations of the disease. Host immune factors are important in the pathogenesis of TSS. Group A streptococcus is an invasive organism and circulating group A streptococcus organisms induce the production of TNF-α and other cytokines by mononuclear cells.[64]

BOX 118.8 Risk Factors for Toxic Shock Syndrome

Use of superabsorbent tampons
Postoperative wound infections
Postpartum period
Nasal packing
Cancer
Common bacterial infections
Ethanol abuse
Infection with influenza A virus
Infection with varicella virus
Diabetes mellitus
Human immunodeficiency virus (HIV) infection
Chronic cardiac disease
Chronic pulmonary disease
Nonsteroidal antiinflammatory drug (NSAID) use (may mask symptoms rather than be a risk factor)

Clinical Features

The clinical presentations of streptococcal TSS and staphylococcal TSS are similar. The primary difference is that an identifiable infectious source is virtually always present with streptococcal TSS, and colonization alone may be the source in staphylococcal TSS.

TSS should be considered in patients who present with fever, rash, hypotension, and evidence of end-organ damage, such as respiratory failure or altered mental status. Patients may have a prodromal illness with fever, chills, nausea, vomiting, watery diarrhea, headache, myalgias, and pharyngitis, which can last 2 to 3 days before progression to frank sepsis and organ dysfunction. Other patients may become abruptly symptomatic within hours. Rapid progression is more typical of streptococcal TSS. Patients may complain of pain at a site of infection more often with streptococcal TSS. Risk factors for TSS are listed in Box 118.8.

The fever is usually high and abrupt in onset, although patients may have hypothermia. The classic rash is a nonpruritic, diffuse, blanching, macular erythroderma. It develops in the first few days of the illness and may be faint, evanescent, and mistaken for the flush associated with a fever. It is usually diffuse but may be localized to the trunk, extremities, or perineum. After about a week, fine flaky desquamation occurs on the face, trunk, and extremities, followed by full-thickness peeling of the palms, soles, and fingers. This classic rash progression is much more common in staphylococcal TSS and is present in less than 10% of patients with streptococcal TSS. Patients with streptococcal TSS may have a scarlet fever–like rash, petechiae, or maculopapular lesions. Mucosal involvement may also occur, including conjunctival and scleral hemorrhages, "strawberry tongue," and mucosal ulceration.

Altered mental status such as confusion, somnolence, agitation, and combativeness are present in 55% of patients with streptococcal TSS and in even more patients with staphylococcal TSS. Other findings on physical examination include pharyngeal and conjunctival erythema and peripheral edema. Vaginal mucosal erythema and purulent vaginal discharge may be present in menstrual TSS but are not required make the diagnosis. As multiple organ systems become involved, a wide constellation of signs and symptoms may be seen. Gastrointestinal involvement is manifested by vomiting, diarrhea, and severe abdominal pain. Hepatomegaly may be present. Acute respiratory distress syndrome

(ARDS) develops in more than half of patients and is manifested by rales on pulmonary examination and hypoxia (see Chapter 2). Comparisons between staphylococcal and streptococcal TSS are presented in Table 118.7.

Complications of TSS include shock, gangrene, DIC, and a constellation of neuropsychiatric symptoms. Renal failure occurs in 80% of patients but is irreversible in only 10%. Less common findings in staphylococcal TSS include rhabdomyolysis, seizures, pancreatitis, pericarditis, and cardiomyopathy. Women with the menstrual form of TSS may experience recurrent episodes; recurrences of the nonmenstrual form are rare. Complication rates are higher with streptococcal TSS. Rhabdomyolysis occurs in up to 63% of patients with streptococcal TSS and is usually related to the underlying soft tissue infections.

Differential Diagnoses

The differential diagnosis of TSS includes any septic illness with exanthems. Other diseases to consider include heatstroke, cellulitis, Kawasaki disease, staphylococcal scalded skin syndrome, scarlet fever, drug reactions such as Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), Rocky Mountain spotted fever, clostridial gas gangrene, leptospirosis, meningococcemia, gram-negative sepsis, atypical measles, and viral illnesses.

Kawasaki disease occurs almost exclusively in children, usually does not progress to shock, lacks multisystem involvement, is manifested with a protracted fever, and is associated with thrombocytosis later in its course.[65] Staphylococcal scalded skin syndrome presents with a desquamating rash acutely, whereas the desquamation of TSS occurs in the convalescent phase. Staphylococcal scalded skin syndrome does not progress to shock, is not associated with multisystem illness, and lacks mucous membrane involvement. Scarlet fever differs in its clinical course by lack of shock and multisystem involvement, positive cultures for group A streptococcus, and a rise in the convalescent titer. Stevens-Johnson syndrome usually occurs after drug administration, has characteristic mucous membrane lesions, and lacks desquamation. TEN may be challenging to distinguish from TSS; TEN patients are typically febrile, are in shock, and can progress to multisystem failure. The desquamation of TEN occurs early in the course of the disease, and it usually occurs after administration of a drug.[66] Rocky Mountain spotted fever occurs after a tick bite, has a distinctive rash, and is associated with a severe headache without an altered mental status or hypotension. Leptospirosis occurs in endemic areas and may be distinguished by positive serologic studies and cultures. Petechiae and purpura occurring anywhere on the skin characterize the rash of meningococcemia.

Diagnostic Testing

Diagnosis of TSS does not require a positive culture for *S. aureus,* but isolation of *Streptococcus* organisms is a criterion. The case definitions (see Boxes 118.6 and 118.7) are useful, but they are neither specific nor foolproof. Suspecting the disease is key rather than meeting all CDC criteria for diagnosis.

No specific laboratory changes are associated with TSS, but many abnormalities are common. Leukocytosis or leukopenia with bandemia is common, and myelocytes and metamyelocytes may be seen. Elevated creatinine levels and hemoglobinuria occur in most patients. Renal dysfunction occurs before hypotension in half of the patients. Hypoalbuminemia (85%) and life-threatening hypocalcemia (79%) are prominent initially and persist throughout the disease. Other abnormalities include anemia, thrombocytopenia, prolonged prothrombin and activated partial thromboplastin times, hyper-bilirubinemia, elevated transaminase levels, severe metabolic acidosis, and sterile pyuria. Creatine phosphokinase (CPK) levels may be elevated in patients with necrotizing fasciitis and myonecrosis.[64]

TABLE 118.7 Comparison of Staphylococcal and Streptococcal Toxic Shock Syndrome

Feature	Staphylococcal	Streptococcal
Age	Primarily 15 to 35 years old	Primarily 20 to 50 years old
Sex	Greatest in women	Either
Severe pain	Rare	Common
Hypotension	100%	100%
Erythroderma rash	Very common	Less common
Renal failure	Common	Common
Bacteremia	Low	60%
Tissue necrosis	Rare	Common
Predisposing factors	Tampons, packing, NSAID use?	Cuts, burns, bruises, varicella, NSAID use?
Thrombocytopenia	Common	Common
Mortality rate	<3%	30% to 70%

NSAID, Nonsteroidal antiinflammatory drug.

Blood cultures are positive for bacteria in 60% of cases associated with group A streptococcus but are rarely positive in staphylococcal TSS. Gram stains and cultures from wounds may identify the organism. Culture of the cervix or vagina is positive in 90% of menstrual cases of TSS, even in the absence of local infection.

A CXR may reveal bilateral heterogeneous opacities, consistent with ARDS, or a pulmonary source of the organism. Plain radiographs of any infected skin or soft tissue site typically show only soft tissue swelling but may reveal a retained foreign body or air in the soft tissue. A lack of air in the soft tissue does not rule out a necrotizing soft tissue infection.

An ECG may reveal evidence of ischemia, arrhythmias, and varying degrees of atrioventricular block associated with sepsis. A blood gas analysis may indicate metabolic acidosis secondary to hypotension or hypoxia. A lumbar puncture should be performed in febrile patients with altered mental status to evaluate for meningitis. It is prudent to wait for the results of a coagulation profile before the lumbar puncture is performed because these patients may have DIC at presentation. The CSF is normal in patients with TSS.

Management

Patients with TSS should receive fluid resuscitation with crystalloids due to severe volume depletion and third spacing from capillary leaking. Supplemental oxygen should be administered to treat an Spo_2 less than 95%, and mechanical ventilation with low tidal volumes may be necessary in patients with ARDS. The source of bacteria, such as tampons, nasal packs, and other foreign bodies, should be removed. Prompt surgical consultation should be obtained to débride wounds. If specimens are sent for culture, the laboratory should be informed of the suspected diagnosis. Patients who do not respond to fluid resuscitation require vasopressors, such as norepinephrine, vasopressin, and epinephrine (see Chapter 3).

Antibiotics should be initiated early in the treatment of TSS because the clinical presentation of the disease is similar whether the source is staphylococcal or streptococcal. For septic patients without an identified organism, broad-spectrum antibiotics should be administered. Although the penicillinase-resistant penicillins (nafcillin, oxacillin) have been widely used in TSS treatment, we recommend clindamycin as

a first-line agent. Clindamycin is a potent suppressor of bacterial toxin synthesis; it also facilitates phagocytosis of streptococci by inhibiting M protein synthesis, decreases monocyte synthesis of cytokines, and has a more prolonged post-antibiotic effect than the β-lactams. The dose is 900 mg IV every 8 hours. (The pediatric dose is 20-40 mg/kg/day divided every 6 to 8 hours.)[64] Linezolid in combination with clindamycin may be better than either agent alone based on isolated case reports.

Patients who do not respond to appropriate fluid resuscitation, antibiotics, and vasopressors should be considered for intravenous immune globulin (IVIG) treatment, especially if pulmonary edema develops and mechanical ventilation is required. Pooled immune globulin has high titers for antibodies to TSST-1 and other exotoxins, and significant improvement has been reported with its use in streptococcal TSS. Because the data in staphylococcal TSS are inconclusive, and the mortality is relatively low, immunotherapy should be reserved for life-threatening cases. If used, the recommended dose is 1 to 2 g/kg on day 1 administered intravenously during several hours, followed by 400 to 500 mg/kg/day for up to 5 days.[61]

Hemodialysis or hemoperfusion may be necessary because more than half of streptococcal TSS patients develop renal failure. Both modalities may reduce concentrations of circulating toxins, and a study in Sweden demonstrated the lowest mortality rate ever recorded for strep TSS.[64]

The value of corticosteroids in TSS is unresolved. They are not currently recommended to treat staphylococcal or streptococcal TSS, but should be given to patients thought to have adrenal insufficiency related to underlying disease or chronic steroid use.

Disposition

All patients thought to have TSS should be admitted to an ICU. Prompt surgical consultation should be obtained for patients with a wound source.

CHAPTER 118: QUESTIONS AND ANSWERS

1. An 18-year-old male recent immigrant presents with acute-onset sore throat, fever, and weakness. He has no past medical history. Examination is remarkable for a grayish white exudative coat over both tonsils and the posterior pharynx. There is modest neck swelling with cough, low-grade fever, and hoarseness. Rapid strep testing and monospot results are negative. Which of the following statements regarding this patient's disease is *true?*

a. Antibiotics and corticosteroids are the main therapy.
b. Neuromuscular examination is critical.
c. Rapid treatment will obviate the need for intubation.
d. The electrocardiogram (ECG) is a sensitive indicator of myocarditis.

Answer: B. Diphtheria can be a more benign upper respiratory/nasal infection or a "malignant" process with airway obstruction, myocarditis, and neuropathy (palate is involved first; the only cells spared are cortical). Antibiotics stop further organism growth, but diphtheria equine antitoxin is the key to therapy. Death is usually from myocarditis or airway obstruction, with the highest mortality seen in patients with the "bull neck" appearance. The ECG is an insensitive indicator of myocarditis.

2. An 11-year-old child presents with coughing paroxysms for 10 days. This was preceded by a mild upper respiratory tract infection. The paroxysms occur multiple times per day and have occasionally caused vomiting. The child is relatively well between paroxysms. Vaccination history is unknown. Which of the following statements regarding this patient's disease is *true?*

a. Antibiotics will shorten illness duration.
b. Erythromycin should be given to unimmunized contacts.
c. Fever is expected.
d. Thoracic petechiae should prompt a septic evaluation.

Answer: B. Pertussis, caused by a gram-negative bacterium, is a three-phase illness: catarrhal (upper respiratory tract infection), paroxysmal, and convalescence of weeks to months. The coughing phase is characterized primarily by complications related to the paroxysms, such as subconjunctival hemorrhage, pneumomediastinum, headache, rectal prolapse, chest wall petechiae, and even seizures. Fever is rare unless there is secondary infection. Antibiotics only reduce the carrier state. Corticosteroids may help younger children. Antibiotic prophylaxis is indicated for nonimmunized contacts. Nasal culture is diagnostic. Standard cough suppressants are ineffective.

3. After which of the following circumstances has tetanus been reported?

a. Childbirth
b. Chronic skin ulcers
c. Corneal abrasion
d. All of the above

Answer: D. It has also been reported after dental procedures, abortions, and intestinal operations. In these cases, the source of the bacteria is endogenous because up to 10% of humans harbor *Clostridium tetani* in the colon.

4. Which of the following statements concerning the tetanus neurotoxin (tetanospasmin) is *true?*

a. A shorter incubation period portends a better prognosis.
b. It blocks presynaptic release of gamma-aminobutyric acid (GABA).
c. Sensory nerves are blocked, followed by motor nerves.
d. Synaptic binding is reversible and overcome by acetylcholinesterase therapy.

Answer: B. The toxin migrates in the motor nerve from the injury site to the central nervous system (CNS). Presynaptic release of the

inhibitory neurotransmitter GABA and glycine is diminished. The unopposed excitatory action results in muscle spasm. Presynaptic inhibition of the autonomic nervous system is also lost, and wide heart rate and blood pressure fluctuations are seen. The toxin binding is irreversible and diminishes only with axon synaptic regeneration. A shorter incubation period is a harbinger of a worse outcome.

5. A 62-year-old male farmer with no medical problems presents with leg pain and muscle spasms. He reports moderate to severe pain and muscle spasms in the calf that have occurred and worsened during 3 days. Two weeks prior, he suffered a puncture wound to his ankle just above his boot top with a piece of metal. Examination is remarkable for a heart rate of 115 beats/minute, blood pressure of 170/110 mm Hg, and a healing clean wound above the medial malleolus with no evidence of active infection. The calf is in active spasm with some increased tone in the peroneal musculature also. Which of the following statements regarding this patient's disease is *true?*

a. A radiograph should be obtained to assess for subcutaneous air.
b. Admission for intravenous (IV) antibiotics is indicated.
c. Outpatient management is indicated.
d. Tetanus immune globulin is indicated.

Answer: D. Localized tetanus reflects a local neuromuscular process with pain and spasm. It is likely due to a partial immunity. Immune globulin is indicated. Although mortality is lower, it can progress to generalized tetanus, and admission is warranted.

KEY CONCEPTS

- Recent outbreaks of vaccine-preventable childhood infections have occurred secondary to unvaccinated individuals and travel to areas where disease is still endemic. Emergency clinicians should recognize the possibility of these once rare diseases.
- Herpes simplex encephalitis is fatal if untreated. Clinicians should suspect this diagnosis when evaluating severely ill patients for suspected meningitis or encephalitis and promptly institute empirical therapy with IV acyclovir while awaiting diagnostic results.
- Primary varicella can be dangerous in select populations, including older children, adults, and pregnant patients. These patients require treatment with acyclovir.
- Zoster patients should be treated with acyclovir if they present within 72 hours of symptoms onset or if they are immunocompromised regardless of duration of illness. Disseminated zoster should be treated with IV acyclovir.
- In healthy patients with influenza infection, the duration of illness can be shortened by almost 1 day if antiviral treatment is administered within 48 hours of symptom onset. Hospitalized patients with influenza infection should be treated with antiviral medication regardless of duration of symptoms, because it may decrease mortality and influenza complications.
- Rabies has the highest case fatality rate of any recognized infectious disease.
- Almost 60,000 deaths per year worldwide are caused by dog-mediated human rabies, and this burden falls disproportionately on children and the poor in rural areas.
- Globally, human rabies results from bites by infected dogs. In North America human rabies results predominantly from wildlife exposures (bat, raccoon, and skunks).
- Treatment is rarely effective once symptoms of human rabies occur.
- Rabies postexposure prophylaxis (PEP) given strictly according to the World Health Organization (WHO) or US Centers for Disease Prevention and Control (CDC) guidelines is extremely effective. Discussion with public health officials is recommended to guide decisions regarding when PEP should be considered. The CDC clinician information line is 877-554-4625 or 800-CDC-INFO.
- Many emerging viral infections, including SARS-CoV2 and Ebola, should be considered in febrile patients. It is important to identify patients at risk by determining travel history and exposure history to individuals with confirmed infection. Once a patient is deemed at risk, the patient should be promptly isolated according to established guidelines while further investigation occurs. It is also important to immediately inform the hospital infection control program and public health agencies.

FOUNDATIONS

The vast majority of viral infections, such as the common cold, are minor and self-limiting. However, some are highly pathogenic, contagious, and have the potential to cause devastating illness. In addition to centuries-old infections such as chicken pox, there are also newer infections such as avian influenza, Middle East respiratory syndrome (MERS), enterovirus D68 (EV-D68), as well as SARS-CoV2 (see Chapter 120). With increasing international travel, emergency clinicians should be familiar with emerging infections spreading beyond their endemic origins. In addition to recognizing symptoms and knowing the treatment for these infections, emergency clinicians should be familiar with isolation and reporting practices vital to preventing global pandemics.

Advances in molecular biology have increased our knowledge of these infections, improved our diagnostic ability, and allowed more treatment options. Viruses are classified according to the type and structure of nucleic acid, capsid, and presence or absence of an envelope (Table 119.1). In practice, it is useful to group viruses based on clinical syndromes. This chapter reviews select viral illnesses with high morbidity and mortality, those with specific treatments, and those with major public health consequences. The chapter begins by reviewing several preventable diseases reemerging because of decreasing immunization rates caused by unfounded fears of complications or side effects.

VACCINE-PREVENTABLE INFECTIONS OF CHILDHOOD

Childhood immunization is among the most important public health measures globally. Immunizations save 2 to 3 million children per year from serious illness, disability, and death. However, there has been a troubling trend of people in industrialized nations refusing routine immunizations. These groups advocate for nonmedical exemptions from mandated school-entry vaccines in developed nations, and routine immunizations have been rejected by some over questions of safety and the lack of perceived threat for serious vaccine-preventable diseases.[1] The emergency clinicians may therefore play a significant role in educating parents on the safety and efficacy of childhood immunizations. The United States (US) Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians recommend a specific childhood immunization schedule each year. Table 119.2 summarizes the currently available viral vaccines and recommended schedule.

Mumps

Mumps is an RNA virus that is a member of the *Paramyxoviridae* family. It causes a febrile illness with swelling and tenderness of the parotid gland. Since the advent of the mumps vaccine in 1967, there has been a 99% decrease in mumps in the United States. Despite the vaccine, recent outbreaks in industrialized nations, even in vaccinated individuals, raised concerns about resurgence of mumps.[2]

Mumps is spread via infected respiratory secretions that enter a susceptible respiratory tract. The incubation period is typically 16 to 18

TABLE 119.1 Classification of Viruses

DNA Viruses		
Poxviridae	Variola	Smallpox
	Orf	Contagious pustular dermatitis
Herpesviridae	HSV-1, HSV-2	Mucocutaneous ulcers, herpes encephalitis
	Cytomegalovirus	Pneumonitis in immunocompromised patients
	VZV	Chickenpox, shingles
	HHV-6	Roseola infantum
	EBV	Mononucleosis
	Kaposi sarcoma herpesvirus	Kaposi sarcoma
Adenoviridae	Adenovirus (50+ species)	Upper respiratory tract infections, diarrhea
Papillomaviridae	Papillomavirus (80+ species)	Warts (e.g., plantar, genital)
Polyomaviridae	JC virus	PML
Hepadnaviridae	Hepatitis B	Hepatitis
Parvoviridae	Parvovirus B19	Aplastic anemia
RNA Viruses		
Reoviridae	Colorado tick fever	Fever and rash
	Rotavirus	Gastroenteritis
Togaviridae	Eastern equine encephalitis	Epidemic encephalitis
	Rubella	German measles
Flaviviridae	Yellow fever	Hemorrhagic fever
	Dengue	Dengue hemorrhagic fever
	Zika	Fever, rash, arthralgias
	West Nile virus	West Nile encephalitis
	Hepacivirus, hepatitis C	Chronic hepatitis
Coronaviridae	Coronavirus	Upper respiratory tract infections
	SARS-CoV	SARS
	MERS-CoV	MERS
	SARS-CoV-2	COVID-19
Paramyxoviridae	Respiratory syncytial virus	Bronchiolitis
	Measles	Measles (rubeola), SSPE
	Parainfluenza	Croup
Rhabdoviridae	Rabies	Rabies
Filoviridae	Ebola	Hemorrhagic fever
Orthomyxoviridae	Influenza A, B	Influenza
Bunyaviridae	La Crosse	Encephalitis
	Hanta	Hemorrhagic fevers, ARDS
Arenaviridae	Lassa	Hemorrhagic fever
	Lymphocytic choriomeningitis virus	Meningoencephalitis
Retroviridae	HIV	AIDS
Picornaviridae	Poliovirus	Polio
	Coxsackie B	Myocarditis
	Hepatitis A	Enteric hepatitis
	Rhinovirus (115+ species)	Upper respiratory infections
Caliciviridae	Norwalk virus	Gastroenteritis
Unclassified viruses	Hepatitis E	Enteric hepatitis

AIDS, Acquired immunodeficiency syndrome; *ARDS,* acute respiratory distress syndrome; *COVID-19*, coronavirus disease 2019; *EBV,* Epstein-Barr virus; *HHV,* human herpesvirus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *MERS-CoV*, Middle East respiratory syndrome coronavirus; *PML,* progressive multifocal leukoencephalopathy; *SARS-CoV,* severe acute respiratory syndrome–coronavirus; *SSPE,* subacute sclerosing panencephalitis; *VZV,* varicella-zoster virus.

TABLE 119.2 Viral Vaccines

Virus	Vaccine	Type	Indication	Recommended Schedule
Smallpox	Vaccinia	Live	For persons at risk or for emergency responders	Once, before anticipated risk of exposure
Polio	Oral polio vaccine (Sabin)	Live	During outbreaks Unvaccinated travelers	Inactivated polio vaccine preferred in almost all cases
	Inactivated polio vaccine (Salk)	Inactivated	All children	At 2, 4, 6–18 months, and at 4–6 years
Measles	Measles, mumps, rubella (MMR)	Live	All normal children	At 12–15 months and 4–6 years
Mumps	MMR	Live	All normal children	Same as for measles
Rubella	MMR	Live	All normal children	Same as for measles
Hepatitis A	HAV vaccine	Inactivated	Persons at risk (e.g., travelers, persons living in areas of high prevalence)	Two doses, 6 months apart. Ideally should be given one month prior to travel. Immune globulin should be given if travel is imminent
Hepatitis B	HBV vaccine	Inactivated or recombinant	All children	At birth, 1–2 months, and 6–18 months
			Persons at risk of exposure (e.g., health care workers)	Hepatitis B immune globulin (HBIG) should be given in addition in case of high-risk exposure
Influenza A and B	Influenza vaccine	Inactivated	In 2010, CDC expanded recommendation for annual influenza vaccination to include all persons aged 6 months and older	One dose yearly in the fall or winter
	Intranasal vaccine	Live, cold adapted	As above, for persons 2–49 years of age. Avoid if pregnant, immunosuppressed, young children with asthma, allergic to eggs	As above
Rabies	Human diploid cell vaccine (HDCV)	Inactivated	Postexposure prophylaxis or for preexposure prophylaxis in high-risk individuals	Postexposure: HDCV or PCEC 1.0 mL IM in the deltoid region on days 0, 3, 7, and 14. Rabies immune globulin (RIG) 20 IU/kg should be administered around the wound site, as possible, with the remainder given IM at an anatomically distant site. Preexposure: HDCV or PCEC 1.0 mL IM in the deltoid region on days 0, 7, 21, and 28.
	Purified chick embryo cell (PCEC)	Inactivated	Postexposure prophylaxis or for preexposure prophylaxis in high-risk individuals	As above
Yellow fever	17D virus strain	Live	Persons 9 months to 59 years of age traveling to endemic areas. Contraindicated in children younger than 6 months of age, precaution in age 6–8 months and 60 years or older	Boosters every 10 years
Rotavirus	RV1	Live	All healthy children	2 dose series, at 2 months and 4 months of age
	RV5	Live	All healthy children	3 dose series, at 2, 4, and 6 months of age
Varicella	Varicella	Live	All healthy children	At 12–15 months and 4–6 years
			At-risk adults (those without evidence of immunity and high risk for exposure or transmission)	Persons older than 13 years should receive two doses 4–8 weeks apart
Zoster	Zoster	Live	Anyone 60 years of age and older, contraindicated in severe immunodeficiency	A single one time dose in adults aged 60 years or older

Fig. 119.1 Mumps infection demonstrating parotitis. (Courtesy of CDC website: http://phil.cdc.gov/phil/details.asp?pid=130)

days, ranging from 12 to 25 days. Infected patients are most contagious 1 to 2 days before onset of disease but can be contagious as early as 7 days before symptoms and up to 9 days after symptoms start.

Clinical Features

Parotitis, either unilateral or bilateral, is the hallmark of this infection, occurring in over 95% of symptomatic patients (Fig. 119.1). Other salivary glands are not commonly affected. Symptoms usually begin with fever, malaise, and headache, but about one-third of mumps infections are asymptomatic. Up to 30% of mumps infections cause orchitis, which usually occurs 1 week after the onset of parotitis and is more commonly seen in older patients. Orchitis is usually unilateral but can occur in both testes in up to one-third of the cases. There is a high incidence of cerebrospinal fluid (CSF) pleocytosis in patients with mumps, but less than 10% have symptomatic meningitis, and less than 1% have encephalitis. The mortality from mumps is very low, and the majority of morbidity and mortality associated with mumps occurs in cases complicated by encephalitis.

Differential Diagnosis

During an outbreak, mumps can be easy to diagnose. Other viral infections that can cause parotitis (Epstein-Barr virus [EBV], parainfluenza, influenza A virus, coxsackievirus, adenovirus, parvovirus B19, lymphocytic choriomeningitis virus, and human immunodeficiency virus [HIV]), bacterial infections, facial cellulitis, and tumor are all other diagnoses that should be considered.

Diagnostic Testing

Mumps can be confirmed by detection of viral RNA, via reverse transcription polymerase chain reaction (RT-PCR), detection of the virus itself from clinical specimens, or detection of antibodies (immunoglobulin M [IgM] or a fourfold rise in immunoglobulin G [IgG] between acute and convalescent serum specimen). This entails collecting a buccal or oral swab specimen for virus isolation and blood sample for serologic testing. Collecting samples early improves yield as virus isolation greatly diminishes after the first week of symptoms.

Management and Disposition

The mainstay of treatment is supportive care with antipyretics and analgesics. There is no specific antiviral treatment. Most cases have a benign, self-resolving course and do not require admission to the hospital. In the hospital setting, these patients should have droplet precautions observed. Patients should be isolated for 5 days after the onset of parotid swelling. Individuals with close contact with the infected patient should receive vaccinations if not immunized.

Fig. 119.2 Koplik spots. (Courtesy of CDC website: http://phil.cdc.gov/phil/details.asp?pid=6111.)

Measles (Rubeola)

Measles is an RNA virus thought to be the most contagious infection known to humans. It was a common childhood illness, causing 3 to 4 million cases per year in the United States the 1960s, but the number of cases has dramatically decreased since the advent of the measles vaccine. Despite introduction of the measles vaccine in the 1960s, measles remains common in developing countries, mostly in parts of Africa and Asia. Global health initiatives aimed at eliminating measles focus on reaching and maintaining over 95% coverage with two doses of measles-containing vaccination. Progress has been made toward measles elimination; the World Health Organization (WHO) reported that from 2000 to 2018, the annual measles incidence decreased by 66% and measles-related deaths decreased by 73%.[3]

Measles still occurs in the United States and other developed nations, mostly among unvaccinated or incompletely vaccinated individuals who have exposures to individuals infected from an endemic region. In 2011, France had a measles outbreak with nearly 15,000 cases. A recent outbreak in New York City was linked to an unvaccinated child returning home from Israel with measles with over 600 cases occurring.[4]

Clinical Features

The incubation period for measles is 7 to 21 days. The first symptoms manifest during the prodromal phase, which lasts approximately 3 days. During this phase patients have fever, malaise, and the classically taught three Cs (cough, coryza, and conjunctivitis). Koplik spots, small raised bluish white spots on the buccal mucosa, often opposite the lower first and second molars, or the roof of mouth (Fig. 119.2), are pathognomonic for the diagnosis and can be seen during the prodromal phase. The patient will then develop the typical rash; a nonpruritic maculopapular rash beginning on the head and face and spreading down the entire body over the next 2 to 3 days (Fig. 119.3). Patients are contagious 4 days before and 4 days after the onset of the rash.

Complications of measles include otitis media, laryngitis, tracheobronchitis, bronchiolitis, pneumonitis, severe diarrhea, and acute encephalitis. The virus itself can also cause pneumonia. Bacterial superinfection can also occur. The populations that are at high risk for severe disease or complications include children younger than 5 years old, adults older than 20 years old, pregnant women, and the immunocompromised.

Subacute sclerosing panencephalitis (SSPE) is a rare but fatal complication of measles. SSPE is a slow progressive infection of the central nervous systems (CNS) that results from a prior measles infection. It is

Figure 119.3 Typical rash associated with measles infection. (Kremer JR, Muller CP. Measles in Europe—there is room for improvement. *Lancet*. 2009;373(9661):356-358.)

thought to be due to continual measles infection of the CNS. The mean time of onset of SSPE is 7 years after measles infection. Symptoms include behavior change, decreased intellect, ataxia, and myoclonic seizures followed by progressive neurologic deterioration and death. Since the development of measles vaccine, this disease has almost disappeared in the United States.

Differential Diagnosis

Measles can be mistaken for other acute respiratory viral illnesses with rash or even noninfectious illnesses that present with fever and rash. Other diagnoses to consider include rubella, roseola, dengue, Kawasaki disease, and drug rash. Measles should be considered in patients that have traveled to endemic regions and return with fever and rash.

Diagnostic Testing

The diagnosis was usually made clinically by visualizing both Koplik spots and the characteristic rash along with cough, coryza, and conjunctivitis. However, the disease is not common in the developed world, and it may be mistaken for other illnesses. Clinicians suspecting a diagnosis of measles should contact local health departments. They can help instruct practitioners to obtain the necessary samples for diagnosis and surveillance. The most common methods of confirmation are serologic testing for measles-specific IgM antibody and detection of measles RNA from a nasopharyngeal specimen, blood, or urine by RT-PCR.

Management

The mainstay of treatment is supportive care. Bacterial superinfection should be treated appropriately. Postexposure prophylaxis is important in individuals who do not have evidence of measles immunity and have a measles exposure, because it can provide protection or lessen the severity of disease. Postexposure prophylaxis consists of either the measles, mumps, and rubella (MMR) vaccine within 72 hours, or immunoglobulin within 6 days. Healthy infants should receive 0.25 mL/kg of immunoglobulin intramuscularly, and immunocompromised children should be given 0.5 mL/kg intramuscularly, up to 15 mL. Children and malnourished patients who are hospitalized with severe measles may benefit from vitamin A.

Disposition

Patients with measles require admission to the hospital based on the severity of illness. Uncomplicated measles patients should be treated at home to prevent spread of the disease. It is important, however, to observe appropriate isolation precautions in the hospital setting. All suspected cases of measles should be evaluated with airborne isolation precautions in place. Infected individuals should have airborne isolation for 4 days after they develop the rash, and those who are immunocompromised should remain on airborne precautions until complete recovery.

Rubella (German Measles)

Rubella is a single-stranded RNA virus that is a member of the *Togaviridae* family. Since the wide-scale implementation of the vaccine, cases have dropped by greater than 99%. As a result, rubella is no longer endemic in the United States. The virus is spread via contact with respiratory droplets. In pregnant patients, the virus spreads to the placenta with subsequent infection of fetal organs.

Clinical Features

Acquired rubella is a mild febrile illness associated with a diffuse maculopapular rash, malaise, headache, and arthritis. Encephalitis and thrombocytopenia are rare complications. Rubella is generally a mild disease, but consequences in pregnant patients can be devastating. It can cause miscarriage, intrauterine death, premature delivery, or congenital rubella syndrome. Congenital rubella syndrome is characterized by severe birth defects, including hearing impairment, cataracts, retinopathy, developmental delay, microcephaly, and a variety of congenital heart defects.

Differential Diagnosis

The diagnosis of rubella on a clinical basis can be difficult because of the overlap with many other illnesses. Diseases that share common features include measles, roseola, erythema infectiosum (fifth disease), toxoplasmosis, and scarlet fever.

Diagnostic Testing

The diagnosis of rubella can be made by virus detection or serologic testing. The most common method is detection of IgM antibodies or fourfold increase in IgG antibody titer between acute and convalescent specimen. Virus culture and RT-PCR can also be isolated from blood or the nasopharynx.

Management and Disposition

There is no specific antiviral treatment for rubella. The management centers on symptom control with antipyretics and analgesics. The course of this disease is short and benign. These patients can generally be treated at home but should be educated about the risks to pregnant women.

VIRAL INFECTIONS WITH VESICULAR RASH

Herpes Simplex

Herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) are double-stranded DNA viruses of the *Herpesviridae* family. Herpes simplex infections primarily involve the skin or mucosal

Fig. 119.4 Herpes labialis. (Courtesy of CDC website: http://phil.cdc.gov/phil/details.asp?pid=1573.)

surfaces with occasional severe involvement of organs. Herpes simplex virus (HSV) infections range in acuity from asymptomatic to life-threatening. HSV-1 typically causes orofacial infections but can affect liver, lung, eye, genitalia, and the CNS. HSV-2 typically causes genital herpes but can also affect the other systems as well. HSV infections are common; the seroprevalence of HSV-1 has been reported to be 57.7% in persons aged 14 to 49 years old in the United States, and the seroprevalence of HSV-2 has been reported to be 17.0% in the same population.

Initial HSV-1 infection usually occurs in childhood. HSV gains entry via breaks in the skin or mucosal surfaces. Viral replication is then initiated in epidermal and dermal cells. The infection then spreads to the nervous system, where it lays latent in the sensory nerve ganglia. Any stressor such as acute illness, emotional stress, trauma, intense sunlight, or fever can trigger reactivation of the virus. Recurrence rates are high for herpes infections. HSV-2 infections usually are acquired in adolescence or adulthood through sexual contact. Neonatal HSV-2 infections occur during childbirth via contact with the infected mother's birth canal.

Clinical Features

Oral Infection. The first episode of HSV-1 infections usually occurs early in life and manifests as a gingivostomatitis and pharyngitis. Symptoms include fever, malaise, and vesicular lesions anywhere in the mouth or oropharynx. Infections typically last between 10 to 14 days. Reactivation is usually much less severe and occurs as herpes labialis, small vesicles at the vermilion border of the lip (Fig. 119.4). These vesicles usually crust over within 48 hours.

Genital Herpes. This infection is characterized by painful vesicles and ulcers on the external genitalia. The first infection is usually the most severe and can be accompanied by systemic symptoms like fever, headache, malaise, and myalgias. It is also common to have dysuria and tender inguinal lymphadenopathy. Infections can also spread to the perianal and rectal region as well.

Central Nervous System Infection. HSV-1 is a common cause of infectious encephalitis; it causes necrotizing hemorrhagic encephalitis, typically involving the temporal lobes. Herpes simplex encephalitis is characterized by acute onset of symptoms, including fever, headache, altered mental status, seizures, and focal neurologic deficits resulting from frontal and temporal lobe necrosis. If left untreated, mortality is greater than 70%. HSV-2 can cause meningitis in over 25% of patients with primary infection, more commonly in women. In contrast to HSV encephalitis, HSV meningitis has a benign course. Neonatal HSV encephalitis is caused by HSV-2 acquired during vaginal delivery of an infected mother.

Other Infections. Herpes can cause a variety of cutaneous manifestations. They typically present with the classic painful grouped vesicles on an erythematous base on the affected area. Herpetic whitlow refers to these vesicles occurring on the finger. Herpes gladiatorum is a skin infection that can arise anywhere on the body and is associated with contact sports. Herpes can also cause ocular infections, including keratitis, conjunctivitis, and acute retinal necrosis. Immunocompromised patients are at risk for rare infections like HSV pneumonitis, esophagitis, or hepatitis.

Differential Diagnosis

When suspecting orofacial HSV infection, considerations include other diseases with vesicles and ulcers, such as aphthous ulcers, coxsackievirus infections (herpangina and hand-foot-and-mouth disease), infectious mononucleosis, Stevens-Johnson syndrome, or Behçet disease. The differential diagnosis for genital herpes infection should include other sexually transmitted infections with ulcers and vesicles, such as syphilis or chancroid or noninfectious diseases like Behçet disease. HSV encephalitis can be difficult to distinguish from other acute CNS emergencies like bacterial meningitis, brain abscess, other viral encephalitides, brain tumor, or stroke.

Diagnostic Testing

Frequently, clinicians diagnose oral or genital HSV infections clinically, given the classic appearance of the vesicles and ulcers. However, because of the risk of transmission and the impact of this diagnosis on a patient, testing should be performed if possible. Definitive diagnosis can be made by viral culture, direct fluorescent antibody (DFA), or polymerase chain reaction (PCR) from vesicles, ulcers, or mucocutaneous sites. PCR is more sensitive than viral culture. Tzanck smear has a low sensitivity and specificity and is mainly of historical interest. Serology can differentiate between acute infection and reactivation.

The diagnosis of HSV encephalitis is made by PCR from the CSF. The routine laboratory tests sent after a lumbar puncture (LP) to assess for bacterial meningitis do not adequately assess for HSV encephalitis. Classically, CSF analysis shows an elevated white blood cell (WBC) count, with lymphocyte predominance. Depending on the degree of brain necrosis, an elevated red blood cell (RBC) count can also be seen. Although it is rare, CSF results can be normal in HSV encephalitis, particularly in immunocompromised individuals.[5] This underscores the importance of waiting for PCR results before considering discontinuation of treatment in suspected cases of HSV encephalitis. In cases of negative CSF PCR with a high suspicion of HSV encephalitis, especially those with who present early in their illness, we recommend continuing empirical treatment and resending CSF PCR in 72 hours. Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) can be highly suggestive of HSV encephalitis, but imaging can be negative early in the course of illness (Fig. 119.5).

Management

Antiviral agents are the mainstay of treatment. The treatment dose and duration for herpes simplex depends on the clinical syndrome that is present. Acyclovir, valacyclovir, and famciclovir are the commonly used antiviral drugs with activity against HSV. These drugs are nucleoside analogues that work by inhibiting viral DNA synthesis. Acyclovir is the only agent that is available in an intravenous (IV) formulation.

Herpes gingivostomatitis or labialis: First episodes are treated with oral acyclovir 200 mg five times a day (alternative regimen: 400 mg three times a day), valacyclovir 1 g twice daily, or famciclovir 250 mg three times a day for 7 days. Recurrent infections are treated with

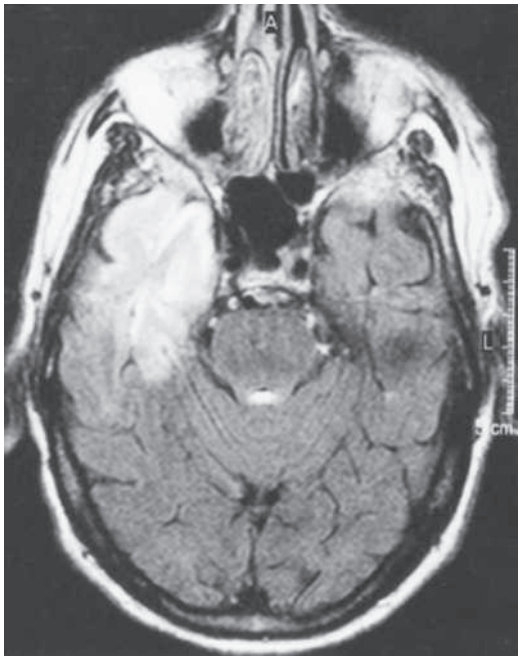

Fig. 119.5 T-2 weighted MRI with gadolinium demonstrating temporal lobe enhancement secondary to HSV-1 encephalitis. (Martin K, Franco-Paredes C. Herpes encephalitis. *Lancet*. 2002;360(9342):1286.)

acyclovir 400 mg five times a day for 5 days, valacyclovir 2 g twice daily for 1 day, or famciclovir 1500 mg as a single dose.

Genital herpes: First episodes are treated with oral acyclovir 200 mg five times a day (alternative regimen: 400 mg three times a day), valacyclovir 1 g twice daily, or famciclovir 250 mg three times a day for 7 to 10 days. A shorter course is usually adequate for treatment of recurrence. For suppression of recurrent episodes, acyclovir 400 to 800 mg twice daily or valacyclovir 500 mg daily can be used.

Herpetic whitlow and other mucocutaneous manifestations: Administer acyclovir 200 mg five times a day or 400 mg three times a day for 5 days.

Herpes keratitis: Administer acyclovir 400 mg five times a day or valacyclovir 500 mg three times a day. Topical antiviral therapy with trifluridine, acyclovir, or ganciclovir are all equally effective.[6]

HSV encephalitis: Administer IV acyclovir 10 mg/kg every 8 hours for 14 to 21 days. Given the high mortality associated with this condition, antiviral therapy should be started as soon as the diagnosis is suspected.

Disposition

The majority of herpes infections can be treated with oral antiviral therapy on an outpatient basis. Patients who are immunocompromised and have severe mucocutaneous disease or disseminated disease benefit from inpatient admission with IV acyclovir treatment. All patients with suspected encephalitis should be admitted for empirical treatment and diagnostic testing. Intensive care unit (ICU) admission may be necessary depending on the severity of neurologic symptoms. For HSV encephalitis patients, we recommend early involvement of infectious disease consultants to help guide treatment and neurology for management of cerebral edema and severe neurologic symptoms.

Varicella-Zoster Virus

The varicella-zoster virus (VZV) is another double-stranded DNA virus that is a member of the *Herpesviridae* family. VZV causes two common infections: varicella (chicken pox) and zoster (shingles). Transmission occurs via the respiratory tract through respiratory droplets and also by direct contact with virus present in the fluid-filled vesicles. VZV initially infects the nasopharynx and spreads to the lymphoid tissue. The virus is present in vesicles that develop on the skin and then infects the nerve endings in the skin and migrates to the dorsal ganglia where it lays latent.

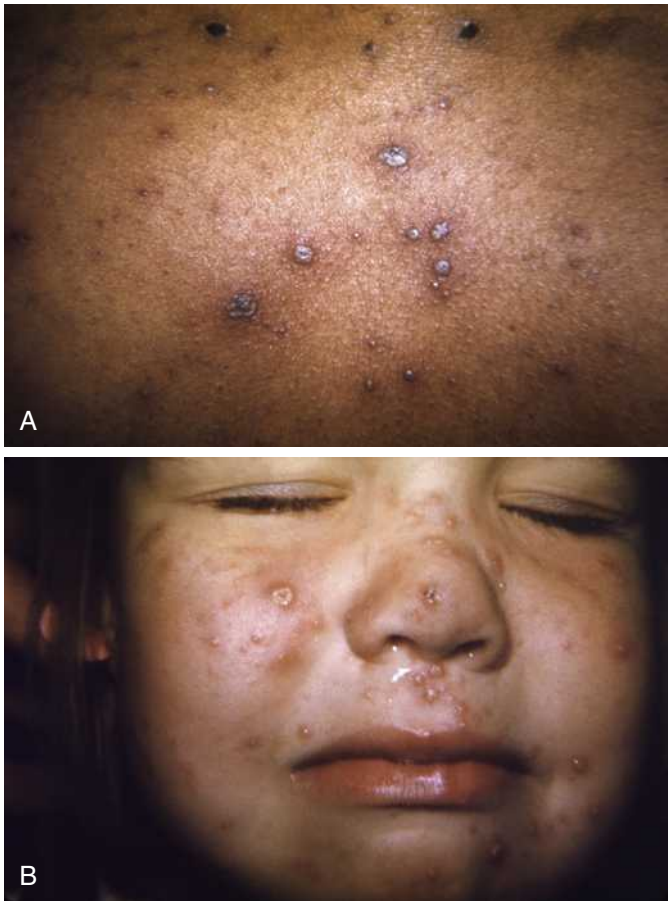

Fig. 119.6 (A and B) Varicella infection demonstrating the typical rash with lesions in different stages of healing. (Courtesy of CDC website: http://phil.cdc.gov/phil/details.asp?pid=10484 http://phil.cdc.gov/phil/details.asp?pid=10486.)

Primary infection of VZV occurs as varicella (chicken pox). Varicella is highly contagious and historically occurred year round with a predilection for winter and spring months. Prior to the development of the varicella vaccine in 1995, most people would develop this infection in childhood. After widespread uptake of the vaccine, the incidence of varicella has decreased by 90%, with a subsequent decline in mortality. Zoster (shingles) is a result of reactivation of the latent virus. Risk factors for developing shingles include older age and immunosuppression.

Clinical Features

Varicella. Chicken pox is a febrile illness characterized by malaise and rash. The rash begins first on the scalp and face and then spreads to the trunk and extremities. The lesions start as maculopapular, and progress to fluid-filled vesicles that eventually crust over and form scabs (Fig. 119.6). The lesions occur as crops at various stages of development. Patients are contagious until all lesions are scabbed over, which can typically take 1 to 2 weeks.

This disease typically has a benign course, although adults have a more severe course than children. The most common complication is a secondary bacterial infection of the skin lesions. VZV has been

Fig. 119.7 Herpes zoster infection.

associated with invasive group A streptococcal infections and necrotizing fasciitis.[7] Immunocompromised patients are at risk for disseminated disease and visceral organ involvement. Pregnant patients are also at risk for severe disease. Varicella pneumonia accounts for most of the morbidity related to this disease. Neurologic complications are rare but can include encephalitis, aseptic meningitis, transverse myelitis, and Reye syndrome. Although exceedingly rare, it is important to recognize the association of aspirin use with Reye syndrome, a progressive encephalopathy with acute liver injury. Thus aspirin and other salicylates should be avoided in varicella treatment, especially in children.

Zoster. Herpes zoster typically causes a vesicular rash with an erythematous base that occurs unilaterally in a single dermatome (Fig. 119.7). The rash is often painful and preceded by paresthesias or hypesthesia. In immunocompetent individuals, the rash crusts in 7 to 10 days, and at that time patients are no longer contagious. Postherpetic neuralgia, defined as pain that persists for more than 90 days, is the feared complication. Risk factors for post-herpetic neuralgia include older age and severity of pain at onset.[8]

Herpes zoster ophthalmicus is viral reactivation within the trigeminal nerve ganglion. Ocular involvement occurs in over 50% of these cases. The Hutchinson sign, a vesicle on the tip of the nose, is associated with ocular involvement. Herpes zoster oticus (Ramsay Hunt syndrome) is characterized by facial nerve palsy, pain, and vesicular rash on the ear and in the auditory canal. Disseminated zoster involving multiple dermatomes can occur in immunocompromised patients.

Differential Diagnosis

Classic varicella is distinctive, but the other major diagnoses to consider are other febrile illnesses with rashes like disseminated HSV infection, coxsackievirus infection, measles, or rickettsialpox. Prior to eradication, smallpox was a consideration, presenting with lesions in the same stage of development. The rash of zoster is also usually very characteristic. Other diagnoses to consider include herpes simplex infection or contact dermatitis.

Diagnostic Testing

The majority of chickenpox and shingles diagnosis is made clinically. Confirmatory diagnosis can be made through viral culture, DFA, or PCR testing of the vesicle fluid.

Management

Varicella. The management is mainly supportive care with antipyretics and antihistamines to decrease the pruritus caused by the skin lesions. Salicylates should be avoided in children because of the association with Reye syndrome. Antiviral therapy with acyclovir has been shown to decrease the duration of fever and total number of lesions in healthy children. It does not reduce the number of varicella-related complications, however. Therefore, we typically do not recommend treatment of otherwise healthy children with varicella. We recommend treating high-risk groups with acyclovir, including those older than 12 years old, pregnant patients, persons with chronic cutaneous or pulmonary disorders, persons on long-term salicylate therapy, persons on aerosolized corticosteroids, and immunocompromised patients. The treatment should be initiated within 24 hours after the rash appears for the most benefit. The dose of acyclovir for VZV treatment is higher than that of HSV, 800 mg orally four times a day for 5 days. If the patient is immunocompromised and has severe disease, IV acyclovir should be administered.

Zoster. The goals of treatment for zoster are to treat the viral infection and control the pain that occurs with the rash. Uncomplicated zoster in the immunocompetent host can be treated with the following regimens for 1 week: acyclovir 800 mg five times a day, famciclovir 500 mg three times a day, or valacyclovir 1 g three times a day. Antiviral treatment should be initiated within 72 hours of the onset of rash because the efficacy beyond 72 hours is unclear. Immunocompromised patients should be treated regardless of time of onset of rash. Zoster involving more than one dermatome or disseminated zoster should be treated with IV acyclovir. The disease is often painful enough to require opioid agents. Currently, there are no treatments that have reliably shown a reduction in the occurrence of post-herpetic neuralgia. Antiviral treatment has shown mixed results and is likely not useful in preventing post-herpetic neuralgia.[9] Corticosteroids have been studied extensively, but a recent review did not support their use in preventing post-herpetic neuralgia.[10]

Disposition

Most patients with varicella and zoster can be treated at home. Patients with varicella are highly contagious and should be instructed to avoid people who have not been fully vaccinated or never had the disease, immunocompromised persons, or pregnant individuals until all of their lesions have crusted over. Immunocompromised patients, patients with disseminated zoster, or patients with complications require admission to the hospital.

In general, patients with varicella should be under contact and airborne precautions until all of the lesions have crusted over. An immunocompetent localized zoster patient only requires standard precautions, whereas an immunocompromised or disseminated zoster patient is treated like a patient with varicella, requiring contact and airborne precautions.

VIRAL INFECTIONS CAUSING NONSPECIFIC FEBRILE ILLNESS

Epstein-Barr Virus

EBV is a member of the *Herpesviridae* family. It is classically known for causing infectious mononucleosis. It is also associated with several types of cancer, including Burkitt lymphoma, nasopharyngeal carcinoma, Hodgkin disease, and B cell lymphoma. EBV is ubiquitous, with most individuals testing positive for antibodies by adulthood. One British study demonstrated that 70% of 0- to 5-year-olds had antibodies to EBV, whereas 95% of 20- to 25-year-olds tested positive.[11] EBV is spread via salivary secretions. The virus infects the oropharynx and then spreads through the bloodstream and infects B lymphocytes resulting in proliferation of infected B lymphocytes and T lymphocytes, leading to enlargement of lymphoid tissue.

Clinical Features

EBV infection in young children is usually asymptomatic or presents as mild pharyngitis. Adolescents and young adults tend to have the classic infectious mononucleosis (fever, exudative pharyngitis, lymphadenopathy, myalgias, and fatigue). Splenomegaly is common, seen in up to 50% of cases. Hepatomegaly and jaundice occur less than 10% of the time. The symptom duration is typically 1 to 3 weeks, with some cases having malaise and fatigue for several months. Splenic rupture is rare, occurring in less than 0.5% of patients. It should be suspected in patients with left upper quadrant pain and is more common during the first 3 weeks of illness. Airway obstruction occurs in less than 5% of children with mononucleosis and is one of the common causes of hospital admission. Rare neurologic complications include encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, retrobulbar neuritis, and peripheral neuropathies. Patients treated with amoxicillin or ampicillin for presumed streptococcal pharyngitis may develop a nonallergic maculopapular rash.

Differential Diagnosis

EBV causes 90% of infectious mononucleosis; the remaining 10% is caused by cytomegalovirus (CMV). Acute HIV infection, streptococcal pharyngitis, toxoplasmosis, and other viral pharyngitis causes should be considered in potential mononucleosis patients.

Diagnostic Testing

It is difficult to diagnose mononucleosis based on history and physical examination alone. Laboratory data can help confirm the diagnosis. Historically, the heterophile antibody test (monospot) has been the test of confirmation for primary EBV infection. The test has a sensitivity ranging from 63% to 84% and specificity ranging from 84% to 100%. The test is often not positive in younger children. The WBC count typically demonstrates lymphocyte predominance with many atypical lymphocytes. A lymphocyte count less than 4×10^9/L in adults is highly predictive of a negative monospot test. Health care providers can test for antibodies to EBV viral capsid and nuclear antigen if other testing is equivocal.

Management

Infectious mononucleosis typically has a self-limiting course. The treatment is supportive care with rest, antipyretics, and analgesia. Glucocorticoids have been used to decrease severity of symptoms, but there is insufficient evidence to support this practice. Antiviral treatment with acyclovir does not reduce the clinical symptoms of the disease. It is important to advise patients to avoid contact sports for at least 3 weeks to avoid the feared complication of splenic rupture. Abdominal ultrasound for assessment of spleen size may have a role in determining when it is safe to return to sports.[12]

Disposition

The majority of patients can be treated at home. Admission is necessary for airway obstruction and in patients with significant complications, such as splenic rupture.

Cytomegalovirus

CMV is a double-stranded DNA virus that belongs to the *Herpesviridae* family. Depending on geographic location, the seroprevalence ranges from 66% to 90%.[13] The spectrum of illness caused by CMV ranges from asymptomatic to severe disseminated disease in the immunocompromised patient. CMV is particularly harmful in pregnant patients because it can lead to congenital infection, causing profound neurologic defects and permanent hearing loss. CMV is present in breast milk, saliva, feces, urine, semen, cervical secretions, and blood. The virus spreads via prolonged exposure to these body fluids. After primary infection, CMV establishes a lifelong latent infection.

Clinical Features

The primary CMV infection is subclinical in most individuals. Some immunocompetent adults develop a mononucleosis-like syndrome. The illness can last from 2 to 6 weeks and is characterized by fever, fatigue, malaise, myalgia, and headache. Unlike EBV mononucleosis, exudative pharyngitis and lymphadenopathy are less common. Although it is rare, CMV can cause severe disease in the immunocompetent individual. CMV colitis and CNS infection (meningitis, encephalitis, transverse myelitis) are the most frequent forms of severe CMV infection in the immunocompetent host. Up to one-third of critically ill immunocompetent patients have evidence of CMV reactivation.

The majority of newborns who are infected with congenital CMV appear healthy or normal at birth. Common problems caused by congenital CMV infection include premature birth, intrauterine growth retardation, microcephaly, seizures, thrombocytopenia, hepatosplenomegaly, or pneumonitis. Sequelae of congenital CMV infection can present up to 2 years after birth. Frequent complications that occur are hearing loss, neurologic impairment, and ocular disturbances.

CMV can cause life-threatening disease in immunocompromised patients. CMV infection occurs in over 40% of solid organ transplant patients during the first 3 months when immunosuppressive therapy is the strongest. Transplant patients that are CMV seronegative and receive a CMV seropositive donor are at highest risk. HIV patients with CD4 count less than 100/μL are at high risk of CMV infection as well. In the immunocompromised host, CMV manifests initially as fever, malaise, and myalgias. The infection can then progress to cause leukopenia, pneumonia, esophagitis/gastritis, hepatitis, colitis, encephalitis, polyradiculopathy, and retinitis. CMV retinitis is the most common cause of blindness in patients with AIDS.

Differential Diagnosis

It is difficult to make the diagnosis of CMV infection solely on a clinical basis. Infectious mononucleosis caused by EBV presents very similarly. In the perinatal phase, infants with apparent infections should be evaluated for the other common congenital infections: toxoplasmosis, rubella, herpes simplex, syphilis, VZV, and parvovirus B19. Because the CMV infection can cause a wide array of disease in the immunocompromised host, the differential diagnosis should be broad and include other viral pathogens, bacterial infections, *Pneumocystis* infection, and fungal infections.

Diagnostic Testing

Making the diagnosis of CMV is unlikely in the ED. Confirmation of this diagnosis centers on either virus isolation, serologic testing, or histopathology. Common methods involve PCR, viral culture, or antibody testing. The WBC count may show lymphocyte predominance with more than 10% atypical lymphocytes, much like EBV infections.

Management

For the most part, CMV infection in the immunocompetent host only requires symptomatic care for the mononucleosis-like syndrome. The treatment recommendations for critically ill immunocompetent patients with CMV infection are less clear.[14] Immunocompromised patients with CMV infection are treated more aggressively. Antiviral treatment is necessary in sight and life-threatening infections.

Ganciclovir is an IV agent that is used to treat CMV infections. The treatment for CMV retinitis is induction therapy: 5 mg/kg/dose every 12 hours for 14 to 21 days followed by 5 mg/kg/dose once daily maintenance therapy for a prolonged course. Fever, diarrhea, and thrombocytopenia

are common adverse reactions. Valganciclovir is an oral prodrug that is metabolized to ganciclovir. The treatment regimen is induction: 900 mg twice daily for 21 days followed by maintenance of 900 mg once daily. Foscarnet and cidofovir are IV agents used to treat CMV resistant to ganciclovir, and both can also be used to treat HSV resistant to acyclovir. The primary limiting toxicity of these drugs is renal toxicity.

Disposition

Most immunocompetent patients with CMV infection can be managed at home. In contrast, immunocompromised patients with CMV infection will usually require admission to the hospital, and depending on the extent of end-organ damage, may require ICU admission.

Enteroviruses

Enteroviruses are a group of single-stranded RNA viruses that can multiply within the gastrointestinal tract. Most infections are asymptomatic or mild undifferentiated illnesses. Despite their name, their major manifestation is not gastroenteritis. There are many enteroviruses; common ones include poliovirus, coxsackievirus A and B, echovirus, and enterovirus. These viruses are found globally and are transmitted via the fecal-oral route. Vaccination exists for poliovirus; in the United States and other industrialized nations, the disease has been declared eradicated.

Clinical Features

Most of the infections caused by enteroviruses are asymptomatic or self-limiting febrile illnesses. More of the severe infections are discussed in the following sections.

Poliovirus. The poliovirus causes a nonspecific febrile illness with malaise, myalgias, headache, and sore throat. The most feared presentation of the poliovirus infection is paralytic poliomyelitis. This manifests as aseptic meningitis followed by back, neck, and muscle pain and then the development of motor weakness. The paralysis is usually asymmetrical and affects proximal muscles more. Usually some recovery of motor function occurs months later, but approximately two-thirds of patients have some form of permanent weakness.

Non-Polio Enteroviruses. Most enterovirus infections are subclinical, but they can also cause a variety of symptoms and syndromes. Enteroviruses account for most causes of viral meningitis and encephalitis. Enteroviruses commonly cause pericarditis and myocarditis, particularly coxsackievirus B. Symptoms usually include chest pain, fever, dyspnea, and can progress to severe heart failure. Enteroviruses are a common cause of viral exanthems as well. Herpangina is caused by coxsackievirus A and presents with fever, sore throat, odynophagia, and vesiculopapular lesions on the cheeks and soft palate (Fig. 119.8). Hand-foot-and-mouth disease is caused by coxsackievirus A or enterovirus 71 and commonly manifests as fever and malaise, followed by vesicles in the mouth, and vesicles on the hands and feet (Fig. 119.9). Pleurodynia is a painful illness characterized by fever and spasms of the chest wall and abdomen that occur in paroxysms.

In 2014, there was an outbreak across the United States of EV-D68.[15] The virus affected mostly children and was severe in children with asthma. Typically EV-D68 causes mild respiratory illness, rhinorrhea, sneezing, cough, and myalgias but occasionally causes severe disease with wheezing and respiratory distress. There has also been an association with flaccid paralysis with anterior myelitis with EV-D68 infection.[16]

Differential Diagnosis

Clinicians should consider other diagnoses depending on the specific symptoms and syndrome caused by enterovirus infection. For the

Fig. 119.8 Herpangina. (Originally from: Cohen J, Powderly WG. *Infectious Diseases*, ed 2. St. Louis: Mosby; 2004. Also found in: Bennett, JE. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, ed 8. Philadelphia: Elsevier; 2015.)

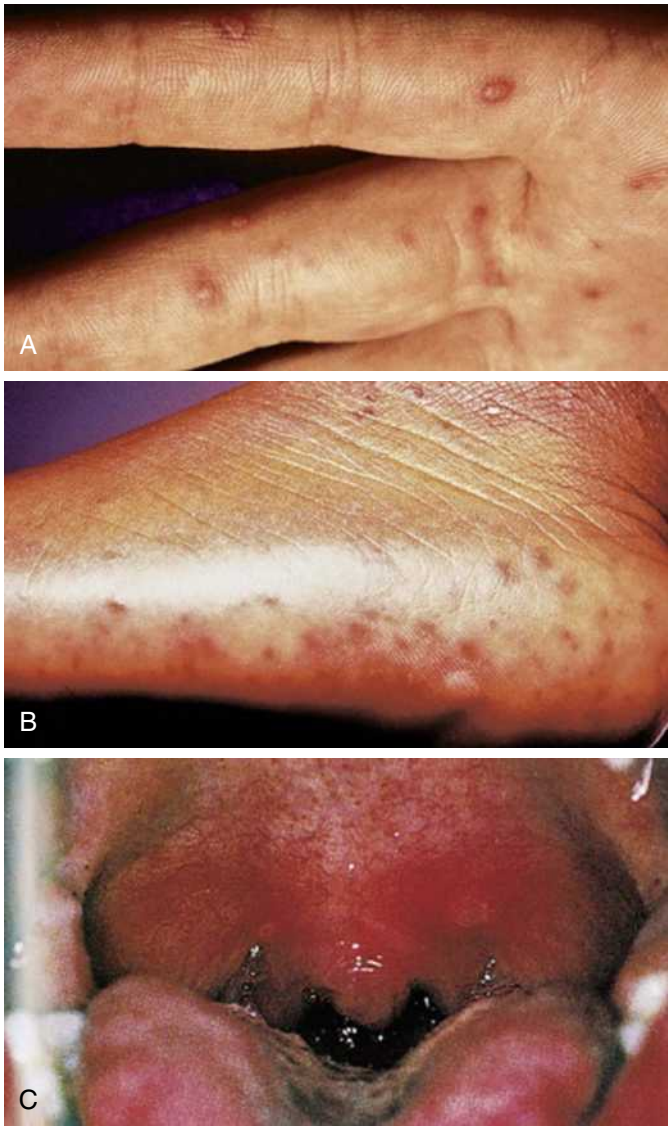

Fig. 119.9 Hand-foot-and-mouth disease. (From: Cohen BA. *Pediatric Dermatology*, ed 4. Philadelphia: Elsevier; 2013: 110.)

diseases with skin and oropharyngeal lesions, herpes simplex, aphthous stomatitis, mononucleosis, and bacterial pharyngitis should be considered. The diseases with primary neurologic manifestation present similarly to bacterial meningitis and other causes of viral meningitis or encephalitis, including herpes simplex encephalitis. Myopericarditis can present similar to pulmonary embolism, myocardial infarction, or pneumonia (see Chapter 68).

Diagnostic Testing

Diagnosis is confirmed by viral culture, serology, or PCR. Samples can be sent from nasopharynx or oropharynx via swabs or washings, CSF, serum, stool, or pericardial fluid. Other diagnostic testing should be tailored toward the symptoms, such as ECG, chest x-ray, and cardiac biomarkers for evaluation of myopericarditis. Lumbar puncture should be performed for meningitis or encephalitis evaluation.

Management

The treatment is primarily symptomatic, because currently, there are no recommended specific antiviral therapies for enteroviruses. Hand-foot-and-mouth disease can cause severe dehydration, because children refuse to eat secondary to the painful lesions in the mouth. This illness is typically treated with analgesia and encouragement of oral intake. Topical analgesia with diphenhydramine, aluminum hydroxide, and magnesium hydroxide can be used. Viscous lidocaine and topical benzocaine should be avoided in young children because of the risk of systemic toxicity and questionable efficacy. If there is concern for meningitis, empirical therapy for bacterial meningitis and herpes simplex encephalitis should be instituted while awaiting culture and PCR results because both of the aforementioned diseases have significantly higher morbidity and mortality with delayed treatment.

Disposition

The majority of enteroviruses cause a benign disease, and patients can be treated at home and expect no sequelae. Depending on the severity of symptoms, some patients may require hospitalization for dehydration, severe respiratory illness, or neurologic infection. Viral myocarditis can cause severe heart failure and dysrhythmias requiring hospitalization and ICU care. The outcome after viral myocarditis can be variable and range from return of normal heart function to severe cardiomyopathy requiring heart transplantation (see Chapters 66 and 67).

VIRUSES ASSOCIATED WITH RESPIRATORY INFECTIONS

Influenza

Influenza is an RNA virus from the *Orthomyxoviridae* family that causes acute respiratory symptoms. This virus is highly contagious and is transmitted through large-particle respiratory droplets. Transmission usually requires close contact between individuals less than 1 meter apart. Epidemics and outbreaks occur almost annually, with the peak influenza activity usually occurring in the winter months in the United States. Influenza occasionally causes devastating pandemics. During the 1918 influenza pandemic, approximately 50 to 100 million people were killed across the globe. The most recent pandemic occurred in 2009, when a new strain of H1N1 influenza emerged, killing over 284,000 globally.

There are three major types of influenza: A, B, and C. The majority of human infections are caused by influenza A and B. Influenza can be further subdivided based on the two major surface glycoproteins present, hemagglutinin (H) and neuraminidase (N). Influenza A is responsible for most of the severe epidemics and pandemics because of its ability of surface antigens to undergo periodic changes. This is known as *antigenic drift* when the changes are minor and *antigenic shift* when the changes are major.

BOX 119.1 Conditions that Increase Risk for Severe Influenza and Influenza-Related Complications

- Age less than 2 years
- Age 65 years and older
- Chronic pulmonary disorders, including asthma
- Chronic cardiovascular disorders except hypertension alone
- Chronic renal insufficiency
- Chronic hepatic disorders
- Chronic hematological conditions including sickle cell disease
- Metabolic and endocrine disorders including diabetes mellitus
- Neurologic disorders including disorders of the brain, spinal cord, peripheral nerve, and muscle, such as cerebral palsy, seizure disorders, stroke, intellectual disability (mental retardation), moderate to severe developmental delay, muscular dystrophy, or spinal cord injury
- Immunosuppression, including that caused by medications or by HIV infection
- Pregnancy or postpartum state (within 2 weeks after delivery)
- Ethnicity belonging to American Indians/Alaska Natives
- Morbid obesity (i.e., body mass index is equal to or greater than 40)
- Residency in nursing homes and other chronic care facilities

Adapted from Grohskopf LA, Sokolow LZ, Broder KR, et al. Prevention and control of seasonal influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices—United States, 2017–18 influenza season. *MMWR Recomm Rep* 2017;66:1–20.

Clinical Features

Influenza typically presents as fever with constitutional (headache, malaise, and myalgias) and respiratory symptoms (cough, sore throat, rhinitis). These symptoms typically last for 3 to 7 days. Individuals are usually contagious 1 day prior to symptom onset and up to 1 week after. The majority of influenza is a benign self-limited disease, but some patients are at risk for severe influenza and influenza-related complications (Box 119.1). The common influenza-related complications are bacterial pneumonia (typically due to *Staphylococcus aureus*), sinusitis, and otitis media. Influenza can also assert its pathogenic effects by exacerbating underlying cardiopulmonary and other chronic health conditions. Occasionally influenza itself can cause a rapidly progressing pneumonia that leads to acute respiratory distress syndrome (ARDS).

Differential Diagnosis

The differential diagnosis is broad, because many different infectious diseases can present with similar symptoms. Other respiratory viruses like RSV, rhinovirus, or coronavirus can have a similar presentation. Additionally, bacterial infections, like pneumonia and meningitis, can present similarly.

Diagnostic Testing

Influenza can be diagnosed clinically based on signs and symptoms, especially during influenza season, but the accuracy of clinical diagnosis in the absence of supportive tests is not high because influenza

shares common features with many viral and bacterial infections. Clinical diagnosis alone is poor, with a sensitivity less than 50% and a specificity near 70%.[17]

There are several diagnostic tests available to emergency clinicians. Rapid influenza diagnostic tests are based on immunochromatographic assays that detect specific influenza antigens, yielding results in less than 30 minutes. The sensitivity of these tests can vary from 50% to 65%, with specificities above 95%.[18] Molecular assays, such as RT-PCR or rapid antigen tests, are far more sensitive than traditional rapid influenza tests. RT-PCR is the most sensitive test and, if available, is preferred. However, rapid molecular tests have sensitivity and specificity that approach RT-PCR, and results can be back in less than 20 minutes. Rapid molecular tests have sensitivities of over 90%.

Management

The management of influenza centers on symptom control with antipyretics, analgesics, and hydration. Several antiviral agents are available to treat influenza, but some controversy surrounds treatment with these agents.

Neuraminidase Inhibitors. Oseltamivir, zanamivir, and peramivir are the currently available neuraminidase inhibitors. They work by inhibiting the release of viral progeny from infected cells. These drugs are active against both influenza A and B.

Oseltamivir is available orally as a capsule or suspension. The treatment dose in adults and children weighing more than 40 kg is 75 mg twice daily for 5 days. For children younger than 1 year old, the dose is 3 mg/kg twice daily. For children 1 year or older, the dose varies by weight: for those weighing less than or equal to 15 kg the dose is 30 mg twice daily, for those weighing more than 15 to 23 kg it is 45 mg twice daily, and for those weighing more than 23 to 40 kg it is 60 mg twice daily. The dosing does require adjustment in renally impaired individuals based on creatinine clearance. The main side effects reported have been nausea and vomiting.

Zanamivir is available as an aerosol powder and is administered via inhalation through a specialized inhaler. It is approved for use in patients 7 years old and older. The treatment dose is two inhalations twice daily for 5 days. It is not recommended in patients with underlying asthma and chronic obstructive pulmonary disease (COPD), because it can cause bronchospasm. Peramivir is the first IV neuraminidase inhibitor available for treatment in influenza patients. The treatment dose is 600 mg IV administered once as a single dose.

Adamantane Antivirals. Amantadine and rimantadine are the currently available adamantane antivirals. They prevent or greatly reduce the uncoating of the viral RNA of influenza A after attachment and endocytosis by host cells. They have no activity against influenza B. In the past, they have been used for prophylaxis and treatment for influenza A. In recent years, the circulating influenza strains have demonstrated greater than 90% resistance to these drugs. They are not recommended for use for influenza treatment.

Other Antivirals. Baloxavir is a novel antiviral that gained US Food and Drug Administration (FDA) approval to treat influenza A and B in patients 12 years of age and older in 2018. Its unique mechanism of action is inhibition of influenza cap-dependent endonuclease. Studies have demonstrated similar efficacy to oseltamivir.[19] The treatment is a single oral dose based on weight. For 40 kg to less than 80 kg, it is 40 mg as a single dose within 48 hours of the onset of influenza symptoms. For 80 kg or greater, it is 80 mg as a single dose within 48 hours of the onset of influenza symptoms.

The controversy surrounding the use of antivirals for treatment of influenza, specifically neuraminidase inhibitors (NIs) has centered on its modest effect with treatment. The most recent Cochrane review found that oseltamivir reduced symptom duration by 16.8 hours in those treated within 48 hours of symptom onset but did not affect hospitalization or reduce severe influenza complications.[20] However, another recent meta-analysis found that treatment with oseltamivir was associated with accelerated symptom improvement, reduced risk in lower respiratory tract complications, and decreased admission to hospital.[21] Investigations have also found that treatment of hospitalized patients with NIs is associated with reduced hospital length of stay and mortality.[22,23] The greatest benefit is in very early treatment, but some studies have demonstrated benefit up to 5 days after symptoms onset in hospitalized patients.[24] The Infectious Diseases Society of America (IDSA) recommendations are to treat all patients as early as possible who are hospitalized, have severe progressive illness regardless of duration, or are at high risk for influenza-related complications.[25]

Disposition

The majority of patients with influenza are discharged home with symptomatic treatment instructions, although this depends on the specific virulence of the circulating strain of the season. Patients with severe influenza require admission. These patients usually have accompanying cardiopulmonary comorbidities. A small number of influenza patients will require ICU admission because of primary influenza or acute exacerbation of an underlying illness. Influenza can cause rapidly progressive ARDS with refractory hypoxemic respiratory failure. These patients with rapidly progressive ARDS may benefit from transfer to centers that perform extracorporeal membrane oxygenation (ECMO). During the 2009 H1N1 pandemic, some centers had success with managing ARDS patients on ECMO.

Coronavirus

Coronaviruses are single-stranded RNA viruses that typically cause respiratory illness. They are covered in detail in Chapter 120.

Rhinovirus

Human rhinovirus is the most common cause of the common cold. Infections peak in the fall and spring but can occur all year. The infection is spread via infected respiratory secretions and direct contact with infected patients. The virus can remain contagious on surfaces for several hours. Hand-to-face inoculation is likely one of the predominant mechanisms of spread, underscoring the importance of frequent handwashing to decrease transmission.

Clinical Features

Symptoms of rhinovirus infection are usually limited to the nose, nasopharynx, and pharynx. The common symptoms that occur are sore throat, nasal congestion, low-grade fever, sneezing, and cough. Less commonly in children, rhinovirus can cause lower respiratory tract infections like pneumonia and tracheobronchitis.

Differential Diagnosis

Other viruses that cause respiratory illness, such as coronaviruses, respiratory syncytial virus (RSV), parainfluenza viruses, influenza viruses, adenoviruses, and enteroviruses, can produce clinical syndromes similar to those produced by the rhinoviruses.

Diagnostic Testing

Definitive diagnostic testing is usually not necessary for rhinovirus. Viral panels do exist that use nucleic acid testing to detect rhinovirus.[26] Samples are typically taken from nose, nasopharynx, or oropharynx.

Management and Disposition

The cornerstone of treatment is symptomatic relief with analgesics and antipyretics. Cough medicines should be avoided in children younger

than 6 years old. This infection has a benign course and can be treated at home.

Adenovirus

Adenoviruses are double-stranded DNA viruses consisting of 7 species (A–G) and greater than 100 types. They commonly cause upper respiratory tract infections, gastrointestinal symptoms, and conjunctivitis. Infection is spread via respiratory droplets and close contact. Outbreaks have been reported in crowded settings such as military personnel undergoing training and students living in dormitory style housing. In 2018 to 2019 there was a multistate outbreak on 5 college campuses, resulting in 168 infections, 11 hospitalizations, and 2 deaths.[27]

Clinical Features

The most common presentation of adenovirus is as a URI with sore throat, cough, and fever. Gastroenteritis and conjunctivitis are also common manifestations. Other syndromes less frequently caused by adenoviruses include hemorrhagic cystitis, urethritis, infantile diarrhea, myocarditis, encephalitis, and meningoencephalitis. In infants and immunocompromised patients, particularly hematopoietic stem cell transplant and solid organ transplant patients, adenovirus can cause severe life-threatening illness.

Differential Diagnosis

Other pathogens causing similar atypical pneumonia syndromes include influenza and parainfluenza viruses and *Mycoplasma pneumoniae*. Diarrheal syndromes may be similar to those caused by rotaviruses.

Diagnostic Testing

Because adenovirus mostly causes a benign self-limiting disease, routine diagnostic testing is unnecessary. If testing is required, qualitative or quantitative PCR from serum, tissue, or body fluid is the most diagnostic method.

Management and Disposition

The majority of these infections require only symptomatic treatment. There is no specific antiviral therapy that is routinely recommended. There have been reports of using cidofovir in immunocompromised patients with life-threatening adenovirus infection, but this is not routinely recommended. The majority of these patients will be treated at home. The most severe cases may require admission.

Parainfluenza

Parainfluenza is a single-stranded RNA virus that belongs to the *Paramyxoviridae* family. This infection is usually acquired in childhood. In the United States, parainfluenza infections have been reported to account for up to a quarter of respiratory disease in children. In adults, the burden of illness caused by parainfluenza is much less. Parainfluenza is transmitted by close contact via infected respiratory secretions. There are four types, each with its own clinical presentation.

Clinical Features

Parainfluenza type 1 is the most common cause of croup. Parainfluenza type 2 is also associated with croup but causes less morbidity. Croup symptoms usually worsen at night and are characterized by a barky cough. Typically patients have a fever and URI symptoms 1 to 2 days before the cough. Tachypnea and hoarse voice are common as well. In severe cases, stridor at rest may be present. Parainfluenza type 1 and 2 also cause lower respiratory tract infections in children. Parainfluenza type 3 more often causes bronchitis, bronchiolitis, and pneumonia. Parainfluenza type 4 is less common and causes a mild respiratory illness. In adults and older children, parainfluenza infections are mild and present as a simple URI.

Differential Diagnosis

Adenoviruses, rhinoviruses, influenza viruses, RSV, echoviruses, coxsackieviruses, and coronaviruses all can cause similar URI symptoms. If the primary presentation is croup, it is important to differentiate this from epiglottitis as a potential diagnosis.

Diagnostic Testing

Diagnosis is made from viral culture, rapid antigen test, or nucleic acid testing, either rapid testing or RT-PCR. Specimens are usually obtained from nasal swabs, throat swabs, or nasopharyngeal washings.

Management

There is no specific antiviral treatment for parainfluenza infection. The treatment is mainly symptomatic. For mild and moderate croup, a single dose of oral dexamethasone (0.15–0.6 mg/kg, maximum dose 20 mg) or oral prednisolone (1 mg/kg) can be given.[28] For severe croup, nebulized racemic epinephrine should be administered in addition to oral or intramuscular dexamethasone (0.6 mg/kg, maximum dose 20 mg). Glucocorticoids improve symptoms, reduce rates of return visits, admissions, and readmissions.[29]

Respiratory Syncytial Virus
